where f_m represents fraction metabolized, P refers to parent drug, and MI and MII refer to metabolites I and II, respectively. The classical approach to the determination of the fractions metabolized (Eq. 1) using blood data requires three separate studies: administration of parent drug, metabolite I, and metabolite II to the same subject at different times. This approach involves several assumptions of constancy of metabolite clearances among the three studies. As a result, estimates of the various fractions of Eq. 1 are subject to significant error. This type of metabolic problem arose during the elucidation of the pharmacokinetic profile of cinromide (3-bromo-*N*-ethylcinnamamide)(P), a new antiepileptic drug. This drug is metabolized by *N*-deethylation to 3-bromocinnamamide (I) and by amide hydrolysis to 3-bromocinnamic acid (II). However, I is also metabolized to II by amide hydrolysis. The resolution of this metabolic scheme prior to the efficacy evaluation of cinromide in the primate model (1, 2) was of particular significance because I was found to have anticonvulsant properties (3, 4) and II reached steady-state levels 10–20-fold higher than those of the parent drug (2). In an earlier study where the classical approach (administration of cinromide, I, and II separately) was used in a group of six rhesus monkeys, several unrealistic findings were obtained (5). The fraction of dose of cinromide metabolized directly to II ranged from 5 to 100% (mean ± *SD* = 48 ± 32%). Also, the sum of the two fractions (f_m(P → I) + f_m(P → II, direct)) ranged from 64 to 140% and was larger than 100% in three of six monkeys. This large variability was attributed to the intrasubject variability in clearances of I and II among the three studies. To test this hypothesis, a new approach using stable isotope methodology was devised. This approach involved the simultaneous administration of cinromide, and different stable isotope-labeled variants of I and II, in which case the clearances of I and II were obtained while these metabolites were formed *in situ*.

Five chaired normal male rhesus monkeys (chronically catheterized) were used in this study. Dideuterated I (I–d_2) and monodeuterated II (II–d_1) were administered along with the unlabeled parent drug (d_0). These were synthesized using the methods described for the corresponding unlabeled species (6–8). The deuterium labels were placed on the α, β ethylene carbons of I–d_2, and the β carbon of II–d_1 to minimize any possible isotope effect. Any secondary kinetic deuterium isotope effect on deethylation and amide hydrolysis or on epoxide formation and ring opening of the ethylene carbons would generally not be significant (9). Single intravenous doses of cinromide–d_0 (75 mg) and II–d_1 (80 mg) were administered consecutively to each monkey. I–d_2 (70 mg) was administered intravenously 2 h later such that the concentrations of II–d_2 would not be too far apart from those of II–d_0 and II–d_1 and could be analyzed at the same time. Solutions of cinromide–d_0, I–d_2, and II–d_1 were prepared in 60% polyethylene glycol 400 to concentrations of 25, 25, and 10 mg/mL, respectively. Blood samples (2 mL) were taken at 0.2, 0.5, 0.75, 1, 1.5, 2, 2.25, 2.5, 3, 4, 5, 6, 8, 10, 12, and 16 h after administration of II–d_1. EDTA was used as an anticoagulant in each blood sample. After the administration of cinromide–d_0, I–d_2 and II–d_1, six species were monitored in each blood sample: the three administered species as well as I–d_0 and II–d_0 formed from cinromide (d_0) and II–d_2 formed from I–d_2. Aliquots of 0.2 mL of each sample were used to analyze cinromide by HPLC (10). Aliquots of 0.5 to 0.8 mL of blood were used to analyze I and II by direct probe insertion chemical ionization mass spectrometry. Compounds I and II were separated by successive extractions at different pH. Blood samples were extracted with benzene under neutral conditions to extract I; the aqueous phases were acidified and extracted with benzene to recover II and benzene extracts containing I were washed with 0.1 M NaOH. Benzene extracts containing II were shaken with 0.1 M NaOH, then reacidified and extracted back into benzene. Chlorinated analogues of I and II were used as internal standards for

the assays. The MS (VG-7070)[1] was interfaced with a data system (VG-2035F/B)[1] and operated in the selected ion monitoring mode. Methane was used as reagent gas for chemical ionization. The source temperature was 190°C. The protonated molecular ions of internal standard, d_0, d_1, and d_2 were monitored (m/z 182, 226, 227, and 230 for the analysis of I; 183, 227, 228, and 231 for the analysis of II). To avoid the interference of ^{81}Br–d_0 and ^{79}Br–d_2, the ion of ^{81}Br–d_2 was monitored in each dideuterated metabolite. The natural abundance of carbon-13 in each species was taken into consideration in calculating concentrations.

The kinetic analysis of the data was aimed at the determination of the various fractions metabolized required in Eq. 1 and was based on area calculations (11). The fraction metabolized[2] was calculated by the following equation:

$$f_m = \frac{(AUC_{met})p/mol.\ wt._{met} \times CL_{met}}{Dose\ p/mol.\ wt.\ p} \quad \text{(Eq. 2)}$$

where $(AUC_{met})p$ represents the area under the metabolite concentration curve after a dose of the precursor, CL_{met} is the elimination clearance of the metabolite, and mol. wt. represents the molecular weight. The area under the blood concentration–time curve for each compound was measured by the trapezoidal rule with extrapolation to infinity using the last several points of each curve. On the average, the area obtained without extrapolation accounted for 83% of the total area. Clearance was calculated from dose–area ratio. In this study, both metabolites had low extraction ratios and, therefore, are not subject to hepatic sequential single pass metabolism (13).

The average clearances of cinromide, I–d_2 and II–d_1 were 8.04 ± 3.32, 0.91 ± 0.29, and 0.77 ± 0.3 L/h, respectively. Table I lists individual values of the fraction metabolized *via* the various pathways of the cinromide–metabolite I–metabolite II system. The fraction of dose of cinromide metabolized to II by all routes (directly and indirectly) was 53 ± 16%. The fraction of dose of cinromide metabolized to I was 39 ± 6%, while the fraction of dose of I metabolized to II was 34 ± 14%. The fraction of dose of cinromide metabolized directly to II calculated according to Eq. 1 was 39 ± 10%. Thus, as primary metabolites of cinromide, I and II together account for 77 ± 11% of a dose. The corresponding fractions metabolized obtained in a previous study by the classical approach are also given in Table I. Although the values obtained in the present study were generally smaller, comparison of the values obtained by both methods showed no statistically significant difference for any of the pathways (Mann–Whitney test). However, the variability in the various fractions metabolized determined in the present study was much smaller. There were significant decreases in variance in the fraction of cinromide metabolized to I, in the fraction of cinromide metabolized to II directly, and in the sum of these two fractions (variance ratio test, $p < 0.05$). The superiority of the stable isotope method is also supported by the fact that no unrealistic value, (larger than 100%) was obtained for the sum of the two fractions of cinromide metabolized to I and II (directly). The reduction in the coefficient of variation of the fraction cinromide → I (45% to 15%) is of particular interest. In the previous study, it was found that the half life of I was significantly longer after a dose of cinromide (5.8 ± 1.2 h) than after administration of I (4.4 ± 0.8 h) which suggested that the clearance of I measured when it is administered would be an overestimate of its clearance when formed *in situ*. In such a case, the stable isotope approach offers unique advantages since it allows an estimate of the clearance of the metabolite formed *in situ*.

The findings of the present study can be put in broader perspective if an analysis of the limitations inherent to the classical approach is considered. This approach requires three studies (1, 2, and 3) in which three species (cinromide, I, and II) are administered separately (Table II). To solve Eq. 1, four assumptions of constancy of clearance are

[1] VG-Analytical, Altrincham, Cheshire, U.K.

[2] In light of the experimental design (intravenous administration of parent drug and metabolites), this fraction refers to the fraction of total body clearances as well as the fraction of dose of parent drug (12).

required. Three clearances operating in study 1 are estimated in studies 2 and 3. Study 2 estimates the elimination clearance of I while study 3 estimates the elimination clearance of II. Studies 2 and 3 together estimate the formation clearance of II from I. Also, the elimination clearance of II operating in study 2 is measured in study 3. Intrasubject variability in any of these clearances leads to unrealistic values for the fraction of parent drug metabolized directly to metabolite II. This variability can be minimized by the simultaneous administration of metabolite(s) and precursor(s). This is possible with the use of stable isotope methodology.

BOOKS

Natural Product Chemistry—A Mechanistic and Biosynthetic Approach to Secondary Metabolism. By KURT B. G. TORSSELL. John Wiley & Sons, Inc., One Wiley Drive, Somerset, NJ 08873. 1983. 401 pp. 16 × 23 cm. Price $54.95.

This book presents an overview of the current known and postulated biosynthetic pathways of the secondary metabolites, those natural products whose precursors are the common α-amino acids, sugars, and low-molecular weight carboxylic acids of the Krebs cycle. Although the physiological functions of many of these natural products have not yet been established, some have been found to play important roles in the regulation of animal and insect social behavior and development, and plant protection mechanisms.

The contents of this volume are organized into eight chapters, each of which is subdivided into various topics. An overview of the natural products field and the importance of these metabolites are presented in the first chapter. The remaining chapters present the biosynthetic pathways for seven different classes of natural products in addition to a brief introduction about the general chemistry, nomenclature, and background of each class. In the second chapter on carbohydrates, photosynthesis, the Krebs or citric acid cycle, monosaccharides, and polysaccharides are among the topics discussed. The biosynthesis of shikimic acid; its conversion to aromatic amino acids, such as tryptophan, tyrosine, and phenylalanine; biological hydroxylation mechanisms, and the biosynthesis of aromatic carboxylic acids, coumarins, quinones, and lignins are included in the third chapter. Chapter 4 details the biosyntheses of compounds (such as saturated and unsaturated fatty acids and the aromatic anthraquinones, flavonoids, and tropolones) that originate from the polyketide pathway by condensation of acetyl CoA. The mevalonic acid pathway to the terpenes, squalene, steroids, and carotenes is the subject of the fifth chapter. In the sixth chapter, the biosyntheses of amino acids, peptides, and proteins are presented. The alkaloids derived from the amino acids ornithine, lysine, tyrosine, and tryptophan, from anthranilic acid, and from the amination of terpenes are found in the seventh chapter. In the last chapter, the *N*-heterocyclic aromatic compounds, including pyrimidines, purines, pteridines, pyrroles, porphyrins, and corrin ring-containing compounds, are discussed. Each chapter also includes historical and biological information about some of the metabolites. The inclusion of this material appreciably enhances reader interest. A set of biosynthetic mechanistic problems and a bibliography are presented at the end of each chapter. Answers to the problems and author and subject indices are included at the end of the volume.

On the basis of the table of contents, this work appears to be an informative and valuable text on natural product biosynthesis which emphasizes the biosynthetic pathways in an organic mechanistic approach. This book is recommended by the publishers as a text for undergraduates and graduate students and a reference work for researchers in the field. However, many mechanistic discussions are vague and not very clear. The internal organization of paragraphs is poor. For example, the section on the NIH shift is very confusing for a reader not familiar with this topic. This lack of clarity is found in many other areas of this book. The absence of numbered structures forces the reader to search each figure or reaction sequence for a particular compound that is being discussed in the text. The absence of carbon atom numbering on some of the structures is not helpful. In conclusion, only those scientists well-versed in biosynthetic pathways will find this an easily readable text. The literature cited is very current, and the notable accomplishments of workers in the area of metabolic biosynthetic pathways have been included. The mechanistic approach to biosynthetic processes used by the author is a valuable and informative one.

Host Factors in Human Carcinogenesis. (IARC Scientific Publications, No. 30.) *Edited by* H. BARTSCH, B. ARMSTRONG, *and* W. DAVIS. International Agency for Research on Cancer, Health and Biomedical Information Programme, World Health Organization, Geneva 27, Switzerland. 1982. 581 pp. 17 × 24 cm. Price $50.00 (Sw. Fr. 100).

Current research on carcinogenesis from many laboratories is beginning to elucidate several facets of the complex cascade and progression of events that lead from the initiation of the biochemical lesions to the development of metastatic potential. Along with this progress in the areas of biochemistry and the molecular biology of cancer, other laboratories are reporting both human epidemiological and animal model studies which indicate that conditions within the individual at risk may influence the development of cancer and thereby susceptibility. A knowledge of the interactions between these "host factors" which influence susceptibility and the various stages of carcinogenesis will allow for the development of strategies to aid in the prevention of cancer.

The main goal of this book is to update the knowledge concerning the mechanisms by which various factors inherent in the host may alter the initiation and developmental progression of events leading to cancer. To meet this goal, the editors have drawn together investigators from the most promising research areas concerning host susceptibility to carcinogenesis.

The volume represents a compilation of papers presented at an international symposium and suffers from uneven presentation, as is often the case of such volumes. However, it does make the material presented available to a larger audience. The individual contributions take the format of either short reviews of the literature or reviews of the research efforts of a particular laboratory and presentations of specific research reports. Several of the latter lack sufficient introductory material to determine the significance of the studies in the overall field. This problem is somewhat overcome by the inclusion of a rapporteur's report summarizing and placing in perspective the individual presentations within each section. Most areas of the subject are given adequate coverage, with the exception of diet and nutrition. Only two reports are concerned with this topic (although it is mentioned in several others), which is rapidly being shown to be an important host factor in chemical carcinogenesis and which is generally under the control of the individual. It is hoped that this volume will inspire further studies to develop the mechanisms by which factors inherent within the host alter cancer susceptibility.

Overall, this volume makes a successful attempt to combine the divergent research interests concerned with the role of various host factors in altering susceptibility, and I can recommend it for those who are interested in developing more knowledge in this area. It will be useful for those considering this topic for the first time and even those whose individual research interest in host factors do not allow them to maintain current knowledge of the many areas of research concerned with this topic.

Techniques of Solubilization of Drugs. (Drugs and the Pharmaceutical Sciences Series, Vol 12.) Edited by SAMUEL H. YALKOWSKY. Marcel Dekker, 270 Madison Avenue, New York NY 10016. 1981. 224 pp. 15 × 23 cm. Price $34.50 (20% higher outside the U.S.).

Techniques of Solubilization of Drugs is a very useful handbook for researchers involved in drug development. The problem and necessity of proper solubilization of drugs are nicely discussed in the two chapters by the editor, S. Yalkowsky. Of the other four chapters, the one on solubilization in surfactant systems by A. T. Florence deserves particular attention, as the author gives a rather complete overview of the subject. In the chapter on the solid-state manipulation, probably more attention should be given to the very important polymeric carriers and solid dispersions in matrices. The chapter on the use of complex formation for drug solubilization appears to use old literature data, and it seems that either the approach does not have much use or the field was not thoroughly searched for this review. The chapter on drug derivatization points out the importance and, in many ways, how to solve the problem of solubility by chemical means, such as prodrugs, but the examples seem to concentrate primarily on the potential usefulness of some amino acid esters. There are some misquotes from the literature.

Overall, the book is a very useful one and it defines the highly multidisciplinary field of effecting drug solubility by a variety of manipulations.

Diuretics: Chemistry, Pharmacology, and Medicine. Edited by EDWARD J. CRAGOE, Jr. Wiley-Interscience, 605 Third Avenue New York, NY 10016. 1983. 694 pp. 15 × 23 cm. Price $80.00.

Diuretics: Chemistry, Pharmacology, and Medicine is the second volume in the "Chemistry and Pharmacology of Drugs" series. The series is edited by Daniel Lednicer, and this volume is edited by Edward J. Cragoe, Jr. The book has the following two goals: updating the field of diuretic research since the last comprehensive review was written by George deStevens in 1963 and laying the groundwork for the next era in diuretic research. It succeeds admirably on both counts by giving a balanced account of physiological principles, structure–activity relationships, mechanistic considerations, clinical data, and biochemical perspectives.

The book begins with a chapter on kidney physiology by Edward H. Blaine. Although not an exhaustive treatment, it is appropriate to the beginning of the book and serves as a useful digest of information with a good list of references. Nine subsequent chapters, describing the medical chemistry of diuretics, are divided according to chemical structure. Some decisions regarding chemical class were clearly difficult (4-anilino-3-pyridinosulfonamides are found under six-membered heterocycles rather than under sulfonamides), but any confusion is readily cleared up by consulting the index. The emphasis in these chapters is on structure–activity relationships: molecules have been dissected and the effect of substitution at each chemically accessible atom has been tabulated.

The chapter on sulfonamide diuretics by Richard C. Allen is a comprehensive and thorough treatment of the subject (153 pages). It is richly illustrated with figures and tables, and documents with over 700 references the 20 years of development in this area since the deStevens review. The chapters on (aryloxy)acetic acids and 2-aminomethylphenols have already appeared in large part in a 1978 ACS monograph, "Diuretic Agents," also edited by Dr. Cragoe. To their credit, the authors (Edward J. Cragoe and Robert L. Smith) have updated the tables on older chemical series with additional entries and have included new compounds that have appeared in the literature between 1978 and 1982. The next six chapters—covering pyrazine diuretics, three- and five-membered heterocyclic diuretics, tri- and tetracyclic heterocycles, six-membered monocyclic heterocycles, bicyclic heterocycles, and the inevitable "others"—were all written by Dr. Cragoe and maintain a standard of clarity and conciseness throughout.

The book concludes with a chapter on hormonal regulators of the kidney (R. L. Smith), which this reviewer found to be a lucid and scholarly synthesis of a large amount of diverse information (600 references). This chapter succeeds in bringing together the myriad effects and complex interrelationships among antidiuretic hormone, the renin–angiotensin–aldosterone system, the kallikrein–kinin system, and the prostaglandins, as well as considering the possible role of the hypothetical natriuretic hormone.

Throughout the book, tables have been effectively used to clarify structure–activity relationships, and the chapters have a logical organization, which is reinforced with a detailed outline at the beginning of each chapter. Inexplicably, the figures and tables are printed with a quality that varies from sharp to almost smudged. Although not a serious flaw, this reviewer found it an unfortunate distraction in a book that is otherwise crisply reproduced. Also distracting is the use of various scoring systems (rather than actual data) to present diuretic activity in several chapters. Although the format in which data were presented was clearly out of the authors' control in most cases, these scoring systems never-

Host Factors in Human Carcinogenesis. (IARC Scientific Publications, No. 30.) *Edited by* H. BARTSCH, B. ARMSTRONG, *and* W. DAVIS. International Agency for Research on Cancer, Health and Biomedical Information Programme, World Health Organization, Geneva 27, Switzerland. 1982. 581 pp. 17 × 24 cm. Price $50.00 (Sw. Fr. 100).

Current research on carcinogenesis from many laboratories is beginning to elucidate several facets of the complex cascade and progression of events that lead from the initiation of the biochemical lesions to the development of metastatic potential. Along with this progress in the areas of biochemistry and the molecular biology of cancer, other laboratories are reporting both human epidemiological and animal model studies which indicate that conditions within the individual at risk may influence the development of cancer and thereby susceptibility. A knowledge of the interactions between these "host factors" which influence susceptibility and the various stages of carcinogenesis will allow for the development of strategies to aid in the prevention of cancer.

The main goal of this book is to update the knowledge concerning the mechanisms by which various factors inherent in the host may alter the initiation and developmental progression of events leading to cancer. To meet this goal, the editors have drawn together investigators from the most promising research areas concerning host susceptibility to carcinogenesis.

The volume represents a compilation of papers presented at an international symposium and suffers from uneven presentation, as is often the case of such volumes. However, it does make the material presented available to a larger audience. The individual contributions take the format of either short reviews of the literature or reviews of the research efforts of a particular laboratory and presentations of specific research reports. Several of the latter lack sufficient introductory material to determine the significance of the studies in the overall field. This problem is somewhat overcome by the inclusion of a rapporteur's report summarizing and placing in perspective the individual presentations within each section. Most areas of the subject are given adequate coverage, with the exception of diet and nutrition. Only two reports are concerned with this topic (although it is mentioned in several others), which is rapidly being shown to be an important host factor in chemical carcinogenesis and which is generally under the control of the individual. It is hoped that this volume will inspire further studies to develop the mechanisms by which factors inherent within the host alter cancer susceptibility.

Overall, this volume makes a successful attempt to combine the divergent research interests concerned with the role of various host factors in altering susceptibility, and I can recommend it for those who are interested in developing more knowledge in this area. It will be useful for those considering this topic for the first time and even those whose individual research interest in host factors do not allow them to maintain current knowledge of the many areas of research concerned with this topic.

Techniques of Solubilization of Drugs. (Drugs and the Pharmaceutical Sciences Series, Vol 12.) Edited by SAMUEL H. YALKOWSKY. Marcel Dekker, 270 Madison Avenue, New York NY 10016. 1981. 224 pp. 15 × 23 cm. Price $34.50 (20% higher outside the U.S.).

Techniques of Solubilization of Drugs is a very useful handbook for researchers involved in drug development. The problem and necessity of proper solubilization of drugs are nicely discussed in the two chapters by the editor, S. Yalkowsky. Of the other four chapters, the one on solubilization in surfactant systems by A. T. Florence deserves particular attention, as the author gives a rather complete overview of the subject. In the chapter on the solid-state manipulation, probably more attention should be given to the very important polymeric carriers and solid dispersions in matrices. The chapter on the use of complex formation for drug solubilization appears to use old literature data, and it seems that either the approach does not have much use or the field was not thoroughly searched for this review. The chapter on drug derivatization points out the importance and, in many ways, how to solve the problem of solubility by chemical means, such as prodrugs, but the examples seem to concentrate primarily on the potential usefulness of some amino acid esters. There are some misquotes from the literature.

Overall, the book is a very useful one and it defines the highly multidisciplinary field of effecting drug solubility by a variety of manipulations.

Diuretics: Chemistry, Pharmacology, and Medicine. Edited by EDWARD J. CRAGOE, Jr. Wiley-Interscience, 605 Third Avenue New York, NY 10016. 1983. 694 pp. 15 × 23 cm. Price $80.00.

Diuretics: Chemistry, Pharmacology, and Medicine is the second volume in the "Chemistry and Pharmacology of Drugs" series. The series is edited by Daniel Lednicer, and this volume is edited by Edward J. Cragoe, Jr. The book has the following two goals: updating the field of diuretic research since the last comprehensive review was written by George deStevens in 1963 and laying the groundwork for the next era in diuretic research. It succeeds admirably on both counts by giving a balanced account of physiological principles, structure–activity relationships, mechanistic considerations, clinical data, and biochemical perspectives.

The book begins with a chapter on kidney physiology by Edward H. Blaine. Although not an exhaustive treatment, it is appropriate to the beginning of the book and serves as a useful digest of information with a good list of references. Nine subsequent chapters, describing the medical chemistry of diuretics, are divided according to chemical structure. Some decisions regarding chemical class were clearly difficult (4-anilino-3-pyridinosulfonamides are found under six-membered heterocycles rather than under sulfonamides), but any confusion is readily cleared up by consulting the index. The emphasis in these chapters is on structure–activity relationships: molecules have been dissected and the effect of substitution at each chemically accessible atom has been tabulated.

The chapter on sulfonamide diuretics by Richard C. Allen is a comprehensive and thorough treatment of the subject (153 pages). It is richly illustrated with figures and tables, and documents with over 700 references the 20 years of development in this area since the deStevens review. The chapters on (aryloxy)acetic acids and 2-aminomethylphenols have already appeared in large part in a 1978 ACS monograph, "Diuretic Agents," also edited by Dr. Cragoe. To their credit, the authors (Edward J. Cragoe and Robert L. Smith) have updated the tables on older chemical series with additional entries and have included new compounds that have appeared in the literature between 1978 and 1982. The next six chapters—covering pyrazine diuretics, three- and five-membered heterocyclic diuretics, tri- and tetracyclic heterocycles, six-membered monocyclic heterocycles, bicyclic heterocycles, and the inevitable "others"—were all written by Dr. Cragoe and maintain a standard of clarity and conciseness throughout.

Polyether Antibiotics, Volume 2: Naturally Occurring Acid Ionophores. Edited by JOHN W. WESLEY. Marcel Dekker, 270 Madison Avenue, New York, NY 10016. 1983. 415 pp. 15 × 23 cm. Price $65.00 (20% higher outside the U.S. and Canada).

This work is the second of a two-volume set on polyether antibiotics. As the title indicates, it concentrates on the chemical aspects in this field whereas the microbiology, biosynthesis, pharmacology, and veterinary applications were covered in the first volume. The editor has chosen an excellent array of contributing authors, each of whom has done important original work in this field. The resulting volume therefore has the added advantage of being authoritative as well as informative.

The first chapter by Yoshito Kishi is an excellent review of the total synthesis of many of the polyethers which not only includes the author's own contributions, but also a critical view of other major contributors to this field. This is followed by a review of known chemical modifications of this class of antibiotics, which focuses attention on the lack of progress in this aspect of polyether chemistry in light of the high level of understanding brought to bear by X-ray crystallography. The remainder of this book covers the major contributions made to polyether chemistry by physical chemistry including X-ray crystallography, mass spectrometry, and ^{1}H- and ^{13}C-NMR. The authors of each of these sections used similar formats with illustrations, figures, and stereoviews. Each also tried to highlight the strengths and limitations of these various techniques.

The general tone of this book is to give the reader an overview and an exposition with an eye on future research. As such, this volume as well as the previous one, should prove useful as both a primer for the novice researcher and as a review and reference source for the established investigator. As the reviewer of Volume I noted in this journal, the subject index of Volume II is also somewhat inadequate and may prove a hindrance for those less familiar with this field. This book generally includes work up to 1980—only one author (Y. Kishi) attempted to update his chapter to cover work done in 1981.

In conclusion, this volume gives an excellent coverage of the subject matter it sets out to review. It has been well edited, is authoritative, and generally error free. It will surely be of great value to anyone interested in these fascinating antibiotics.

Applied Statistics: A Handbook of Techniques, 5th Ed. By LOTHAR SACHS (translated by ZENON REYNAROWYCH). Springer-Verlag New York, Inc., 175 Fifth Avenue, New York, NY 10010. 1983. 706 pp. 16 × 24 cm.

This book was written "... both as an introductory and follow-up text ... and as a reference book with a collection of formulas and tables, numerous cross-references, and extensive bibliography." Satisfying such divergent purposes in one book is difficult, and the author does not entirely succeed. Although written at an introductory level, I found the organization of the material too confusing and the coverage too encompassing for an introductory text.

The book extensively covers the techniques relevant to most data analysis problems addressed in introductory texts in applied statistics. Chapter 0 covers arithmetic operations. Chapter 1 covers a wide variety of techniques relating to one variable. Chapter 2 suggests the diversity of specialized statistical problems and techniques arising in medicine and engineering and directs the reader to the relevant literature. Chapters 3–7 cover the comparison of two or more samples, correlation and regression, the analysis of contingency tables, and analysis of variance. In each case, most of the relevant parametric and nonparametric techniques are presented. Keeping with the introductory level of the book, general linear and categorical models are not discussed.

For a handbook, the inclusion of material could be better delineated. You might find a relatively unknown technique such as the minimum discrimination information statistic for analyzing multiway contingency tables or the Thorndike nomogram for evaluating Poisson probabilities. However, you will fail to find techniques for analyzing covariance studies, repeated measure studies, or studies with missing data. But, if the technique is there, its stepwise execution is lucidly illustrated. Assumptions are stated in practical terms and cross-referenced to techniques for testing their validity. The original and related references are always given. Statistical tables are readily accessible due to their placement in the text and convenient page referencing.

This easy use is one of the joys of this book. Another is the pleasure of perusing the book. To quote the author, "The numerous cross-references appearing throughout the text point out various *interconnections*. A serendipitous experience is possible." I concur.

Structure–Activity Correlation as a Predictive Tool in Toxicology: Fundamentals Methods, and Applications. Edited by LEON GOLDBERG. Hemisphere Publishing Corp., 19 W. 44th St., New York, NY 10036. 330 pp. 16 × 23 cm. Price $49.50.

This book is a reasonably current review of the application of quantitative structure–activity relationships (QSAR) to problems in toxicology. Although the work is the result of a symposium which was held in February 1981, it is remarkably well-written and not at all like the usual symposia proceedings. The book is divided into four sections that, for the most part, are well-organized and show little evidence of overlap or duplication.

The first section covers biological activities and describes moderately well the problems that toxicologists have in defining and measuring the biological effects of toxic substances. Of particular interest are the examples in Chapter 2 on inhibition of chemical carcinogenisis by various factors which modify procarcinogen activation. The survey of literature and computer-accessible data bases for obtaining information on both toxicological responses and physical and chemical properties of toxicants is particularly helpful.

The second section contains a somewhat sketchy but suggestive survey of biochemical mechanisms underlying the toxic action of chemicals (Chapter 4) and an excellent historical overview of the physical and chemical parameters that have been correlated to biological activities (Chapter 5).

The third section, "Correlative Methods," contains the heart of the material presented in this book. An excellent review (Chapter 6) of multiple regression (Hansch) analysis by Y. C. Martin clearly states the fundamental assumptions that are frequently not met by the novice. Criteria for the acceptable quality of the biological data, for the selection of appropriate physiochemical parameters, and for the intellegent use of regression analysis methods are all succinctly stated. Chapter 7, by P. C. Jurs, contains a reasonably intelligible introduction to the use of pattern-recognition techniques for QSAR; however, the novice unfamiliar with the statistical basis for this method may find the discussion somewhat confusing. Finally, Chapter 8 contains a discussion of the application of quantum chemical methods to predicting the relative carcinogenicity of a series of polycyclic aromatic hydrocarbons.

The remainder of the book consists of examples of applications of QSAR methods to toxicological problems. Although the quality of those application reviews varies considerably, each topic is covered with sufficient depth such that these reviews should serve as a useful guide to the recent literature. Chapters 10 (Computer-Assisted Prediction of Me-

theless make it difficult to compare data across chemical classes without excessive page flipping.

This is followed by a review of known chemical modifications of this class of antibiotics, which focuses attention on the lack of progress in this aspect of polyether chemistry in light of the high level of understanding brought to bear by X-ray crystallography. The remainder of this book covers the major contributions made to polyether chemistry by physical chemistry including X-ray crystallography, mass spectrometry, and ^{1}H- and ^{13}C-NMR. The authors of each of these sections used similar formats with illustrations, figures, and stereoviews. Each also tried to highlight the strengths and limitations of these various techniques.

The general tone of this book is to give the reader an overview and an exposition with an eye on future research. As such, this volume as well as the previous one, should prove useful as both a primer for the novice researcher and as a review and reference source for the established investigator. As the reviewer of Volume I noted in this journal, the subject index of Volume II is also somewhat inadequate and may prove a hindrance for those less familiar with this field. This book generally includes work up to 1980—only one author (Y. Kishi) attempted to update his chapter to cover work done in 1981.

In conclusion, this volume gives an excellent coverage of the subject matter it sets out to review. It has been well edited, is authoritative, and generally error free. It will surely be of great value to anyone interested in these fascinating antibiotics.

Applied Statistics: A Handbook of Techniques, 5th Ed. By LOTHAR SACHS (translated by ZENON REYNAROWYCH). Springer-Verlag New York, Inc., 175 Fifth Avenue, New York, NY 10010. 1983. 706 pp. 16 × 24 cm.

This book was written "... both as an introductory and follow-up text ... and as a reference book with a collection of formulas and tables, numerous cross-references, and extensive bibliography." Satisfying such divergent purposes in one book is difficult, and the author does not entirely succeed. Although written at an introductory level, I found the organization of the material too confusing and the coverage too encompassing for an introductory text.

The book extensively covers the techniques relevant to most data analysis problems addressed in introductory texts in applied statistics. Chapter 0 covers arithmetic operations. Chapter 1 covers a wide variety of techniques relating to one variable. Chapter 2 suggests the diversity of specialized statistical problems and techniques arising in medicine and engineering and directs the reader to the relevant literature. Chapters 3–7 cover the comparison of two or more samples, correlation and regression, the analysis of contingency tables, and analysis of variance. In each case, most of the relevant parametric and nonparametric techniques are presented. Keeping with the introductory level of the book, general linear and categorical models are not discussed.

For a handbook, the inclusion of material could be better delineated. You might find a relatively unknown technique such as the minimum discrimination information statistic for analyzing multiway contingency tables or the Thorndike nomogram for evaluating Poisson probabilities. However, you will fail to find techniques for analyzing covariance studies, repeated measure studies, or studies with missing data. But, if the technique is there, its stepwise execution is lucidly illustrated. Assumptions are stated in practical terms and cross-referenced to techniques for testing their validity. The original and related references are always given. Statistical tables are readily accessible due to their placement in the text and convenient page referencing.

This easy use is one of the joys of this book. Another is the pleasure of perusing the book. To quote the author, "The numerous cross-references appearing throughout the text point out various *interconnections*. A serendipitous experience is possible." I concur.

Structure–Activity Correlation as a Predictive Tool in Toxicology: Fundamentals Methods, and Applications. Edited by LEON GOLDBERG. Hemisphere Publishing Corp., 19 W. 44th St., New York, NY 10036. 330 pp. 16 × 23 cm. Price $49.50.

This book is a reasonably current review of the application of quantitative structure–activity relationships (QSAR) to problems in toxicology. Although the work is the result of a symposium which was held in February 1981, it is remarkably well-written and not at all like the usual symposia proceedings. The book is divided into four sections that, for the most part, are well-organized and show little evidence of overlap or duplication.

The first section covers biological activities and describes moderately well the problems that toxicologists have in defining and measuring the biological effects of toxic substances. Of particular interest are the examples in Chapter 2 on inhibition of chemical carcinogenisis by various factors which modify procarcinogen activation. The survey of literature and computer-accessible data bases for obtaining information on both toxicological responses and physical and chemical properties of toxicants is particularly helpful.

The second section contains a somewhat sketchy but suggestive survey of biochemical mechanisms underlying the toxic action of chemicals (Chapter 4) and an excellent historical overview of the physical and chemical parameters that have been correlated to biological activities (Chapter 5).

The third section, "Correlative Methods," contains the heart of the material presented in this book. An excellent review (Chapter 6) of multiple regression (Hansch) analysis by Y. C. Martin clearly states the fundamental assumptions that are frequently not met by the novice. Criteria for the acceptable quality of the biological data, for the selection of appropriate physiochemical parameters, and for the intellegent use of regression analysis methods are all succinctly stated. Chapter 7, by P. C. Jurs, contains a reasonably intelligible introduction to the use of pattern-recognition techniques for QSAR; however, the novice unfamiliar with the statistical basis for this method may find the discussion somewhat confusing. Finally, Chapter 8 contains a discussion of the application of quantum chemical methods to predicting the relative carcinogenicity of a series of polycyclic aromatic hydrocarbons.

The remainder of the book consists of examples of applications of QSAR methods to toxicological problems. Although the quality of those application reviews varies considerably, each topic is covered with sufficient depth such that these reviews should serve as a useful guide to the recent literature. Chapters 10 (Computer-Assisted Prediction of Me-

tabolism), 14 (Quantitative Structure–Mutagenicity Relationships), 18 (Molecular Basis for the Structure–Carcinogenicity Relationships of Polynuclear Aromatic Hydrocarbons), and 20 (Concept of the Integrated Approach)—the last a description of the EPA GENE-TOX program—provide some especially interesting applications to toxicological research.

QSAR methods should become increasingly important in toxicology, since the toxicologist is confronted with the problem of assessing the safety of millions of chemical entities which may cause injury or death to living organisms by only a reasonably small number of distinct toxic mechanisms. For example, genetic effects of toxic chemicals can be assessed by a half-dozen or so distinct classes of bioassays for different types of genetic damage. As the mechanisms underlying various types of toxic responses become better understood, QSAR methods will become more useful as a screening tool for predicting the adverse effects of new chemical entities. This book can serve as a useful introduction to the literature on QSAR for the practicing toxicologist and other scientists concerned with safety assessment of drugs and chemicals. The novice will find Chapters 5 and 6 particularly useful as an introduction to the field. Chemists who routinely use SAR approaches in research will find this work less helpful, since the problems of defining toxicological endpoints are not treated with the same standards of quality as the chapters on SAR methods. Nevertheless, this book is a valuable review.

New Calcium Antagonists: Recent Developments and Prospects. Edited by A. FLECKENSTEIN, K. HASHIMOTO, M. HERRMANN, A. SCHWARTZ, and L. SEIPEL. Gustav Fischer Verlag, D-7000 Stuttgart 72, Postfach 720143, West Germany. 1983. 236 pp. 15 × 23 cm. Price DM 36.

This book represents the proceedings of a workshop on the calcium channel blocker diltiazem, held in May 1982 in honor of Professor A. Fleckenstein (the "father of calcium antagonists") on the occasion of his 65th birthday. Twenty-four international experts and their coworkers contributed chapters dealing almost exclusively with the authors' personal experimental findings. Of the 24 chapters in the book, only two are of a review nature. However, all the chapters provide recent and fascinating data on calcium antagonists. Although the focus of the workshop is on diltiazem, many other calcium antagonists are discussed throughout the book.

Eleven chapters are devoted to clinical experience with diltiazem and other calcium antagonists in the treatment of angina pectoris, coronary artery stenosis, coronary atherosclerosis, hypertension, and cardiac arrhythmias. The concensus from these chapters, is that the calcium antagonists are most valuable in treating all of these cardiovascular diseases.

Thirteen chapters deal with various aspects of the basic pharmacology of diltiazem and other calcium antagonists. Of these, nine chapters are concerned with the basic and applied pharmacology of calcium antagonists on the cardiovascular system. Among them, a notable chapter discussing the value of calcium antagonists in the prevention of arterial calcinosis provides tantalizing information and paves the way for future preventive clinical uses of this group of drugs. One chapter briefly suggests a therapeutic use for calcium antagonists in cerebrovascular disease, and another chapter details the molecular aspects (and pitfalls) of the binding properties of calcium antagonists to their presumptive membrane receptors and the relation of these receptors to the calcium channels which are blocked by these drugs. A review of the cellular mechanisms by which calcium antagonists preserve the integrity of myocardial cells and intracellular structures provides insightful reading. One chapter outlines the evidence for an interaction of calcium antagonists with presynaptic and postsynaptic α-adrenoreceptors, and serves to remind the reader of the complexity of the mechanism(s) of action of the calcium antagonists. Another reminder is provided in a chapter dealing with inhibition of adrenergic transmission by calcium antagonists at the vascular neuromuscular junction.

Despite the excellent scientific information provided in this book, a number of negative attributes are worth mentioning. The reader is repeatedly distracted by typographical errors which abound in virtually all chapters. Even the title on the front cover suffered from lack of proper proofreading. Furthermore, some chapters appear to have been transcribed from taped presentations, since incomplete sentences, verbless phrases, improper paragraph breakdown, and other miscellaneous grammatical oddities abound. A few chapters do not include a bibliography, and only one chapter was updated prior to publication. Finally, the absence of an index is unnerving, as is the absence of summaries or conclusions in a few chapters and English language summaries for two German language chapters.

In general, the book is most valuable to cardiovascular physiologists, pharmacologists, and clinicians who are involved in research aspects of calcium antagonists. It complements a half-dozen books on the same subject which appeared in the 1980's.

Having a Voice in APhA Scientific Policy

There is a familiar story that most of us have heard in one variation or another. Essentially, it is that people fall into one or another of three groups: (*a*) the great majority, who are doing well if they know what has occurred; (*b*) the relatively few, who are aware of what is presently happening; and (*c*) the very, very few, who are able to foresee where things are headed and what is likely to happen.

This classification has great relevance to policy establishment within the American Pharmaceutical Association. All too many APhA members—as in the case of most professional or scientific societies—learn belatedly of some position the organization has adopted. At that point their reaction is either "why wasn't I told?" or "when was this done?" or "how did that happen?" or "why didn't the leadership inform or consult the membership?"

No one wants to admit that he or she might have been "asleep at the switch," and that he or she has only one's own self to blame for being ignorant on the status of the subject.

At one time or another, we probably have all had this experience and the same reaction to it. Our point in discussing it in this column is simply to be sure that all our readers are aware that they can avoid this situation—at least as far as APhA policy positions that will be established by the Association's House of Delegates during the 1984 Annual Meeting this coming May.

Right now, the 1983–1984 Policy Committee reports, including the recommendations of the Policy Committees, are being released and publicized through APhA publications and *via* news releases to the pharmacy professional and trade press.

At this stage, the recommendations are only in a proposed status. They are open for review, debate, and consideration until early May when Reference Committee open hearings will be held to listen to verbal testimony and to review written comments that have been submitted. The Reference Committees will then make their recommendations to the House of Delegates for final action and policy establishment—but, again, only after further opportunity for debate on the issues within the full House of Delegates.

So, between now and early May, there is ample time for individual members to express their views and to offer their input before those proposals are acted upon. Consequently, everyone has plenty of opportunity to be numbered among the usually select few, who are in the category of knowing not only where we've been, and where we are, but even where we are going.

In addition to presenting this reminder, we would like to clarify another point. That is, the fact that APhA policy issues cover the full spectrum of concerns that are of interest to the membership. Four separate Policy Committees (and four similarly oriented Reference Committees) are appointed each year and are assigned topics considered most appropriate to their individual designations—which are, respectively, Educational Affairs, Professional Affairs, Public Affairs, and Scientific Affairs.

Hence, there is a committee specifically established to study, review, and recommend policy positions on scientific issues.

In recent years, the Association has formally adopted official policy positions emerging from its Policy Committee on Scientific Affairs on such diverse subjects as: (1) the pharmacist's role in postmarketing surveillance for approved drugs, (2) the utilization of institutional review boards (IRBs) for expediting new drug approval, (3) federal regulation of salt in processed foods, (4) the use of animals in drug research, (5) carcinogenicity testing, (6) needed drugs of limited commercial value (orphan drugs), (7) vaccine liability programs, (8) drug product therapeutic equivalence, (9) food labeling, (10) therapeutic orphans, and (11) the medicinal use of marijuana.

When many of these issues were originally debated and the policies established, there was relatively little public interest in those matters. At most, public awareness was just beginning to stir. But then, when the issue "caught fire" in the public eye and in the national political arena, APhA was ready with a well researched, thoughtfully considered, and clearly articulated policy position.

Two typical examples were the use of animals in research and the development of orphan drugs; both of these issues developed into hotly debated topics within the U.S. Congress over the past 2 years, and the Association was ideally positioned to influence the direction of legislation because of its already adopted policy statements.

Currently, APhA members have an opportunity to react to recommendations regarding four subjects, as just proposed by the 1983–1984 Policy Committee on Scientific Affairs. These are relative to: (1) abbreviated new drug applications (ANDAs) for post-1962 drugs, (2) a national center for human organ acquisition, (3) the freedom of scientific information, and (4) the availability of potassium iodide for nuclear accidents.

Moreover, many of the subjects that have been considered by the other three APhA Policy Committees have scientific-related aspects which make them of interest to pharmaceutical scientists.

Therefore, it behooves every member to take the time and effort to study these issues and their corresponding policy proposals. Having done so, any views—either pro or con—ought to be conveyed to the pertinent Reference Committee, either by letter or at the open hearing in May.

Obviously, everyone's wishes cannot be satisfied, particularly when different members will express diametrically opposite views. However, every voice will be heard and every opinion will be taken into consideration in formulating the ultimate policy statement.

And, in a democratic organization—as in a national democracy—that is what we can expect, and all that we can expect.

RESEARCH ARTICLES

In Vivo and *In Vitro* Pharmacokinetics and Fate of Furaltadone in Meat- and Milk-Producing Animals

L. L. NG *§x, R. F. BEVILL, JR ‡, and E. G. PERKINS *

Received August 13, 1981, from the **Burnsides Research Laboratory* and the ‡*College of Veterinary Medicine, Department of Pharmacology, University of Illinois at Champaign–Urbana, Urbana, IL 61801.* Accepted for publication January 26, 1983. §Present address: Merck Sharp & Dohme, West Point, PA 19486.

Abstract □ The metabolism of furaltadone was examined by an *in vitro* hepatic study in cows and goats and an *in vivo* study in goats using ^{14}C-labeled and unlabeled drug. The half-life of furaltadone was 13 min in the homogenates of caprine and bovine liver and 35 min in the *in vivo* study of the goat. Less than 2% of the parent drug was present in the urine of animals dosed either intravenously or intramammarily. No furaltadone was detected in the milk after 24 h. Overall, the parent compound was rapidly absorbed, distributed, and widely degraded in the lactacting goat. The compound, labeled at the 2-formyl carbon of the furan ring, had a radioactivity recovery of 81% in the feces and urine. Of the total radioactivity, 99.4% infused into the udder had been absorbed after 72 h. Tissue distributions of radioactivity in decreasing order of abundance were: kidney, udder, liver, duodenum, muscular tissue, adipose tissue, and bile.

Keyphrases □ Furaltadone—*in vitro* and *in vivo* metabolism, fate in cattle and goats, pharmacokinetics □ Metabolism—furaltadone, *in vitro* and *in vivo*, fate in cattle and goats, pharmacokinetics □ Pharmacokinetics—furaltadone, *in vitro* and *in vivo* metabolism, fate in cattle and goats

The nitrofuran furaltadone, (±)-5-(morpholinomethyl)-3-[(5-nitrofurfurylidene)amino]-2-oxazolidinone (I), had been commonly administered intramammarily to lactating and dry cows for treatment against the micrococci in mastitis (1, 2). In 1973, Cohen *et al.* (3) reported that this nitrofuran had a strong carcinogenic response, and soon after, this compound was withdrawn from the market because of a lack of information on residues of the compound in animals. Paul *et al.* (4) demonstrated the presence of furaltadone in the bile of the chicken and dog and in the urine, but not the feces, of the rat. No furaltadone was found in animal tissues after oral administration, with sensitivity to 1 ppm. Other investigators were unable to detect the parent drug in milk 48 h after treatment using methods with detection limits at 10 ppb (5) and 5 ppm (6). Although these studies showed that furaltadone is biodegradable in mammals, an evaluation of its metabolsim and excretion in livestock and of residues in the blood, milk, and tissues has never been reported.

In the present study, the hepatic metabolism of furaltadone in goats and cattle are evaluated. Data from a pharmacokinetic study in lactating goats, as a model for the cow, are also presented. The distribution and metabolic fate of furaltadone, labeled at the 2-formyl carbon of the furan ring, and unlabeled drug administered intramammarily are compared.

EXPERIMENTAL

Materials—Unlabeled furaltadone was obtained from Norwich Pharmaceutical Co., Norwich, N.Y. [^{14}C]Furaltadone (0.106 μCi/mg) was synthesized in our laboratory[1]. The chemical purity of the compound was determined by TLC in acetone–chloroform (3:1, v/v) on a plate[2]. The spot corresponding to furaltadone in reference to a standard was cut from the plate and counted by liquid scintillation counting (LSC). Purity was >99%. Nonradioactive furaltadone was synthesized by the same preparative procedure. This product was compared with the commercial standard using melting point; elemental analysis; IR, UV, ^{1}H-NMR, ^{13}C-NMR, and MS spectrometry to support the identity of the [^{14}C]-furaltadone.

***In Vitro* Metabolism**—Fresh goat and cattle livers of known weights (~6 g) were homogenized[3] in 0.05 M sodium phosphate buffer, pH 7.4. The 125-mg/mL homogenate was centrifuged[4] at 5°C and 4500 × *g* (7000 rpm) for 10 min and then at 14,000 × *g* (12,500 rpm) for 30 min using a

fixed-angle rotor. The pellet containing the nuclei and mitochondria was discarded and the supernatant was saved.

In vitro experiments were carried out by adding the following ingredients in sequence into test tubes immersed in ice:

1. One milliliter of ^{14}C-labeled or unlabeled furaltadone (~2 μmol) and magnesium chloride (25 μmol) in water,
2. One milliliter of a tissue blank. For the control without furaltadone, magnesium chloride (25 μmol) in water was added.
3. Cofactor buffer mixture consisting of 0.65 μmol of NADP monosodium[5], 10.0 μmol of glucose-6-phosphate disodium[5], and 50.0 μmol of nicotinamide[5] dissolved in 3 mL of 0.5 M sodium phosphate buffer, pH 7.4.
4. Two milliliters of enzymes, containing microsomes equivalent to 250 mg of liver added while the tube was in the incubation bath. The resulting mixture in each test tube was incubated aerobically at 37°C with magnetic stirring in a water bath[6]. Samples in duplicate were removed from the water bath at 0, 5, 10, 20, 30, 40, and 90 min. The control containing no nitrofuran was incubated for 90 min.

***In Vivo* Metabolism with Unlabeled Furaltadone**—Two lactating goats, acclimatized in individual metabolism cages, were fitted with catheters[7] the evening before dosing, and control samples of urine and blood (10 mL) from the jugular vein were collected. A balanced diet consisting of alfalfa hay and water was provided *ad libitum* and a 12% concentrate[8] was given in limited amounts. The animals were milked once a day.

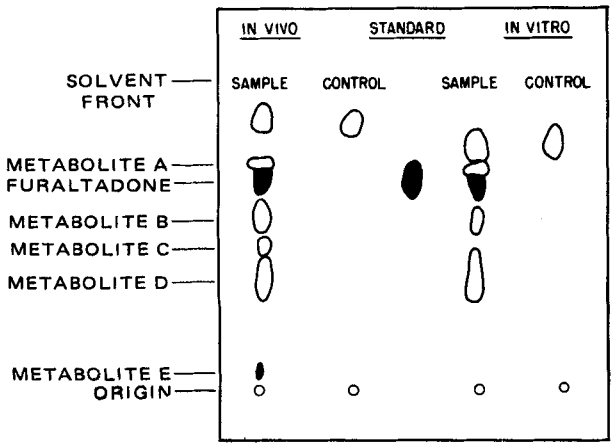

Figure 2—*Comparison of extracts of* in vivo *and* in vitro *metabolites of furaltadone by TLC in acetone–methanol–glacial acetic acid (50:50:1).*

Table I—*In Vivo* Metabolites of Furaltadone by TLC in Two Discrete Systems

Compound	Appearance Under UV Light	R_f Values: Acetone–Acetic Acid (100:1)	R_f Values: Acetone–Methanol–Acetic Acid (50:50:1)
Metabolite A	Bright yellow fluorescent	0.47	0.75
Furaltadone	Dark quenched	0.50	0.66
Metabolite B	Purple fluorescent	0.19	0.55
Metabolite C	Blue fluorescent	0.06	0.46
Metabolite D	Bright yellow fluorescent	0.00	0.42
Metabolite E	Dark quenched	0.00	0.05

Intravenous Dosing—Furaltadone dissolved in acidified water just before dosing was injected into the jugular vein utilizing an intravenous catheter[9] at a dose of 10 mg/kg of body weight immediately after the morning milking. Blood and urine samples were collected at 15, 30, 45, 60, 75, 90, 105, 120, 135, 150, 180, and 210 min.

Intramammary Dosing—The two goats were administered furaltadone equivalent to 37.5 mg/kg of body weight. The nitrofuran was suspended in pure peanut oil[10] using an ultrasonicator[11]. Blood and urine samples were collected at 0.5, 1, 2, 3, 4, 6, 8, 10, 12, 14, 16, 19 and 23 h.

***In Vivo* Metabolism with ^{14}C-Labeled Furaltadone**—A 31-kg milking goat was accommodated and fed under similar conditions as the goats in the unlabeled study. One day prior to treatment, control samples of feces, urine, milk, and blood were collected. The goat was dosed with 777 mg (82.6 μCi) of [^{14}C]furaltadone dispersed in an equal amount of pure peanut oil into the udders immediately after the morning milking. The goat was milked twice a day. Blood and urine were collected at 0.5, 1, 2, 3, 4, 6, 8, 10, 14, 24, 30, 36, 48, 54, 60, and 72 h. The goat was milked every 12 h after infusion for a total of 72 h. Feces were collected every 6 h for the first 12 h and every 12 h for the remainder of the experiment. Aliquots of urine were frozen at −40°C for later analysis. The goat was slaughtered 72 h after treatment. Selected tissue samples and organs were collected and frozen for subsequent analysis.

Analytical Methods—The *in vitro* incubation mixtures were analyzed for furaltadone by direct UV measurement[12] at 360 nm as well as by HPLC. An incubated control served as the background. No metabolite was detectable by HPLC at the concentrations used. All the *in vivo* samples were quantitated in duplicate on a reverse-phase column[13] by HPLC[14] (7) at 360 nm.

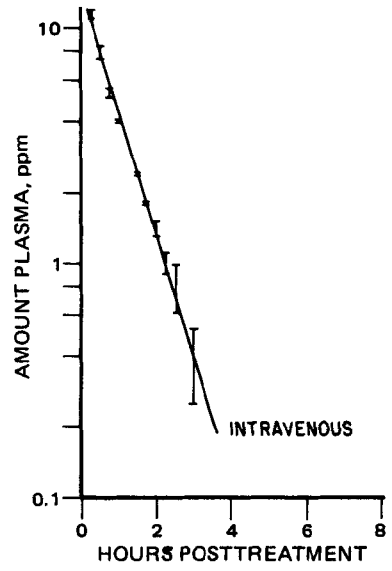

Figure 3—*Concentration of furaltadone in plasma in two intravenously dosed goats: $K_e = 1.17\ h^{-1}$; $t_{1/2} = 0.59\ h$; r = 0.996.*

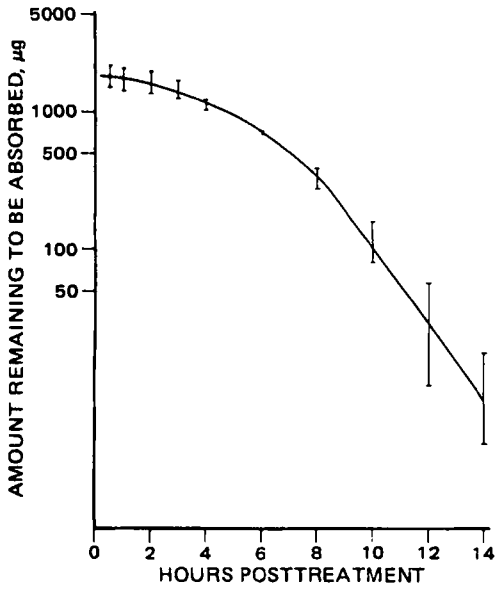

Figure 4—*Amount of furaltadone remaining to be absorbed at various times following its intramammary administration to two goats:* $K_a = 0.53\ h^{-1}$; $t_{1/2} = 1.31\ h$.

The *in vivo* radioactive urine samples were analyzed by TLC. Quantitation was as described for the chemical purity evaluation. Control urine served as the background.

Total Radioactivity Quantitation—Fecal pellets were blended with water (1:8, w/v) in a blender[15]. An aliquot of slurry, in triplicate, equivalent to ~50 mg of feces and 1.5 mL of solubilizer[16] was heated at 52°C for 90 min, cooled, and 0.5 mL of hydrogen peroxide added for decolorization. Radioactivity was determined by LSC[17] after the addition of 10 mL of a fluor[18] and 0.8 mL of 1 M HCl. Whole blood (0.2 mL) was swirled with 0.5 mL of solubilizer[16]–ethanol (1:2) at 60°C. After cooling, 0.5 mL of hydrogen peroxide was added. Whole milk was similarly treated with the elimination of the hydrogen peroxide step. Both milk and blood samples, each in triplicate, were mixed with 10 mL of the fluor and 0.5 mL of 0.5 M HCl and counted by LSC after dark adaptation. Radioactivity in the urine was determined by counting of a mixture containing 0.2 mL of urine, 0.2 mL of water, and 10 mL of fluor. These determinations were carried out at each time period. The level of radioactivity in

Table II—Radioactivity Distribution in a Goat Dosed Intramammarily with [^{14}C]Furaltadone [a]

Source	Recovery After 72 h, % of dose
Blood	0.093
Milk	0.76
Feces	25.11
Urine	56.01
Kidney	0.13
Liver	0.51
Total	82.61

[a] Dose: 82.57 µCi/776.97 mg of furaltadone.

the bile was quantitated by counting 0.2 mL of bile with 10 mL of fluor. Tissues, cut in small pieces, were quick-frozen and ground to a powder. An equivalent of 100 mg of tissue powder was mixed with 0.4 mL of water and 2 mL of solubilizer[16] and warmed at 52°C until dissolved. The total radioactivity was quantitated by LSC after the addition of 10 mL of the fluor and 0.8 mL of 1 M HCl and dark adaptation. Each tissue sample was counted in quadruplicate. The internal standard method with [^{14}C]toluene was employed for all samples. Counting efficiencies were 65–86% for urine, 49–64% for feces, 71–82% for blood, 84–88% for milk, and 73–85% for tissues.

Determination of Bound and Free Radioactivity in the Tissues—The powdered adipose tissue was extracted directly with chloroform (1:7, w/v). The fluor[18] was added to 1- and 2-mL aliquots of chloroform extracts from LSC. The liver, kidney, udder, duodenum, and muscular tissue powders were homogenized with water (1:5, w/v) and extracted with dichloromethane–isopropyl alcohol–water (75:25:2). Each tissue extraction was duplicated and subsequently counted as three phases: organic, aqueous, and a residue pellet. The tissue, expressed in gram-equivalent of protein, was determined by a modified Folin–Lowry assay (8).

Metabolites—A homogenate mixture incubated for 3 h at 37°C was extracted by chloroform and by dichloromethane–isopropyl alcohol–water (75:25:2). Urine from the *in vivo* experiment was extracted by the same solvents. Furaltadone and its metabolites were separated by TLC on silica gel G[19] and developed in discrete systems of acetone–methanol–glacial acetic acid (50:50:1) and acetone–acetic acid (100:1).

RESULTS AND DISCUSSIONS

The first-order disappearance of furaltadone and [^{14}C]furaltadone in supernatants obtained from cattle and goat livers is illustrated in Fig. 1. The half-life of furaltadone disappearance was 13 min during the first 40 min of incubation. Three metabolites (A, B, and D) of furaltadone were

isolated from the liver supernatant using TLC. The metabolites obtained from cattle and goats were similar. The metabolites obtained from the liver supernatant preparations were compared with those in the urine of animals dosed intravenously with furaltadone (Fig. 2 and Table I). Urine from furaltadone-treated animals contained two metabolites (C and E) not isolated from the *in vitro* liver preparations.

The metabolites of furaltadone and furaltadone isolated from liver supernatants failed to account for all the radioactivity present. An incubation mixture was fortified with 3.95 μg/mL of [¹⁴C]furaltadone. Following incubation the mixture contained 0.98 μg/mL. The postincubation supernatant was deproteinized and filtered. The filter cake contained 24.7% of the total radioactivity, the filtrate 72.6%. The presence

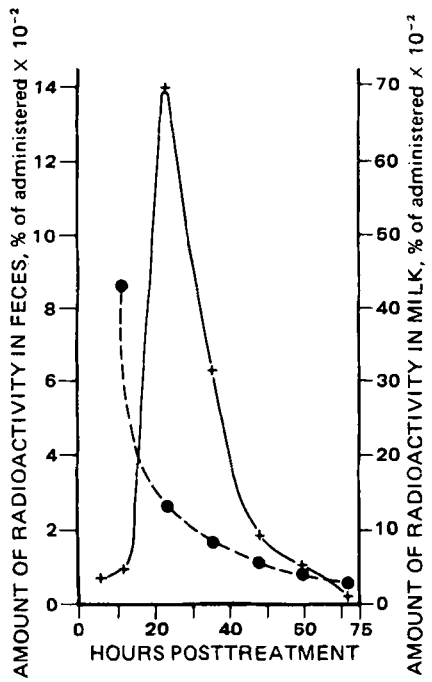

Figure 8—*Radioactive materials found in the feces and milk of a goat intramammarily dosed with [¹⁴C]furaltadone. Key: (+) feces; (●) milk.*

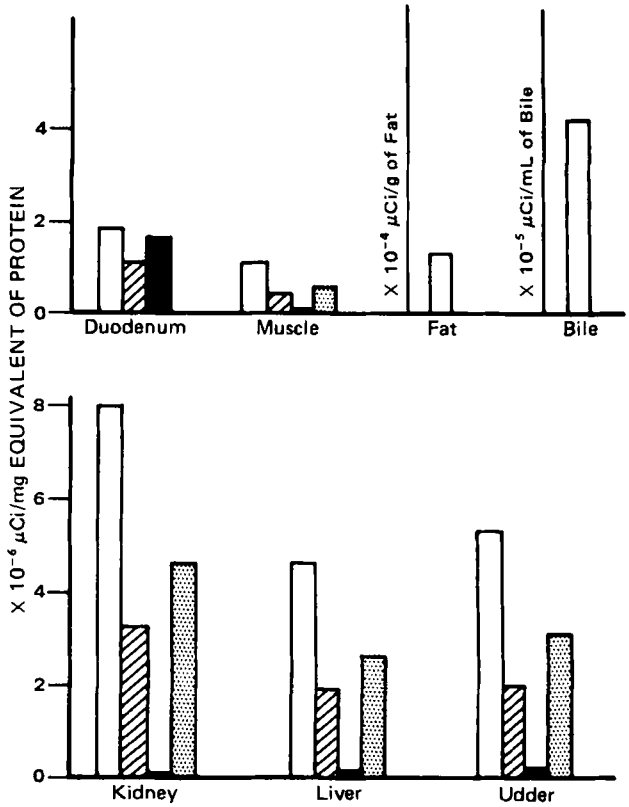

Figure 9—*Distribution of bound and free radioactivity in selected caprine tissues. Key: (□) before extraction; (▨) aqueous phase; (■) organic phase; (▩) residue.*

of carbon-14 in the filter cake indicated that nonextractable radioactivity from [¹⁴C]furaltadone was present. The bound material probably accounted for the persistence of the furaltadone in bovine and caprine liver during the 40–90-min incubation period, illustrated in Fig. 1. When the filtrate was extracted with dichloromethane–isopropyl alcohol–water the ratio of radioactivity in the organic extract to the aqueous filtrate was 1:1, which implied that polar metabolites were present. Similarly, in the *in vivo* study, chloroform and dichloromethane–isopropyl alcohol–water each extracted 13% of the radioactivity in urine.

An *in vivo* absorption, distribution, and elimination study was carried out with unlabeled furaltadone in two milking goats. The linear disappearance of furaltadone from plasma on a semilogarithmic plot of concentration *versus* time (Fig. 3) indicated that the data could be described by a one-compartment open kinetic model. The estimated half-life of furaltadone disappearance in goats was 35.4 min; this was comparable with 33 min in the rat and 37 min in the dog (9). At time zero, the plasma concentration was 14 mg/L. If the plasma occupied 5% of the body weight, the calculated concentration in plasma would have been 200 mg/L based on a dose of 10 mg/kg of body weight. This discrepancy between the observed and calculated concentrations of furaltadone in plasma indicated that furaltadone was rapidly distributed to and sequestered at an extracellular or intracellular site. Similar findings in rats were reported by Buzard and Conklin (9).

The amount of furaltadone remaining to be absorbed was calculated by the method reported previously by Wagner and Nelson (10). The calculated amount absorbed at each time period was plotted against time following drug administration (Fig. 4). The value of K used for calculation was the K_e determined in the intravenous study (1.17 h^{-1}). The half-life of absorption was determined from the linear segment of the curve and used for calculation of the absorption rate constant (10). A comparison of the doses administered and the calculated amounts of drug absorbed during a 14-h postdose period following intramammary drug infusion indicated that an average of 112.3% of the administered dose was absorbed. Although the calculated amount absorbed exceeded 100% and was therefore somewhat in error, the magnitude of the value indicated that furaltadone was almost totally absorbed from the udder. Further support for the almost complete absorption from the udder comes from results obtained following the intramammary infusion of [¹⁴C]furaltadone, where 99.4% of the infused dose was absorbed.

An examination of the rate of excretion of furaltadone and its metabolites in urine following intravenous administration (Fig. 5) indicated that the metabolites were excreted faster than the parent nitrofuran. Less than 2% of the furaltadone administered was recovered as such following intravenous and intramammary administration (Fig. 6).

The two metabolites that were quantitated accounted for <3%, expressed as furaltadone equivalent of the total administered dose. Similar recovery of furaltadone was observed following intramammary [^{14}C]-furaltadone administration to a lactating goat. The 5% recovered as unchanged drug and two metabolites is minor compared with the 56% radioactivity in the urine. Hence, the remainder of the radioactivity must be attributed to the presence of metabolites.

Of the 82.6% radioactivity accounted for in the [^{14}C]furaltadone study, 81% was present in the feces and urine (Table II). Within 48 h after administration, 99% of the radioactivity had been excreted in the urine, (Fig. 7), 95% in the feces, and only 0.06% of the radioactive dose was detectable in the milk (Fig. 8). Furaltadone was rapidly absorbed from the udder, as less than half the radioactivity was detected in the milk from the 12-h to the 24-h milkings. This was also supported in the unlabeled study by the absence of detectable furaltadone in milk 24 h after intramammary dosing.

Radioactive materials were present in decreasing levels of radioactivity in these tissues: kidney, udder, liver, duodenum, muscularis, and adipose tissues (Fig. 9). Of the total radioactivity administered, 1.16 ppm (expressed as furaltadone equivalent) was present per gram of fat, 2.1 ppm per gram of muscle, and 0.5 ppm per milliliter of bile. In the adipose tissue, no radioactivity was extractable with chloroform, which implied the absence of free furaltadone. In the organic solvent extract of the muscle, the equivalent of 0.19 ppm of the original radioactivity was recovered. The remainder of the radioactivity was bound to the tissue residue or was in the aqueous phase. Since furaltadone is lipophilic, and if the parent compound migrated to the tissues in its unchanged form, more radioactivity would be expected in the fatty tissues than in the lean meat. Labeling of normal body constituents as a result of metabolic degradation of furaltadone may explain why more radioactivity was present in the aqueous phase of the muscular tissue. The normal sites of absorption, metabolism, and excretion of furaltadone contained a relatively high amount of radioactivity. However, most of the radioactivity was retained in the aqueous and residue pellet of the udder, liver, and kidney tissue. In the duodenum, on the other hand, more radioactivity was present in the organic extract.

Radioactivity was found in the udder after 72 h, but since the majority of the activity was present in the unextractable residue and in the aqueous phase, it was presumed that furaltadone as such had disappeared from the udder. Of the total radioactivity. 99.4% infused into the udder had been absorbed. From the results obtained, it would appear that the absorption, distribution, and biotransformation of furaltadone in the goat is rapid and extensive.

Vaginal Absorption of a Potent Luteinizing Hormone-Releasing Hormone Analogue (Leuprolide) in Rats IV: Evaluation of the Vaginal Absorption and Gonadotropin Responses by Radioimmunoassay

HIROAKI OKADA ˣ, IWAO YAMAZAKI, TAKATSUKA YASHIKI, TSUGIO SHIMAMOTO, and HIROYUKI MIMA

Received October 12, 1982, from the *Central Research Division, Takeda Chemical Industries, Ltd., 2-17-85 Juso, Yodogawa, Osaka 532, Japan.* Accepted for publication January 11, 1983.

Abstract □ The vaginal absorption of leuprolide (a potent luteinizing hormone-releasing hormone analogue), which has the potential for producing regression of hormone-dependent tumors as well as high gonadotropin-releasing and ovulation-inducing activities, was evaluated in rats by radioimmunoassay. Gonadotropin (luteinizing hormone and follicle-stimulating hormone) release was concomitantly determined. Although leuprolide disappeared rapidly from the serum after intravenous administration (the biological half-lives were 8.4 min in the α-phase and 33.2 min in the β-phase), long-lasting serum levels were observed when the analogue was administered vaginally. The vaginal absorption was enhanced by adding citric acid to the test solution. The absolute bioavailability, estimated by the AUC of serum leuprolide levels, was 25.8% over 6 h and 38.0% over 12 h in the 5% citric acid solution (pH 3.5). The sustained release of gonadotropin was also obtained after vaginal administration of the analogue. A linear dose absorption correlation of leuprolide was obtained in the range of 10–1000 μg/kg in an aqueous solution or methylcellulose jelly. The release of gonadotropin showed a plateau level at >10 μg/kg, which corresponds to an effective dose for antitumor activity. The vaginal absorption of leuprolide varied with the estrous cycle, but this effect was eliminated by prior subcutaneous pretreatment with the analogue.

Keyphrases □ Leuprolide—vaginal absorption in rats, gonadotropin responses, effect of the estrous cycle, radioimmunoassay □ Gonadotropin response—leuprolide in rats, vaginal absorption, effect of the estrous cycle, radioimmunoassay □ Estrous cycle—effect on the vaginal absorption of leuprolide in rats, gonadotropin responses, radioimmunoassay

Leuprolide (I), a potent luteinizing hormone-releasing hormone (II) analogue (desGly^{10}-D-Leu^{6}-II ethylamide), has high gonadotropin-releasing and ovulation-inducing activities (1, 2). Recently, multiple high doses of leuprolide were found to effect regression of hormone-dependent mammary tumors (3, 4) and to have birth control potential in both sexes (5–8).

In our previous studies (9–11), investigations were conducted on the various routes of leuprolide administration for long-term therapy or convenient self-administration and on the absorption enhancement by assessing the ovulation-inducing activity in rats. We found that vaginal absorption was good and was enhanced by adding organic acids such as citric or succinic acid to the test solution. Although the estrous cycle influenced the vaginal absorption of phenolsulfonphthalein and insulin (used as hydrophilic markers), this influence was eliminated by a consecutive daily subcutaneous pretreatment with the analogue. Thus, the vaginal application of leuprolide was proposed as a practical route for long-term usage.

In the present study, we used a newly developed radioimmunoassay (RIA) for leuprolide (12) to investigate the pharmacokinetics of the analogue after intravenous administration, vaginal absorption, absorption enhancement, dose–absorption correlation, and the effect of the estrous cycle on vaginal absorption. Gonadotropin [luteinizing hormone (III) and follicle-stimulating hormone (IV)] release after vaginal administration of leuprolide was also determined by the RIA.

EXPERIMENTAL

Animals and Materials—Mature female Sprague–Dawley rats[1], 120–150 d of age, 250–330 g, which exhibited two or more consecutive 4-d estrous cycles were used. Leuprolide was administered to rats in the morning during the diestrus, except when studying the effect of the estrous cycle. Leuprolide was prepared as described previously (2) and was dried at 50°C under vacuum for 5 h before use. The analogue contained 6.2% acetic acid (as salt) and 2.5% water.

Radioimmunoassay of Leuprolide and Gonadotropin—Serum levels of leuprolide were determined in duplicate by the double-antibody RIA method reported previously (12). The serum sample or standard solution (0.2 mL) was mixed with 0.4 mL of 1% bovine serum albumin[2]–0.01 M phosphate-buffered saline (pH 7.0), 0.2 mL of rabbit anti-leuprolide serum diluted 1:10,000 in 1% bovine serum albumin–phosphate-buffered saline (pH 7.0) containing 0.05 M EDTA, and 0.1 mL of [^{131}I]leuprolide in 0.1% bovine serum albumin–phosphate-buffered saline (pH 7.0). After 48 h of incubation at 4°C, 0.2 mL of an appropriate dilution of goat anti-rabbit γ-globulin serum[3] (0.05 mL) and normal rabbit serum[3] (0.15 mL) in the buffered saline solution was added to each tube and the contents were mixed. Following an additional 24-h incubation at 4°C, the tube was centrifuged at 1000×g for 30 min, the supernatant aspirated, and the precipitate counted in an automatic gamma-counter[4].

Iodination of leuprolide was performed by the lactoperoxidase method (13). [^{131}I]Leuprolide was purified by gel filtration[5] with 0.2 M acetic acid as eluant. The specificity, sensitivity, and accuracy of the RIA for leuprolide have been described and characterized previously (12). The minimum measurable amount of the analogue using the antiserum was ~5 pg/tube (range: 5–10,000 pg/tube); the CV was <11.2% (50–1000 pg/tube) intra-assay and <19.2% (50–1000 pg/tube) interassay.

Gonadotropins (III and IV) in rat sera were also determined in duplicate by double-antibody RIA (14, 15) using kits[6]. Values are expressed in terms of the standard rat gonadotropins, NIAMDD-Rat-LH (RP-1) and NIAMDD-Rat-FSH (RP-1). The measurable range of both gonadotropins in this system was 1–800 ng/tube. The serum samples, stored at −20°C until assayed, were diluted to an adequate concentration with 0.01 M phosphate buffer (pH 7.0) before the assay.

Intravenous, Subcutaneous, and Vaginal Administration—Leuprolide was administered in the morning intravenously (100 μg/kg/0.1 mL of physiological saline), subcutaneously (100 μg/kg/0.1 mL of saline), and vaginally (500 μg/kg/0.2 mL) to diestrous rats under pentobarbital (50 mg/kg ip) and phenobarbital (100 mg/kg ip) anesthesia. For vaginal administration, leuprolide was dissolved in 5% citric acid solution at pH 3.5 (Solution A) and administered with a cotton ball (~12 mg) using a glass inserter (5-mm o.d.). After administration, the orifice of the vagina

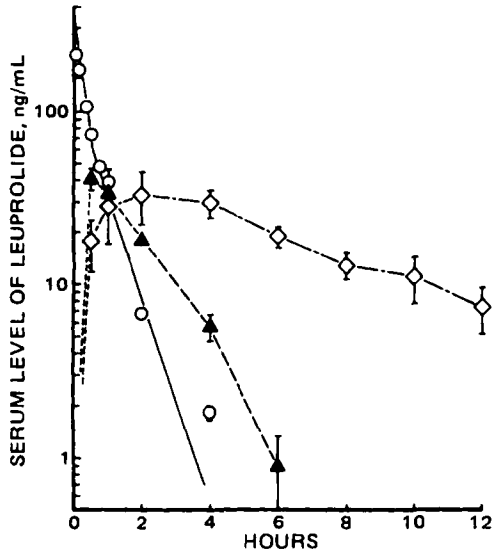

Figure 1—*Serum levels (log scale) of leuprolide after intravenous (○), subcutaneous (▲), and vaginal (◇) administration to diestrous rats. The analogue was administered intraveneously and subcutaneously at a dose of 100 μg/kg/mL in saline, and vaginally at 500μg/kg/0.2 mL in solution A, 5% citric acid solution (pH 3.5). Each point represents the mean ± SE of three or five (vaginal) rats.*

was sealed with a surgical adhesive agent. Blood (~0.5 mL) was collected from the tail vein at appropriate times during 12 h, and the serum was stored until assayed. In cases of intravenous administration, a group of three rats was used for blood collections (0.2–0.5 mL) at 5, 20, 45, 120, and 360 min postadministration and another group was used for collections at 10, 30, 60, and 240 min to prevent physiologically abnormal conditions (hypovolemia).

The pharmacokinetic parameters were obtained by fitting the individual rat data during 6 h to a two-compartment open model *via* the nonlinear least-squares regression computer program NONLIN (16). The

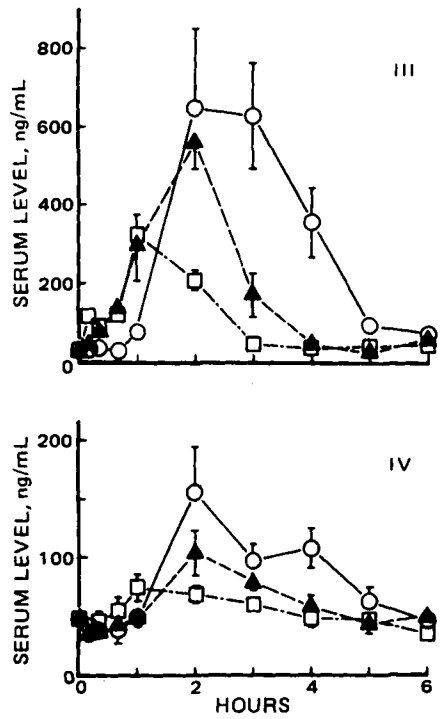

Figure 2—*Serum gonadotropin levels after intravenous (□), subcutaneous (▲), and vaginal (○) administration of leuprolide to diestrous rats. The analogue was administered at a dose corresponding to the ED_{50} of ovulation-inducing activity (38 ng/kg iv, 58 ng/kg sc, and 99 ng/kg) in 5% citric acid solution (pH 1.8) vaginally. Each point represents the mean ± SE of five rats.*

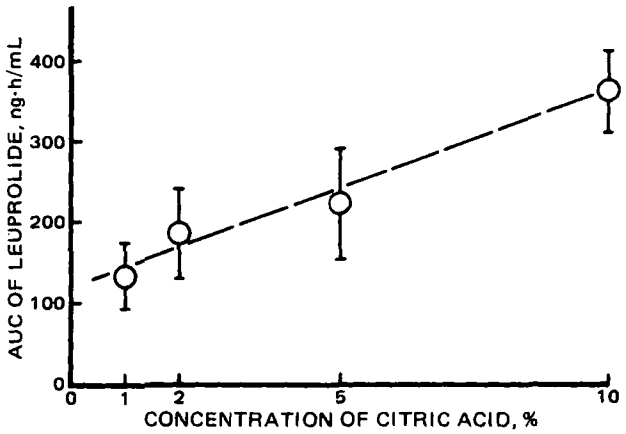

Figure 3—*AUC of leuprolide over 6 h after vaginal administration in the pH 3.5 aqueous solutions containing different concentrations of citric acid to diestrous rats. Dose of the analogue was 500 μg/kg/0.2 mL in the acid solution. Each point represents the mean ± SE of five rats.*

area under the serum level–time curve (AUC) of leuprolide was calculated by a trapezoidal method within the last collected time value, and the bioavailability was obtained using:

$$\text{Bioavailability (\%)} = \frac{AUC^{t}_{0,vag} \text{ or } AUC^{t}_{0,sc}}{AUC^{t}_{0,iv}} \times 100 \qquad \text{(Eq. 1)}$$

where t is the last collection time.

Gonadotropin release was determined after intravenous, subcutaneous, and vaginal administration of leuprolide at the dose corresponding to the ED_{50} of the ovulation-inducing activity [38, 58, and 99 ng/kg, respectively (9, 10)] in unanesthetized rats at diestrus. The analogue was dissolved in physiological saline containing 0.1% bovine serum albumin, 20 U/mL of aprotinin[7], and 0.01 M HCl for intravenous and subcutaneous administration, and in 5% citric acid solution (pH 1.8) for vaginal administration. Whole blood was taken from the abdominal aorta with the rats under ether anesthesia 10, 20, 40, 60, 120, 180, 240, 300, and 360 min after administration.

Enhancement of Vaginal Absorption—Aqueous solutions of leuprolide (500 μg/kg/0.2 mL) containing four different concentrations of citric acid were administered vaginally (cotton ball technique) to anesthetized diestrous rats. Each solution was previously adjusted to pH 3.5 by 10 M NaOH and 2 M HCl and to an isotonic preparation with sodium chloride. Blood was collected from the tail vein to determine the serum levels of leuprolide.

Dose-Absorption and Response Correlations—Four different doses (10–1000 μg/kg) of leuprolide in Solution A or 5% methylcellulose[8] jelly

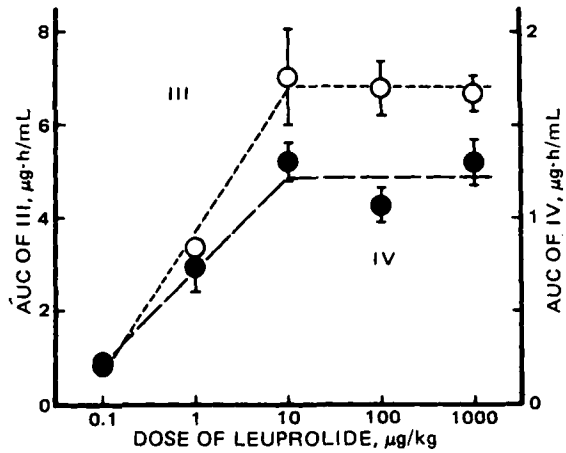

Figure 4—*Dose response (AUC of serum gonadotropin levels over 6 h) curves after vaginal administration of leuprolide to diestrous rats. The analogue was dissolved in solution A and administered at a dose of 0.1, 1, 10, 100 μg, and 1 mg/kg. Each point represents the mean ± SE of five rats.*

[a] 5% citric acid solution, pH 3.5. [b] AUC was calculated from 0 to 6 h; each value represents the mean ± *SE* of five rats.

containing Solution A were administered vaginally to anesthetized diestrous rats to assay the serum levels of the analogue. Leuprolide was also administered vaginally at a dose range of 0.1–1000 μg/kg/0.2 mL in Solution A, and serum levels of gonadotropin were determined.

Effect of the Estrous Cycle—Leuprolide was administered vaginally at a dose of 500 μg/kg/0.2 mL in Solution A to proestrous, estrous, metestrous and diestrous rats under anesthesia, and the serum level of the analogue was determined. To determine the gonadotropin-releasing responses, an oleaginous suppository[9] containing 100 ng of leuprolide and 10% citric acid was administered vaginally to anesthetized rats exhibiting the four different stages of the estrous cycle.

For the determination of the effect of prior pretreatment of leuprolide on the vaginal absorption, 100 μg/kg of the analogue was given subcutaneously daily for 10 d to rats initially exhibiting the four different stages. The following morning, each rat received a single vaginal administration of 500 μg/kg of leuprolide in Solution A, and the serum levels of the analogue were assayed. Vaginal smears during the subcutaneous administration were examined daily to determine the change of the estrous cycle. The vagina and ovaries were removed for histological examination after taking the 6-h-blood samples.

RESULTS

Intravenous, Subcutaneous, and Vaginal Administration—Serum levels of leuprolide after intravenous, subcutaneous, and vaginal administration to diestrous female rats are shown in Fig. 1.

The pharmacokinetic parameters after intravenous administration were obtained by simulating to a two-compartment open model; the serum level (C_t) at time t was expressed by:

$$C_t = Ae^{-\alpha t} + Be^{-\beta t} \qquad \text{(Eq. 2)}$$

with A = 241.5 ± 99.6 ng/mL, B = 122.4 ± 43.1 ng/mL, α = 8.37 ± 4.12 h^{-1}, and β = 1.35 ± 0.23 hr^{-1}. Leuprolide rapidly disappeared from the serum: the half-lives were 8.4 ± 4.0 min in the α-phase and 33.2 ± 6.8 min in the β-phase. The transfer rate constants between central and tissue compartments were 2.99 ± 2.32 h^{-1} (from central to tissue) and 3.79 ± 1.35 h^{-1} (from tissue to central). The elimination rate constant from the central compartment was 2.94 ± 0.92 h^{-1}, and the volumes of distribution were 0.32 ± 0.07 L/kg for the central compartment and 1.31 ± 0.71 L/kg for the tissue compartment. Each value represents the mean ± *SE* of three rats.

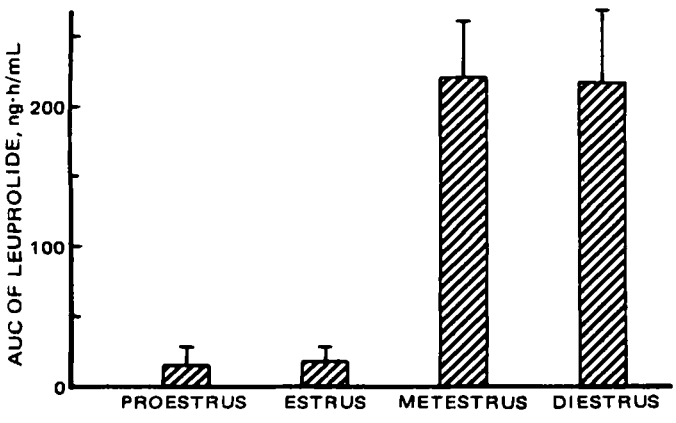

Figure 5—*AUC of leuprolide over 6 h after vaginal administration during different stages of the estrous cycle in rats. Dose of the analogue was 500 μg/kg/0.2 mL in solution A. Each bar represents the mean ± SE of five rats.*

[9] Witepsol S55; Dynamit Nobel Aktiengesellshaft, W. Germany.

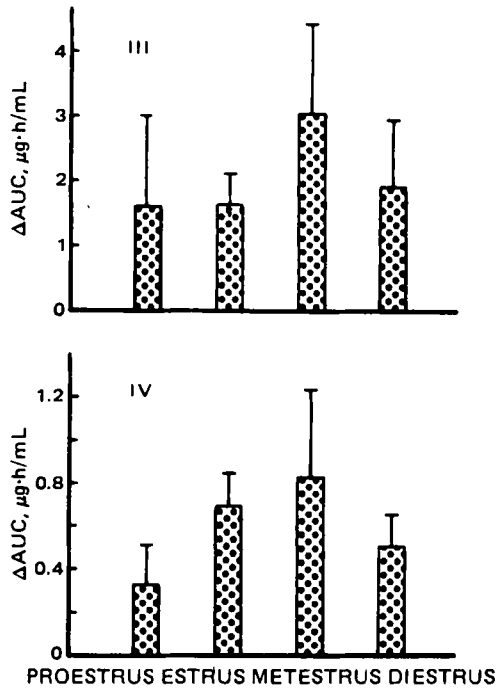

Figure 6—*AUC increment (ΔAUC) of serum gonadotropin levels over 6 h after vaginal administration of leuprolide during different stages of the estrous cycle in rats. The analogue was administered at a dose of 100 ng/rat in an oleaginous suppository containing 10% citric acid. Each bar represents the mean ± SE of three rats.*

The subcutaneous administration resulted in a sustained serum level: the serum level at 4 h after the administration was 3 times higher than that after the intravenous administration. The absolute bioavailability, determined by the AUC over 6 h, was 68.1%. In the case of vaginal administration, leuprolide was absorbed rapidly, and a long-lasting serum level was observed. The maximum serum level was observed 2 h after administration, but values were high and relatively constant over the 6-h period. The absolute bioavailability was 25.8% over 6 h and 38.0% over 12 h.

Gonadotropin-releasing responses to the analogue given by the three routes at doses corresponding to the ED_{50} of ovulation-inducing activity are shown in Fig. 2. The peak times of serum gonadotropin levels were the shortest after intravenous administration, whereas the serum levels after vaginal administration were the highest and had the longest duration. The total release of gonadotropin (which can be represented by the AUC values) after administration of leuprolide by the three routes were directly proportional to the doses given.

Enhancement of the Vaginal Absorption—Serum leuprolide levels after vaginal administration with four different concentrations of citric acid were determined, and the AUC over 6 h is shown in Fig. 3. The AUC increased progressively with the addition of citric acid up to 10%. The absolute bioavailability was 36.0% in the 5% citric acid solution and 58.7% in the 10% solution, which was 2.7 times larger than that in the 1% solution.

Dose Absorption and Response Correlations—Serum leuprolide levels after vaginal administration in either an aqueous solution or a methylcellulose jelly, both containing 5% citric acid, were determined at the dose range of 10–1000 μg/kg, and the AUC values were calculated (Table I). AUC values of serum gonadotropin levels after vaginal administration of leuprolide in Solution A are shown in Fig. 4. A linear relationship between the dose and AUC of leuprolide was observed over the entire range, whereas for the gonadotropin-releasing responses, a linear dose–response correlation was obtained only in the dose range of 0.1–10 μg/kg with a plateau at >10 μg/kg.

Effect of the Estrous Cycle—The AUC (mean ± *SE*) of leuprolide over 6 h after vaginal administration was 15.5 ± 13.0 ng·h/mL during proestrus, 17.4 ± 9.68 ng·h/mL during estrus, 221.3 ± 42.2 ng·h/mL during metestrus, and 218.8 ± 60.8 ng·h/mL during diestrus (Fig. 5). The AUC

values during metestrus and diestrus were 13 times higher than those during proestrus and estrus.

Gonadotropin release after vaginal administration of leuprolide during the four different stages of the cycle showed large variation, and the effect was not so clear as that seen for serum levels of the analogue (Fig. 6). However, the AUC increments of serum gonadotropin levels during metestrus and diestrus were larger than those seen during proestrus and estrus. The serum level of IV at estrus before vaginal administration was twice that seen at the other stages.

Vaginal absorption of leuprolide in rats pretreated with daily subcutaneous administrations of the analogue for 10 d was rapid and of increased magnitude; the maximum serum levels obtained between 1 and 2 h after vaginal administration were ~3 times larger than those in nontreated diestrous rats. The AUC values (mean ± *SE*) over 6 h after vaginal administration were 577.9 ± 59.0 ng·h/mL for proestrus (of the initial stage before cycle was disrupted due to the subcutaneous pretreatment), 530.4 ± 119.6 ng·h/mL for estrus, 571.0 ± 49.5 ng·h/mL for metestrus, and 550.0 ± 6.4 ng·h/mL for diestrus, respectively (Fig. 7).

Despite initiation of the pretreatment at different stages of the estrous cycle, the AUC values of leuprolide showed small fluctuations and were 2.5 times larger than that in nonpretreated diestrous rats. The examination of vaginal smears revealed that the estrous cycle was halted at diestrus in all rats as a result of subcutaneous pretreatment with the analogue. The histological observation after this experiment showed a thinner vaginal epithelium than that seen at normal diestrus, infiltration of neutrophil leucocytes in the vagina, and an increase in the number of corpora lutea with no Graafian follicles in the ovaries.

DISCUSSION

The disappearance of leuprolide from the serum of rats after intravenous administration was rapid; the biological half-lives were 8.4 min in the α-phase and 33.2 min in the β-phase. The half-life in the α-phase was identical to that of [^{3}H]II in female (17) and male rats (18). This result supports the idea that the potent and long-lasting activity of leuprolide is due not to the slow disappearance from the circulation, but rather to the high uptake in the anterior pituitary (19) or to a high receptor-binding affinity (20). The serum level of the analogue after subcutaneous administration was maintained for a longer period than that after intravenous administration, and the absolute bioavailability was 68.1%. After vaginal administration, high and long-lasting serum levels of leuprolide were observed with the absolute bioavailability up to 6 h being 25.8%. Although the true availability should be estimated to be much larger when sampling blood for a longer period, the bioavailability over 6 h paralleled the case of ovulation-inducing activity (10).

Gonadotropin release after leuprolide administration by the three routes, which was evaluated at the lowest dose exhibiting a linear dose–response correlation, was not identical, despite using doses corresponding to the ED_{50} of the ovulation-inducing activity. The different responses are possibly due to the lag time of distribution to the target organ (anterior pituitary), the releasing balance of gonadotropins III and IV, hormonal feedback, and sensitivity of the target cells. Nevertheless, these results do indicate that the vaginal absorption of leuprolide resulted in a maintenance of high serum levels and pituitary responses.

In our previous studies (9, 10) we demonstrated, by the determination of ovulation-inducing activity, that citric acid enhanced the vaginal absorption of leuprolide. In this study, it was directly confirmed that the acid progressively enhanced the vaginal absorption of the analogue at the concentrations used (Fig. 3).

Linear correlations between dose and vaginal absorption of leuprolide in an aqueous solution and methylcellulose jelly (as a practical dosage form) were obtained by determining the serum level of the analogue (Table I). However, both gonadotropin-releasing responses were proportional to the dose within 0.1–10 μg/kg and showed a plateau between 10–1000 μg/kg. Such saturation of the gonadotropin-releasing response at higher doses of II and its analogues has been reported (21–23) and is possibly due to the negative feedback effect of estrogen (24–26) or to the decrease of gonadotropin-releasing hormone receptor cells in the pituitary ("down regulation") (27–29). On the other hand, the minimum effective dose of leuprolide to produce regression of rat mammary tumors induced by 7,12-dimethylbenz[*a*]anthracene was ~100 μg/kg by vaginal administration[10], which is well within the dose range that caused a maximum pituitary stimulation in the present study.

In a previous study, we found that the estrous cycle of rats affected the vaginal absorption of insulin and phenolsulfonphthalein, used as markers

[10] Unpublished data.

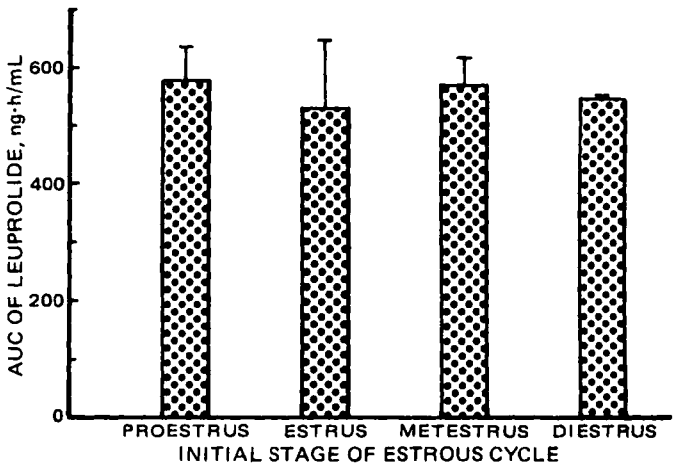

Figure 7—*AUC of leuprolide over 6 h after vaginal administration. Rats were pretreated subcutaneously with the analogue at a dose of 100 μg/kg/d for 10 d followed by a single vaginal dose of 500 μg/kg in solution A. Each bar represents the mean* ± SE *of three rats.*

of hydrophilic compounds (11). The vaginal absorption of leuprolide also was affected by the estrous cycle to the same degree as seen with phenolsulfonphthalein; the vaginal absorption during metestrus and diestrus was 13 times greater than that during proestrus and estrus. The effect of the estrous cycle can be explained by the change of pore-like pathways in the vaginal epithelium (11, 30), producing an unavoidable fluctuation in the vaginal absorption of drugs.

Gonadotropin release after vaginal administration of leuprolide throughout the estrous cycle has not been shown to be clearly dependent on the cycle, as is the case with the serum level of the analogue; high serum levels of gonadotropin were observed even during proestrus and estrus. This phenomenon is ascribed to increased absorbability due to alteration of the vaginal epithelium and to the pituitary responsiveness due to feed-back by progestins and estrogens (31–34) or due to regulation of gonadotropin-releasing hormone receptors (29, 35) during the estrous cycle. The responsiveness of III and IV to leuprolide is the highest at proestrus and estrus, respectively (36–38). Furthermore, the spontaneous surge is provoked in the afternoon of proestrus for III, and from the afternoon of proestrus to the morning of estrus for IV (35, 39). Nevertheless, the high serum levels of gonadotropin during metestrus and diestrus (with the lower pituitary responsiveness) should support the good vaginal absorption of the analogue.

Undue influence of the estrous cycle on the absorption of drugs is unfavorable for effective vaginal application. However, in the case of leuprolide, the pretreatment administration halted the cycle at diestrus, and resulted in a good vaginal absorption of the analogue with less variation. The augmented absorption compared with that in nonpretreated diestrous rats may be attributed to the thinner epithelium of the vagina, as seen histologically. Likewise, the enhancement of vaginal absorption of a hydrophilic marker compound by pretreatment with leuprolide was demonstrated in our previous study (11); cessation of the cycling at diestrus was also demonstrated by the vaginal smear examination and by histological observations.

In summary, leuprolide was absorbed sufficiently through the vagina in diestrous rats; prolonged serum levels of the radioimmunoreactive analogue and potent gonadotropin-releasing responses were observed, and the vaginal absorption of the analogue was enhanced by adding citric acid. Modifying effects of the estrous cycle on the vaginal absorption were observed, but such variations were eliminated by prior parenteral pretreatment with the analogue. From these results, we conclude that vaginal application of leuprolide can be a potentially effective method as self-administration or long-term treatment for anticancer or fertility control. Moreover, we propose that vaginal application of leuprolide be performed as a maintenance dose following consecutive parenteral administration, in order to terminate the menstrual cycle and provide a vaginal environment conducive to maximal analogue absorption with less variation.

In Vitro Release of Salicylic Acid from Lanolin Alcohols–Ethylcellulose Films

ARSHAD R. KHAN *§, BALASUBRAMANIAN V. IYER *‡, ROSETTA A. CIRELLI *, and RAVINDRA C. VASAVADA *x

Received March 11, 1982, from the **School of Pharmacy, University of the Pacific, Stockton, CA 95207* and ‡*Department 947, Lederle Laboratories Inc., Pearl River, NY 10965.* Accepted for publication February 1, 1983. §Present address: Agha Brothers, Karachi, Pakistan.

Abstract □ Lanolin alcohols–ethylcellulose films were investigated as a potential drug delivery system for the controlled release of salicylic acid. The effects of changes in film composition, drug concentration, drug solubility, and stirrer speed on the *in vitro* release of salicylic acid have been examined. The drug release has been found to obey a diffusion-controlled matrix model and square root of time release profile both in the suspension and solution cases.

Keyphrases □ Salicylic acid—*in vitro* release from lanolin alcohols–ethylcellulose films, drug diffusion □ Lanolin alcohols—films with ethyl cellulose, *in vitro* release of salicylic acid, drug diffusion □ Ethylcellulose—films with lanolin alcohols, *in vitro* release of salicylic acid, drug diffusion □ Drug diffusion—*in vitro* release of salicylic acid from lanolin alcohols–ethylcellulose films

The film-forming potential of nonpolymeric materials such as lanolin alcohols, which are extensively used in cosmetic and pharmaceutical formulations, has been recently investigated in our laboratory (1). Lanolin alcohols were found to form isolatable thin films on a mercury substrate. The incorporation of small percentages of ethylcellulose, a known film former (2), and a plasticizer such as propylene glycol with lanolin alcohols was found to give tack-free films of improved quality.

Effective utilization of nonpolymeric substances such as lanolin alcohols in film-forming composition holds considerable promise for a variety of reasons. Such delivery systems could be designed and formulated to provide sustained drug delivery. The potential hazards associated with monomeric impurities in polymers are avoided. Nonpolymeric materials are easy to manipulate and compound, and are relatively easy to obtain in a state of definable composition. They also can be washed from the skin with relative ease using soap and water.

In Vitro Release of Salicylic Acid from Lanolin Alcohols–Ethylcellulose Films

ARSHAD R. KHAN *§, BALASUBRAMANIAN V. IYER *‡, ROSETTA A. CIRELLI *, and RAVINDRA C. VASAVADA *x

Received March 11, 1982, from the **School of Pharmacy, University of the Pacific, Stockton, CA 95207* and ‡*Department 947, Lederle Laboratories Inc., Pearl River, NY 10965.* Accepted for publication February 1, 1983. §Present address: Agha Brothers, Karachi, Pakistan.

Abstract □ Lanolin alcohols–ethylcellulose films were investigated as a potential drug delivery system for the controlled release of salicylic acid. The effects of changes in film composition, drug concentration, drug solubility, and stirrer speed on the *in vitro* release of salicylic acid have been examined. The drug release has been found to obey a diffusion-controlled matrix model and square root of time release profile both in the suspension and solution cases.

Keyphrases □ Salicylic acid—*in vitro* release from lanolin alcohols–ethylcellulose films, drug diffusion □ Lanolin alcohols—films with ethyl cellulose, *in vitro* release of salicylic acid, drug diffusion □ Ethylcellulose—films with lanolin alcohols, *in vitro* release of salicylic acid, drug diffusion □ Drug diffusion—*in vitro* release of salicylic acid from lanolin alcohols–ethylcellulose films

The film-forming potential of nonpolymeric materials such as lanolin alcohols, which are extensively used in cosmetic and pharmaceutical formulations, has been recently investigated in our laboratory (1). Lanolin alcohols were found to form isolatable thin films on a mercury substrate. The incorporation of small percentages of ethylcellulose, a known film former (2), and a plasticizer such as propylene glycol with lanolin alcohols was found to give tack-free films of improved quality.

Effective utilization of nonpolymeric substances such as lanolin alcohols in film-forming composition holds considerable promise for a variety of reasons. Such delivery systems could be designed and formulated to provide sustained drug delivery. The potential hazards associated with monomeric impurities in polymers are avoided. Nonpolymeric materials are easy to manipulate and compound, and are relatively easy to obtain in a state of definable composition. They also can be washed from the skin with relative ease using soap and water.

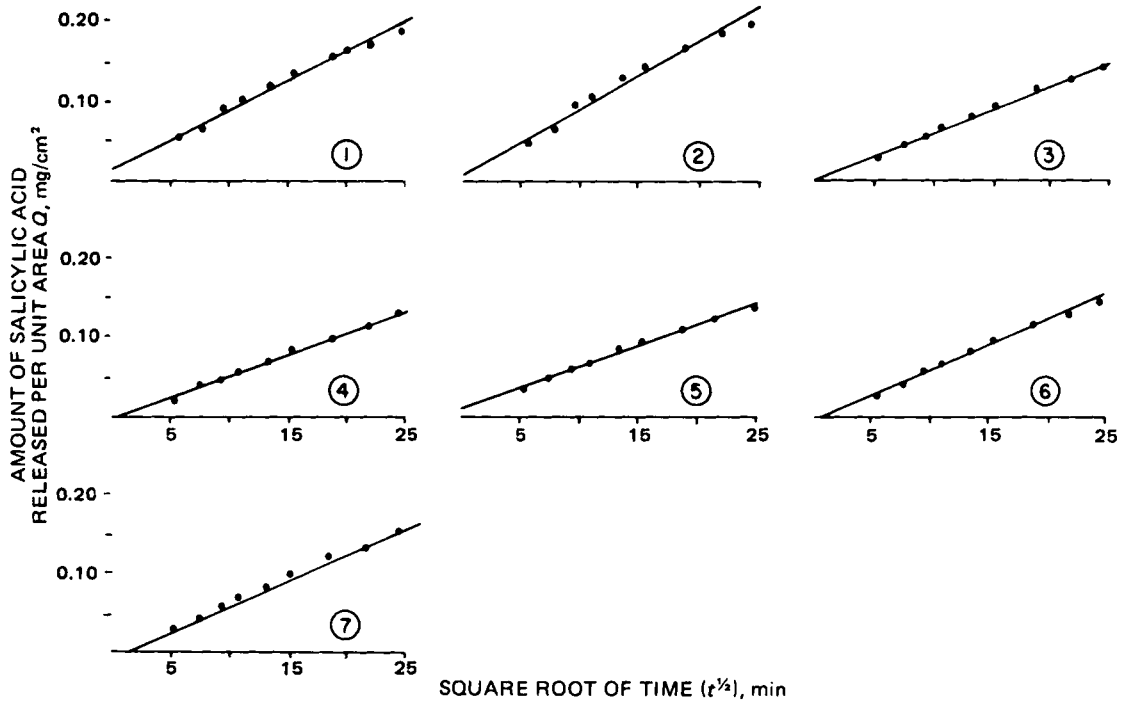

Figure 1—*Release of salicylic acid from films 1–7. Key: (1)* r = 0.992, b = 7.11; *(2)* r = 0.990, b = 7.82; *(3)* r = 0.998, b = 0.11; *(4)* r = 0.999, b = 5.76; *(5)* r = 0.993, b = 5.63; *(6)* r = 0.997, b = 6.34; *(7)* r = 0.999, b = 6.46.

It is the purpose of this study to investigate the *in vitro* release of salicylic acid (a known keratolytic agent) from selected lanolin alcohols–ethylcellulose film compositions with or without propylene glycol as a solvent–plasticizer.

THEORETICAL

In the present study, salicylic acid is assumed to be uniformly dispersed in the film matrix. The solubility of salicylic acid in lanolin alcohols or ethylcellulose is considered negligible based on preliminary work.

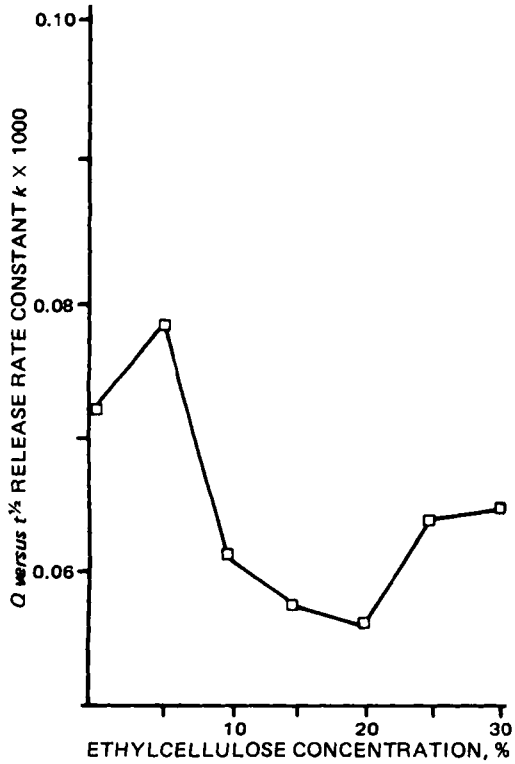

Figure 2—*Effect of vehicle composition on the release rate.*

The release from a planar system having a drug dispersed in a granular matrix has been shown by Higuchi (3) to follow a diffusion-controlled mechanism described by the relationship:

$$Q = \left[\frac{D}{\tau}(2A - \epsilon C_s)C_s \cdot t\right]^{1/2} \quad \text{(Eq. 1)}$$

where Q is the amount of drug released per unit area at time t, D and C_s refer to the diffusion coefficient and solubility of the drug in the permeating fluid, respectively, τ refers to the tortuosity and ϵ to the porosity of the matrix, and A is the amount of drug present in the matrix per unit volume. This equation describes drug release as being linear with the square root of time:

$$Q = kt^{1/2} \quad \text{(Eq. 2)}$$

where k is the rate constant of release:

$$k = \left[\frac{D\epsilon}{\tau}(2A - \epsilon C_s)C_s\right]^{1/2} \quad \text{(Eq. 3)}$$

The release of drug from a granular matrix in which the drug is present as a solution was shown by Desai *et al.* (4) to be:

$$Q = 2\epsilon C_0\left[\frac{Dt}{\tau\pi}\right]^{1/2} \quad \text{(Eq. 4)}$$

with the rate constant of release:

$$k = 2\epsilon C_0\left[\frac{D}{\tau\pi}\right]^{1/2} \quad \text{(Eq. 5)}$$

where C_0 is the solution concentration and the other parameters are as defined earlier. This equation is applicable when the drug released from the vehicle is <50%.

EXPERIMENTAL

Materials—Lanolin alcohols[1] (mp 61–64°C, *d* 0.98 g/mL), ethylcellulose[2] (*d* 1.38 g/mL), propylene glycol USP[3], and salicylic acid USP[4] (*d* 1.44 g/mL) were used as received. The solvents used were anhydrous methanol[5] (spectral grade) and isopropyl alcohol[5].

Solubility Studies—The solubility of salicylic acid in propylene glycol was determined at room temperature (22°C) and 37°C by adding excess

salicylic acid to 20 mL of propylene glycol contained in 50-mL screw-capped glass bottles. A polytef-coated magnetic bar was placed in each of the bottles prior to sealing. The contents of the bottle were then stirred in water baths for a period of 4 d to ensure attainment of equilibrium. All studies were conducted in triplicate.

Prior to sampling, the stirring was stopped and salicylic acid was allowed to settle. An aliquot was then filtered[6]. The filtration and sampling apparatus were equilibrated at 22°C or 37°C for a period of 48 h, and all operations were conducted in a constant-temperature room. Actual measurements of salicylic acid concentration were made using a scanning spectrophotometer[7] at 305 nm[8] after appropriate dilutions with anhydrous methanol to ensure compliance with Beer's Law.

Preparation of Solutions—Solutions containing appropriate amounts of lanolin alcohols, ethylcellulose, salicylic acid, and propylene glycol (if added) were prepared in the following manner. Weighed amounts of ethylcellulose were sprinkled onto 25 mL of isopropyl alcohol over a 2-h period with gentle stirring at 50–55°C. The lanolin alcohols were then dissolved in a similar manner. Prior to addition of the salicylic acid, the solutions were cooled to room temperature, transferred to a 50-mL volumetric flask, allowed to stand for 24 h, and the final volume was adjusted with isopropyl alcohol to give a 10% w/v solution.

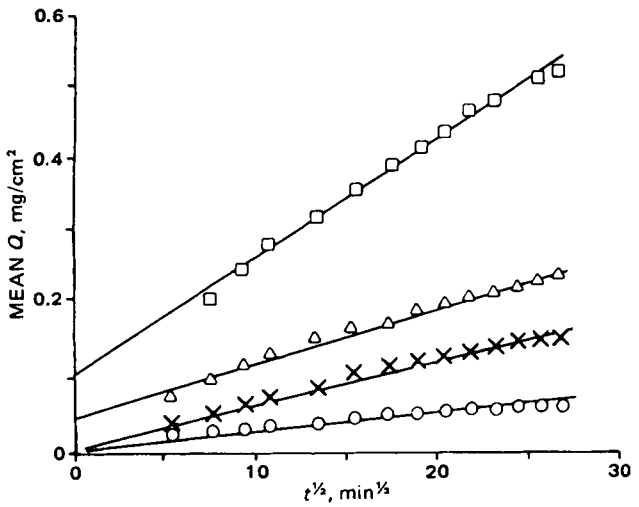

Figure 3—*Drug release from films containing lanolin alcohols–ethylcellulose (8.5:1.5) at different concentrations of salicylic acid. Key: (□) 9.09% w/w; (△) 4.76% w/w; (×) 2.91% w/w; and (○) 0.99% w/w.*

[a] Weight of drug per weight of dry film. [b] All correlation coefficients and k values were computed from the regression line drawn from the data obtained by triplicate runs at each level by using the Tektronix (Model 4005-1) graphics terminal.

Preparation of Films—Two milliliters of an appropriate 10% w/v solution was transferred onto a preweighed glass petri dish (area = 18.1 cm²), placed on a flat surface at room temperature. The petri dishes were kept partially covered for 48 h to ensure slow and uniform evaporation of the solvent and to prevent blistering of the film, this also ensured uniform distribution of drug particles in the film matrix. Complete evaporation was ensured by drying to a constant weight. The film-coated petri dishes were stored in a desiccator (anhydrous calcium chloride) for at least 24 h prior to the release studies.

Release Studies—The release studies were conducted following the method reported previously (1), at 37 ± 0.5°C and a stirring rate of 40 rpm. Three-milliliter samples were drawn at definite intervals over a period of 10 h and, each time, replaced with an equal volume of distilled water. The salicylic acid concentrations were determined spectrophotometrically at 297 nm[9]. The unidirectional release of salicylic acid from the films was ensured by good adherence of the film to the bottom of the petri dish, as confirmed by frequent visual examinations during and at the termination of the release studies. No evidence of peeling was ever recorded. All release studies were conducted in triplicate.

RESULTS AND DISCUSSION

The solubility of salicylic acid in propylene glycol at 22°C and 37°C was found to be 0.481 ± 0.028 and 0.543 ± 0.025 g/mL, respectively; values are expressed as the mean ±SD of three measurements. The solubility of salicylic acid in lanolin alcohol or ethylcellulose was found to be negligible. The film compositions studied are described at appropriate locations in the text.

Release from Films Containing Solid Drug—Adherence of drug release to the Q *versus* $t^{1/2}$ relationship requires that the drug concentration in the film matrix far exceeds solution drug concentration at the interface ($A \gg C_s$ or $\epsilon\ C_s$). In the systems studied, this criterion was satisfied (Table I). The release data were examined in terms of the Higuchi model for a granular matrix. The correlation coefficient (r) for the regression line and the values of the intercept (time) were used as the principal criteria for evaluation.

Q *versus* $t^{1/2}$ plots for films 1–7 containing 2.5% w/w drug are shown in Fig. 1. On examination of the release data for compliance with the Higuchi model (Table II), it was observed that the correlation coefficients were consistently high (0.990–0.999). Three film compositions (*i.e.*, 1, 2, and 5) had negative intercepts, but the values were relatively small. Negative intercepts may be attributed to the immediate release of the drug present on the film surface. The calculated release rate constant

7.5:1.5:1.0	2.91	30.90	−0.05	0.985	0.516
7.5:1.5:1.0	4.76	51.50	−12.22	0.982	0.776

[a] Proportion of lanolin alcohols, ethylcellulose, and propylene glycol expressed as % w/w. [b] Weight of drug per weight of dry film. [c] All correlation coefficients and k values were computed from the regression line drawn from the data obtained by triplicate runs at each level by using the Tektronix (Model 4005-1) graphics terminal.

represents the steady-state region. The variation of rate constant as a function of the film composition is shown in Fig. 2. Interestingly, the release rate constant increased at first with inclusion of ethylcellulose and then declined sharply with increases in ethylcellulose concentration, passing through a minimum value at ~15–20% ethylcellulose before increasing again. Increases in the concentration of ethylcellulose (>20% w/w) resulted in an increased rate of drug release, with a tendency to level off at ~30% ethylcellulose concentration.

Analysis of release data from films containing a fixed proportion of lanolin alcohol and ethylcellulose but varying drug concentrations of salicylic acid (Table III, Fig. 3) further supported earlier observations favoring the Higuchi model. A test previously used by Schwartz *et al.* (5) was then applied. By taking the logarithm, Eq. 2 can be rewritten as:

$$\log Q = \log k + \tfrac{1}{2}\log t \qquad \text{(Eq. 6)}$$

If the Higuchi model indeed described the release mechanism, the slope of log Q *versus* log t plots should be 0.5. The calculated values for the slope ranged from 0.42 to 0.53 with a mean of 0.49.

The effect of change in drug concentration on release rate constant, k, was tested using the four drug concentrations of salicylic acid for one film composition (Table III, Fig. 3). The k *versus* A plot was found to be more linear ($r = 0.996$) than k *versus* $A^{1/2}$ plot ($r = 0.850$). Although Eq. 1 predicts a linear relationship between k and $A^{1/2}$, the observed results could also be explained in terms of Eq. 1 if the initial porosity of the granular matrix was assumed to be very small. Higuchi (3) has shown that if the fraction of the matrix volume occupied by the drug is relatively large or if the initial porosity of the matrix is very small, $\epsilon = VA$ where V is the specific volume of the drug if A is expressed in terms of grams per milliliter. Eq. 3 then reduces to:

$$k = A\frac{DV}{\tau}(2 - VC_s)\,C_s \qquad \text{(Eq. 7)}$$

predicting a direct proportionality between k and A.

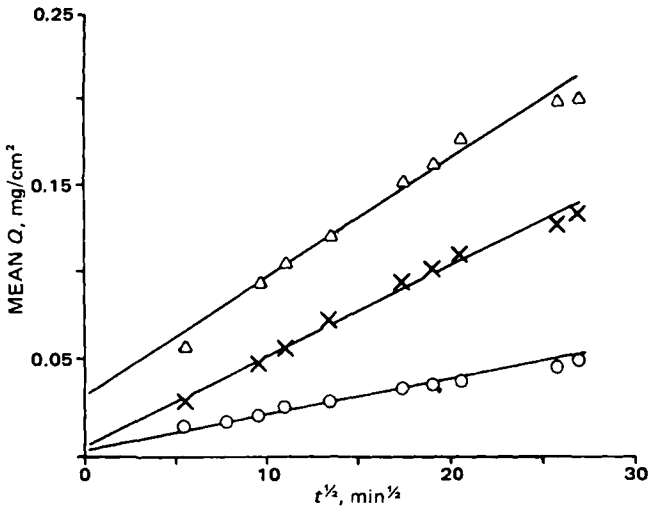

Figure 4—*Drug release from films containing lanolin alcohols–ethylcellulose–propylene glycol (7.5:1.5:1.0) at different concentrations of salicylic acid in solution. Key: (△) 4.76% w/w; (×) 2.91% w/w; and (○) 0.99% w/w.*

Drug Release from Film Matrices Containing the Drug in Solution—The release studies were conducted from lanolin alcohols–ethylcellulose films containing 10% w/w propylene glycol as solvent for the drug. The three drug concentrations examined were 0.99, 2.91, and 4.76% w/w, respectively. In each case the drug concentration was well below the saturation solubility of salicylic acid in propylene glycol. Furthermore, comparative examination of films with and without propylene glycol further established that the drug was in fact in solution.

The Q *versus* $t^{1/2}$ treatment of data showed linearity, but not as good as in the suspension case (Table IV, Fig. 4). It should be noted that the drug released rose to 71%, which was well above the constraints imposed on Eq. 5. The lag times were extremely small except in the case of films containing 4.76% w/w of drug. Equation 5 predicts a linear relationship between k and C_0 for the same system containing different concentrations of the drug in solution. Analysis of the data in Table IV revealed that there is an excellent linear correlation between k and C_0.

The release of both propylene glycol and salicylic acid is not predicted or accounted for by Eqs. 4 and 5. The square root of time dependency would be expected whether or not propylene glycol is released faster than the drug.

This study further demonstrated the potential application of lanolin alcohols–ethylcellulose films in controlled drug-delivery systems. Kinetic analysis suggests that the unidirectional release of salicylic acid from these films (whether the drug was suspended or in solution) follows a diffusion-controlled granular matrix model. The rate and extent of drug release from these films can be effectively manipulated by varying the drug concentration, film composition, and choice of solvent–plasticizer.

On the Mechanism of Dehydration of a β-Hydroxycyclopentanone Analogue of Prostaglandin E_1

HYUK-KOO LEE *x, **HOWARD J. LAMBERT** ‡, and **RICHARD L. SCHOWEN** §

Received August 17, 1978, from the *Pharmacy R&D Department, Ayerst Laboratories, Rouses Point, NY 12979, the ‡Product Development Department, Searle Laboratories, Skokie, IL 60076, and the §Department of Chemistry, University of Kansas, Lawrence, KS 66045. Accepted for publication January 25, 1983.

Abstract □ The dehydration of the β-hydroxycyclopentanone, 11,16-dihydroxy-16-methyl-9-oxo-13-*trans*-protenoic acid methyl ester, an analogue of prostaglandin E_1, proceeds with acid catalysis (pH < 3), by uncatalyzed routes (pH ≃ 4 and ≃ 7), and with base catalysis (pH ≃ 5–6 and > 8). Deuterium from the solvent is not introduced α to the reactant keto function at 60% reaction at pH ≃ 1, but ~30% exchange has occurred at pH ≃ 5, 50% at pH ≃ 7, and 80% at pH ≃ 9. The data are consistent with a mechanism in which the substrate is initially enolized with catalysis by acid, base, and water to a 1,3-enediol, which looses water with catalysis by acid, base, and water. The first stage is rate determining in very acidic solution, while the second stage assumes the limitation of rate to an ever greater degree as the solution becomes more basic.

Keyphrases □ Prostaglandin E_1—β-hydroxycyclopentanone analogue, dehydration kinetics, mechanism □ Kinetics—dehydration of the β-hydroxycyclopentanone analogue of prostaglandin E_1, mechanism □ Dehydration—β-hydroxycyclopentanone analogue of prostaglandin E_1, mechanism, kinetics

The prostaglandins are a structural class of compounds exhibiting the most diverse biological activities (1). Prostaglandin E_1 (alprostadil, Ia) possesses, among other capacities, the potential for inhibiting gastric secretion in humans (2). The analogue of prostaglandin E_1 (Ib) also possesses this activity and is in fact 30-fold more potent than the parent compound when administered orally (3).

E-type prostaglandins tend to undergo dehydration to yield the unsaturated A (II) and B (III) forms (4–6) (Scheme I). We report here some observations on the dehydration of Ib, which illuminate the mechanistic character of its degradation.

EXPERIMENTAL

Materials—Racemic mixtures of the 16α- and 16β-hydroxy epimers and their respective antipodes for 11,16-dihydroxy-16-methyl-9-oxo-13-*trans*-protenoic acid methyl ester (Ib, SC-29333) and its dehydration products, IIb and IIIb, were used as supplied[1].

Kinetics—The UV assay method developed by Monkhouse *et al.* (5) was adopted to follow the dehydration kinetics of Ib. Stock solutions of Ib (2.53×10^{-3} M in methanol) were diluted 50-fold with thermostated aqueous buffer (glycine–HCl, acetic acid–sodium acetate, sodium dihydrogen phosphate–sodium hydroxide, boric acid–sodium hydroxide), purged with nitrogen, and maintained at a constant temperature. Samples were withdrawn at measured intervals and spectra were recorded in Suprasil cells[2] from 200–350 nm. First-order rate constants were calculated; the pH values of the highly acidic solutions were calculated from the known concentrations of hydrochloric acid, with mean activity coefficients obtained or extrapolated from literature data (7). The pH values of the buffer solutions were read at the temperature of study with a pH-meter[3] standardized at the same temperature.

Deuterium Exchange—Exchange reactions were carried out to ~60% dehydration under each set of conditions, in a 44% (v/v) deuterated methanol–deuterated water solvent (CD_3OD–D_2O) of 4.5-mL volume, containing 20 mg of Ib. This solution was then extracted with 5 mL of $CDCl_3$; the extract was evaporated under nitrogen and reconstituted to 3 mL with $CDCl_3$. The NMR spectrum at 350–500 Hz downfield from tetramethylsilane was recorded with 150-Hz scale expansion and time averaging. The ratio of integrated peak areas for the α-H at C-10 (368 Hz) to that of the β-H at C-11 (448 Hz) was calculated.

Experiments were initiated by combining 2 mL of a CD_3OD solution of Ib with 2.5 mL of a D_2O solution of appropriate materials. The latter solutions were: (*a*) 0.1 M DCl in D_2O; (*b*) 29 mg of CH_3COONa and 0.1 mL of CD_3COOD in 10 mL of D_2O; (*c*) 68 mg of KH_2PO_4 and 1.49 mL of 0.2 M NaOD in 10 mL of D_2O; and (*d*) 31 mg of H_3BO_3 and 4.4 mL of 0.1 M NaOD in 10 mL of D_2O. The corresponding temperature and reaction times were: (*a*) 60°C, 3.5 h; (*b*) 70°C, 113 h; (*c*) 80°C, 6 h; and (*d*) 50°C, 2 h.

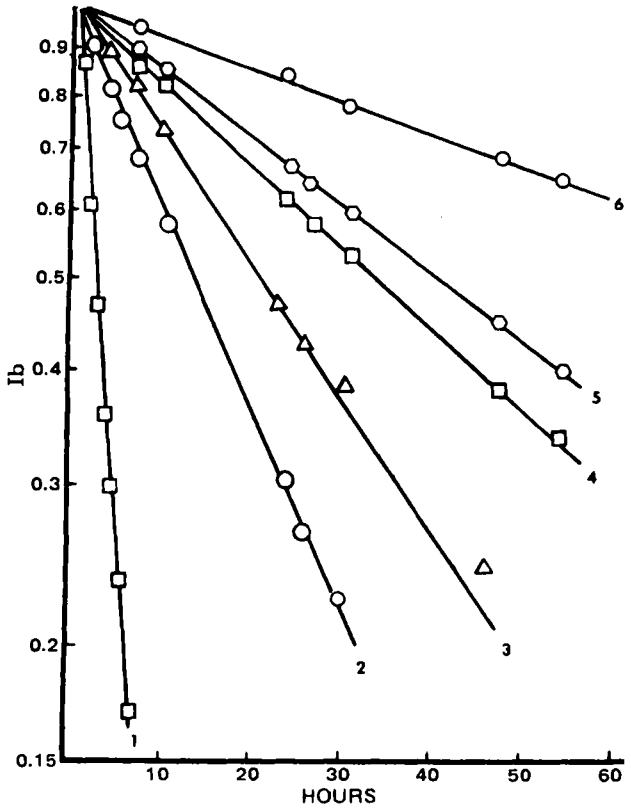

Figure 1—*Typical apparent first-order plots for the dehydration reaction of Ib at 60°C. Key: (1) 0.1 M HCl, pH 1.11; (2) 2.60 × 10^{-3} M KH_2PO_4-NaOH, pH 7.65; (3) 3.18 × 10^{-3} M KH_2PO_4-NaOH, pH 7.23; (4) 2.60 × 10^{-3} M KH_2PO_4-NaOH, pH 6.72; (5) 3.30 × 10^{-3} M KH_2PO_4-NaOH, pH 6.24; (6) 1.6 × 10^{-3} M CH_3COOH-CH_3COONa, pH 5.14.*

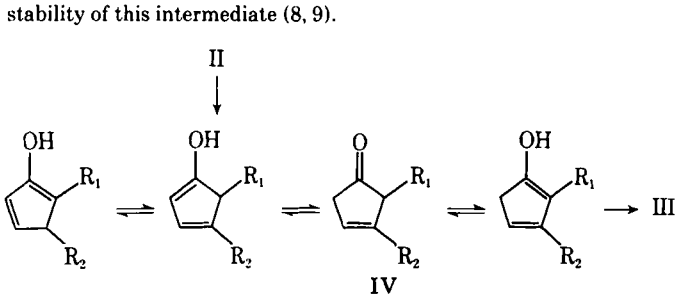
Solvent Isotope Effect—The solvent isotope effect in acidic solution was monitored at 80°C. This study utilized 0.01 M HCl (pH 2.0) with 1% methanol and ~0.01 M DCl (pD was adjusted to 2.0) with 1% CD_3OD.

RESULTS AND DISCUSSION

Stoichiometry—The dehydration of Ib was followed by the appearance of UV bands characteristic of IIb (λ_{max} 222 nm, ϵ 11,000) and IIIb (λ_{max} 288, ϵ 28,000), as shown by independent synthesis and spectral study of IIb and IIIb. Compound IIb appeared to be formed first and then converted to IIIb, which also decreased in concentration after some time. Small amounts of other products, including the 8-epimers of Ib and IIb, could be detected by HPLC, but were minor (<10%) in comparison with IIb and IIIb in 0.1 M HCl and pH 7.4 solutions at 60°C. It is very unlikely that the 8-epimer formation affects the rate of the dehydration reaction of Ib (I → II).

Another possible reaction intermediate, a prostaglandin C-type product (IV), could be formed (Scheme II). Jones (8) reported that prostaglandin C in methanol exhibits a UV λ_{max} at 234 nm (ϵ 21,000) with shoulders occurring at 228 and 243 nm. However, there was no indication of formation of this type of intermediate in the UV spectra throughout the course of the present kinetic studies. It may, of course, be formed but not accumulated in sufficient amounts to be detected because of the instability of this intermediate (8, 9).



Scheme II

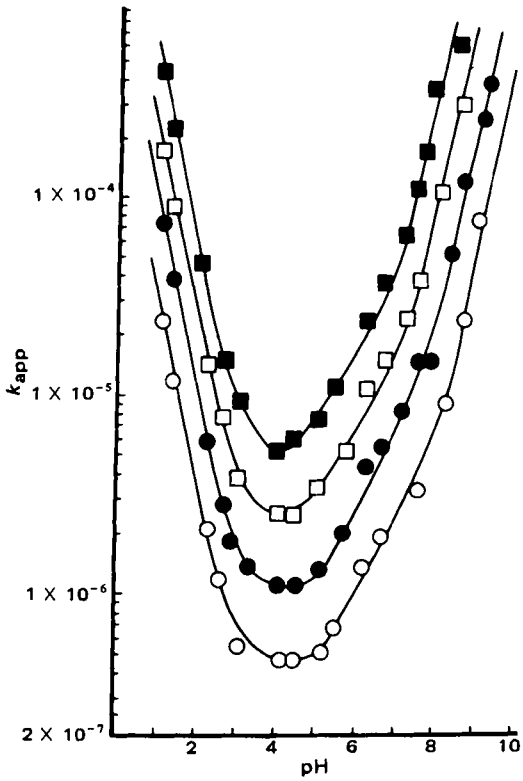


Figure 2—*Log k_{app}-pH profiles for the dehydration kinetics of Ib at several temperatures, where all points were experimentally obtained and the solid lines were fitted by Eq. 1. Key: (○) 50°C; (●) 60°C; (□) 70°C; (■) 80°C.*

When the concentration of Ib at any time was calculated from [Ib] = $[Ib]_0$ − ([IIb] + [IIIb]), with [IIb] and [IIIb] determined spectrophotometrically, first-order plots for loss of Ib were linear for two or more half-lives. Typical first-order plots at various pH values are given in Fig. 1. These data suggest that the major process under study is the irreversible conversion of Ib to IIb, which then proceeds to IIIb and other materials (Scheme I). Our observations do not bear on the conversion of IIb to IIIb or other products, although it is easy to see how IIIb might form from IIb by two simple proton-transfer reactions.

Effect of pH—The complete log k_{app}-pH profiles for the dehydration reaction of Ib at four temperatures are given in Fig. 2. Buffers were used to maintain the pH, but at a concentration of only 3 × 10^{-3} M so that the effects are essentially those of pH. The points of Fig. 2 are experimental; the lines are theoretical and are derived from:

$$k_{app} = k_H a_H + k_0 + k_B \frac{K_a}{K_a + a_H} + k_{OH} \frac{K_w}{a_H} \qquad \text{(Eq. 1)}$$

The rate constants k_H, k_0, k_B, and k_{OH}, as well as the apparent dissociation constant K_a, were shown to be a complex combination of rate constants (no simple definition of those empirical constants can reliably be made at the present stage; however, see Eqs. 13–17). These constant values were determined from the best fit of the log k_{app}-pH profiles in accordance with Eq. 1 (Table I).

Activation Parameters—The Arrhenius plots for the rate constants of Eq. 1 are shown in Fig. 3. The enthalpies and entropies of activation

[a] Determined from the best fit of the log k_{app}-pH profiles in accordance with Eq. 1.

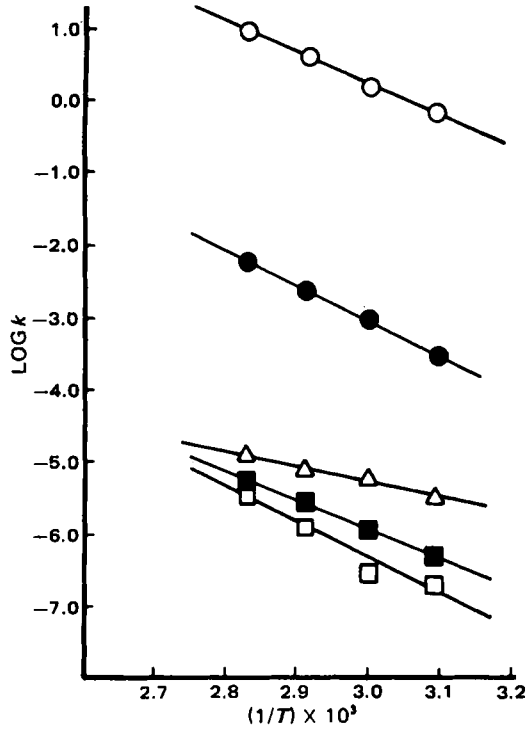

Figure 3—*Arrhenius plots for the apparent catalytic rate constants and the kinetic dissociation constant of dehydration kinetics of I, where each constant was defined by Eqs. 13–17 and each unit was shown as in Table I. Key:* (○) k_{OH}; (●) k_H; (△) k_B; (■) k_0; (□) K_a.

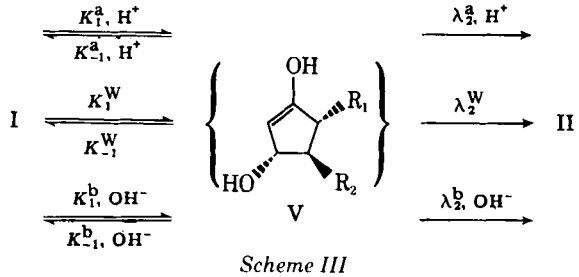
for each constant of Eq. 1 are shown in Table II.

Solvent Isotope Effect—At 80°C and pH (pD) 2.0, the ratio $k_H(H_2O)/k_H(D_2O)$ was found to be 0.8.

Deuterium Exchange at C-10 of Ib—It was possible to make an approximate determination of the degree of deuterium incorporation at the methylene carbon next to the keto function of Ib (C-10) by comparing the intensity of the NMR signal for the α-hydrogen at C-10 (368 Hz) to that of the β-hydrogen at C-11 (448 Hz). The NMR spectrum of IIb obtained from the dehydration reaction of Ib in a medium of 0.05 M DCl–45% CD_3OD showed that no incorporation occurred up to 60% reaction at 60°C. In deuterated acetate buffer in the same solvent at 70°C, ~30% of the C-10 hydrogen had been exchanged at 60°C reaction. A similar experiment with deuterated phosphate buffer showed 50% exchange at 80°C and with deuterated borate buffer 80% exchange at 50°C.

General base catalysis of enolization by buffers might give a larger ratio of exchange to dehydration at the higher buffer concentrations used in the exchange experiments in comparison with the kinetic experiments. However, it seems very unlikely that it could have resulted in an incorrect assignment of the rate-determining steps, since enolization seems clearly established as rate determining at low pH and the shape of the pH–rate profiles requires a partial change in the rate-determining step at pH >7 (*cf., Mechanistic Analysis*).

Formulation of the Rate Equation—A simple mechanism for loss of I, consistent with these findings, is shown in Scheme III. This postulates the conversion of I to its enolic form (V), which is assumed to be present in low steady-state concentrations, by pathways involving acid, base, and water catalysis (10). The enol V then decomposes by three similar pathways to II. Of course, V will be partly or wholly converted to enolate in the more basic solutions, but this will not affect the observable



Scheme III

Table II—Activation Parameters[a] Associated with the Catalytic Constants for the Dehydration of Ib

Catalytic Constant[b]	$\Delta H^{\ddagger}$, kcal/mol	$\Delta S^{\ddagger}$, cal/K·mol
k_H	22 ± 1	−7 ± 3
k_0	18 ± 1	−31 ± 3
k_B	10 ± 1	−54 ± 3
k_{OH}	20 ± 1	+2 ● 3
K_a	19 ± 2[c]	+29 ± 6[c]

kinetics (and cannot be deduced from the kinetics, only assumed on the basis of analogy).

In Scheme III, k_1^a, k_1^w, and k_1^b are the rate constants for hydronium ion-, neutral (water), and hydroxide ion-catalyzed enolization. The terms k_{-1}^a, k_{-1}^w, and k_{-1}^b are for the reverse enolization reaction. For dehydration, λ_2^a, λ_2^w, and λ_2^b are the rate constants for the hydronium ion-, neutral (water), and hydroxide ion-catalyzed dehydration reaction (V → II).

The rate of change in concentration of I, II, and V is described by:

$$-\frac{d[I]}{dt} = (k_1^a a_H + k_1^w + k_1^b K_w/a_H)[I] - (k_{-1}^a a_H + k_{-1}^w + k_{-1}^b K_w/a_H)[V] \quad \text{(Eq. 2)}$$

$$\frac{d[V]}{dt} = (k_1^a a_H + k_1^w + k_1^b K_w/a_H)[I] - (k_{-1}^a a_H + k_{-1}^w + k_{-1}^b K_w/a_H)[V] - (\lambda_2^a a_H + \lambda_2^w + \lambda_2^b K_w/a_H)[V] \quad \text{(Eq. 3)}$$

The steady-state kinetic law for this mechanism is:

$$k_{app} = \frac{(k_1^a a_H + k_1^w + k_1^b K_w/a_H)(\lambda_2^a a_H + \lambda_2^w + \lambda_2^b K_w/a_H)}{k_{-1}^a a_H + k_{-1}^w + k_{-1}^b K_w/a_H + \lambda_2^a a_H + \lambda_2^w + \lambda_2^b K_w/a_H} \quad \text{(Eq. 4)}$$

It is convenient to multiply the numerator and denominator of Eq. 4 by the equilibrium constant (K_1) for enolization of I:

$$K_1 = (k_1^a/k_{-1}^a) = (k_1^w/k_{-1}^w) = (k_1^b/k_{-1}^b) \quad \text{(Eq. 5)}$$

This yields Eq. 6, in which $k_2^a = K_1\lambda_2^a$, $k_2^w = K_1\lambda_2^w$, and $k_2^b = K_1\lambda_2^b$:

$$k_{app} = \frac{(k_1^a a_H + k_1^w + k_1^b K_w/a_H)(k_2^a a_H + k_2^w + k_2^b K_w/a_H)}{(k_1^a + k_2^a)a_H + (k_1^w + k_2^w) + (k_1^b + k_2^b)K_w/a_H} \quad \text{(Eq. 6)}$$

This formulation has the advantage that each rate constant has an initial reference state of I, rather than some referring to I (the K values) and some to V.

The mechanistic kinetic law of Eq. 6 can be related to the phenomenological law of Eq. 1 by expanding the numerator of Eq. 6. Each term in the expansion will be important in a particular pH region:

1. In acidic solution, only terms in a_H are important, and so Eq. 6 can be simplified to:

$$k_{app} \cong \frac{k_1^a k_2^a}{(k_1^a + k_2^a)} a_H \quad \text{(Eq. 7)}$$

2. In less acidic conditions (pH ~4), only k_1^w and k_2^w may be important, so that:

$$k_{app} \cong \frac{k_1^w k_2^w}{(k_1^w + k_2^w)} \quad \text{(Eq. 8)}$$

3. Near neutral pH, acid-catalytic terms are not important, so that:

$$k_{app} \cong \frac{k_1^w k_2^w (a_H)^2 + k_1^b k_2^b (K_w)^2 + k_1^w k_2^b K_w a_H + k_1^b k_2^w K_w a_H}{[(k_1^w + k_2^w)a_H + (k_1^b + k_2^b)K_w]a_H} \quad \text{(Eq. 9)}$$

where $k_1^w k_2^w (a_H)^2$ and $k_1^b k_2^b (K_w)^2$ are negligible, so that Eq. 9 gives:

$$k_{app} \cong \left(\frac{k_1^b k_2^w + k_2^b k_1^w}{k_1^b + k_2^b}\right) \frac{\left[\frac{(k_1^b + k_2^b)K_w}{k_1^w + k_2^w}\right]}{\left[\frac{(k_1^b + k_2^b)K_w}{k_1^w + k_2^w}\right] + a_H} \quad \text{(Eq. 10)}$$

4. At high pH (pH >9) only the k_1^b and k_2^b are important, so that Eq. 6 is simplified to:

$$k_{app} \cong \frac{k_1^b k_2^b}{(k_1^b + k_2^b)}\left(\frac{K_w}{a_H}\right) \quad \text{(Eq. 11)}$$

The overall rate expression, k_{app}, may be represented as the sum of Eqs. 7, 8, 10, and 11, because when one term is important, all the others are not:

$$k_{app} \cong \left(\frac{k_1^a k_2^a}{k_1^a + k_2^a}\right) a_H + \left(\frac{k_1^w k_2^w}{k_1^w + k_2^w}\right) + \left(\frac{k_1^b k_2^w + k_1^w k_2^b}{k_1^b + k_2^b}\right) \cdot \frac{\left[\frac{(k_1^b + k_2^b)K_w}{k_1^w + k_2^w}\right]}{\left[\frac{(k_1^b + k_2^b)K_w}{k_1^w + k_2^w}\right] + a_H} + \left(\frac{k_1^b k_2^b}{k_1^b + k_2^b}\right) \cdot \frac{K_w}{a_H} \quad \text{(Eq. 12)}$$

A comparison of Eqs. 1 and 12 reveals that both have the same mathematical form, so that Eq. 11 provides the correct log k_{app}–pH profiles for the dehydration of I. From Eqs. 1 and 12, the relationships shown in Eqs. 13–17 are obtained:

$$k_H = \frac{k_1^a k_2^a}{k_1^a + k_2^a} \quad \text{(Eq. 13)}$$

$$k_0 = \frac{k_1^w k_2^w}{k_1^w + k_2^w} \quad \text{(Eq. 14)}$$

$$k_B = \frac{k_1^b k_2^w + k_1^w k_2^b}{k_1^b + k_2^b} \quad \text{(Eq. 15)}$$

$$k_{OH} = \frac{k_1^b k_2^b}{k_1^b + k_2^b} \quad \text{(Eq. 16)}$$

$$K_a = \frac{(k_1^b + k_2^b)K_w}{k_1^w + k_2^w} \quad \text{(Eq. 17)}$$

Mechanistic Analysis—The deuterium exchange data and solvent isotope effect can aid in bringing out further detail. First, at low pH, as Eq. 13 emphasizes, either hydronium-catalyzed proton removal from I (k_1^a) or hydronium-catalyzed elimination of water from V (k_2^a) determines the rate. Lack of deuterium exchange suggests that $k_2^a > k_1^a$ (no reversion from V), so that $k_{app} \simeq k_1^a a_H$, with a rate-limiting transition state resembling VI (where L = H in H_2O, D in D_2O).

The solvent isotope effect at 25°C for such a transition state would be given (11) by $k_{H_2O}/k_{D_2O} = (0.69)^3/\phi_1\phi_2^2$, where ϕ_1 and ϕ_2 are isotopic fractionation factors relative to water for the hydrogen attached to the keto group (ϕ_1) and those of the reacting water molecule (ϕ_2). For a limiting reactant-like structure, $\phi_1 \sim 0.69$, $\phi_2 \sim 1.0$ and $k_{H_2O}/k_{D_2O} = 0.48$. For a limiting product-like structure, $\phi_1 \sim 1.0$, $\phi_2 \sim 0.69$, and $k_{H_2O}/k_{D_2O} = 0.69$. Rough correction to 80°C gives limiting predictions of 0.53 (reactant-like) and 0.73 (product-like). The latter is not far from the observed effect of 0.8 ± 0.1.

In acetate buffer, exchange of deuterium concurrently with reaction was observed, with ~30% exchange accompanying 60% dehydration. In this pH range, the dominant term is k_0 (Eq. 14). The exchange indicates some reversion from enol to reactant, so that apparently $k_2^w \gtrsim k_1^w$, with enol formation more important than elimination but not exclusively rate determining ($k_{app} \simeq k_1^w$).

Setting aside the phosphate buffer experiment momentarily, we can examine the borate buffer findings. These pertain to the high pH region governed by k_{OH} (Eq. 16). Since exchange exceeds dehydration (80% exchange, 60% dehydration), base-catalyzed decomposition of the enol dominates but does not wholly control rate limitation ($k_1^b \gtrsim k_2^b$, $k_{app} \simeq k_2^b K_w/a_H$).

Returning to the phosphate buffer exchange data, we note that these are related to the pH region of ~7, where:

$$k_{app} = k_B \frac{K_a}{K_a + a_H} \quad \text{(Eq. 18)}$$

with k_B given by Eq. 15 and K_a by Eq. 17. At low pH in this range, $k_{app} \simeq k_B K_a/a_H$ or:

$$k_{app} = \frac{(k_1^b k_2^w + k_1^w k_2^b)K_w}{(k_1^w + k_2^w)a_H} \quad \text{(Eq. 19)}$$

From arguments in the last two paragraphs, $k_1^b \gtrsim k_2^b$ and $k_2^w \gtrsim k_1^w$, so we can expect that $k_1^b k_2^w > k_1^w k_2^b$ in Eq. 19, or:

$$k_{app} = \frac{(k_1^b k_2^w)K_w}{(k_1^w + k_2^w)a_H} \simeq k_1^b K_w/a_H \quad \text{(Eq. 20)}$$

so that the main rate-limiting process at the acidic end of this pH range is base-catalyzed enolization (presumably proton abstraction from I by the hydroxide ion). At the high pH end of the range, $k_{app} \simeq k_B$ (*cf.* Eq. 15), and by the same arguments as just given:

$$k_{app} \simeq \frac{k_1^b k_2^w}{k_1^b + k_2^b} \simeq k_2^w \quad \text{(Eq. 21)}$$

so that the rate-determining step now tends toward water-catalyzed elimination from V. If enol formation truly determined the rate below pH 7, no exchange would be expected there, and if elimination from the enol truly determined the rate above pH ~7, then 100% exchange would be expected there. In fact, in a phosphate buffer, ~50% exchange was observed at 60% reaction.

We can compare finally the deductions made from the kinetics and the exchange experiments with the activation parameters for consistency. For example, we conclude that k_H is dominated by k_1^a with a transition-state structure like VI. From Table II, the formation of VI from I and hydronium ion is indicated to require $\Delta H^\ddagger \simeq 22$ kcal/mol, $\Delta S^\ddagger \simeq -7$ eu. These are acceptable in terms of the hypothesis, a small negative $\Delta S^\ddagger$ being consistent with a bimolecular process in which some solvation (presumably from the hydronium ion) is released.

For the region of pH 4–5 where k_0 rules, the most important rate constant was k_1^w with some contribution from k_2^w. Speculative structures for the transition state would be VII and VIII, respectively. According to Table II, conversion of I in aqueous solution to chiefly VII and some VIII is accompanied by $\Delta H^\ddagger = 18$ kcal/mol, $\Delta S^\ddagger = -31$ eu. The entropy change, in particular, is reasonable for the "freezing" of water molecules associated with proton transfer and development of change. Since k_B is roughly determined by k_2^w (see argument for Eq. 21), its activation parameters should also correspond to those expected for a transition state like VIII. Indeed the values found ($\Delta H^\ddagger = 10$ kcal/mol, $\Delta S^\ddagger = -54$ eu) are of the magnitudes anticipated.

For k_{OH}, determined chiefly by k_2^b with some contribution from k_1^b, the appropriate transition-state structures are IX and X. Here, as for formation of VI, the energy-requiring, entropy-producing release of water on binding of the strongly solvated hydroxide ion to generate a charge-delocalized transition state leads to relatively large $\Delta H^\ddagger$ (20 kcal/mol) and—from compensation with entropy loss in the bimolecular reaction—to a negligible $\Delta S^\ddagger$ (2 eu).

Lastly we have the equilibrium constant K_a, defined by Eq. 17. This equilibrium constant is for the reaction of Eq. 22; the reactant state for this equilibrium:

$$\begin{Bmatrix} \text{VII} \\ \text{VIII} \end{Bmatrix} \rightarrow H^+ + \begin{Bmatrix} \text{IX} \\ \text{X} \end{Bmatrix} \quad \text{(Eq. 22)}$$

is a weighted average of activated complexes VII and VIII (for water-catalyzed enolization and elimination, respectively), the more stable transition state contributing more to the average, while the product state is a similar weighted average of IX and X (for base-catalyzed formation and decomposition of enol). As the values of K_a in Table I show, the water-catalysis activated complexes are acids of $pK_a \simeq 5.4$–6.7 at 50–80°C, with pK_a estimated at 7.6 at 25°C. As anticipated, this is intermediate between values of 1.74 for H_3O^+ (product-like structure for VII–X) and 15.74 (reactant-like structure for VII–X).

On the other hand, the thermodynamic parameters of ionization are unlike those of stable acids, as judged by the very extensive collection of Izatt and Christensen (12). Most stable acids have smaller, positive ΔH (compared with 19 kcal/mol) and much more negative ΔS (*versus* 29 eu) of ionization than these activated complexes. Conceivably this is a reflection of a greater internal structural plasticity of activated complexes and the greater attendant release of solvation upon ionization.

α,α-Diphenylsuccinimide: Evaluation of Anticonvulsant and Hydrophobic Properties

GARY L. JONES **, ROBERT J. AMATO, and MARY F. JONES

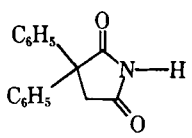
Received December 13, 1982, from the *Department of Pathology, Texas College of Osteopathic Medicine, Fort Worth, TX 76107.* Accepted for publication January 13, 1983. *Present address: Physiology Department, University of Utah, Salt Lake City, UT 84117.

Abstract □ The anticonvulsant potencies (ED_{50}) of α,α-diphenylsuccinimide, phenytoin, and phenobarbital were evaluated in mice by a standard maximal electroshock technique. Potencies were expressed in terms of intraperitoneal dosage and blood and brain concentrations. Overt neurotoxicity (TD_{50}) was assessed by the rotorod method. These data were compared with relative hydrophobicities for the above compounds and three others [carbamazepine, cyheptamide, and (diphenylacetyl)urea] taken from the literature. An approximate parabolic dependence of anticonvulsant potency on hydrophobicity was observed regardless of the means of expressing potency (intraperitoneal dosage, blood concentration, or brain concentration); approximate optimal hydrophobicities were in the range of 2.18–2.23 (log P). Calculated therapeutic indices (TD_{50}/ED_{50}) also displayed a parabolic dependence on hydrophobicity, while toxic potency (TD_{50}) displayed a linear dependence (within the limited range of log P values studied). Implications of the parabolic dependence of anticonvulsant potency and linear dependence of toxic potency on hydrophobicity are discussed with respect to the possible mechanisms involved.

Keyphrases □ α,α-Diphenylsuccinimide—anticonvulsant potency, hydrophobic properties, overt neurotoxicity, maximal electroshock screen in mice □ Anticonvulsants—α,α-diphenylsuccinimide, hydrophobic properties, overt neurotoxicity, maximal electroshock screen in mice □ Hydrophobicity—α,α-diphenylsuccinimide, anticonvulsant potency, overt neurotoxicity, maximal electroshock screen in mice

The synthesis of α,α-diphenylsuccinimide (I) was reported by Miller and Long in 1951 (1). The anticonvulsant profile of the compound was evaluated in rats by a pentylenetetrazole model and in mice by a maximal electroshock (MES) model of epilepsy (1, 2). The compound was judged ineffective (500 mg/kg) in the prevention of pentylenetetrazole-induced seizures. However, sufficient dosage conferred complete protection against MES seizures; the ED_{50} (oral) in the MES model was 45 mg/kg (1, 2). A quantitative estimate of neurotoxicity was not provided. Since this early work, additional reports on the pharmacology of this compound have not appeared, and after three decades its profile remains unclear.

The present study was undertaken (*a*) to evaluate the anticonvulsant, neurotoxic, and hydrophobic properties of α,α-diphenylsuccinimide, phenytoin, and phenobarbital and (*b*) to compare these properties with the same properties for carbamazepine, cyheptamide, and (diphenylacetyl)urea (3, 4). Relative anticonvulsant potencies, determined using a standard MES model of epilepsy (5), are expressed in terms of intraperitoneal dose and blood and brain concentrations. Neurotoxicity was assessed using a rotorod method (6). Relative neurotoxicities and therapeutic indices are reported on the basis of intraperitoneal dose. Relative hydrophobicities were approximated using hydrophobic π-constants (7). Inspection of the data suggests that the potency of α,α-diphenylsuccinimide is subject to the same parabolic dependence on hydrophobicity already described for other compounds (8).



I

EXPERIMENTAL

Drugs—Phenytoin sodium[1] and phenobarbital sodium[2] were gifts. α,α-Diphenylsuccinimide was prepared utilizing a modification of a method described previously (1). The procedure involved the addition of ethyl bromoacetate to a mixture of diphenylacetonitrile in sodium ethoxide. The intermediate ethyl β-cyano-β,β-diphenylpropionate was hydrolyzed, initially in potassium hydroxide to β-cyano-β,β-diphenylpropionic acid and subsequently in concentrated hydrochloric acid to α,α-diphenylsuccinic acid. At this point the synthesis deviated from the published procedure. α,α-Diphenylsuccinic acid was heated at reflux in acetyl chloride to give the anhydride, an ethereal solution of which was treated with ammonia. The intermediate α,α-diphenylsuccinamic acid was removed by filtration and heated at reflux with acetyl chloride to give α,α-diphenylsuccinimide, which was recrystallized from methyl alcohol, mp 140–142°C (reported mp (1) 140–142°C). This material showed one spot on TLC (silica gel, alumina; chloroform). IR (chloroform): 1770 and 1740 cm^{-1} (5-membered ring, imide C=O's); ^1H-NMR (deuterochloroform): δ 3.38 (s, 2, CH_2), 7.16 (s, 10, ArH), and 8.84 ppm (s, 1, NH).

Animal Studies—Phenytoin sodium was suspended in 30% polyethylene glycol 400, and α,α-diphenylsuccinimide was suspended in 5% gum acacia. Phenobarbital sodium was dissolved in 0.9% NaCl. The suspensions were sonicated (probe-type) for ~5 min to produce a fine suspension. The drugs were administered intraperitoneally in a volume of 0.01 mL/g of body weight to male CF_1 mice[3], average weight 22 g. The mice, 30–32 d of age when received, were allowed several days to acclimatize before testing. Food and water were given *ad libitum*.

The anticonvulsant activity of each drug was evaluated by a standard MES test (5). A 60-Hz alternating current (50 mA) was applied for 0.2 s *via* corneal electrodes. Protection was defined as the absence of tonic

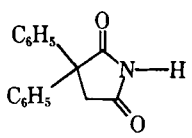
Since this early work, additional reports on the pharmacology of this compound have not appeared, and after three decades its profile remains unclear.

The present study was undertaken (*a*) to evaluate the anticonvulsant, neurotoxic, and hydrophobic properties of α,α-diphenylsuccinimide, phenytoin, and phenobarbital and (*b*) to compare these properties with the same properties for carbamazepine, cyheptamide, and (diphenylacetyl)urea (3, 4). Relative anticonvulsant potencies, determined using a standard MES model of epilepsy (5), are expressed in terms of intraperitoneal dose and blood and brain concentrations. Neurotoxicity was assessed using a rotorod method (6). Relative neurotoxicities and therapeutic indices are reported on the basis of intraperitoneal dose. Relative hydrophobicities were approximated using hydrophobic π-constants (7). Inspection of the data suggests that the potency of α,α-diphenylsuccinimide is subject to the same parabolic dependence on hydrophobicity already described for other compounds (8).



I

EXPERIMENTAL

Drugs—Phenytoin sodium[1] and phenobarbital sodium[2] were gifts. α,α-Diphenylsuccinimide was prepared utilizing a modification of a method described previously (1). The procedure involved the addition of ethyl bromoacetate to a mixture of diphenylacetonitrile in sodium ethoxide. The intermediate ethyl β-cyano-β,β-diphenylpropionate was hydrolyzed, initially in potassium hydroxide to β-cyano-β,β-diphenylpropionic acid and subsequently in concentrated hydrochloric acid to α,α-diphenylsuccinic acid. At this point the synthesis deviated from the published procedure. α,α-Diphenylsuccinic acid was heated at reflux in acetyl chloride to give the anhydride, an ethereal solution of which was treated with ammonia. The intermediate α,α-diphenylsuccinamic acid was removed by filtration and heated at reflux with acetyl chloride to give α,α-diphenylsuccinimide, which was recrystallized from methyl alcohol, mp 140–142°C (reported mp (1) 140–142°C). This material showed one spot on TLC (silica gel, alumina; chloroform). IR (chloroform): 1770 and 1740 cm^{-1} (5-membered ring, imide C=O's); ^1H-NMR (deuterochloroform): δ 3.38 (s, 2, CH_2), 7.16 (s, 10, ArH), and 8.84 ppm (s, 1, NH).

Animal Studies—Phenytoin sodium was suspended in 30% polyethylene glycol 400, and α,α-diphenylsuccinimide was suspended in 5% gum acacia. Phenobarbital sodium was dissolved in 0.9% NaCl. The suspensions were sonicated (probe-type) for ~5 min to produce a fine suspension. The drugs were administered intraperitoneally in a volume of 0.01 mL/g of body weight to male CF_1 mice[3], average weight 22 g. The mice, 30–32 d of age when received, were allowed several days to acclimatize before testing. Food and water were given *ad libitum*.

The anticonvulsant activity of each drug was evaluated by a standard MES test (5). A 60-Hz alternating current (50 mA) was applied for 0.2 s *via* corneal electrodes. Protection was defined as the absence of tonic

hind limb extension greater than a 90° angle with the trunk. The time of peak anticonvulsant effect was determined as described previously (9). Complete dose-response profiles were determined for each drug at its time of peak effect.

Immediately after the MES test, 100 μL of blood was collected in 2% sodium fluoride, and the animal was decapitated. The entire brain was removed and blotted on filter paper. The specimens (including blood) were stored at −80°C until assayed. Blood and brains from 10 mice were pooled for each dose, and at least five doses were employed for each drug.

Relative neurotoxicity was assessed by the rotorod method (6) in which the rodent is placed on a 2.54-cm diameter knurled rod, rotating at 6 rpm. Minimal neurological deficit was defined as the inability of a mouse to remain on the rotating rod for 1 min in at least two of three trials.

The anticonvulsant and neurotoxicity data were evaluated with 95% confidence limits by a quantal statistical method (10). The relative anticonvulsant potencies (ED_{50}) are expressed in terms of blood and brain concentrations, as well as intraperitoneal dosage. The relative neurotoxicity data (TD_{50}) are expressed in terms of intraperitoneal dosage only.

Analytical Methods—The blood and brain concentrations for each drug were assayed by GC. The method for extraction from blood and brain is similar for all three compounds. Aqueous suspensions of blood and homogenized whole brain were saturated with ammonium sulfate and acidified with concentrated hydrochloric acid. These suspensions were extracted with toluene, and the toluene layer was back-extracted with tetramethylammonium hydroxide. The drugs were then derivatized with methyl iodide (11) and extracted into chloroform in the presence of excess 1 M monobasic potassium phosphate. 5-(*p*-Methylphenyl)-5-phenylhydantoin was used as internal standard for the analysis of phenytoin and α,α-diphenylsuccinimide, and 5-ethyl-5-tolylbarbituric acid was used for the phenobarbital assay. Phenytoin was recovered from brain and blood specimens with 77 and 86% efficiency, respectively. Phenobarbital and α,α-diphenylsuccinimide were recovered from either specimen with at least 86% efficiency. Each drug was chromatographed using Supelcoport, 80–100 mesh.

Blood and brain extracts of phenytoin were assayed isothermally at 230°C on 3% OV-17 (injector port and detector temperature 300°C). The retention times for phenytoin and its internal standard were 5.9 and 8.3 min, respectively. Phenobarbital was assayed isothermally in brain extracts at 210°C on 3% OV-17 (injector port temperature 280°C, detector temperature 300°C) and in blood extracts at 170°C on 3% OV-101 (injector port temperature 270°C, detector temperature 340°C). The retention times for phenobarbital and its internal standard were 2.3 and 3.3 min, respectively, for the brain extract, and 2.2 and 3.3 min, respectively, for the blood extract. α,α-Diphenylsuccinimide (I) in brain extracts was assayed with a programmed run from 170°C to 240°C (10°C/min) on 3% OV-17 (injector port and detector temperature 300°C). Assay of I in blood extracts was programmed as follows: 130°C held for 2 min, followed by a 10°C/min increase to 210°C, where it was held for a final 2 min (3% OV-101; injector port temperature 270°C, detector temperature 300°C). The retention times for α,α-diphenylsuccinimide and its internal standard were 8.3 and 3.1 min, respectively, for the brain extract, and 8.9 and 3.7 min, respectively, for the blood extract.

Each method employed flame-ionization detection. The carrier gas (nitrogen), flow rates (50 mL/min), and column dimensions (2-mm i.d. × 1.83 m) were also common for the three drugs, in both blood and brain extracts. An example of a typical chromatogram for α,α-diphenylsuccinimide extracted from brain tissue is depicted in Fig. 1.

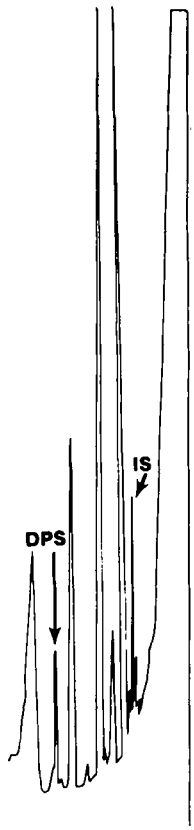

Figure 1—*Chromatogram of α,α-diphenylsuccinimide (DPS) from brain extract. Internal standard (IS) was 5-(p-methylphenyl)-5-phenylhydantoin. See text for methods.*

RESULTS AND DISCUSSION

α,α-Diphenylsuccinimide produced qualitatively the same alteration of MES-induced seizure pattern as that produced by phenytoin or phenobarbital; *i.e.*, the tonic hind limb extension was abolished with sufficient dosage of each drug. The ED_{50} (intraperitoneal dosage) for α,α-diphenylsuccinimide was 26.5 mg/kg (95% confidence limits: 23.4–30.0) (Table I). This is lower than the 45 mg/kg estimate reported for an oral dosage (1, 2). (The apparently greater potency by the intraperitoneal route can likely be ascribed to the greater surface area for absorption by this route.) In comparison, phenytoin and phenobarbital are more potent than α,α-diphenylsuccinimide when estimates are based on intraperitoneal dosage (Table I). However, the difference in potency among these drugs is much smaller when estimates are based on blood or brain concentrations. In fact, α,α-diphenylsuccinimide is more potent than phenobarbital when blood or brain concentration forms the basis of comparison (Table I).

Much of the variation in anticonvulsant potency among these drugs can be explained by a parabolic dependence of potency on hydrophobicity, already described for other agents (8). This is evident if one compares the potency and log P (logarithm of the partition coefficient) values of phenobarbital, carbamazepine, phenytoin, α,α-diphenylsuccinimide, cyheptamide, and (diphenylacetyl)urea (Table I). It will be seen that potency (expressed in terms of intraperitoneal dosage or blood concentrations) increases from phenobarbital to carbamazepine to phenytoin, with the increase of log P from 1.63 to 2.18 to 2.23, respectively. However, potency decreases from phenytoin to α,α-diphenylsuccinimide to cyheptamide to (diphenylacetyl)urea, with the continued increase of log P from 2.23 to 2.63 to 2.74 to 2.83, respectively. If expressed in terms of brain concentrations, potency increases from phenobarbital to carbamazepine with the increase of log P from 1.63 to 2.18, respectively; further increases in log P result in decreased potency. Thus, the optimal hydrophobicity among these compounds is expressed by log P values in the range of 2.18–2.23. This is not too different from the optimal hydrophobicities (log P_O) predicted by others for antielectroshock activity in rats (1.8) and mice (3.7) (12) and for hypnotic activity in rats and mice (2.0) (13). (The fact that log P_O for anticonvulsant activity does not differ significantly from log P_O for hypnotic activity indicates that changes in hydrophobicity alone may not result in more selective anticonvulsant agents.)

A conceptual explanation for the parabolic dependence of potency on hydrophobicity is that molecules must possess a certain degree of lipid solubility in order to "dissolve" in and penetrate the lipid matrix of membranes, and increases in lipophilicity (hydrophobicity) will, within limits, facilitate this process. However, increases beyond a certain optimal hydrophobicity (log P_O) result in lower potency because the molecules increasingly partition within the lipid matrix of the membrane. Because the probability of membrane penetration is thus diminished, higher concentrations of drug are necessary to permit an eventual efficacious engagement of receptors.

If the data in Table I are arranged to express brain–blood concentration ratios, it will be seen that the distribution of drug between the two compartments also follows an approximate parabolic relationship with hydrophobicity. The ratios increase from phenobarbital (0.87) to carbamazepine (2.04) to phenytoin (2.41) with increases in log P up to 2.23;

Table I—Anti-Maximal Electroshock Potency (ED_{50}), Overt Neurotoxicity (TD_{50}), and Calculated Log P of α,α-Diphenylsuccinimide, Phenytoin, Phenobarbital, Carbamazapine, Cyheptamide, and (Diphenylacetyl)urea

	Phenobarbital (III)	Carbamazepine	Phenytoin (II)	α,α-Diphenyl-succinimide (I)	Cyheptamide	(Diphenyl-acetyl)urea
ED_{50} intraperitoneal, mg/kg	19.0(17.1–21.2)	9.7(8.5–11.0)	7.1(6.5–7.8)	26.5(23.4–30.0)	81.0(52.0–127.0)	406(349–472)
blood, μg/mL	17.2(15.5–19.1)	2.4(2.2–2.7)	2.2(1.8–2.8)	5.0(3.4–7.2)	5.5(3.9–7.8)	23(12.6–42.1)
brain, μg/g	15.0(13.6–16.5)	4.9(4.1–5.7)	5.3(4.7–5.9)	8.4(6.4–11.1)	8.9(7.5–10.6)	40(25.5–62.8)
TD_{50}, mg/kg ip[a]	66(62–71)	71[b]	91(84–98)	220(200–241)	170[b]	—[c]
Therapeutic index[d] Log P	3.5(3.1–3.9)	7.6	12.8(11.4–14.3)	8.3(7.3–9.5)	2.1	—[c]
	1.63[e]	2.18[f]	2.23[f]	2.63[g]	2.74[f]	2.83[f]

[a] Overt toxicity was assessed by the rotorod method (Ref. 6). [b] Obtained from the literature (Refs. 15 and 16). [c] Not available from the literature. [d] Calculated for each drug as the ratio TD_{50}/ED_{50} with respect to the intraperitoneal dose (mg/kg). [e] Calculated by π (barbiturate function) + π (C_6H_5) + π (ethyl) = −1.35 (Ref. 13) + 1.96 (Ref. 7) + 1.02 = 1.63 (Ref. 7). The calculated log P was used in preference to the experimental value (1.42, Ref. 13) to maintain consistency among calculated values. [f] Obtained from the literature (Refs. 3 and 4). [g] Calculated by π (succinimide) + 2π(C_6H_5) = −1.29 (Ref. 12) + 3.92 = 2.63.

further increases in log P result in lower ratios. (The only compound which is in poor compliance with this relationship is (diphenylacetyl)-urea.) This, of course, is expected on the basis of the conceptual framework discussed above. Each membrane interposed along the pharmacokinetic path a drug might follow to its receptor will lessen the probability that the drug will ever engage its receptor. The greatest reduction in such probability occurs at extreme values of the partition coefficient. Since one or more membranes must separate the blood from the brain (and receptor) compartments, the decrease in the brain–blood ratios with either very low or very high log P values is likely the result of a failure to enter the lipid bilayer or a failure to penetrate once entry has been made, respectively.

After a comparison was made of the average potency ratios among the above drugs within each category (*i.e.*, intraperitoneal dosage, blood concentration, and brain concentration), it was found that the smallest average potency ratio (3.1, $SD = 2.2$, $n = 15$) was for potencies expressed in terms of brain concentrations; the largest average ratio was for potencies expressed in terms of intraperitoneal dosage (12.1, $SD = 16.5$, $n = 15$), and the average ratio in terms of blood concentrations (4.2, $SD = 3.1$, $n = 15$) was intermediate. This also can be explained within the conceptual framework already discussed. As the number of membranes a drug must penetrate increases, the probability of a particular molecule penetrating all of the membranes decreases; this decrease is disproportionately greater for drugs with hydrophobicities at either extreme. Hence, the smaller average potency ratios expressed on the basis of brain concentrations might simply be an expression of a smaller difference in probability permitted by fewer barriers separating the drug from its receptor. In the formalism of shallow *versus* deep compartmentalization (14), the receptors exist in a relatively more shallow compartment when potency is expressed in terms of brain concentrations than when expressed in terms of intraperitoneal dosage or blood concentration.

Another factor which might partially explain the larger average potency ratios for intraperitoneal dosage is limited aqueous solubility. The log P value is an index of relative solubility in a hydrophobic *versus* aqueous solvent; it is not a measure of the absolute aqueous solubility of a compound. Thus, the role that variance in log P might play in the parenteral absorption of the above drugs might be insignificant in comparison with the variance imposed by significant differences in absolute aqueous solubility. If the drug is not sufficiently soluble in water to permit intimate association with the membrane, the role of hydrophobicity in drug absorption will be minimized.

In contrast with the MES data, overt neurotoxicity assessed by the rotorod method did not exhibit an apparent parabolic dependence on log P. Neurotoxicity data are not available for (diphenylacetyl)urea, but the rotorod TD_{50} values for carbamazepine and cyheptamide in mice are 71 (15) and 170 mg/kg (16), respectively (the estimate for cyheptamide was based on oral dosage). Thus, neurotoxicity seems to be inversely related to log P; higher log P values are associated with lower toxic potency (*i.e.*, higher TD_{50} values). This observation is supported by regression analysis of 16 compounds (15) which provided the following:

$$\log 1/C = 15.94\log MW - 0.97\log P + 0.55\mu - 33.19 \quad \text{(Eq. 1)}$$

where C is the dose producing (in mice) measurable toxicity in 50% of the test population (*i.e.*, TD_{50}), MW is the molecular weight, and μ is the dipole moment. If one compares the above equation with one of several equations which have been written to characterize anti-MES potency, it becomes apparent that overt neurotoxicity is not simply an extension of anticonvulsant activity. For example, anti-MES potency in mice has been characterized by:

$$\log 1/C = -0.22(\log P)^2 + 1.15\log P - 0.37\mu + 2.99 \quad \text{(Eq. 2)}$$

where C is the dose conferring protection against seizures in 50% of the test population (*i.e.*, ED_{50}). Thus, there is considerable evidence for a linear dependence of neurotoxicity on log P (within the dosage range evaluated) and a parabolic dependence of anticonvulsant potency on log P. Furthermore, neurotoxic potency is directly proportional to μ, whereas anticonvulsant potency is inversely proportional to μ. Therefore, it is apparent that the mechanisms conferring toxicity are fundamentally different than those that confer an anticonvulsant effect.

This can also be rationalized if one compares the therapeutic indices (TD_{50}/ED_{50}) for the above drugs. These indices exhibit the same parabolic dependence on log P as does anticonvulsant potency. For example, the therapeutic indices increase from phenobarbital (3.5) to carbamazepine (7.6) to phenytoin (12.8) with successive increases in log P, but the indices decrease from phenytoin (12.8) to α,α-diphenylsuccinimide (8.3) to cyheptamide (2.1) with continued increases in log P (the therapeutic index is not yet known for (diphenylacetyl)urea). This parabolic dependence of therapeutic ratio would not be expected if the toxic and anticonvulsant actions were the result of identical mechanisms.

Although at first thought it might seem that the uniqueness of mechanisms involved might make it easier to design more selective (less toxic) anticonvulsant compounds, the parabolic dependence of therapeutic index on log P severely limits the utility of this parameter in such design. However, it is also apparent that other indices, such as dipole moment, should be explored more thoroughly. As is apparent from the above equations, larger dipole moments might be associated with lower anticonvulsant potency, but greater toxic potency. Thus, it might make sense to screen hypothetical compounds for dipole moment as well as hydrophobicity. Furthermore, as the quantitative structure–activity relationships (QSAR) of anticonvulsant compounds become more fully documented, it is distinctly possible that other physicochemical or empirical indices will contribute still more to rational drug design. The potency data provided herein should be useful in QSAR studies of anticonvulsant compounds, in particular because potency expressed in terms of brain concentration appears more suited for such analysis than potency expressed as parenteral dosage.

Pharmacokinetic Analysis of Concentration–Time Data Obtained Following Administration of Drugs that are Recycled in the Bile

WAYNE A. COLBURN

Received October 4, 1982, from the *Department of Pharmacokinetics and Biopharmaceutics, Hoffmann-La Roche Inc., Nutley, NJ 07110.* Accepted for publication January 18, 1983.

Abstract □ A pharmacokinetic model for calculating the pharmacokinetic parameters for a compound that is recycled in the bile is presented and tested using theoretical as well as experimental data. The results indicate that this method is stable and only slightly susceptible to sampling and recycling times. It is apparent from the present study that pharmacokinetic terms that have been used in classical situations are not directly applicable to drugs that enter the enterohepatic circulation. Effective half-life and effective clearance are used to describe the intrinsic ability of the eliminating organs to remove drug from the blood, whereas net half-life and net clearance are used to describe the irreversible elimination of the drug from the body.

Keyphrases □ Pharmacokinetics—biliary recycling of drugs, theoretical model, applications to cimetidine and isotretinoin □ Biliary excretion—incorporation in pharmacokinetics, model, applications to cimetidine and isotretinoin □ Mathematical models—incorporation of biliary recycling in pharmacokinetics, application to cimetidine and isotretinoin

The ability to predict plasma concentration–time profiles observed following repetitive doses from data obtained following a single dose is an important aspect of pharmacokinetic analysis. In most cases, drugs that follow linear pharmacokinetic models allow these predictions to be made with reasonable certainty. However, when plasma concentration–time data cannot be adequately described by classical pharmacokinetic equations, *i.e.*, saturable processes or enzyme induction, this predictive capability becomes impaired. When a compound is excreted in the bile and subsequently reabsorbed from the GI tract, a similar situation exists in that classical equations cannot be used to sufficiently characterize the erratic and fluctuating plasma concentration–time curves. The purpose of the present investigation was to develop a biliary recycling model, to test its susceptibility to sampling times and experimental error, and to apply it to experimental data from drugs that are known to recycle in the bile.

THEORETICAL

Two distinct types of compounds must be considered when discussing biliary excretion and enterohepatic circulation. In the first category, there are compounds that are recycled but still are eliminated in ≤24 h; indomethacin (1), cimetidine (2), and imipramine (3) are examples from this category. In the second category are compounds that persist for much longer than 24 h; isotretinoin (4), digitoxin (5), and phenprocoumon (6) are examples from this category of substances. For compounds that are eliminated from the body in ~24 h or less, extensive sampling of body fluids is required over the entire interval, whereas for compounds that take substantially longer than 24 h to be eliminated from the body, extensive sampling during the first 24 h and subsequent samples at 24-h intervals are required. The modeling procedure developed herein considers both types of compounds.

Model Development—The following compartmental models (Fig. 1) are among those applicable to the study of blood concentration–time data profiles of compounds that undergo enterohepatic circulation. The models differ only in the sites of elimination. It can be shown that models

1A and 1B are pharmacokinetically differentiated from model 1C when recycling occurs at nonuniform intervals. However, within the limits of analytical precision and considering the biological variation that is associated with experimental data, the four models are not structurally identifiable when blood concentration–time data are evaluated. The four models are pharmacokinetically unique only if blood, urine, feces, and bile are collected following both intravenous and oral doses and analyzed for both parent drug and all metabolites.

One of these models (1A) has been previously described by Veng-Pedersen and Miller (7) and Steimer *et al.* (8), but the integrated equation derived in these manuscripts included only one recycling of bile during the experiment (7). For the purpose of testing the impact of sampling time and experimental error on the model predictions, data will be simulated assuming that the gallbladder empties at each meal ingestion (9) (e.g., at 0700, 1300, 1900 on each day of the study) and that drug is administered at 0700 on day 1 with no meal being ingested at that time. Therefore, the first gallbladder emptying occurs at 1300 on day 1. In the first example (case I) it is assumed that reabsorption begins each time (t_{bile}) that the gallbladder empties. However, in many cases, a conjugate of parent compound is excreted in the bile, deconjugated in the lower intestinal contents, then reabsorbed (10–12). This situation could result in substantial time delay between meal ingestion and subsequent reabsorption (13). For this purpose, blood concentration–time data were simulated after incorporating a 3-h (case II) or 6-h (case III) transit-time lag between gallbladder emptying and the onset of reabsorption (t_{bile}) such that the first reabsorption begins 9 or 12 h after the dose, respectively.

Model Testing—The ability of the recycling model to adequately describe simulated blood concentration–time data following a single dose of drug was tested under the following experimental conditions:

1. Ideal data sets (cases I–III) with four different sampling schedules (see Table I).
2. Ten errant data sets (case II only) with uniformly distributed random error using each of the four different sampling schedules.
3. Ten errant data sets assuming that gallbladder emptying occurred at 5 and 11 h and 10 errant data sets assuming gallbladder emptying occurred at 7 and 13 h during the first 24-h period after dosing to determine the effect of nonsampled recycling times.

In addition, two sets of experimental data were fitted with the model to assess the impact of repeated recycling during the experimental interval. In the first example, cimetidine concentration–time data (14) were *fitted with* model 1A. Patient data were obtained following a single 300-mg oral dose 3 h prior to breakfast (14); no mention was made of subsequent meal times. The results from the present curve-fitting technique are compared with previous attempts to fit the data with the single recycling technique (2). For the second example, blood concentration–time data from a recently completed single 100-mg oral dose pharmacokinetic study with isotretinoin (4) were fitted with model 1A.

Table II—Ideal Theoretical Data Sets Curve-Fitted Using the Different Sampling Schedules

	t_{bile}, h	k_a, h^{-1}	k_{12}, h^{-1}	k_{10}, h^{-1}	V, L
		Case I			
Ideal Schedule	6.00	0.693	0.420	0.0800	400
A	6.00	0.695	0.419	0.0801	401
B	6.00	0.694	0.420	0.0802	400

D	6.00	0.696	0.419	0.0801	401
		Case II			
Ideal Schedule	9.00	0.693	0.420	0.0800	400
A	9.00	0.695	0.419	0.0800	401
B	9.00	0.694	0.420	0.0800	400
C	9.00	0.695	0.419	0.0801	401
D	9.00	0.706	0.411	0.0800	406
		Case III			
Ideal Schedule	12.0	0.693	0.420	0.0800	400
A	12.0	0.695	0.419	0.0801	400
B	12.0	0.695	0.419	0.0800	400
C	12.0	0.696	0.418	0.0800	401
D	12.0	0.695	0.419	0.0802	401

In this second example, it was assumed that the gallbladder emptied at meal ingestion and that the time to transit in the intestine to sites where deglucuronidation could occur was constant after each meal. In this way, a single recycling parameter could be estimated and used to calculate subsequent recycling times on the basis of meals ingested. All concentration (C_B) data were fitted with the differential equations required to describe model 1A in conjunction with the nonlinear least-squares regression program, NONLIN (15), using $1/C_B$ weighting[1].

In addition, a net elimination rate constant during recycling (β_R) can be determined by performing log-linear regression on concentration–time data at 24-h intervals during the elimination phase, *e.g.*, 24, 48, 72, and 96 h or 12, 36, 60, and 84 h. The determination of β_R is based on the assumption that gallbladder emptying and subsequent reabsorption occur at the same times each day. Therefore, if recycling occurs at the same time during each 24-h interval, the β_R obtained by fitting data points collected at 24-h intervals should reflect the true elimination rate since the concentration–time points fall on the same portion of the sinusoidal recycling curve. Experimentally, this can be achieved by controlling the time and type of food intake. This curve-fitting procedure was tested by introducing uniform random error into theoretical concentrations.

RESULTS

The parameters estimated for ideal theoretical data sets from cases I–III with the four different sampling schedules (Table I) are presented in Table II. The parameters estimated for 10 errant data sets from case II using the four different sampling schedules are presented in Table III. The parameters estimated for 10 errant data sets from 5- and 11-h recycling data and from 7- and 13-h recycling data are presented in Table IV.

It is apparent from the parameter estimates in Table II, that when no error is present in the data, the curve-fitting procedure is not dependent on either the times of recycling or sampling. Similarly, the mean parameter estimates presented in Tables III and IV would indicate that, on the average, the curve-fitting procedure is not strongly influenced by either recycling or sampling times. However, the variation around the mean values are greater for sampling schedules C and D than for schedules A and B, *i.e.*, when nonsampled intervals (Table I) become >2 h.

By introducing ±10% error into the 24-, 48-, 72-, 96-, and 120-h samples, it was possible to assess the impact of random error on the estimation of β_R. For the purpose of testing an extreme case, 10% error was added to the 24-h concentration and subtracted from either a 48-, 72-, 96-, or 120-h concentration. When 10% error was subtracted from the 48-, 72-, 96-, and 120-h concentration, the error introduced into β_R was 29.0, 14.5, 9.7, and 7.3%, respectively. It is apparent that the more time points and the longer the time used to calculate β_R, the more precise will be the estimate.

The results from curve-fitting the cimetidine blood concentration–time

[1] A listing of the FORTRAN program used in this study is available from the author on request.

data are presented in Table V, and a representative plasma concentration–time profile is presented in Fig. 2. Similarly, the results obtained by curve-fitting isotretinoin blood concentration–time data are presented in Table VI, and a representative curve is presented in Fig. 3. The parameter estimates determined by curve-fitting experimental data from the literature for cimetidine (14) and blood concentration–time data presently being generated in this laboratory for isotretinoin show the applicability of the procedure.

Comparing the results of the present analysis of cimetidine blood concentration–time data with those reported in the literature using the single-recycling model of Veng-Pedersen and Miller (2), it appears that the complexities associated with the previously reported model may not be required to fit the data. If one assumes that a second recycling occurs during the time-course of the study, one can adequately fit the data without having to involve the complexities inherent in the two-compartment distribution model of Veng-Pedersen and Miller. It is difficult to justify the more complex model when recycling occurs at 2–6 h intervals and sampling is not sufficiently frequent to differentiate biphasic distribution characteristics from the recycling characteristics. In fact, it can be shown that when sampling is infrequent a recycled drug that conforms to model 1A in Fig. 1 exhibits what appears to be a two-compartment model profile. In addition, when it is not possible to simultaneously fit data from several routes and modes of administration, parsimony dictates that the simplest model should be chosen.

DISCUSSION

A model-dependent method for calculating the pharmacokinetic parameters for a compound that is recycled in the bile has been presented and tested using simulated theoretical data as well as experimental data. The results indicate the the method is stable, only slightly susceptible to changes in sampling and recycling times, and adequate to describe the blood concentration–time profiles of drugs that recycle in the bile.

The results of the present analysis suggest that more explicit terms are required to describe the pharmacokinetic parameters of compounds that are recycled in the bile. The blood clearance (CL_B) determined by the classical method:

$$CL_B = \frac{\text{Dose}}{AUC_{0-\infty}} \qquad \text{(Eq. 1)}$$

does not reflect the *effective* clearance (CL_E) of the drug by the liver. From model 1A, it can be shown that:

$$CL_E = V \cdot K \qquad \text{(Eq. 2)}$$

where the *effective* elimination rate constant (K) is the sum of k_{10} and k_{12} in model 1A. However, the *net* clearance (CL_N) derived from model 1A according to the following equation:

$$CL_N = V \cdot k_{10} \qquad \text{(Eq. 3)}$$

is equivalent to CL_B. This distinction in clearance terms is similar to the approach previously employed by Kwan *et al.* (1) with indomethacin. However, it is a more unified approach which incorporates the differences in clearance into a single pharmacokinetic modeling technique.

Levy (16) has stated that fitting concentration–time data obtained following the administration of drugs that are involved in the enterohepatic circulation to classical pharmacokinetic models results in an overestimate of the true volume of distribution and an overestimation of the true half-life of the compound. In fact, curve-fitting data from compounds that are recycled to classical bi- or triexponential equations does overestimate the true volume of distribution and the *effective* elimination half-life ($t_{1/2E}$), derived from $0.693/K$. However, curve-fitting with classical equations may not, depending on the erratic nature of the blood concentration–time profile, overestimate the *net* elimination half-life ($t_{1/2N}$), derived from $0.693/\beta_R$ where β_R is the net elimination rate constant. β_R is related to the elimination rate constant (k_{10}) by:

$$\beta_R = F_1 \cdot k_{10} \qquad \text{(Eq. 4)}$$

where F_1 is the average fraction of the total amount of drug in the body that is in the blood compartment during any 24-h interval. This net elimination half-life ($t_{1/2N}$) is in fact the true elimination half-life, since it reflects the fraction of a dose that still remains to be irreversibly eliminated (17).

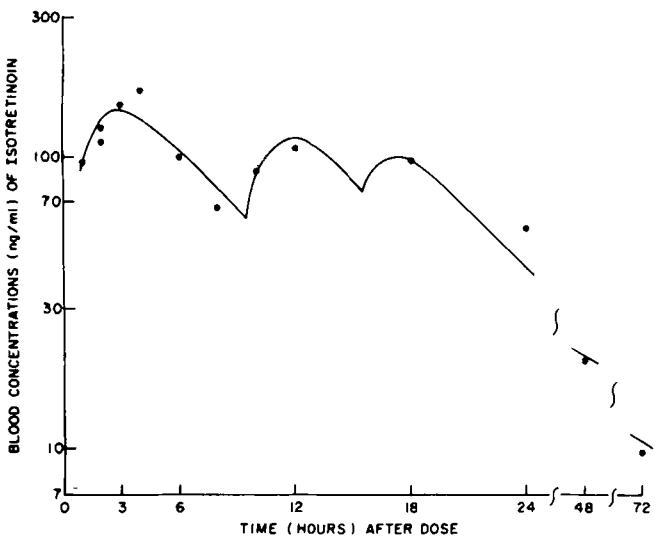

Figure 3—*Representative blood concentration–time profile of isotretinoin from subject 8 along with the model-predicted curve.*

If one applies these concepts to the data obtained for cimetidine and isotretinoin, interesting results are obtained. For cimetidine CL_E = 1393 mL/min (range 849–2170) and CL_N = 777 mL/min (range 81–1151), suggesting a first-pass effect ($E = CL_E/Q + CL_E$) of 0.36–0.59. However, using the net clearance to calculate the apparent first-pass effect ($E = CL_N/Q + CL_N$) yields values of 0.05–0.43, which are consistent with the conclusions from the original report (14). For isotretinoin, CL_E = 1906 mL/min (range 1116–3253) and CL_N = 571 mL/min (range 191–1150), suggesting a true first-pass effect of ~0.40. However, since isotretinoin is eliminated solely by liver clearance, 65–77% of the drug that is cleared by first-pass will be returned through enterohepatic circulation, resulting in an apparent first-pass effect of ~0.28. The average fraction (F_1) of the total amount of drug in the body that was in the blood compartment was 0.32.

It became apparent during these curve-fitting procedures that the pharmacokinetics of drugs that are incorporated into the enterohepatic circulation are complex, and development of their profiles will require specialized clinical studies. Two important aspects of performing clinical pharmacokinetic studies with compounds that recycle in the bile is to establish an appropriate experimental design and to maintain well-controlled conditions. Sufficient blood samples must be obtained to adequately characterize the recycling time course during a 24-h interval, and the time of meal ingestion must be controlled to ensure that the variation in recycling times is minimized.

In conclusion, a model-dependent method for analyzing pharmacokinetic data from drugs that are recycled in the bile has been developed and tested. It is apparent that the pharmacokinetic terms used in other situations are not directly applicable to drugs that enter the enterohepatic circulation. Effective half-life and effective clearance have been introduced to describe the intrinsic ability of the liver to remove drug from

the blood, whereas net half-life and net clearance have been used to describe the permanent elimination of the drug from the body.

Quantitative Determination of *N*-(*trans*-2-Dimethylaminocyclopentyl)-*N*-(3′,4′-dichlorophenyl)propanamide and Its *N*-Demethyl Metabolite in Dog Serum by Gas Chromatography

DUANE B. LAKINGS ˣ, RONALD P. STRYD, and TERRY J. GILBERTSON

Received July 23, 1982, from the *Pharmaceutical Research and Development, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication February 17, 1983.

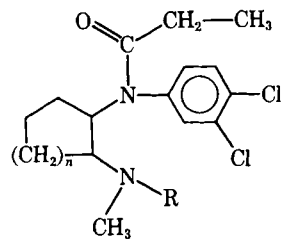
Abstract □ A gas chromatographic–electron capture (GC–EC) method has been developed for the determination of *N*-(*trans*-2-dimethylaminocyclopentyl)-*N*-(3′,4′-dichlorophenyl)propanamide, a potential antidepressant drug, and its *N*-demethyl metabolite in serum. The GC–EC system employed a 3% OV-17 on 100/120 mesh Supelcoport, 2-m × 2-mm i.d. glass column and an isothermal temperature of 195°C. The parent drug and metabolite were extracted from alkalinized serum (pH ~ 13) with toluene, back-extracted into an acidic solution (pH ~ 1), and finally, after adjusting to pH 13, extracted again with toluene. The extensive sample cleanup was necessary to remove serum components which interfered with the analysis. The analytical method was shown to give quantitative recovery of the drug and metabolite, to be linear over a 100-fold concentration range, and to have the necessary precision and sensitivity to detect and quantify as little as 1 ng/mL of the drug or its metabolite. The method has been employed to determine the serum level of drug and metabolite in dogs receiving a single oral dose and to determine the possible correlation between the administered dose and serum levels.

Keyphrases □ *N*-(*trans*-2-Dimethylaminocyclopentyl)-*N*-(3′,4′-dichlorophenyl)propanamide—quantitative determination, *N*-demethyl metabolite in dog serum, gas chromatography–electron capture □ Gas chromatography—electron capture, quantitative determination of *N*-(*trans*-2-dimethylaminocyclopentyl) -*N*- (3′,4′-dichlorophenyl) propanamide and its *N*-demethyl metabolite, dog serum

Some tricyclic antidepressants (*e.g.*, imipramine) used in the treatment of endogenous depression require an induction period of several days before improvement is noted and have been reported to have frequent side effects (1, 2). A potential antidepressant drug, *N*-(*trans*-2-dimethylaminocyclopentyl)-*N*-(3′,4′ - dichlorophenyl)propanamide (I) which may have a more rapid onset of therapeutic activity and fewer side effects was recently reported (3).

For definition of the pharmacokinetic and metabolic profiles of this potential antidepressant drug, a sensitive, precise, and specific analytical method is required. The presence of two chlorine moieties in the aromatic ring provides sufficient electronegativity for electron-capture (EC) detection after gas chromatographic (GC) separation. Initial studies[1] had shown that the drug was quickly demethylated at the dimethylamine functional group to give II. Also, a homologue of I with a cyclohexyl ring in place of the cyclopentyl ring was available (III) and was an ideal internal standard.

This report describes the GC–EC method for the quantitative determination of I, its *N*-demethyl metabolite, and the internal standard and the sample preparation procedure necessary to isolate the compounds from serum and to provide a sample amenable to GC–EC determination. Application of the methodology was demonstrated by the determination of serum levels of I and II in dogs



I: R = CH_3, n = 1

Quantitative Determination of *N*-(*trans*-2-Dimethylaminocyclopentyl)-*N*-(3′,4′-dichlorophenyl)propanamide and Its *N*-Demethyl Metabolite in Dog Serum by Gas Chromatography

DUANE B. LAKINGS ˣ, RONALD P. STRYD, and TERRY J. GILBERTSON

Received July 23, 1982, from the *Pharmaceutical Research and Development, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication February 17, 1983.

Abstract □ A gas chromatographic–electron capture (GC–EC) method has been developed for the determination of *N*-(*trans*-2-dimethylaminocyclopentyl)-*N*-(3′,4′-dichlorophenyl)propanamide, a potential antidepressant drug, and its *N*-demethyl metabolite in serum. The GC–EC system employed a 3% OV-17 on 100/120 mesh Supelcoport, 2-m × 2-mm i.d. glass column and an isothermal temperature of 195°C. The parent drug and metabolite were extracted from alkalinized serum (pH ~ 13) with toluene, back-extracted into an acidic solution (pH ~ 1), and finally, after adjusting to pH 13, extracted again with toluene. The extensive sample cleanup was necessary to remove serum components which interfered with the analysis. The analytical method was shown to give quantitative recovery of the drug and metabolite, to be linear over a 100-fold concentration range, and to have the necessary precision and sensitivity to detect and quantify as little as 1 ng/mL of the drug or its metabolite. The method has been employed to determine the serum level of drug and metabolite in dogs receiving a single oral dose and to determine the possible correlation between the administered dose and serum levels.

Keyphrases □ *N*-(*trans*-2-Dimethylaminocyclopentyl)-*N*-(3′,4′-dichlorophenyl)propanamide—quantitative determination, *N*-demethyl metabolite in dog serum, gas chromatography–electron capture □ Gas chromatography—electron capture, quantitative determination of *N*-(*trans*-2-dimethylaminocyclopentyl) -*N*- (3′,4′-dichlorophenyl) propanamide and its *N*-demethyl metabolite, dog serum

Some tricyclic antidepressants (*e.g.*, imipramine) used in the treatment of endogenous depression require an induction period of several days before improvement is noted and have been reported to have frequent side effects (1, 2). A potential antidepressant drug, *N*-(*trans*-2-dimethylaminocyclopentyl)-*N*-(3′,4′ - dichlorophenyl)propanamide (I) which may have a more rapid onset of therapeutic activity and fewer side effects was recently reported (3).

For definition of the pharmacokinetic and metabolic profiles of this potential antidepressant drug, a sensitive, precise, and specific analytical method is required. The presence of two chlorine moieties in the aromatic ring provides sufficient electronegativity for electron-capture (EC) detection after gas chromatographic (GC) separation. Initial studies[1] had shown that the drug was quickly demethylated at the dimethylamine functional group to give II. Also, a homologue of I with a cyclohexyl ring in place of the cyclopentyl ring was available (III) and was an ideal internal standard.

This report describes the GC–EC method for the quantitative determination of I, its *N*-demethyl metabolite, and the internal standard and the sample preparation procedure necessary to isolate the compounds from serum and to provide a sample amenable to GC–EC determination. Application of the methodology was demonstrated by the determination of serum levels of I and II in dogs

N-demethyl metabolite (II), and the internal standard (III) were used as obtained[4]. All other reagents and chemicals were of the highest quality available.

Chromatographic Conditions—A 3% (w/w) OV-17 on 100/120 mesh Supelcoport[5] in a 2-m × 2-mm i.d. glass column was used throughout these studies. The column was conditioned at 270°C for 24 h and deactivated by injecting 20 × 5 μL of bis(trimethylsilyl)trifluoroacetamide[6]. The conditioning and deactivation were necessary to prevent tailing by the compounds. The injector and detector temperatures were maintained at 300°C, and the column was isothermal at 195°C. The argon–methane (95:5, v/v) carrier gas flow rate was 25 mL/min, and the purge flow was 40 mL/min. The ^{63}Ni EC detector was operated in the pulse mode. All injections were made with a 10-μL syringe[7], and injection volumes varied from 2 to 5 μL.

Stock Solution Preparation—Stock solutions of I and II were prepared by accurately weighing 10.0 mg of I and II each into 100 mL of toluene–methanol (80:20, v/v), with concentrations of I and II at 100 μg/mL. Aliquots from this stock solution were diluted to give a working stock containing 1000 ng/mL of each compound. The working stock solution was used to prepare reference standard solutions and to fortify serum samples at various levels of I and II. An internal standard stock solution was prepared in a similar manner. The working internal standard stock solution concentration was 250 ng/mL.

Sample Preparation Procedure—The analysis of low levels, *i.e.*, nanograms per milliliter, of compounds in physiological fluids by GC–EC techniques requires that the compounds of interest be isolated from most components present in the sample and be dissolved in an organic solvent amenable to EC detection. The following sample preparation procedure employed liquid–liquid extraction to isolate I and II from serum components.

One milliliter of serum was transferred into a culture tube with a pol-

ytef-lined screw cap. An equal volume of 1 M NaOH containing 100 mg/mL of NaCl was added, and the solution was mixed thoroughly. A 250-μL aliquot of the 250-ng/mL internal standard stock solution was added, followed by the addition of 4 mL of toluene–methanol (80:20, v/v). The solution was capped, vortexed for 45 s, and centrifuged at 2000 rpm for 10 min. The organic layer was transferred to a clean culture tube, and the extraction was repeated with 2 × 3 mL of toluene.

The organic phase was combined with the previous extract, and 2 mL of 1 M HCl was added. The solution was vortexed for 30 s, the organic phase was discarded, and the aqueous phase was washed by vortexing with 3 mL of toluene. The toluene was discarded, and the aqueous phase was made alkaline by adding 1 mL of 4 M NaOH containing 100 mg/mL of NaCl. This solution was extracted with 3 × 3 mL of toluene by vortexing for 30 s and centrifuged if necessary.

The toluene extracts were combined in a clean culture tube and evaporated to dryness at 40°C under a stream of nitrogen. The residue was dissolved in 100 μL of toluene–methanol (80:20, v/v); a 4-μL aliquot was injected into the chromatographic system.

Samples and Sample Handling—Serum levels of I and II were determined in two dogs, one male and one female, following oral administration of I. Blood samples were obtained prior to dosing and at 0.25, 0.5, 1, 2, 4, and 8 h after dosing. The blood was allowed to clot, and the serum was obtained by centrifugation. The serum was immediately frozen and maintained at −20 °C until sample preparation and analysis.

In addition, serum samples were obtained from a group of dogs being used in the evaluation of I. The dogs were a number of days into the evaluation, and thus, the samples that were collected were considered to be at steady state in relation to I. Four dogs, two male and two female, were selected from the 1-, 3-, and 10-mg/kg dosage levels and controls. Serum samples were obtained at 1 and 4 h after a daily dose. These sampling times were selected to provide samples at the expected highest serum concentration for I (1 h) and II (4 h). The serum samples were maintained at −20°C until sample preparation and analysis.

Calculations—The validation of the analytical method and the determination of I and II levels in dog serum were accomplished using the relative weight response (RWR) to an internal standard calculation method:

$$RWR_{Ref.\ Sol.} = \frac{PH_{cpd}}{PH_{IS}} \times \frac{ng_{IS}}{ng_{cpd}} \qquad \text{(Eq. 1)}$$

The average RWR of reference standard solutions of I and II analyzed with a sample set was employed to calculate the level of I and II in the samples:

$$ng_{cpd/sample} = \frac{PH_{cpd\ sample}}{PH_{IS}} \times \frac{ng_{IS\ sample}}{Avg.\ RWR_{Ref.\ Sol.}} \qquad \text{(Eq. 2)}$$

where PH_{cpd} and PH_{IS} are the peak heights of either I or II and the internal standard, and ng_{IS} and ng_{cpd} are the nanograms of internal standard and I or II in the reference solution or sample. For the serum samples, 1.0 mL of serum was used; thus, $ng_{cpd/sample}$ was equivalent to ng_{cpd}/mL of serum.

The reference standard solutions for each sample set were prepared over a concentration range equal to 15–300 ng/mL of I and II in serum. A minimum of five levels were selected for the reference standard solutions for each sample set. The recovery of I or II added to serum samples to validate the sample preparation procedure and to determine the accuracy of serum sample analyses was calculated as:

$$\%R = \frac{\text{ng of cpd in the fortified sample}}{\text{ng of cpd added + ng of cpd in the neat sample}} \times 100 \qquad \text{(Eq. 3)}$$

where %R is the percent recovery and the calculated amounts of I or II in the fortified and neat (unfortified) serum samples are in nanograms.

Table II—Serum Levels of I and II in Dogs Receiving Different Doses of I

RESULTS AND DISCUSSION

The GC–EC analytical technique was evaluated for linearity, precision, and sensitivity by analyzing triplicate reference solutions of I and II at eight concentration levels. The concentration levels ranged from 160 to 16,000 ng/mL for I and from 140 to 14,400 ng/mL for II. Figure 1 presents graphically the peak height ratio of I and II to the internal standard *versus* the concentrations of I and II. Linear regression equations and correlation coefficients for these data were $y = 1.97x + 0.42$ ($r = 0.999$) and $y = 1.54x + 0.16$ ($r = 0.996$) for I and II, respectively. The figure also shows two standard deviations around the average peak height ratio at each concentration. These data indicate the precision of the analytical

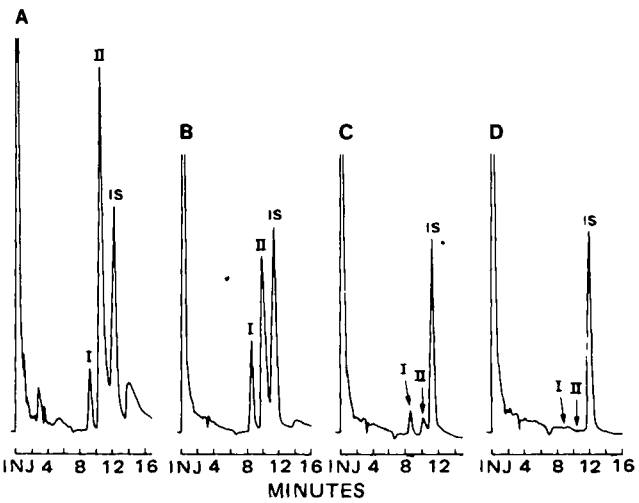

Figure 4—*GC–EC determination of I and II in serum from dogs receiving different doses of I. Key: (A) dose of 10 mg/kg; (B) dose of 3 mg/kg; (C) dose of 1 mg/kg; (D) control.*

technique. The sensitivity of the GC–EC (signal to noise ratio >5:1) was demonstrated to be <10 ng/mL for I and II. Assuming an initial serum volume of 1.0 mL and a final sample volume of 0.1 mL, the analytical technique can detect and quantify 1 ng/mL of serum for I and II.

The sample preparation procedure for the extraction of I and II from serum was developed through a series of experiments. The choice of toluene as the extraction solvent was made because of its low EC response and the high solubility of the compounds in this solvent. The serum samples were made alkaline to ensure a un-ionized species for extraction, and the addition of the salt to increase the ionic strength improved the extractability of the compounds. Initial studies indicated that stable emulsions formed when serum was extracted with toluene alone. By adding a small amount of methanol to the first toluene extraction, the emulsion problem was eliminated and the extraction efficiency was not affected. When only the first toluene extractions were employed to remove I and II from the serum, acceptable results were obtained for high levels, *i.e.*, >150 ng/mL, of I or II. However, interfering serum components at the GC elution positions of I and II prevented the single extraction technique from providing acceptable results below 150-ng/mL levels. Acidification of the toluene extracts from the serum removed I and II from the organic phase. The aqueous phase was alkalinized, and I and II were extracted with toluene. The double extraction gave very clean GC–EC chromatograms, and the recovery of I and II from the serum was high considering the extensive cleanup procedure employed. Figure 2 presents representative chromatograms of a reference solution, a blank serum sample, and a serum sample fortified with 64 ng/mL of I and 58 ng/mL of II.

The final sample preparation procedure was validated by preparing and analyzing replicate serum samples with added I and II at 16 concentration levels. The concentration ranges were 8–1600 and 7–1440 ng/mL for I and II, respectively. The results for these analyses are summarized in Table I. The average amount found for I and II at each concentration level and the standard deviation and relative standard deviation of the average are presented. Linear regression of the average amount found *versus* the amount added gave the following equations and correlation coefficients: $y = 0.947x + 8.5$, $r = 0.999$ for I and $y = 0.981x - 0.6$, $r = 0.999$ for II.

A small interfering serum component was observed at the elution position of I and gave a y-intercept of 8.5 ng/mL for I. The level of this unknown component in the blank serum was uniform and, thus, the level of I can be obtained by substracting the amount of the interfering component in blank serum from the level of I in the samples. However, serum levels of I <10 ng/mL must be considered questionable due to the possible presence of the unknown serum component. The percent recovery (%R) of I and II added to the serum gave average recoveries of 93.5 ± 7.9 for I and 97.7 ± 8.5 for II, indicating that the extraction efficiencies for I, II, and the internal standard were very similar and that no corrections for recovery of I and II from serum were necessary. These data demonstrate that the sample preparation procedure and analytical technique can provide reliable quantitative data over a large concentration range and that the recovery of I and II extracted from serum is quantitative.

The analytical method was utilized to determine the serum levels of I and II in two dogs administered a single oral 10-mg/kg dose of I. Blood samples were obtained before dosing and at 0.25, 0.5, 1, 2, 4, and 8 h after dosing. The serum from each dog was assayed for I and II, and the results are presented graphically in Fig. 3. Little or no compound was detected until 2 h after dosing. The level of the parent drug (I) in the serum was considerably lower than the *N*-demethyl metabolite (II), indicating possible extensive first-pass metabolism in the liver. Since both I and II have been reported to have similar therapeutic effects (3), the combination of the serum levels of I and II must be used to determine the concentration of active drug substance.

The method was also employed to assess if the serum levels of I and II correlated with the oral dose for dogs considered to be under steady-state conditions. Four dogs at each of three dose levels (10, 3, and 1 mg/kg) and four control dogs were evaluated; blood samples were obtained at 1 and 4 h after dosing. The data indicate that the serum levels of the parent drug and its *N*-demethyl metabolite may increase with increasing dose for the 10- and 3-mg/kg levels (Table II). At the 1-mg/kg dose, the levels of I and II in the serum approached the sensitivity limit of the method. Figure 4 presents representative chromatograms of serum samples from dogs at each dose level. The limited number of serum samples analyzed precludes statistical evaluation of the correlation of serum levels of I and II to the administered dose of I.

Effect of pH on Theophylline Transfer Across the Everted Rat Jejunum

DANA F. PERRY *, PHILIP D. WALSON ‡¶, and JAMES BLANCHARD §x

Received July 7, 1980, from the *Departments of *Pharmacology and Toxicology, ‡Pediatrics, and §Pharmaceutical Sciences, Colleges of Pharmacy and Medicine, University of Arizona, Tucson, AZ 85721.* Accepted for publication January 10, 1983. ¶Present address: Departments of Pediatrics and Pharmacology, Columbus Children's Hospital, Columbus, OH 43205.

Abstract □ The effect of pH on the cumulative transfer of theophylline across the everted rat jejunum *in vitro* was ihvestigated. Intestinal integrity was assessed by light and scanning electron microscopy, while the biochemical viability of the intestine was evaluated using glucose transfer measurements. The initial (0–30 min) clearance of theophylline was directly proportional to the fraction un-ionized at pH 5.5, 7.4, 8.0, and 10.0. Plots of cumulative theophylline transfer *versus* time over 60 min were nonlinear, but could be subdivided into two linear segments of 30-min duration. Due to this nonlinearity, differences in theophylline transfer with pH were significant only over the first 30 min of the experiment. Intestinal tissue integrity and viability correlated with the time at which the clearance (slope) increased, while the magnitude of the increase in clearance was proportional to the degree of ionization of theophylline.

Keyphrases □ Theophylline—transfer across the everted-jejunum, rats, effect of pH □ Jejunum—everted, effect of pH on theophylline transfer, rats, □ pH—effect on the theophylline transfer across the everted jejunum, rats

Theophylline, a bronchodilator widely used for treating chronic obstructive pulmonary diseases such as asthma or emphysema, may be given orally or parenterally in the form of various salts. Although theophylline is usually given orally, its absorption from the GI tract can be erratic. Nausea and gastric irritation often accompany the oral

Blood samples were obtained before dosing and at 0.25, 0.5, 1, 2, 4, and 8 h after dosing. The serum from each dog was assayed for I and II, and the results are presented graphically in Fig. 3. Little or no compound was detected until 2 h after dosing. The level of the parent drug (I) in the serum was considerably lower than the *N*-demethyl metabolite (II), indicating possible extensive first-pass metabolism in the liver. Since both I and II have been reported to have similar therapeutic effects (3), the combination of the serum levels of I and II must be used to determine the concentration of active drug substance.

The method was also employed to assess if the serum levels of I and II correlated with the oral dose for dogs considered to be under steady-state conditions. Four dogs at each of three dose levels (10, 3, and 1 mg/kg) and four control dogs were evaluated; blood samples were obtained at 1 and 4 h after dosing. The data indicate that the serum levels of the parent drug and its *N*-demethyl metabolite may increase with increasing dose for the 10- and 3-mg/kg levels (Table II). At the 1-mg/kg dose, the levels of I and II in the serum approached the sensitivity limit of the method. Figure 4 presents representative chromatograms of serum samples from dogs at each dose level. The limited number of serum samples analyzed precludes statistical evaluation of the correlation of serum levels of I and II to the administered dose of I.

Effect of pH on Theophylline Transfer Across the Everted Rat Jejunum

DANA F. PERRY *, PHILIP D. WALSON ‡¶, and JAMES BLANCHARD §x

Received July 7, 1980, from the *Departments of *Pharmacology and Toxicology, ‡Pediatrics, and §Pharmaceutical Sciences, Colleges of Pharmacy and Medicine, University of Arizona, Tucson, AZ 85721.* Accepted for publication January 10, 1983. ¶Present address: Departments of Pediatrics and Pharmacology, Columbus Children's Hospital, Columbus, OH 43205.

Abstract □ The effect of pH on the cumulative transfer of theophylline across the everted rat jejunum *in vitro* was ihvestigated. Intestinal integrity was assessed by light and scanning electron microscopy, while the biochemical viability of the intestine was evaluated using glucose transfer measurements. The initial (0–30 min) clearance of theophylline was directly proportional to the fraction un-ionized at pH 5.5, 7.4, 8.0, and 10.0. Plots of cumulative theophylline transfer *versus* time over 60 min were nonlinear, but could be subdivided into two linear segments of 30-min duration. Due to this nonlinearity, differences in theophylline transfer with pH were significant only over the first 30 min of the experiment. Intestinal tissue integrity and viability correlated with the time at which the clearance (slope) increased, while the magnitude of the increase in clearance was proportional to the degree of ionization of theophylline.

Keyphrases □ Theophylline—transfer across the everted-jejunum, rats, effect of pH □ Jejunum—everted, effect of pH on theophylline transfer, rats, □ pH—effect on the theophylline transfer across the everted jejunum, rats

Theophylline, a bronchodilator widely used for treating chronic obstructive pulmonary diseases such as asthma or emphysema, may be given orally or parenterally in the form of various salts. Although theophylline is usually given orally, its absorption from the GI tract can be erratic. Nausea and gastric irritation often accompany the oral

administration of theophylline, a condition which is frequently treated with antacids. A recent study by Shargel *et al.* (1) indicated that the concurrent administration of 15 mL of magnesium aluminum hydroxide antacid did not significantly affect the pharmacokinetics of theophylline. This result contrasts with the work of Arnold *et al.* (2) who reported that 30 mL of magnesium aluminum hydroxide suspension significantly decreased the absorption rate constant for theophylline. Furthermore, a study by Rohr *et al.* (3) indicated that theophylline may be adsorbed onto some antacid materials but not others. Since antacids can possibly alter the GI absorption (4) of drugs, it was of interest to determine how changes in the pH might alter the absorption of theophylline.

Several studies (5–7) have previously demonstrated the utility of everted intestinal preparations for evaluating the *in vitro* absorbability of drugs and nutrients and how various factors influence this process. In this report, cannulated everted jejunal segments of rat intestine (8) were used to evaluate the influence of pH on theophylline transfer. The structural integrity and biochemical viability of the intestinal segments were monitored by means of light and scanning electron microscopy and by measuring the rates of active glucose transfer, respectively.

EXPERIMENTAL

Reagents—The following reagent-grade chemicals were employed: theophylline[1], 1-[2-(β-D-glucopyranosyloxy)-4,6-dihydroxyphenyl]-3-

60	1.05 ± .217	1.10 ± .199	0.898 ± .130	0.910 ± .107

[a] Values represent the cumulative micrograms of theophylline transferred per unit mucosal concentration ±*SD*. All values represent the mean of six segments (proximal and distal combined) except at pH 7.4 and 8.0 where eight segments were used. A one-way analysis of variance was performed on the data to test for significant differences between means at a given time point. Bars enclosing values indicate means are not significantly different ($p > 0.05$). Means not connected are significantly different ($p < 0.05$) from each other.

(4-hydroxyphenyl)-1-propanone (phlorizin)[1], 3-*O*-methyl-D-[1-^{3}H]-glucose (I)[2], glucose[3], and acetonitrile[4]. Monobasic sodium phosphate monohydrate, anhydrous dibasic sodium phosphate, sodium carbonate, and sodium bicarbonate were used in preparing the isotonic buffers.

Preparation of Everted Jejunum—Everted jejunal segments from nonfasted Sprague–Dawley rats of both sexes, weighing 150–300 g, were prepared according to methods described previously (8). The intestines were removed from ether-anesthetized animals following a midline abdominal incision and transection of the intestine at the pyloric and ileocecal junctions. The proximal 30 cm of unstretched intestine was discarded to prevent inclusion of the bile duct. The next 30 cm was separated, rinsed in physiological saline at 37°C, then cut into two 15-cm segments designated as proximal and distal in reference to their original position relative to the pyloric junction.

The everted segments were positioned on the perfusion apparatus as described previously (8), and the total assembly time following removal was 7–10 min. The serosal surfaces were rinsed with 25 mL of serosal buffer solution prior to the first collection. Buffer pH was measured[5] before and after each experiment. Oxygen was bubbled through the mucosal solutions continually. Serosal and mucosal buffer solutions were warmed to 37°C prior to coming in contact with the tissue. Serosal buffer samples (5 mL) were collected at 10-min intervals for 1 h and replaced with fresh buffer within 20 s.

Buffer Composition—A Modified Krebs–Henseleit phosphate buffer was used for all experiments conducted at pH 5.5, 7.4, and 8.0 (9). This buffer was chosen instead of the Krebs bicarbonate, which reportedly provides the best environment for maintaining the viability of the intestine (10), because bicarbonate buffer does not function optimally over the pH range of 5.5–8.0. Experiments conducted at pH 10 used the same Krebs–Henseleit electrolyte solution except that the phosphate buffer was replaced by an equimolar amount of carbonate–bicarbonate buffer (9). Calcium ion was deleted from the buffer solution due to its tendency to precipitate in the presence of phosphate at pH >7.4. The absence of calcium ion was observed to have no effect on drug transfer. Glucose at a concentration of 130 mg% (7 mM) was added to the mucosal buffer only.

Preparation of Tissue Samples for Histological Evaluation—Histology was performed on jejunal segments immediately after eversion ($t = 0$ min) and after 60 min of incubation in a pH 7.4 phosphate buffer ($t = 60$ min). Everted intestinal segments were also examined using light microscopy after 30 min incubation at pH 5.5, 8, and 10. Specimens for light microscopy were fixed in 10% w/v buffered formalin, paraffin sectioned, and stained with hematoxylin and eosin. Specimens for scanning electron microscopy[6] were fixed in isotonic Karnofsky's solution and stained with 1% w/v osmium tetroxide prior to critical point drying from acetone. These specimens were sputter-coated with gold to a thickness of 300 Å and examined.

Transport of 3-*O*-Methyl-D-[1-^{3}H] glucose—The transport of tritiated 3-*O*-methyl-D-glucose (I), specific activity 2 Ci/mmol, was determined using liquid scintillation counting. Fifty microliters of 3-*O*-methyl-D-glucose (1 mCi/mL) was added to each 100 mL of buffer. This solution was used as the mucosal buffer for each intestinal segment. Two segments also has phlorizin (a specific inhibitor of glucose transport) added to give a final concentration of 1 mM, and two did not. The serosal and mucosal concentrations of I were measured by placing 1-mL aliquots of each solution into vials, adding 10 mL of liquid scintillation cocktail[7], and counting in a liquid scintillation counter[8] for 10 min. Intestinal tissue concentrations of I were measured by weighing accurately ~100 mg of jejunum (~1 cm) after rinsing and blotting with absorbant tissue. Samples were digested in a counting vial by the addition of 0.5 mL of 0.6 M NaOH. Ten milliliters of cocktail and 1 mL of water were then added, and the vial was counted for 10 min. Counting efficiencies were determined by the external standard method. Tissue radioactivity was expressed as disintegrations per min per mg of wet tissue (dpm/mg) divided by the mucosal concentrations of I in dpm/mL. D-glucose levels were determined in duplicate in an automated glucose analyzer[9] using the glucose oxidase method.

Table II—Ionization and Mean Intestinal Clearances (±*SD*) for Theophylline at Various pH Values

pH	Un-ionized[a], %	Clearance (mL/min) × 10^2 Period I (0–30 min)	Clearance (mL/min) × 10^2 Period II (30–60 min)	Clearance Ratio (Period II/Period I)
5.5	99.90	1.794 (0.38)	1.894 (0.50)	1.051 (0.11)
7.4	92.64	1.721 (0.31)	2.236 (0.43)	1.309 (0.18)
8.0	75.97	1.321 (0.25)	1.981 (0.27)	1.526 (0.24)
10.0	3.07	1.058 (0.30)	2.328 (0.36)	2.378 (0.82)

[a] The degree of ionization of theophylline was calculated from the Henderson–Hasselbalch equation, using a pK_a of 8.5 (20).

Theophylline Assay—Theophylline analyses were performed using an HPLC assay. A reverse-phase HPLC column[10], 4 mm i.d. × 30 cm, was used. The mobile phase of acetonitrile–water–acetic acid (10:89:1 v/v/v) was pumped[11] through the column at a flow rate of 3 mL/min. Detection of eluted theophylline was accomplished at 280 nm using a *fixed-wavelength detector*[12].

Aliquots (25 μL) of serosal buffer solution were injected directly onto the column. Quantitation was performed by comparing measured peak heights against a standard curve of theophylline peak height *versus* concentration. Samples were either assayed immediately or frozen at −20°C until analyzed. Theophylline concentrations were stable for 7–10 d under these storage conditions.

Measurement of Cumulative Transfer Rates—Theophylline transfer across the everted intestine was expressed as a cumulative mucosal to serosal clearance (transfer rate constant). In essence:

$$\text{Clearance (mL/min)} = \frac{\text{cumulative amount } (\mu g) \text{ transferred per } t \text{ min}}{\text{mucosal concentration } (\mu g/mL) \times t} \quad \text{(Eq. 1)}$$

The clearances were actually determined from the slopes of the plots of the cumulative amount of theophylline transferred per unit mucosal concentration *versus* time. The slopes of these plots were calculated using least-squares linear regression.

The average cumulative amount (μg) of theophylline transferred (±*SD*) was calculated at each 10-min interval throughout the course of the 60-min experiments for the various pH values tested, as shown in Table I. These data were subjected to a one-way analysis of variance (ANOVA) to detect any significant differences in clearance between the various pH values over a given time interval. The level of significance used for all analyses was $p < 0.05$. The Tukey test was employed *post hoc* to determine where pair-wise differences between means existed (11).

RESULTS AND DISCUSSION

The viability and structural integrity of an *in vitro* model must be considered when interpreting data from such a system (12, 13). Viability of the rat jejunal model has been characterized by many investigators.

Figure 2—(*A*) *Appearance of intestinal villus after 60-min incubation at 37°C in pH 7.4 phosphate buffer (original magnification 800×). (B) Scanning electron micrograph of intestinal segment after 60-min incubation at 37°C in pH 7.4 phosphate buffer.*

It has been shown that oxygen uptake is linear for 1–3 h (14, 15), and that active uptake of L-histidine and iodine-131 (14), as well as linear active uptake of D-glucose, occur for up to 1 h (16).

In this study, the structural integrity of the everted rat jejunum was evaluated using both light and scanning electron microscopy. Intestinal segments were examined immediately after eversion (t = 0 min) and after 60 min of incubation in isotonic pH 7.4 phosphate buffer (t = 60 min). At t = 0 min, sections examined by light microscopy had good cytoplasmic and nuclear detail and good detail in submucosal structures (Fig. 1A). Examination by scanning electron microscopy also showed normal surface morphology with well-defined and well-separated villi and no evidence of gross damage (Fig. 1B). After a 60-min incubation, light microscopy revealed minimal disruption of submucosal or muscle layers, but a substantial disruption of the villous epithelium and areas where the basement membrane had separated from the lamina propria (Fig. 2A). Electron microscopy also demonstrated changes in villous structure (Fig. 2B). Everted intestinal segments incubated at pH 5.5, 8, and 10 for 30 min exhibited no gross morphological changes when examined using light microscopy.

The functional integrity of the everted rat jejunum was evaluated by determining the active transport of glucose and I. Since the active transport of glucose by the small intestine *in vitro* is known to require intact, functioning intestinal epithelial cells (17), the rate of appearance of glucose on the serosal side of the preparation over the 60-min incubation period was used as a measure of the biochemical and structural state of the epithelium.

The intestinal transport of glucose at pH 7.4 demonstrated that the amount of glucose appearing in the serosal fluid rose from an initial value at t = 0 min to a maximum at 30 min, then declined back to the initial value by 60 min. This coincides with the findings of Porteus and Pritchard (16) who observed that the rates of glucose transport by the intact intestine increased linearly to 30 min, then slowly decreased to zero by 60 min. The concentration gradient present in the direction of transport (*i.e.*, mucosal to serosal) was disregarded since the *in vitro* small intestine actively transports glucose 10–20 times faster than its rate of diffusion (18). Furthermore, at concentrations of ≤500 mg%, the rate of passive glucose transport up or down a concentration gradient is of the same order of magnitude (18).

The biphasic glucose transfer observed here was taken as evidence of a functioning active-transport system. This is supported by the fact that transport was eliminated when phlorizin, a specific inhibitor of active transport, was added to the mucosal solution. The rates of glucose transfer in the presence of phlorizin were considered to be those maximally obtainable by diffusion alone. Since there was no increase in transfer from 0 to 60 min, in the presence of phlorizin, it was concluded that the integrity of the intestinal membrane was not compromised to the extent of becoming "leaky" toward the relatively small (mol. wt. = 180), hydrophilic glucose molecule.

To examine the role of any metabolic utilization and/or transport of endogenous glucose stores by the intestine, experiments were conducted to measure the transport of I. This glucose analogue is actively transported by the same system that transports glucose across the intestine; however, it is not metabolized by the intestine (19). The transport of I showed a biphasic pattern similar to that found for glucose. In addition, the average tissue concentration of I in the presence of phlorizin was about one-seventh (0.5 *versus* 3.4 dpm/mg of tissue per 10^6 dpm in buffer) the control value. These data indicated that the biphasic nature of the transport curves was not due to the metabolism of glucose by the jejunal segments since I, which was not metabolized, exhibited a similar transport pattern. The histological studies and the biphasic transport of glucose

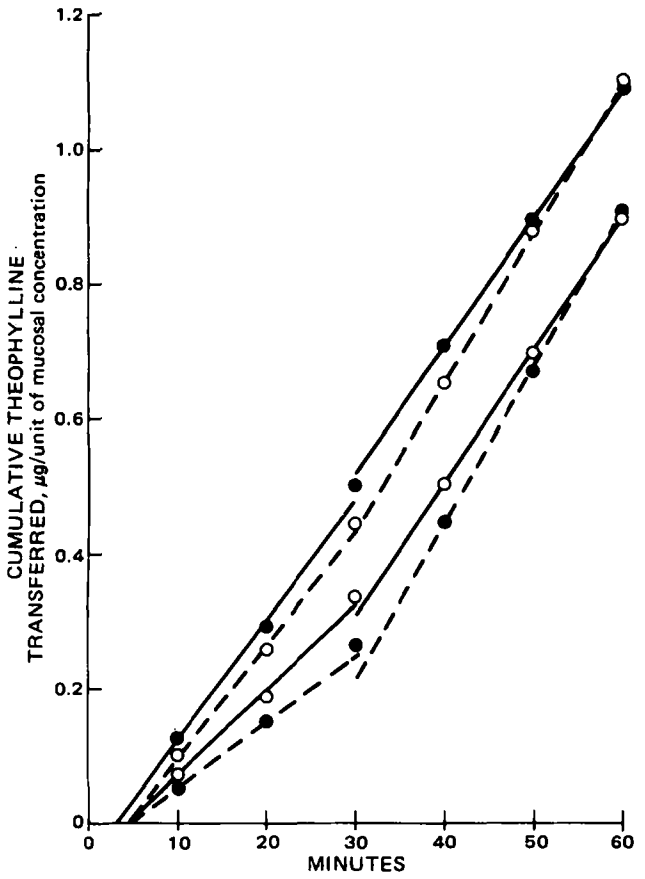

Figure 3—*Cumulative transfer of theophylline across the everted rat jejunum at various pH values as a function of time. All values represent the mean of six segments (proximal and distal combined) except at pH 7.4 and 8.0 where eight segments were used. Error bars are deleted for clarity. Key: (●—●) pH 5.5; (○- - -○) pH 7.4; (○—○) pH 8.0; (●- - -●) pH 10.0.*

and I, together with their inhibition by phlorizin, were taken as evidence that the preparation was biochemically intact up to 30 min, but that after 30 min the functional integrity was decreased, and by 60 min there were signs of both functional and structural disruption.

Effects of pH on Theophylline Transfer Rates—The transfer of theophylline appears to follow zero-order kinetics as is shown by the linear segments of the plots shown in Fig. 3. This linear transfer occurred because the concentration of theophylline in the mucosal solution remained essentially constant and was much higher than that in the serosal solution during the course of the experiment. This was achieved by replacing the serosal fluid at 10-min intervals and by using a large volume of mucosal solution relative to serosal solution. The intestinal clearances of theophylline at various pH values are shown in Table II.

Due to the biphasic nature of theophylline clearance over the 60-min time course of the experiments it was not possible to obtain the clearance at each experimental pH using transfer data from all the time points. Examination of Fig. 3 revealed that the slope of the clearance curve began to increase after 30 min for all pH values tested. This change in slope was such that transfer rates at different pH values were statistically nonsignificant ($p > 0.05$) after the first 40 min. Prior to the 30-min time point, the transfer of theophylline at all pH values tested was judged to be sufficiently linear (*i.e.*, all lines had $r^2 \geq 0.95$) to derive a clearance. Therefore, clearance values for all experiments were derived from the cumulative amount of theophylline transferred in the first 30 min. These initial theophylline clearances were directly proportional to the fraction un-ionized (f_u) as shown in Fig. 4.

If we assume that both the ionized and un-ionized forms of theophylline are capable of being transported across the everted rat jejunal membrane then the total clearance (CL_t) can be expressed as:

$$CL_t = f_i CL_i + f_u CL_u \qquad \text{(Eq. 2)}$$

wher CL_i and CL_u represent the clearances of the ionized and un-ionized species, respectively, and f_i and f_u are the fractions of the drug present in the ionized and un-ionized forms, respectively. Since:

$$f_i = (1 - f_u) \qquad \text{(Eq. 3)}$$

it follows that:

$$CL_t = CL_i + (CL_u - CL_i) f_u \qquad \text{(Eq. 4)}$$

Thus, from Eq. 4, it is evident that in a plot of CL_t *versus* f_u, such as Fig. 4, the intercepts at $f_u = 0$ and $f_u = 1$ will represent CL_i and CL_u, respectively.

Using this approach, linear regression of the data in Fig. 4 indicated that CL_u and CL_i were equal to 1.693×10^{-2} and 0.978×10^{-2} mL/min, respectively. Thus, the ratio of intrinsic clearances for these two species in the 0–30-min time period was $CL_u/CL_i = 1.732$. It is possible that undetected intestinal tissue damage may have occurred which could have artificially altered some of the clearance data in Fig. 4. However, the excellent agreement of the CL_u/CL_i ratio with the value recently reported by Crommelin *et al.* (21) for theophylline transfer across the rat rectum indicates that if such alterations did occur, their effects on theophylline transfer were minor. These authors reported values for the absorption rate constants of the un-ionized and ionized forms of theophylline which were very similar (*i.e.*, $K_u/K_i = 0.805$ and 1.13) and concluded that the absorption rates of the two forms "do not differ much." Our value is also similar in magnitude to the value (1.905) found for lidocaine at pH 6.4 and 7.4 by Cascella and Feldman (22) and to the values that Crouthamel *et al.* (23) calculated for sulfaethidole (5.56) and barbital (3.08) over the pH range of 5.15–8.52. The results indicate that the ionized forms of these compounds cross the *in vitro* rat intestine at a rate which is comparable with that of their un-ionized forms, a condition which may or may not exist *in vivo*. In fact, Turner *et al.* (24) noted that ionized species are more easily transferred across *in vitro* membrane systems, such as the one utilized here, than they are across *in vivo* membranes.

The use of the early time points to determine clearance values has been proposed by other authors (13) who recognized the phenomenon of increasing clearance with time. The assumption that the initial transfer rates are a more appropriate measure of clearance across the everted intestine than those obtained using the total amount of solute transferred over the course of a typical experiment (*i.e.*, 60 min) was also reached independently by Benet *et al.* (10) and is consistent with the assessment of the everted intestine as a method for studying drug transfer made by Levine *et al.* (12).

In our experiments, we observed that only the initial (0–30 min) transfer rates were pH dependent. Therefore, structural integrity of the everted intestine appeared to be necessary to demonstrate the effect of pH on theophylline transport. In contrast, the biochemical integrity of the intestinal segment was relatively unimportant in affecting the transfer of theophylline, since this compound is believed to be transported passively (25).

The change in theophylline clearance across the intestine was observed to increase as the pH increased, as shown by the data in Table II. There was also a time-dependent increase in the clearance at all pH values. This was believed to be due to a time-dependent degradation of the intestinal membrane, which resulted in an increased permeability of the membrane for theophylline, apparently due to a loss of structural integrity of the membrane.

One possible explanation for these observations is that the epithelial and the underlying connective and muscle tissue barriers are both intact only over the first 30 min of the experiment (26, 27), during which time the epithelial barrier is rate limiting (27). This is substantiated somewhat by Fig. 4, in which the initial clearance values are directly proportional to the fraction of theophylline un-ionized, which would be predicted from the pH-partition hypothesis (28). After 30-min incubation, the epithelial barrier may no longer be intact, with the result that the clearance in the 30–60-min time period (period II) is increased at all pH values relative to the corresponding 0–30-min (period I) clearance. Since the ionized form of the drug is less permeable than the un-ionized form, any disruption of the epithelial barrier would be expected to result in a more pronounced change in the clearance of this species. The relatively small effect of changes in the structural integrity of the intestinal membrane on the transfer rates of the un-ionized species over the 30–60-min period, observed at low pH, is consistent with previous suggestions that the epithelium is not the rate-limiting barrier to the transfer of nonpolar, lipid-soluble molecules (such as un-ionized theophylline) across this membrane model (13).

CONCLUSIONS

It has been shown that pH alters the initial (0–30-min) transfer of theophylline across the everted rat jejunum. The cumulative amount of theophylline transferred over the first 30 min was directly proportional to the calculated un-ionized fraction. A time-dependent change in transfer rate was also demonstrated which correlated with the structural integrity of the preparation. These results indicate that intestinal transfer rates measured during the first 30 min may be more valid than measurements taken over longer time periods. The ionized form of theophylline appears to be transported across the everted rat intestine *in vitro* at a rate comparable with that of the un-ionized form.

Relative Bioavailability and Pharmacokinetics: A Combination of Pentazocine and Acetaminophen

ALAN K. FRITZ, DAVID P. BENZIGER, JAMES E. PETERSON, GEORGE B. PARK, and JEROME EDELSON ˣ

Received November 15, 1982, from the *Department of Drug Metabolism, Sterling-Winthrop Research Institute, Rensselaer, NY 12144.* Accepted for publication January 26, 1983.

Abstract □ The relative bioavailability and pharmacokinetics of a combination product containing pentazocine and acetaminophen were studied in 20 healthy human males. Each subject, in a single-dose three-way crossover design, received two different preparations containing 50 mg of pentazocine (as base) and 1300 mg of acetaminophen either as capsule-shaped tablets or as a solution. Plasma concentrations of pentazocine and acetaminophen were determined from 0.25 to 12 h following oral administration. The plasma data for both compounds in the tablet formulation were described by an open one-compartment body model with first-order absorption. The average ($\pm SD$) bioavailability of the tablet relative to that of the solution was 85.0 ± 31.1 and 88.6 ± 13.1% for pentazocine and acetaminophen, respectively. The apparent first-order regression-dependent elimination rate constants for pentazocine from the tablet and solution preparations were 0.19 ± 0.08 and 0.20 ± 0.06 h^{-1}, respectively, while the rate constants for acetaminophen were 0.26 ± 0.03 and 0.25 ± 0.03 h^{-1} for the tablet and solution preparations, respectively. These rate constants correspond to terminal elimination half-lives of ~3.6 h for pentazocine and ~2.7 h for acetaminophen.

Keyphrases □ Pentazocine—relative bioavailability, pharmacokinetics, coadministration with acetaminophen □ Acetaminophen—relative bioavailability, pharmacokinetics, coadministration with pentazocine □ Bioavailability—relative, coadministered pentazocine and acetaminophen, pharmacokinetics □ Pharmacokinetics—coadministered pentazocine and acetaminophen, relative bioavailability

Pentazocine, a weak narcotic antagonist, is a potent analgesic in humans. The analgesic efficacy of both oral (1, 2) and parenteral (3–8) formulations of pentazocine is well documented. Acetaminophen is commonly used as a mild analgesic and antipyretic (9, 10). Both pentazocine and acetaminophen have low incidences of adverse side effects at therapeutic dosages (3, 9, 10).

Since pentazocine is thought to act centrally and acetaminophen acts primarily peripherally, the simple additive effect of a narcotic antagonist and an antipyretic–analgesic given together may be substantially greater than the analgesia obtained from each component separately (11, 12). In our investigation, the bioavailability and pharmacokinetic parameters of pentazocine and acetaminophen were determined in human subjects following administration of two different preparations of pentazocine combined with acetaminophen.

EXPERIMENTAL

Subjects—The subjects were 20 healthy male volunteers, ranging in age from 19 to 33 years and in weight from 53 to 104 kg. No subject had a clinical history or laboratory findings that were suggestive of renal, hepatic, or cardiac dysfunction. Appropriate institutional review and approval were obtained.

Drug Administration and Sampling—Each subject received two different preparations of pentazocine and acetaminophen in a single dose according to a randomized three-way crossover design. One dose was two capsule-shaped tablets[1], each containing 25 mg of pentazocine base and 650 mg of acetaminophen, and the other dose was a solution containing 50 mg of pentazocine base and 1300 mg of acetaminophen (prepared in-house). For the third dose, one-half of the subjects received a repeat dose of the solution and the other half of the subjects received a repeat dose of the tablets. There was a 1-week washout interval between medications. Blood samples were collected by venipuncture prior to drug administration and at 0.25, 0.50, 0.75, 1, 2, 4, 6, 7 and 12 h after treatment; potassium oxalate was used as the anticoagulant. All subjects were fasted for at least 8 h before treatment and 3 h afterwards. Blood samples were centrifuged, and the plasma was separated and frozen until it was assayed.

Analytical Methods—Pentazocine plasma concentrations were determined using a minor modification of the RIA procedure (13) developed in these laboratories; toluene was used for the extraction in place of benzene. The minimum quantifiable level of the assay was estimated as the concentration whose lower 95% confidence limit just encompassed zero and was ~0.4 ng/mL. Blind analyses of plasma samples spiked with pentazocine over the range of 0 and 0.4 to 100 ng/mL revealed a mean intraassay variation coefficient of 8.2% (n = 18) and a mean interassay coefficient of variation of 11.6% (n = 3).

Plasma concentrations of acetaminophen were determined by the HPLC method reported by Horwitz and Jatlow (14), with the following modifications. Plasma was extracted with 7 mL of diethyl ether instead of 5 mL. The residue remaining after evaporation of the solvent was dissolved in 200 μL of the mobile phase, and 50 μL were injected onto a 3.9-mm i.d. × 30-cm phenyl column[2] using a solvent system of 7% acetonitrile in 0.1 M KH_2PO_4 (v/v) adjusted to pH 2.4 with phosphoric acid. The flow rate was increased to 2.0 mL/min. The mean quantifiable level for acetaminophen was estimated by linear regression of the peak-height ratios as the concentration whose lower 80% confidence limit just encompassed zero (15) and was between 0.02 and 0.06 μg/0.5 mL. Blind analyses of acetaminophen standards prepared with human control plasma over the range of 0 and 0.1 to 15 μg/0.5 mL yielded an intraassay coefficient of variation (precision) of ±4.9% (n = 2). The accuracy of the assay, defined as the mean percent difference from a nominal value, ranged from −7.5 to 3.0% (n = 18).

Pharmacokinetic Calculations—Pharmacokinetic parameters for pentazocine and acetaminophen were derived by analysis of the plasma concentration data by means of a weighted nonlinear regression procedure (NLIN) using the Marquardt algorithm (16). The plasma concentrations were weighted as the squares of their reciprocals (17, 18). Where appropriate, results are expressed as the mean $\pm SD$.

The plasma data obtained for pentazocine (tablet and solution) and acetaminophen (tablet) was fitted to an open one-compartment body model with first-order absorption and was described by the following:

$$C = A[e^{-k_e(t-t_0)} - e^{-k_a(t-t_0)}] \qquad \text{(Eq. 1)}$$

where C is the plasma concentration at time, t, t_0 is the lag time (before absorption begins), A is a constant, and k_a and k_e are apparent first-order rate constants for absorption and elimination, respectively. Since the absorption of acetaminophen in solution is very rapid, the data from the analysis of the acetaminophen solution dose was fit to a one-compartment open model assuming instantaneous absorption (intravenous model) by means of a weighted regression analysis as above, and was described by the following:

$$C = B(e^{-k_e t}) \qquad \text{(Eq. 2)}$$

where B is a constant and the other terms are defined above.

The apparent volume of distribution (uncorrected for bioavailability), Vd/F, which relates the plasma concentration to the total amount of drug in the body, was calculated by the use of the following:

$$Vd/F = \frac{\text{Dose} \cdot k_a}{A(k_a - k_e)} \qquad \text{(Eq. 3)}$$

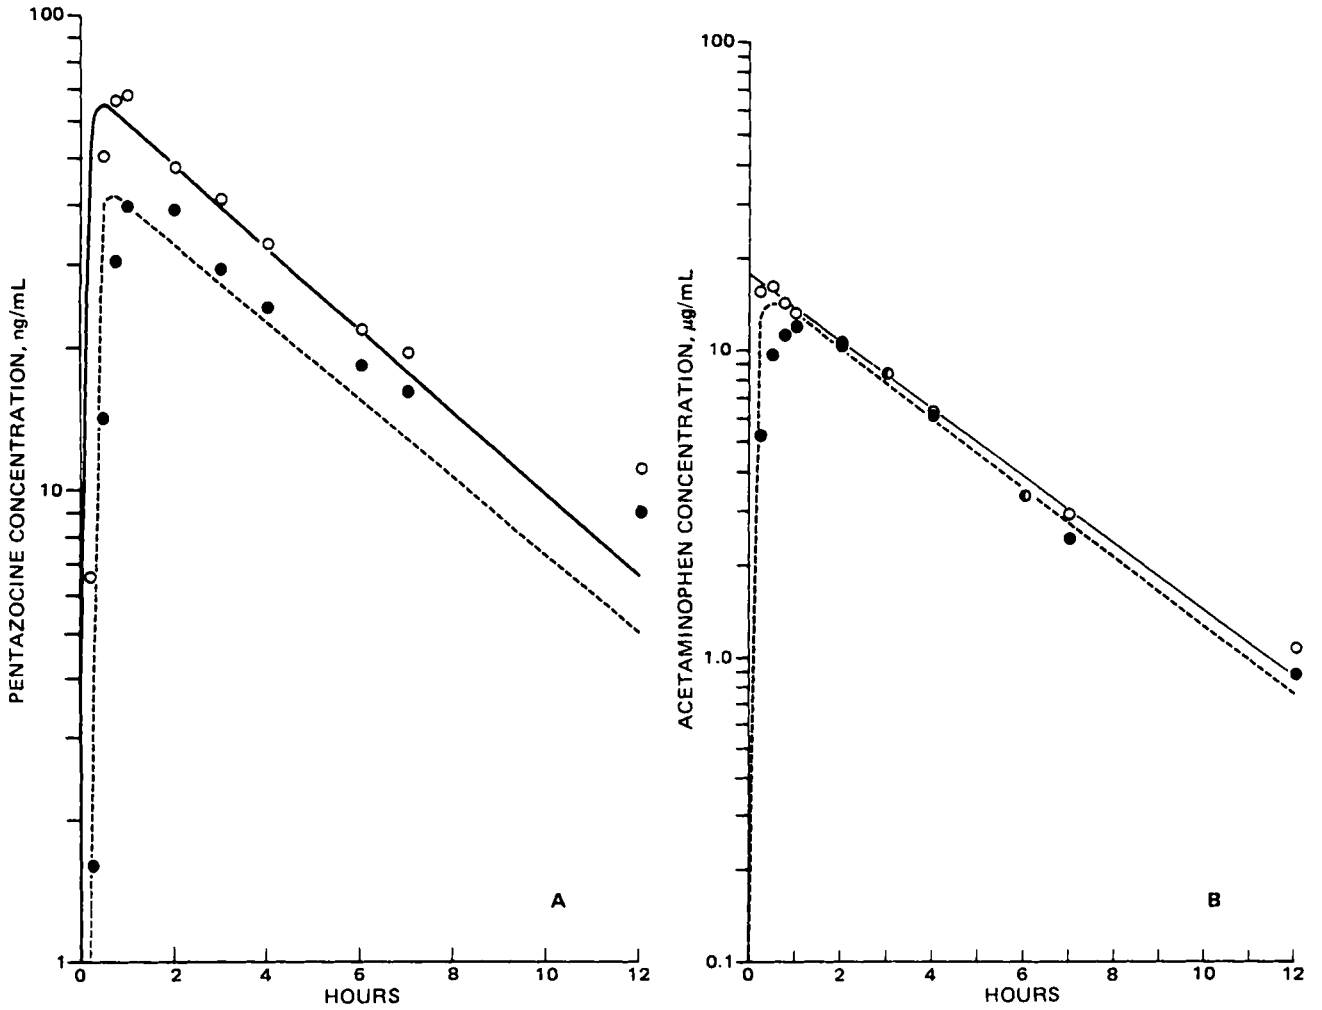

Figure 1—*Mean plasma concentrations of pentazocine (A) and acetaminophen (B) in 20 human volunteers after oral administration of either two tablets (●) or a solution (○) containing 50 mg of pentazocine and 1300 mg of acetaminophen. The lines represent the respective model-dependent curves derived from the mean pharmacokinetic parameters.*

$$Vd/F = \frac{\text{Dose}}{C_0} \qquad \text{(Eq. 4)}$$

where F is the fraction of the administered dose which is available to the systemic circulation; the other terms are defined above. The apparent total plasma clearance (CL_p) relates to drug availability (F) and was calculated from:

$$\frac{CL_p}{F} = \frac{\text{Dose}}{\text{AUC}_0^\infty} \qquad \text{(Eq. 5)}$$

The total area under the plasma concentration *versus* time curve (AUC_0^∞) for each subject was determined from the following:

$$\text{AUC}_0^\infty = \frac{A(k_a - k_e)}{k_a k_e} \qquad \text{(Eq. 6)}$$

$$\text{AUC}_0^\infty = \frac{F \cdot \text{Dose}}{Vd \cdot k_e} \qquad \text{(Eq. 7)}$$

In addition to the regression-dependent parameters (defined above), the plasma concentration data were analyzed with respect to the following regression-independent parameters: the maximum observed plasma concentration (C_{max}^{obs}), the time at which the maximum plasma concentration was observed (t_{max}^{obs}), and AUC_0^{12}. The latter was calculated by the trapezoidal rule, including all of the data for the study period. For those subjects who had detectable concentrations of pentazocine or acetaminophen in the last sample examined, the AUC was extrapolated to infinite time by use of the following:

$$\text{AUC}_0^\infty = \text{AUC}_0^{12} + \frac{C_p}{k_t} \qquad \text{(Eq. 8)}$$

where C_p was the pentazocine or acetaminophen concentration observed in the last measurable sample taken and k_t is the estimated apparent first-order terminal elimination rate constant; k_t was estimated by linear regression on the natural logarithms of the observed plasma concentration from t_{max} to the last data point.

The regression-independent volume of distribution (uncorrected for bioavailability), Vd/F, was determined by the following equation:

$$Vd/F = \frac{\text{Dose}}{k_t \cdot \text{AUC}_0^\infty} \qquad \text{(Eq. 9)}$$

The bioavailability of the tablet doses relative to that of the solution doses was determined from the ratio of their respective extrapolated AUC values:

$$\text{Relative bioavailability} = \frac{\text{AUC}_0^\infty \text{ (tablet)}}{\text{AUC}_0^\infty \text{ (solution)}} \times 100 \qquad \text{(Eq. 10)}$$

RESULTS

Pentazocine—The plasma levels of pentazocine for each subject declined exponentially with time and were best fit with an open one-compartment body model with first-order absorption. The mean plasma concentrations are shown in Fig. 1A. The mean apparent first-order elimination rates for the tablet and solution were 0.19 ± 0.08 and 0.20 ± 0.06 h^{-1}, respectively, which corresponds to a half-life of ~3.6 h for both the tablet and solution preparations. Results are shown in Tables I and II, respectively.

The apparent volume of distribution showed considerable variation between individuals for both preparations. The mean apparent Vd/F for the tablet was 1614 L, with a range of 495–4906 L, and the solution had a mean apparent Vd/F of 1177 L, with a range of 243–2865 L. Plasma clearance (CL_p) and the first-order absorption rate (k_a) demonstrated considerable intersubject variation. The mean AUC_0^∞ values for the tablet

and solution preparations were 362 ± 526 and 404 ± 474 ng·h/mL, respectively. The calculated bioavailability of pentazocine in the tablet relative to the solution demonstrated considerable intrasubject variation, as well as significant interindividual variability, and ranged from 37.0 to 216% with a mean value of 85.0 ± 31.1%. Individual AUC_0^{∞} values and relative bioavailability data are presented in Table III.

The observed regression-independent parameters are in reasonable agreement with those estimated from the open one-compartment body

model with first-order absorption. The C_{max} values for the tablet and solution preparations were 50 ± 34.3 and 79.3 ± 61.1 ng/mL, respectively, and their respective t_{max} values occurred at 1.74 ± 1.32 and 1.06 ± 0.65 h. The regression-independent $t_{1/2}$ values for the tablet and solution preparation were identical to the regression-dependent $t_{1/2}$ values.

Acetaminophen—As seen in Fig. 1B, the plasma levels of acetaminophen in volunteers receiving the tablet declined exponentially with time, suggesting that an open one-compartment body model with first-order absorption would be appropriate. The plasma levels of acetaminophen in volunteers receiving the solution declined exponentially and were best described by a one-compartment body model assuming instantaneous absorption (intravenous model). The mean apparent first-order elimination rates for the tablet and solution were 0.26 ± 0.03 and 0.25 ± 0.03 h^{-1}, respectively, which corresponds to a $t_{1/2}$ of 2.7 h. The pharmacokinetic parameters are shown in Tables IV and V.

The mean apparent volume of distribution (Vd/F) for the tablet and solution were 90.3 ± 17.2 and 76.5 ± 14.7 L, respectively. Clearance of the tablet varied from 14.6 to 37.9 L·h^{-1}, while the plasma clearance of the solution ranged from 12.4 to 24.6 L·h^{-1}. The mean AUC_0^∞ values for the tablet and solution formulation were 57.5 ± 13.0 and 72.0 ± 14.4 μg·h/mL, respectively.

The observed, regression-independent parameters are in reasonable agreement with those calculated from the regression-dependent parameters. The mean apparent first-order terminal elimination rate constants were 0.25 ± 0.04 and 0.24 ± 0.03 h^{-1}, respectively, for the tablet and solution preparations. The C_{max}^{obs} for the tablet data was 13.6 ± 3.7 μg/mL, and the respective t_{max}^{obs} occurred at 0.95 ± 0.64 h.

The calculated bioavailability of the tablet relative to the solution ranged from 58.7 to 123%, with a mean value of 88.6 ± 13.1%. Individual AUC_0^∞ values and relative bioavailability are presented in Table III. The regression-independent AUC_0^∞ for the solution data was in close agreement to that of the AUC_0^∞ calculated from the regression-dependent parameters. This suggests that the model which assumed instantaneous absorption was appropriate for the available data.

DISCUSSION

Pentazocine—Pharmacokinetic parameters for each subject were estimated after computer-fitting of the data by a weighted iterative nonlinear least-squares regression technique. The plasma data from each subject was best fit by an open one-compartment body model with first-order absorption. Attempts to fit the data from each subject to an open two-compartment body model with first-order absorption yielded residual sum-of-squares values significantly greater than the comparable values for an open one-compartment body model. The half-lives for the capsule-shaped tablet and solution data, 3.65 and 3.46 h, respectively, are similar to those reported by Ehrnebo *et al.* (19): 3.38 ± 1.18 and 2.95 ± 0.57 h, following intravenous and oral administration, respectively. The present values are in very close agreement with the mean half-life of 3.83 ± 0.47 h reported by Neal *et al.* (20) for four normal subjects. The elimination half-lives for the urinary excretion rate of intact pentazocine for a period of 24 h ranged from 2.0 to 5.5 h (21, 22), which are in accordance with our plasma values. The mean apparent Vd/F for the tablet and solution preparations were 1610 and 1110 L, respectively, or, dividing by the mean body weight, 21.4 and 14.7 L/kg. These values suggest that pentazocine may be bound or partition favorably into tissues. Ehrnebo *et al.* (19) and studies conducted in our laboratories[3] have demonstrated that first-pass metabolism of pentazocine after oral administration was ~80%. Taking this into account, one obtains mean estimates of 222 and 322 L for the tablet and solution treatments, which are in reasonable agreement with the range of 251–548 L reported by Ehrnebo *et al.* (19)

[a] No meaningful value; not included in the mean.

and similar to those of Neal *et al.* (20), 342 ± 188 L, following intravenous administration of 0.8 mg/kg.

The regression-independent bioavailability of the tablet relative to that of the solution was 85.0 ± 31.1%. The AUC_0^{∞} values varied considerably among these volunteers by a factor of 28 and 15 for the tablet and solution, respectively. The data obtained from the solution did not show the same degree of intrasubject variation as that of the tablet. Others have observed the same interindividual variation (19, 21). In general, it has

been observed that the AUC values vary substantially for drugs with pronounced hepatic clearance, such as nortriptyline (23) and imipramine (24); the data suggest this is also true for pentazocine. In addition, the oral bioavailability of pentazocine was significantly enhanced in patients with cirrhosis of the liver, due to reduction in hepatic clearance (20, 25).

Acetaminophen—The plasma data obtained from the solution was fit to a one-compartment body model assuming instantaneous absorption because the first blood sample obtained, in the majority of the subjects, contained the highest level of acetaminophen, while the data obtained from the tablet treatment was fit to a one-compartment body model with first-order absorption. The half-lives for the tablet and solution, 2.67 and 2.77 h, respectively, are in close agreement with those reported by Lee *et al.* (26): 2.6 h in both obese and nonobese subjects. Divoll *et al.* (27) and Rawlins *et al.* (28) found that the mean half-life was 2.7 and 2.8 h after intravenous administration of 650 mg and 500 mg of acetaminophen, respectively. Others have reported half-lives ranging from 2.24 to 3.0 h (17, 29–34). Sotiropoulus *et al.* (35), based on urinary elimination of acetaminophen, reported half-lives of 2.77, 3.14, and 4.12 h after oral administration of three different commercial tablets.

The apparent Vd/F of acetaminophen ranged from 52.6 to 128 L for subjects receiving the tablet and from 49.4 to 110 L for subjects receiving the solution. The mean apparent volumes of distribution, when corrected by the mean body weight, were 1.2 and 1.02 L/kg, respectively, for the tablet and solution suggesting that acetaminophen distributes into total body water. Divoll *et al.* (27) reported a mean value of 1.09 L/kg after intravenous administration of 650 mg of acetaminophen in young human males. As reported by others, the volume of distribution ranged from 0.60 to 1.36 L/kg (9, 18, 27, 29, 30). The regression-independent bioavailability of the tablet relative to that of the solution was 88.6 ± 13.1%.

In summary, the relative bioavailability of pentazocine and acetaminophen in the capsule-shaped tablet formulation proved to be equivalent to that of the solution. In addition, the pharmacokinetic parameters of pentazocine and acetaminophen were not altered after oral administration of the combination of both drugs.

Pharmacokinetics of the Antirheumatic Proquazone in Healthy Humans

PETER H. HINDERLING *x and ANDRÉ ROOS

Received August 5, 1980, from the *Department of Pharmacology, Biocenter, University of Basle, 4056 Basle, Switzerland.* Accepted for publication November 15, 1982. *Present address: F. Hoffmann-La Roche & Co. AG, Grenzacherstrasse 124, Basle CH-4002, Switzerland.

Abstract □ The pharmacokinetics of the antirheumatic proquazone and its conjugated and unconjugated *m*-hydroxy metabolites were investigated in five healthy male volunteers after both intravenous (75 and 122 mg) and peroral (300 and 900 mg *via* capsules) administration. For adequate intravenous dosing of the poorly water-soluble proquazone, advantage was taken of the high degree of protein binding of the drug. Proquazone was admixed with 40% sterile human albumin, and these proteinaceous drug-containing solutions were injected. The pharmacokinetics of proquazone and of the measured metabolites after intravenous administration and after the 300-mg po dose were first order, whereas deviations from linear kinetics were observed at the 900-mg dose level. The apparent half-lives of the α, β, and γ phases of proquazone in plasma were 2, 14, and 76 min, respectively, on intravenous administration. The total clearance of proquazone was 700 mL/min, which indicated a high hepatic extraction. The apparent volume of distribution at steady state was 40 L, implying extensive binding or partitioning of the lipophilic drug in the tissues. Unchanged proquazone (<0.001%), the *m*-hydroxy metabolite (<1.0%), and the conjugated *m*-hydroxy metabolite (20%) were renally excreted after intravenous administration. The extent of absorption of proquazone was ~7% and was entirely the result of a large first-pass effect. Digital computer analysis of the data after intravenous administration was performed with a linear three-compartment model. A model-independent approach was used in the analysis of the peroral data.

Keyphrases □ Proquazone—*m*-hydroxy metabolites, peroral and intravenous pharmacokinetics, humans, NONLIN, SAAM □ Pharmacokinetics—proquazone and its *m*-hydroxy metabolites, humans, oral and intravenous administration, NONLIN, SAAM □ Antirheumatics—proquazone and its *m*-hydroxy metabolites, oral and intravenous pharmacokinetics in humans, NONLIN, SAAM

Proquazone (I), a nonsteroidal anti-inflammatory drug (1, 2) which has been marketed in several countries in Europe since 1977[1], exhibits activities in animal models and humans comparable with those of classical nonsteroidal anti-inflammatory drugs (1–4). Its primary therapeutic indications are in the treatment of rheumatoid arthritis, osteoarthritis, and gouty arthritis (5, 6). Proquazone is very different chemically from other representatives of this class of drugs. It is a quinazolinone derivative and a weak base which is highly lipophilic and shows poor solubility in water (7).

The goal of this study was to delineate the pharmacokinetics of the parent proquazone and its primary metabolites in healthy humans after intravenous and oral administration. Preliminary pharmacokinetic experiments in healthy humans had been performed only after oral administration of the drug (8, 9). These studies indicated that the drug is extensively metabolized, and seven metabolites have been identified (8). Another investigation claimed an increased bioavailability of proquazone when the drug was administered concomitantly with food (9); first-order disposition kinetics for the drug were assumed in this study. Intravenous studies have not been executed with this drug. The sensitivity of the available assay methods and the poor water solubility of the drug necessitated either administration of too small a dosage in aqueous solution or of higher dosages dissolved in excessive volumes of solubilizers[2].

The study of the plasma protein binding of proquazone showed that the drug was highly bound to albumin (98%) (7). Subsequent experiments with human albumin indicated that the apparent solubility of proquazone was significantly increased in the presence of concentrated albumin solutions (7). Preliminary pharmacokinetic experiments showed that larger intravenous dosages could be administered by means of this "biological solubilizer" (7) and that a follow-up of the plasma concentrations and urinary excretion of proquazone and metabolites over sufficient time was possible with the available fluorometric and HPLC methods[2].

EXPERIMENTAL

Materials—The following were used: proquazone[3] (I), *n*-ethylproquazone[3], and *m*-hydroxyproquazone[3] (II). Proquazone in 4-hydroxymethyl-1,3-dioxolane–5-hydroxy 1,3-dioxane (1:2)[4] (7.5% w/v) was employed in the intravenous studies, and proquazone capsules[5] (300 mg) were administered in the oral studies. The dissolution characteristics of the capsules in 0.1 M HCl using the rotating basket method were 83.1, 93.4, and 97.5% of the drug dissolved after 15, 30, and 60 min postinitiation, respectively. Human albumin[6] (20% w/v) was employed as solubilizer for the intravenous dosages of proquazone; heparin[7] was used to prevent coagulation. β-Glucuronidase–sulfatase[8] was employed for enzymic hydrolysis of conjugated *m*-hydroxyproquazone (III).

Pharmacokinetic Procedures—Five nonsmoking, healthy, male volunteers (A–E), 22–24 years old, were selected for the study. Written

consent was obtained from all volunteers. An individual was considered healthy when he had a normal status, history, and laboratory checkup [complete blood count, hematocrit, sedimentation rate, serum electrophoresis, total proteins, creatinine clearance, urinalysis, bilirubin, serum glutamic oxaloacetic transaminase, serum glutamic pyruvic transaminase, alkaline phosphatase, and serum electrolytes (sodium, potassium, calcium, iron, inorganic phosphate)]. These tests were repeated prior to the second, third, and fourth study on each individual to determine possible adverse drug effects or changes due to the experimental procedures. Creatinine clearance of the individuals (117 ± 24 mL/min) was within the normal range (10).

Four different studies were performed in each of the selected volunteers: intravenous administration of 75 and 122 mg in human albumin solution and oral administration of 300 and 900 mg in capsules. The 122-mg iv dose corresponded to the largest amount of the drug that could safely be administered within 45 mL of human albumin solution. The 75-mg iv dose permitted a follow-up of the plasma concentrations and urinary excretion of proquazone and its main metabolite over sufficient time. The 300- and 900-mg po dosages corresponded, respectively, to a therapeutically effective maintenance dose and a cumulative daily dose during antirheumatic treatment. A total of 20 studies were conducted, and the design of the studies was identical for each volunteer. They first received the 900- and 300-mg po dosages and then the 122- and 75-mg iv dosages in that order. Preliminary experiments with other groups of volunteers had indicated that these dosages were well tolerated[2]. Intervals of at least 2 weeks were maintained between the studies to ensure washing out of the drug and to exclude any possible enzyme induction in the subjects due to repeated administration of the drug.

The volunteers were supine during the first 24 h after administration of the drug. Following this they were ambulatory, but no exercise was allowed. The individuals were fasted 12 h before drug administration in both the intravenous and oral studies. After drug administration, the volunteers fasted 6 h. Within the first 24 h after drug administration, the food intake was restricted to fluids, *e.g.*, soups, shakes, and other beverages. The fluid intake amounted to 3000 mL/24 h for the duration of the study. No beverage or food containing caffeine or other diuretically effective substances were allowed. Three hours prior to drug administration, the volunteers received a peroral water loading (10 mL/kg). One-half hour prior to administration of the drug, a catheter[9] was placed in a cubital vein and a constant drip of 0.45% NaCl[10] (flow rate 2.0 mL/min) was started. In the intravenous studies an additional catheter[9] was inserted in a contralateral cubital vein, and a constant drip of 0.9% NaCl[10] (flow rate, 2.5 mL/min) was started. Both infusion solutions contained 1 USP U of heparin/mL to prevent coagulation. Preliminary experiments had demonstrated, that the presence of heparin did not alter the plasma protein binding of I.

The second catheter was used for administering the drug in the intravenous studies and was removed 2 h after drug administration. The first catheter was employed for blood sampling and was removed 11 h after drug administration. Later blood samples were taken by venipuncture[11]. Blood samples (10 mL) were taken through the catheter with syringes using a three-way stopcock within 10 s at 0, 1.5, 2, 2.5, 3, 5, 7, 10, 15, 20, 25, 30, 40, 50, 60, 75, and 90 min, 2, 2.5, 3, 3.5, 4, 4.5, 5, 5.5, 6, 6.5, 7.5, 8, 9, and 10 h after intravenous administration of the drug and at 0, 2.5, 5, 7.5, 10, 15, 20, 30, 45, 60, 75, and 90 min, 2, 3, 4, 5, 6, 7, 8, 10, 15, 18, 24, 36, 42, and 48 h after oral administration. A total volume of approximately 1200 mL of blood was obtained from the volunteers in the four studies within a period of three months. The initial 2 mL of blood was discarded when blood was sampled through the catheters. The blood samples were immediately transferred to heparinized centrifuge tubes and subsequently centrifuged at 300 × *g* for 10 min. Centrifugation of the samples was always accomplished within 1 h after sampling. The plasma was then immediately transferred to storage tubes and kept at −20°C until assayed. In both intravenous and peroral experiments, total volumes of urine were obtained for the following collection periods: −3–0,

0–1, 1–2, 2–4, 4–6, 6–8, 8–10, 10–12, 12–18, 18–24, 24–36, 36–48, 48–60, 60–72, and 72–96 h after drug administration. The urinary pH was monitored, and aliquots of 20–30 mL were transferred to storage containers and kept at −20°C until assayed. Heart rate and blood pressure were monitored at hourly intervals in all the studies up to 10 h after administration.

Preliminary experiments investigated the possible binding of I to syringes, stopcocks, and urine containers. No significant drug binding was found for the drug with these materials.

Drug Administration—*Intravenous*—Freshly prepared sterile solutions of 1.6 and 1.0 mL of I in 4-hydroxymethyl-1,3-dioxolane-5-hydroxy 1,3-dioxane (1:2) (7.5% w/v) in 2-mL syringes were slowly added to 45 mL of human albumin solution kept in 50-mL syringes[12] using a three-way stopcock[13]. The solutions had been brought to a temperature of 37°C previously. After mixing the combined solutions thoroughly, 2-ml aliquots were taken for the determination of the dosages administered. The drug-containing albumin solutions were injected at a constant rate over a period of 60 ± 5 s through one of the catheters. The catheter was immediately flushed with 10 mL of blood which had been taken previously from the volunteer and had been heparinized subsequently. This time was considered as time zero.

Peroral—The capsules (1 or 3) were swallowed together with 100 mL of water. The time of swallowing was considered as time zero.

Analytical Procedures—Proquazone in plasma and urine was determined by a fluorometric method[2]. The main metabolite (II) and its conjugated product (III) were measured in urine by an HPLC assay[2].

The fluorometric assay involved extraction under alkaline conditions into n-heptane and back-extraction under acidic conditions into an aqueous phase. Fluorescence was determined at an emission wavelength of 510 nm (excitation at 326 nm). Unknown concentrations of I were determined by means of standard curves derived from samples spiked with known amounts of the drug. The individual time zero samples obtained from each volunteer served as blanks. The fluorometric assay was specific for I, and its lower level of sensitivity was at 10 ng/mL in plasma and urine. The mean percentage recovery (±*SD*) of the assay determined from samples which were spiked with known amounts of I was 108 ± 8% (n = 25) and 104 ± 5% (n = 7), respectively, for concentrations between 50 and 100 ng/mL in plasma and 95 ± 7% (n = 11) at a concentration of 50 ng/mL in urine. The mean percent precision (10^2 *SD*/Mean) of the fluorometric assay estimated from measurements of samples spiked with known amounts of I was 3% (n = 6) for the concentration range 10–1000 ng/mL in plasma and 9% (n = 6) for the concentration range 10–10,000 ng/mL in urine.

The HPLC method developed for the measurement of II in urine included an extraction into carbon tetrachloride–chloroform (1:1) prior to injection into the HPLC and measurement of the UV absorbance at 237 nm. HPLC conditions were as follows. A stainless steel column (25 × 0.4-cm i.d.)[14] prepacked with silica gel[15] was used for separation. It was protected by a stainless steel precolumn (4.0 × 0.4-cm i.d.) which was dry-packed with porous beads of silica gel[16]. A ternary mixture of isooctane–ether–ethoxyethanol (650:350:50, v/v/v) was employed as the mobile phase at flow rates of 1.6–2.0 mL/min. n-Ethylproquazone was used as internal standard. The respective retention times for II and n-ethylproquazone were 6.6 and 7.8 min.

For the determination of total [conjugated + unconjugated (II + III)] metabolites, the urine samples were exposed to enzymic hydrolysis at 37°C for 2 h at pH 5.35. The enzymic digests were then extracted into benzene–isopropyl alcohol (5:1) and subsequently injected into the HPLC. The amounts of III were obtained from the difference between the individually determined total metabolites and the amount of II. The lower level of sensitivity of the HPLC method in urine was 20 ng/mL. The mean percent recovery (±*SD*) for II plus III with this method was 98 ± 10 (n = 22) for the concentration range 0.2–1.0 μg/mL. The respective mean percent precisions of the method for II plus III and II obtained from samples spiked with known amounts of the metabolites were similar and were 7 and 11% (n = 6) for the above concentration ranges.

Estimates for the relative precision of the fluorometric and HPLC methods were also calculated from the replicate determinations of the samples obtained in the pharmacokinetic studies. In plasma the relative precision of the fluorometric method was constant over a large concentration range (8000–50 ng/mL) and was high (2%). In the lower concentration range (50–5 ng/mL), the relative precision of the method was clearly smaller (35%). In urine the variability of the fluorometric method for I in the concentration range of 50–5 ng/mL was large, and the relative precision was 60%. Similarly obtained estimates for the relative precision of II and III measurements by the HPLC method yielded average values of 7% (4.0–0.01 μg/mL) and 6% (250–0.01 μg/mL), respectively. All measurements in plasma and urine by fluorometry or HPLC were performed in duplicate. The means of these determinations were used for graphical and digital computer analyses.

[a] Fraction of dose renally excreted as unchanged proquazone at infinite time, obtained using Eq. 9. [b] Fraction of dose renally excreted as *m*-hydroxyproquazone at infinite time, obtained using Eq. 17. [c] Fraction of dose renally excreted as conjugated *m*-hydroxyproquazone at infinite time, obtained using Eq. 17. [d] Fraction of dose renally excreted at infinite time as the sum of unconjugated and conjugated *m*-hydroxyproquazone. [e] Ratio of the renally excreted amounts at infinite time of unconjugated to conjugated *m*-hydroxyproquazone.

on I after intravenous administration used graphical and digital computer methods. Initial (0–2.5 min) and terminal (10 h→∞) concentrations were not available. However determinations of clearance and volume of distribution parameters are based on plasma concentrations from time zero to infinity. Hence, plasma concentrations in the initial and terminal intervals were generated by fitting the experimentally determined plasma concentrations of I (C_p) after intravenous administration to polyexponential functions. The fittings were performed with the individual data using the nonlinear least-squares estimation programs SAAM (11) and NONLIN (12). Best results were obtained with both SAAM and NONLIN when the experimental data were fitted to the class (13) of three-compartment intravenous infusion models (without any assumptions regarding topology of the compartments) in accordance with:

$$C_p = A'e^{-\alpha t'} + B'e^{-\beta t'} + Ce^{-\gamma t'} \qquad \text{(Eq. 1)}$$

where A', B', and C' are the coefficients and α, β, and γ are exponents of the three-exponential equation and t' is the postinfusion time. Different weighting procedures were evaluated in preliminary fitting attempts with both programs. Weighting according to $w = 1/K \cdot C_p$, where K corresponds to a constant, and $w = 1/C_p$ was most adequate for the definitive fitting of the data by SAAM and NONLIN, respectively. The assumption of an intravenous infusion model was justified since the large value of the rate constant of the early disposition phase ($t_{1/2,\alpha}$ = 2 min) necessitated consideration of the 1-min infusion time. Fitting the data to a three-exponential equation, but not to a two-exponential equation, yielded random scatter of the data points about the regression line in all 10 data sets (by NONLIN and SAAM); a typical example (SAAM) is given in Fig. 1. Fitting the data to a four-exponential equation did not produce a significant reduction of the weighted sum of squared deviations (14), although four phases were separable by graphical analysis in some plots.

In fitting the data to the class of three-compartment models, no assumptions were made regarding the topology of the compartments. However, when clearance and steady-state volume of distribution values were derived from the coefficients and exponents of the fits, it was presumed that elimination of the drug occurred exclusively from the measured site, *i.e.*, plasma compartment (15). Only a few of the class of three-compartment models fulfill this requirement. Among those, a mamillary three-compartment model was arbitrarily chosen, and its volume and rate constant parameters calculated from the coefficients and exponents obtained in the fits. Mamillary models, which presume elimination to occur exclusively from the measured site, *i.e.*, the central compartment (15), represent the most often used model type in pharmacokinetic data analysis. The study of a particular type of model permits one to follow the time course of the drug in the tissue compartments and to evaluate depth and capacity of the different body compartments.

The peroral data were analyzed in a different way; they were not fitted to polyexponential equations. Only the terminal logarithmic linear phase plasma concentrations were fitted to obtain plasma concentrations over the entire time course. The plasma concentrations of I after peroral administration were much smaller and showed more scatter than the intravenous data. In addition, a possible deviation from first-order kinetics of I at the 900-mg dose level was implied by the metabolite data and could not be rejected.

m-Hydroxy Metabolites—The urinary data on metabolites II and III after both modes of administration were subjected to a model independent analysis.

Pharmacokinetic Calculations—*Proquazone*—The apparent volume of distribution of the central compartment, V, was estimated by:

$$V = D/C_0 = D/(A + B + C) \qquad \text{(Eq. 2)}$$

where D corresponds to the dose, C_0 is the drug concentration at time zero (intravenous bolus model), and A, B, and C represent the coefficients of the corresponding model equation (16). The total area under the plasma concentration time curve, AUC, was obtained from:

$$\text{AUC} = A/\alpha + B/\beta + C/\gamma \qquad \text{(Eq. 3a)}$$

$$\text{AUC} = \text{AUC}(t_0,t_1) + \text{AUC}(t_1,t_2) + \text{AUC}(t_2,t_\infty) \qquad \text{(Eq. 3b)}$$

where $\text{AUC}(t_0,t_1)$ and $\text{AUC}(t_1,t_2)$ correspond, respectively, to the partial area during the time of infusion and to the partial area during the time interval after the infusion was stopped to the last measured sample, and $\text{AUC}(t_2,t_\infty)$ is the partial area from the time of the last measured sample (10 h) to infinity on the presumption of terminal logarithmic linear decay. $\text{AUC}(t_0,t_1)$ and $\text{AUC}(t_1,t_2)$ were obtained by numerical integration (linear trapezoidal rule) after the plasma concentration at the end of infusion was estimated from Eq. 1. $\text{AUC}(t_2,t_\infty)$ was determined by algebraic integration in accordance with:

$$\text{AUC}(t_2,t_\infty) = C_{10\text{ h}}/\gamma \qquad \text{(Eq. 4)}$$

where $C_{10\text{ h}}$ corresponds to the concentration of the last measured sample. The ratio of the $\text{AUC}(t_0,t_1)$ to AUC was, on average, 0.04; the ratio of $\text{AUC}(t_2,t_\infty)$ to AUC was negligibly small (<0.004). The total clearance of drug, CL, was estimated according to:

$$CL = D/\text{AUC} \qquad \text{(Eq. 5)}$$

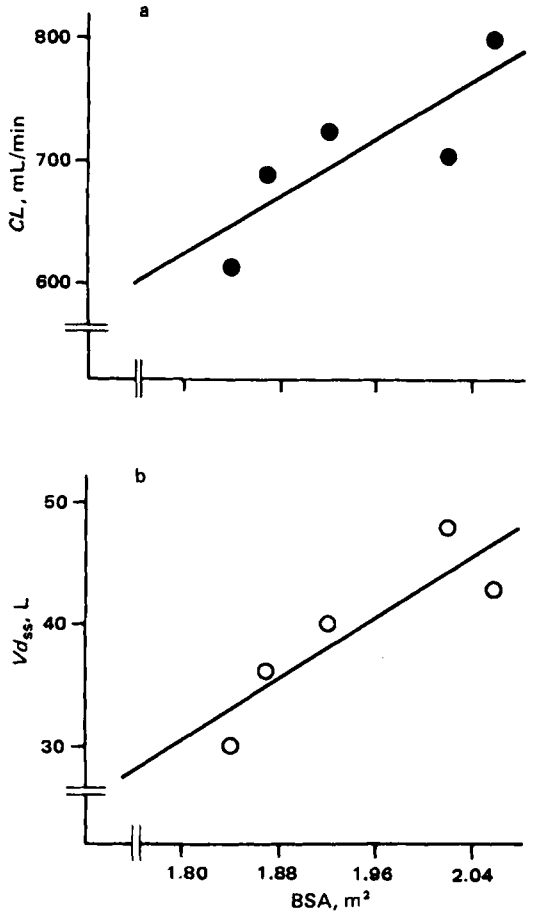

Figure 3—*Linear plots of the clearance (a) and steady-state volume of distribution (b) against body surface area in volunteers A–E, using the mean values obtained in the intravenous experiments for each individual. There are apparent linear relationships between* CL *and BSA [y = 435 (±440) + 588 (±226)·x, r = 0.832, p < 0.05] and* V_{ss} *and BSA [y = 83.6 (±38.5) + 63.4 (±19.8)·x, r = 0.880, p < 0.05].*

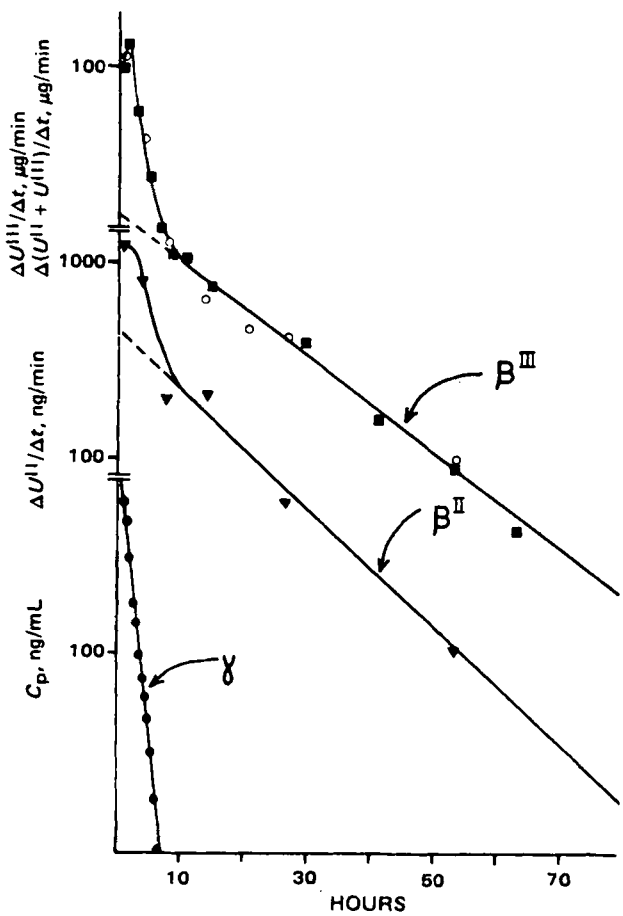

Figure 4—*Semilogarithmic plots against time after intravenous administration of the rates of urinary excretion per minute (*dU/dt*) for II (▼), III (○), and II plus III (■). A semilogarithmic plot of plasma concentration against time of I (●) is included for comparison. The metabolites II and III have similar triphasic profiles with peak rates at 1 h after administration and apparent terminal logarithmic linear phases with slopes of* $-\beta^{II,III}$. *Data were obtained in subject C after an intravenous dose of 122 mg.*

The apparent pseudo-steady-state volume of distribution, V_{ps}, was obtained from:

$$V_{ps} = CL/\gamma \qquad \text{(Eq. 6)}$$

The apparent steady-state volume of distribution was estimated according to:

$$V_{ss} = D\left(\frac{A}{\alpha^2} + \frac{B}{\beta^2} + \frac{C}{\gamma^2}\right) \Big/ \left(\frac{A}{\alpha} + \frac{B}{\beta} + \frac{C}{\gamma}\right)^2 \qquad \text{(Eq. 7)}$$

Amounts of unchanged drug excreted in urine at infinite time, U, were obtained from:

$$U = U_{6\text{ h}} + (dU/dt)_{6\text{ h}}/\gamma \qquad \text{(Eq. 8)}$$

where $U_{6\text{ h}}$ and $(dU/dt)_{6\text{ h}}$ correspond, respectively, to the amounts excreted up to 6 h and to the urinary excretion rate 6 h after drug administration; γ was estimated from semilogarithmic plots of the excretion rate against time. Renal clearance, CL_{ren}, was calculated according to:

$$CL_{ren} = U/\text{AUC} \qquad \text{(Eq. 9)}$$

Glomerular clearance, CL_{glom}, was predicted from:

$$CL_{glom} = CL_{cr} \cdot f_u \qquad \text{(Eq. 10)}$$

where CL_{cr} corresponds to the individually measured creatinine clearance, and f_u is the fraction of drug unbound in the plasma of the individual (7).

On the assumption that all nonrenal elimination occurred in the liver, the hepatic extraction efficiency (hepatic first-pass effect) was computed from:

$$\epsilon^{I,1} = \frac{CL_{hep}}{\hat{V}_{hep}} = \frac{CL - CL_{ren}}{\hat{V}_{hep}} \qquad \text{(Eq. 11)}$$

where CL_{hep} and $\hat{V}_{hep}$ correspond to the liver clearance and liver plasma flow [825 mL/min (17)], respectively.

The percentage of an oral dose of I that reached the systemic circulation unchanged [extent of absorption (18)], E, was estimated according to:

$$E = 10^2 \frac{(AUC/D)_{po}}{(AUC/D)_{iv}} \qquad \text{(Eq. 12)}$$

The fraction of the dose eliminated by first pass on oral administration, ϵ, was estimated from the urinary data of II and III using:

$$\epsilon^{II} = R^{II}\{(U^{II}/D)_{po} - [(U^{II}/D)_{iv} \cdot E/10^2]\} \qquad \text{(Eq. 13a)}$$

$$\epsilon^{III} = R^{III}\{(U^{III}/D)_{po} - [(U^{III}/D)_{iv} \cdot E/10^2]\} \qquad \text{(Eq. 13b)}$$

where $R^{II} = [(D - U^{I})/U^{II}]_{iv}$ and $R^{III} = [(D - U^{I})/U^{II}]_{iv}$ on the assumption that the ratio of drug metabolized to other metabolite(s) or eliminated by routes other than renal to the amount of II and III formed is invariant with route of administration. Estimates for ϵ were also obtained from proquazone data in accordance with:

$$\epsilon^{I,2} = 1 - (E/10^2) \qquad \text{(Eq. 14)}$$

The total extent of absorption of unchanged plus changed drug at the 300-mg dose level, E^{tot}, was estimated from:

$$E^{tot} = 10^2\epsilon^{I,1} + E \qquad \text{(Eq. 15)}$$

m-*Hydroxy Metabolites*—The respective amounts of II or III excreted in urine at infinite time, $U^{II,III}$, were obtained from:

$$U^{II,III} = [U_{72\text{ h}} + (dU/dt)_{72\text{ h}}/\beta]^{II,III} \qquad \text{(Eq. 16)}$$

where $U^{II,III}_{72\text{ h}}$ corresponds to the excreted amounts of II or III at 72 h and

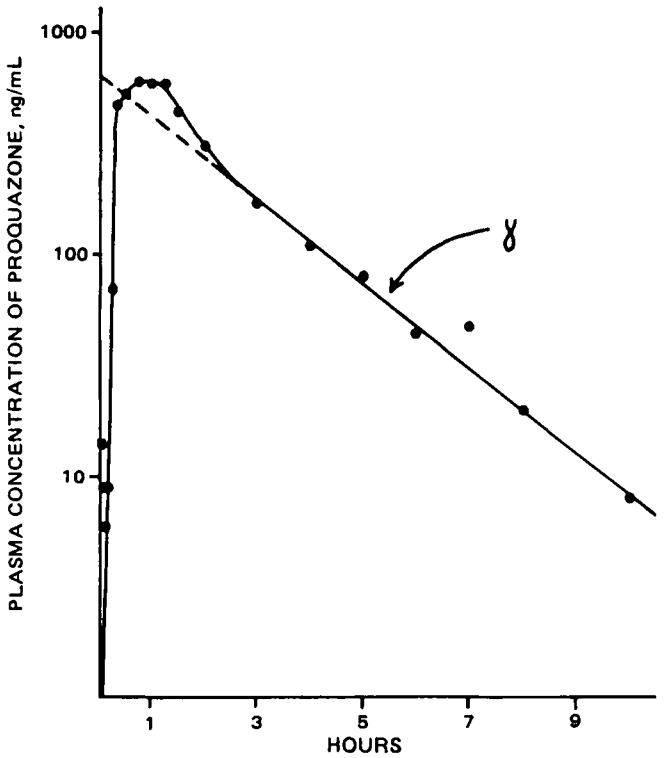

Figure 5—*Semilogarithmic plot against time of proquazone plasma concentration following administration of 900 mg po to subject A showing a triphasic profile. The apparent terminal logarithmic phase is linear with a slope of* $-\gamma$.

$(dU/dt)^{II,III}_{72\ h}$ to the excretion rates of II and III 72 h after drug administration; $\beta^{II,III}$ was estimated from semilogarithmic plots of the respective urinary excretion rates against time. The ratios of $(U_{72\ h-\infty}/U)^{II}$ and $(U_{72\ h-\infty}/U)^{III}$ were insignificant (<0.01).

Statistics—Paired *t* test statistics were performed with the proquazone and metabolite data after peroral administration of the drug.

RESULTS

Procedural and Adverse Effects—The values of the clinical laboratory data that were obtained prior to each of the four administrations of proquazone were always within the normal range for males of this age group (19). Proquazone at the four dosage levels was well tolerated, and no adverse drug effects were observed. Blood pressure and heart rate did not show significant changes in the interval up to 10 h after administration of the drug.

Pharmacokinetics of Proquazone and Its *m*-Hydroxy Metabolites—Mean values for the parameters as estimated by NONLIN are given hereafter in the text; the plus and minus values for these means refer to the standard deviation. The number of values considered was 10 unless otherwise specified. The volume and clearance parameters of I are referenced to total (bound plus unbound) drug concentration in plasma. It was assumed that the concentration ratio of total to unbound drug in plasma was maintained during the passage of I through the capillaries of the liver. Negligible concentrations of I were found in erythrocytes in whole blood (7).

Intravenous Administration—*Proquazone*—The NONLIN and SAAM estimates for the coefficients and exponents of the fitted three-exponential equation were equivalent (Table I). The values respectively obtained for A and α varied the most. There was good agreement between the estimated total clearance (NONLIN, 708 mL/min; SAAM, 689 mL/min) and steady-state volume of distribution (NONLIN, 39.5 L; SAAM, 39.7 L) obtained by the two programs.

The CL estimates by NONLIN and SAAM were close to those obtained by application of the trapezoidal rule (711 mL/min), suggesting that the polyexponential fittings by both programs were adequate. The dose-normalized plasma concentration–time data at the lower and higher dose levels were superimposable and indicated first-order kinetics of I. The dose percentages of unchanged I eliminated by the renal route were extremely small (<0.001%) and could be measured reliably only after the higher intravenous dose (Table II). Three phases with mean apparent half-lives of 2 (±1) min ($t_{1/2,\alpha}$), 14 (±5) min ($t_{1/2,\beta}$), and 76 (±15) min ($t_{1/2,\gamma}$) were separable in the curves in plasma (Fig. 2, Table I). The latter value was confirmed by $t_{1/2,\gamma}$ = 98 (±30) min (n = 5) estimated from semilogarithmic plots of the urinary excretion rates against time. In all the experiments, the plasma samples taken at 1.5 min after the end of the infusion yielded maximum concentrations and indicated fast initial mixing in plasma. The apparent volume of distribution of the central compartment (V) was, on average, 11 (±4.8) L (Table I) and exceeded the plasma volume [3 L (20)] significantly. This suggested fast extravascular distribution of the highly plasma protein-bound drug (7). Total clearance of I, CL, averaged 707 (±83.7) mL/min. The extraction efficiency of the liver for I (ϵ) was 0.86 (±0.101) and suggested that I can be classified as a highly extracted compound (21, 22). There was an apparent linear correlation between CL and body surface (BSA), but not between CL and weight, for the individuals (Fig. 3a). The renal clearance, CL_{ren}, averaged 0.06 (±0.05) mL/min and was smaller than the estimated glomerular clearance, CL_{glom} = 2.5 (±0.50) mL/min, indicating tubular reabsorption in excess of possible tubular secretion for the highly lipophilic drug.

[a] Slopes of the apparent terminal logarithmic linear γ phase. [b] Times of the maximum plasma concentration of proquazone. [c] Maximum plasma concentration of proquazone at time t_{max} after peroral administration. [d] Dose corrected quasi total areas under the plasma concentration time curve from time zero to 10 h after administration, obtained using Eq. 3.

There was no indication for urine flow or urine pH dependency of the renal elimination of I. The volumes of distribution at pseudo-steady-state (V_{ps}) and at steady state (V_{ss}) were 82 (±26) and 39 (±7.7) L, respectively, (Table I). The large difference between these values indicated that the microscopic rate constants of distribution into the tissue compartment T′ ($k_{BT'}$ and $k_{T'B}$) were small relative to the rate constant of elimination (k_{BE}) (Table I). The slower equilibrating tissue compartment T′ (Fig. 1) must be regarded as a deep compartment. Its capacity for the drug is much larger than that of the shallow compartment T (Table I). The volume of distribution at steady state, V_{ss}, depended linearly on the BSA of the individuals (Fig. 3b). In contrast, no such correlation existed between V_{ss} and weight of the individuals, indicating that the widely used principle of weight normalization of kinetic parameters may be questionable.

m-Hydroxy Metabolites—Semilogarithmic plots against time of the urinary excretion rates of II and III showed triphasic profiles with terminal half-lives $t_{1/2\beta}$ of 6.7 (±3.1) h (n = 5) for II and 10.6 (±3.0) h (n = 5) for III (Fig. 4). This implied that the *m*-hydroxy metabolites have a considerably larger time of residence in the body than the parent drug. Metabolite II is reportedly pharmacologically active[2]. The percentages of the administered dose renally excreted as *m*-hydroxy metabolites (II plus III) were 20.4 ± 3.80% and 19.9 ± 5.03% (n = 5) (Table II) after the lower and higher intravenous dosages, respectively. This implied first-order kinetics of the metabolites. The combined urinary recoveries of I, II, and III amounted to 20%, indicating that 80% of the dose was eliminated by alternative routes. The renally recovered dose percentages of III [19.6 ± 4.97% (n = 5)] clearly exceeded those of II [0.25 ± 0.01% (n = 5)] (Table II).

A model comprising all the experimental findings after intravenous administration is given in Scheme I. As mentioned previously, a model-dependent data analysis was performed with the parent drug data,

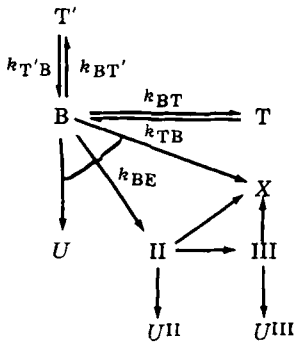
[a] *Calculated from Eq. 12.* [b] *Computed according to Eq. 15.* [c] *Obtained using Eq. 11.* [d] *Estimated from Eq. 13a using III data.* [e] *Calculated from Eq. 13b using II data.* [f] Obtained in accordance with Eq. 14 after rearrangement.

whereas a model-independent approach was effected with the metabolite data. Scheme I reflects this approach. The model depicted is the most simple that can account for all the kinetic events observable with the type of data analysis chosen. The parent drug is represented by a three-compartment body model with extrarenal [formation of II, formation of unidentified metabolite(s), and biliary excretion (X)] and renal (U) elimination. The identified metabolites II and III are represented each by a body compartment (II, III) with renal (U_{II}, U_{III}) and extrarenal [formation of III, formation of unidentified metabolite(s), and biliary excretion (X)] elimination. As can be seen, the amounts of I, II, and III passing through all routes of elimination, which were not monitored directly, are lumped together (X).

Peroral Administration—*Proquazone*—Maximally, three (Fig. 5) or two phases were separable in the plasma concentration–time profiles of I after administration of the two peroral dosages. The triphasic profiles peaked earlier than the biphasic profiles. These findings indicated that absorption was faster than early disposition (β) in the former, but slower than early disposition in the latter experiments. The times of peak plasma concentration (t_{max}), the dose-normalized peak plasma concentrations ($10^2C_{max}/D$), and the dose-normalized areas under the plasma concentration time curves ($10^2AUC_{0-10\ h}/D$) were not significantly different for the two dose levels (Table III). The slopes of the terminal logarithmic linear phase (γ) after oral dosing agreed with those previously found after intravenous dosing. These results suggest that first-order kinetics were operative for I after oral dosing at both dosage levels. In four of the five individuals tested (A–D), the dose-normalized AUC values were remarkably similar at both dosage levels, whereas in one individual (E) this parameter was clearly larger after 900 mg than after 300 mg (Table III). The extent of absorption (18) averaged 6.1 ± 2.8% (n = 5) and did not differ significantly from E = 8.2 ± 8.2% (n = 5) after the 900-mg dose (Table IV). The small dose fractions of drug reaching the systemic circulation unchanged implied a poor absorption or a large first-pass effect for I.

m-*Hydroxy Metabolites*—Semilogarithmic plots of the urinary excretion rates against time after oral dosing showed profiles similar to those observed after intravenous administration except that they peaked later (Figs. 4 and 6). The percentages of the administered dose renally excreted as II and III after the 900-mg dose tended to be smaller than after the 300-mg dose, representing respectively 65 and 50% of the recoveries found at the lower dose level (Table II). The ratios of the urinary recoveries of II to III were equivalent after administration of the two peroral dosages (Table II), suggesting that the observed dose-dependent, nonlinear kinetics were associated with the formation of II. This was in contrast to the previously observed linear kinetics of disposition of I after peroral dosing, which implied linear kinetics of formation for II. When the dose fractions of I eliminated during first pass at the 300-mg dose level were estimated from II and III data assuming linear kinetics, average values of ϵ^{II} = 0.60 and ϵ^{III} = 0.96 were obtained (Table IV). Only the latter value was in accordance with ϵ estimates by proquazone data [$\epsilon^{I,1}$ = 0.86, $\epsilon^{I,2}$



Scheme I—Model for intravenous administration of proquazone.

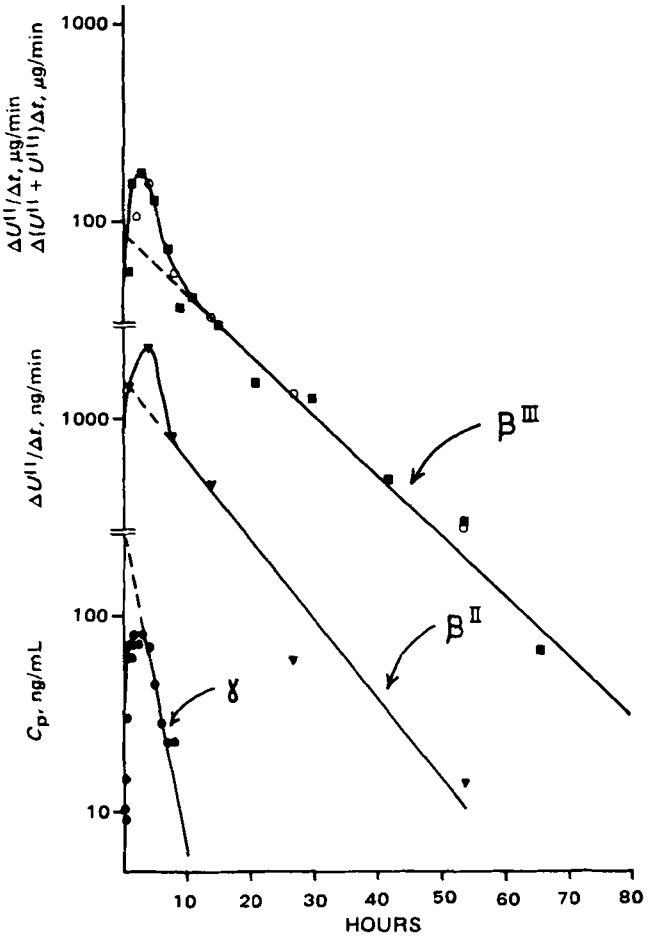


Figure 6—*Semilogarithmic plots against time after oral administration of the rates of urinary excretion per minute, (dU/dt) for II (▼), III (○), and II plus III (■). A semilogarithmic plot of plasma concentration against time of I (●) is included for comparison. The metabolites II and III have similar triphasic profiles with peak rates at 3 h after administration and apparent logarithmic linear phases with slopes of $-\beta^{II,III}$. Data were obtained in subject C after an oral dose of 300 mg.*

= 0.92, (Table IV)]. The underestimated values for ϵ obtained from II data (Table IV) implied that a significant percentage of I (~40%) was metabolized not only to II but subsequently to III during the first pass. The total extent of absorption (unchanged plus changed drug) of I was complete [E^{tot} = 103 ± 15% (n = 5), Table IV]. These results suggested that (*a*) the total first-pass effect should be assessed from III data, not from II data; (*b*) the low extent of absorption found for I was due to a large first-pass effect, and not due to poor absorption in accordance with the lipophilic nature of the compound; and (*c*) the assumption of first-order kinetics at the 300-mg dose level was reasonable.

DISCUSSION

The plasma and urinary data of proquazone and its *m*-hydroxy metabolites after administration of 75 and 122 mg iv and 300 mg po were indicative of first-order kinetics. Nonlinear, dose-dependent kinetics of formation for II were evident from the metabolite data at the 900-mg po dose level, whereas the parent drug data implied first-order kinetics of disposition for I (and hence first-order kinetics of generation for II) at this dose level. These findings were irreconcilable only if presystemic or systemic metabolism of I to II were the sole or major route of elimination for the parent drug, as equivalent 35% deviations from linear kinetics should then be found with both parent drug and metabolite data. However, if the percentage of I metabolized to II were smaller (≤40%), the parent drug data would deviate from linear kinetics by ≤14% (0.40·35%), whereas a unvariable 35% (1.0·35%) deviation from linear kinetics would be found with the metabolite data. Two other studies with administrations of 100 and 400 mg po of drug to 15 healthy volunteers determined quantitatively not only II and III, but all the metabolites which could be derivatives of II and III[2]. These studies used urinary data and permitted a quantitative assessment of the *m*-hydroxy pathway. The results showed that the percentage of I metabolized to II was ≤35%. Hence, the findings obtained at the 900-mg po dose level in the present study can be rationalized, and that the nonlinearity of the kinetics of I were recognized only with the metabolite data is reasonable. Considering the variability of the peroral plasma data of I, deviations on the order of ≤14% were too discrete to become apparent.

A major fraction of II (and III) after peroral administration of I was generated during first pass of drug through the liver; only a minor fraction of II (and III) was formed systemically from I (Table IV). The observed dose-dependent kinetics of formation of II (and III) at the 900-mg dose level was largely the result of a saturation of this first-pass effect. Whether or not the kinetics of systemically formed II (and III) were dose dependent at the higher peroral dose level could not be decided based on the available experimental evidence. A delineation as to the type of the nonlinear kinetics observed, *i.e.*, Michaelis–Menten kinetics (23), product inhibition kinetics (24), or blood flow-dependent kinetics (21, 22) (pharmacologically induced temporal decrease of the liver blood flow), was not possible with the available experimental data. However it is interesting to note that primarily hydroxy metabolites cause "product inhibition" (25).

The statistical design of the present study was not balanced. However, it is improbable that the nonlinearity of the kinetics observed at the 900-mg po dose level was a period- (procedure-) rather than a treatment- (dose-) related effect. First, the laboratory data gave no evidence for the existence of procedural effects. Second, the 900-mg dose was the first treatment given to the volunteers and procedural effects are more likely to become significant in the later experiments (300 mg po and 122 and 75 mg iv) as a result of a cumulative (carry over) effect. However, the kinetics of the parent drug and metabolites were first order in these experiments. Third, the intervals of at least 2 weeks which were maintained between the studies should have minimized possible carry-over effects.

Reports on data-fitting obtained by different computer programs can rarely be found in the literature (26, 27). The results of the present study indicated that there was reasonable agreement for the parameter estimates obtained by NONLIN and SAAM. There is a need for more of these comparative fitting efforts, so that the reliability and interchangeability of pharmacokinetic data obtained with different computer programs can be assessed definitively.

APPENDIX: GLOSSARY

D = Dose of proquazone (mg)
C_p = Concentration of proquazone in plasma (ng/mL)
C_0 = Concentration of proquazone in plasma at time zero after intravenous injection (ng/mL)
C_{max} = Maximum plasma concentration of proquazone at time t_{max} after peroral administration (ng/mL)
B = Amount of proquazone in the central compartment
T = Amount of proquazone in the shallow peripheral compartment
T′ = Amount of proquazone in the deep peripheral compartment
II = Amount of *m*-hydroxyproquazone in the body compartment
III = Amount of the conjugated *m*-hydroxyproquazone in the body compartment
U_t, U = Respective amounts of proquazone renally excreted unchanged at time t and at infinite time after administration
$U_t^{II,III}$, $U^{II,III}$ = Respective amounts of *m*-hydroxyproquazone and conjugated *m*-hydroxyproquazone renally excreted at time t and at infinite time
X = Amounts of proquazone, *m*-hydroxyproquazone, and conjugated *m*-hydroxyproquazone eliminated by routes that were not monitored directly: amounts of I, II, III excreted in bile and/or metabolized to unidentified metabolites
dU/dt = Amount of drug or metabolite excreted in urine, dU, (μg or ng) during a time interval, dt (min)
A', B', C', α, β, γ = Parameters of the three-exponential fit of the plasma concentrations of proquazone according to an intravenous infusion three-compartment model, where A', B', and C' are in ng/mL and α, β, and γ are in min
A, B, C = Parameters of the corresponding intravenous injection three-compartment model for proquazone, where A, B, and C are in % of dose/L
k_{ij} = Generalized form for the microscopic first-order rate constant from the ith to the jth compartment for proquazone (min^{-1})
$\beta^{II,III}$ = Slope of the apparent terminal logarithmic linear phase of *m*-hydroxyproquazone and conjugated *m*-hydroxyproquazone
V = Volume of distribution of proquazone in the central compartment (L)
V_{ps} = Apparent pseudo-steady-state volume of distribution of proquazone (L)
V_{ss} = Apparent steady-state volume of distribution of proquazone (L)
$AUC_{0-t'}$ AUC = Respective areas under the plasma concentration–time curve from time zero to time t and from time zero to infinity of proquazone
CL = Total clearance of proquazone (mL/min)
$\dot{V}_{hep}$ = Hepatic plasma flow (mL/min)
CL_{ren} = Renal clearance of proquazone (mL/min)
CL_{glom} = Glomerular clearance of proquazone (mL/min)
f_u = Fraction of proquazone in plasma unbound
E = Extent of absorption of unchanged proquazone
E^{tot} = Total extent of absorption of unchanged plus changed proquazone
ϵ^I, ϵ^{II}, ϵ^{III} = Respective estimates of first-pass effect (hepatic extraction efficiency) for proquazone from proquazone, *m*-hydroxy metabolite, and conjugated *m*-hydroxy metabolite data
t' = Postinfusion time (min)
BSA = Body surface area (m^2)

We thank Ms. R. Leder and the nursing staff of the Merian Iselin Hospital in Basle for their expert technical assistance in performing the pharmacokinetic studies and Dr. W. Pacha, Dr. H. P. Keller, and the Sandoz Laboratories in Basle for performing the assays in plasma and urine.

Quantitative Determination of Captopril in Blood and Captopril and Its Disulfide Metabolites in Plasma by Gas Chromatography

M. S. BATHALA ˣ, S. H. WEINSTEIN, F. S. MEEKER, JR., S. M. SINGHVI, and B. H. MIGDALOF

Received December 8, 1982, from the *Department of Drug Metabolism, The Squibb Institute for Medical Research, Princeton, NJ 08540.* Accepted for publication February 11, 1983.

Abstract □ A sensitive, quantitative gas chromatographic–electron capture (GC–EC) method for the determination of captopril in blood and captopril and its disulfide metabolites (collectively) in plasma was developed. After addition of an internal standard and *N*-ethylmaleimide to the biological samples, excess *N*-ethylmaleimide and naturally occurring interfering substances were removed by extraction with benzene followed by acidification and extraction with hexane. The *N*-ethylmaleimide adducts of captopril and of the internal standard were then extracted with benzene and converted to their hexafluoroisopropyl esters. For the assay of captopril and its disulfide metabolites, tributylphosphine was used to reduce the disulfide metabolites to captopril prior to derivatization. The hexafluoroisopropyl esters of the *N*-ethylmaleimide adducts of captopril and of the internal standard, the 4-ethoxyproline analogue of captopril, were separated by GC on a column packed with 3% OV-101 on Chromosorb W-HP. The lower limits of sensitivity were 20 ng/mL for captopril in blood and 50 ng/mL for captopril and its disulfide metabolites in plasma. Linearity, precision, and accuracy were excellent. The method was validated by comparison of results obtained for total captopril in dog plasma by the GC–EC assay with results obtained by a published GC–MS method. The assay was applied to dog and human samples to explore its general utility.

Keyphrases □ Captopril—quantitative determination in blood and plasma, disulfide metabolites, gas chromatography □ Metabolites, disulfide—captopril, plasma, quantitative determination by gas chromatography □ Gas chromatography—captopril, quantitative determination in blood and plasma, disulfide metabolites

Captopril, 1-[(2*S*)-3-mercapto-2-methylpropionyl]-L-proline (I), the first orally active inhibitor of angiotensin-converting enzyme (peptidyl dipeptide hydrolase, kininase II, E.C. 3.4.15.1) to be used clinically, is a potent antihypertensive agent used to treat both renovascular and essential hypertension (1, 2). It is of particular value in treating hypertension resistant to conventional drugs (3), and shows great promise for use in congestive heart failure (2, 4).

The predominant route of excretion of captopril is *via* the kidneys (5–7). Since kidney function is often impaired in patients with hypertension, a sensitive assay for the drug in blood or plasma using readily accessible analytical equipment would be of value in optimizing dosage. Assays for both unchanged captopril and its disulfide metabolites would be useful, since interconversions occur among these compounds in rats, dogs, and humans (8–11). Metabolites of captopril include the symmetrical disulfide (IIA), captopril–L-cysteine mixed disulfide, captopril–glutathione mixed disulfide, and mixed disulfides of captopril with plasma proteins (IIB). Current methods for measurement of the drug in biological fluids are either not sensitive enough for monitoring therapeutic levels (12–14) or involve analytical equipment not available to the average clinical laboratory (15–17). Therefore, a sensitive method has been developed for quantifying captopril in blood and captopril

and its disulfide metabolites in plasma by gas chromatography with electron capture detection (GC–EC).

EXPERIMENTAL

Materials—*N*-Ethylmaleimide[1], hexafluoro-2-propanol[2], trifluoroacetic anhydride[2], sodium chloride[3], hydrochloric acid[3], and tributylphosphine[4] were obtained from commercial sources and used without further purification. Benzene, hexane, and methanol were suitable for HPLC analysis and used as supplied[5]. Captopril and the 4-ethoxyproline analogue of captopril (SQ 25,761, the internal standard) were of pharmaceutical quality and were used as received[6].

The chromatographic column was glass, 1.8 m × 2 mm i.d., packed with 3% methyl silicone on 100–120 mesh chromatographic (high-performance) diatomaceous earth[7]. Nitrogen and argon–methane (95:5) of the highest available[8] purity were used.

Equipment—GC was performed using an instrument[9] equipped with a nickel-63 electron-capture detector. All extractions were carried out by shaking the samples on a reciprocating shaker[10]. An analytical evaporator[11] was used for removing solvents from extracts with a nitrogen stream. The reduction of the biological samples with tributylphosphine and subsequent esterification with hexafluoro-2-propanol were performed by incubating in a heating block[12].

Extraction, Derivatization, and Chromatography of Unchanged Captopril in Blood—For spiking blood or plasma samples, separate stock solutions of captopril and the internal standard (III) were prepared in distilled water containing excess *N*-ethylmaleimide (1:5 molar ratio). Control dog or human blood (1 mL) containing 5 mg of *N*-ethylmaleimide was spiked with aqueous solutions of captopril containing *N*-ethylmaleimide to give standard solutions containing 20–200 ng/mL of captopril. The internal standard, 400 ng in 50 μL of aqueous solution, was added to each sample. All samples were extracted in acid-washed (16 × 125-mm) glass culture tubes. Twelve milliliters of benzene was added to each sample, and the samples were shaken on a reciprocating shaker for 10 min. After centrifuging the sample for 10 min at 3000×*g*, the benzene (upper) layer was removed by aspiration and discarded. One milliliter of 1 M HCl and 2 g of NaCl were added to each tube, and the contents of each tube was mixed on a vortex mixer for ~30 s. Ten milliliters of hexane was added to each sample, and the contents of each tube was again shaken for 10 min and then centrifuged for 10 min. The hexane (upper) layer was removed by aspiration and discarded. Each sample was then extracted with 12 mL of benzene by shaking for 20 min, followed by centrifugation for 10 min.

The organic layer was transferred to a clean tube and evaporated to dryness under a stream of nitrogen. The residue in each tube was derivatized with 100 μL of hexafluoro-2-propanol and 10 μL of trifluoroacetic anhydride at 50°C for 1 h. Excess reagents were removed by evaporation under a stream of nitrogen. Each residue, which contained derivatized captopril and internal standard, was reconstituted in 1 mL of benzene;

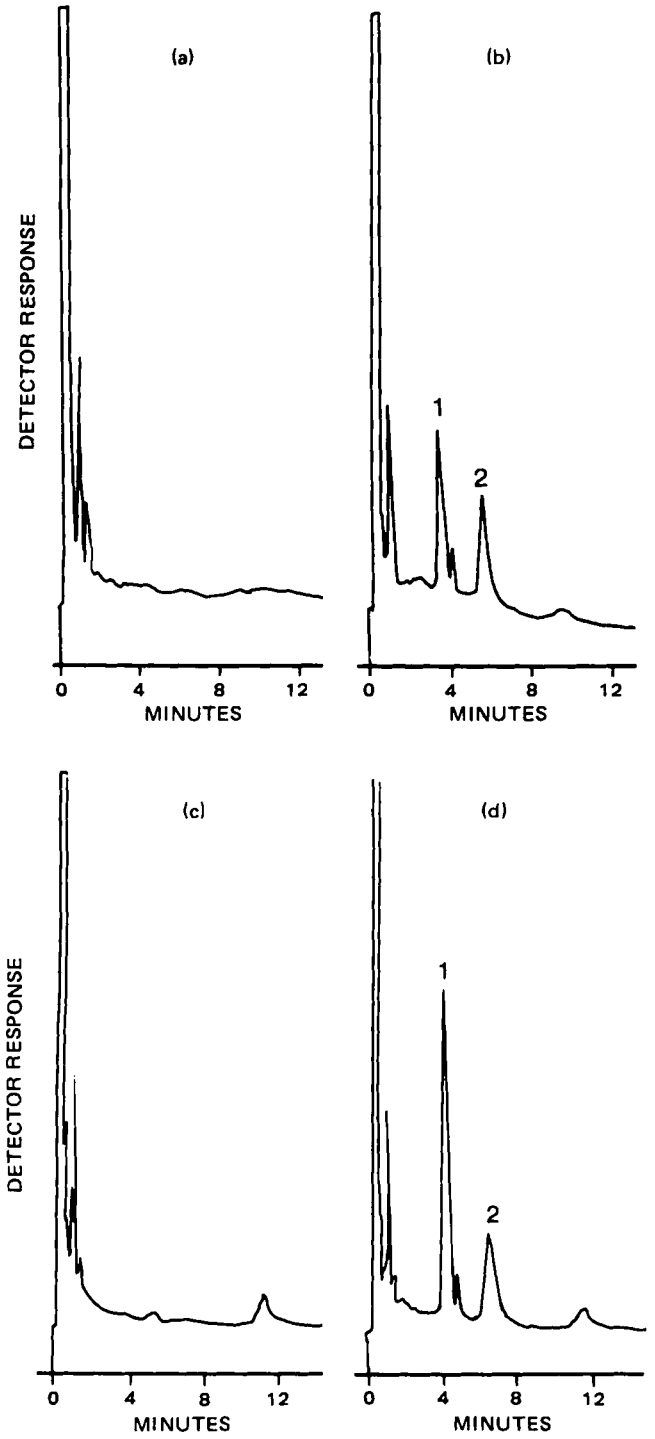

Figure 1—*Typical chromatograms of control human blood (a), control human blood containing derivatized captopril and internal standard (b), control dog plasma (c), and control dog plasma containing derivatized captopril and internal standard (d). Key: (1) captopril; (2) internal standard.*

an aliquot (≤5 μL) of each benzene solution was injected into the GC column. The column had been previously conditioned for 24 h at 250°C with the carrier gas (argon–methane, 95:5) at a flow rate of 10 mL/min. The detector and injector temperatures were 250°C and 225°C, respectively. The column operating temperature was 220°C, and the carrier gas flow rate was 40 mL/min.

Standard curves were constructed from spiked blood samples containing 0–200 ng/mL of captopril and a constant amount (400 ng/mL) of the internal standard. The peak height ratios of the unknown to the internal standard were plotted against concentrations. A new calibration curve was constructed daily. Comparison of peak height ratios from the unknown samples to those from the calibration curve permitted quantitation of the assayed samples.

Extraction, Derivatization, and Chromatography for Quantitation of Captopril and its Disulfide Metabolites in Plasma—One-milliliter samples of plasma containing 800 ng of the internal standard (III) were transferred to acid-washed glass culture tubes (16 × 125 mm); 0.1 mL of a 2% solution of tributylphosphine in methanol was added to each sample. All tubes were mixed on a vortex mixer for ~30 s and then were heated for 30 min at 50°C. The samples were washed with 10 mL of hexane to remove excess tributylphosphine. The plasma layer was then mixed with 0.2 mL of a freshly prepared 2.5% aqueous solution of *N*-ethylmaleimide and allowed to stand for 15 min at room temperature. Further extraction, derivatization, and GC analyses then were performed as outlined for captopril in blood. Standard curves were constructed from spiked plasma samples containing 0–1000 ng/mL of captopril and 800 ng of the internal standard. Calibration curves, constructed on each day that analyses were performed, were used to quantitate the unknown samples.

Gas Chromatography–Mass Spectrometry—The derivatives of captopril and the internal standard were subjected to GC–MS analyses to confirm their structures. Mass spectra were obtained on a hyperbolic quadrupole mass spectrometer[13] in the electron-ionization mode.

RESULTS AND DISCUSSION

Derivatization of Captopril—Because of the reactivity of the thiol moiety of captopril, it was necessary to prevent oxidative degradation of captopril by adding *N*-ethylmaleimide to the samples of blood. *N*-Ethylmaleimide immediately reacts with captopril to form a stable thioalkyl derivative (IA) and prevents formation of the symmetrical (IIA) or mixed disulfides (IIB). The assay procedure for captopril and its disulfide metabolites is based on the quantitative reduction of its disulfide metabolites with tributylphosphine, as reported by Kawahara *et al.* (13).

[13] Hewlett-Packard, Palo Alto, Calif.

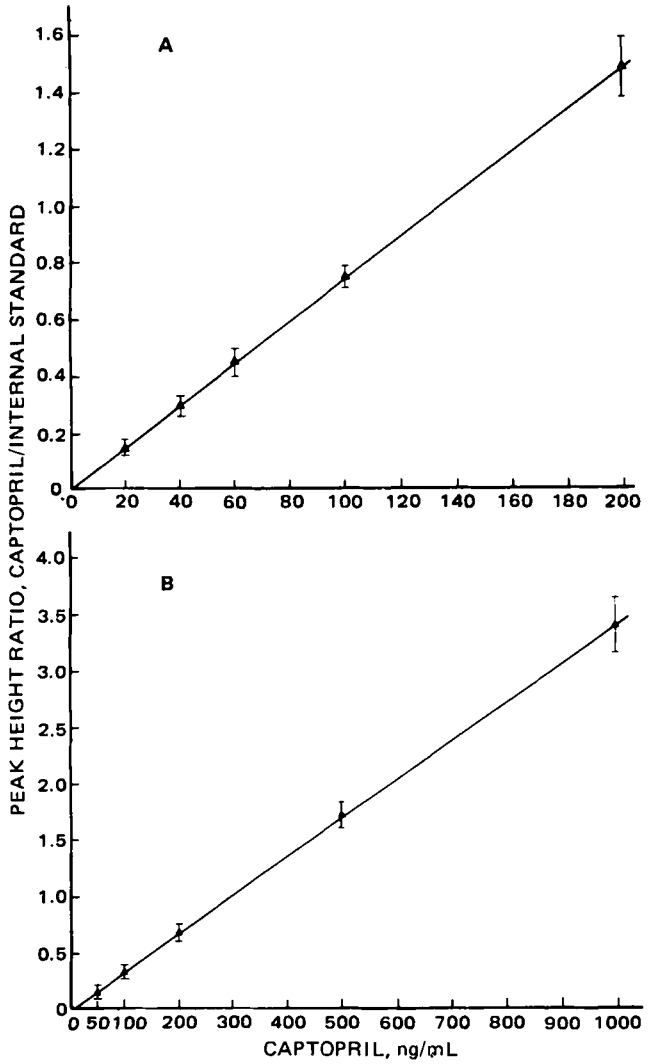

Figure 2—*Calibration curves for unchanged captopril in spiked human blood (A) and captopril and its disulfide metabolites measured as derivatized captopril in spiked dog plasma (B). Each point is the mean of six (A) or five (B) sets; the bars represent the ranges for each mean.*

The liberated captopril was treated with *N*-ethylmaleimide to form the stable derivative (IA). Compound IA formed from either unchanged captopril or captopril arising from reduced disulfides was further derivatized to give the hexafluoroisopropyl ester. The structures of the esters of the thioalkyl derivatives of both captopril (IB) and the internal standard (IIIA) were confirmed by GC–MS. The molecular ion peak (*m/z* 492), base peak (*m/z* 264), and other fragment ion peaks (*m/z* 366 and 228) obtained in the spectrum of derivatized captopril were in good agreement with those reported by Matsuke *et al.* (12). The characteristic fragmentation pattern of the derivatized internal standard (IIIA) agreed well with the known structure (*m/z* M^+ 536, 410, and 264).

The retention times of the derivatized captopril and internal standard were 3.4 and 5.8 min, respectively. No interfering peaks were observed in the extracts of the control human or dog blood. Typical chromatograms of an extract of human blood are shown in Fig. 1a and b. After treatment of plasma samples with tributylphosphine, no interfering peaks were observed in extracts of control human or dog plasma samples. Typical chromatograms of an extract of dog plasma are shown in Fig. 1c and d.

Linearity and Reproducibility—Known amounts of captopril and the internal standard were added to control dog or human blood to give standards suitable for captopril analysis. A plot of chromatographic peak height ratios *versus* concentrations was linear for captopril from 20 to 200 ng/mL (Fig. 2A); the linearity and reproducibility of the assay for captopril by the GC–EC method in human blood was demonstrated by six consecutive calibration curves. Linearity and reproducibility of the GC–EC method for captopril and its disulfide metabolites (50–1000 ng/mL) in dog plasma was demonstrated by five consecutive calibration curves (Fig. 2B). The correlation coefficient and the *y*-intercept for the straight lines were 0.999 and 0.004, respectively, for the captopril assay, and 0.999 and −0.001, respectively, for the assay of captopril and its disulfide metabolites. The average coefficient of variation (*CV*) for all the peak height ratios for both procedures was ±8%.

Table II—Analysis for Captopril and Captopril plus its Disulfide Metabolites in Spiked Human Blood and Plasma

Actual Conc., ng/mL	Observed Conc., ng/mL	Percent Deviation[a]
	Captopril in Human Blood	
0	0	—

832	839	+0.8
878	967	+10.1

[a] Percent deviation = [(Observed Conc. − Actual Conc.)/Actual Conc.] × 100.

Precision and Accuracy—The precision of the method for captopril was determined by analysis of replicate human blood samples spiked at three concentrations (20, 100, and 200 ng/mL). Captopril and its disulfide metabolites were also assayed in replicate samples of dog plasma spiked at four concentrations (50, 100, 500, and 1000 ng/mL). For unchanged captopril assays, the *CV* was 20% at 20 ng/mL and 3% at 200 ng/mL; the *CV* for the assays of captopril and its disulfide metabolites was <10% (Table I).

To determine the relative accuracy of the methods, coded, spiked human blood and plasma samples were analyzed for captopril and captopril and its disulfide metabolites. The plasma samples spiked with various amounts of captopril (I), captopril disulfide (IIA), and captopril–L-cysteine mixed disulfide (IIB) were analyzed for captopril and its disulfide metabolites. Good agreement was observed between the actual concentrations and the experimentally determined concentrations for

both assays (Table II). The accuracy of the methods was further validated by comparing results from the assay of captopril and its disulfide metabolites by the GC–EC method with results from the GC–MS assay (15) in plasma from dogs that had been given oral doses of captopril (2.5 mg/kg). The generally excellent agreement obtained for the two methods is shown in Table III.

The GC–EC assay described appears suitable for determining blood concentrations of unchanged captopril and plasma concentrations of captopril and its disulfide metabolites in samples from dogs and humans. In the range of blood concentrations (captopril) from 20 to 200 ng/mL and plasma concentrations (captopril and its disulfide metabolites) from 50 to 1000 ng/mL, the linearity, reproducibility, precision, and accuracy of the assays were generally excellent. The lower limits for quantitation of captopril and its disulfide metabolites by the GC–EC method are comparable to the existing GC–MS (15) and liquid chromatography–electrochemical detector methods (16, 17). The thin-layer radiochromatographic method (18) is more sensitive when high specific activity [^{14}C]captopril is used. The GC–EC method is 4- to 10-fold more sensitive than the other quantitative methods (12, 14) previously reported.

Cascade Impactor Method for the Droplet Size Characterization of a Metered-Dose Nasal Spray

CHENG DER YU ˣ, RICHARD E. JONES, and MAIDA HENESIAN

Received April 30, 1982, from the *Institute of Pharmaceutical Sciences, Syntex Research, Palo Alto, CA 94304.* Accepted for publication February 2, 1983.

Abstract □ A relatively rapid and simple method was developed to characterize the droplet size of a metered-dose nasal spray. The study primarily concerned the measurement of the relative proportion of small to large droplets. A small droplet could potentially reach bronchi or alveoli, depending on its size, and was therefore undesirable for the topical corticosteroid therapy of rhinal disease. The nasal spray was a solution of flunisolide, a topically active anti-inflammatory corticosteroid, administered by a manually operated, metered-dose pump spray system. The method utilized a cascade impactor fitted with a glass chamber; the cascade impactor collected and sized droplets into six fractions 0.5–16 μm in diameter, while the glass chamber collected droplets >16 μm in diameter as another fraction. Results showed that the majority of the spray droplets deposited in the glass chamber. Less than 0.5% by weight of the spray dose was delivered in droplets <8 μm aerodynamic diameter. These results are in good agreement with the droplet size distribution obtained by laser holography. The cascade impactor method showed that the number of undesirable small droplets produced by the flunisolide nasal spray unit was negligible. The method can be used with other aerosols where there is a similar concern for the inhalation of small particles.

Keyphrases □ Cascade impactor method—droplet-size characterization, metered-dose nasal spray □ Nasal spray—metered-dose, cascade impactor method for the droplet-size characterization □ Droplet-size characterization—cascade impactor method, metered-dose nasal spray

The particle or droplet size of an aerosol spray dosage form is important for both efficacy and toxicity. Inhalation aerosols intended for local activity in the lung must have the majority (by weight) of the particles in the size range of 2–6 μm in diameter to reach the terminal bronchi and alveoli (1). Particles <0.5 μm may fail to remain in this area (2), while particles >10 μm in diameter are mostly deposited in the upper respiratory tract (3).

In contrast, a nasal spray such as the metered-dose flunisolide nasal solution requires a majority of droplets having diameters >10 μm to localize delivery in the nose and to avoid possible undesired effects resulting from the material reaching the lung. It is therefore important, from an efficacy standpoint, to ensure that the nasal spray unit primarily produces droplets >10 μm in diameter. However, droplets <10 μm in diameter inevitably exist in small quantity in a spray. The ability of these small droplets to advance in the trachea–bronchi system depends on their

sizes. Therefore, it is equally important, from a safety standpoint, to determine the amount and the size distribution of droplets <10 μm in diameter.

BACKGROUND

Numerous methods for sizing aerosol particles have been developed in the past (4–6), the most common of which are direct microscopy (7), light scattering (8), laser holography (9), and the impaction method (10–12). In the microscopic method, particles collected on a slide are counted and sized simultaneously. The method is simple, but tedious without the aid of an automatic image analyzer. Furthermore, in the case of liquid aerosols (as opposed to solid aerosols) the observed sizes need to be corrected for the spreading of the droplets. Light-scattering methods are based on the phenomenon that particles suspended in air are capable of scattering incident light. The method determines the particle size directly in the aerosol cloud. Laser holography employs a pulsed laser of short pulse duration to illuminate moving particles and consequently obtain the stop-action image of the droplets. The image is usually video-taped and replayed in slow motion for manual or automatic sizing. This method gives relatively accurate particle sizes and distributions, since the reconstructed hologram is essentially an undistorted image of

[a] Percentage based on the weight difference of the spray unit before and after the experiment; converted to micrograms of flunisolide using density = 1.04 and concentration = 0.025% (w/v). [b] Number in parentheses is the recovery of the internal standard added into the washing solvent to quantitate the evaporation during washing.

particles in the aerosol cloud. However, the equipment is costly.

A cascade impactor, on the other hand, is relatively inexpensive. Various stages of the cascade impactor are capable of collecting and classifying particles ranging from 0.5–16 μm in diameter; a glass chamber can be employed to collect droplets >16 μm in diameter. The use of a cascade impactor fitted with a suitable glass chamber could therefore adequately provide the aforementioned critical droplet size information for the nasal spray product, namely the percentage of droplets >16 μm in diameter and the size distribution of the remaining small droplets. Although a 10-μm cutoff point is more desirable, the 16-μm cutoff point is dictated by the design of the cascade impactor. The six stages of the cascade impactor collect and size the droplets into 16-, 8-, 4-, 2-, 1-, and 0.5-μm diameter fractions. Nevertheless, since the primary concern about the particle size of a nasal spray is the relative proportion of small to large particles, the cascade impactor method is well suited for the purpose. This report describes the design of a glass chamber and its use with a cascade impactor for the droplet size characterization of a metered-dose nasal spray.

EXPERIMENTAL

Materials—The flunisolide nasal solution consisted of flunisolide[1] (0.25 mg/mL) in an aqueous vehicle containing propylene glycol, polyethylene glycol 3350, citric acid, sodium citrate, and benzalkonium chloride.

Assembly and Operation of the Nasal Spray—The nasal spray system consisted of four basic elements: a plastic bottle, a cap, a pump, and a shroud (plus its dust cap). Flunisolide nasal solution was packaged in the plastic bottle and capped, with the pump and shroud presented unassembled. Prior to the experiment, the original cap was removed from the bottle and discarded, and the pump/shroud system was assembled onto the bottle. During the experiment, the system was operated by rapid, firm finger and thumb pressure on the shroud and the base of the bottle, which forced a metered amount of drug solution up through the actuator to exit as a fine spray at the orifice. Metering was accomplished by the length of stroke of the pump piston, which forced the drug solution through the orifice. The meter chamber and the sealing action of the steel

ball on release of the actuator provided a fixed volume of drug solution for dosing. Each actuation of the pump system administered ~100 μL of the solution.

Assembly and Operation of the Cascade Impactor—The single-orifice metal cascade impactor[2] (10) was constructed of a succession of six jets, each followed by a glass impaction slide. It was based on the principle that particles in a moving air stream impacted on a slide placed in their path, if their momentum was sufficient to overcome the drag exerted by the air stream as it moved around the slide. As each jet was smaller than the preceding one, the velocity of the air stream, and therefore that of the dispersed particles, was increased as the aerosol advanced through the impactor. Consequently, small particles eventually acquired enough momentum to impact on a slide, and a complete particle sizing of the aerosol was achieved.

The air flow rate was maintained at 12.5 L/min in the system by applying a suitable vacuum at the impactor outlet and was monitored by a flow meter[3]. At this flow rate, the 50% cutoff diameters for each of the six jet stages were precalibrated[4] to be 16, 8, 4, 2, 1, and 0.5 μm. The 50% cutoff diameter is defined as the diameter of spherical particles of unit density for which 50% will impact on a given slide and 50% will pass around to a succeeding stage.

The impaction glass slide was attached to each of the six jets and the jets were assembled prior to the experiment. No entrapment was used for the impaction glass slide because flunisolide droplets remained liquid after spraying and, thereby, self-entrapping.

Glass Chamber—The design of the glass chamber for this study was similar to that of Sciarra *et al* (12). The glass chamber was made of a 5-L three-necked round-bottom flask with the bottom removed, and the remaining part of the flask joined to a 4-L beaker. The chamber was placed upside down on top of the cascade impactor with a ground glass joint and a polytetrafluoroethylene[5] adapter connecting a side-neck of the flask to the top stage of the impactor as depicted in Fig. 1. The other side-neck of the flask was left open for the air inlet, while the central neck of the flask was attached to the spray unit. Introduction of the spray mist into the chamber was accomplished by a vertical upward spraying at the central neck. A polytetrafluoroethylene[5] stopper with an opening to fit the head of the spray unit was employed to prevent the loss of the mist from the central neck.

Droplet Size Characterization Study—The glass chamber and cascade impactor were connected as shown in Fig. 1. After establishing an airflow of 12.5 L/min, the flunisolide nasal solution was sprayed into the glass chamber a total of 20 times at 10-s intervals. The glass chamber and its parts were removed and washed with the HPLC mobile phase. The impaction glass slide of stages 1–6 were detached and washed separately with the HPLC mobile phase. Washings from stages 2–6 were combined in certain experimental runs as indicated in the tabulated results. The amounts of flunisolide in the washings were then determined by HPLC.

Liquid Chromatographic Assay for Flunisolide—A high-performance liquid chromatograph[6] equipped with a variable-wavelength UV detector[7] and a 100-μL fixed-loop injector[8] was used for the quantitation of flunisolide. The wavelength chosen for detection was 240 nm. A commercially available microparticulate reverse-phase column[9] was operated at ambient temperature. A mixture of acetonitrile–water–acetic acid (35:64:1, v/v/v) was used as the mobile phase. Fluocinonide[10] was used as an internal standard. None of the excipients other than flunisolide and the internal standard appeared on the chromatogram.

Table III—Droplet Size Distribution of Flunisolide Nasal Spray by a Cascade Inpactor

Stage	50% Cutoff Diameter[a], μm	Flunisolide Recovered, % Exp. 1	Exp. 2[b]
1	16.0	1.30	1.14
2	8.0	0.38	0.20
3	4.0	0.29	0.13
4	2.0	0.12	0.04
5	1.0	0.07	0.01
6	0.5	0.00	0.00
Glass chamber	—	97.82	98.74

[a] Diameter of spherical particles of unit density for which 50% will impact on a given slide and 50% will pass around to a succeeding stage. [b] The same spray unit was used.

RESULTS AND DISCUSSION

Design of the Glass Chamber—The design of the glass chamber is critical for sizing aerosol sprays. Care must be taken to ensure that: (*a*) the aerosol cloud is carried through the cascade impactor by the imposed air flow and not by the imparted pumping force, in the case of a manually operated spray unit, or by the force of the propellant, in the case of a propellant-driven spray unit; (*b*) there is no dripping of the condensed liquid from the chamber wall into the cascade impactor and onto the first slide; (*c*) there is no retention of the small droplets, which are to be sized by the cascade impactor, by the glass chamber.

Sciarra *et al.* (12) studied several designs of glass chambers for sizing an aerosol hair spray. They claimed that a 1- or 2-L round-bottom flask with the bottom removed to fit the top stage of a cascade impactor, and the neck enlarged and extended at an angle 105° to the body was most suitable. However, in their design, the aerosol was sprayed into the chamber along with the imposed air flow at the neck which extended at an angle of 105° to the body of the cascade impactor. It is questionable that their design best fulfilled the aforementioned caution *a*. Furthermore, their design was not tested for fulfillment of caution *c*. Violation of caution *c* would result in a lower weight percentage of the impactor-detectable small droplets, which might lead to a misconception of product safety.

The glass chamber for the present study, to overcome the aforementioned shortcomings, was designed in such a manner that the mist produced by the spray unit would lose the momentum imparted by the pump operation and be carried into the cascade impactor by the imposed airflow. The large volume (9 L) of the chamber and the long distance (45 cm) between the tip of the spray unit and the top of the chamber helped to reduce the probability of droplets hitting the glass wall. The glass joint connecting the chamber and the cascade impactor aided in preventing the condensed liquid from dripping into the cascade impactor.

Total Recovery—The total recovery of the flunisolide sprayed into the system was checked by comparing the weights of the materials recovered from the various components of the system and the weight differences of the spray unit before and after the experiment, as shown in Table I. Of the six trials conducted, the total recoveries ranged from 99.50 to 102.10% with a mean value of 100.78%. The satisfactory total recovery indicated that there was no loss of the droplets through the open air inlet. Also listed in Table I are the recoveries (the numbers in parentheses) of the internal standard which was added to the washing solvent to determine the possible evaporation during washing. This procedure is necessary because only 1 mL of the HPLC mobile phase was used to wash an impaction slide plate of 3.8 cm in diameter. The increase in concentration

Total	100.0	100.0	100.0	100.0

[a] The sample was taken at either 2.54 or 7.62 cm downstream from the tip of the unit.

as a result of the evaporation was found to be only a few percent (Table I).

Condensation on the Chamber Wall—As discussed in the section on the design of the glass chamber, the condensation of droplets on the chamber wall could retain some small droplets which should have entered the cascade impactor. The relative proportion of small to large droplets determined by this device could potentially be biased if this phenomenon is not accounted for. The degree of condensation of the small droplets was therefore examined using a nebulizer[11] which generated primarily 1–2-μm size droplets[12]. The procedure was the same as that for the nasal spray. The nebulizer was equipped with a squeeze bulb. Each complete squeeze delivered approximately one one-hundredth of the amount delivered by one spray of the nasal unit. Table II lists the flunisolide recovered from various stages of the cascade impactor and the sampling chamber for three experiments with the nebulizer. The distribution patterns agreed well with one another. The majority of the droplets had diameters between 1 and 2 μm (Table II) which was consistent with the data from the manufacturer's technical report. As can be seen in Table II, the flunisolide retained by the glass chamber was essentially undetectable for a total of 20 squeezes. Evidently, the deposition of small droplets on the glass chamber is negligible.

Droplet Size Characteristics of the Nasal Spray—Results of the droplet size characterization are shown in Tables I and III. As can be seen in Table I, 98.84 ± 0.72% (mean ± *SD*) (by weight) of the spray was found in the glass chamber. The glass chamber was shown (Table II) not to retain droplets <16 μm in aerodynamic diameter, as discussed in the previous section. It is therefore believed that the nasal spray unit primarily produces droplets of >16-μm aerodynamic diameter.

The data in Table I were produced with six randomly selected spray units. The unit-to-unit variation was reasonably small, as shown by the standard deviation. The amounts of flunisolide found in stage 1 (16 μm) and in stages 2–6 combined (8–0.5 μm) were 0.83 and 0.34%, respectively (Table I). Details of the size distribution of this small droplet portion of the spray are shown in Table III. Only two experiments on one spray unit were performed because their purpose was to illustrate the size distribution obtained by the cascade impactor, not to show the within-unit variability. A clear trend can be seen, *i.e.*, the smaller the droplet size, the smaller their weight percentage.

Table IV shows the reproducibility among operators and the effect of emptying of the spray unit on the droplet size. The study was a part of a use test (13) in which 17 units were sprayed by 17 operators according to label instructions until the units ceased to deliver. Only three units were analyzed for the droplet size, among other parameters studied (13), because the assay reduced the availability of the nasal solution for other testings. It can be seen that the relative proportion of small to large droplets is reasonably consistent among the operators and between a full unit and an almost empty unit for each operator.

Table V lists results of the droplet size distribution[13] obtained independently by laser holography[14]. Examining Tables I, III, IV, and V, one can see that the relative proportion of small to large droplets obtained by the cascade impactor agrees well with that obtained by laser holography. The laser holographic results (Table V) reveal that the weight percentage of the small droplets between 0.5 and 10.0 μm in diameter is 0.13 ± 0.24% (mean ± *SD*). The weight percentage of the small droplets collected on stages 2–6 of the cascade impactor (i.e., droplets 0.5–8.0 μm in diameter) is 0.34 ± 0.15% (Table I). Evidently, there is no statistical difference between the two results.

CONCLUSION

Since concern for the droplet size of a nasal spray is primarily to ensure that the weight percentage of droplets <10 μm in diameter (and thereby potentially deliverable to the lower respiratory tract) produced by the spray unit is negligble, the cascade impactor method was demonstrated to be quite satisfactory for this purpose. The cascade impactor method developed here is a simple, economical, and reliable method for the droplet size characterization of a metered-dose flunisolide nasal spray. The method can be used for other aerosol products where there is a similar concern for the inhalation of small particles.

Pharmacokinetics of Diazepam and Nordiazepam in the Cat

S. COTLER ˣ, J. H. GUSTAFSON, and W. A. COLBURN

Received May 11,1982, from the *Department of Pharmacokinetics and Biopharmaceutics, Hoffmann-La Roche Inc., Nutley, NJ 07110.* Accepted for publication February 1, 1983.

Abstract □ The cat has been used extensively as an experimental model for studying the pharmacology of compounds that exhibit CNS activity including diazepam and nordiazepam. However, since little is known about the distribution and elimination of diazepam in this species, the pharmacokinetics of diazepam and nordiazepam were studied in the cat following intravenous doses of 5, 10, and 20 mg/kg of diazepam and 5 and 10 mg/kg of nordiazepam. The disappearance of diazepam and nordiazepam from blood was fitted with classical equations. Theoretical and trapezoidal areas under the curve (AUC_{th} and AUC_{tr}) were calculated. The volumes of distribution (Vd_{β}) were calculated as model-independent parameters for diazepam and nordiazepam. Intrinsic hepatic clearance, extraction ratio, and tissue binding parameters were also calculated for diazepam. From the observed data, it is apparent that the blood concentrations and the resulting areas under the curves are proportional to the dose of diazepam administered and that the pharmacokinetics of diazepam were linear over the dose range studied. In addition, nordiazepam formed after diazepam administration appeared to be proportional to the dose of diazepam administered. The terminal elimination rate constant of nordiazepam remained constant over the dose range studied. It appears that both diazepam and nordiazepam are highly bound to tissue. The total body clearance of diazepam (4.72 ± 2.45 mL/min/kg) is approximately six times that of nordiazepam (0.85 ± 0.25 mL/min/kg). Approximately 50% of an administered dose of diazepam was biotransformed to nordiazepam in the cat.

Keyphrases □ Diazepam—pharmacokinetics in the cat, nordiazepam □ Nordiazepam—pharmacokinetics in the cat, diazepam □ Pharmacokinetics—diazepam and nordiazepam in the cat after intravenous doses

The benzodiazepines are centrally active compounds that reduce anxiety, produce sedation and sleep, have anticonvulsant effects, and may cause muscle relaxation. In addition, the benzodiazepine diazepam is also used in the treatment of alcohol abusers during potentially life-threatening withdrawal episodes (1). Diazepam has a long effective duration of action, probably due to slow elimination of parent compound and biotransformation to active metabolic products including nordiazepam (2). Many of the pharmacological properties of the benzodiazepines seen in humans are present in the cat (3–5). Diazepam has been shown to be effective in the cat in the control of seizures in experimental epilepsy (6) and with the sudden abstinence of alcohol after chronic use (5). Although the cat has been used extensively to study the effects of diazepam, little is known about the pharmacokinetics of diazepam and nordiazepam in this species. Morselli *et al.* (7) described the distribution of diazepam and its major metabolites in plasma and in several areas of the brain of the cat. A direct correlation was established between blood flow to various tissues of the brain and the diazepam found in these tissues. However, the accumulation of nordiazepam, the major blood metabolite, in the brain appeared to be inversely related to blood flow. Unfortunately, this data did not lend itself to an overall pharmacokinetic profile of diazepam or nordiazepam in this species.

The present study in the domestic short-hair cat was performed to (*a*) establish the pharmacokinetics of diazepam and nordiazepam following 5-, 10-, and 20-mg/kg iv doses of diazepam and (*b*) to compare the pharmacokinetic profile of nordiazepam after nordiazepam administration to its profile observed after the administration of diazepam in this species. These data will establish the fundamental pharmacokinetic profile of diazepam and nordiazepam in the cat.

EXPERIMENTAL

Animal Model—Domestic short-haired female cats (2.5–3.0 kg) were used for all experiments. Hematocrit values were determined before surgery and drug administration and were found to be within the normal range (8). Cats were anesthetized with 0.33–0.44 mL of a solution containing 100 mg/mL of ketamine and 7.5 mg/mL of promazine[1]. An incision was made in either the right or left leg exposing a branch of the femoral vein. A butterfly infusion set[2] with the needle removed, leaving the tubing and Luer fitting intact, was used as a cannula. The catheter was inserted into the vein, exteriorized, and the incision was closed with 000 surgical silk[3]. The catheter was cleared daily and kept patent with a sodium heparin flush. Diazepam or nordiazepam (10 mg/mL) was dissolved in dimethylacetamide[4] immediately prior to administration.

Study Design—Unanesthetized fasted cats, with a femoral vein catheter previously implanted to facilitate blood sampling, were administered 5-, 10-, and 20-mg/kg doses of diazepam or 10 mg/kg of nordiazepam intravenously as a short infusion (20 s) *via* a peripheral vein. Two weeks were allowed for recuperation between doses.

Sampling and Analysis—Blood specimens (0.5 mL) were obtained from the femoral vein catheter. The first specimen was obtained 2.5 min following intravenous administration and subsequent specimens were obtained for as long as 96 h. The blood specimens were collected in tubes containing dried heparin[5] and kept at −20°C until analyzed. The samples were analyzed simultaneously for diazepam and nordiazepam using the electron capture GC method of Weinfeld *et al.* (9) with the following modifications. Whole blood (0.1 mL) was extracted into 1 mL of benzene after adjusting the pH to 9.0 with a 1 M H_3BO_3–KCl–Na_2CO_3 buffer. The percent standard deviation for the intraassay variability averaged 3.6% for diazepam and 3.4% for nordiazepam over the range of 50–2000 ng/mL

of blood for diazepam and 100–4000 ng/mL of blood for nordiazepam. The interassay variability for the same range was 6.0 and 8.9% for diazepam and nordiazepam, respectively.

Blood-to-plasma ratios were determined for diazepam and nordiazepam. Diazepam and nordiazepam (1500 ng) were added to 3-mL aliquots of blood, previously collected in a tube[5] containing dried heparin. The blood and the two components were gently shaken in a reciprocal shaker[6] at ~60 excursions per minute for 1.5 h. A 0.5-mL aliquot of whole blood was removed and the remainder was centrifuged for 30 min at 2500 rpm to separate the plasma from the red blood cells. A 0.5-mL volume of plasma was taken for each analysis. Both whole blood and plasma were analyzed for diazepam and nordiazepam by a specific and sensitive HPLC method (10).

Pharmacokinetic Analysis—Following rapid intravenous infusion of diazepam and nordiazepam, blood concentration–time curves were analyzed by a weighted iterative nonlinear least-squares regression technique (11). Data points were fitted with one of the following equations:

$$C_b = Be^{-\beta t} \quad \text{(Eq. 1)}$$

$$C_b = Ae^{-\alpha t} + Be^{-\beta t} \quad \text{(Eq. 2)}$$

$$C_b = Pe^{-\pi t} + Ae^{-\alpha t} + Be^{-\beta t} \quad \text{(Eq. 3)}$$

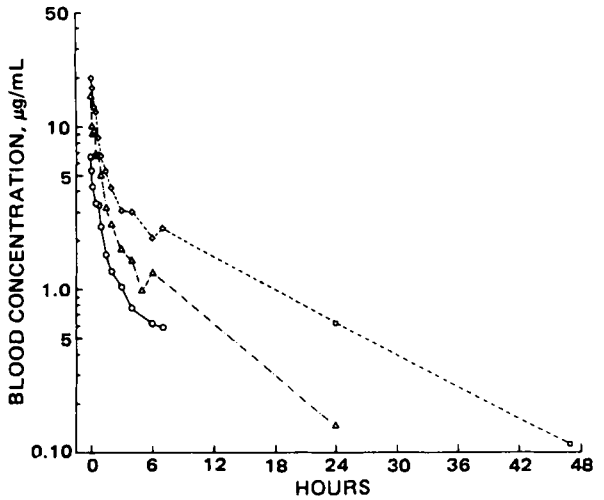

Figure 1—*Diazepam blood concentrations for Cat 3 after intravenous administration of 5- (○), 10- (△), and 20- (□) mg/kg doses of diazepam.*

[6] Eberbach Corp., Ann Arbor, Mich.

In all equations, C_b is the blood diazepam or nordiazepam concentration at time t after the dose. P, A, and B are coefficients and π, α, and β are hybrid rate constants that describe the disposition and elimination phases, respectively.

The equation selected for fitting the data was determined by comparing the sum of the squared deviations using the F-ratio test (12) and by scatter of the actual data points around the fitted function. Model-dependent pharmacokinetic parameters such as the theoretical areas under the blood concentration–time curves (AUC_{th}) were calculated from the following equations:

$$AUC_{th} = \frac{B}{\beta} \quad \text{(Eq. 4)}$$

$$AUC_{th} = \frac{A}{\alpha} + \frac{B}{\beta} \quad \text{(Eq. 5)}$$

$$AUC_{th} = \frac{P}{\pi} + \frac{A}{\alpha} + \frac{B}{\beta} \quad \text{(Eq. 6)}$$

The volume of the central compartment (V_c) was calculated by dividing the dose (mg/kg) by the sum of the coefficients, and the volume of distribution (Vd_β) was determined with the following:

$$Vd_\beta = \frac{\text{Dose}}{(AUC_{th}) \cdot \beta} \quad \text{(Eq. 7)}$$

where β is the terminal elimination rate constant. The theoretical total body clearance (TBC_{th}) was determined from the relationship of dose to the theoretical area under the curve:

$$TBC_{th} = \frac{\text{Dose}}{AUC_{th}} \quad \text{(Eq. 8)}$$

[a] % *CV* in parentheses.

The model-independent areas under the blood concentration time curves were also calculated from time zero to infinity (AUC_{tr}) by adding the area from time t, of the final measurable concentration estimated by trapezoidal summation (AUC_{0-t}), to the area from time t to infinity ($AUC_{t-\infty}$) calculated with the following (13):

$$AUC_{t-\infty} = C_b{}^t/\beta \qquad \text{(Eq. 9)}$$

where $C_b{}^t$ is the observed blood concentration at time t and β is the terminal elimination rate constant estimated by nonlinear regression. The calculated total clearance (TBC_{tr}) was calculated as the dose divided by AUC_{tr}. In addition, the intrinsic clearance CL_I was calculated as:

$$CL_I = \frac{HBF \cdot CL_{tr}}{HBF - CL_{tr}} \qquad \text{(Eq. 10)}$$

where HBF is the hepatic blood flow. The extraction ratio (ER) was calculated as:

$$ER = \frac{CL_I}{HBF + CL_I} \qquad \text{(Eq. 11)}$$

as described by Wilkinson and Shand (14). The blood-to-plasma distribution ratio was calculated from the concentration of drug in whole blood divided by the concentration of drug in plasma.

RESULTS AND DISCUSSION

The mean ±*SD* blood-to-plasma distribution ratios for diazepam and nordiazepam in the cat were 0.56 ± 0.13 and 0.65 ± 0.19, respectively, which are similar to the 0.64 and 0.60 values observed for diazepam and nordiazepam in humans (15). From the blood-to-plasma distribution ratios, it is possible to estimate from blood concentration data the amount that would be in a corresponding plasma sample by simply dividing the blood concentration by the distribution ratio (16). In addition, it is possible to correct the pharmacokinetic parameters V and CL calculated from the blood concentration data for comparison with similar parameters calculated from plasma concentration data in other studies (16). Similarly, it was possible to calculate blood free fraction from known plasma free fraction values.

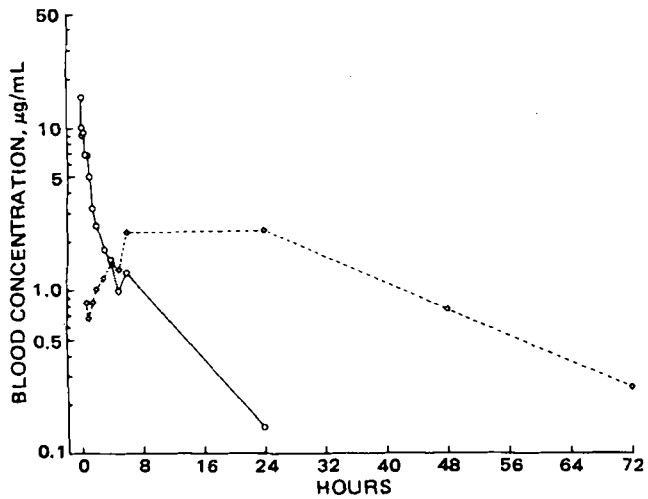

Figure 2—*Diazepam and nordiazepam blood concentrations after 10-mg/kg diazepam intravenous administration to Cat 5. Key: (○) diazepam; (◇) nordiazepam.*

Typical diazepam blood concentration–time curves following the administration of 5, 10, and 20 mg/kg of diazepam to a representative cat are presented in Fig. 1. The decline of diazepam blood concentrations were described by exponential functions. Visual inspection of the observed points about the fitted curve indicated a satisfactory randomness of scatter. Percent coefficients of variation of the parameters, P, π, A, α, B, and β were <50% (Table I), indicating that the good fit was dependent on each of these parameters. The disposition (α) phase was rapid with a harmonic mean half-life[7] of 0.35 h, and the harmonic mean terminal elimination half-life was 5.46 h.

The theoretical areas are virtually identical with the areas calculated from the trapezoidal rule. There is a proportional increase in diazepam blood concentrations between the 5-, 10-, and 20-mg/kg dose (Fig. 1). This relationship was supported by a doubling of the AUC_{tr} of diazepam with a doubling of the administered dose of diazepam (Table I). The mean ±*SD* total body clearance of diazepam is 4.72 ± 2.45 mL/min/kg, which represents an extraction ratio of 0.12 based on a total hepatic blood flow of 40 mL/min/kg (17) and assuming that diazepam is eliminated totally by hepatic clearance. The average intrinsic clearance (CL_I) is 5.35 mL/min/kg, which indicates that total body clearance is only slightly dependent on the hepatic blood flow. The total body clearance varied among cats, but for a single cat the clearance was constant over the dose range studied. It was concluded from the linear relationship of the blood concentrations and the areas under the blood concentration–time curves to the dose of diazepam administered, and the constant clearance within animals, that the pharmacokinetics of diazepam in the cat are linear over the dose range studied.

The mean ±*SD* of V_c and Vd_β were 651 ± 235 and 3075 ± 1603 mL/kg, respectively. The ratio of V_c/Vd_β (0.23 ± 0.094) suggests that ~23% of the dose of diazepam in the animal is in the central compartment available for elimination at any time, whereas ~77% of the dose is in a peripheral compartment unavailable for elimination. Distribution to a peripheral compartment tends to reduce the overall elimination of diazepam in humans, as previously observed by Kaplan *et al.* (18). The value for Vd_β was greater than total body water, which is generally indicative of extensive binding and/or localization in the tissue space. Previous studies with the cat also indicated that diazepam is highly bound to plasma protein (94%)[8].

From the following equation (19), one can estimate the average fraction (F_T) of diazepam in tissue space that is not bound to tissue:

$$F_T = \frac{V_T \cdot F_B}{Vd_\beta - V_B} \qquad \text{(Eq. 12)}$$

where the volume of distribution (Vd_β) was 3075 mL/kg, the volume of the blood (V_B) was 66.7 mL/kg (20), the average volume of the tissue (V_T) (21, 22) was 563 mL/kg, and the calculated fraction of the drug that is free in blood (F_B) was 0.11. Solving Eq. 12 for F_T yields a value of 0.019. Therefore, an estimate of the fraction of diazepam in the tissue that is bound to tissue protein is 0.981.

Figure 2 shows typical blood concentration–time curves for diazepam and its major blood metabolite, nordiazepam, observed after a 10-mg/kg iv dose of diazepam. The concentrations and the resulting AUC values of nordiazepam, the major blood metabolite seen after diazepam administration, appeared to increase in proportion to the dose of diazepam administered (Table II). Initially, the formation rate of nordiazepam after diazepam administration appeared to be rapid for 6–8 h and slower thereafter. Similar rate phenomena were observed in humans (18). The

[7] Since β rather than half-life appears to have a normal distribution, harmonic rather than arithmatic mean half-lives are reported. (P. R. Gwilt and S. P. Sytsma. Paper presented at 29th national meeting of the American Pharmaceutical Association, San Antonio, Texas, Nov. 1980.)

[8] Data on file, Hoffmann-La Roche, Nutley, NJ 07110.

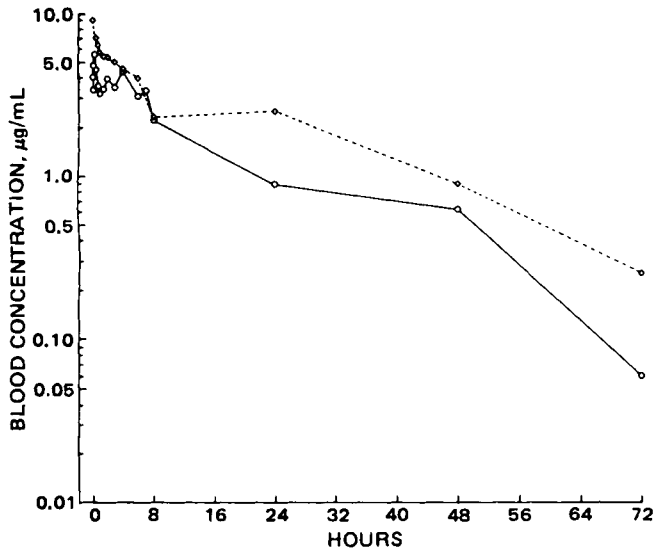

Figure 3—*Nordiazepam blood concentrations for Cat 1 after intravenous administration of 5- (○) and 10- (◇) mg/kg doses of nordiazepam.*

maximum blood concentrations of nordiazepam were generally observed at 24 h after diazepam administration. The value is only an approximation since no samples were obtained between 7 and 24 h after drug administration. The mean $\pm SD$ terminal elimination rate constant for nordiazepam was $0.032 \pm 0.012\ h^{-1}$, with a harmonic mean half-life of 21.3 h, which is 4.3 times slower than diazepam. From this data for nordiazepam after diazepam administration, it can be inferred that the amount of nordiazepam present is also directly proportional to the dose of diazepam administered and that the elimination of nordiazepam is not affected by the presence of diazepam over the dose range studied.

Corresponding nordiazepam data (Table III) were obtained following 10-mg/kg nordiazepam administration as a short (20-s) infusion to the same cats that received diazepam. In addition, one cat received 5 mg/kg of nordiazepam. Figure 3 is a typical nordiazepam blood concentration–time curve; the observed nordiazepam data could be satisfactorily described by a biexponential equation except for the cat that received 5 mg/kg, whose data appeared to be monoexponential. The disposition phase (α) for nordiazepam was rapid and variable (Table III). The terminal elimination phase (β) was much slower and less variable, with a harmonic mean elimination half-life of 21 h. The t test ($p < 0.05$) showed no significant difference between the terminal elimination half-lives of nordiazepam formed from diazepam and those for nordiazepam itself. This substantiates the earlier observation that the terminal elimination of nordiazepam after diazepam administration is not affected by the presence of diazepam nor by the rate of nordiazepam formation following diazepam administration.

The clearance of nordiazepam (mean $\pm SD = 0.85 \pm 0.24$ mL/min/kg) was approximately one-sixth the clearance of diazepam. This clearance value suggests a negligible potential for first-pass metabolism for nordiazepam. The model-independent value for the volume of distribution (Vd_β) for nordiazepam is also greater than total body water, which is generally indicative of extensive binding and/or localization in the tissue space as previously indicated for diazepam. As seen with diazepam (18), the distribution of nordiazepam into peripheral compartments reduces the overall elimination of nordiazepam from the cat.

Comparing the area of nordiazepam after nordiazepam administration to area of nordiazepam after the administration of an equivalent dose of diazepam (Table II), it was estimated that an average of 54% of the diazepam dose was biotransformed to nordiazepam in the cat. This observation of 54% conversion of diazepam to nordiazepam in the cat is in good agreement with the 50% fractional conversion of diazepam to nordiazepam observed in humans (23).

The observation that the pharmacokinetics in the cat were linear with respect to dose has been observed in humans. Greenblatt *et al.* (24) observed that in cases of diazepam overdose in humans, the terminal elimination half-lives for diazepam fell within the range observed in individuals after a therapeutic dose of diazepam. When the pharmacokinetic data in the cat are compared with those known for humans, a much more rapid elimination for diazepam and nordiazepam is apparent in the cat. The elimination half-lives of diazepam in humans are reported to be in the range of 24–48 h for adults (23) and 18 h for children, and the terminal elimination half-lives for nordiazepam are reported to be in the range of 51–120 h (25). It is apparent that nordiazepam has a longer elimination half-life than diazepam in humans; this relationship in the half-lives was also observed for the cats during this study. The first-pass effect of diazepam and nordiazepam in the cat and human is negligible compared with other animal species.

In conclusion, the cat has been previously used as an experimental model for studying the CNS pharmacology of diazepam and nordiazepam. The similarities between cat and human with respect to the pharmacokinetics of these compounds suggest that the cat may not only be a good model species for pharmacological studies but for pharmacokinetic studies as well.

Structure–Activity Relationships of Sulfonamide Drugs and Human Carbonic Anhydrase C: Modeling of Inhibitor Molecules into the Receptor Site of the Enzyme with an Interactive Computer Graphics Display[1]

ANGELO VEDANI and EDGAR F. MEYER, JR. ˣ

Received October 15, 1982, from the *Biographics Laboratory, Department of Biochemistry and Biophysics, Texas A&M University, College Station, TX 77843.* Accepted for publication January 5, 1983.

Abstract □ We have analyzed the molecular interaction of 28 sulfonamide inhibitors with human carbonic anhydrase C (HCAC) using an interactive computer graphic display. Small aromatic sulfonamides gain most of their inhibitory power towards HCAC from the interaction of hydrogen bond acceptors at the *para* or *meta* positions with hydrophilic residues of the enzyme. Additional coordinated water molecules stabilize the complexes of heterocyclic sulfonamides (*i.e.*, thiophenes, 1,3-thiazoles, and 1,3,4-thiadiazoles) with HCAC. We propose two different modes of binding of the heterocyclic ring with respect to the active site cleft: the heterocyclic sulfur atom of a 3,4-unsubstituted thiophene approaches the oxygen atom of a coordinated water molecule (sulfur "out"), whereas in 3,4-unsubstituted 1,3,4-thiadiazoles, the sulfur is in contact with a hydrophobic part of the receptor site (sulfur "in"). This proposal is consistent with crystallographic evidence. Sulfonamides with two aromatic or heterocyclic rings also interact with a hydrophobic pocket of the enzyme located >10 Å away from the active site metal Zn^{2+}. We also discuss the possibility that the relative inactivity of thiazide diuretics is due to the steric interaction of the *ortho* chlorine atom with the enzyme receptor cavity.

Keyphrases □ Sulfonamides—structure–activity relationships with human carbonic anhydrase C, interactive computer graphic display □ Human carbonic anhydrase C—structure–activity relationships with sulfonamides, interactive computer graphic display □ Structure–activity relationships—enzyme–inhibitor complexes, modeling by interactive computer graphic display, sulfonamides with human carbonic anhydrase C

The isoenzymes of human carbonic anhydrase (HCAB, HCAC) reversibly catalyze the decomposition of carbonic acid into carbon dioxide and water at a remarkably fast rate (up to 1×10^6 s^{-1}). These zinc-containing enzymes consist of 260 amino acids with a molecular mass of ~30 kDa. The active site of human carbonic anhydrase contains a four-coordinated zinc ion: three nitrogen atoms (N—ϵ_2 of His 94, N—ϵ_2 of His 96, and N—δ of His 119) and one oxygen atom (coordinated water molecule, at higher pH values a hydroxide anion) leading to distorted tetrahedral metal coordination (1).

Aromatic and heterocyclic sulfonamides are very specific inhibitors of carbonic anhydrase when the sulfonamido group is unsubstituted. The inhibition of carbonic anhydrase was first reported by Keilin and Mann (2). Kinetic studies have shown sulfonamides to be competitive to the dehydration of carbonic acid as well as the hydration of carbon dioxide (3).

The detailed interaction of sulfanilamide, acetazolamide, and acetoxymercury sulfanilamide with HCAB and HCAC has been reported by Kannan *et al.* (4, 5). The sulfonamido group binds the metal ion at the fourth coordination site (replacing the water molecule from the native enzyme) through the nitrogen or oxygen atom of the sulfonamido moiety, probably through the amide nitrogen atom. This atom is also hydrogen-bonded to the hydroxyl group of Thr 199 in the same way as the fourth coordinated water molecule in the native enzyme. One of the two oxygen atoms is liganded to a fifth coordination site of the zinc. The sulfur atom (or carbon atoms) from the heterocyclic (or aromatic) ring interact with Ala 121 in HCAB and with Val 121 in HCAC, respectively.

Little attention has been paid thus far to enzyme–inhibitor interactions removed from the active site. Nevertheless, these interactions with protein side chains may contribute significantly to the stability of the enzyme–sulfonamide complex. While 4-methylbenzenesulfonamide forms an enzyme–inhibitor complex with a K value of 1.95×10^6 mol^{-1}, the complex formation constant of *p*-(salicyl-5-azo)-benzenesulfonamide is 2.38×10^8 mol^{-1}, two orders of magnitude greater. This is only explainable by the interaction of the salicyl group with side chains of the enzyme located >10 Å from the active site metal (*i.e.*, Ile 91, Trp 123, and Phe 131 in HCAC). We have, therefore, investigated sulfonamide–carbonic anhydrase (HCAC) interactions in an extended environment of the active site using original crystallographic coordinates and an interactive computer graphic display.

THEORETICAL

Several experimental and computational methods are now sufficiently developed to provide insight to the interaction of a small molecule with a macromolecule. Interactive computer graphic techniques are very useful for the study of molecular interactions characterized as recognition, binding, enzyme catalysis, and inhibition.

Basic adjustments of the model (*i.e.*, inhibitor molecule) to the receptor structure (*i.e.*, enzyme) on a 3-dimensional display are possible in real time (no intermediate keyboard commands) by means of the program FIT (6):

1. Model: (*a*) complete or subunit model translations relative to the receptor; (*b*) individual atom translation; (*c*) complete or subunit model rotation; (*d*) complete subunit rotation about a given bond; and (*e*) dihedral rotation before or after any selected bond.
2. Receptor: in principle the same as for the model, but due to the complexity of the protein only reorientations of amino acid side chains have been performed so far by dihedral rotation about single bonds.

In addition to the above functions, which are basic to any model-fitting method, several utility functions are furnished including (*a*) picture scale; (*b*) stereo image separation (right–left or top–bottom); (*c*) global picture translation and rotation; (*d*) receptor–model relative intensities; and (*e*) I/O functions to exchange or modify the receptor structure, exchange models, print any geometric information about the model (*i.e.*, atom identification, bond length, bond angles, dihedral angles), save the current picture and output the current model coordinates, calculate distances of enzyme–inhibitor interactions, and facilitate still or motion-picture photography.

Thus, a flexible substrate may be fit into a relatively rigid receptor site. While potentially limiting, this assumption is reasonably valid for "lock and key"-type enzymes. These methods are entirely general in terms of the size and functionality of the receptor site and ligand. A number of advantages of graphically generated models (reproducibility, instant quantification of geometric parameters, and accessibility to refinement procedures) make this approach superior to desk-top modelling approaches.

EXPERIMENTAL[2]

Except for modified enzyme side-chain positions, the crystal structure parameters of the native human isoenzyme C were used [HCAC; Protein Data Bank 1976, 2.0-Å resolution (7)]. Individual side chains in the active site were repositioned, if necessary, by appropriate torsional rotations. The molecular coordinates (sulfonamides) were taken from crystal structure determinations or generated by the program PAD (8). To obtain a more realistic fitting, the side chains of the enzyme were not restricted to their native conformation. These dihedral rotations were also performed with the program FIT.

The starting coordinates for the sulfonamido group in the fitting routine were taken from the crystal structure determination of the HCAC–acetazolamide enzyme–inhibitor complex (5). The potency of some inhibitors can only be explained if one takes into account their interaction with additional coordinated water molecules; these were generated by PAD and inserted with FIT.

[2] The following standard designations for amino acids are used throughout this paper: (Ala) alanine; (Asn) asparagine; (Gln) glutamine; (Gly) glycine; (His) histidine; (Ile) isoleucine; (Leu) leucine; (Phe) phenylalanine; (Pro) proline; (Ser) serine; (Thr) threonine; (Trp) tryptophan; (Val) valine.

RESULTS AND DISCUSSION

A large number of sulfonamides have been examined by kinetic and thermoanalytical methods by Taylor *et al.* (9), Kakeya *et al.* (10), and Sprague (11); an abstract of these data is given in Table I. The general features of sulfonamide interactions with HCAC are presented in Table II.

Aromatic Sulfonamides—In addition to the interaction of the sulfonamido group with the enzyme, two additional types of interactions are observed for aromatic sulfonamides:

1. Hydrophobic interactions of the benzene ring and aliphatic substituents with nonpolar residues of the enzyme.
2. Hydrogen bonding involving hydrophilic substituents and polar residues of the enzyme.

The orientation of the benzene ring is very sensitive to the number and type of hydrogen bond interactions of its substituents and may be constrained in a less favorable position with respect to its hydrophobic contacts and *vice versa*. For example, 4-aminobenzenesulfonamide shows a threefold smaller inhibition constant than the unsubstituted 4-*H*-benzenesulfonamide (*cf.* Table I or Ref. 10). The crystal structure determination of the 4-aminobenzenesulfonamide–HCAC complex (5) shows that the interaction of the benzene ring with the hydrophobic part of the enzyme forces the amino group in the *para* position to a repulsive

Table II—General Features of Sulfonamide Interaction with HCAC

Functional Group of Inhibitor	Interaction with HCAC Residue	Type of Interaction

interaction with the amido group of Gln 92. (A reorientation of the amido moiety is not very probable, since its carbonyl oxygen atom is also hydrogen-bonded to the N—H of His 94).

Hydrogen bond acceptors are favorably oriented with respect to the *para* and *meta* positions, since more hydrophilic residues of HCAC are located in this region and the active site funnel is open to the solvent (hydrogen bonds to Asn 67 and Pro 201 through coordinated water molecules). 3-Sulfamoyl-4,5-dichlorobenzenesulfonamide is a very potent inhibitor of HCAC. The *ortho* position is not very favorable for hydrophilic or bulky hydrophobic substituents; steric hindrance with Leu 198 requires a rearrangement of the backbone of the enzyme. 4-Nitro-2-carboxybenzenesulfonamide inhibits HCAC three orders of magnitude less than 4-nitro-2*H*-benzenesulfonamide [$<10^4$ *versus* 1.60×10^7 (9)].

As an example, *p*-nitrobenzenesulfonamide will be discussed in detail (Fig. 1). The sulfonamido group has discrete interactions with the enzyme:

1. The amino group (2.14% ionized in free solution at pH 7.38) occupies the fourth coordination site at the Zn^{2+} ion (d = 2.5 Å) and is hydrogen-bonded to Thr 199 (d = 2.8 Å). This position is identical with the coordinated water molecule in the native enzyme.
2. O-1 occupies the fifth coordination site at the Zn^{2+} ion (d = 3.0 Å).

Table III—Main Interactions of Various Sulfonamides with HCAC[a]

[a] Atomic coordinates for the inhibitors in the proposed model fits are available from the author on request. [b] Het = Protein Data Bank notation for any hetero atom or group. [c] Values in parentheses are calculated using atomic coordinates from the crystal structure determination of the HCAC–acetazolamide complex; taken from Ref. 5.

Because the dehydration of carbonic acid requires both the fourth and fifth coordination sites at the zinc, sulfonamides are competitive inhibitors to this reaction.

3. For O-2 no strong interaction could be found using the native conformation of the backbone of HCAC. However, it seems possible that a small reorientation of residues 196–200 would allow a better interaction of this oxygen atom with Thr 199 (NH of the backbone) and increase the distance to Leu 198 (Table III).

The benzene ring interacts with the hydrophobic part of the enzyme: C-2 and C-3 approach Val 121 at d = 3.6 Å and d = 4.0 Å, respectively. A hydrogen bond between the O-2 of the nitro group towards Gln 92 is present, d = 2.9 Å. Additional solvent molecules (H_2O) could be expected to bridge the oxygens of the nitro group with the carbonyl groups of Pro 201 and Asn 67. Since the most powerful aromatic inhibitors (*cf.* Table I) have good hydrogen bond acceptors in the *para* or *meta* position, these additional bridging water molecules may contribute significantly to the enzyme–inhibitor complex stability.

Heterocyclic Sulfonamides—*Participation of Solvent Molecules*—A 1,3,4-thiadiazole ring attached to the sulfonamido group facilitates sulfonamide–HCAC complex formation. Acetazolamide (2-acetamido-1,3,4-thiadiazole-2-sulfonamide) shows a 45-fold greater inhibition constant than 4-acetamidobenzenesulfonamide ($K = 7.1 \times 10^7$ *versus* 1.6×10^6 mol^{-1}). A crystal structure study of the acetazolamide–HCAC complex shows the heterocyclic sulfur atom of the 1,3,4-thiadiazole ring pointing towards Val 121. This interaction was reported to be the main reason why acetazolamide binds 10 times stronger to HCAC than to HCAB, where the ring sulfur atom approaches Ala 121.

We propose that in the acetazolamide–HCAC complex an additional significant contribution to the complex stability can be attributed to the interaction of the two heterocyclic nitrogen atoms through a coordinated water molecule with the backbone of Thr 200 or Pro 201 (Fig. 2). The structural rigidity of the portion of the receptor cavity occupied by Pro 201 and *cis*-Pro 202 should be noticed. The fixed backbone carbonyl groups, nevertheless, are well positioned for hydrogen bonding. Because this part of the enzyme is open to the solvent, the water molecule might be dynamically exchanged making it undetectable by X-ray diffraction analysis at ambient temperatures. In the receptor site of HCAB this coordinated water would interact in an unfavorable manner with His 200 (HCAC has a Thr residue at this position) and, thus, would be less probable.

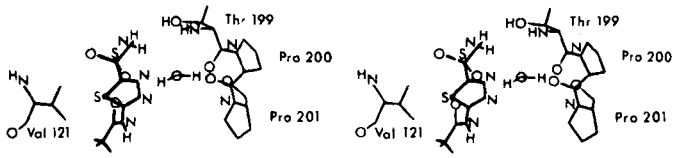

Figure 2—*H_2O molecule bridging the heterocyclic nitrogen atoms of the 1,3,4-thiadiazole ring of acetazolamide and the carbonyl group of Thr 200 or Pro 201.*

Such a coordinated water molecule is very probably present in all heterocyclic sulfonamides with a 3,4-unsubstituted 1,3,4-thiadiazole ring interacting with HCAC, as well as with thiophene ring systems (Fig. 3). Another water molecule may be expected to bridge the amino terminus of Asn 67 with the carbonyl function(s) of inhibitor molecules. Because no good interaction of O-4 of the sulfonamido group could be found with HCAC complexes, one might expect an additional water molecule between O-4 and an hydrophilic residue or the backbone in the vicinity (*i.e.*, Gly 196, Ser 197, Leu 198, Thr 199, Thr 200). With the coordinates of the native enzyme, however, no good site could be detected within the limits of the rigid receptor assumption.

Orientation of the Heterocyclic Ring—2-Nitrothiophene-5-sulfonamide is a very strong inhibitor for HCAC [$K = 2.38 \times 10^8$ *versus* 7.10×10^7 for acetazolamide (11)]. Assuming the same orientation as found in acetazolamide, the ring sulfur atom would point toward Val 121 and the 3,4-ring carbon atoms outward into the solvent. This would not contribute favorably to the binding energy of the enzyme–inhibitor complex and could not explain the large binding constant.

We therefore propose that 3,4-unsubstituted thiophenesulfonamides show an inverted binding to the active site cleft with respect to the orientation of the ring sulfur atom. 2-Nitrothiophenesulfonamide would thus achieve very good interactions of the ring carbon atoms with Val 121

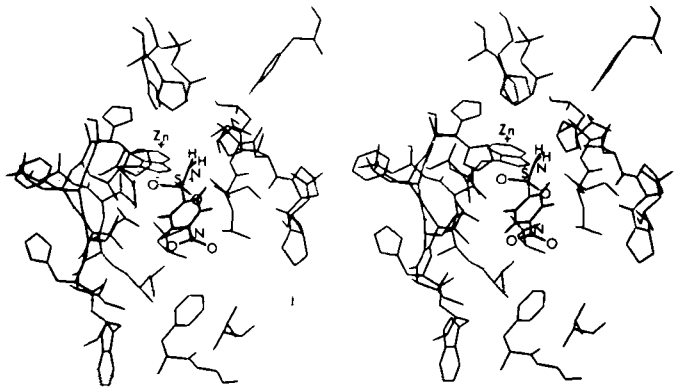

Figure 1—*Stereoprojection of the model fit of* p*-nitrobenzenesulfonamide in the receptor site of HCAC. The hydrogen atoms of the enzyme are not shown; the Zn^{2+} ion is represented by a cross (+).*

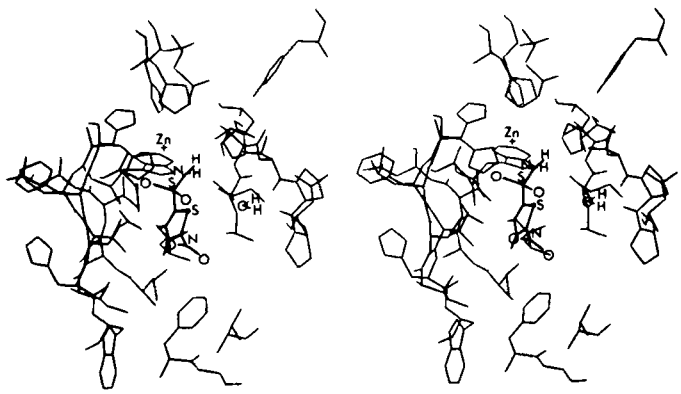

Figure 3—*Stereoprojection of the model fit of 2-nitrothiophene-5-sulfonamide into the receptor site of HCAC, with the bridging H_2O molecule to the right of the ring S atom.*

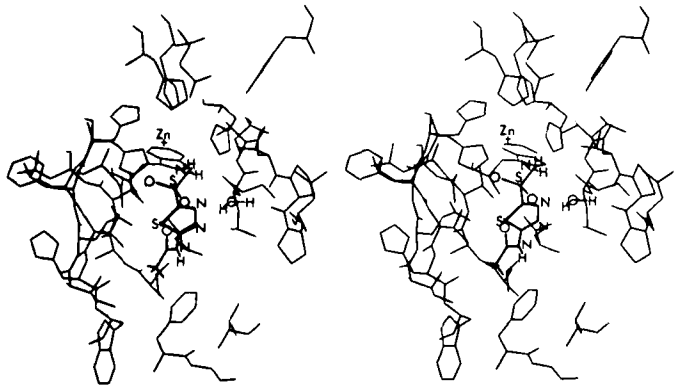

Figure 4—*Stereoprojection of the model fit of 2-acetamido-1,3,4-thiadiazole-5-sulfonamide (acetazolamide) into the receptor site of HCAC, with the bridging H_2O to the right of the ring N atoms.*

and Leu 141, and the sulfur atom would approach the oxygen atom of the coordinated water molecule (Fig. 3, Table III).

For 3,4-unsubstituted 1,3-thiazolesulfonamides, both orientations of the heterocyclic ring seem possible (Table II). This could also explain the unusually strong activity of 5-*H*-1,3-thiazole-2-sulfonamide *versus* 2-acetamido-1,3-thiazole-5-sulfonamide (Table I). For 3,4-unsubstituted 1,3,4-thiadiazolesulfonamides, an inverted binding of the heterocycle is very improbable, since the 3,4-ring nitrogen atoms would point into a hydrophobic part of the enzyme (*i.e.*, Val 121 and Leu 141).

The sulfonamido group of these inhibitors interacts with HCAC in the same manner as described for the aromatic sulfonamides. The main difference is that due to the lower pK value, heterocyclic sulfonamides may bind in the ionized form. At pH 7.38 (pH 6.50) acetazolamide is 49.9% (11.2%) deprotonated and metazolamide is 54.6% (13.7%) deprotonated.

With the inverted binding of the thiophene ring, 4-nitrothiophenesulfonamide achieves the following interactions with HCAC. The ring carbon atoms C-3 and C-4 are in contact with Val 121 and Leu 141 (d = 3.2 Å, d = 3.4 Å; d = 3.4 Å, d - 3.5 Å), whereas the ring sulfur atom approaches the oxygen atom of the postulated coordinated water molecule (d = 3.8 Å) which would be hydrogen bonded to the carbonyl group of Thr 200 (d = 3.0 Å) and Pro 201 (d = 2.7 Å). The nitro group would be hydrogen bonded to Gln 92 (d = 2.8 Å) and probably to the open solvent (Fig. 3, Table III).

The fit of acetazolamide, disregarding the additional water molecule bridging the heterocyclic ring with Thr 200 or Pro 201, is derived from crystal structure data reported by Kannan (5). Interactions include the heterocyclic sulfur atom with Val 121 (d = 3.1 Å and d = 3.2 Å), the acetamido oxygen with Gln 92 (d = 2.6 Å), and the methyl group with Phe 131 (d = 3.2 Å). The acetamido group is therefore tilted 74° out of the ring plane. In the crystal structure of molecular 2-acetamido-1,3,4-thiadiazole-5-sulfonamide (acetazolamide), this group is reported to be almost coplanar (4.9°) with the 1,3,4-thiadiazole ring, which allows an intramolecular S(ring)· · ·O(acetamido) contact of 2.75 Å (12). The two ring nitrogen atoms are located 2.9 Å from the water molecule (Fig. 4, and Table III), which is hydrogen bonded to Thr 200 (d = 3.4 Å) or Pro 201 (d = 3.1 Å).

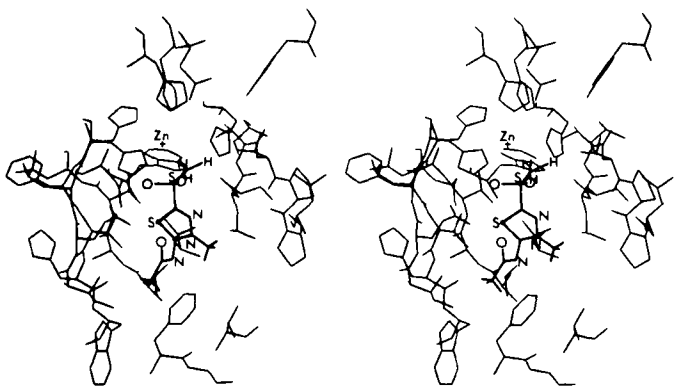

Figure 5—*Stereoprojection of the model fit of 2-acetamido-3-methyl-1,3,4-thiadiazole-5-sulfonamide (metazolamide) into the receptor site of HCAC.*

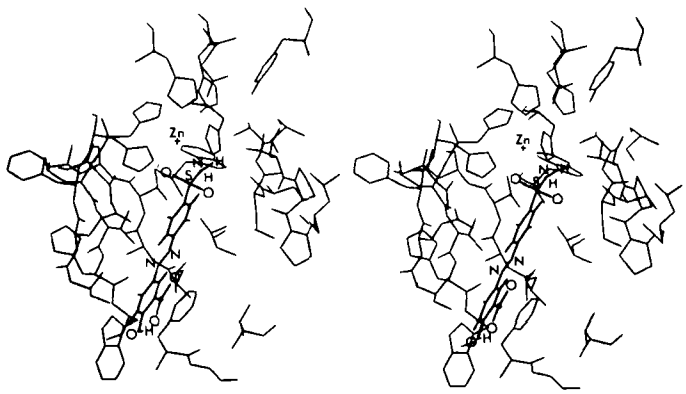

Figure 6—*Stereoprojection of the model fit of* p-*(salicyl-5-azo)-benzenesulfonamide into the receptor site of HCAC.*

The inhibitory power of metazolamide (2-acetamido-3-methyl-1,3,4-thiadiazole-5-sulfonamide) is reported to be 60% higher than in acetazolamide (11). This may be attributed to an additional interaction of either the 3-methyl group or the imido nitrogen atom of metazolamide with HCAC (Fig. 5). The heterocyclic sulfur atom is in contact with Val 121 (d = 3.0 Å, d = 3.3 Å). The ring methyl group is located in a hydrophobic pocket: Phe 131 (d = 4.1 Å), Leu 141 (d = 3.9 Å) and Leu 198 (d = 3.8 Å). The acetamido oxygen is hydrogen bonded to Gln 92 (d = 2.7 Å), whereas the methyl group is in contact with Ile 91 (d = 3.6 Å) and Phe 131 (d = 2.7 Å). The carbonyl group is tilted 35° out of the ring plane, and the intramolecular O(carbonyl)· · ·S(thiadiazole) distance is 3.27 Å.

Complex Sulfonamides—The interactions of *p*-(salicyl-5-azo)-benzenesulfonamide and furosemide (4-chloro-*N*-furfuryl-5-sulfamoylanthranylic acid) with HCAC will be discussed in detail. The benzene ring of *p*-(salicyl-5-azo)-benzenesulfonamide has close contacts to Val 121 (d = 2.5 Å, d = 3.1 Å, d = 3.2 Å, and d = 3.6 Å) (Fig. 6). The azo nitrogen atoms are 2.8 Å and 3.1 Å away from Phe 131, respectively. The amido nitrogen atom of Gln 92 interacts with the π-system of N-1 (d = 3.6 Å). The apparently short contacts of the salicyl group to Ile 91 and Phe 131 are not unrealistic if one takes into account that the backbone of the enzyme is not rigid and will relax to a more favorable conformation. (This additional degree of freedom is one of the subjects of our future investigations using force-field refinement.) The hydroxyl and carboxyl groups form hydrogen bonds with the surrounding solvent, which probably bridges these groups to the carbonyl group of Asn 67. A fit of the salicyl group into the hydrophobic pocket between Phe 131 and Val 135 was also investigated, but leads to less favorable contacts of the benzene ring.

Earlier investigations on aromatic sulfonamides indicated an enhancing effect of certain substituents (*i.e.*, halogens, trifluoromethyl, nitro, and methyl) *ortho* to the sulfonamido group with respect to diuretic activity. This structural alteration has decreased enzyme inhibitory activity and shifted the excretion pattern to a saluretic response. This separation of the two biological activities has been maintained and extended in the thiazide diuretics (11).

We therefore have investigated the steric interactions of such a sulfonamide drug, furosemide, with HCAC. With the native conformation of HCAC no favorable fit of furosemide could be obtained (Cl· · ·Leu 141: d = 2.5 Å). The chlorine in the *ortho* position of the benzene ring hinders

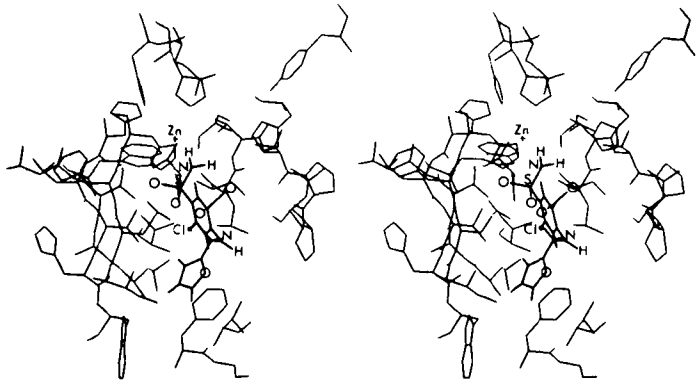

Figure 7—*Stereoprojection of the model fit of furosemide into the receptor site of HCAC.*

the molecule from entering deeply enough into the active site cleft to form good contacts (*i.e.*, sulfonamido group with Zn^{2+} and Thr 199, CO_2^- with Gln 92, furyl ring with Ile 91 and Phe 131). More drastic rearrangements of the hydrophobic part of the receptor site would be necessary in order to form good interactions. Therefore, simply for steric reasons, furosemide is expected to be a rather poor inhibitor of carbonic anhydrase; this is confirmed by *in vitro* measurements (11).

Figure 7 and Table III show that furosemide (without a chlorine atom in the *ortho* position) would be a good inhibitor of HCAC. The carboxyl group could hydrogen-bond to Gln 92 (d = 2.6 Å) and probably through a coordinated water molecule to the carbonyl groups of Pro 201. The furfuryl group would be located in the hydrophobic pocket between Ile 91 and Phe 131 (d = 2.8 Å through $d \approx 3.3$ Å), its oxygen atom pointing out into the solvent.

CONCLUSIONS

We have investigated 28 sulfonamide–HCAC complexes with interactive computer graphics in order to obtain a realistic starting conformation for force-field refinement. Aromatic sulfonamides gain most of their inhibitory power toward HCAC from the interaction of hydrogen bond acceptors in the *para* and *meta* positions with Gln 92 and Pro 201 and (*via* a coordinated water molecule) with Asn 67. No significant rearrangement of the backbone *versus* the conformation of native HCAC is expected, so long as the benzene ring is not substituted with bulky or multiple ligands.

In general, heterocyclic sulfonamides (*i.e.*, thiophenes, 1,3-thiazoles, and 1,3,4-thiadiazoles) are more potent inhibitors of HCAC than aromatic sulfonamides. This is due to the interaction of their heterocyclic ring with a hydrophobic part of the receptor site (Val 121$\cdots$S) and with Thr 200 and Pro 201 *via* a coordinated water molecule (S,N$\cdots H_2O\cdots$O=C$\langle$). We propose two different orientations of the heterocyclic ring with respect to the active site cleft:

1. The ring sulfur atom is in contact with Val 121, whereas the ring nitrogen atoms build hydrogen bonds to Thr 200 and Pro 201 (sulfur "in") for 3,4-unsubstituted 1,3,4-thiadiazoles. This is confirmed by the crystal structure determination of the acetazolamide–HCAC complex (5).
2. The ring sulfur atom is in contact with the oxygen atom of a coordinated water molecule, whereas the ring carbon atoms are located in a hydrophobic part of the receptor site such as Val 121 and Leu 143 (sulfur "out") for 3,4-unsubstituted thiophenes.

In addition to those interactions mentioned above, complex sulfonamides (two or more aromatic or heterocyclic rings) also show interactions of the "bridge" between the two ring systems (*e.g.*, —N=N—, —CO—NH—) with Gln 92 and the solvent. A significant contribution to the complex stability is derived from the interaction of aliphatic and aromatic substituents with the hydrophobic pocket around Ile 91, Trp 123, and Phe 131. Such sulfonamides, as well as aromatic or heterocyclic sulfonamides with larger substituents, may require a rearrangement of parts of the enzyme in order to bind. The hydrophobic pocket (Ile 91, Trp 123, Phe 131) for bulky aromatic or aliphatic parts of the inhibitor and the backbone around Leu 198 may need to be rearranged in order to obtain better interactions between the second sulfonamide oxygen atom and the enzyme.

Bulky ligands in the *ortho* position of the aromatic ring are not very favorable to inhibitory activity. Steric hindrance with Leu 141 and Leu 198 is the main reason why thiazide diuretics (Cl in the *ortho* position) are rather poor inhibitors of HCAC.

While crystallographic studies offer definitive information on the locus of binding and type of coordination of the sulfonamides with HCAB and HCAC, individual details cannot always be elucidated at the atomic level. By surveying the literature and applying known rules of stereochemistry and weak interactions, we have been able to propose alternative modes of binding of these small-molecule inhibitors that are consistent within the limits of the crystallographic studies and offer a better explanation for kinetic values. Interactive computer graphics, therefore, is a useful tool in surveying a broad literature data base to seek detailed correlations of structure and function. Such methods, when aided by the developing discipline of force-field refinement, offer the potential for detailed structure–activity studies. They may be extended by the intuitive chemist to include the prediction and design of novel drugs, inhibitors, and transition state analogues.

Abstract □ The bioavailability of hydrochlorothiazide was determined following single oral 25-, 50-, 100-, and 200-mg tablet and suspension doses in 12 healthy male volunteers. Plasma and urine levels of hydrochlorothiazide were determined by HPLC. Plasma levels of hydrochlorothiazide were satisfactorily described by a triexponential function. Mean peak plasma levels, C_{max} (127–135, 270–280, and 437–490 ng/mL from the 25-, 50-, and 100-mg doses, respectively) were dose proportional, as were areas under plasma profiles, $AUC_{0-\infty}$. Mean percentage recovery of unchanged hydrochlorothiazide in 48-h urine samples accounted for 50–59, 54–55, 60–63, and 54–57% of the 25-, 50-, 100-, and 200-mg doses, respectively. There were no significant differences among these values. Correlation coefficients between 48-h urinary recovery of hydrochlorothiazide and the plasma values (C_{max} and AUC_{0-36}) for the 25-, 50-, and 100-mg doses were 0.73 and 0.84. There were no differences in the net increases in electrolyte excretion among the treatments during the 0–12-h postdose period. The systematic availability of hydrochlorothiazide, unlike that of chlorothiazide, is dose proportional in the therapeutic range.

Keyphrases □ Hydrochlorothiazide—bioavailability from tablets and suspensions, pharmacokinetics □ Bioavailability—hydrochlorothiazide, tablets and suspensions, pharmacokinetics □ Pharmacokinetics—hydrochlorothiazide, bioavailability from tablets and suspensions

Despite their close molecular similarity, the diuretics chlorothiazide and hydrochlorothiazide appear to have different absorption characteristics after oral dosing. It has been reported that chlorothiazide absorption is incomplete and dose dependent, being more efficient with decreasing dosage (1–4). On the other hand, preliminary studies have suggested that hydrochlorothiazide absorption is dose proportional (5). Hydrochlorothiazide is also absorbed more efficiently than chlorothiazide, but is administered at lower doses (6). At a dose of 50 mg, the bioavailabilities of chlorothiazide and hydrochlorothiazide are similar (4).

The objective of this study was to explore the preliminary observation that hydrochlorothiazide absorption is dose proportional (5). The previous observation was based on 25–100-mg tablet doses to two individuals. In the present study, both tablet and suspension dosage forms were administered at a range of 25–200 mg to 12 individuals.

EXPERIMENTAL

Protocol—Twelve healthy male volunteers[1], 22–29 years of age (mean 24 years) and weighing 67–84 kg (mean 78 kg) participated in the study after passing a physical examination and giving informed consent. Each subject was instructed to refrain from taking any other medication for 2 weeks prior to and during the study and caffeine-containing beverages were restricted for 24 h prior to and during the study.

Subjects were divided into six groups of two, and the single oral 25-, 50-, and 100-mg oral tablet[2] and suspension doses of hydrochlorothiazide were administered as a 6 × 6 crossover design. Doses were administered 1 week apart. All doses were given at 8 a.m. after overnight fast; no food was permitted until 4-h postdose. Tablets were administered with 240 mL of water. Suspension doses were prepared by grinding the appropriate tablet to a fine powder in a beaker, adding 50 mL of water, and administering directly from the beaker. Quantitative dosing was ensured by repeated washes of the beaker with water to complete intake of 240 mL. Additional 240-mL water volumes were administered at 2, 4, 6, 8, and 12 h after each drug dose to ensure adequate urine output. Total urine output during the 12-h period prior to dosing and aliquots of urine collected during the 12-h postdose period were retained for electrolyte (K^+, Na^+, Cl^-) analysis.

Urine for drug analysis was collected quantitatively through 48 h postdose. Twenty-milliliter urine aliquots were stored at −20°C until assayed. Heparinized blood samples (~8 mL) were obtained from a forearm vein immediately before and at 0.5, 1, 1.5, 2, 3, 4, 6, 8, 12, 24, and 36 h postdose. Plasma was separated and stored at −20°C until assayed. Plasma and urine were assayed within 2 weeks of sampling.

In a separate study, the same 12 subjects received single oral 200-mg doses of hydrochlorothiazide (2 × 100-mg tablets) under the same conditions as those described above. Urine was collected through 48 h to determine hydrochlorothiazide excretion. Plasma drug levels and electrolyte excretion were not determined in this study.

Analytical Procedures—Concentrations of hydrochlorothiazide in plasma and urine were determined by HPLC, as described previously (7). Assay response was linear for hydrochlorothiazide concentrations of 10–750 ng/mL in plasma and 1–100 μg/mL in urine, with correlation coefficients of 0.999 and 0.996, respectively. The coefficient of variation in assay response was <10%. Concentrations of K^+, Na^+, and Cl^- ions in urine were determined by direct potentiometry[3].

Data Analysis—Individual plasma hydrochlorothiazide concentration profiles following the 25-, 50-, and 100-mg doses were fitted to a triexponential function of the form:

$$C = xe^{-\alpha t} + ye^{-\beta t} + ze^{-\gamma t} \qquad \text{(Eq. 1)}$$

where C is the concentration of drug in plasma at any time t and other values are constants. Initial parameter estimates were obtained graphically. Improved estimates, with statistical analyses were obtained by nonlinear regression using the NREG computer program (8). Plasma and urine data were examined by ANOVA for crossover design. When significant treatment effects were observed, differences between specific dosages were examined by means of Tukey's test (9).

RESULTS

Mean plasma hydrochlorothiazide levels from the six treatments are given in Table I, the data are summarized in Fig. 1. Plasma pharmacokinetic values are given in Table II.

Absorption was rapid from all dosages, and peak drug levels in plasma occurred uniformly at ~2 h. Suspension doses tended to produce somewhat higher drug levels than the equivalent tablet doses at early sampling times and, with the 50- and 100-mg doses, somewhat lower values at later times. However, differences between the two dosage forms were significant ($p < 0.05$) only at 0.5 h. When plasma drug levels from all dosages were normalized for dose size, there were no significant treatment effects at sampling times after 0.5 h. The mean peak drug levels, C_{max}, were dose proportional: 127–134 ng/mL for the 25-mg doses, 270–280 ng/mL for the 50-mg doses, and 437–490 ng/mL for the 100-mg doses. Increasing the tablet dose from 25 to 100 mg resulted in a 3.4-fold increase in the

r^2	0.97 ± 0.03	0.96 ± 0.03	0.97 ± 0.02	0.97 ± 0.01	0.98 ± 0.02	0.97 ± 0.02

[a] Mean ± *SD*; $n = 12$. [b] Half-life of the slowest rate constant β, calculated from $t_{1/2\beta} = \ln 2/\beta$. [c] Coefficient of determination, $r^2 = (\Sigma_{obs}^2 - \Sigma_{dev}^2)/\Sigma_{dev}^2$.

mean value of C_{max} and a 3.8-fold increase in the mean area under the drug plasma curve for 0 to 36 h, $AUC_{0\text{-}36}$. Increasing the suspension dose from 25 to 100 mg resulted in a 3.7-fold increase in C_{max} and a 3.5-fold increase in $AUC_{0\text{-}36}$.

Plasma levels from all dosages exhibited the familiar triphasic characteristic (3, 6, 7). After peak concentrations had been reached, drug levels declined rapidly through 12 h and then at a slower rate. In some subjects there was evidence of curvature in the logarithmic drug level *versus* time profiles throughout the postabsorptive period.

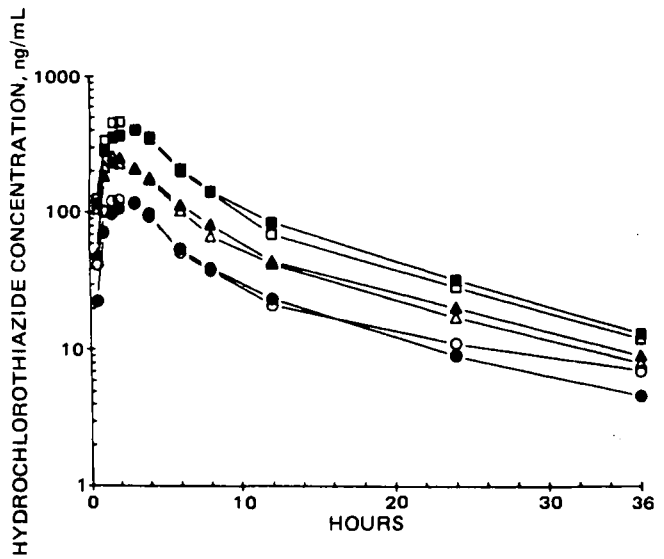

Figure 1—*Mean plasma levels of hydrochlorothiazide following single 25- (●), 50- (▲), and 100-mg (■) tablet and 25- (○), 50- (△), and 100-mg (□) suspension doses (n = 12).*

Analysis of individual drug curves in terms of Eq. 1 yielded the numerical values for the first-order rate constants α, β, and γ shown in Table III. The value of each constant was similar for all treatments, and no significant treatment effects were detected by ANOVA. The uniformly high coefficients of determination (r^2) show that individual drug profiles are satisfactorily described by a triexponential function. The mean half-life of the slowest rate constant β, which represents the terminal drug elimination half-life in plasma, ranged from 8.2 to 12.1 h; this is consistent with previously reported values (6, 7).

The mean cumulative recovery of hydrochlorothiazide in urine at 6, 24, and 48 h is summarized in Fig. 2. Recovery was markedly consistent between dose levels at each collection interval. The mean percentage urinary recoveries from the 25-, 50-, 100-, and 200-mg tablet doses were 62.9, 54.5, 50.3, and 54.0%, respectively. From equivalent suspension doses, the percentage recovery was 60.2, 54.1, 59.0, and 57.3%. There were no significant dosage or formulation effects in the percentage recovery at any collection time. The mean renal clearance of chlorothiazide (Table II), 222–257 ng/mL, was similar from all treatments for which this parameter could be calculated and is in close agreement with values reported earlier (6, 7).

The mean net increases in electrolyte excretion during the 0–12-h post-dose period following the 25-, 50-, and 100-mg doses, compared with the 12–0-h predose period are summarized in Table IV. There was considerable individual variation in these values. The mean net increases were 93–140 mmol for Na^+, 15.2–23.0 mmol for K^+, and 132–176 mmol for Cl^-. The increases were independent of dose size and formulation. Similar observations to these have been made with chlorothiazide administered over a 125–500-mg dosage range (2).

DISCUSSION

Previous studies have shown that the absorption efficiency of orally administered chlorothiazide is dose dependent over a dosage range of

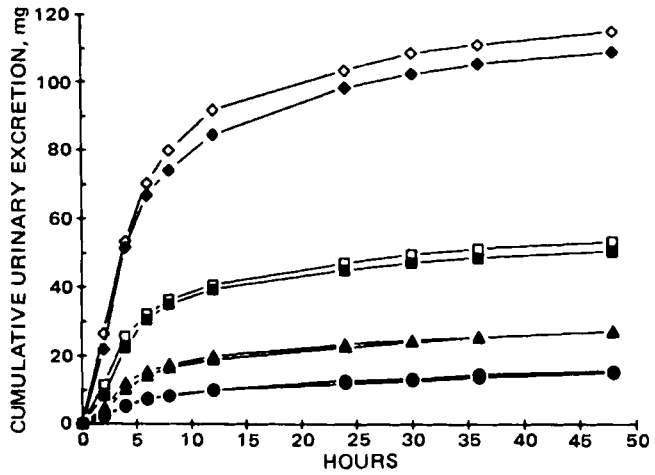

Figure 2—*Mean cumulative urinary recovery of hydrochlorothiazide following 25- (●), 50- (▲), 100- (■), and 200-mg (◆) tablet and 25- (○), 50- (△), 100- (□), and 200-mg (◇) suspension doses (n = 12).*

50–500 mg, the efficiency decreasing with increasing dose (1–4). The results of this study confirm the previous suggestion that the absorption efficiency of oral hydrochlorothiazide, unlike that of chlorothiazide, is independent of dose size (5).

The original objectives of this study were (*a*) to examine the absorption efficiency of hydrochlorothiazide from tablets and suspension doses within the normal therapeutic range of 25- 100 mg, (*b*) to compare urinary excretion and plasma levels, and (*c*) to evaluate the effect of dose size on electrolyte excretion. Mean plasma levels of hydrochlorothiazide were independent of formulation and proportional to dose size, and mean urinary recovery accounted for 50–60% of all dosages.

To determine whether hydrochlorothiazide absorption continued to be dose proportional at dose levels similar to those of chlorothiazide, and also in view of the good agreement between urinary excretion of hydrochlorothiazide and plasma levels, an additional dose of 200 mg was administered to the same subjects and absorption efficiency was assessed from urinary recovery alone. The percent urinary recovery of hydrochlorothiazide from this dose was the same as from the lower doses. The absorption efficiency of oral hydrochlorothiazide is thus independent of dose size over an eight-fold dosage range, which extends into the therapeutic dosage range for chlorothiazide.

These data show that hydrochlorothiazide and chlorothiazide exhibit different absorption characteristics. Whereas chlorothiazide exhibits a marked saturation or "absorption window" effect, hydrochlorothiazide absorption is constant over a wide dosage range. The absorption efficiency of chlorothiazide approaches that of hydrochlorothiazide only at the 50-mg dose level (4).

The reason for the different absorption behavior of the two thiazides is uncertain. The small differences in their molecular structure and physical and chemical characteristics should not cause differences in their absorption if both drugs are absorbed by passive mechanisms.

A possible explanation for their different behavior is that hydrochlorothiazide is efficiently absorbed by a passive process, while chlorothiazide absorption is controlled by an active, saturable component, together with a passive component which is less efficient than that of hydrochlorothiazide. Alternatively, chlorothiazide availability may be influenced by an "absorption window" to a far greater extent than that of hydrochlorothiazide.

Table IV—Net Increase in Electrolyte Excretion in Urine During the 12-h Interval Following All Hydrochlorothiazide Administrations

Dosage, mg	Increase in Electrolyte Excretion, mmol		
	Na^+	K^+	Cl^-
Tablet			
25	102 ± 64	20.2 ± 17.9	136 ± 71
50	93 ± 62	23.0 ± 12.5	132 ± 66
100	109 ± 76	15.2 ± 20.3	142 ± 85
Suspension			
25	103 ± 57	15.3 ± 21.3	137 ± 61
50	125 ± 58	20.7 ± 19.3	160 ± 67
100	140 ± 95	20.4 ± 16.6	176 ± 106

[a] Mean ± *SD*.

Whereas other studies in this laboratory and elsewhere have reported poor correlations between plasma levels and urinary excretion of hydrochlorothiazide (6, 10, 11), good agreement was obtained between these parameters over the dosage range used in this study. Typically, linear regressions of 48-h urinary recovery against AUC_{0-36} and C_{max} values for the combined 25-, 50-, and 100-mg tablet and suspension dosages yielded quite high correlation coefficients of 0.84 and 0.73, respectively. Thus, both plasma level and urinary data may be suitable for determining hydrochlorothiazide bioavailability, but the relative ease of obtaining urine data makes this the method of choice.

The electrolyte excretion data indicate that regardless of the absorption efficiency of hydrochlorothiazide, the maximum pharmacological effect occurs at low doses. There were no increases in net electrolyte excretion as doses were increased from 25 to 100 mg. These results are similar to those reported elsewhere (12, 13). Whether the plateau in pharmacological effect is due to maximal response at lower doses or to an inhibition effect at higher doses (13) cannot be ascertained from our data. Whatever the reason for the plateau effect it is evident that the therapeutic effectiveness of both chlorothiazide and hydrochlorothiazide may be limited at high doses, but for different reasons.

The mechanism causing biphasic elimination of hydrochlorothiazide is uncertain; the prolonged α phase of decline, extending to 12 h postdose, is probably too long to explain in terms of tissue uptake or redistribution according to usual two-compartment model concepts (14). A factor common to studies in which this phenomenon has been reported is water loading during the initial 12 h postdose in order to ensure adequate urine output (4, 5). This may influence hydrochlorothiazide elimination by a variety of mechanisms, including decreased reabsorption of drug from the bladder (15).

Determination and Prediction of Tissue Binding of Prednisolone in the Rabbit

NAWAL KHALAFALLAH [‡] **and WILLIAM J. JUSKO** [*x]

Received December 27, 1982, from the [*]*Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Buffalo, NY 14260* and the [‡]*Department of Pharmaceutics, Faculty of Pharmacy, University of Alexandria, Alexandria, Egypt.* Accepted for publication February 25, 1983.

Abstract □ Binding of prednisolone to rabbit tissue was determined experimentally and by computation to assess factors and proteins responsible for tissue distribution of this corticosteroid. Binding in tissue slices ranged from 36% in the lung to 83% in the liver. The results obtained were compared with steady-state tissue distribution data generated *in vivo* in the rabbit. Linear uptake with good agreement between the two sets of data was observed for the skeletal muscle and kidney, but not for the liver and lung. *In vivo* uptake of prednisolone in the liver is severely affected by metabolism and biliary excretion, while *in vitro* distribution into liver slices showed a pattern typical of saturation of a low-capacity site followed by linear nonspecific binding at higher concentrations. Specific saturable binding ($K_1 = 1.95 \times 10^7\ M^{-1}$) accounted for 74% of drug bound at a steroid concentration in the liver of 0.3×10^{-6} M, but its contribution decreased to 5% at a concentration of 20×10^{-6} M. Expected prednisolone binding in rabbit tissue was calculated based on various effective protein concentrations in tissues and binding parameters of prednisolone to rabbit plasma. The use of total Lowry protein concentrations markedly overestimates, while albumin (and transcortin) concentrations severely underestimate the tissue binding of prednisolone. The thiopental effective protein fraction best approximates the *in vivo* and tissue slice binding of prednisolone. Metabolism and saturable binding in liver complicate the otherwise relatively linear uptake of prednisolone into various tissues where macromolecules other than albumin dominate in tissue binding of the steroid.

Keyphrases □ Prednisolone—pharmacokinetics, tissue distribution, tissue binding, rabbits □ Tissue binding—prednisolone in the rabbit, liver, muscle, kidney, lung, albumin, effective protein fractions

Current interest in tissue binding stems partly from its uncertain nature and a growing recognition of the magnitude of effect on drug pharmacokinetics exerted by this process. The volume of distribution (1), biological half-life (2), and, of course, total tissue concentrations (3) are influenced by, and respond linearly in some cases to, changes in the fraction bound in tissue. Simulations and limited experimental evidence suggest a stronger influence of tissue binding on these aspects of drug pharmacokinetics compared with plasma binding (3). Occasionally, evidence of saturable tissue uptake invalidates or complicates the assumptions implied in linear pharmacokinetic models (4). Accurate estimates of individual tissue binding parameters over the therapeutic range of concentration are usually required as direct input data in mass-balance equations of physiological pharmacokinetic models (5).

From a pharmacodynamic point of view, the effect elicited by many drugs, including steroids, is a function of the amount of drug bound to receptors in tissues (6). In characterizing receptor binding as a unique type of tissue binding, it is important to be aware of the influence of methodological and pathophysiological factors on both specific and nonspecific tissue binding.

Several approaches have emerged for generating tissue binding data. *In vivo* methods involve measurement of drug uptake in mammalian tissue, with drug gaining access to the tissue while the animal is alive. Drug in tissue, in excess of that diffused into the tissue water, is considered bound to cellular constituents in the absence of time factors, metabolism, active transport, and pH effects. Steady-state conditions are necessary to be certain of the true degree of tissue binding or distribution.

A semiphysiological approach involves the use of perfused animal organs such as kidney, liver, and lung tissues (7, 8). However, the limited duration of organ viability may limit this approach, and it is best used for examining clearance processes.

In vitro determination of tissue binding requires tissue reduction to a near-liquid state manageable in equilibrium dialysis and ultrafiltration procedures (9, 10). The question is often raised, however, as to the degree that the intact tissue characteristics are retained in the homogenate. A milder alternative method is to measure drug uptake into tissue slices suspended in a physiological medium (11, 12). However, as with many other methods, the net drug uptake into slices may be the sum of several processes (transport, metabolism, and ion trapping) including binding.

Prednisolone, a synthetic corticosteroid, is used under various dosage regimens, during which body tissues are exposed to a wide range of concentrations. Specific glucocorticoid receptors have been identified in numerous tissues (6). However, little information is available in the literature concerning binding to mammalian tissues over the therapeutic plasma concentration range. We have found that this steroid is taken up by the majority of tissues of the rabbit in amounts exceeding the diffusion of free drug into tissue water (13). This species also appears to handle prednisolone pharmacokinetically in a manner similar to humans (14).

The aim of the present study was to determine prednisolone binding to rabbit tissue *in vitro* using tissue slices and to compare it with data obtained *in vivo* in rabbits (13). Further comparison will be made with predictions based on various effective (15) protein concentrations of rabbit tissues.

EXPERIMENTAL

Materials—Female New Zealand White rabbits, weighing 3.6–4.2 kg, were used. The animals were sacrificed with ether, and blood was drained from the abdominal aorta. Skeletal muscle, liver, kidney, and lung samples were obtained, washed with ice-cold saline, blotted dry, wrapped in aluminum foil, and frozen. The steroids used were prednisolone[1], prednisone[1], hydrocortisone[1], and dexamethasone[1].

Binding to Tissue Slices—The frozen tissues were cut with a razor blade into slices ~0.5 mm thick, weighing 500 mg. Slices were blotted, weighed, and placed in stoppered vials containing 3.0 mL of steroid solution in isotonic phosphate-buffered saline, pH 7.4. The vials were oscillated at 37°C for 3 h, which was predetermined to be adequate for equilibrium uptake of drug in the tissue slices. At equilibrium, slices were removed, washed quickly with 3 mL of ice-cold saline, blotted, weighed,

and homogenized (1:5) with water in a cell disrupter. Vials containing steroid solution but devoid of tissue slices were included in all runs. Initial solutions, solutions remaining at equilibrium, and tissue homogenates were analyzed by HPLC, as described elsewhere (13). The assay yielded equilibrium drug concentrations in the slice (S) and medium (M). Percent bound in tissue (% TB) was calculated from:

$$\%TB = \frac{S - M \cdot f_w}{S \cdot 0.01} \quad \text{(Eq. 1)}$$

where f_w is the fractional tissue water, determined by drying tissue slices to a constant weight (13).

Distribution to Rabbit Tissues *In Vivo*—Distribution data were obtained in an *in vivo* study of prednisolone pharmacokinetics in the rabbit (13). Briefly, the study involved administration of a zero-order intravenous infusion of prednisolone and measurement of the steady-state uptake of the steroid in rabbit tissues and plasma. Apparent percent binding was calculated for each tissue concentration (C_{tissue}) and unbound plasma concentration (C_f) from:

$$\%TB = \frac{C_{tissue} - C_f \cdot f_w}{C_{tissue} \cdot 0.01} \quad \text{(Eq. 3)}$$

It follows that:

$$\%TB = \frac{K_p - f_w}{K_p \cdot 0.01} \quad \text{(Eq. 4)}$$

where K_p is the tissue–free plasma distribution ratio as reported previously (13).

Prediction of Binding to Rabbit Tissues—The *in vivo* tissue distribution data obtained previously in the rabbit (13), indicated linear binding of prednisolone in most rabbit tissues over the concentration range examined. Hence, bound (C_b) and free (C_f) concentrations are related by:

$$C_b = nK \cdot P \cdot C_f \quad \text{(Eq. 5)}$$

and the fraction bound (f_b) is:

$$f_b = \frac{nK \cdot P}{1 + nK \cdot P} \quad \text{(Eq. 6)}$$

where nK is the composite binding parameter (number of binding sites × association constant) and P is the effective protein concentration in tissue. The assumption was then made that the nK value obtained from binding of prednisolone to rabbit plasma can characterize its binding to other tissue proteins. The value of nK was calculated from steady-state plasma *Pn* binding, determined *in vivo* (13), using (16):

$$nK = \frac{1}{[Prot]} \cdot \frac{\beta_0}{1 - \beta_0} \quad \text{(Eq. 7)}$$

where β_0 is the extrapolated fraction bound in the linear binding range

Table I—Binding of Prednisolone to Rabbit Tissue Slices

Tissue	Medium Prednisolone Concentration at Equilibrium, ng/mL	Recovery[a] (*SD*), %	Bound[a] (*SD*), %

and [Prot] is the molar concentration of binding proteins in plasma, calculated from the sum of albumin and transcortin concentrations reported in rabbit plasma (14).

Fraction bound in tissue was then predicted (Eq. 6) using P values corresponding to total protein concentrations in tissue (17), albumin concentrations in tissue (18), and effective tissue protein concentrations reported for thiopental (15). The protein values used were reported as fractions of tissue weight and were converted to molar concentration assuming a molecular weight of 69,000 and tissue density of unity. For tissue albumin content, we employed the extravascular albumin spaces determined in rats by Studer and Potchen (18), except in the case of liver where data from dogs (19) were used because of inaccuracy in the rat value.

RESULTS

***In Vivo* Distribution of Prednisolone**—Steady-state tissue-to-plasma distribution of prednisolone was measured in five rabbits. Confirmation of assay methodology, stability, recovery data, and other experimental results are provided elsewhere (13). The equilibrium tissue–unbound prednisolone in plasma ratios for four tissues is shown in Fig. 1. All tissues except the liver showed linear distribution ratios.

Binding in Tissue Slices—Steroid recoveries and percent tissue binding for the tissue slices are reported in Table I. Recovery data were generated by comparing the amount of prednisolone found in tissue slices and medium at equilibrium to the amount of drug initially added to the medium. Both liver and kidney slices generated prednisone when incubated with prednisolone. The recovery values and standard deviations indicate good reproducibility of the data, with marked loss of drug occurring only in the liver.

Binding Kinetics in Muscle and Liver Slices—Uptake of prednisolone into muscle and liver slices was examined over a wide range of

[a] Based on brain to CSF ratios (Ref. 13).

concentrations (Figs. 2 and 3). Linear binding to the muscle was evident throughout the concentration range examined. Binding to liver slices was nonlinear in the low concentration range but progressed linearly beyond that. The insert in Fig. 3 is a Scatchard plot of the binding data. Drug bound in the liver (D_b) at each concentration was calculated from S − M·f_w, while M·f_w yielded free drug (D_f) in the tissue. The shape of the plot suggests both nonlinear (subscript 1) and linear (subscript 2) binding in accordance with:

$$\frac{D_b}{D_f} = \frac{n_1K_1P_1}{1 + k_1D_f} + n_2K_2P_2 \qquad \text{(Eq. 8)}$$

Individual parameters were calculated as follows. At high drug concentration the first term in Eq. 8 could be neglected and $n_2K_2P_2$ was calculated from the slope of a plot of D_b *versus* D_f. For each data point, drug bound nonspecifically (D_{bNS}) was calculated using $D_{bNS} = n_2K_2P_2 \cdot D_f$. Subtracting this term from the total drug bound yielded D_{bSP}. Plotting D_{bSP}/D_f *versus* D_{bSP} gave a straight line with an abscissa intercept of n_1P_1, and a slope of $-K_1$. The parameters generated were: $n_2K_2P_2 = 1.23$ (no units); $n_1P_1 = 0.142$ μg/g of liver; and $K_1 = 54.2$ g/μg or 1.95×10^7 M^{-1}.

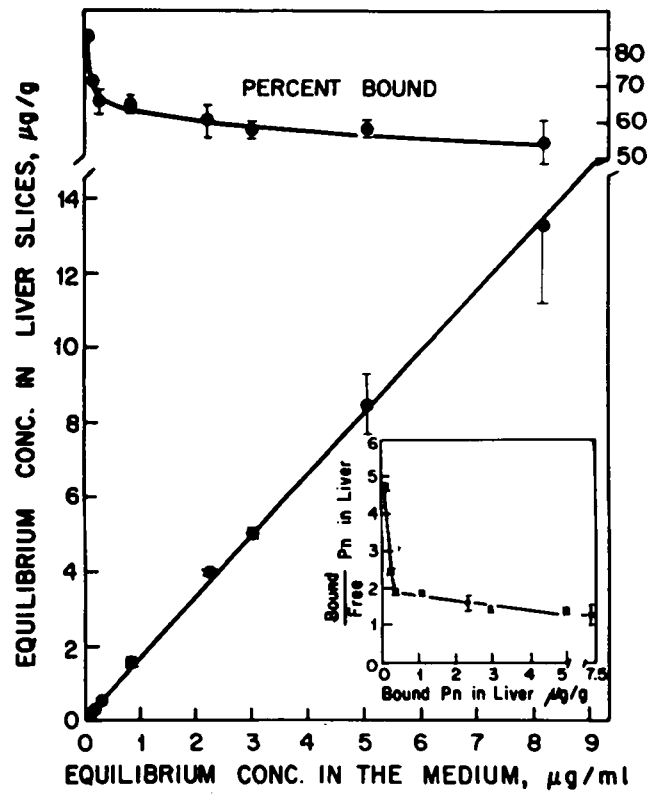

Figure 3—*Uptake of prednisolone in rabbit liver slices at 37°C. The insert is a Scatchard plot of the binding data.*

Calculated Tissue Binding—The protein fractions of the rabbit tissues, obtained from three literature sources, are listed in Table II. Of the total solids of the various rabbit tissues measured in our previous study (13), the Lowry assay-reactive proteins comprise 64–83%, except for brain (42%). The albumin fraction is extremely small and does not change perceptibly when transcortin is included. The effective protein fraction with respect to thiopental binding generally reflects 1.8–3.6% of the tissue weights.

The calculated percentage binding of prednisolone using the three protein fractions are compared with the *in vivo* and *in vitro* tissue binding values in Table III. The use of total protein concentrations markedly overestimates, while albumin concentrations severely underestimate, the tissue binding of prednisolone. The effective protein fraction best approximates both the *in vivo* and tissue slice binding of prednisolone.

DISCUSSION

The present study reports tissue binding data for prednisolone in the rabbit, obtained using different methods. The binding data were generated over a range of steroid concentrations where linear tissue uptake was evident in most tissues both *in vivo* and *in vitro*. The range of concentrations investigated in tissue slices reached an equilibrium medium concentration of 8 μg/mL, which exceeds human plasma exposure to free drug at usual therapeutic doses. However, some corticosteroids such as hydrocortisone and methylprednisolone are sometimes prescribed in large

doses, resulting in plasma levels of 1 mg/mL of total (bound and free) steroid (20, 21), and it is of interest to investigate the manner by which mammalian tissues handle high steroid concentrations.

Binding to Slices Compared with *In Vivo* Data—There was good agreement between slice uptake and *in vivo* distribution of prednisolone in the case of skeletal muscle and kidney. This permits some speculation concerning the mode of entry of the drug into rabbit tissue. The fact that *in vivo* uptake of prednisolone in tissues such as the skeletal muscle was linear and could be quantitatively reproduced in slices under the conditions described, suggests the absence of an active transport process. If the latter occurs *in vivo*, but only partly *in vitro*, drug uptake in slices may underestimate *in vivo* distribution, as reported for the tetraethylammonium ion (22).

Uptake of prednisolone into lung slices markedly differed from the *in vivo* situation. Many aspects of *in vivo* drug localization in lung tissue are not well understood, and underestimation of *in vivo* drug binding when using lung homogenates has been reported (23, 24).

Prednisolone Binding in the Liver—The liver showed a strikingly different uptake pattern *in vivo* compared with the other tissues (Fig. 1). We thus chose to further examine the uptake over a wide range of concentrations in both liver and a tissue such as skeletal muscle using the slice technique. The *in vivo* and *in vitro* data indicated a disparate type of nonlinear binding or uptake of the steroid to the liver tissue. *In vitro*, the results showed a pattern typical of saturation of a low-capacity site followed by linear, nonspecific binding at higher concentrations. The *in vivo* data showed the opposite saturation pattern in the high concentration range. However, these data were probably confounded by rapid metabolism and appreciable excretion in the bile (13) resulting in gross underestimation of the true tissue binding (5). In this respect, the slice technique offers the advantage of measuring drug uptake in the liver in the absence of total expression of its metabolic activity. However, judging by the relatively low recovery values of prednisolone from liver slices compared with other tissues (Table I), steroid metabolism in liver slices cannot be ruled out and may consequently have resulted in some underestimation of binding in the liver.

In generating binding data, part of the information sought is identification of the binding constituent, usually protein, and characterization of the ligand–protein reaction by numerical parameters. Binding data in liver slices yielded an apparent association constant (K_1) for specific nonlinear binding ($1.95 \times 10^7\ M^{-1}$), while for linear binding, only a value for percent bound (59.6%) could be calculated.

The association constant of the liver protein, exhibiting high affinity but low capacity for prednisolone, fits within the range reported for the glucocorticoid receptor, but is also compatible with steroid affinities of other liver proteins such as ligandin and transcortin. Values reported for liver receptor binding range between $5–74 \times 10^7\ M^{-1}$ for dexamethasone in humans (25), rabbits (26), and rats (27), and for hydrocortisone and corticosterone in rats (28, 29). The ligandin association constants for steroids are in the range of $10^5\ M^{-1}$ for purified ligandin, but native cytosol binding may be greater (30). Receptors have been identified in numerous rabbit tissues including the skeletal muscle (31). Prednisolone uptake in muscle slices showed no evidence of high-affinity–low-capacity binding in the low concentration range, which suggests that the corresponding binding seen in liver slices may not necessarily be to the glucocorticoid receptors.

Whatever the identity of the liver protein exhibiting high affinity for prednisolone, and whether or not it is directly involved in expression of steroid activity, it contributed significantly to drug uptake. The percent prednisolone bound specifically (related to total drug bound in liver slices) was as high as 74% at a total drug concentration of 0.3×10^{-6} M, but decreased to 5% at a corresponding concentration of 20×10^{-6} M. The activity of this protein, ($K_1 = 1.95 \times 10^7\ M^{-1}$) is higher than that of albumin in plasma ($nK = 6 \times 10^3\ M^{-1}$) and is as high as that of transcortin in plasma ($K = 2 \times 10^7\ M^{-1}$) (14). It may thus be an important factor in the mechanism of uptake and concentration of prednisolone in liver cells.

Predicted Tissue Binding Data Compared with *In Vivo* Results—The possibility of predicting prednisolone binding to rabbit tissue, based on parameters obtained for binding to rabbit plasma and an estimate of effective protein concentration, was explored in the present study (Table III). Only a portion of tissue proteins are effective in drug binding (32); hence, the observation that total tissue protein binding overestimates prednisolone binding is not unexpected. Albumin, by virtue of its high concentration, is a major binding species in plasma, but apparently assumes a less significant role in tissues. Binding of prednisolone to albumin accounts for less than half of the calculated and measured *Pn* binding in the rabbit tissues (Table III). Owing to the extremely low tissue concentrations, the addition of tissue transcortin to this calculation barely affects the binding values based on albumin alone.

It was intriguing to note that the effective protein fraction calculated for thiopental from binding data to rabbit tissue homogenates (15) yielded good estimates of prednisolone binding in the same species (Table III). Values of the effective protein fraction for prednisolone, and possibly other drugs, may be similar to those reported for thiopental. The concept of a common array of tissue binding proteins for certain types of drugs in various species is worth contemplating, bearing in mind that the binding data presented in this study correspond to a concentration range governed mainly by nonspecific binding, a likely situation for most therapeutic agents.

Recently, some criticism has been raised regarding the assumptions made when utilizing the concept of effective protein fraction in predicting tissue binding. Particularly strong are arguments against extrapolation of binding data from one species or from one protein concentration to another with the inherent assumptions that binding is independent of these factors. Experimental data and simulations have appeared which invalidate these assumptions (32, 33). Furthermore, the effective protein fraction was shown to vary with drug concentration in some of the protein media examined (33). In the present study, mingling of data from different species was minimal. The data presented, whether determined experimentally or predicted (apart from tissue albumin concentration) all pertain to the rabbit. Furthermore, the composite binding parameter, nK (Eq. 7), was determined over the same range of plasma concentration used in the determination of tissue binding *in vivo*. Hence, it is felt that the present data provided a good opportunity to test the usefulness of the effective thiopental protein fraction in predicting the tissue binding of other drugs.

Deaza Analogues of Adenosine as Inhibitors of Blood Platelet Aggregation

IPPOLITO ANTONINI *, GLORIA CRISTALLI *, PALMARISA FRANCHETTI *, MARIO GRIFANTINI *x, SANTE MARTELLI *, and FRANCO PETRELLI ‡

Received May 24, 1982, from the **Institute of Pharmaceutical and Organic Chemistry* and ‡*Institute of Physiology, University of Camerino, 62032 Camerino (MC) Italy.* Accepted for publication December 22, 1982.

Abstract □ A number of deaza analogues of adenosine were prepared and tested as inhibitors of platelet aggregation induced by ADP and collagen to investigate the structure–activity relationships in this class of nucleoside analogues. The results showed that the presence of a 6-amino group and nitrogen atoms at positions 3 and 7 of the purine moiety are required for inhibitory activity.

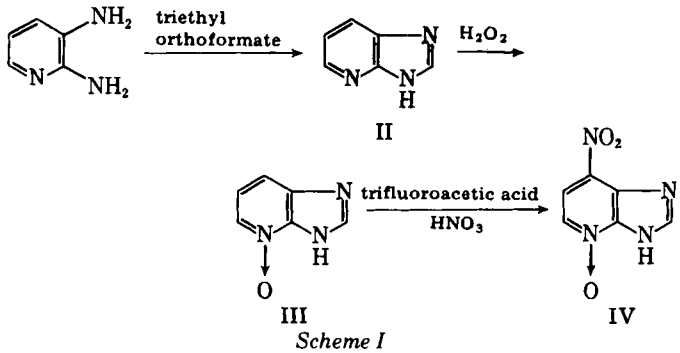
Keyphrases □ Adenosine—deaza analogues, inhibition of ADP- and collagen-induced platelet aggregation □ Platelet aggregation—induction by ADP and collagen, inhibition by deaza analogues of adenosine □ Nucleoside analogues—deazaadenosines, inhibition of ADP- and collagen-induced platelet aggregation

Blood platelets seem to play a dominant role in both the physiological and pathological events of hemostasis (1). In fact, platelet aggregation leads to the formation of either hemostatic plugs or thrombi. Several tissue constituents can give rise to platelet aggregation (2, 3). Among these substances, adenosine diphosphate (ADP) has been shown to be important as it can initiate aggregation (4) and can also mediate aggregation induced by other agents (3, 5).

Adenosine, a structural analogue of ADP, is a powerful inhibitor of platelet aggregation induced by ADP (6). A number of adenosine derivatives and analogues have been synthesized and tested in an attempt to clarify the structure–activity relationships in this class of platelet-aggregation inhibitors (6–9). The present paper investigates the influence of the purine nitrogen atoms on adenosine activity. Some deaza analogues of adenosine and purine riboside have been prepared and tested *in vitro* as inhibitors of platelet aggregation induced by ADP and collagen.

DISCUSSION AND RESULTS

Adenosine[1] (Ia), 7-deazaadenosine[2] (Ie), and purine riboside[2] (Ig) were purchased from commercial sources. 3-Deazaadenosine (Ic) was synthesized using a method previously described (10). 1-Deazaadenosine (Ib) was synthesized using a modification of previous methods (11–14) (Scheme I). Imidazo[4,5-*b*]pyridine (II) (11) was prepared in a 73% yield by the condensation of 2,3-diaminopyridine with triethyl orthoformate.



Scheme I

Nitration of *N*-oxide III, employing a nitric acid–trifluoroacetic acid mixture instead of a nitric acid–acetic acid mixture (12), gave 7-nitroimidazo[4,5-*b*]pyridine-4-oxide (IV) in good yield. The other steps involved following known procedures (13, 14). 1,3-Dideazaadenosine (Id) was synthesized as shown in Scheme II instead of the method reported

Deaza Analogues of Adenosine as Inhibitors of Blood Platelet Aggregation

IPPOLITO ANTONINI *, GLORIA CRISTALLI *, PALMARISA FRANCHETTI *, MARIO GRIFANTINI *x, SANTE MARTELLI *, and FRANCO PETRELLI ‡

Received May 24, 1982, from the **Institute of Pharmaceutical and Organic Chemistry* and ‡*Institute of Physiology, University of Camerino, 62032 Camerino (MC) Italy.* Accepted for publication December 22, 1982.

Abstract □ A number of deaza analogues of adenosine were prepared and tested as inhibitors of platelet aggregation induced by ADP and collagen to investigate the structure–activity relationships in this class of nucleoside analogues. The results showed that the presence of a 6-amino group and nitrogen atoms at positions 3 and 7 of the purine moiety are required for inhibitory activity.

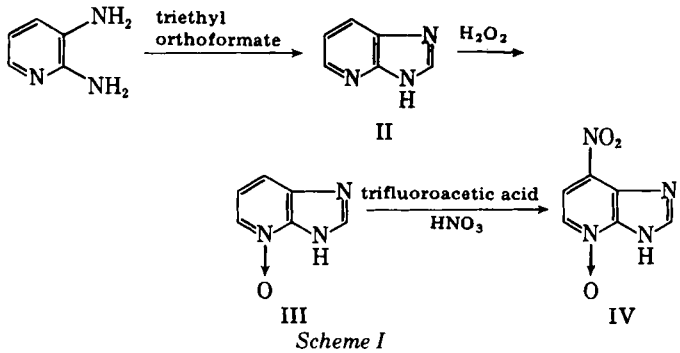
Keyphrases □ Adenosine—deaza analogues, inhibition of ADP- and collagen-induced platelet aggregation □ Platelet aggregation—induction by ADP and collagen, inhibition by deaza analogues of adenosine □ Nucleoside analogues—deazaadenosines, inhibition of ADP- and collagen-induced platelet aggregation

Blood platelets seem to play a dominant role in both the physiological and pathological events of hemostasis (1). In fact, platelet aggregation leads to the formation of either hemostatic plugs or thrombi. Several tissue constituents can give rise to platelet aggregation (2, 3). Among these substances, adenosine diphosphate (ADP) has been shown to be important as it can initiate aggregation (4) and can also mediate aggregation induced by other agents (3, 5).

Adenosine, a structural analogue of ADP, is a powerful inhibitor of platelet aggregation induced by ADP (6). A number of adenosine derivatives and analogues have been synthesized and tested in an attempt to clarify the structure–activity relationships in this class of platelet-aggregation inhibitors (6–9). The present paper investigates the influence of the purine nitrogen atoms on adenosine activity. Some deaza analogues of adenosine and purine riboside have been prepared and tested *in vitro* as inhibitors of platelet aggregation induced by ADP and collagen.

DISCUSSION AND RESULTS

Adenosine[1] (Ia), 7-deazaadenosine[2] (Ie), and purine riboside[2] (Ig) were purchased from commercial sources. 3-Deazaadenosine (Ic) was synthesized using a method previously described (10). 1-Deazaadenosine (Ib) was synthesized using a modification of previous methods (11–14) (Scheme I). Imidazo[4,5-*b*]pyridine (II) (11) was prepared in a 73% yield by the condensation of 2,3-diaminopyridine with triethyl orthoformate.



Scheme I

Nitration of *N*-oxide III, employing a nitric acid–trifluoroacetic acid mixture instead of a nitric acid–acetic acid mixture (12), gave 7-nitroimidazo[4,5-*b*]pyridine-4-oxide (IV) in good yield. The other steps involved following known procedures (13, 14). 1,3-Dideazaadenosine (Id) was synthesized as shown in Scheme II instead of the method reported

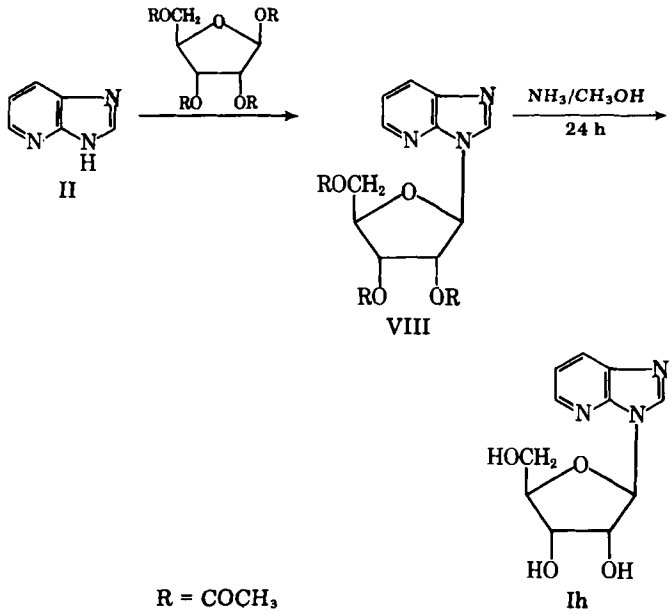
Table I—Effect of Deaza Analogues of Adenosine on Human Platelet Aggregation

	Compound	W	X	Y	Z	Inhibition of Aggregation[a] ADP Induced %	ADP Induced RAD[b]	Collagen Induced %	Collagen Induced RAD[b]
Ia	Adenosine	N	N	N	NH_2	93	1	97	1
Ib	1-Deazaadenosine	CH	N	N	NH_2	82	0.88	87	0.89
Ic	3-Deazaadenosine	N	CH	N	NH_2	<10	<0.1	<10	<0.1
Id	1,3-Dideazaadenosine	CH	CH	N	NH_2	<10	<0.1	<10	<0.1
Ie	7-Deazaadenosine (tubercidin)	N	N	CH	NH_2	<10[c]	<0.1	<10	<0.1
If	1,7-Dideazaadenosine	CH	N	CH	NH_2	<10	<0.1	<10	<0.1
Ig	Purine riboside	N	N	N	H	<10[c]	<0.1	<10	<0.1
Ih	1-Deazapurine riboside	CH	N	N	H	<10	<0.1	<10	<0.1

[a] Compounds were tested at 1.10^{-4} M final concentration. [b] RAD is the relative potency of the compounds to adenosine tested at the same conditions. [c] Values obtained for Ie and Ig are in agreement with literature data (6, 8).

by Mizuno *et al.* (15). Fusion of 4(7)-nitrobenzimidazole (V) (16) with tetra-*O*-acetyl-β-ribofuranose followed by deacetylation with methanolic ammonia at room temperature gave VII in good yield. Ribonucleoside Id was then obtained by catalytic hydrogenation of VII with palladium-on-carbon (17). The same synthetic procedure was followed to prepare 1-deazapurine riboside (Ih) as shown in Scheme III, instead of the syntheses previously described (18, 19). The synthesis 1,7-dideazaadenosine (If) has been described elsewhere (20).



Scheme III

The compounds in Table I were tested as inhibitors of ADP- and collagen-induced human platelet aggregation *in vitro* according to the method of Born and Cross (6). The inhibitory activity of each compound was estimated by the extent of the decrease in optical density after the addition of ADP and collagen and compared with adenosine activity (RAD). 7-Deazaadenosine (Ie) and purine riboside (Ig) were tested previously and found to be ~1% as active as adenosine (6, 8). The results of the aggregation tests are shown in Table I.

1-Deazaadenosine (Ib) proved to be the only deaza analogue of adenosine showing significant inhibitory activity at 1×10^{-4} M concentration. When 1-deazaadenosine was tested at different concentrations between 5×10^{-6} M and 1×10^{-4} M, its effect on platelet aggregation induced by ADP and collagen was dose dependent, as shown in Fig. 1. The activity, also affected by the incubation period, was maximal after 7.5 min of preincubation (Fig. 2).

When adenosine and 1-deazaadenosine were coadministered, the cumulative effect was almost equal to the sum of the effects elicited by the substances separately. The results of aggregation tests clearly indicated that the nitrogen atoms at positions 3 and 7 of the purine ring are required for inhibitory activity. In fact 3-deazaadenosine (Ic), 7-deazaadenosine (Ie), 1,3-dideazaadenosine (Id), and 1,7-dideazaadenosine (If) did not show any significant inhibitory activity at a concentration of 1×10^{-4} M.

Elimination of the 6-amino group both in adenosine and 1-deazaadenosine resulted in loss of activity, as shown by the fact that purine riboside (Ig) and 1-deazapurine riboside (Ih) did not inhibit platelet aggregation induced by ADP and collagen (Table I). On the other hand, the nitrogen atom at position 1 of the purine ring appeared to be less critical than the other nitrogen atoms suggesting that some substituent changes can be made without loss of the inhibitory activity against platelet aggregation.

EXPERIMENTAL[3]

Imidazo[4,5-*b*]pyridine (II)—A mixture of 20 g (0.183 mol) of 2,3-diaminopyridine[1] and 400 mL of triethyl orthoformate was heated at reflux for 3 h. The solution was evaporated to dryness *in vacuo*, and then the residue was heated at reflux with 200 mL of concentrated hydrochloric acid for 1 h. The mixture was allowed to cool, neutralized with solid Na_2CO_3, and extracted with ethyl acetate. The combined extracts were dried (Na_2SO_4), and the solvent was removed at reduced pressure. The residue was dissolved in absolute ethanol, treated with charcoal, filtered, and then the solvent was evaporated to give 16 g of II as colorless needles (73% yield), mp 152–153°C [lit. (11) mp 153–154°C]; ^{1}H-NMR (DMSO-d_6): δ 7.3 (m, 1, 6-H), 8.11 (d, 1, J = 8 Hz, 7-H), 8.45 (d, 1, J = 5 Hz, 5-H), and 8.54 ppm (s, 1, 2-H).

7-Nitroimidazo[4,5-*b*]pyridine-4-oxide (IV)—To a cold (0°C) solution of 13.6 g (0.1 mol) of imidazo[4,5-*b*]pyridine-*N*-oxide (III) (12) in 100 mL of trifluoroacetic acid was added, in a dropwise manner, 65 mL of 90% fuming nitric acid. The mixture was heated at 90°C for 3 h, cooled, and then poured into crushed ice. The mixture was neutralized with concentrated ammonium hydroxide while maintaining the temperature below 30°C. The resulting solid was filtered, washed with ice water, and dried to give 13.5 g of IV as light-yellow needles (75% yield). The structure of IV was confirmed by comparison of the data obtained with that in the literature (12).

1-(2′,3′,5′-Tri-*O*-acetyl-β-D-ribofuranosyl)-4-nitrobenzimidazole (VI)—A mixture of 4(7)-nitrobenzimidazole (1g, 6.13 mmol) (17), 1,2,3,5-tetra-*O*-acetyl-β-D-ribofuranose (3.9 g, 12.25 mmol) and *p*-toluenesulfonic acid (50 mg) was heated at 160°C with stirring *in vacuo* (25 mm) for 20 min. The mixture was cooled, and the resulting solid was neutralized with a saturated Na_2CO_3 solution and extracted with chloroform. The organic layers were dried (Na_2SO_4), filtered, and evaporated to dryness. The residue was chromatographed on silica gel (ethyl acetate) to give 1.6 g (60%) of VI as light-yellow needles, mp 75–77°C; ^{1}H-NMR ($CDCl_3$): δ 2.08–2.15 (m, 9, 3 CH_3), 4.4–4.63 (m, 3, 4′-H and 5′-CH_2), 5.36–5.63 (m, 2, 2′-H and 3′-H), 6.16 (d, 1, J = 5 Hz, 1′-H), 7.3 (t, 1, 6-H),

[3] The melting points were determined with a Büchi apparatus and are uncorrected. The NMR spectra were obtained with a Varian EM-390 90-MHz spectrometer, using tetramethylsilane as the internal standard. For column chromatography silica gel 60 Merck was used.

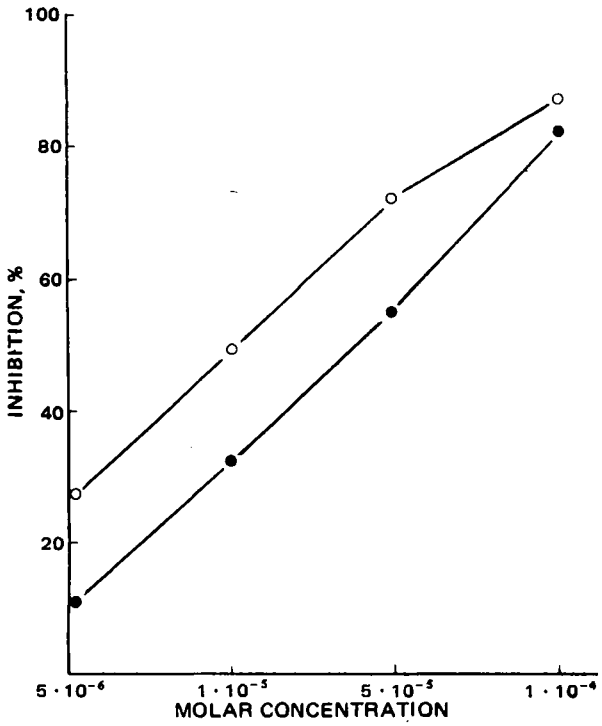


Figure 1—*Inhibitory effects of 1-deazaadenosine (Ib) at different concentrations on human platelet aggregation induced by ADP (●) and collagen (○). Ib was incubated in platelet-rich plasma at 37°C for 5 min before the addition of ADP and collagen.*

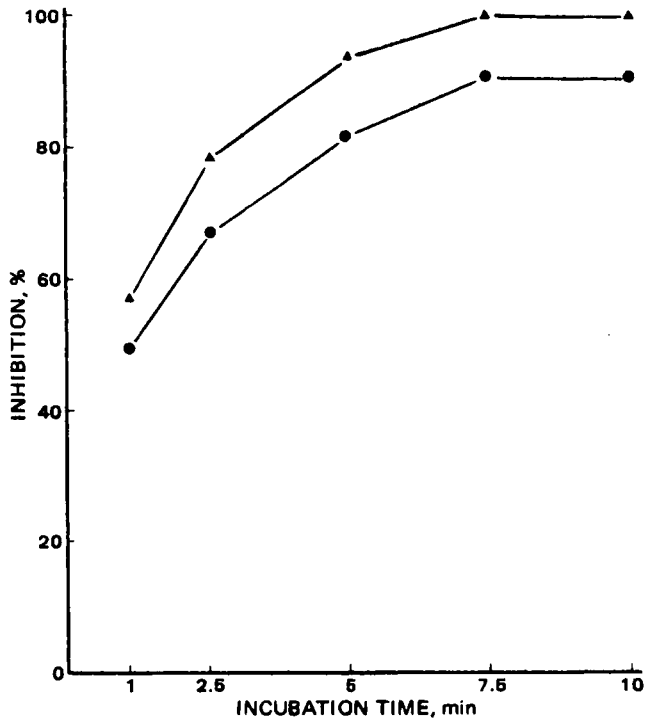

Figure 2—*Effect of 1-deazaadenosine (Ib) (●) and adenosine (Ia) (▲) on ADP-induced human platelet aggregation. The compounds were added to platelet-rich plasma at 1 × 10⁻⁴ M concentration and incubated at 37°C for increasing intervals before the addition of ADP.*

7.98 (d, 1, J = 8 Hz, 7-H), 8.17 (d, 1, J = 5 Hz, 6-H), and 8.41 ppm (s, 1, 2-H).

Anal.—Calc. for $C_{18}H_{19}N_3O_9$: C, 51.31; H, 4.55; N, 9.97. Found: C, 51.18; H, 4.59; N, 10.06.

3 - (2',3',5'-Tri -*O*- acetyl-β-D-ribofuranosyl)-3*H*-imidazo-[4,5-*b*]pyridine (VIII)—An intimate mixture of II (200 mg, 1.66 mmol), 1,2,3,5-tetra-*O*-acetyl-β-D-ribofuranose (1 g, 3.3 mmol), and *p*-toluenesulfonic acid (20 mg) was heated at 160°C with stirring *in vacuo* (25 mm) for 20 min. The solid was neutralized with a saturated Na_2CO_3 solution and extracted several times with ethyl acetate. The combined extracts were concentrated *in vacuo* to dryness, and the residue was chromatographed on silica gel (ethyl acetate–methanol, 9:1) to give 320 mg (50%) of VIII as a vitreous solid.

Anal.—Calc. for $C_{17}H_{19}N_3O_7$: C, 54.11; H, 5.08; N, 17.28. Found: C, 53.98; H, 5.11; N, 17.42.

3-β-D-Ribofuranosyl-3*H*-imidazo[4,5-*b*]pyridine (Ih)—A solution of VIII (280 mg, 0.74 mmol) in methanol saturated with ammonia (15 mL) was set aside at room temperature for 24 h. The solvent was removed *in vacuo*, and the residue was crystallized from water to yield 160 mg (85%) of Ih, mp 220–221°C [lit. (18) mp 220–222°C]. ^{1}H-NMR (DMSO-d_6): δ 3.65 (m, 2, 5'-CH_2), 4.02 (m, 1, 4'-H), 4.22 (t, 1, 3'-H), 4.7 (t, 1, 2'-H), 6.1 (d, 1, J = 5.5 Hz, 1'-H), 7.36 (m, 1, 6-H), 8.16 (d, 1, J = 8 Hz, 7-H), 8.4 (d, 1, J = 4 Hz, 5-H), and 8.72 ppm (s, 1, 2-H).

Inhibition of Platelet Aggregation—Platelet aggregation was measured by the method of Born and Cross (5), using a platelet aggregation meter[4]. The aggregative agents ADP and collagen were purchased[5]; blood was obtained by venipuncture in the forearms of apparently healthy humans and collected in polyethylene tubes containing a 1:9 volume of 3.8% sodium citrate. Platelet-rich plasma was obtained by centrifugation at 1200 rpm for 10 min, while platelet-poor plasma was obtained by centrifugation at 4500 rpm for 20 min. The platelet-rich plasma was adjusted to ~250,000 platelets/mL by adding platelet-poor plasma.

A 50-μL aliquot of the test sample dissolved in Michaelis buffer was added to a cuvette containing 0.5 mL of platelet-rich plasma, and a 50-μL aliquot of Michaelis buffer was added to the test control. The cuvette was placed in the aggregation meter and allowed to incubate at 37°C for 5 min, after which 50 μL of ADP or collagen was added to the platelet-rich plasma. The final concentration of each sample is reported in Table I and in Figs. 1 and 2. The percent inhibition of aggregation by a test compound was calculated by dividing the maximal deflection in the optical density curve in the presence of the compound by that observed in the control, then multiplying by 100. As inhibition percentage differed from preparation to preparation of platelet-rich plasma, relative potency (RAD) to a reference standard (adenosine) in the same concentration was a direct measure of the potency of inhibition.

Degradation and Epimerization Kinetics of Moxalactam in Aqueous Solution

NAOFUMI HASHIMOTO ˣ, TAKENOBU TASAKI, and HIROYOSHI TANAKA

Received September 7, 1982, from the *Shionogi Research Laboratories, Shionogi & Co., Ltd., Fukushima-ku, Osaka 553, Japan.* Accepted for publication January 26, 1983.

Abstract □ The kinetics of epimerization and degradation of moxalactam in aqueous solution was investigated by HPLC. The pH–rate profiles of the degradation and epimerization were determined separately over the pH range of 1.0–11.5 at 37°C and constant ionic strength 0.5. The degradation and simultaneous epimerization were followed by measuring both of the residual *R*- and *S*-epimers of moxalactam and were found to follow pseudo-first-order kinetics. The degradation was subjected to hydrogen ion and hydroxide ion catalyses and influenced by the dissociation of the side chain phenolic group. The epimerization rates were influenced significantly in the acidic region by the dissociation of the side chain carboxylic acid group and in the basic region by hydroxide ion catalysis. The pH–degradation rate profile of moxalactam showed a minimum degradation rate constant between pH 4.0 and 6.0. The pH–epimerization rate profiles of moxalactam showed minimum epimerization rate constants at pH 7.0. The epimerization rate constants of the *R*- and *S*-epimers were not very different.

Keyphrases □ Moxalactam—degradation and epimerization in aqueous solutions, kinetics, HPLC □ Degradation—moxalactam in aqueous solutions, kinetics, epimerization □ Epimerization—moxalactam in aqueous solutions, kinetics, degradation □ Kinetics—moxalactam degradation and epimerization in aqueous solutions, HPLC

Stereoisomers, occurring widely in nature, display different biological and pharmacological effects than their racemic mixtures. Many β-lactam antibiotics have stereoisomers with different antibacterial activities (1). Few reports (2, 3) describe the kinetics of the epimerization of β-lactam antibiotics, a process which should offer valuable information for predicting and improving antibacterial activity.

Moxalactam (6059-S)[1] is a new semisynthetic (4), broad-spectrum (5) 1-oxacephalosporin which exists as the *R*- and *S*-epimers, epimeric at C-7. The *in vitro* activity of the *R*-epimer is twice that of the *S*-epimer (1). In the present study, the epimerization and degradation of moxalactam were investigated kinetically.

EXPERIMENTAL

Materials—*R*- and *S*-epimers of moxalactam disodium and decarboxy-moxalactam monosodium (decarboxylated in the 7-side chain)[1] were used as obtained. All other chemicals were of reagent grade. Water was purified with an ion-exchange column and distilled before being used.

pH—The pH of the solution was controlled throughout the reaction by a pH-stat[2]. The titrated volume of diluted hydrochloric acid or sodium hydroxide solution was at most 2% of the reaction volume. The ionic strength was adjusted to 0.5 by the addition of potassium chloride. No significant pH change was observed throughout the reaction. The pH meter[3] was standardized with the combination of standard buffer solutions of pH 4 and 7 or pH 7 and 9 at the temperature of the kinetic experiments.

Analytical Procedures—HPLC[4] was used to determine the concentrations of *R*- and *S*-epimers of moxalactam and decarboxy-moxalactam. Quantification was based on integration of peak areas using an integrator[5]. The elution was carried out on a 4.0 × 250-mm stainless steel column packed with octadecylsilane chemically bonded on silica gel[6] at room temperature. The mobile phase employed to resolve *R*- and *S*-epimers in the HPLC operation consisted of 0.05 M ammonium acetate–methanol (50:3). The mobile phase employed to resolve the decarboxy-moxalactam consisted of a solution containing 5.2 g of tetra-*n*-butylammonium hydroxide (10% in water), 6.1 g of tetra-*n*-propylammonium hydroxide (10% in water), 1.0 g of dibasic sodium phosphate, and 1.0 g of monobasic sodium phosphate, adjusted to pH 6.0 by acetic acid, and methanol (7:3). The mobile phases were prepared by micropore filtration[7] and deaerated. No difference in absorbance between *R*- and *S*-epimers was observed at any wavelength of the UV spectrum (6). Accordingly, the peak areas of *R*- and *S*-epimers represent their intact concentrations. The calibration curves of the peak area against the concentration of moxalactam was satisfactorily linear.

Kinetic Procedure—All kinetic experiments were carried out at 37

Degradation and Epimerization Kinetics of Moxalactam in Aqueous Solution

NAOFUMI HASHIMOTO ˣ, TAKENOBU TASAKI, and HIROYOSHI TANAKA

Received September 7, 1982, from the *Shionogi Research Laboratories, Shionogi & Co., Ltd., Fukushima-ku, Osaka 553, Japan.* Accepted for publication January 26, 1983.

Abstract □ The kinetics of epimerization and degradation of moxalactam in aqueous solution was investigated by HPLC. The pH–rate profiles of the degradation and epimerization were determined separately over the pH range of 1.0–11.5 at 37°C and constant ionic strength 0.5. The degradation and simultaneous epimerization were followed by measuring both of the residual *R*- and *S*-epimers of moxalactam and were found to follow pseudo-first-order kinetics. The degradation was subjected to hydrogen ion and hydroxide ion catalyses and influenced by the dissociation of the side chain phenolic group. The epimerization rates were influenced significantly in the acidic region by the dissociation of the side chain carboxylic acid group and in the basic region by hydroxide ion catalysis. The pH–degradation rate profile of moxalactam showed a minimum degradation rate constant between pH 4.0 and 6.0. The pH–epimerization rate profiles of moxalactam showed minimum epimerization rate constants at pH 7.0. The epimerization rate constants of the *R*- and *S*-epimers were not very different.

Keyphrases □ Moxalactam—degradation and epimerization in aqueous solutions, kinetics, HPLC □ Degradation—moxalactam in aqueous solutions, kinetics, epimerization □ Epimerization—moxalactam in aqueous solutions, kinetics, degradation □ Kinetics—moxalactam degradation and epimerization in aqueous solutions, HPLC

Stereoisomers, occurring widely in nature, display different biological and pharmacological effects than their racemic mixtures. Many β-lactam antibiotics have stereoisomers with different antibacterial activities (1). Few reports (2, 3) describe the kinetics of the epimerization of β-lactam antibiotics, a process which should offer valuable information for predicting and improving antibacterial activity.

Moxalactam (6059-S)[1] is a new semisynthetic (4), broad-spectrum (5) 1-oxacephalosporin which exists as the *R*- and *S*-epimers, epimeric at C-7. The *in vitro* activity of the *R*-epimer is twice that of the *S*-epimer (1). In the present study, the epimerization and degradation of moxalactam were investigated kinetically.

EXPERIMENTAL

Materials—*R*- and *S*-epimers of moxalactam disodium and decarboxy-moxalactam monosodium (decarboxylated in the 7-side chain)[1] were used as obtained. All other chemicals were of reagent grade. Water was purified with an ion-exchange column and distilled before being used.

pH—The pH of the solution was controlled throughout the reaction by a pH-stat[2]. The titrated volume of diluted hydrochloric acid or sodium hydroxide solution was at most 2% of the reaction volume. The ionic strength was adjusted to 0.5 by the addition of potassium chloride. No significant pH change was observed throughout the reaction. The pH meter[3] was standardized with the combination of standard buffer solutions of pH 4 and 7 or pH 7 and 9 at the temperature of the kinetic experiments.

Analytical Procedures—HPLC[4] was used to determine the concentrations of *R*- and *S*-epimers of moxalactam and decarboxy-moxalactam. Quantification was based on integration of peak areas using an integrator[5]. The elution was carried out on a 4.0 × 250-mm stainless steel column packed with octadecylsilane chemically bonded on silica gel[6] at room temperature. The mobile phase employed to resolve *R*- and *S*-epimers in the HPLC operation consisted of 0.05 M ammonium acetate–methanol (50:3). The mobile phase employed to resolve the decarboxy-moxalactam consisted of a solution containing 5.2 g of tetra-*n*-butylammonium hydroxide (10% in water), 6.1 g of tetra-*n*-propylammonium hydroxide (10% in water), 1.0 g of dibasic sodium phosphate, and 1.0 g of monobasic sodium phosphate, adjusted to pH 6.0 by acetic acid, and methanol (7:3). The mobile phases were prepared by micropore filtration[7] and deaerated. No difference in absorbance between *R*- and *S*-epimers was observed at any wavelength of the UV spectrum (6). Accordingly, the peak areas of *R*- and *S*-epimers represent their intact concentrations. The calibration curves of the peak area against the concentration of moxalactam was satisfactorily linear.

Kinetic Procedure—All kinetic experiments were carried out at 37

± 0.1°C and ionic strength 0.5 unless otherwise stated. The accurately weighed sample (*R*-epimer, *S*-epimer, or decarboxy-moxalactam) was dissolved in 1 mL of 0.5 M KCl and immediately diluted with 20 mL of 0.5 M KCl adjusted to the appropriate pH by the pH-stat and preheated to 37°C by a thermoregulator[8] with ±0.1°C precision. The final sample concentration was between 1×10^{-4} and 1×10^{-3} M. Portions were removed from the reaction solution at appropriate intervals and quickly frozen in a solid carbon dioxide–acetone bath. These were thawed just before HPLC analysis, and the remaining substances were determined.

Determination of Ionization Constants—The apparent ionization constants of moxalactam were determined potentiometrically (7) at ionic strength 0.5 and 37°C. The apparent ionization constants pK_{a1}, pK_{a2}, and pK_{a3}, which refer to the dissociation of the 4-carboxylic acid, the

7-side chain carboxylic acid, and the phenol group, were 2.17, 3.38, and 9.60, respectively (Scheme I).

RESULTS AND DISCUSSION

Order of Degradation and Observed Rate Constants—Typical chromatograms of acidic (pH 1.0) and basic (pH 10.2) reaction mixtures, sampled at suitable times, are shown in Fig. 1, indicating that the *R*-epimer, the *S*-epimer, and the degradation products can be reasonably separated from one another. The chromatogram taken at pH 1.0 shows the reaction mixture which started with the *R*-epimer and that taken at pH 10.2 shows the reaction mixture which started with the *S*-epimer. Decarboxy-moxalactam, one of the degradation products, was found as a single broad peak with a longer retention time under the HPLC conditions which separated the *R*- and *S*-epimers. So, decarboxy-moxalactam is not shown in the chromatograms of the reaction mixtures starting with the *R*- and *S*-epimers in Fig. 1. Figure 1 also shows a typical chromatogram of the basic (pH 9.0) reaction mixture of the decarboxy-moxalactam. The parent compound can be separated from the degradation products.

As shown in Fig. 2, the semilogarithmic plots of the percent residual total moxalactam and the percent residual decarboxy-moxalactam *versus* time were reasonably linear and indicated that the degradation of the drug and its analogue followed pseudo-first-order kinetics at constant pH, temperature, and ionic strength 0.5 under various pH conditions. The disappearance of the *R*-epimer and the appearance of the *S*-epimer and *vice versa* were measured under various pH conditions. Figure 3 shows typical plots of the percent residual *R*- and *S*-epimers of the initial concentration of moxalactam, which is the total concentration of *R*- and *S*-epimers at the time when the first portion was removed, at pH 2.32, 2.36 and 10.20. A reversible epimerization was found to occur between *R*- and *S*-epimers. Furthermore, since the total amount of *R*- and *S*-epimers decreased in a semilogarithmic linear fashion with time as shown in Figs. 2A and 3, the *R*- and *S*-epimers probably decompose to other products with almost the same degradation rate constant. If either the *R*- or *S*-epimer decomposes faster than the other, the semilogarithmic plots of the percent residual moxalactam *versus* time must curve at the early stage of the decomposition.

From these results, the concentration–time profiles at various pH values are thought to be a consequence of the reaction illustrated in Scheme II, where k_1 is the epimerization rate constant from *R*-epimer to *S*-epimer, k_2 is the reverse, and k_3 is the degradation rate constant of moxalactam (*R*- and *S*-epimers).

According to Scheme II, the following kinetic equations can be written for the *R*- and *S*-epimers:

$$d(R)/dt = -k_1(R) + k_2(S) - k_3(R) \quad \text{(Eq. 1)}$$

$$d(S)/dt = k_1(R) - k_2(S) - k_3(S) \quad \text{(Eq. 2)}$$

The differential equations for *R*- and *S*-epimers (Eqs. 1 and 2) can be solved using Laplace transforms. The solutions of Eqs. 1 and 2 are:

$$(R) = \frac{(R_0)k_2 + (S_0)k_2}{k_1 + k_2} \cdot e^{-k_3 t} + \frac{(R_0)k_1 - (S_0)k_2}{k_1 + k_2} \cdot e^{-(k_1+k_2+k_3)t} \quad \text{(Eq. 3)}$$

$$(S) = \frac{(R_0)k_1 + (S_0)k_1}{k_1 + k_2} \cdot e^{-k_3 t} - \frac{(R_0)k_1 - (S_0)k_2}{k_1 + k_2} \cdot e^{-(k_1+k_2+k_3)t} \quad \text{(Eq. 4)}$$

$$(R) + (S) = [(R_0) + (S_0)]e^{-kst} \qquad \text{(Eq. 5)}$$

where (R) and (S) represent the concentrations of the R- and S-epimers at time t, and (R_0) and (S_0) represent the initial concentrations of R- and S-epimers, respectively. The experimental data, typified in Fig. 3, were fitted using the integrated forms of the equations through nonlinear regression analysis (NONLIN) (8) and yielded excellent fits to the theoretical solid lines calculated from Eqs. 3 and 4.

Primary Salt Effects—The primary salt effects on the epimerization of R- and S-epimers were studied at pH 3.50 and 37°C. The ionic strength was varied by adding potassium chloride. Figure 4 shows semilogarithmic plots of the apparent epimerization rate constant, k_{pH}, *versus* the square root of ionic strength ($\sqrt{\mu}$) based on an extended and modified form of the Debye–Hückel equation (9). Plots based on this equation should yield a linear relationship with a slope proportional to the product of the charges carried by the reactive species forming the activated complex. Although this modified equation holds, in theory, only up to an ionic strength of ~0.01, it has been shown to predict the kinetic salt effect reliably in some pharmaceutical systems to as high as an ionic strength of unity.

The slopes of the regression lines in Fig. 4 fitted to the data at pH 3.50 were slightly negative, −0.08 and −0.19 for k_1 and k_2, respectively. Neither of these slopes exactly fits any theoretical model predicted by the equation used, but their relatively low values are probably more consistent with the absence of ionic charge on at least one reactant rather than charges on all reactants.

Dissociation Equilibrium—In the pH range studied, moxalactam exists in four different forms: as free RH_3, a monoanion RH_2^-, a dianion RH^{2-}, and a trianion R^{3-}. Some reports indicate that the pK_a value of the carboxylic acid group at the 4-position of cephalosporins is between 1.9 and 2.9 (10, 11).

These results support the assignment of $pK_{a1} = 2.17$ to the carboxylic acid group at the 4-position of the drug. Accordingly, the value of $pK_{a2} = 3.38$ can be attributed to the carboxylic acid group in the 7-side chain. The apparent pK_a values of RH_3, RH_2^-, and RH^{2-} are 2.17, 3.38, and 9.60, respectively (Scheme I).

pH–Rate Profile—The pH dependencies of overall first-order rate constants k_1 and k_2 of moxalactam epimerization and k_3 of moxalactam degradation at 37°C and ionic strength 0.5, are shown in Figs. 5 and 6. Figure 5 shows that the observed rates of the epimerization increased rapidly and uniformly with increasing pH above pH 7.5. Since the slopes of these straight-line portions of log k_{pH} *versus* pH profiles are unity, it is likely that dissociation of the phenolic group has no effect on the epimerization, and the specific hydroxide ion-catalyzed reactions of RH^{2-} and R^{3-} take place at almost the same rate in this pH region.

The profiles bent over to constant rates at pH values lower than pH 4, indicating that a dissociation constant, pK_{a2}, affected the epimerization rates. But the two reaction mechanisms, the hydrogen ion-catalyzed epimerization reaction of RH^{2-} and the water-catalyzed epimerization

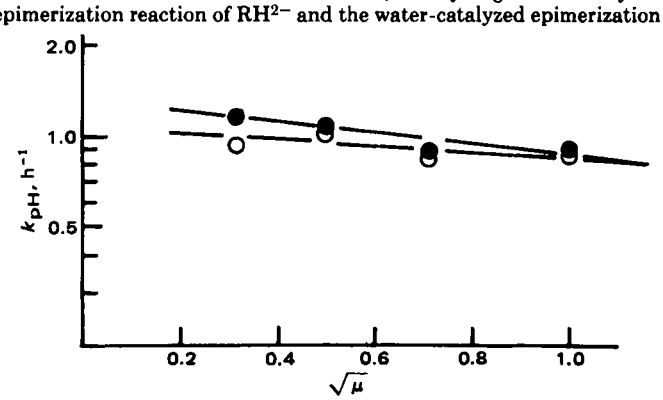

Figure 4—*Semilogarithmic plots of* k_{pH} versus *the square root of ionic strength* ($\sqrt{\mu}$) *for the epimerization of moxalactam at pH 3.50 and 37°C. Key:* (○) k_1; (●) k_2.

reactions of RH_3 and RH_2^- (undissociated moxalactam of the 7-side chain carboxylic acid group), give the same pH–rate profile and are kinetically equivalent in this pH range. However, it is possible to distinguish between the two reaction mechanisms according to the results of the primary salt effect of *R*- and *S*-epimers. The near lack of the primary salt effect at pH 3.50, where the concentrations of the undissociated and dissociated forms of the 7-side chain carboxylic acid group are almost the same (Fig. 4) indicates that the water-catalyzed epimerization reactions may occur below pH 6. Proton abstraction, which is important for epimerization, by the water-catalyzed reaction is more likely to occur than the hydrogen ion-catalyzed reaction due to water having stronger basicity than the hydrogen ion.

The total shape of log *k versus* pH profiles of moxalactam epimerization (k_1 and k_2) can be expressed by the following rate law:

$$k_{pH} = k_a\left(\frac{a_H}{K_{a2} + a_H}\right) + k_b + k_{OH}\left(\frac{K_w}{a_H}\right) \qquad \text{(Eq. 6)}$$

where k_a and k_b are the first-order rate constants of the undissociated and dissociated forms of the 7-side chain carboxylic acid group for the water-catalyzed epimerization, respectively, k_{OH} is the second-order rate constant for the hydroxide ion-catalyzed epimerization, and a_H and K_{a2} are the activity of hydrogen ion measured by the glass electrode and the dissociation constant of the 7-side chain carboxylic acid group, respectively. The value for the autoprotolysis constant of water, K_w, at 37°C is 2.38×10^{-14} (12). The solid lines in Fig. 5 represent the theoretical curves calculated by NONLIN and the points are the experimental results. The rate constants k_1 and k_2 with the best fits of the observed rate–pH profiles are given in Table I.

Figure 6 shows the log k_{pH}–pH profile for the degradation of moxalactam (k_3). The observed rate of the degradation decreased uniformly with increasing pH, and the slope of the straight-line portion of the log k_{pH} *versus* pH curve is negative unity below pH 2.5. The degradation rate of moxalactam between pH 4 and 6 showed pH independence, although there was a little dispersion. This implies that the overall degradation consists of the water-catalyzed or spontaneous reactions of moxalactam. Such a pH-independent degradation is known to be a common feature for the degradation of the β-lactam moiety of cephalosporins (10). There was a sigmoid dependence of k_{pH} on pH at pH values near pK_{a3}, followed by a rapid decrease of almost positive unity as the pH decreased. This inflection indicates that the degradation rate was influenced by the dissociation equilibria of the 7-side chain phenolic group (pK_{a3}). The observed rate of the degradation increased by positive unity with increasing pH above pH 10.5, which shows the hydroxide ion-catalyzed degradation.

The total shape of the log k_{pH}–pH profile of moxalactam degradation can be expressed by the following rate law:

$$k_{pH} = k_H a_H + k_c + k_d\left(\frac{K_{a3}}{K_{a3} + a_H}\right) + k_{OH}\left(\frac{K_w}{a_H}\right) \qquad \text{(Eq. 7)}$$

where k_c and k_d represent the first-order rate constants for the water-catalyzed degradation of dianionic and trianionic moxalactam, k_H and k_{OH} represent the second-order rate constants for the specific hydrogen ion-catalyzed and specific hydroxide ion-catalyzed degradation, and K_{a3} is the dissociation constant of the 7-side chain phenolic group.

In Fig. 6, the solid line represents the theoretical curve calculated by NONLIN. The rate constants in Eq. 7 that produced the best fit to the observed rate–pH profile are given in Table I; the white circles show the experimental results. The good agreement indicates that this equation adequately describes the kinetics of moxalactam degradation. The solid circles in Fig. 6 show the degradation rates of the decarboxy-moxalactam obtained from the slopes in Fig. 2B. The degradation rate of the drug is 1.5–3 times as large as the degradation rate of the decarboxy-moxalactam at pH 7.5 and 9.0, and little difference exists between the degradation rates at pH 0.9, 3.1, 10.2, and 11.0. These results suggest that a sigmoidal dependency of the degradation rate on pH below pH 10 comes from the spontaneous decarboxylation reaction of the dissociated moxalactam of

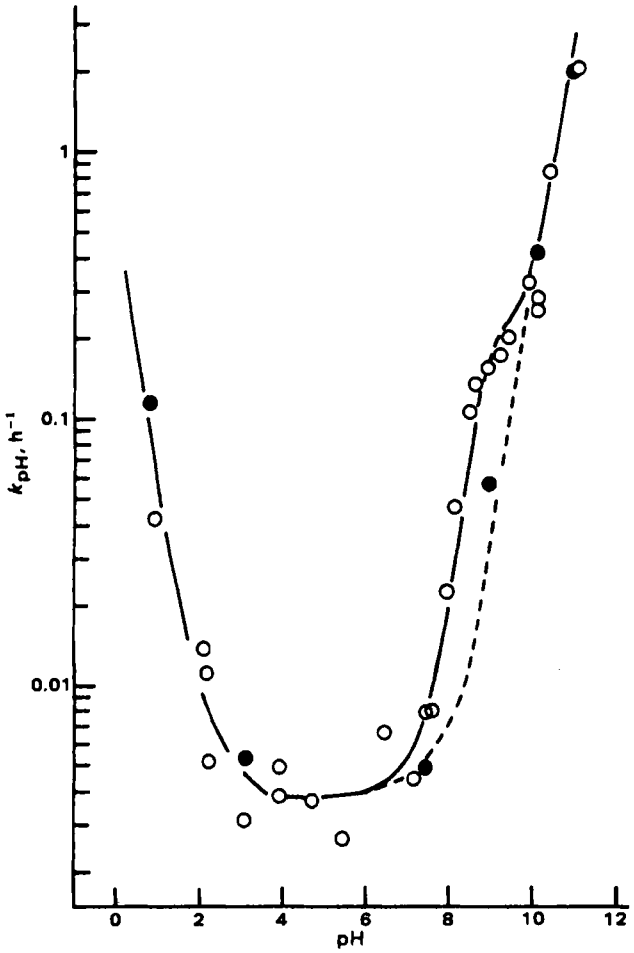

Figure 6—*Log k_{pH}–pH profiles for moxalactam (○) degradation (k_3) and the decarboxy-moxalactam (●) in aqueous solution at 37°C and ionic strength 0.5. The points are experimental values, and the solid line is the theoretical curve of moxalactam calculated from Eq. 7 and the constants in Table I.*

the 7-side chain phenolic group in parallel with the specific hydroxide ion-catalyzed degradation of the drug.

Epimerization Mechanism—The pH–epimerization rate profiles yielded straight lines with a slope of unity verifying first-order dependence on hydroxide ion in the basic region. The mechanism for the epimerization reaction can be written in terms of the abstraction of the α-proton by hydroxide ion leading to the formation of a planar carbanion (2). The mechanism for the epimerization reaction in the acidic region can be explained by the abstraction of the α-proton by water mainly from the undissociated moxalactam of the 7-side chain carboxylic acid group to the formation of a planar carbanion.

The relative order of k_a and k_b in Table I agrees with the decrease in electron-withdrawing by the dissociation of the 7-side chain carboxylic acid group attached to the α-carbon and causes a corresponding decrease in the rate of epimerization. On the other hand, the dissociation of the 7-side chain phenolic group had little influence on the epimerization rates. This is because the contribution of hydroxide ion toward the α-proton abstraction dominates in the basic region, and the influence of the dissociation of the phenolic group may disappear. However, factors other than the inductive effect of the substituents attached to the α-carbon may be considered in determining the rate of epimerization, as the stability of an enolate intermediate consisting of an amido or a carboxylic acid group resulting from the α-proton abstraction.

Structure–Activity Studies on Antihyperlipidemic *N*-Benzoylsulfamates, *N*-Benzylsulfamates, and Benzylsulfonamides

STEVEN D. WYRICK *x, IRIS H. HALL *, and AGNES DUBEY ‡

Received November 19, 1982, from the **Division of Medicinal Chemistry, School of Pharmacy, University of North Carolina, Chapel Hill, NC 27514* and the ‡*Chemistry and Life Sciences Group, Research Triangle Institute, Research Triangle Park, NC 27709.* Accepted for publication February 1, 1983.

Abstract □ A series of aryl substituted *N*-benzoyl- and *N*-benzylsulfamic acid sodium salts and benzylsulfonamide sodium salts have been prepared and examined for antihyperlipidemic activity in male CF_1 mice at a dose level of 20 mg/kg/d ip for 16 d. These substances were also subjected to toxicological evaluation and chemical stability studies. In general, both series of sulfamates and sulfonamides significantly lowered serum cholesterol and triglyceride levels in mice. The compounds were nonmutagenic, showed no acute toxicity or impaired liver or kidney function in male mice, and were chemically stable both as the monohydrates and in aqueous solution over a pH range of 3.5–7.4. While both series of sulfamates and sulfonamides lowered serum cholesterol and triglyceride levels, the sulfamates were relatively more potent with regard to decreasing cholesterol levels, while the sulfonamides were more effective in lowering serum triglyceride levels in mice.

Keyphrases □ *N*-Benzoylsulfamates—potential antihyperlipidemic agents, structure–activity relationships, mutagenicity, toxicity in mice □ *N*-Benzylsulfamates—potential antihyperlipidemic agents, structure–activity relationships, mutagenicity, toxicity in mice □ Benzylsulfonamides—potential antihyperlipidemic agents, structure–activity relationships, mutagenicity, toxicity in mice

Cardiovascular disease is currently a major cause of death of males in Western civilized societies. Atherosclerosis is characterized by partial or complete occlusion of the vessels that supply blood to the myocardial tissues, due primarily to the formation of the fibrous lesion known as a sclerotic plaque within the vessel lumen (1). Elevated levels of cholesterol and triglycerides have been detected in plaque cells, and there appears to be a link between plaque formation and long-term elevated serum lipids (2, 3). Therefore, lowering of elevated serum lipid levels either by dietary restriction or chemotherapy appears desirable.

It has been demonstrated that a wide structural variety of chemical agents are active as antihyperlipidemics (1) including the synthetic sweetening agent, saccharin (4). Saccharin has demonstrated significant antihyperlipidemic activity in male mice, with the optimum dose level of 20 mg/kg/d ip affording serum cholesterol levels 67 ± 10% of control values after 16 d of administration and triglyceride levels 51 ± 16% of control values after 14 d. A series of *N*-benzoylsulfamic acid sodium salts as acyclic analogues of saccharin were prepared in an attempt to improve the antihyperlipidemic activity while eliminating the undesirable effects which are associated with saccharin (5, 6). Also prepared were two other structurally related classes of compounds, *N*-benzylsulfamates and benzylsulfonamides. Structural modifications among the series include aromatic substitutions with groups that vary in their lipophilicity, electronic character, and steric parameters. In addition, replacement of the carbonyl function (*N*-benzoylsulfamates) by a methylene group (*N*-benzylsulfamates) and alteration of the relative position of the nitrogen atom with regard to the aromatic and sulfonyl functions (benzylsulfonamides) were examined.

Benzylsulfonamide (sodium salt)

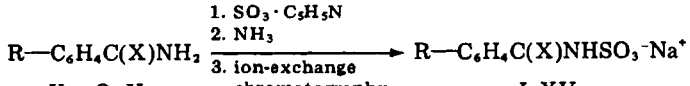
BACKGROUND

Few reports exist concerning the synthesis of *N*-benzoylsulfamates. The unsubstituted prototype was prepared by Baumgarten and Marggraff (7) by heating benzamide and pyridine–sulfur trioxide complex (pyr·SO_3) to the melting point with subsequent conversion to the sodium salt with aqueous sodium hydroxide. In our hands, this procedure afforded extremely low yields of the prototype and no product for any aryl-substituted derivative. Dipyridinium imidodisulfonate (8) has also been employed for the sulfonation of benzamide but, again, yields are on the order of 5–10%. Two procedures have been developed in this laboratory which permit the preparation of the series of aryl-substituted *N*-benzoyl- and *N*-benzylsulfamic acid sodium salts in significantly greater yields. The appropriate benzamide or benzylamine was treated with pyr·SO_3 in pyridine solution for 3–5 h at 80–90°C. The product was isolated as the ammonium salt and converted to the sodium salt by ion-exchange chromatography (Scheme I). In addition, the *N*-benzoylsulfamates may also be prepared by benzoylation of pyridinium sulfamate with the acid chloride in pyridine.

The benzylsulfonamides were prepared from the corresponding sulfonyl chlorides, which were obtained by treatment of the benzylisothioureas with chlorine at 0–10°C (9) (Scheme II). This procedure is satisfactory for derivatives that are substituted with electron-withdrawing groups or hydrogen atoms on the aromatic ring, whereas strong electron-releasing substituents (*i.e.*, OCH_3) induce chlorination of the aromatic ring during conversion to the sulfonyl chloride as evidenced by ^{1}H-NMR and MS data. This problem was circumvented by obtaining the nitrobenzylsulfonamide by the above procedure followed by introduction of the methoxy substituent *via* the diazonium tetrafluoroborate salt. The compounds prepared were examined for chemical stability at room temperature, both as the monohydrates and in aqueous solution, over a pH range of 3.5–7.4 using both reverse-phase HPLC and TLC to detect the formation of hydrolysis products (*i.e.*, benzamides and benzylsulfonic acids).

RESULTS AND DISCUSSION

Chemical stability studies using reverse-phase HPLC revealed that all of the compounds except VI were stable at room temperature both



$R—C_6H_4C(X)NH_2$ → $R—C_6H_4C(X)NHSO_3^-Na^+$

X = O, H_2 I–XV

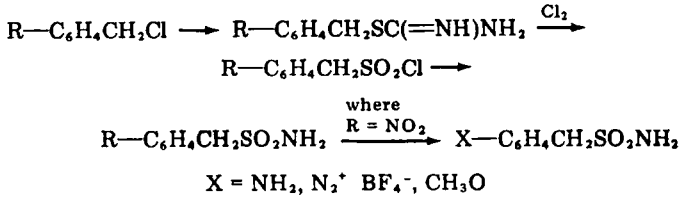
as the monohydrate and in aqueous solution over a pH range of 3.5–7.4 for a period of at least 60 d. Compound VI underwent 55–60% hydrolysis in solution after 30 d and was completely degraded after 60 d. This compound was also found to be completely hydrolyzed after 3 months when stored in solid form, and was therefore not evaluated biologically.

None of the compounds were found to be mutagenic in the Ames assay; however, all of the compounds exhibited toxicity to bacteria at the high-dose level of 3000 μg/plate. It is advisable to include one toxic dose level when testing unknown compounds for mutagenicity (10). The toxicity assay indicated essentially no cell death; therefore, the toxic effect at 3000 μg/plate was not due to cell death, but rather to the inhibition of revertent colony growth *via* another mechanism. Results of acute toxicity testing in male mice indicated that none of the compounds tested produced abnormal levels of alanine amino transferase (ALT) activity or urea nitrogen, nor were any signs of toxicity or abnormal behavior observed during the 14-d period. No abnormalities or irregular fluctuations in body weight were observed on termination of the study and gross necropsy. Likewise, no toxicity was observed during the course of the antihyperlipidemic study.

Of the two series, the *N*-benzoylsulfamates appear to be the more potent antihypercholesteremic agents with the *o*- and *p*-chloro derivatives (IV, II) being the most active (Table I). As indicated in Table II, electron-withdrawing substituents on the aromatic ring lend slightly greater activity to the series than do electron-releasing substituents. Activity decreases somewhat with increasing substituent size. In general, activity within the series does not appear to be heavily dependent on the size, electronic properties, or lipophilicity of the aromatic substituents as the unsubstituted prototype (VII) is also quite active. A significantly greater structural dependence within this series resides in the side-chain



Scheme II

requirement for the carbonyl function. By comparison of the *p*-Cl, *o*-Cl, *p*-OCH_3, and unsubstituted derivatives (II, IV, I, and VII, respectively) with their carbonyl-reduced counterparts among the *N*-benzylsulfamates (XV, XIV, XII, and XIII, respectively), it is evident that antihypercholesteremic activity is markedly reduced in the absence of the carbonyl function. This structural requirement for antihyperlipidemic activity has also been noted for saccharin as well as other imides (11).

Serum triglyceride levels are moderately reduced by the *N*-benzoylsulfamates, with the exception of the *p*-Cl (II) and *p*-isopropyl (XI) derivatives, which lower serum triglyceride levels to 55 ± 7% and 49 ± 8% of control values, respectively, by day 16. As in the case of antihypercholesteremic activity, the dependence on the presence of the side-chain carbonyl for antihypertriglyceridemic activity appears evident when comparing I, II, and VII with XII, XV, and XIII, respectively. However, *N*-benzylsulfamate (XIV) showed increased antihypertriglyceridemic activity compared with *N*-benzoylsulfamate (IV). Each of the *N*-benzoylsulfamates shows greater antihypercholesteremic activity than clofibrate, which is not active at 20 mg/kg, requiring dose levels of 150–200 mg/kg to reduce serum cholesterol ~15% in rodents. Saccharin at 20 mg/kg/d lowered serum cholesterol levels 35% and serum triglyceride

levels 46% in mice. Compounds I, II, III, IV,and VII are more active than saccharin in lowering serum cholesterol levels, but less active in lowering triglyceride levels.

Within the benzylsulfonamide series (Table III), the *o*-OCH_3 derivative (XVII) was the most active antihypercholesteremic agent, being equal in activity to saccharin. In general, moderate antihypercholesteremic activity is displayed by this series, whereas antihypertriglyceridemic activity surpasses that of the *N*-benzoylsulfamates and clofibrate. The *p*-Cl derivative (XXII) is equally active with saccharin in this respect. Compounds XVIII and XX are more active than saccharin, lowering serum triglyceride levels to 42% of control values. Comparing the activities of XVI, XVIII, XX, and XXII, the most active antihypertriglyceridemic agents in the series, no dependence on substituent parameters is evident.

EXPERIMENTAL

All chemicals were used as received from the manufacturer[1]. Melting points were obtained on a capillary melting point apparatus[2]. ^{1}H-NMR spectra[3] were obtained for all novel products. Elemental analyses[4] of all products were within ±0.4% of the theoretical values. Ion-exchange chromatography was performed using sodium-form resin[5]. Reverse-phase HPLC was performed on a gradient programmable high-pressure liquid chromatograph[6] with a C_{18} column[7] and radial compression module. Male CF_1 mice[8] were used for antihyperlipidemic testing.

Aryl-Substituted Benzamides—According to the procedure of Vogel (12), the appropriate benzoyl chloride was treated with cold concentrated NH_4OH. The product was filtered, dried, and recrystallized from ethanol–water.

***N*-Benzoyl- and *N*-Benzylsulfamic Acid Sodium Salts (I–XV)**—*General Procedure A*—The appropriate benzamide or benzylamine (5.0 g) and 1.1 equivalents of pyridine–sulfur trioxide complex were dissolved with warming in 50 mL of dry pyridine under nitrogen. The reaction was stirred at 80–90°C for 3–5 h, at which time TLC (ethyl acetate–acetic acid–water, 6:3:1) showed no further reaction. The solution was cooled in ice, and the excess precipitated pyridine–sulfur trioxide was removed by filtration and washed with cold pyridine. The filtrate was treated with gaseous ammonia for 10 min, concentrated *in vacuo* to approximately one-third its volume, and poured into ether–methanol (4:1) with vigorous stirring. The precipitated ammonium salt was collected, washed with ether, and dried. Conversion to the sodium salt was effected by dissolving the crude ammonium salt in the least amount of water (warming if necessary) followed by rapid elution with water from an ion-exchange resin (sodium ion form). The aqueous eluant was concentrated *in vacuo*, and the resulting crystals were stored at 3–5°C. The product was collected, washed with cold water, dried, and recrystallized from methanol to give material melting at ~100°C up to ~200°C (Table I).

General Procedure B—Pyridinium sulfamate (4–7 g) was suspended in 25 mL of dry pyridine under nitrogen. The appropriate benzoyl chloride (1.2 equivalents) was added dropwise, followed by stirring at 60°C for 3–4 h. Methanol (3.0 mL) was added, and the mixture was stirred for an additional 30 minutes, cooled to room temperature, treated with gaseous ammonia for 10 min; the sodium salt was prepared as in procedure A (Table I).

Aryl-Substituted Benzyl Chlorides—According to the procedure of Brooks and Snyder (13), the appropriate benzyl alcohol was treated with thionyl chloride in pyridine at room temperature and the product was distilled.

S-(*Substituted Benzyl*) *Isothiourea Hydrochlorides*—The procedure of Johnson and Sprague (9) was utilized. The appropriate benzyl chloride (0.05–0.2 mol) and one equivalent of thiourea were stirred under reflux in absolute ethanol (25 mL/0.05 mol of benzyl chloride) for 3–4 h. On cooling, the product crystallized in 85% yield. This material was used in the next step.

Substituted Benzylsulfonyl Chlorides—The appropriate *S*-(substi-

tuted benzyl) isothiourea hydrochloride was dissolved in water (600–700 mL/0.2 mol depending on solubility) and cooled in ice to 0–10°C. The solution was then treated with gaseous chlorine for 30 min while maintaining the temperature <10°C. The solid or oily product was extracted into ether, and the ether extracts were dried (sodium sulfate) and evaporated *in vacuo* to afford the product which was sufficiently pure for conversion to the sulfonamide.

Substituted Benzylsulfonamides (XVI, XX, XXI, and XXII)—The appropriate benzylsulfonyl chloride was dissolved in liquid ammonia, the resulting yellow solution was kept at −78°C for 1 h, and then the excess ammonia was allowed to evaporate. The residue was dissolved in chloroform and filtered. The filtrate was dried (sodium sulfate) and evaporated to afford the crude sulfonamide which was either recrystallized from ethanol or column chromatographed[9]. This material was converted to the sodium salt by treating an ethanolic solution with 1.0 equivalent of 12 M aqueous NaOH. On cooling, the precipitated salt was collected and dried *in vacuo*. These products were obtained in varying degrees of hydration (Table II). Melting points were >250°C.

Catalytic Reduction of Nitrobenzylsulfonamides—A solution of the appropriate nitro-substituted benzylsulfonamide (prior to sodium salt formation) was dissolved in absolute ethanol (1600 mL/34 g of substrate) and was shaken for 6–8 h at 40°C[10] with 1.0 g of 5% palladium-on-charcoal under 60 psi of hydrogen. When the reaction was complete by TLC, the catalyst was removed by filtration, and the filtrate was evaporated *in vacuo* to afford an essentially quantitative yield of the aniline compound.

Diazotization of Aminobenzylsulfonamides (14)—A 24% solution of fluoroboric acid (0.12 mol) was added dropwise with cooling and stirring to 9–10 g of the aniline. The resulting solution was maintained at 0–5°C while an aqueous solution of $NaNO_2$ (0.048 mol) was added dropwise with stirring, and then the mixture was stirred at 0–5°C for 1.5 h. The precipitated salt was collected by filtration, washed with 5% HBF_4, cold methanol, and cold ether, and then was dried *in vacuo* to afford light-tan crystals.

Methoxybenzylsulfonamides (15) (XVII, XVIII, and XIX)—A solution of the above diazonium fluoroborate salt in methanol (1200 mL/10 g) was heated at 50°C for 5 h. The orange solution was then evaporated to dryness *in vacuo*, and the residue was column chromatographed[11] to afford material which was converted to the sodium salt as described above (Table II).

Ames Mutagenicity Assay (16, 17)—Compounds I–V, VII, and XII–XXII were each added to test culture plates in triplicate with and without mammalian microsomal activator S-9 present in the culture medium at dose levels of 0.3, 3, 30, 300, and 3000 μg/plate. Each compound was tested with five strains of non-histidine-producing *Salmonella typhimurium*. A threefold increase in the number of colonies per plate over background control constituted a positive mutagenic result. Control groups were treated only with the dosing vehicle (dimethyl sulfoxide).

Acute Toxicity Studies—Compounds I–V, VII, and XII–XXII were subjected to acute toxicity studies in male CD-1 mice (20–30 g)[12] in full compliance with the Food and Drug Administration Good Laboratory Practices Regulations for Nonclinical Laboratory Studies (18). Blood samples were taken by tail vein bleeding 3 d before dosing and at sacrifice on day 14 to be used for biochemical testing of liver and kidney function. Animals were weighed on days 0, 7, and 14. A single 100-mg/kg dose as a 1% solution in sterile water was administered by oral intubation on day 0. At this time and at various times throughout the day for 14 d, the animals were observed for signs of toxicity and/or abnormal behavior. Six animals were used per test compound. The animals were maintained on rodent diet[13] and water *ad libitum*. On day 14, the animals were weighed, sacrificed, and gross necropsies performed. The blood samples were assayed for alanine amino transferase activity as a test for liver function and urea nitrogen as a test for kidney function. The tests were performed on a miniature centrifugal fast analyzer. Each individual assay included 1 blank, 13 samples, and 2 controls (commercial sera samples of normal and abnormal alanine amino transferase and urea nitrogen levels). Abnormal values were defined as being >2 *SD* from untreated group values.

Assay for Antihyperlipidemic Activity—Compounds I–V and VII–XXII, as well as saccharin and clofibrate, were administered daily to male CF_1 mice (~28 g) as a 1% carboxymethylcellulose suspension at 20 mg/kg/d ip. On days 9 and 16, blood was obtained by tail vein bleeding and, after centrifugation to obtain serum, 25-μL samples were assayed for total cholesterol by the procedure of Ness *et al.* (19). Serum triglycerides were assayed using a commercial kit[14] on blood collected on the 16th day. By comparison to standards, the amounts of cholesterol (mg %) and triglycerides (mg/dL) were calculated. Treated values were expressed as percent of control (Table III).

Chemical Stability Studies—A 1% solution of each compound prepared in pH 3.5 citrate buffer, distilled water, and phosphate buffer (pH 7.4) was allowed to stand at room temperature. These solutions, as well as a 1% solution in distilled water of each compound which had been stored in solid form at room temperature, were analyzed directly by reverse-phase HPLC (C_{18}, 254 nm, 10% aqueous acetonitrile) for the presence of benzamides, benzylsulfonic acids, or other decomposition products on days 2, 6, 18, 30, and 60. These studies were paralleled using reverse-phase TLC plates[15] with methanol–water (9:1).

Antihyperlipidemic Activity of *o*-Chlorobenzylsulfonamide in Rodents

IRIS H. HALL *, STEVEN D. WYRICK *x, P. JOSÉE VOORSTAD *, and AGNES DUBEY ‡

Received November 19, 1982, from the **Division of Medicinal Chemistry, School of Pharmacy, University of North Carolina, Chapel Hill, NC 27514* and ‡*Research Triangle Institute, Research Triangle Park, NC 27709.* Accepted for publication February 1, 1983.

Abstract □ *o*-Chlorobenzylsulfonamide was observed to be a potent hypolipidemic agent in rodents, reducing serum cholesterol levels 71% and triglyceride levels 49% at 60 mg/kg/d. The agent was effective both in normal and hyperlipidemic mice and was active both orally and intraperitoneally. *o*-Chlorobenzylsulfonamide significantly inhibited phosphatidate phosphohydrolase activity and marginally inhibited *sn*-glycerol-3-phosphate acyl transferase activity both *in vitro* and *in vivo*. The lowering of serum cholesterol levels appeared to be correlated with the accelerated excretion of cholesterol *via* the bile into the feces, with a marginal reduction of cholesterol absorption from the intestine. Reduced concentrations of lipids, *e.g.*, cholesterol, triglycerides, and neutral lipids, were observed in the liver, small intestine, and blood lipoprotein fractions of rats.

Keyphrases □ *o*-Chlorobenzylsulfonamide—antihyperlipidemic activity, rodents, cholesterol, triglycerides □ Antihyperlipidemic agents—potential, *o*-chlorobenzylsulfonamide, activity in rodents, cholesterol, triglycerides

Recently a series of *N*-benzoylsulfamates, *N*-benzylsulfamates, and benzylsulfonamides were shown to be potent hypolipidemic agents in mice (1). These agents were examined for hypolipidemic activity because of their structural resemblance to saccharin, which has been shown to lower serum cholesterol levels 33% and serum triglyceride levels 49% in mice (2) at a dose of 20 mg/kg/d for 16 d. *o*-Chlorobenzylsulfonamide was observed to lower serum cholesterol levels 27% and serum triglyceride levels 48% after dosing for 16 d at 20 mg/kg/d in mice (1). This series of compounds was nonmutagenic and demonstrated no acute toxicity or impaired liver or kidney functions in male mice (1). Since the saccharin moiety has been associated with potential carcinogenicity, and consequently may not be a desirable hypolipidemic agent, we decided to investigate the effects of *o*-chlorobenzylsulfonamide on lipid metabolism to assess the possibility of this compound being a more feasible therapeutic agent.

EXPERIMENTAL

Source of Compound—The sodium salt of *o*-chlorobenzylsulfonamide was prepared as described previously (1).

Antihyperlipidemic Screens in Normal Rodents—The sodium salt of *o*-chlorobenzylsulfonamide was suspended in 1% carboxymethylcellulose–water and administered to male CF_1 mice (~25 g) intraperitoneally for 15 d or male Holtzman rats (~350 g) orally by an intubation needle for 14 d. On days 9 and 14 or 15, blood was obtained by tail vein bleeding, and the serum was separated by centrifugation for 3 min. The serum cholesterol levels were determined by a modification of the Liebermann–Burchard reaction (3). Serum was also collected on day 14 or 15 and the triglyceride content was determined by a commercial kit[1].

Testing in Atherogenic Mice—Male CF_1 mice (~25 g) were placed on a commercial diet[2] which contained butterfat (400 g), cellulose[3] (60 g), cholesterol (53 g), choline dihydrogen citrate (4 g), salt mixture oil[4] (40 g), sodium cholate (20 g), sucrose (223 g), vitamin-free casein (200 g), and total vitamin supplement for 10 d. After the cholesterol and triglyceride levels were assayed and observed to be elevated, the mice were administered test drugs at 20 mg/kg/d ip for an additional 12-d period. Serum cholesterol and triglyceride levels were measured after 12 d of drug administration.

Animal Weights and Food Intake—Periodic animal weights were obtained during the experiments and expressed as a percentage of the animal's weight on day 0. After dosing for 14 d with test drugs, selected organs were excised, trimmed of fat, and weighed.

Toxicity Studies—The acute toxicity (LD_{50} value) (4) was determined in male CF_1 mice by administering test drugs intraperitoneally from 100 mg to 2 g/kg as a single dose. The number of deaths were recorded over a 7-d period for each group.

Enzymatic Studies—*In vitro* enzymatic studies were determined using 10% homogenates of male CF_1 mouse liver with 2.5–10 μmol of the test drugs. *In vivo* enzymatic studies were determined using 10% homogenates of liver from male CF_1 mice obtained after administering the agents for 15 d at a dose ranging from 10–60 mg/kg/d ip. The liver homogenates for both *in vitro* and *in vivo* studies were prepared in 0.25 mM EDTA [(ethylenedinitrilo)tetraacetic acid].

Acetyl-CoA synthetase (5) and adenosine triphosphate-dependent citrate lyase (6) activities were determined spectrophotometrically at 540 nm as the hydroxamate of acetyl CoA formed after 30 min at 37°C. Mitochondrial citrate exchange was determined by the procedure of Robinson *et al.* (7, 8) using sodium [^{14}C]bicarbonate (41 mCi/mmol) incorporated into mitochondrial [^{14}C]citrate after isolating rat mitochondria (9000×*g* for 10 min) from the homogenates. The exchange of the [^{14}C]citrate was determined after incubating the mitochondrial fraction, which was loaded with labeled citrate and test drugs, for 10 min. Radioactivity was measured in the mitochondrial and supernatant fractions in scintillation fluid[5] and expressed as a percentage. Cholesterol side-chain oxidation was determined by the method of Kritchevsky and Tepper (9) using [26-^{14}C]cholesterol (50 mCi/mmol) and mitochondria isolated from rat liver homogenates. After an 18-h incubation at 37°C with the test drugs, the generated $^{14}CO_2$ was trapped in the center well in {2-[2-(*p*-1,1,3,3-tetramethylbutylcresoxy)ethoxy]ethyl}dimethylbenzylammonium hydroxide[6] and counted[5]. 3-Hydroxy-3-methylglutaryl CoA reductase (HMG-CoA reductase) was measured using [1-^{14}C]acetate (56 mCi/mmol) and a postmitochondrial supernatant (9000×*g* for 20 min) incubated for 60 min at 37°C (10). The digitonide derivative of cholesterol was isolated and counted (11). Acetyl-CoA carboxylase activity was measured by the method of Greenspan and Lowenstein (12). Initially, the subunits of the enzyme had to be polymerized for 30 min at 37°C, and then the assay mixture containing sodium [^{14}C]bicarbonate (41.0 mCi/mmol) was added and incubated for 30 min at 37°C with test drugs. Fatty acid synthetase activity was determined by the method of Brady *et al.* (13) using [2-^{14}C]malonyl CoA (37.5 mCi/mmol), which was incorporated into newly synthesized fatty acids that were extracted with ether and counted[5]. *sn*-Glycerol-3-phosphate acyl transferase activity was determined with glycerol-3-phosphate [2-^{3}H] (7.1 Ci/mmol) and the microsomal fraction of the liver homogenates (14). The reaction was terminated after 10 min, and the lipids were extracted with chloroform–methanol (1:2) containing 1% concentrated HCl and counted. Phosphatidate phosphohydrolase activity was measured as the inorganic phosphate released after 30 min from phosphatidic acid by the method of Mavis *et al.* (15). The released inorganic phosphate after development with ascorbic acid and ammonium molybdate was determined at 820 nm.

Liver, Small Intestine and Fecal Lipid Extraction—In male CF_1 mice that had been administered test drugs for 15 d, the liver, small intestine, and fecal materials (24-h collection) were removed and a 10%

[j] 537,800 ± 43,024 dpm of triglyceride formed/g of wet tissue/10 min. [k] $p \leq 0.001$.

homogenate in 0.25 M sucrose plus 0.001 M EDTA was prepared. A 2-mL aliquot of the homogenate was extracted by the methods of Folch *et al.* (16) and Bligh and Dyer (17) and the milligrams of lipid were determined. The lipid was taken up in methylene chloride and the cholesterol level (3), triglyceride levels[7], neutral lipid content (18), and phospholipid content (19) were determined.

[^{3}H]Cholesterol Distribution in Rats—Male Holtzman rats (~350 g) were administered test agents orally for 14 d. On day 13, 10 μCi of [^{3}H]cholesterol was administered intraperitoneally to mice and orally to rats, and feces were collected after 24 h. Twenty-four hours after cholesterol administration, the major organs were excised and samples of blood, chyme, and urine were obtained. Homogenates (10%) of the tissues were prepared, combusted[8], and counted[5]. Some tissue samples were plated on filter paper[9], dried, and digested for 24 h in base[6] at 40°C and counted[5]. Results were expressed as dpm per total organ.

Cholesterol Absorption Study—Male Holtzman rats (~400 g) were administered test drug intraperitoneally for 14 d at 20 mg/kg/d. On day 13, 10 μCi of [1,2-^{3}H]cholesterol (40.7 Ci/mmol) was administered to the rat orally. Twenty-four hours later, blood was collected and the serum separated by centrifugation (20). Both the serum and the precipitate were counted[5].

Bile Cannulation Study—Male Holtzman rats (~400 g) were treated with test drugs at 20 mg/kg/d orally for 14 d. The rats were anesthetized with chlorpromazine[10] at 25 mg/kg followed after 30 min by pentobarbital[11] (22 mg/kg ip). The duodenum of the small intestine was isolated and ligatures were placed around the pyloric sphincter and distally to a site approximately one-third of the way down the duodenum. Sterile isotonic saline was injected into the sectioned off duodenal segment. The saline expanded the duodenum and the common bile duct. Once the bile duct was identified, a loose ligature was placed around it, an incision was made, and plastic tubing[12] was introduced into the duct. Once past the ligature, the tubing was tied in place, and the ligatures around the duodenum were removed. Once bile was freely moving down the cannulated tube, [1,2-^{3}H]cholesterol (40.7 mCi/mmol) was injected subcutaneously into the rats. The bile was collected over the next 6 h and measured (in milliliters). Aliquots were counted[5] as well as analyzed for cholesterol content (3).

[12] PE-10 Intramedic polyethylene tubing.

Plasma Lipoprotein Fractions—Male Holtzman rats (~400 g) were administered test drugs at 20 mg/kg/d for 14 d. On day 14, blood was collected from the abdominal aorta. Serum was separated from whole blood by centrifugation at 3500 rpm. Aliquots (3 mL) were separated by density gradient ultracentrifugation into the chylomicrons, very low-density lipoproteins, high-density lipoproteins, and low-density lipoproteins according to the methods of Hatch and Lees (21) and Havel *et al.* (22). Each of the fractions was analyzed for cholesterol (3), triglyceride[7], neutral lipids (18), phospholipids (19), and protein levels (23).

RESULTS

Data in the tables are expressed as the mean percent of control ± the standard deviation. The probable significant level (p) between each test group and the control group was determined by the Student's t test.

o-Chlorobenzylsulfonamide was found to effectively lower serum cholesterol and triglyceride levels in rats and mice (Table I). In mice, the agent lowered serum cholesterol levels after intraperitoneal administration in a dose-dependent manner with 60 mg/kg/d affording 44% reduction, the maximum effect observed. Serum triglyceride levels were also reduced in a dose-dependent manner, with 60 mg/kg/d resulting in 71% reduction on day 15. After 14 d of oral administration at 20 mg/kg/d to rats, *o*-chlorobenzylsulfonamide reduced serum cholesterol levels 29% and serum triglyceride levels 49%, comparable to the same reductions observed in mice at 20 mg/kg/d. Subsequent to inducing a hyperlipidemic state in mice, in which case serum cholesterol levels were elevated 183% (354 mg%) above normal control values (125 mg%), the agent reduced serum cholesterol levels to 76% (220 mg%) above normal serum cholesterol levels. Serum triglyceride levels were elevated 168% (367 mg/dL) above the control value (137 mg/dL) by the high lipid diet; however, drug administration reduced the serum triglyceride levels to 40% (192 mg/dL) above control triglyceride values. Whereas the agent did not lower serum lipids absolutely to the normal value in male CF_1 mice, a significant reversal of the induced hyperlipidemic state was observed by drug administration for 12 d. The LD_{50} value for the agent was 400 mg/kg.

In vitro mouse liver enzymatic studies (Table II), with *o*-chlorobenzylsulfonamide at 50–200 μM final concentration, showed that citrate lyase and acetyl CoA synthetase activities were not inhibited by the agent. Mitochondrial citrate exchange and HMG-CoA reductase activity were marginally inhibited by the agent (0–20%). Acetyl-CoA carboxylase activity was reduced 30% at 50 μM, and fatty acid synthetase was inhibited 20–30%. *sn*-Glycerol-3-phosphate acyl transferase activity was reduced in a dose-dependent manner, with 200 μM affording 39% inhibition. Phosphatidate phosphohydrolase activity was markedly inhibited

(76–78%) by *o*-chlorobenzylsulfonamide from 50–200 μM. Cholesterol side-chain oxidation was reduced 52% at 100 μM.

In vivo enzymatic studies (Table III) in mice showed similar patterns of inhibition by *o*-chlorobenzylsulfonamide. Citrate lyase, HMG CoA reductase, and acetyl CoA carboxylase activities were essentially unaffected by drug administration. Acetyl-CoA synthetase and fatty acid synthetase activities were inhibited 22 and 23%, respectively, at 40 mg/kg/d after 15 d of drug administration. Acyl transferase activity was inhibited 22–27% at doses from 20–60 mg/kg/d.

Phosphatidate phosphohydrolase activity was inhibited 72% at 10 and 20 mg/kg/d, 68% at 40 mg/kg/d, and 46% at 60 mg/kg/d. The inhibition of phosphatidate phosphohydrolase activity was of a magnitude to account for the degree of reduction of serum triglyceride levels observed after *o*-chlorobenzylsulfonamide treatment. However, the enzymes involved in cholesterol synthesis were essentially unaffected by the agent. Thus, it seemed important to examine the effect of the agent on cholesterol distribution and excretion (Tables IV and V).

o-Chlorobenzylsulfonamide markedly accelerates the movement of cholesterol through the normal excretion routes, *i.e.*, high values of [^{3}H]cholesterol content were observed in fecal and urine collections. Both kidney and urine showed increases (16% and 40%, respectively) of [^{3}H]-cholesterol content after drug administration. The small intestine (115%), large intestine (71%), chyme (77%), and feces (185%) all demonstrated increases of [^{3}H]cholesterol content in the respective organs above that of the control. Studies of the actual lipid content of the liver and small intestine of the rats showed a decrease in cholesterol, triglycerides, and neutral lipid levels compared with the control. The reduction of small intestine lipids was greater than that observed in liver. Feces showed an increase in cholesterol and phospholipid levels, but a reduction in triglyceride and neutral lipid levels. The bile cholesterol, triglyceride, and phospholipid levels were increased, with neutral lipid levels being affected the least. Marginal inhibition (20%) by the agent of cholesterol absorption from the intestine after oral administration of [^{3}H]cholesterol was observed.

The lipoprotein fractions were also examined for cholesterol content, which was lower in the chylomicron, low-density, and high-density fractions. All four fractions were reduced in triglyceride and neutral lipid content; however, phospholipid content was elevated in all four fractions after drug administration. Protein content of the lipoprotein fractions was not altered by drug administration.

Table V—Rat Organ Weights and Radioactivity Distribution of 10 μCi of [^{3}H]Cholesterol After 14 d of Dosing with *o*-Chlorobenzylsulfonamide at 20 mg/kg/d[a]

[a] Administered as a suspension of the sodium salt in 1% carboxymethylcellulose.

DISCUSSION

o-Chlorobenzylsulfonamide appears to be active in a safe therapeutic range. Whereas it was more effective in lowering serum triglycerides, significant effects were also observed for serum cholesterol. The agent was active orally and intraperitoneally in both normal and hyperlipidemic mice and was shown to be a more potent hypolipidemic agent than clofibrate. Clofibrate at 150–200 mg/kg lowers rat cholesterol levels 15% maximally and serum triglyceride levels 25% (24). *o*-Chlorobenzylsulfonamide did not suppress *de novo* cholesterol synthesis in a manner similar to clofibrate at HMG CoA reductase, the regulatory site. However, like clofibrate, *o*-chlorobenzylsulfonamide did accelerate cholesterol excretion *via* the bile and feces. The lipids removed from the blood compartment were not deposited in the major organs. This can be observed from three different types of studies: (*a*) there was no increase in organ weight, (*b*) lipid content of the organs examined was reduced, and (*c*) the [^{3}H]cholesterol distribution studies showed lower content in the treated animals than the normal tissue.

The reduction of serum triglyceride levels can be explained by the observed reduction of phosphatidate phosphohydrolase and *sn*-glycerol-3-phosphate acyl transferase activities by *o*-chlorobenzylsulfonamide. There appears to be a positive correlation between the two events, since clofibrate (14), saccharin (2), and phthalimide (25) all reduce the activity of these two enzymes and reduce serum triglyceride levels in rodents. Both enzymes play a major regulatory role in the synthesis of triglycerides.

The effects of *o*-chlorobenzylsulfonamide on the lipid content of lipoprotein fractions were varied. Nevertheless, a marked reduction of triglyceride content of chylomicrons and very low-density lipoproteins (*i.e.*, the lipoproteins which have the highest triglyceride content), as well as minor reduction of low- and high-density lipoprotein triglyceride content, were observed after drug treatment. Cholesterol content was marginally reduced (29–15%) in the chylomicron and high-density fractions. Whereas it is difficult to extrapolate observations of lipid reduction of rat lipoprotein fractions by an agent to human lipoproteins, these studies do indicate that *o*-chlorobenzylsulfonamide has the capability to modulate lipid content of lipoprotein fractions and may have the potential to affect the lipoprotein lipid levels of humans.

Received October 25, 1982, from the *Faculty of Pharmaceutical Sciences, Kumamoto University, Kumamoto, 862, Japan, ‡Research Institute, Ono Pharmaceutical Co., Ltd., Osaka, 618, Japan, and §Biophysics Division, National Cancer Research Institute, Tokyo, 104, Japan. Accepted for publication January 27, 1983.

Abstract □ A solid complex of prostaglandin $F_{2\alpha}$ (dinoprost) with γ-cyclodextrin in a molar ratio of 1:1 was obtained on the basis of the B_S-type phase solubility diagram. The mode of interaction in the solid state was studied by powder X-ray diffractometry, thermal analysis, and carbon-13 cross polarization/magic angle spinning nuclear magnetic resonance (^{13}C-CP/MAS-NMR) spectrometry. The X-ray diffraction and NMR data suggested that prostaglandin $F_{2\alpha}$ is included in the cylindrical channels formed by coaxial alignment of γ-cyclodextrin molecules to give a channel type structure. Dissolution and thermal behaviors of the prostaglandin $F_{2\alpha}$–γ-cyclodextrin complex were examined and compared with the drug itself. The result indicated that the γ-cyclodextrin complex may have great utility as a rapidly dissolving form of prostaglandin $F_{2\alpha}$ with improved thermal stability.

Keyphrases □ Prostaglandin $F_{2\alpha}$—inclusion complex with γ-cyclodextrin, solution and solid phases, solubility, dissolution behavior □ γ-Cyclodextrin—inclusion complex with prostaglandin $F_{2\alpha}$, solution and solid phases, solubility, dissolution behavior □ Solubility—prostaglandin $F_{2\alpha}$–γ-cyclodextrin inclusion complex, dissolution behavior □ Dissolution—prostaglandin $F_{2\alpha}$–γ-cyclodextrin complex, solubility

Prostaglandins are essentially long-chain fatty acids containing a substituted cyclopentane ring system. The relative hydrophobic environment of the cyclodextrin cavity seems to be particularly favorable for inclusion of the highly hydrophobic prostaglandin molecules. The complexation of α- and β-cyclodextrins with some prostaglandin analogues including prostaglandin $F_{2\alpha}$ (dinoprost)[1] have been reported (1–3). Frank and Cho have recently reported the complexing behavior of dinoprostone (prostaglandin E_2) with β-cyclodextrin in water (4). Unfortunately, an attempt to isolate the solid complex from α- or β-cyclodextrin solution was unsuccessful because the prostaglandin molecule is too bulky to be completely included into the cavities of α- and β-cyclodextrins.

Continuing these investigations, we now report an inclusion complexation of prostaglandin $F_{2\alpha}$ with γ-cyclodextrin, which has a larger hydrophobic cavity than α- and β-cyclodextrins [internal diameters of α-, β-, and γ-cyclodextrins are 5.0, 6.2, and 7.9 Å, respectively (5)]. Solubility analysis, X-ray diffractometry, and thermal analysis were used in the present study, and in addition carbon-13 cross polarization/magic angle spinning nuclear magnetic resonance (^{13}C-CP/MAS-NMR) spectrometry was employed to gain insight into the mode of interaction in the solid phase. Furthermore, the dissolution and thermal behaviors of the complex were examined.

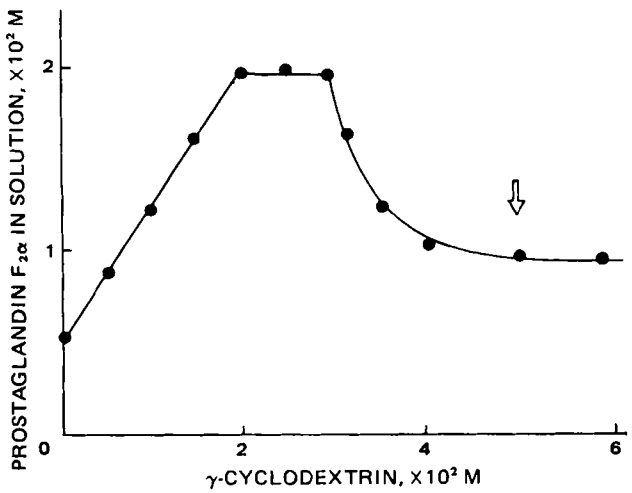

Figure 1—*Phase solubility diagram of the prostaglandin $F_{2\alpha}$–γ-cyclodextrin system in water at 25°C. The arrow shows the experimental condition of the preparation of the solid complex (see text).*

EXPERIMENTAL

Materials—Prostaglandin $F_{2\alpha}$[2] and γ-cyclodextrin[3] were used as supplied. All other materials and solvents were of analytical reagent grade. Deionized, double-distilled water was used.

Solubility Studies—Solubility measurements were carried out according to Higuchi and Lach (6). Excess amounts of prostaglandin $F_{2\alpha}$ were added to aqueous solutions containing various concentrations of γ-cyclodextrin and were shaken at 25 ± 0.5°C. After equilibration was attained (~2 d), an aliquot was centrifuged and pipetted through a cotton filter. A 0.5-mL aliquot of the sample solution was extracted with 5 mL of ether from acidified media, and 3 mL of the ether phase was evaporated to dryness under reduced pressure. The concentration of prostaglandin

Table I—Diffraction Data for Prostaglandin $F_{2\alpha}$–γ-Cyclodextrin Complex

hkl[a]	d, Å Observed	d, Å Calculated
200	14.68	14.68
220	8.47	8.48
420	5.54	5.55
620	4.07	4.07

[a] Hexagonal indices.

$F_{2\alpha}$ was determined by GC according to the method of Roseman and Yalkowsky (7). The chromatographic conditions were the same as those reported previously (1). The apparent 1:1 stability constant (K') was calculated from the slope and intercept of the initial straight-line portion of the phase solubility diagram according to the following (8):

$$K' = \frac{\text{slope}}{\text{intercept}\,(1 - \text{slope})}$$

Preparation of the Solid Complex—The solid complex was derived by mixing appropriate amounts of prostaglandin $F_{2\alpha}$ and γ-cyclodextrin in water. The amounts were calculated from the descending curvature of the phase solubility diagram. For example, 100 mg of prostaglandin $F_{2\alpha}$ and 650 mg of γ-cyclodextrin were added to 10 mL of water, sealed in a flask, and stirred at 25°C for 2 d. The complex, which precipitated as a microcrystalline powder, was filtered and dried under vacuum at room temperature for 2 d. This powder corresponded to a complex of prostaglandin $F_{2\alpha}$–γ-cyclodextrin, in a molar ratio of 1:1 which had a molecular weight of 1652 (±5%).

X-Ray Diffractometry—The powder X-ray diffractometer[4] was operated under the following conditions: X-ray, Ni-filtered Cu-K_α radiation; voltage, 30 kV; current, 20 mA; time constant, 2 s; scanning speed, 1°/min.

Differential Thermal Analysis (DTA)—The thermometer[5] was operated at a scanning rate of 10°C/min over the temperature range of 10–350°C. The sample weight was 2–10 mg.

^{13}C-NMR Spectrometry—Single-contact ^{13}C-CP/MAS measurements[6] were obtained at 75.46 MHz with a spectrometer equipped with a CP/MAS accessory. The sample (~300 mg) was placed in a Andrew–Beams-type rotor machined from perdeuterated poly(methyl methacrylate) and spun as fast as 3–4 kHz. The contact time was chosen as 1 ms (not optimized, but chosen to avoid buildup of strong signals from residual signals from the rotor and probe assembly), and repetition time was 2 s. The spectral width and data points were 30 kHz and 4K, respectively. Carbon-13 chemical shifts were calibrated indirectly through external benzene (128.5 ppm from tetramethylsilane).

Dissolution Studies—The dissolution behaviors of prostaglandin $F_{2\alpha}$ and its γ-cyclodextrin complex in water were compared at the same concentration of prostaglandin $F_{2\alpha}$ according to the dispersed-amount method (9). An 850-mg sample of the complex as a 100-mesh powder was weighed and put in a dissolution cell. Because prostaglandin $F_{2\alpha}$ is easy to melt at room temperature (the melting temperature is ~30°C), an ether solution containing 182 mg of the drug was placed in the dissolution cell and evaporated to dryness. The dissolution medium (25 mL) was maintained at 25°C and stirred at 91 rpm. At an appropriate interval, 0.5 mL of solution was sampled by a pipet with a cotton filter. The assay procedure for prostaglandin $F_{2\alpha}$ was the same as that used in the solubility studies.

RESULTS AND DISCUSSION

Figure 1 shows the equilibrium phase solubility diagram obtained for prostaglandin $F_{2\alpha}$ with γ-cyclodextrin in water. The plot shows a typical B_S-type solubility curve (8). The initial rising portion is followed by a plateau region and then decreases in total concentration of prostaglandin $F_{2\alpha}$ with precipitation of a microcrystalline complex at high γ-cyclodextrin concentration. In sharp contrast, the phase solubility diagrams of prostaglandin $F_{2\alpha}$ with α- and β-cyclodextrins showed an A_L-type curve, and no precipitation of the complexes was observed (1). The apparent 1:1 stability constant (K') of the γ-cyclodextrin complex was calculated to be 480 M^{-1} from the initial straight-line portion of the solubility diagram in Fig. 1. The K' value of the γ-cyclodextrin complex was found to be intermediate between the α-cyclodextrin complex (254 M^{-1}) and the β-cyclodextrin complex (1240 M^{-1}) values reported previously (1). The 1:1 stoichiometry of the γ-cyclodextrin complex in the solid phase was ascertained on the basis of data in the plateau region of the solubility diagram. The result was in good agreement with that obtained by isolation and analysis of the solid complex. Thus, the 1:1 solid complex isolated from the descending curvature of the B_S-type solubility diagram was used for further study.

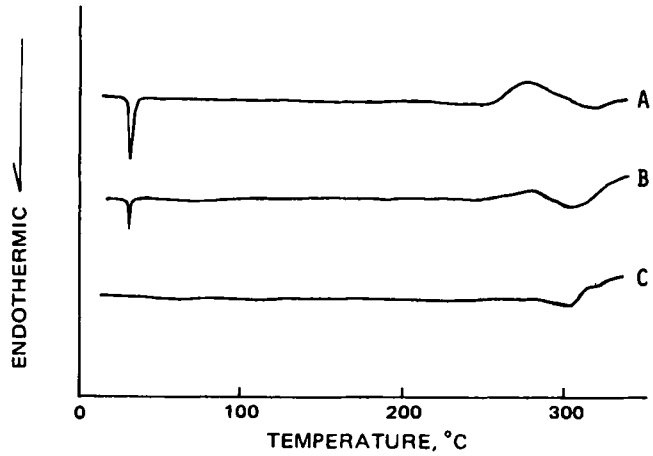

Figure 3—*DTA thermograms of prostaglandin $F_{2\alpha}$–γ-cyclodextrin system. Key: (A) prostaglandin $F_{2\alpha}$; (B) physical mixture of prostaglandin $F_{2\alpha}$ and γ-cyclodextrin in a molar ratio of 1:1; (C) prostaglandin $F_{2\alpha}$–γ-cyclodextrin complex.*

Figure 2 shows the powder X-ray diffraction pattern of the prostaglandin $F_{2\alpha}$–γ-cyclodextrin complex, comparing with that of γ-cyclodextrin itself. It was difficult to obtain the diffraction pattern of prostaglandin $F_{2\alpha}$ under these experimental conditions because of the low melting temperature. The diffraction pattern of the complex was apparently different from that of γ-cyclodextrin, indicating the constitution of a new solid phase. It was noted that the diffraction diagram of the complex in Fig. 2 showed a hexagonal nature of pattern similar to that observed for the *n*-propyl alcohol–γ-cyclodextrin complex (10). The *n*-propyl alcohol–γ-cyclodextrin complex is known to have a channel structure (10, 11) with a hexagonal close packing of the cylinders of γ-cyclodextrin molecules. Therefore, the diffraction pattern of the complex was indexed on the basis of a two-dimensional hexagonal unit cell having $a = b = 33.90$ Å, where *d*-spacing for the 200 reflection peak on the diagram was used to calculate the unit cell dimensions (10). As shown in Table I, the calculated *d*-spacing was in excellent agreement with that observed. This suggests that prostaglandin $F_{2\alpha}$ is included

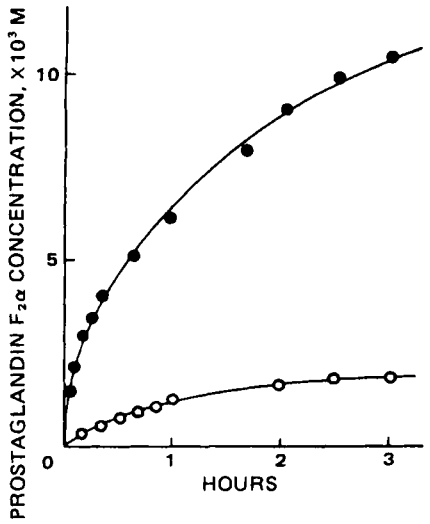

Figure 5—*Dissolution profiles of prostaglandin $F_{2\alpha}$ and its γ-cyclodextrin complex in water at 25°C. Key: (○) prostaglandin $F_{2\alpha}$; (●) prostaglandin $F_{2\alpha}$–γ-cyclodextrin complex.*

within the cylindrical channels formed by coaxial alignment of γ-cyclodextrin molecules to give a channel type structure.

Figure 3 shows DTA thermograms of the prostaglandin $F_{2\alpha}$–γ-cyclodextrin system. In the cases of prostaglandin $F_{2\alpha}$ and its physical mixture with γ-cyclodextrin (1:1 molar ratio), an endothermic peak due to the melting was observed around 30°C. In sharp contrast, the complex showed no appreciable endothermic peak within the degradation temperature of γ-cyclodextrin (~290°C) (12), suggesting that the complexed form of prostaglandin $F_{2\alpha}$ is considerably stable compared with the drug itself.

^{13}C-CP/MAS-NMR techniques were employed to gain further insight into the mode of interaction between prostaglandin $F_{2\alpha}$ and γ-cyclodextrin in the solid state. Figure 4 shows the ^{13}C-CP/MAS-NMR spectra of γ-cyclodextrin and its inclusion complex with prostaglandin $F_{2\alpha}$. The signals are readily assigned to the individual carbons of the glucose residues, as indicated in Fig. 4 [signals marked by the + are ascribed to the residual signals from the rotor of magic angle spinning machined from perdeuterated poly(methyl methacrylate)]. In the case of the complex, no appreciable signal from the guest molecule was observed under the experimental conditions used. Carbon-13 signals from guest molecules are known to be, in many instances, lost or obscured because the amount of the guest molecules is usually low compared with that of the glucose residues; also, buildup of the ^{13}C-magnetization might be strongly influenced by plausible molecular motions within the cavity (13, 14). Nevertheless, it is clearly seen that the complex formation resulted in the substantial reduction of the line widths of the glucose residues, especially in the C-1, C-4, and C-6 region, as well as the significant displacement of these signals. The distinct spectral change on complex formation might arise from a macrocyclic conformational change associated with the inclusion of the guest molecule.

In this connection, it is emphasized that the C-1 and C-X carbon-13 shifts at the glycosidic linkages for a number of polysaccharides (15, 16) are substantially displaced depending on their conformations. In particular, such displacements of the C-1 and C-4 shifts of α-D-(1,4)-linked glucans are well related to the dihedral angles ϕ and ψ for the C(1)—O_{gly} and O_{gly}—C(4) rotations (13, 14), respectively, which characterize the conformation of the individual glucose residues, as manifested from the previous ^{13}C-CP/MAS-NMR studies on polymorphs of amylose and various types of cyclodextrin complexes (13, 14). Therefore, broad carbon-13 signals in the γ-cyclodextrin are explained in terms of superposition of slightly displaced signals from glucose residues whose dihedral angles are distributed to some extent because of distorted macrocyclic conformation (15). It should be also noted that the ^{13}C-chemical shift changes of this complex are identical to those of γ-cyclodextrin–*n*-propyl alcohol complex within the experimental error (±1 ppm) (13, 14). Obviously, this finding is consistent with the X-ray diffraction study described above and also with the work by Lindner and Saenger (11).

The dissolution behavior of the γ-cyclodextrin complex was examined in anticipation of improved dissolution characteristics of prostaglandin $F_{2\alpha}$. It would be interesting to compare the effect of complexation on the dissolution rate for the three cyclodextrins, but an attempt to isolate the solid complexes of prostaglandin $F_{2\alpha}$ with α- and β-cyclodextrins was unsuccessful.

Figure 5 shows the dissolution profiles of prostaglandin $F_{2\alpha}$ and its γ-cyclodextrin complex in water. It was found that the complex dissolved much more rapidly (>10-fold) than prostaglandin $F_{2\alpha}$ itself. The observed increase in the rate may be due to the increase in solubility, as expected from Fig. 1, although other factors such as diffusion coefficient, wettability, and the dissociation of the complex in the dissolution medium (17) should be considered in the rate enhancement.

Thus, the increased dissolution rate suggests that prostaglandin $F_{2\alpha}$–γ-cyclodextrin complex may have great utility in the development of fast-dissolving dosage forms with improved bioavailability. Furthermore, the increased melting temperature and/or thermal stability of prostaglandin $F_{2\alpha}$ by γ-cyclodextrin complexation may facilitate the ease of handling the pharmaceutical preparations.

Improved Delivery Through Biological Membranes XIV: Brain-Specific, Sustained Delivery of Testosterone Using a Redox Chemical Delivery System

NICHOLAS BODOR [x] **and HASSAN H. FARAG** *

Received July 6, 1982, from the *Department of Medicinal Chemistry, College of Pharmacy, J. Hillis Miller Health Center, Gainesville, FL 32610.* Accepted for publication February 24, 1983. *Permanent address: Faculty of Pharmacy, University of Assiut, Egypt.

Abstract □ The dihydropyridine ⇌ pyridinium salt redox delivery system was used for the specific delivery and sustained release of testosterone in the brain. Administration of the *N*-methyl-1,4-dihydro nicotinate ester of testosterone in female rats gave high and sustained brain levels of the corresponding quaternary ester, testosterone trigonellinate. This contrasted with rapid elimination from the general circulation. Release of testosterone "locked into" brain as the quaternary salt was sustained, $t_{1/2}$ = 20 h.

Keyphrases □ Testosterone—brain-specific delivery, redox chemical delivery system, rats □ Delivery systems—redox chemical, brain-specific sustained delivery of testosterone, rats □ Tissue-specific drug delivery—testosterone in brain tissues, rats, redox chemical delivery system

Our earlier studies with phenylethylamine and dopamine (1–5)[1] established the feasibility of using the biological oxidation of dihydropyridine derivatives to the corresponding quaternary salts as the basis for a potentially selective drug-delivery system. We now report further investigation of this redox delivery concept as it applies to the selective retention and subsequent release of testosterone in the brain. One objective was to extend the redox concept to a larger molecule, testosterone, representative of a biologically important class of compounds, the steroids. A second objective was to study the effects of an ester linkage on the redox properties, distribution, and site-specific delivery of the target drug testosterone. Finally, it is suggested that this type of drug delivery system would also be useful for specific and/or enhanced delivery of drugs to the testes.

BACKGROUND

The selection of testosterone as the target drug and brain as target organ was motivated by our earlier work with phenylethylamine and dopamine derivatives (1–3) and by other considerations, both theoretical and practical. The potentially practical value of selective delivery and sustained release of testosterone in the brain resides in its physiological and biochemical roles in reproductive functions. It has been suggested that testosterone controls male sexual behavior by direct action on the brain (6, 7), and evidence indicates that gonadal steroids are concentrated in brain tissue relative to plasma (8). It has been shown that brains of mammals concentrate sex-related steroids in cells that form a stable core for a hormone-concentrating neural structure (9, 10) and that androgens influence male reproductive behavior by direct action on these discrete areas of the brain known as the anterior hypothalamic–preoptic complex. There is substantial evidence (11, 12) that estradiol is formed from testosterone by aromatization in the preoptic region and that it is the principal, centrally acting steroid in the maintenance of copulatory behavior. The use of androgen to treat breast cancer cases that respond to male hormones is well known (13), but despite the reported antiestrogenic action of testosterone (14), the exact mechanism through which advanced postmenopausal breast cancer responds to testosterone is unknown. A sustained-action form of testosterone that selectively concentrates in brain tissue clearly would be of value in studying the mechanisms through which testosterone exerts its effects on sexual behavior, sexual development, and reproduction. Similarly, it would be of value in studying any possible central role of androgens in the control of breast cancer.

The existence of a blood–testis barrier (BTB) by which some substances are prevented from being carried into the seminiferous tubules long has been suspected (15–18), and some investigators have suggested a similarity between the blood–brain barrier (BBB) and the BTB (19–22). Fawcette *et al.* (23) suggested that the permeability barrier is not in the testis capillary walls because these more closely resemble the capillaries of muscle than those involved in the BBB. Dym and Fawcette (24) concluded that the epithelioid contractile layer around the seminiferous tubules constitutes a significant permeability barrier augmented by an apparently more efficient barrier involving tight cell-to-cell junctions between Sertoli cells that inhibits penetration of substances through the germinal epithelium. Despite such histological differences, pharmacokinetic studies (25, 26) have demonstrated that the functional BTB resembles the BBB in transport characteristics, both depending on lipid solubility and molecular size.

As will be apparent from subsequent considerations, concentration of testosterone in the brain tissues of female rats by biological quaternization is accomplished without significant elevation of serum testosterone levels. The low serum levels would allow one to use such a drug in prepubertal hypoganodism tests, without fear of epiphyseal closure. Similarly, if androgens exert antineoplastic and other effects through central actions, concentration in the brain without elevated peripheral circulatory levels would minimize peripheral side effects such as edema and masculinization.

Our earlier work with phenylethylamine and dopamine derivatives (1–3) led us to conclude that the 17-β(1,4-dihydrotrigonelline) ester of testosterone (I) would, by virtue of its good lipid solubility, cross both the BBB and the BTB (in male rats). As shown in Scheme I, it was also anticipated that biological oxidation to the corresponding quaternary derivative would follow, causing a "lock in" of the corresponding ionic, hydrophilic product in the brain and in the testes in male animals. Conversely, oxidation in locales not involving a permeability barrier would favor rapid clearance from blood because the quaternary derivative (II) is excreted more rapidly than the unoxidized form (I). Thus, oxidation would favor the accumulation of II in the brain while yielding minimal blood levels. A subsequent slow hydrolysis to free testosterone in the brain, therefore, would provide a site-specific, prolonged testosterone action and minimal peripheral effects. In a systematic study of some trigonelline and dihydrotrigonelline esters (III, IV), where R = C_nH_{2n-1} and n = 1–10 (5), we have demonstrated that the quaternary esters (III) hydrolyze in different biological media at rates much slower than those of the uncharged analogues. Esters IV also are very difficult to hydrolyze, and although it was expected that $K_8 \gg K_9$ and $K_5 \gg K_4$, the slow rates of quaternary hydrolysis were expected to ensure a sustained release of testosterone in both testes and brain while yielding minimal levels in blood and other tissues. Earlier studies (1, 2) also led us to expect that trigonelline released in the brain by the hydrolytic process would be excreted easily and at comparable rates (25)[1].

EXPERIMENTAL

All melting points were taken on a melting point apparatus[2] and are uncorrected. Elemental analyses were performed at Atlantic Microlabs, Inc., Atlanta, Georgia. IR spectra were determined using a double-beam recording spectrophotometer[3]. ^{1}H-NMR spectra were determined using a spectrometer[4]. All chemical shifts reported are in δ units (ppm) relative

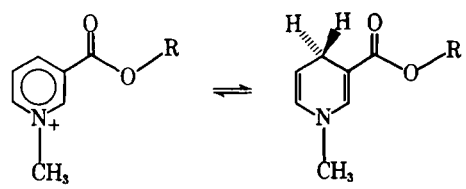
to tetramethylsilane. UV absorbance spectra were determined using a spectrophotometer[5]. HPLC analyses were performed on a ternary liquid chromatograph[6] with a solvent delivery system[7], injector[8], absorbance detector[9], and controller[10].

Testosterone Nicotinate (V)—Thionyl chloride (2.mL) was added to 0.7 g (5.7 mmol) of nicotinic acid[11] and the mixture was refluxed for 3 h. The excess thionyl chloride was removed under reduced pressure, and 10 mL of dry pyridine was then added to the cold residue followed by 1.44 g (5.0 mmol) of testosterone[11]. The mixture was heated with continuous stirring at 100°C for 4 h. The pyridine was removed *in vacuo*, and 5 mL of methanol was added to the oily residue. The mixture was cooled, and the solid that crystallized was filtered and recrystallized from methanol–acetone to give 1.4 g of V as white crystals (yield 71%), mp 187–188°C. This material was used without further purification.

17β-[(1-Methyl-3-pyridiniumcarbonyl) oxy] androst-4-en-3-one Iodide (II)—To a solution of 1.0 g (2.5 mmol) of the aforementioned



III IV

testosterone nicotinate (V) in 15 mL of acetone was added 1 mL of methyl iodide, and the mixture was heated at reflux overnight. The yellow material that separated was removed by filtration, washed with acetone, and crystallized from methanol–ether to yield 1.25 g (92%) of II as yellow crystals, mp 215–220°C (dec.). UV (CH_3OH): λ 270 nm (shoulder), ε = 4579; 240 nm (shoulder), ε = 19,375. ^{1}H-NMR ($CDCl_3$): δ 10.0–8.3 (m, 4, C_5H_5N), 5.73 (s, 1, C_4 vinyl H), 4.86 (s, 3, N—CH_3), and 2.40–1.06 ppm (m, 26, methylene H).

Anal.—Calc. for $C_{26}H_{34}INO_3$: C, 58.32; H, 6.40; N, 2.62. Found: C, 58.17; H, 6.48; N, 2.60.

17β-[(1,4-Dihydro-1-methyl-3-pyridinylcarbonyl)oxy]androst-4-en-3-one (I)—To an ice-cold solution of 1.1 g (2 mmol) of testosterone nicotinate-*N*-methyl iodide (II) in 150 mL of deaerated 10% aqueous methanol were added 0.67 g (8 mmol) of sodium bicarbonate and 1.37 g (8 mmol) of sodium dithionite. The mixture was stirred for 20 min at room temperature, and the separated pale-yellow material was removed by filtration, washed with water, and dried over P_2O_5 under vacuum to yield 0.82 g (98%) of I, mp 172–175°C. UV (CH_3OH): λ 356 nm, ε = 9511. IR (KBr): 1700 and 1660 cm^{-1} (C=O). ^{1}H-NMR (DMSO-d_6): δ 6.90 (br s, 1, C_2 dihydropyridine H), 5.83–5.70 (m, 1, C_6 dihydropyridine H), 5.56 (s, 1, C_4 vinyl H), 4.7–4.33 (m, 1, C_5 dihydropyridine H), 3.26 (br s, 2, C_4 dihydropyridine H), 2.93 (s, 3, N—CH_3), and 2.5–0.83 ppm (m, 26, methylene H with CH_3's at 1.16 and 0.83).

Anal.—Calc. for $C_{26}H_{35}NO_3$: C, 76.25; H, 8.61; N, 3.42. Found: C, 76.07; H, 8.65; N, 3.38.

Analytical Methods—An HPLC method was developed for the studies of the degradation of the quaternary (II) and dihydropyridine derivatives (I) using the system described earlier. The absorbance detector was operated at 254 nm. A 15-cm × 4.6-mm i.d., 5-μm particle size, Ultrasphere reverse-phase C_{18} column[12], operated at ambient tempera-

Table I—Kinetics of *In Vitro* Oxidation of the Dihydropyridine Ester I to the Quaternary Derivative II in Biological Fluids [a]

Medium	k, s^{-1}	$t_{1/2}$, min	r	Method [b]
80% Plasma	8.12×10^{-5}	142	0.959	A
20% Brain homogenate	1.72×10^{-4}	67	0.997	A
Whole blood	1.74×10^{-4}	66	0.997	A, B

[a] At 37°C, initial concentration of I = 2.4×10^{-4} M. [b] Method A: following appearance of [II]; Method B: following disappearance of [I].

ture, was used for all separations. The mobile phase used for the separation of the dihydropyridine derivative, its degradation products, and oxidation products consisted of a 0.002 M solution of 1-heptanesulfonic acid sodium salt[13] in CH_3CN–0.01 M aqueous Na_2HPO_4 (7:3). At a flow rate of 2.0 mL/min, II has a retention time of 12 min and I has a retention time of 5 min. For the analysis of testosterone in the *in vivo* brain delivery studies, the solvent consisted of a 0.002 M solution of 1-heptanesulfonic acid sodium salt in CH_3CN–0.01 M aqueous Na_2HPO_4 (1:1). At a flow rate of 2.0 mL/min, testosterone has a retention time of 3.3 min and II has a retention time of 36.5 min (very broad peak).

Chemical Oxidation Studies—*By Silver Nitrate*—One milliliter of a 5% methanolic solution of the dihydropyridine derivative (I) was added to 5 mL of saturated methanolic $AgNO_3$ solution. The mixture was shaken, left 10 min for complete oxidation, centrifuged, and the UV spectrum checked.

By Hydrogen Peroxide—To a standardized solution of H_2O_2 (0.18 M) contained in a UV cuvette equilibrated at 37°C was added a solution of dihydropyridine derivative (I) to make a concentration of $\sim 5 \times 10^{-6}$ M. The mixture was thoroughly mixed and monitored for the disappearance of the dihydropyridine maximum at 356 nm using a spectrophotometer[5] interfaced with microprocessor[14] with an enzyme kinetic software package.

By Diphenylpicrylhydrazyl Free Radical—To 2 mL of a 9.3×10^{-5} M solution of 2,2-diphenyl-1-picrylhydrazyl free radical in acetonitrile, equilibrated at 26°C, was added 20 μL of a 1.5×10^{-2} M solution of the dihydropyridine derivative in acetonitrile to make a final concentration of 1.48×10^{-4} M. The mixture was monitored at 515 nm using the same instrumentation as for the hydrogen peroxide method against a reference cuvette containing the same mixture in exactly the same concentrations which was previously prepared and left for at least 10 min (reference for A_∞).

Determination of *In Vitro* Rates of Oxidation of I in Biological Media—*Human Plasma*—The freshly collected plasma used was obtained at the Civitan Regional Blood Center, Inc. (Gainesville, Fla.) and contained ~80% plasma diluted with the anticoagulant citrate phosphate dextrose solution USP. The plasma was stored in a refrigerator and used the next day. One hundred microliters of a freshly prepared 0.024 M solution of I in dimethyl sulfoxide was added to 10 mL of plasma, previously equilibrated to 37°C in a water bath, and mixed thoroughly to result in an initial concentration of 2.4×10^{-4} mol/L. One-milliliter samples of plasma were withdrawn every 20 min from the test medium, added immediately to 5 mL of ice-cold acetonitrile, shaken vigorously, and placed in a freezer. When all samples had been collected, they were centrifuged and the supernatants were filtered through nitrocellulose membrane filters (0.45 μm pore size) and analyzed by HPLC, following the appearance of II (method A).

Human Blood—The freshly collected heparinized blood was obtained at the Civitan Regional Blood Center, Inc. (Gainesville, Fla.). The blood was stored in a refrigerator and used the next day. One hundred microliters of a freshly prepared 0.048 M solution of I in dimethyl sulfoxide was added to 20 mL of blood, previously equilibrated to 37°C in a water bath, and mixed thoroughly to result in an initial concentration of 2.4×10^{-4} mol/L. One-milliliter samples of blood were withdrawn from the test medium every 10 min, added immediately to 5 mL of ice-cold acetonitrile, shaken vigorously, and placed in a freezer. When all samples had been collected, they were centrifuged and the supernatants were filtered using nitrocellulose membrane filters (0.45-μm pore size) and analyzed by HPLC following the appearance of II (method A) and the disappearance of I (method B).

Rat Brain Homogenate—Five female Sprague–Dawley rats were decapitated, and the brains were removed, pooled, weighed (total weight 9.2 g), and homogenized in 36.8 mL of aqueous 0.11 M phosphate buffer, pH 7.4. One hundred microliters of a 0.024 M solution of I in dimethyl sulfoxide was mixed with 20 mL of the homogenate, previously equilibrated to 37°C in a water bath, to result in an initial concentration of 2.4×10^{-4} mol/L. Samples of 1.0 mL were withdrawn every 10 min from the test medium, added immediately to 5 mL of ice-cold acetonitrile, shaken vigorously, and placed in a freezer. When all samples had been collected, they were centrifuged and the supernatants were filtered through nitrocellulose membrane filters (0.45-μm pore size) and analyzed by HPLC (method A).

***In Vitro* Determination of the Site-Specific Conversion of II to Testosterone**—A fresh brain homogenate was prepared as previously described. One hundred microliters of a 0.017 M solution of the quaternary compound (II) in methanol was mixed with 10 mL of the brain homogenate, previously equilibrated to 37°C, to result in an initial concentration of 1.7×10^{-4} M. Samples of 1.0 mL were withdrawn every 20 min from the test medium, added immediately to 5 mL of ice-cold acetonitrile, and placed in a freezer. When all samples had been collected, they were centrifuged, and the supernatant was filtered through a nitrocellulose membrane filter (0.45 μm pore size) and analyzed for the quaternary compound II.

***In Vivo* Brain Delivery of Testosterone Following its Administration**—Female Sprague–Dawley rats with an average weight of 225 ± 10 g were injected intravenously with testosterone at a dose level of 28.2 mg/kg. Samples of brain and blood were collected as previously described (1, 3, 4) and were analyzed for testosterone using HPLC.

Distribution of II after Intravenous Administration—Following the same procedure, female Sprague–Dawley rats were injected intravenously with quaternary solution (0.18%) in dimethyl sulfoxide at a dose level of 13.0 mg/kg. The brain samples collected were analyzed for the presence of quaternary II using HPLC.

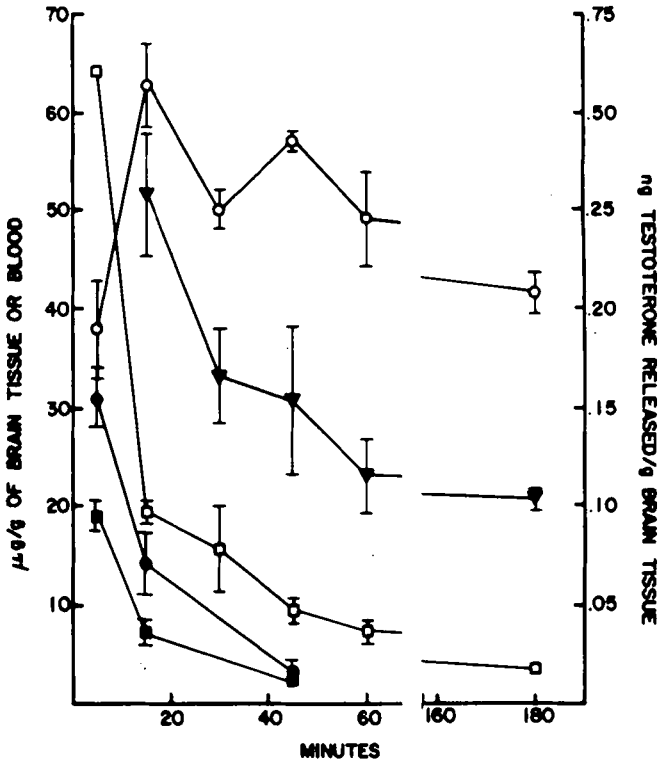

Figure 1—*Concentrations against time for the testosterone-17-nicotinate-N-methyl cation, calculated as iodide, in brain (○) and in blood (□) and concentration of released testosterone (ng/g) in brain (▼) following administration of the corresponding dihydropyridine derivative I. Concentrations of testosterone in brain (●) and blood (■) following administration of testosterone are also included. Bars represent the standard errors.*

RESULTS AND DISCUSSION

Compound I was prepared *via* quaternization of testosterone nicotinate (V) with methyl iodide followed by reduction of the quaternary salt II

[13] PIC B-7; Eastman Kodak Co.
[14] Apple II computer.

using sodium dithionite. The rates of oxidation of the dihydro derivative (I) with silver nitrate, hydrogen peroxide, and diphenylpicrylhydrazyl free radical ($DPP^{\cdot}$) were determined. The reactions were carried out under pseudo-first-order conditions, either with higher concentrations of the oxidant in the case of hydrogen peroxide or higher concentrations of I in the case of the picryl reagent. With $DPP^{\cdot}$ a reference sample was made using the same amounts as the test sample, but prepared 10 min before mixing and monitoring the test sample. This reference is used as a measure of A_∞, and these were the data used to calculate the kinetic parameters. The *in vitro* rates of oxidation of the dihydro derivative were also determined in biological fluids, *e.g.*, 80% plasma, whole blood, 20% brain homogenate, and 20% liver homogenate. The rate of disappearance of the ester II and appearance of testosterone in medium was also determined. Finally, the *in vivo* brain delivery and blood concentration profile of the quaternary derivative and testosterone released, against time, was determined following a single injection of the dihydropyridine derivative (I) to female rats. These results were compared with the blood and brain kinetics of testosterone following administration of the hormone itself.

Chemical Oxidation of the Dihydropyridine Derivative I—*By Silver Nitrate*—It was observed that this dihydro derivative is more stable towards oxidation than the previously studied analogous (1, 3, 4) derivatives containing amido functions; it takes a few minutes standing for the silver to form. The product is exclusively the quaternary salt II, as verified by the change in the UV and NMR spectra.

By Hydrogen Peroxide—Using low concentrations of the dihydro derivative I (5×10^{-6} M) and higher concentrations of the peroxide (0.18 M), the oxidation proceeds according to a first-order kinetics: $k = 2.7 \pm 0.3 \times 10^{-3}\ s^{-1}$; $t_{1/2} = 3.98 \pm 0.7$ min; $r = 0.995$. At higher concentrations I is insoluble in H_2O_2.

By Diphenylpicrylhydrazyl Free Radical—The reaction was carried out under pseudo-first-order conditions using excess dihydropyridine derivative. With the concentrations used, all of the runs gave first-order plots every 3 half-lives, with a correlation coefficient of >0.9998: $k = 4.87 \pm 0.31 \times 10^{-2}$; s^{-1} $t_{1/2} = 14.1 \pm 0.6$ s.

***In Vitro* Oxidation and Hydrolysis in Biological Media**—Table I shows the rates, half-lives, and correlation coefficients for the process of oxidation of the 1,4-dihydropyridine derivative I in different biological media. The rate of hydrolysis of the quaternary II in 20% brain homogenate was also determined, and it was found to be $3.6 \times 10^{-5}\ s^{-1}$, corresponding to a half-life, $t_{1/2}$, of 5.16 h.

***In Vivo* Administration of I and Testosterone**—Figure 1 illustrates the concentrations of quaternary derivative II in brain and blood and the concentration of testosterone released in the brain following intravenous administration of the 1,4-dihydropyridine derivative I. Also, it shows the concentration of testosterone in the brain and blood following administration of testosterone.

17β-[(1,4-Dihydro-1-methyl-3-pyridinylcarbonyl)oxy]androst-4-en-3-one (I) could be obtained in a high yield, >90%, from testosterone 17β-nicotinate by simple chemical procedures. The dihydro product obtained directly from the reduction reaction medium was found to be quite pure by HPLC, and a single crystallization from hot methanol afforded an analytically pure product. No signs of oxidation were observed during crystallization (even from hot methanol), filtration, or drying. The crystalline solid dihydro compound did not show signs of oxidation, decomposition, or polymerization when tested by HPLC during the 2-month shelf storage at ambient temperature under nitrogen. This compound (I) was found to be quantitatively oxidizable to the corresponding quaternary derivative (II), as identified by UV spectrometry, whether by silver nitrate or hydrogen peroxide. The process of oxidation with silver nitrate is slower than that with the dihydropyridine derivatives of phenylethylamine (3) or dopamine (4). Oxidation with hydrogen peroxide or $DPP^{\cdot}$, under pseudo-first-order conditions, was found to take place at measurable rates ($t_{1/2} = 3.98 \pm 0.7$ min and 14.1 ± 0.6 s, respectively) compared with the rates of oxidation of the corresponding phenylethylamine and dopamine derivatives, which were found to be too fast to be monitored using the same procedure. The *in vitro* investigation in biological fluids indicated a facile oxidative conversion of the dihydro form (I) to the corresponding quaternary (II), but at a slower rate than that of the analogous amides of phenylethylamine or dopamine.

For the *in vivo* studies of I, female Sprague–Dawley rats were chosen because the concentration of endogenous testosterone in the blood and brain of these animals is below the range of sensitivity of the procedure used for its analysis. The results shown in Fig. 1 indicate that the dihydro derivative penetrates the BBB and is readily oxidized in the brain to the quaternary precursor II. The *in vivo* rate of oxidation of the dihydro derivative seems faster than that obtained from the *in vitro* experiment. No dihydro derivative could be detected in the brain within the sensitivity limits of the procedure. After II reaches its maximum concentration, within ~15 min, its concentration starts a decline phase corresponding to overall excretion and/or metabolism–hydrolysis. The overall rate of this phase was calculated to be $2 \times 10^{-3}\ min^{-1}$ ($t_{1/2} = 5.7$ h). In the same time the concentration of II in blood was decreasing progressively from the beginning at a rate $1.27 \times 10^{-2}\ min^{-1}$ or with a half-life of 54 min.

Equimolar administration of testosterone using the same solvent (dimethyl sulfoxide) and the same route of administration showed a rapid absorption of testosterone into the brain, reaching a maximum concentration within 5 min, followed by fast clearance from both brain and blood ($t_{1/2}$ = 12.6 and 14.5 min, respectively). The ratio of brain/blood concentration for testosterone was found to be 1.6 at 5 min and 1.8 at 15 min postadministration. The ratio of brain/blood concentration of the quaternary II was found to increase progressively with time (3.23 at 15 min, 6.33 at 45 min, and 12 at 3 h postadministration). This indicates the predicted "lock in" property for the quaternary II.

Testosterone was found to be released from the quaternary ester II and could be detected in the brain following administration of the dihydro derivative I. Analysis of the time concentration curve for release of testosterone (Fig. 1) indicated two-phase kinetics for disappearance from the brain. The first is a fast descending phase at a rate of $1.2 \times 10^{-2}\ min^{-1}$ followed by a slow clearance phase with a rate of $5.8 \times 10^{-4}\ min^{-1}$ and a half-life of ~20 h, which corresponds to ~130 h for complete clearance from the brain. This result, if compared with that obtained by Frey *et al.* (27), for the clearance of testosterone from plasma after oral administration (~6 h), is very promising. Although the concentrations of testosterone in the brain following administration of I are low compared with that following administration of testosterone, this is by no means a disadvantage, because such high concentration of testosterone may not be needed for receptor saturation. By dose manipulation of the dihydro derivative, a concentration of testosterone just sufficient for receptor saturation for a delayed period could be attained.

Angular Dependence of the Interaction Energy Between the N Lone Pair of Amines and a Proton: Relevance to Drug–Receptor Systems

VERA M. KOLB ˣ and STEVE SCHEINER

Received October 8, 1982, from the *Department of Chemistry and Biochemistry, Southern Illinois University, Carbondale, IL 62901.* Accepted for publication February 11, 1983.

Abstract □ *Ab initio* molecular orbital calculations with a 4-31G basis set have been performed to study the angular dependence of the interaction energy between a lone electron pair of nitrogen and a proton. In this study ammonia and trimethylamine were used as models of biologically active amines. A proton was used as a model of an electrophilic site at the receptor. Results obtained confirm previous indications that the energy required to bend the proton from the lone pair direction decreases markedly as the two species are further separated from one another. Implications regarding the interactions of drugs and hormones at specific receptors are discussed.

Keyphrases □ Interaction energy—nitrogen lone electron pair of amines and a proton, angular dependency, drug–receptor systems □ Drug–receptor systems—interaction energy of the nitrogen lone electron pair of amines and a proton, angular dependency □ Amines—biologically active, interaction energy of the lone electron pair and a proton, angular dependency

Many hormones and drugs elicit their biological response through interactions with specific receptors (1–10). These interactions are typically weak, reversible, and specific (11) and, in addition, do not involve covalent bonding (1, 2, 8, 9). Many such interactions are of the electrophile–nucleophile type between sterically fixed groups. Because the nucleophilic pharmacophore frequently contains nitrogen at a critical position, we focus here specifically on the nature of the interaction of nitrogen with an electrophile.

One way nitrogen could interact with the specific electrophilic center at the receptor is *via* its lone electron pair. Such a mechanism has been suggested for opiate–receptor interactions (12–15). The influence of the directionality of the lone pair of biologically active amines on their activity has been demonstrated experimentally in some cases (12). One may envisage the most productive interaction as that in which the N lone pair is aligned exactly in the direction of the electrophilic site. This concept of amine–receptor interaction is illustrated in Fig. 1, which schematically depicts the binding of a (tertiary) amine to its receptor. Both the amine molecule and the electrophilic site are visualized as being sterically fixed at the receptor. We consider the distance between the N lone pair and the electrophilic site as longer than the normal bonding distance, since covalent bonding of nitrogen to the receptor does not occur (1). Figure 1A shows a perfect fit between the N lone pair and the electrophilic site. Figure 1B depicts a case of a substituted amine whose substituent (shown as a "bump" at the left-hand side of the molecule) interferes with the proper fit with the receptor cavity. There may of course be other factors leading to poor fit, and the effect shown in Fig. 1B is used only as an example. The repulsion between the substituent and the receptor cavity causes a small tilting of the molecule, which changes the position of the nitrogen atom and, therefore, its lone electron pair, relative to the electrophilic site. The N lone pair forms a "bent" complex with the electrophilic site.

Since the activity of the amine depends on the nucleophile–electrophile complexation, it is very important to learn about the energetics of the "bent" complexation of

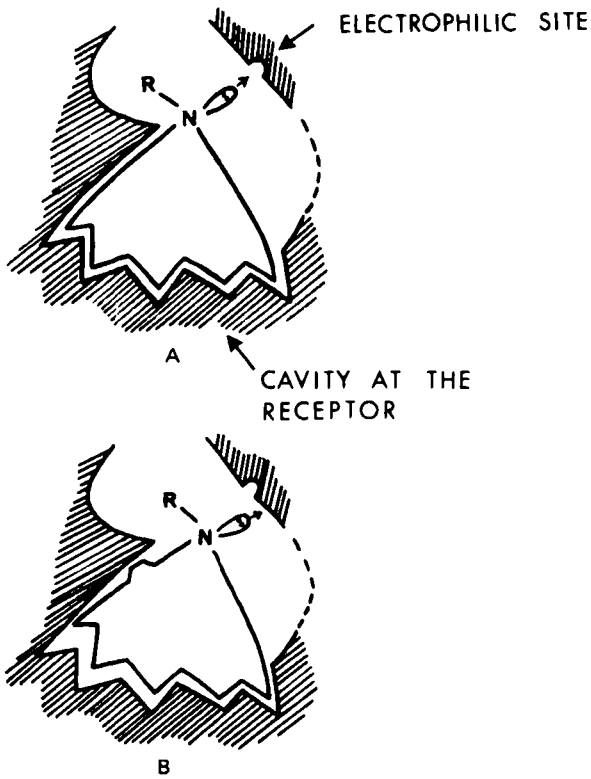

Figure 1—*Schematic representation of the binding of a biologically active (tertiary) amine to its receptor. Key: (A) perfect fit between the amine and its receptor; (B) less than perfect fit due to presence of a substituent (shown as bump on left of molecule).*

Scheme I

the N lone pair (Fig. 1B) as compared with the "straight" complexation (Fig. 1A). The knowledge acquired about this problem may help to predict the activity of the derivatives of active amines and to understand better the mechanism of action of biologically active amines in situations where they are sterically restricted at the receptors.

Specifically, we wanted to determine the effects of the relative steric disposition of the nitrogen lone electron pair and an electrophilic site on the energetics of the interaction at distances longer than the normal bonding distance. Quantum chemical methods are particularly well suited for this purpose, since the relative orientations of molecules may be precisely specified. In addition, the wave functions may be analyzed to determine electron densities at various regions in the space between the two molecules to provide insights concerning the interaction. To perform *ab initio* calculations it was necessary to model the usually large biomolecules by smaller representative systems. Ammonia and trimethylamine were chosen as models of the nitrogen-containing portion of a biologically active amine. The proton, a spherically symmetrical species with no intrinsic steric requirements, was chosen as the simplest model for an electrophilic site at the receptor (the nature of such sites is generally poorly understood).

EXPERIMENTAL

Molecular orbital calculations were carried out within the *ab initio* restricted Hartree–Fock formalism. The GAUSSIAN-70 package of computer codes (16) was used to construct molecular orbitals as linear combination of atomic orbitals. The split valence–shell 4-31G basis set (17) was used rather than a minimal basis set, since the former provides greater flexibility to the valence orbitals and is expected to furnish a more realistic picture of long-range interactions between the amine and the proton than would the latter.

The experimentally determined geometries of ammonia (18) and trimethylamine (19) were used in our calculations. Ammonia belongs to the C_{3v} point group and has r(N—H) = 1.01 Å and θ(HNH) = 106.7°. The N—C bond distances in trimethylamine are 1.45 Å and the θ(CNC) is 110.9°. Each methyl group is staggered with respect to the other two C—N bonds.

A proton was placed at various positions relative to the amines. As shown in Scheme I, these positions are characterized by the N—H^+ distance r and ϕ, the angle between the N—H^+ axis and the C_{3v} symmetry axis of the R_3N molecule. (The latter axis coincides with the expected direction of the N lone pair.) A positive value of ϕ, shown in Scheme I, indicates a bend of H^+ toward R_a, while a negative value corresponds to a bend in the opposite direction.

The variation of the total energy of the $(H_3N\cdots H)^+$ system with changing ϕ is illustrated in Fig. 2 for values of r between 0.70 and 3.0 Å. Dashed lines represent curves for $r < 1.02$ Å, the equilibrium N—H bond length. For each value of r, the lowest energy structure is that with ϕ = 0°, in which the proton lies directly along the C_3 symmetry axis of NH_3. Increasing ϕ results in a monotonic increase in the energy corresponding to a less stable complex. The sensitivity of the energy to ϕ decreases as r is increased. For example, for r = 1.02 Å the $(H_3N\cdots H)^+$ complex with

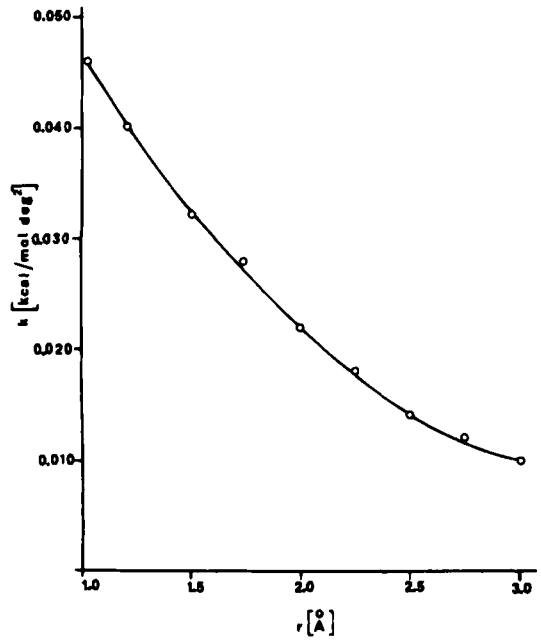

Figure 3—*Dependence of the bending force constant* k *on distance* r *for the* $(H_3N\cdots H)^+$ *system.*

Also shown are the corresponding values for* $(H_3N\cdots H)^+$ *for the same distances* r (○ *and* - - -, *right ordinate). For the* $((CH_3)_3N\cdots H)^+$ *system* E (r = ∞) = −173.00797 *a.u.*

the proton bent 20° off the C_3 axis is 11.6 kcal/mol less stable than that for $\phi = 0°$, whereas the analogous quantity is only 2.4 kcal/mol for r = 3.0 Å. Additional data concerning the energetics of deformation for angles $\phi = 20°$, 40°, and 60° are presented in Table I. Each value of ΔE is defined as the difference in energy between the indicated value of ϕ and that for $\phi = 0°$. Fitting these data to a parabola for each value of r *via* least-squares analysis yields the bending force constants, k ($\Delta E = 0.5k\phi^2$). Figure 3 shows how these bending force constants decrease with increasing r.

Deformation energies for selected conformations of $((CH_3)_3N\cdots H)^+$ are listed in the final column of Table I. Figure 4 shows a comparison of the results for the latter system (solid line) with those for the $(H_3N\cdots H)^+$ system (dashed line) at r = 1.20 and 1.75 Å. A strong similarity is clearly evident for the energetics of bending in the two amine systems. For values of $\phi > 20°$, we note that the energy for $((CH_3)_3N\cdots H)^+$ rises somewhat faster with increasing ϕ than does $(H_3N\cdots H)^+$. This difference is probably a result of steric repulsion between the incoming proton and the methyl hydrogen atoms of trimethylamine, which are not present in NH_3.

The deformation energy for trimethylamine is quite uniform in the + and − direction of ϕ, as indicated by similar ΔE values for $\phi = 20°$ and $-20°$. This is contrary to the $(H_3N\cdots H)^+$ case, where the deformation energy for positive ϕ is noticeably greater than for negative angles. In the latter case the proton fits "in between" (in a staggered manner) two ammonia hydrogen atoms (H_b and $H_{b'}$; see Scheme I) while for positive ϕ, the proton is eclipsed with one hydrogen (H_a). Thus, the three H^+—H distances for $\phi = 20°$ and r = 1.75 Å are 2.02, 2.44, and 2.44 Å, as compared with 2.52, 2.20, and 2.20 Å for $\phi = -20°$. For trimethylamine the hydrogen atoms are more uniformly distributed around the central nitrogen. The four shortest H^+—H distances in the $((CH_3)_3N\cdots H)^+$ system, again for r = 1.75 Å, are 2.33, 2.33, 2.81, and 2.81 Å for $\phi = 20°$, which is very similar to the corresponding values of 2.37, 2.37, 2.73, and 2.73 Å for $\phi = -20°$.

DISCUSSION

We have presented calculated results of the energetics of deformation of the amine–proton system. The preferred or lowest energy structure in each case is one in which the proton lies directly along the lone pair direction of the amine. (A similar conclusion was reached by Baird (20) for the interaction of NH_3 with both NH_4^+ and NH_3.) Calculated bending energies extended over a wide range of values, varying up to 90 kcal/mol for 60° bends at the equilibrium r(NH) distance of 1.02 Å for the $(H_3N\cdots H)^+$ system.

Our calculated results show a greatly diminished sensitivity of the amine–electrophile interaction energy to angular deformation as the distance between the two species is increased. Qualitatively similar conclusions may be reached by examination of the molecular electrostatic potentials in the vicinity of the amine group of morphines (21, 22). Although these potential maps include only nonperturbing effects of a unit charge and thereby neglect polarization, charge transfer, and exchange terms, the results indicate preferred binding of a positive charge along the lone pair direction of nitrogen. The maps (21, 22) further suggest that the decreasing sensitivity of the binding energy to angle at longer distances, found here for simple amines, is common to morphines as well. Thus, the formation of a bent complex may be only a little less favorable energetically than a "straight" complex at separations of perhaps 2.5 or 3.0 Å. For example, while a bend of 20° in the $(H_3N\cdots H)^+$ system leads to a deformation energy of 11.6 kcal/mol at 1.02 Å, the strain energy for a similar bend is only 2.4 kcal/mol at r = 3.0 Å.

It is therefore important to consider what might be expected for the distance between the nucleophile and the electrophile at the receptor when the (noncovalent) interaction occurs. A distance of 2 Å was used in the "transition-state complex" between the propene nucleophile and a proton by Caramella *et al.* (23). Distances between nucleophiles and electrophiles of as long as 3 Å have been observed in crystal structure studies (24). Bürgi *et al.* interpreted these long distances as indicating nonbonded interactions of the donor–acceptor and dipole–dipole types (24). Therefore, distances between the amine nucleophile and electrophile of ≥2 Å at the receptor would not be an unreasonable estimate.

At interaction distances >2 Å, the lone pair and electrophile may be significantly misaligned without large deformation energies. For example, for the $(H_3N\cdots H)^+$ system, at r = 2.0 Å, a bend of 15° from optimal orientation produces an energy increase of 3 kcal/mol, while the analogous bend yielding a similar increase at r = 3.0 Å is 24°.

While it would be presumptuous to generalize our data on the $(H_3N\cdots H)^+$ and $((CH_3)_3N\cdots H)^+$ systems and claim that they are directly applicable to all nitrogen-containing drugs and hormones, we believe that our findings should be considered qualitatively when picturing the interaction of the N lone pair of biologically active amines with an electrophilic site at the receptor.

The fact that the difference in energy between a "bent" and "straight" complex may become very small for longer r values does not support the orbital steering concept (25). The experimental (26) and theoretical (*e.g.*, 27) work of other investigators has already provided evidence which is not in agreement with the orbital steering concept.

Finally, we may note that our studies on angular dependence of the interaction between the N lone pair of amines with a proton complement

previous studies of the angular dependence of the interaction between nucleophiles and certain electrophiles which possess intrinsic steric requirements (27, 28), as well as electrophiles in general (20, 29–32).

NOTES

Determination of the Average Molecular Weight of Nonionic Emulsifiers by Vapor-Phase Osmometry

FRANCE GUAY and SUZANNE BISAILLON ˣ

Received October 5, 1982, from the *Faculty of Pharmacy, University of Montreal, Montreal, Quebec, H3C 3J7, Canada.* Accepted for publication January 10, 1983.

Abstract □ Standard nonionic emulsifiers are heterogenous by nature. Their reported molecular weight is unreliable, especially when several lots of the product are used in a study. The number-average molecular weights of two nonionic emulsifiers, poloxamer 188 and polyoxyethylene(23) lauryl ether were determined by vapor-phase osmometry. This determination is essential when the concentration should be given in molarity rather than in weight per volume. A discrepancy was noted between the number-average molecular weights of two lots of poloxamer 188. That difference is taken into account prior to the establishment of any comparison of the behavior of the emulsifiers.

Keyphrases □ Poloxamer 188—number-average molecular weight, vapor-phase osmometry □ Polyoxyethylene(23) lauryl ether—number-average molecular weight, vapor-phase osmometry □ Vapor-phase osmometry—determination of number-average molecular weights, poloxamer 188, polyoxyethylene(23) lauryl ether

method chosen must overcome the heterogeneity of the product, which renders impossible the consideration of the reported molecular weight. Methods involving the measurement of colligative properties are extensively used for estimating number-average molecular weights <20,000 (1–3). A prime interest in this area is directed toward vapor-phase osmometry as a rapid and reliable technique (4).

The number-average molecular weights of poloxamer 188 (I) and polyoxyethylene(23) lauryl ether (II) were determined by vapor-phase osmometry. Even if an estimation of the number-average molecular weights can be done from their formulas, a more systematic procedure should be employed to confirm the uniformity of the product, which can vary from lot to lot. These determinations were undertaken on both substances prior to their use in a study dealing with emulsifier behavior at the air–water and soybean oil–water interfaces.

EXPERIMENTAL

Two lots of I (WPTY 175B and WXPG 112)[1] and one lot of II (667)[2] were studied. The emulsifiers were dissolved in benzene (ACS grade) previously dried over calcium sulfate and filtered through a 0.45-μm cellulose membrane. Benzil (practical grade, mol. wt. 210.23) was used as the standard for calibration.

The measurements were performed on a molecular weight apparatus[3]. Since the accurate measurement of vapor pressure is difficult, the determination of the number-average molecular weights is based on the temperature difference between a solution and its solvent at the same vapor pressure. The apparatus consists of a thermostated chamber containing two thermistors where a pool of pure solvent is maintained at equilibrium with the environment. When a drop of solvent is placed on each thermistor, the rates of evaporation and condensation are equal in all parts of the system and the temperature is constant. When a drop of solution is placed on one thermistor, this equilibrium is upset and a change of temperature for one thermistor is reflected by a change in the resistance (ΔR) of the system. The calibration and calculation curves were obtained under the following experimental conditions: main oven temperature, 40.1 ± 0.1°C; sub-oven temperature, 35.3 ● 0.15°C; room temperature, 22°C; and equilibration time, 10 min.

RESULTS AND DISCUSSION

Determination of the Instrument Constant (K)—This constant is the same as the slope of the calibration curve showing the change in the ΔR values for the standard substance (benzil) in benzene at different concentrations (C). The range of concentration was chosen to generate ΔR values from 50 to 150. K was calculated using four sets of data. No significant difference has been noted between the slopes obtained from each set of data based on the Student's t test. Since the origin is included within the confidence limits (1%) of each intercept, the equation of the calibration curve can be represented as follows:

$$\Delta R = KC + b \qquad \text{(Eq. 1)}$$

where $b = 0$. The slope is calculated as the sum of ΔR values divided by the sum of the concentrations obtained for the four sets of data. Accordingly, the instrument constant (K) is equal to 18,000.150.

Determination of the Number-Average Molecular Weights—Sample calculation curves were obtained by plotting $\Delta R/C$ as a function of C for different concentrations of a sample dissolved in benzene (g of sample/kg of benzene). Figures 1 and 2 show the curves obtained for the two lots of I and for II. The number-average molecular weight is calculated using the following equation[4]:

$$\text{Number-average mol. wt.} = \frac{\text{Instrument constant } (K)}{\text{Intercept of the sample calculation curve}} \qquad \text{(Eq. 2)}$$

Table I shows the number-average molecular weights determined for each sample; these results are close enough to those reported, except for one lot of I. This difference may have a twofold significance. This particular lot was stored in our laboratory for over 3 years at room temperature in an air-tight container. One can suppose that the two lots of I were

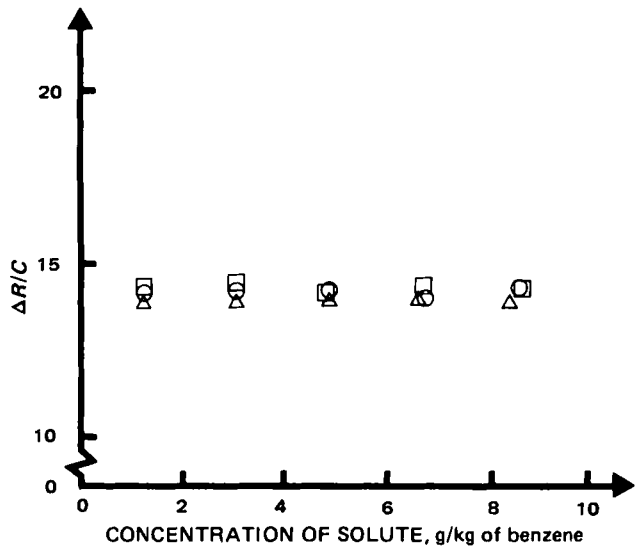

Figure 2—*Sample calculation curves of polyoxyethylene 23 lauryl ether. Key: (□, ○, △) three sets of data for lot 667.*

[4] Since the sample calculation curves were made in duplicate or triplicate, the mean intercept was used in each case for the calculation.

composed of different fractions or that "degradation" occurred during the storage period of lot WPTY 175B. No matter which hypothesis is retained, the product has not lost its activity as far as emulsifying or surface-active properties are concerned.

Nevertheless, the average molecular weight of an emulsifier ought to be known in order to determine its surface excess and to produce the curve of the surface pressure *versus* "molecular" cross-sectional area of the emulsifier (7). Relying on the reported molecular weight can generate misleading values for the aforementioned parameters, especially if the data are obtained from different batches of the same emulsifier. No comparison can be made between the behavior of different lots of one product unless a correction is made for the difference in their molecular weights.

Alloxan Analogues as Potential Pancreatic-Imaging Radiopharmaceuticals

WILLIAM E. ADAMS *, NED D. HEINDEL *x, GENE TUTWILER ‡, and HENRY FAWTHROP ‡

Received August 19, 1982, from the **Center for Health Sciences, Lehigh University, Bethlehem, PA 18015* and the ‡*Biochemistry Department, McNeil Laboratories, Spring House, PA 19477.* Accepted for publication January 10, 1983.

Abstract □ Three families of alloxan derivatives, 5-arylthiobarbituric, 5-aryliminobarbituric, and 5-aryldialuric acids, were prepared as prospective radioiodine-transporting radiopharmaceuticals for the delineation of pancreatic insulinomas. Members of each class were screened for effects on blood sugar levels in a rat glucose tolerance assay. Transient hyperglycemia was observed with 5-(2,4-dichlorophenyl)iminobarbituric acid. No agent evaluated induced permanent diabetes at the doses tested.

Keyphrases □ Alloxan—analogues, potential tumor-imaging agents, pancreatic insulinomas, effect on blood glucose levels, rats □ Tumor-imaging agents—alloxan analogues, pancreatic insulinomas, effect on blood glucose levels, rats

Alloxan and several of its derivatives are diabetogenic (1–3). While no definitive structure–activity studies have been reported, it appears that alloxan, alloxan monohydrate (II), alloxantin (I), and dialuric acid (III), without bulky substituents on nitrogen, are all able to induce frank diabetes (1–3). Some evidence supports a direct effect on the pancreas, for degranulation of β-cells is observed; [^{14}C]alloxan was shown to concentrate in the islet cells by autoradiography (4–7).

Development of radiopharmaceuticals for the scintigraphic imaging of occult pancreatic malignancies has been a goal of these laboratories for several years (8–11). In at least one previous study, it has been shown that substances with direct effects on serum glucose levels can, if radioisotopically labeled, preferentially delineate insulinomas (12, 13). Alloxan analogues would appear worthy of investigation in this regard.

Three classes of alloxan derivatives have been prepared which differ from the parent molecule by possessing an aryl moiety at C-5. This pendant aromatic ring would provide a suitable locus for the attachment of radioiodine in the chemical agent actually selected for the tumor-imaging study. As an initial screen to select analogues for isotopic labeling, a glucose tolerance test was performed to assay diabetogenic potential. This procedure has been described previously (14). Candidates were selected from the three classes synthesized: 5-arylthiobarbituric acids (IV), 5-aryliminobarbituric acids (V), and 5-aryldialuric acids (VI).

A new and more facile synthesis of 5-arylthiobarbituric acids (IVa–c) was developed from triphenylphosphine–alloxan adducts (VII), whose synthesis was described in an earlier publication (15), and aromatic thiols (Scheme

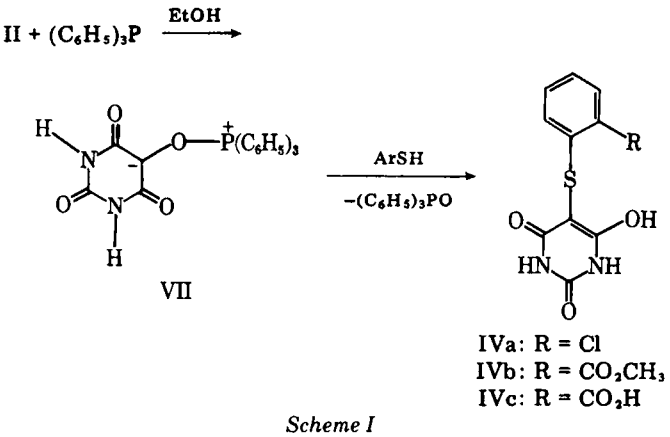


Scheme I

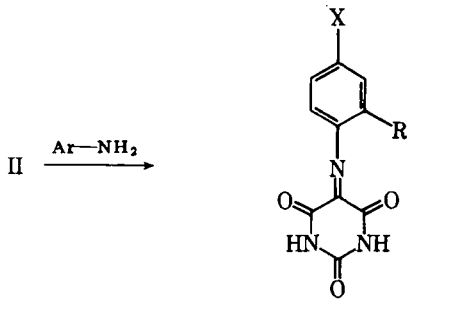
I). The mercapto function displaces the triphenylphosphine oxide to generate the arylthiobarbiturates. Since the alloxan–triphenylphosphine adduct is available in nearly quantitative yield, the overall conversion to the desired products (IVa–c) is more convenient than the published route, which requires the preparation and purification of 5-chlorobarbituric acid and subsequent nucleophilic displacement of the chloro group by an arylthiolate anion (16).

5-Aryliminobarbituric acids have been previously prepared from alloxan anhydride, which was obtained by dehydration of the alloxan monohydrate (II) (17). Here, the alloxan anhydride, generated *in situ* by treatment of the monohydrate with glacial acetic acid, was trapped by the aromatic amine (Scheme II).

The dialuric acids (VIa–g) were generated by condensation of anilines, possessing an unsubstituted *para*-position, with alloxan monohydrate in glacial acetic acid. Even primary aromatic amines with open *para*-positions condense preferentially at the *para* site (to form dialuric acids) rather than at the amino group (to form iminobarbiturates) (17–20).

EXPERIMENTAL[1]

5-Arylthiobarbituric Acids (IVa–c)—Equimolar amounts (5.0 mmol) of the triphenylphosphine–alloxan adduct (VII) (15) and the requisite aromatic thiol (see Scheme I) were refluxed for 2 h in 50 mL of 1:1 glacial acetic acid–absolute ethanol. The solvent was evaporated *in vacuo* to approximately one-half the original volume, the mixture was chilled, and the product was removed by filtration. The resulting thiobarbiturates were recrystallized by dissolution in a minimal quantity of boiling ethanol and reprecipitation by dropwise addition of 1:3 benzene–petroleum ether (60–110°C). The 5-arylthiobarbituric acids were characterized by broad—OH and —NH absorption in the IR between 2800 and 3300 cm^{-1} and by carbonyl absorption at 1725 ± 5, 1705 ± 5, and 1645 ± 5 cm^{-1}. Yields are reported in Table I.



Scheme II

5-Aryliminobarbituric Acids (Va–d)—Equimolar amounts (6.25 mmol) of alloxan monohydrate (II) and the requisite aniline (see Scheme II) were heated at reflux in 15 mL of glacial acetic acid for 0.5 h. The mixture was cooled (0°C); Vb–d crystallized as red-purple solids and Va separated as an oil (crystallized from dioxane–benzene). The solids, Vb–d, were washed with a minimum of warm benzene, filtered, and dried *in vacuo* to yield analytical specimens. The 5-aryliminobarbituric acids were characterized by composite —OH and —NH absorption between 2820 and 3380 cm^{-1} and by carbonyl and imine absorption at 1750 ± 5, 1720 ± 5, and 1680 ± 5 cm^{-1}. Yields are reported in Table I.

5-Aryldialuric Acids (VIa–d)—The dialuric acids were prepared by a previously described method (20) from equimolar amounts (6.25 mmol) of alloxan monohydrate and an aniline with an unsubstituted *para*-position in 20 mL of glacial acetic acid at 25°C. The mixture was stirred at ambient temperature for 30 min, chilled, and the product removed by filtration. The resulting crystalline material was washed with 2 × 10-mL portions of cold glacial acetic acid and then dried (0.01 mm). Yields are reported in Table I. The IR spectra displayed —OH and —NH absorption between 3100 and 3600 cm^{-1} and carbonyl absorption at 1730 ± 5 and 1710 ± 5 cm^{-1}.

[1] Analyses were performed by Dr. G. I. Robertson, Florham Park, N.J. Melting points were determined between glass disks on a Fisher-Johns Apparatus and are reported uncorrected. NMR spectra were obtained on a Perkin-Elmer Hitachi R20A spectrometer and are calibrated against tetramethylsilane. Infrared spectra were taken in 1–2% KBr disks on a Perkin-Elmer Model 257 infrared spectrometer.

Table I—Alloxan Analogues Investigated as Potential Pancreatic Radiopharmaceuticals

Compound	Formula[a]	mp, °C dec.	Yield, %
IVa	$C_{10}H_7ClN_2O_3S$	268.0–268.5	34

RESULTS AND DISCUSSION

Six of the materials prepared in this study, including representatives of each of the three compound classes, underwent a rat glucose tolerance screen. The assay was performed as previously described (14) on sets of three male Sprague–Dawley (210–250 g) rats fasted for 48 h prior to intraperitoneal injection of the test compound as a suspension in 0.5% methylcellulose. Animals were administered glucose (1.0 g/kg of body weight) orally 30 min after injection of the test compound. Blood, withdrawn from the tail vein at the time of glucose administration and at 1, 2, 3, 4, 5, 6, 24, and 48 h postdose, was analyzed for glucose by a previously described method (21). The maximum percent rise in blood glucose and any permanent glycosuria were the test observations made on the candidate agents.

The two dialuric acid derivatives, VIa and b, were inactive at 50 mg/kg ip; VIc was evaluated at 100 mg/kg and was similarly inactive. The thiobarbiturate IVb was inactive at 43 mg/kg, and the iminobarbiturate Vd was inactive at 50 mg/kg. However, the 5-(2,4-dichlorophenyl)iminobarbituric acid (Va) was toxic to all three rats at 100 mg/kg and produced a marked, but transient, rise (*i.e.*, 48% at 2 h) in blood glucose with no permanent hyperglycemia and no toxic deaths at 25 mg/kg ip.

The doses employed in this study were below the diabetogenic levels usually reported for alloxan-induced diabetes in rats (22), but they were in vast excess of the levels which would be employed in radiolabeled, carrier-free, radiopharmaceuticals. The absence of any permanent glycosuria at 48 h postdose and the transient rise in blood glucose (for Va) indicate that at these concentration levels, the alloxan derivatives are probably not cytotoxic to sufficient β-cells to be diabetogenic. The one active imine (Va) may, in fact, induce hyperglycemia by an *in vivo* hy-

drolytic scission to alloxan itself; electron-withdrawing halogens on the aryl ring would be anticipated to activate the anil to hydrolysis. Compound Va would appear to be an attractive candidate for radiohalogenation and study as an insulinoma-imaging agent with the caveat that *in vivo* hydrolysis may separate the label-bearing aniline and thwart target uptake of the tracer.

Analysis of Gossypol and Gossypol–Acetic Acid by High-Performance Liquid Chromatography

GUIDO B. MARCELLE, MOHAMED S. AHMED *, JOHN M. PEZZUTO, GEOFFREY A. CORDELL ˣ, DONALD P. WALLER, D. D. SOEJARTO, and H. H. S. FONG

Received September 16, 1982, from the *Department of Pharmacognosy and Pharmacology, College of Pharmacy, University of Illinois at the Medical Center, Chicago, IL 60612.* Accepted for publication January 10, 1983. *Present Address: Faculty of Pharmacy, Cairo University, Cairo, Egypt.

Abstract □ Gossypol, a bis-sesquiterpenoid cotton pigment, is of current interest as a male fertility-regulating agent. For the purposes of analyzing material to be studied biologically, a method is described for the analysis of gossypol by high-performance liquid chromatography. This has been used for examining the purity of gossypol–acetic acid using a UV-absorbance ratio technique.

Keyphrases □ Gossypol—analysis, gossypol–acetic acid, high-performance liquid chromatography □ Contraceptives, male—gossypol–acetic acid, analysis, high-performance liquid chromatography

Gossypol (I), one of several pigments isolated from *Gossypium* (Malvaceae) (1, 2), is found in concentrations of up to 1.7% in cotton seeds (*G. hirsutum* L.). Because of the toxicity of gossypol, cotton seed flour has limited use for humans and domestic animals; the upper limit of gossypol concentration for human consumption has been set at 0.045% (3). Gossypol is reported to be unstable and is, therefore, usually available as the 1:1 complex with acetic acid (1, 2, 4, 5)[1].

Several analyses of gossypol have been described, including complexation with aromatic amines followed by UV analysis (6, 7), GC analysis of the trimethylsilyl ether (8) and *N,O*-bis(trimethylsilyl) acetamide derivatives (9), paper chromatography (10), and TLC (11). A recent (12) communication describing the high-performance liquid chromatographic (HPLC) analysis of gossypol prompts us to report our own efforts in this area[2].

Our interest in gossypol was stimulated by reports that it possessed *in vitro* spermicidal activity (13, 14) and *in*

Analysis of Gossypol and Gossypol–Acetic Acid by High-Performance Liquid Chromatography

GUIDO B. MARCELLE, MOHAMED S. AHMED *, JOHN M. PEZZUTO, GEOFFREY A. CORDELL ˣ, DONALD P. WALLER, D. D. SOEJARTO, and H. H. S. FONG

Received September 16, 1982, from the *Department of Pharmacognosy and Pharmacology, College of Pharmacy, University of Illinois at the Medical Center, Chicago, IL 60612.* Accepted for publication January 10, 1983. *Present Address: Faculty of Pharmacy, Cairo University, Cairo, Egypt.

Abstract □ Gossypol, a bis-sesquiterpenoid cotton pigment, is of current interest as a male fertility-regulating agent. For the purposes of analyzing material to be studied biologically, a method is described for the analysis of gossypol by high-performance liquid chromatography. This has been used for examining the purity of gossypol–acetic acid using a UV-absorbance ratio technique.

Keyphrases □ Gossypol—analysis, gossypol–acetic acid, high-performance liquid chromatography □ Contraceptives, male—gossypol–acetic acid, analysis, high-performance liquid chromatography

Gossypol (I), one of several pigments isolated from *Gossypium* (Malvaceae) (1, 2), is found in concentrations of up to 1.7% in cotton seeds (*G. hirsutum* L.). Because of the toxicity of gossypol, cotton seed flour has limited use for humans and domestic animals; the upper limit of gossypol concentration for human consumption has been set at 0.045% (3). Gossypol is reported to be unstable and is, therefore, usually available as the 1:1 complex with acetic acid (1, 2, 4, 5)[1].

Several analyses of gossypol have been described, including complexation with aromatic amines followed by UV analysis (6, 7), GC analysis of the trimethylsilyl ether (8) and *N,O*-bis(trimethylsilyl) acetamide derivatives (9), paper chromatography (10), and TLC (11). A recent (12) communication describing the high-performance liquid chromatographic (HPLC) analysis of gossypol prompts us to report our own efforts in this area[2].

Our interest in gossypol was stimulated by reports that it possessed *in vitro* spermicidal activity (13, 14) and *in*

vivo antifertility activity in several male mammalian species (rats, hamsters, and rhesus monkeys) (15, 16) including humans (17–19). A preliminary report of our work (20) indicates that gossypol, but not its chemically related impurities, has antifertility activity in male hamsters. A critical basis for these pharmacological experiments was the need to have highly purified gossypol available to be able, categorically, to indicate the nature of the material used for dosing. In this paper we report our efforts on the analysis of gossypol and a determination of the purity of gossypol–acetic acid by a combination of quantitative HPLC and HPLC–UV absorbance ratio techniques (21, 22).

EXPERIMENTAL

Materials—Gossypol [2,2′-bis(1,6,7-trihydroxy-3-methyl-5-isopropylnaphthalene-8-carboxaldehyde), (I)] was supplied as the acetic acid complex[3]. Gossypol, mp 182–184°C, was liberated from the complex by the procedure of Campbell *et al.* (23), followed by crystallization from petroleum ether–ether. Concordance with previously reported physical and spectroscopic data for gossypol (24) was established. A highly purified sample of gossypol–acetic acid[4] was recrystallized three times from methyl ethyl ketone–acetic acid (3:1).

All chemicals and solvents used in this investigation were reagent grade and when used for HPLC were redistilled in glass or were HPLC grade[5]. The melting point was determined using a Kofler hot-stage instrument and is uncorrected.

Equipment—The initial separations were conducted using a liquid chromatograph[6] equipped with a syringe-loading sample injector with

20-μL sample loop[7], a variable-wavelength UV spectrophotometer[8] at 285 nm, and a 25.4-cm strip-chart recorder[9]. Separations were carried out using 30 × 0.39-cm i.d. prepacked columns with a typical flow rate of 1 mL/min[10]. For subsequent analysis of gossypol–acetic acid, the HPLC apparatus used was a combination instrument consisting of a system controller[11], pumps[9] with an added stop–flow valve, a variable-wavelength UV spectrophotometric detector[12] with an automated control[13], an integrator–recorder[14], and an injector[15].

Separation of Gossypol—Table I indicates the analytical solvent systems which were used in a preliminary attempt to separate gossypol from its impurities. Thus, four systems were used with μ-Styragel 500[10], 17 with μ-Bondapak cyano[10], and 17 with μ-Bondapak C_{18} columns[10]. Only one of these systems [μ-Bondapak C_{18} column, CH_3CN:H_2O:HOAc (7:2:1)] was found to be effective for the required separation. Detection was carried out at 254 nm. Gossypol and gossypol–acetic acid had identical retention times in this system.

Purity of Gossypol–Acetic Acid—To examine the purity of gossypol–acetic acid by HPLC, the best wavelength(s) for its detection were first established. Using the analytical solvent system described above, UV spectra of gossypol–acetic acid were obtained on a grating spectrophotometer[16] [complex dissolved in CH_3CN–H_2O–HOAc (7:2:1)] and using a variable-wavelength UV spectrophotometric detector[11] (directly on the solution eluting from the reverse-phase column). Maxima were observed at 254, 263 (sh), 283, 293, and 371 nm. When the absorbance was monitored at 254 nm[17], 260 nm[17], and 290 nm[17], gossypol–acetic acid eluted as a single peak (retention time, 9.18 min), and integration of the area under the peak indicated a minimum purity of 99.90%[18].

RESULTS AND DISCUSSION

Figure 1 shows typical chromatograms of impure gossypol–acetic acid (A) and the recrystallized gossypol–acetic acid (B) used as a standard. The lower limit of detection was 5 μg at 0.04 AUFS and 5 ng at 0.01 AUFS.

For the chromatographic conditions used, the peak representing gossypol–acetic acid has some tailing. To demonstrate that this peak was intrinsically a single peak and to further substantiate the purity of the gossypol–acetic acid sample, an absorbance ratio technique was utilized (21, 22). In this experiment, the flow of the eluting peak was stopped at the leading edge (point 1), and crest (point 2), and the trailing edge (point 3), as illustrated in Fig. 2. Based on the UV-absorption spectra of gossypol–acetic acid taken in CH_3CN–H_2O–HOAc (7:2:1), absorbancy was

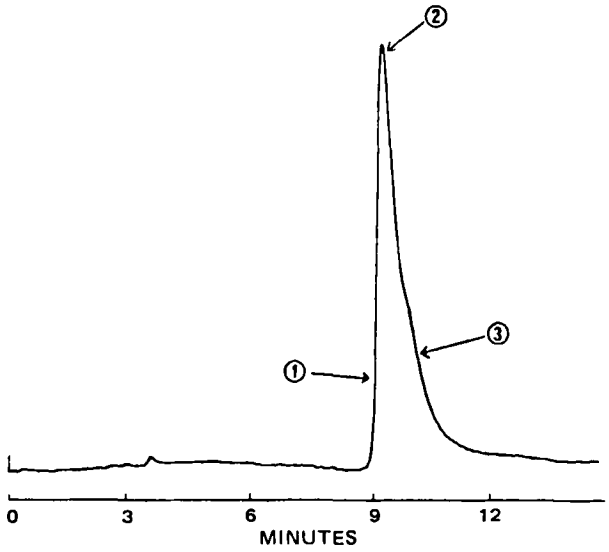

Figure 2—*Points of eluting HPLC peak of gossypol–acetic acid at which absorbance measurements were made at preselected wavelengths. Key: (1) leading edge, (2) crest, (3) trailing edge.*

determined at four preselected wavelengths (254, 260, 290, and 370 nm) each time the flow was stopped. The sensitivity was reduced for higher absorbance readings. Absorbance ratios were then calculated for (λ_1/λ_2) 254/260, 254/290, 254/370, and 290/370 nm. The experiment was done in replicate. The results (Table II) strongly indicate that the chromatographic peak for gossypol–acetic acid consists of a single, spectroscopically (UV, IR, ^{1}H-NMR, ^{13}C-NMR, and MS) pure substance, since the absorbance ratios at the various points of the peak did not differ significantly.

From these results the most consistent and reliable ratios are those involving wavelengths of 254, 260, and 290 nm. From an analysis of variance of the calculated absorbance ratios taking the leading edge, the crest, and the trailing edge as three distinct populations, the results were $F_{2,69} = 0.03$; the reference shows $F_{0.005,2,60} = 5.80$. The three sets of ratios are therefore similar with a 99.5% degree of confidence. This method appears to be a highly effective HPLC technique for the analysis of gossypol–acetic acid, which is superior to those reported previously.

Noninteraction of Temazepam and Cimetidine

DAVID J. GREENBLATT ˣ, DARRELL R. ABERNETHY, MARCIA DIVOLL, ANN LOCNISKAR, JEROLD S. HARMATZ, and RICHARD I. SHADER

Received October 6, 1982, from the *Division of Clinical Pharmacology, Departments of Psychiatry and Medicine, Tufts-New England Medical Center, Boston, MA 02111.* Accepted for publication February 11, 1983.

Abstract □ The possible kinetic interaction of the hypnotic temazepam and the H_2-receptor antagonist cimetidine was evaluated. Nine healthy male and female volunteers received a 30-mg oral dose of temazepam on two occasions in random sequence, separated by at least 1 week. On one occasion, temazepam was given in the otherwise drug-free state; on the other, temazepam was given with concurrent administration of cimetidine, 300 mg every 6 h. Mean pharmacokinetic parameters for temazepam in control *versus* cimetidine trials were: peak plasma concentration, 560 *versus* 498 ng/mL; time of peak concentration, 2.0 *versus* 2.1 h after the dose; volume of distribution, 1.30 *versus* 1.39 L/kg; elimination half-life, 9.9 *versus* 11.4 h; total clearance, 1.59 *versus* 1.60 mL/min/kg; free fraction of temazepam in plasma, 4.1 *versus* 3.8% unbound. Cimetidine has been shown to reduce the metabolic clearance of the benzodiazepines that are biotransformed by oxidative mechanisms. Temazepam, transformed by conjugation, appears unaffected by the coadministration of cimetidine.

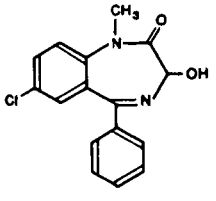
Keyphrases □ Temazepam—noninteraction with cimetidine, pharmacokinetics □ Cimetidine—noninteraction with temazepam, pharmacokinetics □ Pharmacokinetics—noninteraction of temazepam and cimetine

Temazepam (I) is a 3-hydroxybenzodiazepine derivative utilized in clinical practice as an hypnotic (1). Previous studies have suggested that the widely prescribed antiulcer agent cimetidine (2, 3) may have the additional capacity to impair hepatic microsomal oxidizing capacity and thereby impair the metabolic clearance of certain benzodiazepine derivatives when the two are administered together. Cimetidine coadministration reduces the metabolic clearance of the oxidatively biotransformed benzodiazepines chlordiazepoxide, diazepam, desmethyldiazepam, alprazolam, and triazolam (4–9). However, cimetidine has very little influence on the clearance of benzodiazepines transformed by glucuronide conjugation, including oxazepam and lorazepam (8–10). Since temazepam is also metabolized by glucoronide conjugation (11), the present study was undertaken to test the hypothesis that cimetidine coadministration would similarly have little effect on the metabolic clearance of temazepam.

EXPERIMENTAL

Subjects and Procedure—Nine healthy male and female volunteers, aged 21–67 years, participated after giving written informed consent. All were healthy, active, ambulatory adults with no evidence of medical disease and were taking no other medications.

All subjects received a 30-mg oral dose of temazepam[1] on two occasions in random sequence separated by at least 1 week. On one occasion, temazepam was given in the control state without coadministration of other drugs. For the other trial, temazepam was administered during concurrent treatment with cimetidine[2], 300 mg taken every 6 h beginning 12 h prior to temazepam dosage and continuing for the entire 48-h duration of the temazepam kinetic study.



TEMAZEPAM

After an overnight fast, a single 30-mg oral dose of temazepam was administered with 100–200 mL of tap water. Subjects were tested for an additional 3 h after the dose. Venous blood samples were drawn into heparinized tubes prior to temazepam administration and at the following postdosage times: 5, 10, 15, 30, and 45 min, 1, 1.5, 2, 2.5, 3, 4, 6, 8, 12, 24, 32, and 48 h. Blood samples were centrifuged and the plasma separated and frozen until the time of assay.

Analysis of Samples—Plasma concentrations of temazepam were determined by electron-capture GC using a previously described method (12) with minor modifications. The analytical instrument[3] was a gas chromatograph equipped with a 15-mCi electron-capture detector, an automatic sampler, and an electronic data processor–integrator. The column was coiled glass, 183 cm in length by 2-mm i.d., packed with 1% OV-17 on 80/100 Chromosorb WHP. The column temperature was 270°C, and the injection port and detection temperatures were 310°C. The carrier gas was argon–methane (95:5) at 30 mL/min. After addition of 3-hydroxyprazepam as the internal standard, calibration standards and unknown plasma samples were extracted once with benzene–dichloromethane (80:20). After mixing and centrifugation, the organic extract was separated, evaporated to dryness, reconstituted, and injected into the chromatograph using the automatic sampler. Sensitivity, replicability, and linearity were as described previously (12). All samples

[a] NS = not significant.

from a given subject's two trials were extracted and analyzed on the same day using the same calibration standards.

For each subject the influence of cimetidine on temazepam plasma protein binding was determined using a 6-mL sample of plasma obtained in the nonfasting state during the control temazepam trial (without cimetidine treatment). Cimetidine (5 μg/mL) was added to one 3-mL plasma aliquot; no cimetidine was added to the other. Both aliquots were then spiked to contain 3.2 nCi/mL of [^{14}C]temazepam (specific activity: 11 μCi/mg). The extent of temazepam protein binding in each sample was determined in duplicate by equilibrium dialysis for 18 h at 37°C (13, 14). Compliance with the prescribed cimetidine regimen during the temazepam–cimetidine trial was verified by measurement of plasma cimetidine concentrations by HPLC (15) in samples drawn prior to temazepam dosage and at 12, 24, 32, and 48 h after the dose.

Kinetic Analysis—The apparent elimination half-life of temazepam was determined using the slope of the terminal log-linear plot of the plasma concentration curve (Fig. 1). The area under the curve from time zero until the final detectable concentration was determined using the trapezoidal method. To this was added the residual area extrapolated to infinity, calculated as the final concentration divided by the terminal rate constant (β). The sum of these two areas represents the total area under the plasma concentration curve (AUC). The total clearance of temazepam was calculated as dose/AUC, assuming that the entire 30-mg dose was available to the systemic circulation. Likewise, the apparent volume of distribution was calculated as clearance/β. Differences between control and cimetidine treatment conditions were analyzed by the Student's paired *t* test.

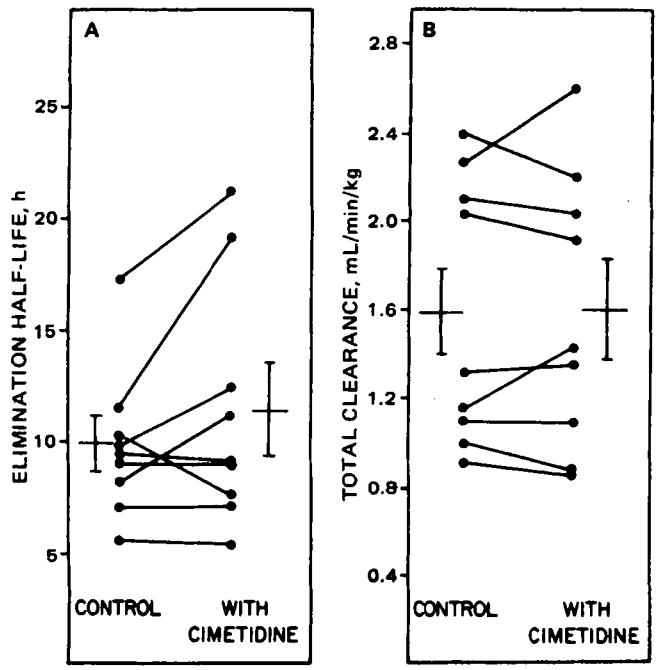

Figure 2—*Temazepam elimination half-life (A) and total metabolic clearance of temazepam (B) in the control state and during coadministration with cimetidine. Individual and mean (±SE) values are shown.*

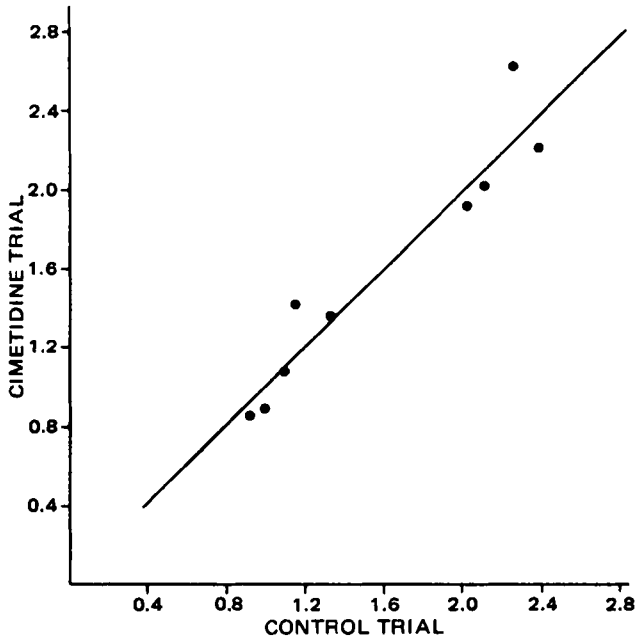

Figure 3—*Values of temazepam clearance (●) in mL/min/kg for the nine individuals during the control trial (x axis) and during coadministration with cimetidine (y axis). Solid line was determined by least-squares regression analysis. Note the high correlation and the regression line slope, which is not significantly different from unity. Slope = 0.98; r = 0.96.*

RESULTS

Compliance with the prescribed cimetidine regimen was acceptable in all subjects. Mean (±*SE*) plasma cimetidine concentrations were: prior to temazepam dosage, 1.43 (±0.32) μg/mL; 12 h postdose, 1.23 (±0.39) μg/mL; 24 h, 2.05 (±0.44) μg/mL; 32 h, 1.06 (±0.23) μg/mL; 48 h, 1.76 (±0.45) μg/mL.

Absorption of temazepam was not significantly influenced by cimetidine. The peak plasma concentration in control and cimetidine treatment conditions averaged 560 and 498 ng/mL, respectively, and the times of peak concentration averaged 2.0 and 2.1 h after the dose. Neither of these differences approached significance (Table I).

Temazepam volume of distribution, elimination half-life, and total clearance were similar between control and cimetidine treatment conditions (Table I, Figs. 1 and 2). Mean half-life values were 9.9 and 11.4 h, respectively, in the two conditions, with an overall range of 6–21 h. None of the differences approached statistical significance. Furthermore, for any given individual, temazepam clearance was highly reproducible between the two trials (Fig. 3). Temazepam free fraction in plasma averaged 4.1 and 3.8% in the two conditions; again the difference did not approach significance.

DISCUSSION

Cimetidine, an H_2-receptor antagonist that is extensively used in the treatment of peptic ulcer disease (2, 3), also has the secondary pharmacological property of impairing hepatic microsomal oxidizing capacity. Previous studies have indicated that benzodiazepines biotransformed by oxidative mechanisms, including diazepam, chlordiazepoxide, desmethyldiazepam, alprazolam, and triazolam, have reduced metabolic clearance during coadministration of cimetidine as opposed to the drug-free control state (4–9). This interaction appears not to occur for benzodiazepines biotransformed by conjugation as opposed to oxidation, including oxazepam and lorazepam (8–10). Temazepam is a 3-hydroxybenzodiazepine biotransformed by conjugation at the 3-position to glucuronic acid, yielding a water-soluble glucuronide metabolite that is excreted in the urine (11). The present study indicated that coadministration of temazepam with cimetidine had no influence on the pattern of temazepam absorption, distribution, or clearance. Consistent with

previous reports (16), absorption of temazepam from the hard gelatin capsule utilized in the United States occurs relatively slowly, with peak plasma concentrations an average of 2.0–2.1 h after dosage. Temazepam elimination half-lives ranged from 6 to 21 h, and total metabolic clearances ranged from 0.9 to 2.6 mL/min/kg. None of these kinetic variables were significantly influenced by cimetidine coadministration, nor was the extent of temazepam binding to plasma protein altered by cimetidine. Furthermore, for any given individual, the kinetic profile for temazepam was highly consistent between the two treatment trials.

The clinical implications of an interaction or noninteraction with cimetidine for any particular benzodiazepine cannot at present be determined. The present study nonetheless suggests that, consistent with its biotransformation pathway mainly involving glucuronide conjugation, the pharmacokinetic profile of temazepam is not influenced by concurrent treatment with cimetidine.

Dissolution Rates of Corticoid Solutions Dispersed on Silicas

CHI-CHOW LIAO and C. I. JAROWSKI ˣ

Received July 21, 1982, from the *College of Pharmacy and Allied Health Professions, St. John's University, Jamaica, NY 11439.* Accepted for publication January 27, 1983.

Abstract □ Two nonporous and three porous amorphous silicas were used as dispersion media to convert corticoid solutions into free-flowing powders. The corticoids (prednisone, prednisolone, and hydrocortisone) were dissolved in *N,N*-dimethylacetamide–polyethylene glycol 400 (7:3 v/v) and their 10% (w/v) solutions were mixed with the silicas (1:3 v/w). Dissolution rates of the corticoids from such powdered solutions were more rapid than their micronized powders in various aqueous media.

Keyphrases □ Dissolution rate—corticoid solutions dispersed on silicas, prednisone, prednisolone, hydrocortisone, free-flowing powders □ Corticoids—solutions dispersed on silicas, dissolution rates, prednisone, prednisolone, hydrocortisone, free-flowing powders □ Powders, free-flowing—corticoid solutions dispersed on silicas, dissolution rates, prednisone, prednisolone, hydrocortisone

The USP (1) requires that ≥60% of the prednisone or prednisolone from their respective tablets must dissolve within 20 min in deaerated water. These water-insoluble neutral drug molecules could exhibit poor dissolution rates from improperly prepared capsule or tablet dosage forms. Oral absorption efficiency of the corticoids from such solid dosage forms could be impaired.

Concentrated solutions of three corticoids (prednisone, prednisolone, and hydrocortisone) had been prepared in *N,N*-dimethylacetamide, a high-boiling, water-miscible liquid (2). These earlier studies had shown that the addition of 30% (v/v) polyethylene glycol 400 to the *N,N*-dimethylacetamide would prevent the softening effect of the latter on hard gelatin capsules. As a consequence, this mixture of solvents was used to prepare 10% (w/v) solutions of the three corticoids.

Simple admixture of the corticoid solutions with amorphous, porous, or nonporous silicas converted them to free-flowing powders. The corticoids in such powdered solutions are thus in a molecular state of subdivision. Dissolution rates of such water-insoluble, neutral compounds should be instantaneous if localized dilution with simulated GI media does not cause their precipitation.

The purpose of this study was to convert solutions of corticoids to free-flowing powders by dispersing them on various silicas. Dissolution rates in simulated GI media are compared with those of micronized powders. A comparison of the dissolution rate with ball-milled or solvent-deposited prednisone–silica dispersions is also presented (3).

Table I—UV Wavelengths Used in the Development of Calibration Curves for the Three Drugs in Various Solvents

Solvent	Wavelength of Light, nm I	II	III
Simulated gastric fluid (without pepsin)	248	243	247
Simulated intestinal fluid (without pancreatin)	248	243	247
Ethanol	248	243	247

[a] Micronized powder. [b] Corticoid was solvent-deposited on the surface of the silica by the method of Yang *et al.* (3).

EXPERIMENTAL

Materials—The following were obtained from commercial sources: anhydrous micronized prednisolone[1] (I); micronized prednisone, USP[1] (II); micronized hydrocortisone[2] (III); three grades of porous silicas[3]; two types of nonporous silicas[4]; *N,N*-dimethylacetamide[5]; polyethylene glycol 400[6]; anhydrous ethanol (UV grade)[7]; hydrochloric acid[7]; sodium chloride[7]; monobasic potassium phosphate (AR)[7]; sodium hydroxide pellets[7]; phosphate buffer, pH 7[8]; phosphate buffer, pH 4[8]; and distilled water. The following equipment was used: double-beam spectrophotometer[9]; pH meter (Model DB-GT)[8]; analytical balance[10]; USP XIX dissolution test basket assembly[11]; polytherm constant-temperature water bath[12]; 13-mm Swinny adapter[13]; filter paper, 0.45-μm porosity[13]; plastic syringe[13]; and quartz electric stopwatch[14].

Methods—Corticoid solutions were prepared by dissolving 1 g of corticoid in a sufficient quantity of *N,N*-dimethylacetamide–polyethylene glycol 400 (7:3 v/v) to make 10 mL of solution. The weights of mixed solvent used are: for I, 9.2031 g; for II, 9.2067 g; for III, 9.2086 g.

Corticoid–silica dispersions were prepared by placing 1 mL of corticoid solution (1 mL of prednisolone solution weighs 1.01 g) in a mortar and adding 3 g of silica. Simple admixture with a pestle produced a homogeneous free-flowing powder. Aliquots of 0.401 g should contain 10 mg of prednisolone. All corticoid solution–silica samples were prepared in duplicate.

Spectrophotometric absorption and calibration curves were obtained by diluting the corticoid solutions with simulated GI media, without enzymes (4), and wavelengths for maximum absorbance were determined (Table I). Absorbance *versus* concentration plots (concentration range 3–12 μg/mL) revealed that Beer's law was followed (regression coefficient, 0.999). To blank out interference from the organic solvents present, stock solutions of simulated GI fluids were used which contained identical quantities of mixed solvent without the corticoid.

The assay of the corticoid solution–silica dispersions involved the extraction of 1 g of corticoid solution–silica dispersion with 15 mL of ethanol four times. The ethanol extracts were combined and centrifuged. Three milliliters of supernatant was diluted to 200 mL with ethanol, and the absorbance was measured at the wavelength shown in Table I.

Dissolution rates of the corticoid solution–silica dispersions were determined by the USP basket method (1) using 1000 mL of simulated gastric juice without pepsin (pH 1.2) or simulated intestinal fluid without pancreatin (pH 7.4). Dispersions which contained the equivalent of 10 mg of corticoid were placed in the basket, which was lowered to a depth 2 cm from the bottom of the vessel and rotated at 150 rpm. All dissolution studies were conducted at 37 ± 0.5°C.

Five-milliliter aliquots were withdrawn midway between the surface

of the dissolution medium and the bottom of the vessel, filtered through 0.45-μm membrane, and assayed spectrophotometrically. The volume of the dissolution medium was maintained at 1000 mL by the addition of the appropriate medium and cumulative corrections were made for the previously removed samples in determining the total amount of drug in solution. The results of all the dissolution studies, which were run in duplicate, are shown in Table II.

RESULTS AND DISCUSSION

The data in Table II clearly show the more rapid presence of I, II, or III in either dissolution medium when the corticoid solutions were dispersed on the five silicas used. As a micronized powder, II (samples 19 and 20) dissolved very slowly in either GI medium; after 20 min <60% had dissolved. However, when a solution of II was dispersed on IV, V, or VI, >70% of II was in solution within 5 min (samples 21, 22, and 23) in simulated gastric juice. In simulated intestinal juice, the rate was not as large; within 10 min >68.5% of II had dissolved (samples 26, 27, and 28).

Silicas IV, V, and VI were consistently more efficient in releasing the drug solutions dispersed on them than were VII and VIII. When silicas VII and VIII were used with a solution of II <100% of II had dissolved in the simulated GI media after 120 min (samples 24, 25, 29, and 30).

A comparison of solvent-deposited I with its silica-dispersed solution is also of interest. In every instance the silica-dispersed solutions were superior (samples 3 *versus* 13, 4 *versus* 14, 5 *versus* 15; 8 *versus* 16, 9 *versus* 17, and 10 *versus* 20). Ball-milled samples were not prepared. However, Yang *et al.* (3) reported that after ball-milling prednisone with a 20-fold excess of IV, V, or VI, a maximum of 65% of II had dissolved after 120 min in simulated GI media. Their dissolution studies were conducted at 100 rpm. Narurkar and Jarowski (5) also reported similar slow dissolution rates for I that had been ball-milled with various ratios of IV, V, VI, or VII. When solutions of I or II were dispersed on IV, V, VI, VII, or VIII and their dissolution rates studied at 100 rpm, all but one sample released 83–99% within 120 min. The exception was a solution of II dispersed on VI; only 60% had dissolved in simulated intestinal fluid after 120 min.

Such reduction in dissolution rate resulting from reduced basket speed is of concern since the anticipated superiority in the *in vivo* performance of silica-dispersed solutions over micronized powders is suspect. A preliminary *in vivo* experiment with salicylamide indicates that more rapid oral absorption does occur when the compound is dissolved and dispersed on silica. This data will be published elsewhere.

Synthesis of New 8-(5-Substituted Amino-1,3,4-oxadiazol-2-yl) and 8-(5-Substituted Amino-1,3,4-thiadiazol-2-yl) Methoxyquinolines with Antibilharzial Activity

RAAFAT SOLIMAN *§x, HASSAN M. MOKHTAR ‡, and SAMIR K. EL SADANY ‡

Received November 8, 1982, from the **Department of Pharmaceutical Chemistry, Faculty of Pharmacy* and the ‡*Department of Chemistry, Faculty of Science, University of Alexandria, Alexandria, Egypt.* Accepted for publication February 1, 1983. §Present address: College of Pharmacy, University of Florida, J. Hillis Miller Health Center, Gainesville, FL 32610.

Abstract □ Several 5-substituted amino-1,3,4-oxadiazol-2-yl and 5-substituted amino-1,3,4-thiadiazol-2-yl derivatives with different 8-hydroxyquinoline moieties in the 2-position were prepared and tested for their antiparasitic activity. Preliminary biological tests on mice experimentally infested with *Schistosoma mansoni* revealed that the new compounds show moderate schistosomicidal activity.

Keyphrases □ 8-(5-Substituted amino-1,3,4-oxadiazol-2-yl) methoxyquinolines—synthesis, antibilharzial activity against *Schistosoma mansoni* □ 8-(5-Substituted amino-1,3,4-thiadiazol-2-yl) methoxyquinolines—synthesis, antibilharzial activity against *Schistosoma mansoni* □ Antischistosomal agents—synthesis of 8-(5-substituted amino-1,3,4-oxadiazol-2-yl) and 8-(5-substituted amino-1,3,4-thiadiazol-2-yl) methoxyquinolines

The fact that lucanthone (1) and its active metabolite hycanthone (2) were the first metal-free compounds to show clinical activity against bilharziasis initiated the synthesis of a distantly related compound 6-chloro-5-(2-diethylaminoethylamino)-8-methylquinoline. The latter exhibited outstanding activity against experimental schistosomiasis (3, 4). Unfortunately, preclinical toxicity studies indicated wide differences among various species of laboratory animals, precluding early clinical trials of this compound (3). A new entry in bilharzial chemotherapy is 1,2,3,4-tetrahydro-2-[[(1-methylethyl)amino]methyl]-7-nitro-6-quinolinemethanol (oxamniquine). It has potent schistosomicidal activity against *Schistosoma mansoni* by causing worms to shift from the mesenteric veins to the liver, where they are destroyed (5).

In our previous work (6) several 3-mercaptotriazoles with the 8-hydroxyquinoline moiety were prepared by cyclization of their corresponding substituted thiosemicarbazides by the action of hot sodium hydroxide solution. Preliminary biological tests revealed that those mercaptotriazoles showed potent schistosomicidal activity. These observations prompted the synthesis of several 5-substituted amino-1,3,4-oxadiazol-2-yl and 5-substituted amino-1,3,4-thiadiazol-2-yl derivatives with different 8-hydroxyquinoline moieties in the 2-position. Contrary to the mercaptotriazoles, the incorporation of the potent antiparasitic drug iodochlorhydroxyquinoline in the 2-oxadiazole or 2-thiadiazole rings produced compounds with moderate or low schistosomicidal activity.

of the dissolution medium and the bottom of the vessel, filtered through 0.45-μm membrane, and assayed spectrophotometrically. The volume of the dissolution medium was maintained at 1000 mL by the addition of the appropriate medium and cumulative corrections were made for the previously removed samples in determining the total amount of drug in solution. The results of all the dissolution studies, which were run in duplicate, are shown in Table II.

RESULTS AND DISCUSSION

The data in Table II clearly show the more rapid presence of I, II, or III in either dissolution medium when the corticoid solutions were dispersed on the five silicas used. As a micronized powder, II (samples 19 and 20) dissolved very slowly in either GI medium; after 20 min <60% had dissolved. However, when a solution of II was dispersed on IV, V, or VI, >70% of II was in solution within 5 min (samples 21, 22, and 23) in simulated gastric juice. In simulated intestinal juice, the rate was not as large; within 10 min >68.5% of II had dissolved (samples 26, 27, and 28).

Silicas IV, V, and VI were consistently more efficient in releasing the drug solutions dispersed on them than were VII and VIII. When silicas VII and VIII were used with a solution of II <100% of II had dissolved in the simulated GI media after 120 min (samples 24, 25, 29, and 30).

A comparison of solvent-deposited I with its silica-dispersed solution is also of interest. In every instance the silica-dispersed solutions were superior (samples 3 *versus* 13, 4 *versus* 14, 5 *versus* 15; 8 *versus* 16, 9 *versus* 17, and 10 *versus* 20). Ball-milled samples were not prepared. However, Yang *et al.* (3) reported that after ball-milling prednisone with a 20-fold excess of IV, V, or VI, a maximum of 65% of II had dissolved after 120 min in simulated GI media. Their dissolution studies were conducted at 100 rpm. Narurkar and Jarowski (5) also reported similar slow dissolution rates for I that had been ball-milled with various ratios of IV, V, VI, or VII. When solutions of I or II were dispersed on IV, V, VI, VII, or VIII and their dissolution rates studied at 100 rpm, all but one sample released 83–99% within 120 min. The exception was a solution of II dispersed on VI; only 60% had dissolved in simulated intestinal fluid after 120 min.

Such reduction in dissolution rate resulting from reduced basket speed is of concern since the anticipated superiority in the *in vivo* performance of silica-dispersed solutions over micronized powders is suspect. A preliminary *in vivo* experiment with salicylamide indicates that more rapid oral absorption does occur when the compound is dissolved and dispersed on silica. This data will be published elsewhere.

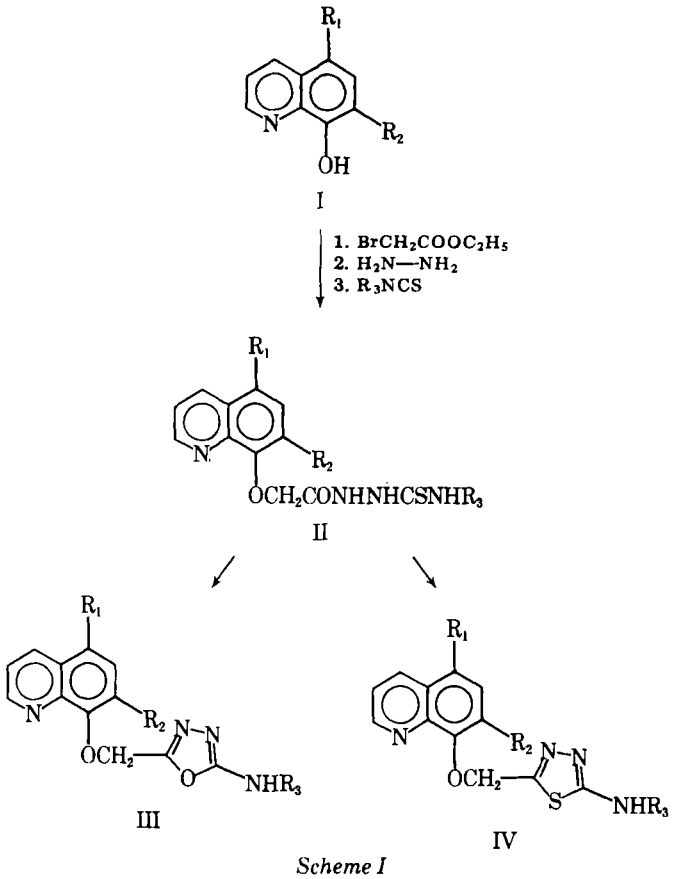

Scheme I

EXPERIMENTAL[1]

The various 1,3,4-oxadiazoles and 1,3,4-thiadiazoles were synthesized by reactions outlined in Scheme I. Conversion of the 8-hydroxyquinoline derivative (I) to the 8-quinolinoxyacetic acid hydrazide was effected by treating the corresponding ethyl ester with 99–100% hydrazine hydrate.

Substituted thiosemicarbazides (II), prepared by the reaction of 8-quinolinoxyacetic acid hydrazide with the appropriate isothiocyanate, were cyclized to the corresponding 8-(5-substituted amino-1,3,4-oxadiazol-2-yl)methoxyquinoline (III) in 4 M NaOH and 5% iodine in potassium iodide solution, and to the corresponding 8-(5-substituted amino-1,3,4-thiadiazol-2-yl)methoxyquinoline (IV) by the action of cold concentrated sulfuric acid (7). All compounds were characterized by their melting points, elemental analysis, and IR and ^{1}H-NMR spectra.

1-(8-Quinolinoxyacetyl)-4-substituted Thiosemicarbazides (II)—Series II compounds were prepared as mentioned previously (6), by refluxing equimolar quantities of 8-quinolinoxyacetic acid hydrazides with the appropriate isothiocyanate in dry benzene.

8-(5-Substituted Amino-1,3,4-oxadiazol-2-yl) Methoxyquinolines (III)—To a suspension of the appropriate 1-(8-quinolinoxyacetyl)-4-substituted thiosemicarbazide (II, 0.01 mol) in water (10 mL) was added a cold solution of sodium hydroxide (4 M, 5 mL) with stirring. When a clear solution was obtained, iodine in potassium iodide solution (5%) was then added in a dropwise manner with stirring until the color of iodine persisted at room temperature. Thereafter, the reaction mixture was heated at reflux on a boiling-water bath, and more iodine solution was carefully added until a permanent tinge of excess iodine remained. After cooling the mixture was poured into ice-cold water, and the precipitated solid was removed by filtration, washed with a dilute solution of sodium thiosulfate and then washed with water, dried, and crystallized from a suitable solvent (Table I).

IIId—^{1}H-NMR ($CDCl_3$): δ 7.2–8.9 (m, ArH), 5.2 (s, 2, OCH_2), and 4.5 ppm (d, N*H*-Ar).

[1] Melting points were determined in open glass capillaries and are uncorrected. IR spectra were determined as Nujol mulls with Beckman IR-4210; ^{1}H-NMR spectra were recorded on a Varian EM-360 60-Hz NMR spectrophotometer in $CDCl_3$ with TMS as internal standard. Microanalyses were performed by the Microanalytical Unit, Faculty of Science, University of Cairo, Cairo, Egypt.

Table I—8-(5-Substituted Amino-1,3,4-oxadiazol-2-yl) Methoxyquinolines (III) and 8-(5-Substituted Amino-1,3,4-thiadiazol-2-yl) Methoxyquinolines (IV) [a]

[a] All compounds were recrystallized from ethanol and showed absorption in the IR range at 3200–3095 cm^{-1} (NH). Elemental analyses (C, H, N, and S for all compounds, I for compounds with R_2 = I) were within ±0.4% from theoretical for all of the methoxyquinolines.

IIIh—^{1}H-NMR ($CDCl_3$): δ 7.0–8.2 (m, ArH), 5.2 (s, 2, OCH_2), 4.1 (t, 2, N—CH_2), 1.8 (m, CH_2), 1.4 (m, CH_2), and 1.0 ppm (t, CH_3).

8-(5-Substituted Amino-1,3,4-thiadiazol-2-yl) Methoxyquinolines (IV)—1-(8-Quinolinoxyacetyl)-4-substituted thiosemicarbazide (II, 0.01 mol) was added in small portions to concentrated sulfuric acid (25 mL) with stirring, maintaining the temperature below 0°C during addition for 1 h. The reaction mixture was allowed to stand at room temperature overnight and then warmed to 50°C. It was then cooled and poured onto crushed ice. The solid product was removed by filtration, washed with water, treated with dilute ammonia to remove any sulfonated product, again washed with water, dried, and crystallized from a suitable solvent (Table I). ^{1}H-NMR ($CDCl_3$) for IVf: δ 7.1–9.0 (m, ArH), 5.7 (s, 2, OCH_2), 5.1 (d, N*H*-Ar), and 2.3 ppm (s, Ar-C*H*$_3$).

Antibilharzial Activity—Swiss albino mice were inoculated with 100 cercariae of *S. mansoni* by the tail immersion technique (8). Eight weeks after infestation, the animals were divided into seven groups: an untreated control group, a group for each of the new drugs to be tested (IIId, IIIh, IVf, IVh, and IVj), and hycanthone as a positive control group. The drugs were given orally as a single 100-mg/kg dose in suspension of 1% carboxymethylcellulose. Hycanthone was given as a single injection, 70 mg/kg im in 0.1 mL of distilled water. Oogram studies of the liver and intestine were made every third day on five animals from each group, (3, 6, 9, and 12 d posttreatment). Table II shows the average oogram pattern in the liver and small intestine during the period of maximum drug effect (9 d), which was usually at the end of the first week, compared with hycanthone (9).

RESULTS AND DISCUSSION

The efficiency of a new antischistosomal drug was assessed in experimentally infested mice by the oogram changes, which were said to be caused by loss of schistosoma worm muscle tone, during action on the parasite reproductive organs, and death of the worms (10). Deviation of the oogram picture from normal was considered to be an absence of any immature stages or when the number of mature ova exceeded 50% (10). Results obtained showed small deviation of the oogram picture from normal. Compounds IVf, IVh, and IVj showed moderate activity, while the others showed only mild activity.

Synthesis and Anticonvulsant Evaluation of *N*-Aminosuccinimides

MILTON J. KORNET

Received December 20, 1982, from the *College of Pharmacy, University of Kentucky, Lexington, KY 40536-0053.* Accepted for publication January 24, 1983.

Abstract □ Twelve new *N*-aminosuccinimides were synthesized by the condensation of hydrazines with succinic anhydrides in glacial acetic acid. The compounds were evaluated in the maximal electroshock seizure and subcutaneous pentylenetetrazol seizure threshold tests for anticonvulsant activity and in the rotorod test for neurotoxicity in mice. The lowest dose at which several of the compounds exhibited anticonvulsant activity was 300 mg/kg.

Keyphrases □ *N*-Aminosuccinimides—synthesis, anticonvulsant and neurotoxic potential, mice □ Anticonvulsants—potential, *N*-aminosuccinimides, synthesis, neurotoxicity, mice

Potential anticonvulsants and hydrazine-derived drugs in general have been a principal interest of ours over several years. Anticonvulsant activity has been found among the 3,5-pyrazolidinediones (1), semicarbazides (2–4), and hydrazino urethans (5, 6). Because of the effectiveness of the succinimides such as phensuximide, methsuximide, and ethosuximide for the treatment of the petit mal condition and the paucity of information (7) concerning *N*-aminosuccinimides, an investigation in this area appeared warranted. A related compound, *N*-amino-3-(*m*-bromophenyl)succinimide, has been shown to possess potent maximal electroshock seizure activity (8). A decrease in spontaneous motor activity by *N*-arylaminosuccinimides has been noted (9).

This paper reports on the synthesis and anticonvulsant activity of a series of *N*-aminosuccinimides. The compounds vary in the nature of the amino nitrogen (alkylated or arylated) and in the α-position of the succinimide ring (unsubstituted, methyl, or phenyl).

RESULTS AND DISCUSSION

The synthesis of the aminosuccinimides (III) was accomplished by treating various succinic anhydrides (I) with substituted hydrazines (II) in glacial acetic acid (Scheme I) (Table I). Others (10) have used a mixture of equal volumes of glacial acetic acid and concentrated sulfuric acid to effect this condensation.

Compounds IIIa–IIIn were tested in the maximal electroshock seizure and subcutaneous pentylenetetrazol seizure threshold tests for anticonvulsant activity and in the rotorod test for neurotoxicity in male mice[1] by reported procedures (2). None of the compounds showed activity at 100 mg/kg in either test. In the maximal electroshock seizure test, IIIc, IIId, IIIf, IIIk, and IIIm exhibited activity at 300 mg/kg at 30 min with no indication of toxicity. One compound, IIIg, showed activity at this same dose at 4 h. In the pentylenetetrazol seizure test, IIIb, IIIl, and IIIm displayed activity at 300 mg/kg at 30 min with no toxicity. Overall, this

Synthesis and Anticonvulsant Evaluation of *N*-Aminosuccinimides

MILTON J. KORNET

Received December 20, 1982, from the *College of Pharmacy, University of Kentucky, Lexington, KY 40536-0053.* Accepted for publication January 24, 1983.

Abstract □ Twelve new *N*-aminosuccinimides were synthesized by the condensation of hydrazines with succinic anhydrides in glacial acetic acid. The compounds were evaluated in the maximal electroshock seizure and subcutaneous pentylenetetrazol seizure threshold tests for anticonvulsant activity and in the rotorod test for neurotoxicity in mice. The lowest dose at which several of the compounds exhibited anticonvulsant activity was 300 mg/kg.

Keyphrases □ *N*-Aminosuccinimides—synthesis, anticonvulsant and neurotoxic potential, mice □ Anticonvulsants—potential, *N*-aminosuccinimides, synthesis, neurotoxicity, mice

Potential anticonvulsants and hydrazine-derived drugs in general have been a principal interest of ours over several years. Anticonvulsant activity has been found among the 3,5-pyrazolidinediones (1), semicarbazides (2–4), and hydrazino urethans (5, 6). Because of the effectiveness of the succinimides such as phensuximide, methsuximide, and ethosuximide for the treatment of the petit mal condition and the paucity of information (7) concerning *N*-aminosuccinimides, an investigation in this area appeared warranted. A related compound, *N*-amino-3-(*m*-bromophenyl)succinimide, has been shown to possess potent maximal electroshock seizure activity (8). A decrease in spontaneous motor activity by *N*-arylaminosuccinimides has been noted (9).

This paper reports on the synthesis and anticonvulsant activity of a series of *N*-aminosuccinimides. The compounds vary in the nature of the amino nitrogen (alkylated or arylated) and in the α-position of the succinimide ring (unsubstituted, methyl, or phenyl).

RESULTS AND DISCUSSION

The synthesis of the aminosuccinimides (III) was accomplished by treating various succinic anhydrides (I) with substituted hydrazines (II) in glacial acetic acid (Scheme I) (Table I). Others (10) have used a mixture of equal volumes of glacial acetic acid and concentrated sulfuric acid to effect this condensation.

Compounds IIIa–IIIn were tested in the maximal electroshock seizure and subcutaneous pentylenetetrazol seizure threshold tests for anticonvulsant activity and in the rotorod test for neurotoxicity in male mice[1] by reported procedures (2). None of the compounds showed activity at 100 mg/kg in either test. In the maximal electroshock seizure test, IIIc, IIId, IIIf, IIIk, and IIIm exhibited activity at 300 mg/kg at 30 min with no indication of toxicity. One compound, IIIg, showed activity at this same dose at 4 h. In the pentylenetetrazol seizure test, IIIb, IIIl, and IIIm displayed activity at 300 mg/kg at 30 min with no toxicity. Overall, this

[a] Cyclohexane–toluene. [b] 70% Ethanol. [c] 60% Ethanol. [d] 95% Ethanol. [e] Reported mp 158°C [A. Michaelis and R. Hermens, *Chem. Ber.*, **25**, 2750 (1892)]. [f] Glacial acetic acid. [g] Reported mp 206–208°C (Ref. 9). [h] 80% Ethanol. [i] Toluene.

group of compounds does not display anticonvulsant activity comparable with currently available drugs.

EXPERIMENTAL[2]

Compound IIId was prepared by the dropwise addition of 3.15 g (0.0315 mol) of *N*-aminopiperidine to a solution of 5.28 g (0.030 mol) of phenylsuccinic anhydride (11) in 15 mL of glacial acetic acid. The initially exothermic reaction mixture was refluxed under nitrogen for 1.5 h, and the acetic acid was evaporated under reduced pressure. Water (10 mL) was added to the residue, and the pH was adjusted to 8 by addition of 5% NaOH solution. The product was extracted into chloroform, dried over magnesium sulfate, the solvent evaporated, and the residue recrystallized from 60% ethanol, affording 6.11 g (79%) of white crystals, mp 101–102°C. The reflux period for arylhydrazines was 3 h, and the NaOH neutralization in the workup was omitted.

[2] Melting points were determined on a Thomas-Hoover melting point apparatus and are uncorrected. The IR spectra were taken on a Perkin-Elmer 700 spectrophotometer as either liquid films or as potassium bromide pellets. NMR spectra were recorded on a Varian EM-360 or T-60 spectrometer, using tetramethylsilane as the internal reference. Mass spectra were obtained on a RMU-7 double-focusing spectrometer by Hitachi/Perkin-Elmer. Elemental analyses for C, H, and N were performed by Baron Consulting Co., Orange, Conn.; values for all compounds were within ± 0.4% of theoretical. All compounds exhibited ^{1}H-NMR and mass spectra consistent with the structures shown.

Synthesis and Antibacterial Activity of Some 5-Nitro-3-phenyliminoindol-2(3*H*)-ones and Their *N*-Mannich Bases

ROY W. DAISLEY ˣ **and VASANTI K. SHAH**

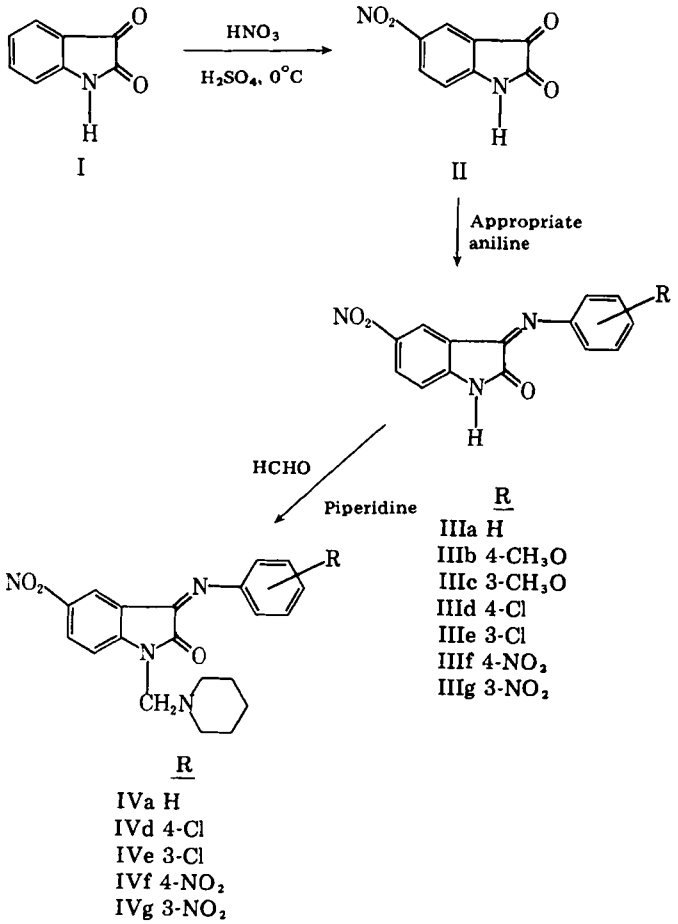
Received November 23, 1982, from the *Department of Pharmacy, Brighton Polytechnic, Brighton, BN2 4GJ, England.* Accepted for publication January 13, 1983.

Abstract □ The antimicrobial and antifungal activities of a series of 5-nitro-3-phenyliminoindol-2(3*H*)-ones and their 1-piperidinomethyl analogues (*N*-Mannich bases) were investigated. Growth inhibition of Gram-positive bacteria was observed with little or no activity against Gram-negative bacteria. Antifungal activity was absent. The syntheses were accomplished from 5-nitroindol-2,3-dione by condensation with the appropriate aniline followed by formation of the *N*-Mannich base.

Keyphrases □ 5-Nitro-3-phenyliminoindol-2(3*H*)-ones—synthesis, antimicrobial and antifungal activity □ *N*-Mannich bases—5-nitro-3-phenyliminoindol-2(3*H*)-ones, synthesis, antimicrobial and antifungal activity □ Antimicrobial agents—potential, 5-nitro-3-phenyliminoindol-2(3*H*)-ones and their *N*-Mannich bases, synthesis

Interest in biologically active indol-2,3-dione (isatin) derivatives has increased rapidly over the past few years. Mannich bases derived from indol-2,3-diones have shown antimicrobial (1, 2), antiviral (3), cytostatic, and antimitotic (4, 5) activities. The corresponding substituted 3-thiosemicarbazones or 3-hydrazones have similarly shown antimicrobial (2), antiviral (6), cytostatic, and antimitotic (4, 5) activities. Recently a series of 3-aryliminoindol-2(3*H*)-ones and their *N*-Mannich bases have been shown to possess antibacterial and antifungal (7) activity and have shown promise as excystment and cysticidal agents against *Schizopyrenus russelli* (8, 9). CNS activity has recently been demonstrated for some *N*,*N*-disubstituted 1-(aminomethyl)-5-alkyl-3-(aryloxyacetylhydrazono)indol-2(3*H*)-ones (10).

The 3-*o*-nitrophenylhydrazone of indol-2,3-dione has shown activity against Walker carcinosarcoma 256 (11). Because of the well-known antibacterial activity of other nitro heterocycles (12) and our interest in this area (13), we decided to prepare and test a series of 5-nitro substituted 3-phenyliminoindol-2(3*H*)-ones and their *N*-Mannich bases for antimicrobial activity.



Scheme I—Synthesis of 5-nitro-3-phenylimino-1-piperidinomethylindol-2(3H)-ones.

RESULTS AND DISCUSSION

The synthetic procedure followed is outlined in Scheme I. The starting material was 5-nitroindol-2,3-dione (II) prepared by the nitration of indol-2,3-dione (I) using a modification of the method reported by Calvery (14) which prevented the formation of resinous side products. Direct condensation of the appropriate aniline with 5-nitroindol-2,3-dione (II) in a boiling mixture of ethanol and dimethyl sulfoxide furnished the corresponding 3-phenylimino derivatives (IIIb–d). The remaining compounds (IIIa, e–f) were prepared similarly, but required the addition of a few drops of glacial acetic acid to the reaction medium. Using dimethyl sulfoxide containing a few drops of glacial acetic acid as solvent allowed the reaction to proceed to completion by standing at room temperature overnight.

The 1-piperidinomethyl derivatives (*N*-Mannich bases) (IVa, d–g) were prepared from the 3-phenylimino derivatives using standard methods (7). The reaction failed for IVb and IVc.

All compounds gave satisfactory elemental analysis for C, H, and N (within ±0.4%), the UV, IR, ^{1}H-NMR, and mass spectra were consistent with the assigned structures. Physical constants of the 3-phenylimino

[a] Average of six determinations. Key: (–) no inhibition; (±) minimally observable inhibition.

and corresponding 1-piperidinomethyl derivatives are listed in Table I.

All the compounds synthesized were evaluated for potential antimicrobial activity against Gram-negative *Escherichia coli*, Gram-positive *Staphylococcus aureus*, and *Candida albicans* using the cup–plate technique with either a pour plate or surface-innoculated (carpet) plate. None of the compounds tested showed any activity against *C. albicans*, and only IVd exhibited slight activity against *E. coli* (Table II). Compounds II, IIIa, IIIf, IVa, and IVf were inactive and IIIb showed only slight inhibitory activity against *S. aureus*. However, IIIc–e, IIIg, IVd–e, and IVg were active, with IVd the most active, followed by IVg.

The Mannich bases were usually more active than the 3-phenylimino compounds, with the exception that IIIe was more active than IVe. This is consistent with the observation of Varma (7) and demonstrates the necessity of the 3-phenylimino group, as 5-nitro-3-piperidinomethylindol-2,3-dione has been shown to be devoid of antimicrobial activity (2).

EXPERIMENTAL

Antimicrobial Evaluation—The organisms used were *E. coli* (NCTC 5933), *S. aureus* (NCTC 8532), and *C. albicans* (NCTC 45348). The cup–plate technique was used with either a pour plate or a surface-innoculated (carpet) plate using nutrient agar for the bacteria and malt extract for *C. albicans*.

The compounds were tested at 1 mg/mL in dimethyl sulfoxide, and 100-μl portions were transferred to 9-mm diameter holes cut into the plates. The agar plates were then incubated at 37°C for 24 h and the malt extract plates at 25°C for 72 h, after which the zones of inhibition around each hole were measured. Table II shows the average of six determinations for each zone of inhibition. Dimethyl sulfoxide showed no inhibitory effects on the test organisms.

Chemistry—Melting point values were determined[1] and are corrected. The ^{1}H-NMR[2] spectra were obtained in DMSO-d_6 using 1% tetramethylsilane as internal standard. IR[3] and UV[4] spectra were recorded on double-beam spectrophotometers. Mass spectra[5] were also recorded. TLC was carried out using plates coated with silica gel, and products were visualized with UV light at 254 nm. All compounds submitted for elemental analysis[6] gave spectral data consistent with the proposed structure and were pure by TLC.

5-Nitroindol-2,3-dione (II)—Indol-2,3-dione (44.2 g, 0.33 mol) was dissolved in concentrated sulfuric acid (208 mL), and the solution was kept at 0°C while nitric acid (d = 1.50, 15.5 mL, 0.34 mol) was added dropwise over a period of 3 h. After the addition was complete, the solution was allowed to stand for 1 h and then poured into ice (1.5 kg). The yellow precipitate was collected and recrystallized from aqueous methanol to yield 5-nitroindol-2,3-dione (II), 48.3 g (85%), mp 254–255°C [lit. (14) mp 254–255°C].

5-Nitro-3-phenyliminoindol-2(3H)-ones (III)—Compounds IIIa–g were prepared by one of the following methods:

1. 5-Nitroindol-2,3-dione (1.92 g, 0.01 mol) and the appropriate aniline (0.01 mol) were suspended in a mixture of ethanol (15 mL) and dimethyl sulfoxide (15 mL). The mixture was heated at reflux for 1 h, an equal volume of warm water was added, and the mixture was allowed to stand at room temperature overnight. The material was removed by filtration, washed with aqueous ethanol (50% v/v), and dried. Analytical and microbiological samples were recrystallized from aqueous methanol (50% v/v) (method A).

2. Identical to method A except that a few drops of glacial acetic acid were added to the reaction mixture (method B).

3. 5-Nitroindol-2,3-dione (1.92 g, 0.01 mol) and the appropriate aniline (0.01 mol) were stirred overnight in dimethyl sulfoxide (25 mL) containing a few drops of glacial acetic acid. The products were isolated by dilution with an equal quantity of warm water as described for method A (method C).

5-Nitro-3-phenylimino-1-piperidinomethylindol-2(3H)-ones (IV)—The appropriate 5-nitro-3-phenyliminoindol-2(3*H*)-one (0.01 mol) was treated with piperidine (0.01 mol), formaldehyde solution (2 mL, 37% w/v), ethanol (10 mL), and dimethyl sulfoxide (10 mL). The mixture was then heated on a water bath until a clear solution was obtained. An equal volume of warm water was then added and the resulting mixture was allowed to stand at room temperature overnight; the product was removed by filtration and then recrystallized from aqueous methanol (50% v/v).

Stability Kinetics of Ginsenosides in Aqueous Solution

ETSUKO MIYAMOTO *, SHIZUO ODASHIMA ‡x, ISAO KITAGAWA §, and AKIRA TSUJI ¶

Received July 7, 1982, from the **School of Pharmacy, Hokuriku University, Kanagawa-machi, Kanazawa 920-11, Japan,* ‡*the Department of Pathology, Kanazawa Medical University, Uchinada-machi, Kahoku-gun 920-02, Japan,* §*the Faculty of Pharmaceutical Sciences, Osaka University, 1-6, Yamada-oka Suita, Osaka 565, Japan, and* ¶*the Faculty of Pharmaceutical Sciences, Kanazawa University, Takara-machi, Kanazawa 920, Japan.* Accepted for publication December 21, 1982.

Abstract □ The stability of ginsenosides (Rb_1, Rb_2, and Rg_1) in aqueous solutions of varying pH was studied kinetically at 37°C and an ionic strength of 0.15, using reverse-phase high-performance liquid chromatography. Degradation readily occurred by a proton-catalyzed reaction, the half-lives being only ~30 min at pH 1. However, under neutral intestinal pH conditions, the degradation was almost negligible throughout the experimental period (~40 h).

Keyphrases □ Ginsenosides—stability kinetics, aqueous solutions of varying pH □ Stability—ginsenosides in aqueous solutions of varying pH, kinetics □ Ginseng—stability kinetics of ginsenosides in aqueous solutions of varying pH

Ginseng has been used as a folkloric medicine in traditional herbal remedies for a long time. It has several noteworthy properties such as an antistress or rehabilitative action (1, 2). Many studies suggest that the pharmacological effects of ginseng come from the ginsenosides. Recently, Odashima *et al.* (3) reported the interesting finding that ginsenosides induced morphological changes and phenotypic transformations in cultured Morris Hepatoma cells (MH_1C_1), calling this "reverse transformation."

We have investigated the stability of the ginsenosides in both water and GI fluid since many herbal medicines seem to be effective when given orally. The ginsenosides have been known to degrade in the presence of acid, and the degradation mechanism and structures of the products have been described (4, 5). However, the detailed stability kinetics of ginsenosides have not been investigated. The present study reports the kinetics of degradation of the ginsenosides Rg_1, as 20*S*-panaxatriol, and Rb_1 and Rb_2, as 20*S*-panaxadiol, in water.

EXPERIMENTAL

Materials—The ginsenosides used in this study were prepared from the dried roots of *Panax ginseng* C. A. Meyer (Araliaceae), which were obtained from a commercial source[1], according to the usual procedures (6). The purity of the ginsenosides was confirmed by TLC (6). All other chemicals were of reagent grade and were used without further purification.

Ginsenosides Hydrolysis—Kinetic studies were carried out at 37 ± 0.1°C, at various pH values, and an ionic strength of 0.15. Each ginsenoside was dissolved in buffer solution preheated at 37°C to give a final concentration of 1×10^{-4} to 4×10^{-4} M. The buffer solutions employed were hydrochloric acid and phosphate (NaH_2PO_4) buffer systems, which were adjusted to a constant ionic strength of 0.15 with potassium chloride. The artificial GI fluids of pH 1.22 and pH 6.84 described in the Japanese Pharmacopeia X were also used. At appropriate intervals, aliquots were withdrawn, cooled, neutralized as necessary to quench the reaction with the same volume of phosphate (NaH_2PO_4–Na_2HPO_4) buffer solution (0.1 M, pH 6.8), and then analyzed. The pH of the reaction mixture was measured[2] both before use and at the end of the experiments. No significant change was observed.

Analytical Procedures—The reaction samples were assayed by reverse-phase HPLC. The liquid chromatograph[3] was equipped with a UV detector[4] set at 207 nm and a radial compression system[5] with an inserted reverse-phase cartridge[6]. The mobile phase was 70% (v/v) methanol–water. The instrument was operated at ambient temperature and a flow rate of 1.0 mL/min. A 100-μL sample was injected through an injector[7] on flow; the samples were filtered through a 0.45-μm membrane filter[8] before injection. Peak heights were used for quantification, and the coefficient of variation (*CV*) was 2.9%.

RESULTS AND DISCUSSION

Figures 1 and 2 show typical chromatograms of intact Rg_1 in the reaction mixture at 37°C, an ionic strength of 0.15, and pH 1.81. The peak of Rg_1 (peak 1) with a retention time (t_R) of 9 min decreased as a function of time and several peaks of degradation products appeared as the degradation reaction proceeded (Fig. 2).

All reactions were followed for 1–3 half-lives. The degradation of Rg_1, Rb_1, and Rb_2 followed first-order kinetics. Furthermore, in the pH range studied (pH 1–3), the rate of degradation was found to be first order with respect to hydrogen ion activity and independent of buffer concentration.

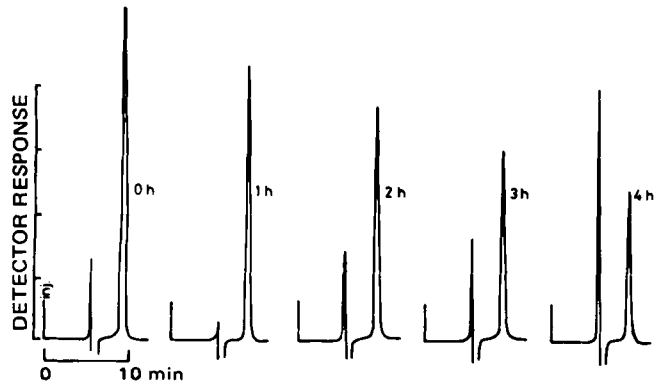

Figure 1—*Chromatograms of Rg_1 in 0.15 M phosphate buffer solution (pH 1.81) at 37°C and an ionic strength of 0.15 with time. t_R in minutes.*

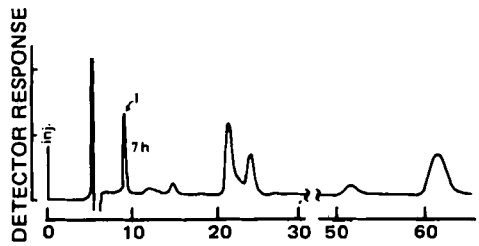

Figure 2—*Typical chromatogram of 80% degraded Rg_1 under the same conditions as in Fig. 1. t_R in minutes.*

The pH dependency of the Rg_1 degradation in the acidic region can therefore be represented by the following:

$$k_{obs} = k_H a_{H^+}$$

where k_{obs} is the observed first-order rate constant, k_H is the specific proton-catalyzed rate constant, and a_{H^+} is the hydrogen ion activity as determined with a glass electrode. The k_H value for each ginsenoside was calculated from the kinetic data, and the observed rate constants and the values of k_H for the respective ginsenosides are listed in Table I. No significant difference among the catalyzed rate constants was observed. If these catalyzed rate constants can be employed to predict the stability of the ginsenosides at constant pH in nonbuffered solution, the half-life at 37°C and pH 1 would be 30 min. At neutral pH, Rg_1 is very stable and the degradation is negligible overnight.

These results suggest that chemical degradation of ginsenosides in the acidic pH region, such as in the stomach, could proceed readily by producing many products (see Fig. 2). On the other hand, the degradation under intestinal pH conditions was negligible.

Table I—Apparent First-Order Rate Constants, k_{obs}, at Various pH Values and Rate Constants, k_H, for the Acid Degradation of Ginsenosides at 37°C and Ionic Strength of 0.15

Ginsenoside	pH	k_{obs} (±*SD*), h^{-1}	k_H, $M^{-1}\,h^{-1}$
Rg_1	0.85[a]	2.096[b]	15.0[c]
	1.22[a]	0.924 (0.012)[d]	
	1.48[a]	0.552[b]	
	1.81[e]	0.224 (0.012)[f]	
	2.04[e]	0.131 (0.006)[f]	
	2.34[e]	0.055 (0.002)[f]	
Rb_1	1.81[g]	0.218[b]	14.0[h]
Rb_2	1.81[g]	0.231[b]	14.9[h]

[a] Hydrochloric acid was used as a buffer solution. [b] Observed value, calculated by the least-squares method using the experimental data. [c] Calculated according to the equation, obtained by the least-squares method using k_{obs} at varying pH. [d] Averaged value, calculated using k_{obs} under the experimental condition of three different initial concentrations of Rg_1. [e] Phosphate buffer solution was used. [f] Averaged value, calculated using k_{obs} under the experimental condition of at least three different buffer concentrations. [g] Phosphate buffer solution (0.15 M) was used. [h] Calculated according to the equation using k_{obs}.

Plant Anticancer Agents XXX: Cucurbitacins from *Ipomopsis aggregata* (Polemoniaceae)

MUNEHISA ARISAWA *, JOHN M. PEZZUTO, A. DOUGLAS KINGHORN ˣ, GEOFFREY A. CORDELL, and NORMAN R. FARNSWORTH

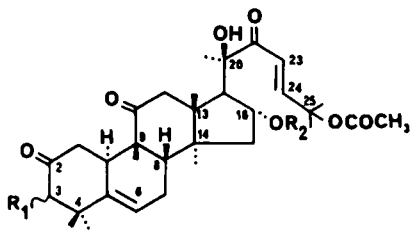
Received January 11, 1983, from the *Department of Pharmacognosy and Pharmacology, College of Pharmacy, University of Illinois at the Medical Center, Chicago, IL 60612.* Accepted for publication February 25, 1983. *Present address: Faculty of Pharmaceutical Sciences, Toyama Medical and Pharmaceutical University, Sugitani 2630, Toyama 930-01, Japan.

Abstract □ Isocucurbitacin B (I), 3-epi-isocucurbitacin B (II), and cucurbitacin B (III) were identified as the principal cytotoxic constituents of *Ipomopsis aggregata* (Pursh) V. Grant (Polemoniaceae). The structure of the new compound, II, was determined through analysis of its spectrometric characteristics.

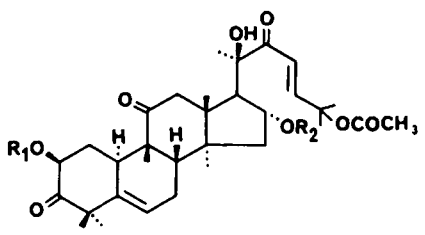
Keyphrases □ *Ipomopsis aggregata* (Polemoniaceae)—isolation and identification of cytotoxic constituents □ Cucurbitacins—cytotoxic principles from *Ipomopsis aggregata* □ 3-Epi-isocucurbitacin B—novel cytotoxic constituent of *Ipomopsis aggregata*

Ipomopsis aggregata represents a small New World genus of herbs in the family Polemoniaceae (1). This species is the most wide-ranging member of the genus, extending in distribution from British Columbia to northwest Mexico (2). In previous phytochemical work, an uncharacterized saponin was isolated from an extract of the entire plant of *I. aggregata* (3), but there appear to have been no prior studies to determine the biological activity of extracts and isolates derived from this taxon.

In a continuing search for tumor inhibitors of plant origin[1], we found that a chloroform extract of the combined roots, stems, leaves, flowers, and fruits of *I. aggregata* exhibited significant cytotoxic activity against Eagle's carcinoma of the nasopharynx in cell culture (KB), but no activity when tested at a dose range of 1.87–15.0 mg/kg (ip) against the P388 lymphocytic leukemic system in mice[2]. In the present contribution we wish to report the isolation of three cytotoxic cucurbitacins from this plant, namely, isocucurbitacin B (I), a new compound 3-epi-isocucurbitacin B (II), and cucurbitacin B (III).



I R_1 = α-OH; R_2 = H
II R_1 = β-OH; R_2 = H
IV R_1 = α-$OCOCH_3$; R_2 = $COCH_3$
V R_1 = β-$OCOCH_3$; R_2 = $COCH_3$



III R_1 = H; R_2 = H
VI R_1 = $COCH_3$; R_2 = $COCH_3$

EXPERIMENTAL[3]

Plant Material—The combined roots–stems–leaves–flowers–fruits of *Ipomopsis aggregata* (Pursh) V. Grant (Polemoniaceae) were collected in Idaho during July 1980[4].

KB Cell Culture Assays—Substances were evaluated for cytotoxic activity essentially by the procedure of Geran *et al.* (5), as described previously (6). All assays were performed in duplicate, and the results were expressed as the effective dose to inhibit 50% of the growth observed in control tubes which were treated with solvent only. Mithramycin was used as a positive cytotoxic control substance (ED_{50} = 0.1 μg/mL).

Extraction and Fractionation—The air-dried, milled plant material (10 kg) was extracted sequentially with petroleum ether (bp 60–80°C) and methanol. The methanol extract was concentrated *in vacuo* to yield a residue (1.57 kg), which was partitioned between 3-L portions of chloroform and water. Cytotoxic activity was found to be concentrated in the chloroform fraction (ED_{50} = 0.64 μg/mL), which was further partitioned between petroleum ether (2 L) and methanol–water (9:1, 2 L). After removal of the solvent, the cytotoxic aqueous methanol extract (600 g, ED_{50} = 0.30 μg/mL) was chromatographed over silica gel[5] (5 kg), by elution with chloroform and mixtures of chloroform–methanol of increasing polarity. A total of 22 fractions (2-L each) were collected. Fractions 9–11, eluted from this column with chloroform–methanol (99:1), were cytotoxic (ED_{50} = 0.27, 0.01, and 0.10 μg/mL, respectively). These combined fractions were chromatographed over a Florisil[6] column that was eluted with chloroform. Fractions eluted with this solvent were combined to afford a cytotoxic residue (1.32 g, ED_{50} = 0.05 μg/mL). Final purification of the cytotoxic constituents was achieved by preparative TLC on silica

[1] For the previous article in this series, see Ref. 4.

[2] Plant extracts and certain fractions were tested under the auspices of the Research and Development Program of the National Cancer Institute. The remaining fractions prepared from this plant, as well as the isolates that are the subject of this paper, were tested at our in-house facilities, as described under *Experimental*. A compound is considered active *in vivo* if it exhibits a prolongation of life >125%, and is regarded as cytotoxic if the ED_{50} is ≤4 μg/mL. For *in vivo* testing, samples were administered intraperitoneally to six male CD_2F_1 P388-infected mice daily for a 10-d period. Evaluation was carried out by comparison of survival times with control tumor-bearing animal groups.

[3] Melting points were determined by means of a Koffler hot-plate apparatus and are uncorrected. Specific rotations were measured on a Perkin-Elmer 241 polarimeter. The UV spectra were obtained with a Beckman DB-G spectrophotometer, and IR spectra on a Beckman model 118-A spectrophotometer, with polystyrene calibration at 1601 cm^{-1}. ^1H-NMR spectra were recorded in $CDCl_3$ with a Varian T-60A instrument operating at 60 MHz, equipped with a Nicolet TT-7 Fourier Transform attachment. Tetramethylsilane was used as internal standard, and chemical shifts are reported on the δ (ppm) scale. Low-resolution mass spectra were obtained with a Varian MAT 112S double-focusing mass spectrometer, operating at 70 eV, and the high-resolution mass spectrum was obtained by peak matching using an AEI MS-902 instrument.

[4] The plant material was collected and identified by staff of the Economic Botany Laboratory, BARC-East, USDA, Science and Education Administration, Beltsville, Md. A voucher specimen representing this collection has been deposited in the Herbarium of the National Arboretum, Washington, D.C.

gel GHLF[7] plates, using cyclohexane–ether–ethyl acetate (1:1:1) and chloroform–acetone–methanol (14:1:2) as solvents. Compounds I (33 mg), II (31 mg), and III (120 mg) were obtained from preparative TLC zones found to be cytotoxic, by crystallization from methanol.

Characterization of Biologically Active Isolates—Isocucurbitacin B (I, 33 mg, 0.00033%) crystallized in the form of colorless needles, mp 220–222°C, $[\alpha]_D^{25}$ +38° (*c* 0.2, $CHCl_3$) [lit. (7) mp 223–223.5°C, $[\alpha]_D$ +43° (*c* 1.61, $CHCl_3$)]; IR ν_{max} (KBr): 3550, 3450, 2950, 1720, 1680, 1620, 1440, 1360, 1230, 1170, 1120, 1090, 1030, and 980 cm^{-1}; UV λ_{max} (MeOH) (log ϵ): 232 (4.32) nm; ^{1}H-NMR (60 MHz): δ 0.81 and 0.96 (two s, 6, 9-CH_3 and 13-CH_3), 1.18 and 1.26 [two s, 6, 4-$(CH_3)_2$], 1.32 (s, 3, 14-CH_3), 1.41 (s, 3, 20-CH_3), 1.54 [s, 6, 25-$(CH_3)_2$], 2.00 (s, 3, 25-$OCOCH_3$), 3.89 (br s, 1, 3-H), 4.25 (br s, 1, 20-OH exchangeable with D_2O), 4.33 (m, 1, 16-H), 5.92 (m, 1, 6-H), 6.42 (d, 1, J = 15.6 Hz, 23-H), and 7.07 ppm (d, 1, J = 15.6 Hz, 24-H); MS *m/z* (70 eV) (relative intensity): 498 (M^+ −60, 2%), 386 (1), 385 (1), 369 (1), 219 (1), 203 (2), 164 (4), 137 (3), 135 (3), 113 (6), 112 (9), 111 (8), 109 (8), 97 (10), and 96 (100). These data (IR, UV, and ^{1}H-NMR) are in agreement with those previously reported for isocucurbitacin B (I) (7, 8), although no mass spectral data for this compound appear to have been published. Identity was established as isocucurbitacin B by direct comparison with an authentic sample[8] (MS, co-TLC).

Isocucurbitacin B (I, 10 mg) was treated with acetic anhydride–pyridine (1:1, 1 mL) at room temperature overnight. Workup in the usual manner afforded a triacetate (IV, 8 mg) as colorless needles, mp 120–123°C; ^{1}H-NMR (60 MHz): δ 0.97 and 1.01 (two s, 6, 9-CH_3 and 13-CH_3), 1.18 (s, 3, 4-CH_3), 1.22 (s, 6, 4-CH_3 and 14-CH_3), 1.39 (s, 3, 20-CH_3), 1.57 [s, 6, 25-$(CH_3)_2$], 1.85 (s, 3, 16-$OCOCH_3$), 2.01 (s, 3, 25-$OCOCH_3$), 2.17 (s, 3, 3-$OCOCH_3$), 4.25 (br s, 1, 20-OH exchangeable with D_2O), 4.93 (s, 1, 3-H), 5.17 (m, 1, 16-H), 5.90 (m, 1, 6-H), 6.37 (d, 1, J = 15.6 Hz, 23-H), and 7.16 ppm (d, 1, J = 15.6 Hz, 24-H); MS *m/z* (70 eV) (relative intensity): 582 (M^+ −60, 1%), 522 (1), 507 (1), 487 (2), 427 (1), 411 (2), 385 (1), 383 (1), 368 (2), 367 (4), 279 (3), 219 (3), 177 (3), 166 (8), 150 (3), 135 (4), 113 (8), 112 (6), 111 (6), 109 (6), 97 (11), and 96 (100).

3-Epi-isocucurbitacin B (II, 31 mg, 0.00031%) was obtained in the form of a white powder, mp 92–98°C, $[\alpha]_D^{25}$ −28.5° (*c* 0.2, $CHCl_3$); IR ν_{max} ($CHCl_3$): 3450, 2960, 2920, 1720, 1690, 1630, 1450, 1360, 1250, 1130, 1090, 980, and 940 cm^{-1}; UV λ_{max} (MeOH) (log ϵ): 229 (4.47) nm; ^{1}H-NMR (60 MHz): δ 0.85 and 0.96 (two s, 6, 9-CH_3 and 13-CH_3), 1.07 and 1.25 [two s, 6, 4-$(CH_3)_2$], 1.31 (s, 3, 14-CH_3), 1.41 (s, 3, 20-CH_3), 1.55 [s, 6, 25-$(CH_3)_2$], 2.00 (s, 3, 25-$OCOCH_3$), 4.11 (s, 1, 3-H), 4.24 (br s, 1, 20-OH exchangeable with D_2O), 4.36 (t, 1, J = 7.4 Hz, 16-H), 5.90 (m, 1, 6-H), 6.44 (d, 1, J = 15.6 Hz, 23-H), and 7.06 ppm (d, 1, J = 15.6 Hz, 24-H); MS *m/z* (70 eV) (relative intensity): 498 (M^+ −60, 2%), 385 (1), 327 (2), 287 (2), 286 (7), 285 (3), 271 (4), 266 (4), 253 (9), 187 (4), 185 (7), 175 (11), 173 (25), 159 (6), 147 (5), 131 (5), 129 (16), 115 (22), 113 (7), 112 (11), 111 (8), 101 (13), 97 (16), and 96 (100); mass measurement: calc. for $C_{30}H_{42}O_6$, 498.2981; observed, 498.2986.

3-Epi-isocucurbitacin B (II, 10 mg) was acetylated as described for I, and the triacetate V (7 mg) obtained after workup was found to exhibit the following data: colorless needles, mp 103–107°C; ^{1}H-NMR (60 MHz): δ 1.05 and 1.10 (two s, 6, 9-CH_3 and 13-CH_3), 1.17 and 1.26 [two s, 6, 4-$(CH_3)_2$], 1.30 (s, 3, 14-CH_3), 1.41 (s, 3, 20-CH_3), 1.58 [s, 6, 25-$(CH_3)_2$], 1.86 (s, 3, 16-$OCOCH_3$), 2.03 (s, 3, 25-$OCOCH_3$), 2.18 (s, 3, 3-$OCOCH_3$), 4.26 (br s, 1, 20-OH exchangeable with D_2O), 5.13 (s, 1, 3-H), 5.19 (m, 1, 16-H), 5.85 (m, 1, 6-H), 6.38 (d, 1, J = 15.5 Hz, 23-H), and 7.16 ppm (d, 1, J = 15.5 Hz, 24-H); MS *m/z* (70 eV) (relative intensity): 582 (M^+ −60, 1%), 522 (1), 487 (4), 427 (4), 411 (9), 385 (3), 367 (6), 325 (4), 219 (4), 189 (5), 187 (7), 177 (6), 171 (5), 161 (4), 159 (7), 137 (5), 135 (9), 133 (6), 121 (5), 113 (14), 112 (41), 111 (30), 109 (9), 105 (9), 97 (19), and 96 (100).

Cucurbitacin B (III, 120 mg, 0.0012%) was obtained in the form of a white powder, mp 160–162°C, $[\alpha]_D^{25}$ +44° (*c* 0.1, $CHCl_3$) [lit. (7) mp 184–186°C, crystallized from EtOH; $[\alpha]_D^{25}$ +87° (EtOH)]; IR ν_{max} (KBr): 3550, 3400, 2950, 1720, 1680, 1620, 1450, 1360, 1230, 1120, 1050, 1020, and 980 cm^{-1}; UV λ_{max} (MeOH) (log ϵ): 229 (4.47) nm; ^{1}H-NMR (60 MHz): δ 0.97 and 1.07 (two s, 6, 9-CH_3 and 13-CH_3), 1.25 and 1.29 [two s, 6, 4-$(CH_3)_2$], 1.34 (s, 3, 14-CH_3), 1.43 (s, 3, 20-CH_3), 1.56 [s, 6, 25-$(CH_3)_2$], 2.01 (s, 3, 25-$OCOCH_3$), 4.25 (t, 1, J = 7.4 Hz, 16-H), 4.28 (br s, 1, 20-OH exchangeable with D_2O), 4.43 (dd, 1, J = 12.8 and 5.7 Hz, 2-H), 5.76 (m, 1, 6-H), 6.49 (d, 1, J = 15.6 Hz, 23-H), and 7.08 ppm (d, 1, J = 15.6 Hz, 24-H); MS *m/z* (70 eV) (relative intensity): 498 (M^+ −60, 4%), 480 (1), 385 (1), 299 (1), 285 (1), 219 (1), 203 (1), 187 (2), 175 (3), 173 (3), 133 (3), 121 (3), 115 (3), 113 (4), 112 (8), 111 (7), 109 (5), 105 (4), 97 (11), and 96 (100). The above spectral data are consistent with those published previously for cucurbitacin B (7–15). Identity as cucurbitacin B was established by direct comparison with an authentic sample[8] (MS, co-TLC).

Cucurbitacin B (III, 15 mg) was acetylated as described for I, and the triacetate VI (9 mg) obtained after workup was found to exhibit the following data: colorless needles, mp 114–117°C; ^{1}H-NMR (60 MHz): δ 1.03 and 1.10 (two s, 6, 9-CH_3 and 13-CH_3), 1.32 [s, 9, 4-$(CH_3)_2$ and 14-CH_3], 1.42 (s, 3, 20-CH_3), 1.58 [s, 6, 25-$(CH_3)_2$], 1.87 (s, 3, 16-$OCOCH_3$), 2.03 (s, 3, 25-$OCOCH_3$), 2.13 (s, 3, 2-$OCOCH_3$), 4.27 (br s, 1, 20-OH exchangeable with D_2O), 5.20 (t, 1, J = 7.3 Hz, 16-H), 5.48 (dd, 1, J = 13.4 and 5.7 Hz, 2-H), 5.77 (m, 1, 6-H), 6.42 (d, 1, J = 15.6 Hz, 23-H), and 7.18 ppm (d, 1, J = 15.6 Hz, 24-H); MS *m/z* (70 eV) (relative intensity): 582 (M^+ −60, 1%), 522 (1), 487 (4), 427 (5), 411 (4), 385 (1), 367 (5), 325 (4), 219 (3), 189 (6), 187 (6), 177 (6), 159 (5), 137 (5), 111 (12), 109 (9), 107 (6), 105 (7), 97 (19), and 96 (100).

Biological Activity of the Isolates—Isocucurbitacin B (I, NSC-106400), 3-epi-isocucurbitacin B (II, NSC-359240), and cucurbitacin B (III, NSC-049451) exhibited ED_{50} values of 0.016, 0.050, and 0.032 μg/mL, respectively, in the KB cell culture system.

DISCUSSION

The known tetracyclic triterpenes isocucurbitacin B (I) and cucurbitacin B (III) were isolated and identified in the present study from a cytotoxic fraction of *I. aggregata* whole flowering plants. The molecular ions of both compounds were characteristically absent from their electron-impact mass spectra (10), so that the highest fragment peaks observed occurred at *m/z* 498, representing in each case a loss of one acetate unit from the parent ion. In its ^{1}H-NMR spectrum, I was typified by the presence of a singlet assignable for the C-3 methine proton at δ 3.89, which, since it was shifted downfield in isocucurbitacin B diacetate (IV) to δ 4.93, suggested the presence of a 2-keto-3-hydroxy ring A moiety in I (8, 15). Isocucurbitacin B (I) is a relatively rare compound, previously being reported only from three species of two Cucurbitaceae genera (9). Cucurbitacin B (III), on the other hand, appears to be the most widely distributed cucurbitacin known, since it occurs in more than 15 genera of the Cucurbitaceae, and in species of the Begoniaceae, Cruciferae, and Euphorbiaceae (9, 12, 16, 17). Cucurbitacins have not previously been reported from the family Polemoniaceae.

The spectrometric parameters (IR, UV, ^{1}H-NMR, and MS) of II were very similar to those observed for isocucurbitacin B (I). Thus, comparable with I, no molecular ion was evident in the mass spectrum of II, with the highest observable fragment peak occurring at *m/z* 498, of elemental composition $C_{30}H_{42}O_6$, as determined by high-resolution MS. In its ^{1}H-NMR spectrum, signals indicating the presence of eight quaternary attached C-methyl groups, one acetate methyl group, two methine protons on carbons bearing hydroxyl groups, and three olefinic protons were observed. Following mild acetylation, triacetate V was produced from II, for which paramagnetic C-3 and C-16 methine proton shifts occurred from δ 4.11 and 4.36, respectively, in II, to δ 5.13 and 5.19 in V. By analogy to conclusions reached on the basis of almost identical C-3 ^{1}H-NMR assignments made for isocucurbitacin D (the C-25 deacetyl derivative of I) and 3-epi-isocucurbitacin D (7), II could therefore be assigned a 2-keto-3-hydroxy ring A moiety, and is the C-3 epimer of I.

The role of cucurbitacin B (III) in nature has been partially characterized. For example, III has been shown to stimulate feeding by the spotted cucumber (18) and diabroctic beetles (19). Further, it acts as an antigibberellin (20). In regard to antitumor activity, both isocucurbitacin B (I) and cucurbitacin B (III) have been shown in earlier work to demonstrate significant inhibitory activity against cultured KB cells (7, 12, 21, 22). We presently extend these results through the demonstration of the cytotoxic activity of II. Previous studies have also shown III to be active *in vivo* against the Walker 256 (im) carcinosarcoma and Lewis lung carcinoma in rats (7). The therapeutic index, however, appears too low for use as a clinical agent (7), and it is likely that the same would be found for I and II. An additional biological activity demonstrated by III, however, which may be worthy of additional investigation, is the prevention of experimentally induced hepatitis and cirrhosis (23).

Interestingly, it has been observed previously that cucurbitacin D, a constituent of *Phormium tenax* Forst. (Liliaceae) is degraded to isocucurbitacin D and 3-epi-isocucurbitacin D as a result of lengthy passage over silica gel during column chromatography (8). Therefore, since large-scale gravity column chromatography was employed in this study to obtain I–III from *I. aggregata*, it is possible that I and II are progeny of III and are not indigenous to this plant. For studies concerned primarily with chemotaxonomic relationships, it may be suggested that rapid techniques of isolation, preferably avoiding the use of silica gel, should be used to obtain cucurbitacins from plants.

Assay of Benzenoid Drugs in Tablet and Capsule Formulations by Second-Derivative Ultraviolet Spectrophotometry

A. G. DAVIDSON ˣ and S. M. HASSAN *

Received December 8, 1982, from the *Department of Pharmacy, University of Strathclyde, Glasgow, G1 1XW, United Kingdom.* Accepted for publication February 2, 1983.

*Present address: Analytical Chemistry Department, Faculty of Pharmacy, Mansoura University, Mansoura, Egypt.

Abstract □ Rapid second-derivative assay procedures are described for tablet and capsule formulations of benzenoid drugs, which eliminate the interference of the formulation excipients in simple UV spectrophotometric methods. Accuracy, precision, and selectivity of the technique are discussed. The general application of the procedures for the batch assay of tablet and capsule dosage forms containing ≥2 mg of a benzenoid drug is indicated by the results obtained for 18 such formulations, in good agreement with pharmacopeial assay results and/or declared amounts. The procedures are sufficiently sensitive to permit unit dose assays of these formulations.

Keyphrases □ Benzenoid drugs—tablet and capsule formulations, second-derivative UV spectrometry □ Formulations—benzenoid drugs, second-derivative UV spectrometry, tablets and capsules □ UV spectrometry, second-derivative—benzenoid drugs, tablet and capsule formulations

The interference of formulation excipients in the conventional ultraviolet (UV) spectrophotometric procedures for certain formulated drugs is well recognized. It is a particular problem in the assay of tablets and capsules of benzenoid drugs, which, in general, are both weakly absorbing and also formulated at a relatively low dosage level (typically 1–50 mg/unit dose). The high excipient–drug ratio and high sample weight required for these formulations result in background-irrelevant absorption of a sufficiently high intensity to possibly prohibit the application of simple spectrophotometric methods.

Techniques that reduce or eliminate matrix interference in the assay of formulated drugs include the Morton–Stubbs (1) correction procedure, which requires that the irrelevant absorption is linear over the wavelength range of the absorption band of the drug; orthogonal polynomials, which can cope with nonlinear irrelevant absorption if the correct choice of the polynomial order, wavelength range, and interval is made (2, 3); compensation spectrophotometry, in which the reference solution contains the matrix or sample at the same concentration present in the sample solution (4, 5); and difference spectrophotometry, which may be applied if an absorbance difference can be

induced between equimolar solutions of the drug by the addition of reagents to one or both of the solutions, provided the matrix absorbance is unaffected by the reagents (6). The accuracy and specificity of UV absorption methods may also be considerably improved by conversion of the normal zero-order spectrum into a higher order (usually second or fourth) derivative spectrum. The improved resolution of overlapping absorption bands and the discrimination in favor of narrow bands against broader bands, which are the principal characteristics of derivative spectrophotometry (7, 8), can result in the complete elimination of both nonspecific matrix interference (8, 9) and specific interference from coformulated compounds (10–12).

The benzenoid drugs are ideal candidates for derivative measurements, as the narrow absorption bands of the fine structure in the 250–270-nm region give derivative bands of greater amplitudes than many of the more strongly absorbing drugs, which have a wider spectral band width. Several applications of derivative spectrophotometry in the assay of individual benzenoid compounds in formulations have been published (11–13). The purpose of this paper is to report the general application of the technique to a much wider range of these drugs in tablet and capsule formulations.

EXPERIMENTAL

Drug Substances—Scopolamine butylbromide[1], orphenadrine hydrochloride[2], bethanidine sulfate[3], bretylium tosylate[3], chlorcyclizine hydrochloride[3], cyclizine hydrochloride[3], methadone hydrochloride[3], trihexiphenidyl hydrochloride[4], benztropine mesylate[5], debrisoquin sulfate[6], meperidine hydrochloride[6], diphenhydramine hydrochloride[7], diphenylpyraline hydrochloride[8], meclizine hydrochloride[9], hydroxyzine hydrochloride[10], oxyphenonium bromide[11], tolazoline hydrochloride[11], and phenelzine sulfate[12] were used.

Spectrophotometry—Second-derivative absorption spectra of standard and sample solutions, equilibrated to room temperature were recorded in 1-cm silica quartz cells using a double-beam UV–visible recording spectrophotometer[13]. The scan speed was 60 nm/min, the spectral slit width 1 nm, response (time constant) 0.5 s, and the maximum and minimum ordinate settings +0.5 and −0.5, respectively. The unit dose assays of trihexiphenidyl hydrochloride, benzotropine mesylate, methadone hydrochloride, and oxyphenonium bromide required more sensitive ordinate settings of ±0.15, ±0.15, ±0.4, and ±0.3 respectively.

Standard Solutions—The second-derivative absorption spectrum was recorded from 290 to 230 nm for a standard solution of the drug, accurately prepared at the analytical concentration specified in Table I. For the unit dose assays of trihexiphenidyl hydrochloride, benztropine mesylate, methadone hydrochloride, and oxyphenonium bromide, standard solutions of 0.2, 0.2, 0.5, and 0.5 mg/mL, respectively, were prepared.

Sample Solutions—Twenty tablets or the contents of 20 capsules were weighed and powdered. A quantity of powder which gave an extract of the drug at the concentration, based on the declared strength of the formulation, that is specified for the drug in Table I was weighed into a 50-mL volumetric flask. The powder was shaken with 0.1 M HCl (40 mL) for 20 min and diluted to 50.0 mL with 0.1 M HCl. The extract was filtered through filter paper[14], the first 10 mL of filtrate was discarded to avoid problems arising from adsorption of the drug to the filter, and the second-derivative absorption spectrum of the filtrate was recorded.

For unit dose assays, a tablet or the contents of a capsule were powdered in a beaker with a glass rod. A suitable volume of 0.1 M HCl, 10.0–500.0 mL (given by declared unit dose in mg/analytical concentration in mg/mL), was added which yielded an extract containing the specified analytical concentration of the drug. Small volume extracts, <20 mL, were filtered through a membrane filter[15] and larger volume extracts through filter paper[14], as described above, and the second-derivative spectrum of the filtrate was recorded. For the unit dose assays of trihexiphenidyl hydrochloride, benztropine mesylate, methadone hydrochloride, and oxyphenonium bromide, 10.0 mL of 0.1 M HCl was used.

RESULTS AND DISCUSSION

Experimental Parameters—The zero-order and second-derivative absorption spectra of meperidine hydrochloride (pethidine hydrochloride), as an example of a benzenoid drug displaying characteristic fine structure in the region of 250—270 nm, are shown in Fig. 1A and B, respectively. The wavelengths of the minima of the inverted bands (a, b, c, and d) in the second-derivative spectrum correspond, after correction for displacement of the spectrum in the direction of the scan (14, 15), with the λ_{max} value (a, b, and c) at 251, 257, and 262.5 nm and shoulder at 268 nm in the zero-order spectrum. The second-derivative spectra of the other

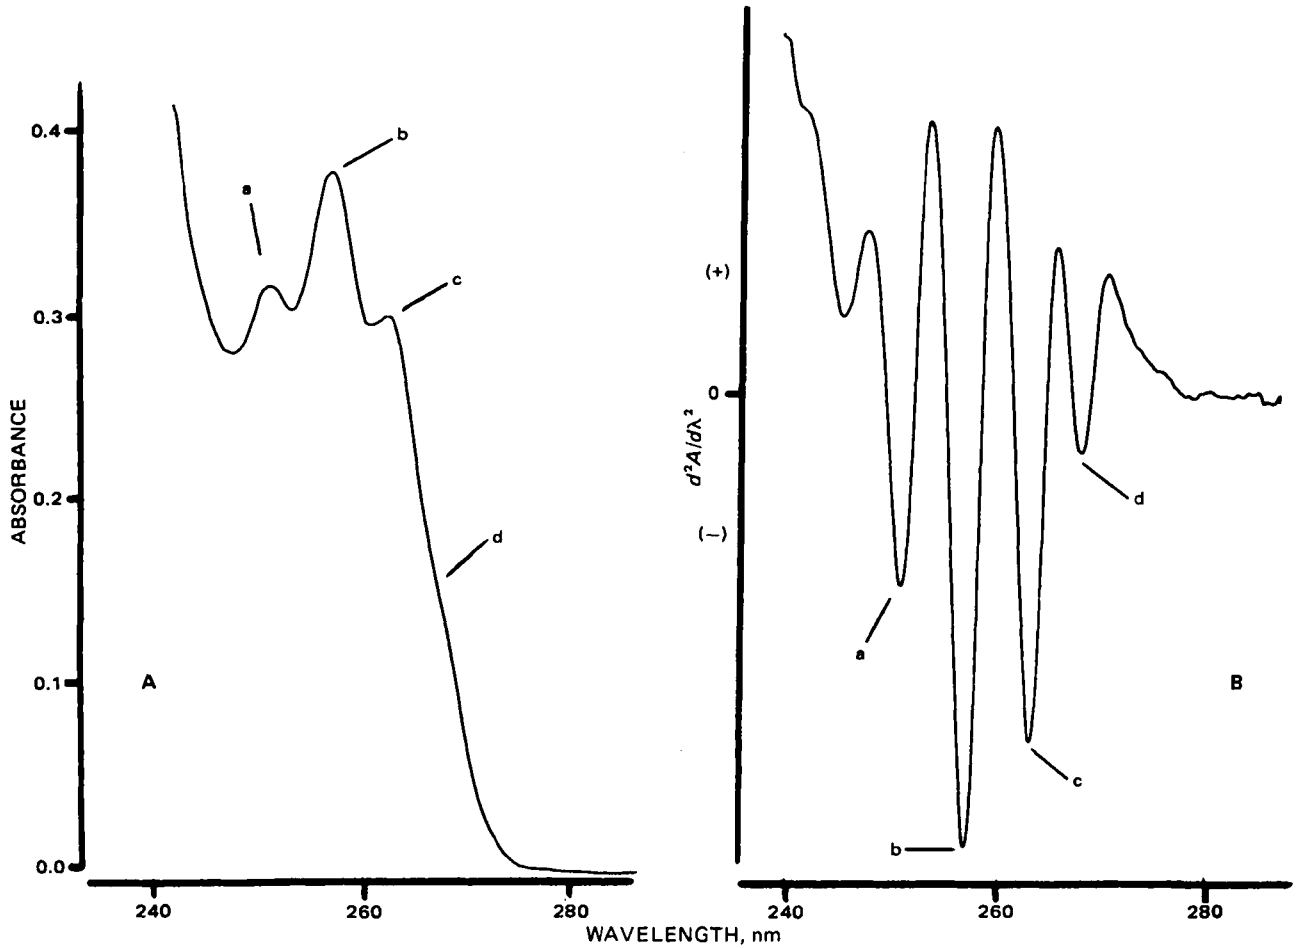

Figure 1—*Zero-order (A) and second-order derivative (B) spectra of meperidine hydrochloride (0.5 mg/mL in 0.1 M HCl).*

benzenoid drugs are similar to that of meperidine, differing only in the relative amplitudes of the vibrational bands and the wavelengths at which they occur. The amplitude of the largest band in the derivative spectrum of each drug (*e.g.*, for meperidine at 257 nm measured to its shorter wavelength satellite), providing the greatest sensitivity, was chosen for the analytical measurement.

The solvent used throughout was 0.1 M HCl, which is a satisfactory extracting solvent for these basic drugs, maintaining them substantially in the protonated form. It has been observed during the present work that certain drugs which show a barely discernible difference between the protonated and nonprotonated forms in the zero-order spectra display considerably larger differences in the derivative spectra. For example, the absorbance at λ_{max} 262.5 nm of meperidine is only 2.6% greater in 0.1 M HCl than in 0.1 M NaOH, whereas the amplitude of the second derivative minimum at 262.5 nm measured to its longer wavelength satellite is 26.3% greater in 0.1 M HCl than in 0.1 M NaOH.

The instrumental variables (absorbance range, spectral band pass, time constant, scan speed, and recorder voltage) were held constant for all the drugs, and the analytical concentration of each drug was selected as that giving the largest derivative amplitude at 50–60% of the chart full range. This approach enabled a direct comparison of the derivative responses at a constant instrumental damping and noise level to be made. Table I lists the analytical concentration together with the specific amplitude of the largest band, calculated as the amplitude, in millimeters, of a 1-mg/mL solution of the drug at 20°C as a ratio of the full chart width (250 mm) of the recorder on the 1-V range, and given by:

$$\text{Specific amplitude} = \frac{\text{Amplitude (mm)}}{\text{Concentration of drug (mg/mL)} \times 250}$$

Validation—The proportionality of the measured amplitude and concentration was checked for each drug by means of a six-point calibration graph at concentrations of 0, 25, 50, 75, 100, and 125% of the analytical concentration. In all cases, a proportional relationship was found to exist, with correlation coefficients ≥0.9996 and intercepts ≤ ±1% of the analytical concentration.

The precision of the amplitude measurements under the instrumental conditions was determined by recording the second-derivative spectra of five drug solutions, at their analytical concentrations, 10 times. The replicate measurements were each made after refilling the cell with fresh solution at room temperature to avoid an increase in the temperature of the solution in the cell compartment, which may reduce the measured amplitude (16). The relative standard deviations of the amplitudes of bethanidine, diphenhydramine, hydroxyzine, cyclizine, and diphenylpyraline all fell in the range of 0.42–0.59%. The similarity of these values is undoubtedly due to the similarity of the measured amplitudes (50–60% of the recorder scale) achieved by the selection of the analytical concentration.

As instrumental noise is a major factor affecting the reproducibility of spectra, the constant instrumental parameters adopted throughout this work would be expected to give constant noise levels, similar signal-to-noise ratios, and simllar satisfactory precision for the other drugs. Furthermore, the sampling procedure for most of the drug formulations may be readily modified to cope with unit dose assays using the same instrumental parameters without loss of precision of the measurement.

Unit dose assays may be carried out by crushing the formulation unit and extracting the drug with a suitable volume of 0.1 M HCl, as little as 10.0 mL if necessary, to obtain the desired analytical concentration, followed by filtration of the extract through a membrane filter or filter paper. It is considered that the systematic error incurred in this procedure by the increase in volume due to the dissolved components of the formulation is negligible.

The only formulations for which the normal instrumental parameters had to be modified for the unit dose assays were of those drugs having small specific amplitude (<1.0) and which are formulated in low dosage (≤5 mg/unit dose), *viz.*, trihexiphenidyl hydrochloride, benztropine mesylate, methadone hydrochloride, and oxyphenonium bromide. The unit dose assay of these formulations required the extraction of a dose unit with 10.0 mL of 0.1 M HCl, membrane filtration, and an increase in the sensitivity of the ordinate scales by factors of 3.33, 3.33, 1.25, and 1.67, respectively, of that of the normal scale. The relative standard deviations of the measurements for those drugs for which the unit dose assay re-

quired the ordinate scale expansion were 0.96, 0.91, 0.62, and 0.58% for trihexiphenidyl hydrochloride, benztropine mesylate, methadone hydrochloride, and oxyphenonium bromide, respectively.

Assay Results—Table I records the results obtained for 18 solid dosage formulations of benzenoid drugs which, with the exception of four, are official in the British Pharmacopoeia 1980 (17). The analytical concentration for each drug is given, and the measured amplitude is specified by the wavelength of the minimum in the derivative spectrum, after correction for scan speed effects (14, 15), measured either to its shorter or longer wavelength satellite. The specific amplitude is included to indicate the relative derivative responses of the drugs on a weight basis.

The presence of irrelevant absorption in all the sample extracts was confirmed by the observation of nonspecific absorption above 285 nm (where the drugs, except methadone, have zero absorptivity) and of the increasing distortion of the spectra toward lower wavelengths. The extent of the interference in the sample extracts is evident from the results (in the last column of Table I) showing the assay results calculated from the absorbance of the extracts at the λ_{max} in the region of 255–270 nm, uncorrected for irrelevant absorption. The background absorption at the λ_{max} of one drug formulation, that of phenelzine sulfate, exceeded the absorbance of the drug itself and many formulations showed interference >10% of that of the drug. The derivative spectra of the sample extracts, however, showed no apparent distortion and were identical in shape to the corresponding standard solutions, indicating the elimination of the broad-band irrelevant absorption of the formulation excipients from the derivative spectra of the sample solutions. In the case of two benzenoid drugs, atropine sulfate and scopolamine hydrobromide, formulated at very low doses (0.3 and 0.6 mg/tablet), there was unacceptable distortion of the second- and even of the fourth-derivative spectra by the tablet excipients. The derivative spectrophotometric assay of these very low-dose formulations by an alternative procedure is the subject of another report (18).

The assay results for the formulations, obtained by the derivative procedure, are in excellent agreement with the declared amount and, where appropriate, with the results given by official procedures of the BP 1980 (17), confirming that second-derivative spectrophotometry is a simple, rapid, and selective technique which has general application in the assay of tablet and capsule formulations containing a single benzenoid drug. The specificity of the procedures for drugs in the presence of degradation products has not been investigated in the present study. It is likely, however, that degradation products will contribute to the derivative spectrum of the sample solution and therefore interfere in the assay, if their zero-order UV spectra, like that of the parent drug, show fine structure in the 250–270-nm region.

Estrogenic and Antiestrogenic Activity of Novel Selenosteroids

SAMY A. SADEK *x, J. THOMAS PENTO ‡, and GARO P. BASMADJIAN ‡

Received November 22, 1982, from the **Faculty of Medicine, Kuwait University, Kuwait*, and the ‡ *College of Pharmacy, The University of Oklahoma, Oklahoma City Campus Health Science Center, Oklahoma City, OK 73190.* Accepted for publication February 8, 1983.

Abstract □ An assay for estrogenic and antiestrogenic activity of seven selenoestrogens has been carried out in immature female rats. The estrogenic activity was compared to the *in vitro* binding affinity data. The study reveals that introduction of selenium substituents on C-16 or C-17 of the steroid nucleus produced a marked reduction in the estrogenic activity. The selenium analogues of ethynylestradiol produced the highest estrogenic activity. None of the compounds produced antiestrogenic activity.

Keyphrases □ Selenoestrogens—estrogenic and antiestrogenic activity in immature rats, comparison with *in vitro* binding affinity □ Estrogens—selenium substituted, estrogenic and antiestrogenic activity in immature rats, comparison with *in vitro* binding affinity □ Binding affinity, *in vitro*—selenium-substituted estrogens, correlation with *in vivo* estrogenic and antiestrogenic activity, rats

The differentiation between estrogen receptor-negative and receptor-positive breast tumors and their metastases is important in the management and treatment of such tumors (1, 2). Present techniques are based on the *in vitro* measurement of estrogen receptors in freshly obtained biopsies of breast tissue. Therefore, a radiopharmaceutical which could be used to image estrogen-dependent breast tumors and metastatic foci by external detection could be a useful diagnostic tool. A number of investigators have attempted to develop such a radiopharmaceutical using radiohalogenated (*e.g.*, iodine-125, bromine-77) estrogens (3, 4). However, most of these studies have met with limited success. Although selenium-75 may not be an ideal radionuclide for diagnostic use, it offers the following advantages (5, 6): (*a*) its long half-life (120 d) allows enough time for synthesis and handling; (*b*) it can be incorporated into organic molecules with minimal difficulty; (*c*) the organoselenium compounds are more stable *in vivo* than the corresponding halogenated derivatives; and (*d*) preliminary studies with selenium-75 could determine the feasibility of using the potentially more useful ^{73}Se-labeled compounds ($t_{1/2}$ = 7 h).

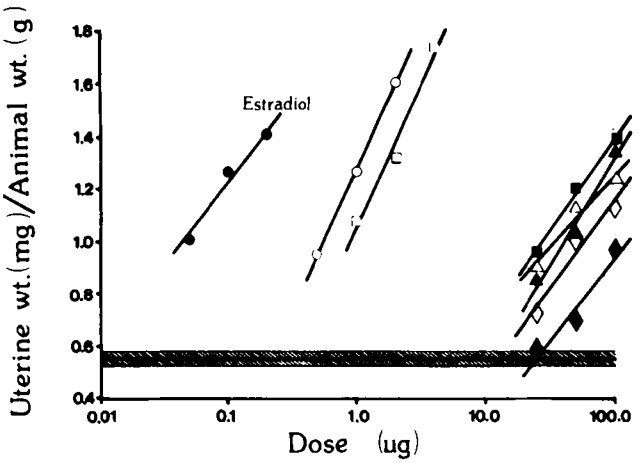

Figure 1—*Dose–uterotropic response curves of the selenosteroids. The horizontal bar represents the mean ± SEM of the control group. Key: (◆) I; (▲) II; (○) III; (□) IV; (△) V; (◇) VI; (■) VII.*

In previous studies (7, 8) we reported the synthesis and the relative binding affinity of various selenosteroids to the cytoplasmic estrogen receptor of rat uteri *in vitro*. In the present study, the uterotropic activity of these selenosteroids was examined and a correlation made between the *in vivo* uterotropic activity and *in vitro* receptor affinity.

EXPERIMENTAL

The uterotropic assay for estrogenic activity was a modification (9) of the original method of Rubin *et al.* (10). Immature female Sprague–Dawley rats weighing 40–50 g (~21 d old) were randomly distributed into groups containing five rats each. Estradiol and the test compounds were dissolved separately in corn oil and administered subcutaneously in a volume of 0.1 mL. Control animals were treated with the same volume of corn oil alone.

All animals were treated daily for three consecutive days with the same test compounds. On the fourth day the animals were sacrificed, and the uteri were carefully dissected, blotted lightly, and weighed to the nearest 0.1 mg; body weights were also recorded. Estradiol was used in a dosage range of 0.5–2 μg (total dose) as the assay standard. Each compound was examined over a dosage range of 5–100 μg (total dose).

The uterotropic assay was also used to evaluate the antiestrogenic activity of the test compounds. The antiestrogenic assay was conducted as described above for estrogenic activity except that each animal in the selenosteroid treatment groups received a standard stimulating dose of estradiol (2 μg). A separate control group which was treated with estradiol alone (2 μg) was also included in this assay. The test compounds and estradiol were administered separately at different injection sites to minimize possible physical interaction or reduce absorption of either compound. The antiestrogenic activity was measured as a decrease in estradiol-stimulated uterotropic response in groups which received both the test compound and estradiol as compared with the control group, which was treated with estradiol alone.

A line of best fit was plotted for each compound that produced an estrogenic response. Regression analysis was used to determine the dose–response line for each test compound. The slope of the response to each

Table I—Relative Uterotropic Activity of the Selenosteroids

Compound	Relative Uterotropic Activity[a]	RBA × 100[b]
Estradiol	100.00	100.00
I	0.06	1.0
II	0.14	5.1
III	10.46	2.0
IV	6.44	18.7
V	0.14	2.8
VI	0.11	0.1
VII	0.17	1.3

[a] Expressed as percentage of estradiol activity according to the method of Bliss (Ref. 11). [b] Ratio of the concentration of nonradioactive estradiol required to inhibit 50% of [^{3}H]estradiol binding to that of the competitor multiplied by 100 (from Ref. 8).

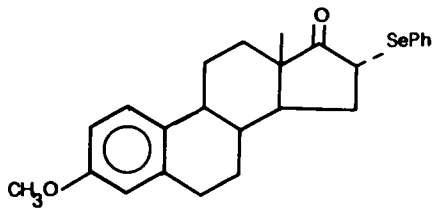
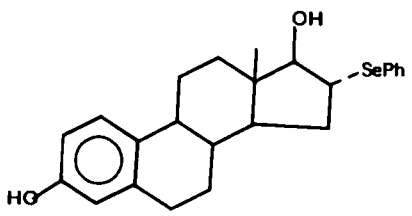
V



VI



VII

analogue was compared with the slope of the estradiol response to determine parallelism in this assay system. The relative uterotropic activity of each compound was expressed as a percentage of estradiol activity according to the method of Bliss (11).

RESULTS

The dose–response curve produced by each of the selenium analogues is presented in Fig. 1. The potency of each compound relative to estradiol is summarized in Table I.

Among the selenosteroids that were examined in this study, III produced the greatest uterotropic activity while I produced the least activity. The selenoanalogues of ethynylestradiol (III and IV) were more active than those of estradiol or estrone. This may be due to the differences in the activity of the parent compounds (12). None of the test compounds produced a significant degree of antiestrogenic activity in this study.

DISCUSSION

In Table I the relative binding affinity of the test compounds was compared with the uterotropic activity. The potency estimates were in good agreement with the relative binding affinities with few exceptions. To correlate *in vitro* and *in vivo* results, metabolism has to be taken into consideration. Even though VI demonstrated a low *in vitro* binding affinity, its *in vivo* potency is almost equal to that of V. This could be as a result of demethylation *in vivo*. Sulfur-containing organic compounds are metabolized to sulfoxides (13); analogously, selenides are expected to oxidize to selenoxides *in vivo*. Reports indicate that aromatic selenoxides are less stable than the aliphatic derivatives (14–16). Therefore, we assume that the greater activity of III as compared with IV, despite a lower affinity for estrogen receptors, is due to the degradation of III to the more potent ethynylestradiol.

It is reasonable to assume that VII has a greater *in vivo* uterotropic activity than V because estradiol (the parent compound of analogue VII) is more potent than estrone (the parent compound of analogue V) (12).

This study indicates that increasing the size of the substituent on C-17 decreases the *in vitro* binding and the *in vivo* potency. These data confirm the importance of the β-hydroxyl group on C-17 to retain the estrogenic activity (17). Since these selenosteroids retain a high degree of estrogenic activity (especially III and IV) *in vivo*, as shown in the present study, and display potent receptor binding *in vitro* (8), it is possible that one of these derivatives might be a suitable imaging agent for estrogen-dependent tumors and metastatic foci. Selenium-75 labeling of II has been accomplished utilizing newly developed methodology (18). Biodistribution studies of this ^{75}Se-labeled compound in tumor-bearing animals are underway.

Diaspirins of Methylenecitric Acid

SOLOMON E. MASSIL, GUEY-YUEH SHI, and IRVING M. KLOTZ ˣ

Received October 25, 1982, from the *Department of Chemistry, Northwestern University, Evanston, IL 60201.* Accepted for publication January 19, 1983.

Abstract □ A series of bissalicylic esters of methylenecitric acid have been prepared and, as a probe of their potential as antisickling agents, tested for their ability to modify hemoglobin. Substantial acylation of hemoglobin was obtained with these dicarboxylate esters at 1–5 mM concentrations.

Keyphrases □ Methylenecitric acid—bissalicylic esters, synthesis, hemoglobin-modifying potential □ Antisickling agents—potential, bissalicylic esters of methylenecitric acid, synthesis, hemoglobin-modifying ability

Diaspirins have been found (1) to modify hemoglobin S and to change its solubility markedly. Consequently, this class of compounds may provide promising antisickling agents. Just as aspirin is an acetate of salicylic acid, so are diaspirins the alkanedioates of salicylic acid. Alkanedioic acids of 4–5 carbon chain length seem to be optimal in modification of hemoglobins, probably because they can readily span the β-cleft of the hemoglobin molecule and form a covalent bridge between the two Lys 82 residues. Such a bridge evidently locks the protein into a conformation out of register for the aggregation that occurs in sickling.

The modified pentanedioic acid, 4-oxo-1,3-dioxolane-5,5′-diacetic acid, also known as methylenecitric acid (A), is a five-carbon span dicarboxylic acid whose monoesters have been examined previously for pharmacological ac-

Diaspirins of Methylenecitric Acid

SOLOMON E. MASSIL, GUEY-YUEH SHI, and IRVING M. KLOTZ ˣ

Received October 25, 1982, from the *Department of Chemistry, Northwestern University, Evanston, IL 60201.* Accepted for publication January 19, 1983.

Abstract □ A series of bissalicylic esters of methylenecitric acid have been prepared and, as a probe of their potential as antisickling agents, tested for their ability to modify hemoglobin. Substantial acylation of hemoglobin was obtained with these dicarboxylate esters at 1–5 mM concentrations.

Keyphrases □ Methylenecitric acid—bissalicylic esters, synthesis, hemoglobin-modifying potential □ Antisickling agents—potential, bissalicylic esters of methylenecitric acid, synthesis, hemoglobin-modifying ability

Diaspirins have been found (1) to modify hemoglobin S and to change its solubility markedly. Consequently, this class of compounds may provide promising antisickling agents. Just as aspirin is an acetate of salicylic acid, so are diaspirins the alkanedioates of salicylic acid. Alkanedioic acids of 4–5 carbon chain length seem to be optimal in modification of hemoglobins, probably because they can readily span the β-cleft of the hemoglobin molecule and form a covalent bridge between the two Lys 82 residues. Such a bridge evidently locks the protein into a conformation out of register for the aggregation that occurs in sickling.

The modified pentanedioic acid, 4-oxo-1,3-dioxolane-5,5′-diacetic acid, also known as methylenecitric acid (A), is a five-carbon span dicarboxylic acid whose monoesters have been examined previously for pharmacological ac-

tivity (2, 3). It seemed interesting, therefore, to prepare salicylic derivatives (B) of this diacid and to examine their effects on hemoglobin. The significant parts of B for its chemical and biological activity are the three C—O—C moieties designated O(1), O(2), and O(3). Classification of the functionality of the C—O—C at O(1) is acid anhydride, at O(2) acetal, and at O(3) acylal, and their relative reactivities toward amino groups are O(1) > O(3) > O(2).

EXPERIMENTAL[2]

To a stirred mixture of salicylic acid (2.00 mmol) or its halogen derivatives and dimethylaniline (4.13 mmol) in 100 mL of dry benzene was added in a dropwise manner 4-oxo-1,3-dioxolane-5,5-bis(acetylchloride) (methylene-citroyl dichloride, 1.02 mmol) dissolved in 20 mL of benzene. After 0.5 h at room temperature, the mixture was further warmed on a water bath (at 60–70°C) for ~10 min and then stirred overnight at room temperature. The solvent was removed *in vacuo*; the residue was suspended in 100 mL of ethyl acetate and then extracted twice with ice-cold 1 M aqueous H_2SO_4 (50 mL) and once with water (50 mL). After the organic layer had been dried ($MgSO_4$), filtered, and evaporated (*in vacuo*), the residue was triturated with several milliliters of petroleum ether to give solid material. Recrystallization either from benzene or a mixture of chloroform–petroleum ether (30–60°C) provided purified bis(substituted 2-carboxyphenyl)4-oxo-1,3-dioxolane-5,5′-diacetates, commonly known as bis(substituted salicyl)anhydromethylene citrates.

The compounds were identified by elemental analysis (Table I), IR, and ^{1}H-NMR spectrometry (1). The C=O stretching vibration of esters occurs in the range 1690–1770 cm^{-1}. NMR data were consistent with the proposed structures. The NMR spectra (DMSO-d_6 tetramethylsilane as internal standard) showed the following common absorption peaks: δ 3.3–3.5 (s, —C—CH_2—CO), 5.4–5.52 (s, O—CH_2—O), and 7.2–8.2 ppm (ArH).

Isoelectric focusing (6, 7) was used to assess the extent of modification of oxyhemoglobin. The acylated protein was separated from the parent protein in a flat gel by electrophoresis[3]. Minor alterations (8) were made in the procedures described by the manufacturer. Before application to the gel surface (on small pieces of filter paper) all hemoglobin samples were saturated with carbon monoxide and made to 0.01 M in NaCN. After focusing had been achieved, the gel was fixed (8) and dried overnight, and a densitometric scan was made with a soft laser scanning densitometer[4] and integrator. From this pattern the extent of modification was calculated.

RESULTS AND DISCUSSION

The extent of modification of oxyhemoglobin by these diesters is shown in Table I. The prototype of this series, the diester with unsubstituted salicylate (I), shows significant modification of the protein even at concentrations as low as 1 mM. The effectiveness increases progressively as one proceeds from the fluoro to the chloro, bromo, and iodo monosubstituted salicylates (II–V). With the monochlorosalicylate, a comparison was also made of the 4-substituted (VI) with the 5-substituted derivative (III), but the difference in behavior is insignificant. Derivatives with disubstituted halosalicylates (VII–IX) are not more effective as acylating agents for hemoglobin than are the monosubstituted derivatives.

Using [^{14}C]acetyl-labeled salicylate, we established previously (8) that acylation of hemoglobin occurs on lysine side chains. Subsequently, with the "double-headed" aspirins, chemical work supplemented by X-ray diffraction (9, 10), showed that the β-subunits of hemoglobin were cross-linked by —C(=O)—CH_2—CH_2—C(=O)— or —C(=O)—CH=CH—C(=O)— bridges connecting β_1 Lys 82 to β_2 Lys 82. Similar cross linking has been observed with five-atom bridges (11). Thus, the methylene citric acid series became a natural candidate for the extension of these structure-function investigations.

At first glance one would have expected (1) the dihalosalicylate diesters to be more effective than the monohalo ones since the additional halogen substituents should increase binding to hemoglobin. However, one must recognize that the extra electron-withdrawing substituents also activate the ester bond and make the compound more sensitive to hydrolysis. Such effects have already been observed (11, 12) with derivatives containing polar substituents on a four-carbon bridge; oxygen moieties adjacent to the carbonyl groups decrease the stability of the bis(dibromo)salicylate

[1] Numbering of substituents in structure B is in terms of salicylate ring.

[2] Elemental analyses were performed by Micro-Tech Laboratories of Skokie, Ill. IR spectra (in KBr pellets) were obtained with a Perkin-Elmer 283 spectrometer. ^{1}H-NMR spectra were obtained with Varian EM-360 (60 MHz) and JEOL FX-270 spectrometers. Melting points were taken in open capillary tubes and are uncorrected. Salicylic acids used herein were purchased from the Aldrich Chemical Co. Methylenecitric acid was prepared from citric acid and paraformaldehyde, and its subsequent conversion into dichloride was by treatment with PCl_5. The physical properties in all cases were in close agreement with those cited in the literature (2, 4, 5).

esters. Corresponding results have also been evident when electron-withdrawing groups were placed on the salicylate ring (13). The doubly halogenated salicylate derivatives of methylenecitric acid have activating groups both on the aromatic rings and on the middle carbon of the five-carbon bridge so that hydrolytic instabilities are magnified. Even in the solid state, traces of moisture lead to slow cleavage of these esters. Thus, as has been emphasized previously (11, 12) a careful balance between stability and reactivity is essential for optimal activity of the double-headed aspirins.

Computer-Interfaced Capacitive Sensor for Monitoring the Granulation Process

Keyphrases □ Granulation—computer-interfaced capacitive sensor, high-intensity mixer, moisture measurement, instrumentation, process control

To the Editor:

Wet granulation of powders is a fundamental process in pharmaceutical technology. The phenomenon of granulation, however, is not well understood because of the many variables involved in the process. The need for a better understanding and control of wet granulation has increased in recent years because greater utilization of high-intensity mixers has dramatically reduced the total time required to reach or exceed a proper granulation end point. Several workers have reported results from studies of the granulation process using instrumented mixers (1–8). These studies have shown that measurements of power consumption by the mixer, torque on the mixer shaft, change in rotation-rate of the mixer shaft, or the force with which granules deflect a strain-gauged beam, provided insight into the changes that occur as a powder is massed.

We wish to report a new approach to study the dynamics of wet granulation, which uses a computer-interfaced capacitive sensor that has been designed in our laboratories. The sensor is constructed from a polytetrafluoroethylene cylinder 1.5 cm in diameter, to which two insulated stainless steel electrodes are attached. The sensor is threaded to fit the existing thermocouple port in the wall of a high-intensity mixer[1]. The sensor extends into the mixer a distance of 5 cm and is 12 cm below the mixer center, with the distal 3 cm of each electrode exposed.

The two electrical leads from the sensor are connected to a moisture analyzer[2] which acts as the interface to the computer. The electronics of the moisture analyzer have been modified to filter signal noise caused by the rotation of the mixer plowshares and to allow for initial baseline adjustments. The moisture analyzer with sensor operates on the principle of power loss from a tuned radio-frequency (R/F) circuit as the dielectric of the medium surrounding the sensor changes. The analog DC voltage output of the moisture analyzer is converted to a digital value by an A/D converter and is fed to a 16-bit microprocessor[3] which is used for data processing and system control. System software is stored in a nonvolatile form in an onboard, programmable, read-only memory and allows for operator control of data sampling rate and text information for hard-copy output. Each data point, taken at 4-s intervals, is the average of 5000 A/D conversions.

Granulations were prepared by charging the mixer with 20 kg of lactose powder and using only the plowshare mixing action. Figure 1 shows the resulting voltage *versus* mixing time profile as incremental additions of water were made to the lactose[4]. The decreases in voltage are the result of rapid moisture distribution throughout the powder after each addition. The plateau reached between each addition is an equilibrium voltage value that is a function of the amount of water in the moist powder. The granules formed with this simple lactose water system, however, were not of good quality.

Figure 2 shows the voltage response when 2.5 kg of a 4% w/w methylcellulose 15 cps[5] aqueous solution was added to 20 kg of lactose at time zero. A similar voltage response

is seen; however, after the initial distribution phase, periodic voltage increases are observed. The difference in voltage response when a granulating agent is used in place of water indicates that the system, as designed, is sensing granule formation as well as moisture distribution. These voltage fluctuations have also been observed with other granulating agents when granules are formed. The height and periodicity of these voltage spikes seem to be associated with granule quality. The favored explanation for these observations is that the apparent density of the moist powder bed fluctuates in a periodic manner as agglomeration and deagglomeration occur during the mixing process. The changes in bed porosity around the sensor are reflected in a greater or lesser power-loss from the tuned R/F circuit.

Table I—Sieve Analysis Comparison of Lactose from Two Sources

	Lactose A[a]	Lactose B[b]
Weight % > 200 mesh	16.2	41.8
Weight % on 325 mesh	33.9	35.5
Weight % < 325 mesh	49.9	22.7

[a] Lactose hydrous USP, No. 80M, Sheffield Products, Memphis, Tenn. [b] Lactose hydrous USP, 310/Regular Grind, Foremost-McKesson, Inc., San Francisco, Calif.

Figure 3 illustrates the difference in sensor response when two lots of lactose having different particle sizes are granulated using the identical procedure described above for Fig. 2. The lower curve is the granulation response seen with fine particle lactose, while the upper curve is that observed with a more coarse lactose. A comparison of results from sieve analyses[6] conducted on the two lots of lactose is given in Table I. It is hypothesized that the finer lactose, because of its smaller particle diameter, forms more stable agglomerates that tend to deagglomerate less readily; therefore, the voltage spikes are fewer and more widely spaced. Conversely, the coarser lactose does not agglomerate as well and tends to deagglomerate rather quickly as indicated by the smaller and more closely spaced voltage spikes. Moreover, the granulation produced from the finer lactose was of better quality than that produced from the coarser lactose.

The dynamic granulation monitor using a computer-interfaced capacitive sensor shows promise both as a research tool to gain better understanding of the granulation phenomenon and as a control system to obtain better reproduction of granulations made in high-intensity mixers. In future communications, we will discuss the system and its applications in greater detail.

Hepatic Tissue Binding and the Oral First-Pass Effect

Keyphrases □ Oral bioavailability—influence of hepatic tissue binding on first-pass effect □ Lidocaine—oral availability in healthy subjects and epileptic patients compared □ Hepatic tissue binding—effect on oral availability of lidocaine, healthy subjects and epileptic patients compared

To the Editor:

The development in recent years of physiological pharmacokinetic models has provided valuable quantitative insights into factors determining drug disposition. This is particularly so for the process of elimination by either a single (1–3) or a series of multiple organs (4, 5). A seminal contribution was that of Rowland and colleagues (1) who conceptualized the quantitative interrelationship between organ clearance and certain determinants:

$$CL = Q\left[\frac{k_m K_P V_E}{Q + k_m K_P V_E}\right] \qquad \text{(Eq. 1)}$$

where Q is the organ blood flow, k_m is the first-order rate constant for drug elimination, K_P is the apparent partition coefficient of total drug between the eliminating organ and the emergent venous blood, and V_E is the actual tissue volume of the eliminating organ. Subsequent refinement of what has become known as the "venous equilibration" or "well-stirred" model of elimination (3) led to the concept of intrinsic clearance of either total (CL_{int}^{tot}) or unbound (CL_{int}^{u}) drug, and the definition of organ clearance in these terms and the other physiological determinants. Namely, organ blood flow and the unbound fraction of drug in the blood (f_B):

$$CL = Q\left[\frac{CL_{int}^{tot}}{Q + CL_{int}^{tot}}\right] = Q\left[\frac{f_B CL_{int}^{u}}{Q + f_B CL_{int}^{u}}\right] \qquad \text{(Eq. 2)}$$

For a drug that is metabolized under linear conditions, free intrinsic clearance is equivalent to the ratio of the net maximal rate of metabolism from liver water, *i.e.*, nonproteinaceous fluid of the liver (V_{max}) to the Michaelis–Menten constant (K_m) for the involved enzyme(s) (6). It is readily apparent, therefore, that organ clearance, *i.e.*, irreversible drug removal, is independent of the extent of tissue binding in the organ, as reflected by the unbound fraction in the tissue. Nevertheless, some confusion over this matter appears to exist (7) presumably because of the apparent involvement of tissue uptake in Eq. 1. This misconception arises because of the failure to recognize the equivalence of the clearance terms $k_m K_P V_E$ (Eq. 1) and $f_B CL_{int}^{u}$ (Eq. 2), and the inverse relationship between the first-order rate constant (k_m) and effective volume of distribution ($K_P V_E$) when clearance is constant. Such equivalence is readily apparent if K_P is expressed according to its physiological determinants, *i.e.*, the ratio of the unbound fractions of drug present in the blood and the liver (f_B/f_L), and CL_{int}^{u} is equated in the conventional fashion to the product of the rate constant (k_m) and the volume of distribution of unbound drug (V_E/f_L).

The conclusion that tissue binding could affect drug clearance by an organ was based on an analysis (7) of data obtained following oral and intravenous administration of lidocaine to normal volunteers and patients who were receiving chronic anticonvulsant therapy with known enzyme-inducing agents (8). In essence, a simple three-compartmental physiological model was postulated to include rapidly and slowly equilibrating noneliminating tissue pools and the hepatoportal system. By assigning parameter values to tissue volumes, partition coefficients between serum and the tissue (referred to as retention factors in Ref. 7), tissue flow rates, and total intrinsic clearance, the study in the normal subjects was simulated with good agreement between the experimental data and the model. Parameter adjustment then permitted a reasonably good simulation of the different pharmacokinetic findings obtained in the epileptic patients, *i.e.*, a significantly reduced area under the serum concentration–time profile following oral but not intravenous administration with essentially no change in the elimination half-lives. It was indicated in the text and in the legend of Fig. 1 of Ref. 7 that the only difference between the two simulations was an increase in the effective liver volume ($V_H R_H$, equivalent to $V_E K_p$ of Eq. 1). However, examination of the parameters provided in Table I of Ref. 7 indicates that the successful simulation of the data from the epileptic patients required modification of *both* the effective liver volume *and* the total intrinsic clearance (referred to as CL_H in Ref.

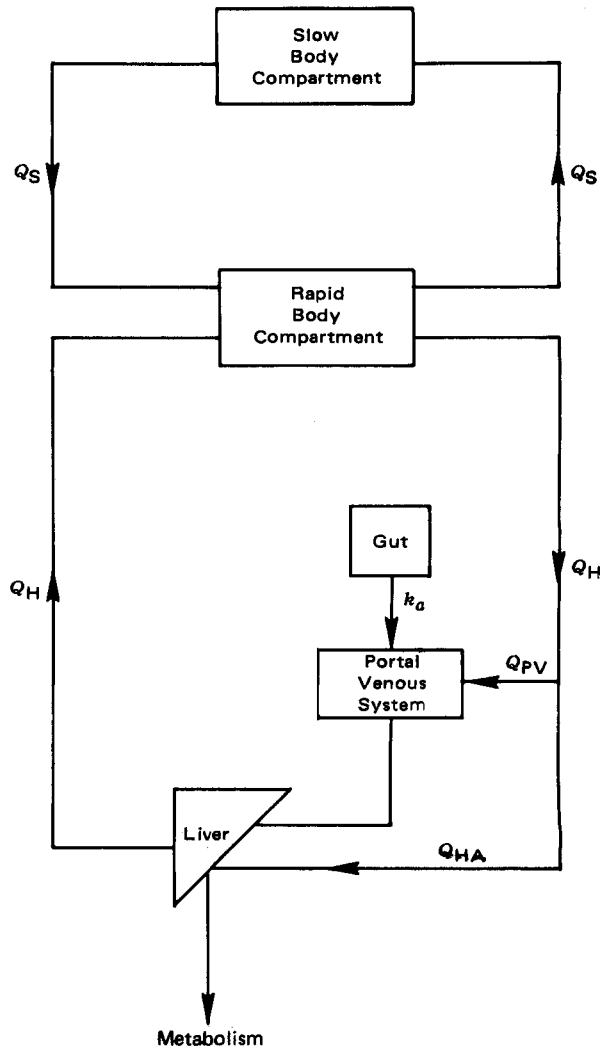

Figure 1—*Physiological model for evaluating the first-pass effect when the body has the characteristics of a two-compartmental system.*

Table I—Model Parameters for Lidocaine

Volume, L	
V_B	5.0
V_L	1.5
V_{PV}	1.0
V_T^R	11.47
V_T^S	23.0
Flow rate, L/h	
Q_{HA}	18.0
Q_{PV}	72.0
Q_S	198.0
Unbound fraction	
f_B	0.40
f_L	0.65
f_T^R	0.176
f_T^S	0.176
Free intrinsic clearance, L/h	390
Absorption rate constant, h^{-1}	1.75

7). It is, therefore, impossible to conclude that the changes in the pharmacokinetics of lidocaine produced by enzyme-inducing agents was caused solely by an increase in the effective volume of the liver. An additional problem with the simulations is the parameter values chosen for the effective liver volumes: 50 and 150 L for the normal and epileptic subjects, respectively; the physiological basis and appropriateness of these values were not indicated.

To clarify the findings with lidocaine in normal and epileptic subjects, and to specifically examine the role of tissue binding in organ clearance and elimination, a number of simulations were performed based on the physiological model shown in Fig. 1 and described by the following mass balance equations.

Rapidly equilibrating compartment:

$$\frac{dA_T^R}{dt} = (Q_{PV} + Q_{HA})\left(C_L\frac{f_L}{f_B} - C_B\right) + Q_T^S\left(C_T\frac{f_T^S}{f_B} - C_B\right) \quad \text{(Eq. 3)}$$

Slowly equilibrating compartment:

$$\frac{dA_T^S}{dt} = Q_T^S\left(C_B - C_T\frac{f_T^S}{f_B}\right) \quad \text{(Eq. 4)}$$

Liver:

$$\frac{dA_L}{dt} = Q_{PV}C_{PV} + Q_{HA}C_B - (Q_{HA} + Q_{PV})C_L\frac{f_L}{f_B} - CL_{int}^u C_L f_L \quad \text{(Eq. 5)}$$

Metabolism:

$$\frac{dM}{dt} = -CL_{int}^u C_L f_L \quad \text{(Eq. 6)}$$

Portal vein:

$$\frac{dA_{PV}}{dt} = k_a G + Q_{PV}C_B - Q_{PV}C_{PV} \quad \text{(Eq. 7)}$$

Gut:

$$\frac{dG}{dt} = -kaD \quad \text{(Eq. 8)}$$

where C_B, C_T, C_L, and C_{PV} refer to the total drug concentrations in the arterial blood, slowly equilibrating tissue, liver, and portal vein, respectively; Q_T^S, Q_{PV}, and Q_{HA} are the blood flows to the slowly equilibrating tissue, portal vein, and hepatic artery; f_B, f_T^R, f_T^S, and f_L are the unbound fractions of drug in the blood, the rapidly equilibrating tissue, the slowly equilibrating tissue, and the liver; CL_{int}^u is the free intrinsic clearance; D is the oral dose; and k_a is the first-order rate constant for oral absorption.

Furthermore, the effective volumes of the various "organs" may be defined assuming equilibration of the emergent and tissue concentrations of unbound drug.

Rapidly equilibrating compartment:

$$V_R = V_B + V_T^R\frac{f_B}{f_T^R} \quad \text{(Eq. 9)}$$

Slowly equilibrating compartment:

$$V_S = V_T^S\frac{f_B}{f_T^S} \quad \text{(Eq. 10)}$$

Liver:

$$V_L = V_T^L\frac{f_B}{f_L} \quad \text{(Eq. 11)}$$

where V_B, V_T^R, V_T^S, and V_T^L correspond to the actual physiological volumes of the blood, the other rapidly equilibrating tissues, the slowly equilibrating tissues, and the liver, respectively.

The present model is essentially the same as that used by Colburn (7) except that the hepatoportal system is separated into its component organs and the apparent partition coefficient of the drug between the blood and tissue is identified by its physiological determinants, namely the ratio of the unbound fractions of drug in the blood and the tissue. Accordingly, Eq. 5 which describes the mass balance relationship in the liver is mathematically equivalent to Eq. 5 of Ref. 7.

Parameter values for the model (Table I) were selected on the basis of standard values of blood volume, hepatic blood flow, liver weight, and portal venous system volume for a 70-kg man. Other values were based on the known disposition characteristics of lidocaine, for example, the unbound fraction in the blood was taken to be 0.4 (9). The liver/emergent venous plasma partition coefficient of lidocaine at steady state has been experimentally determined to be 0.61 ± 0.16 in the rhesus monkey (10). Based on a blood–plasma concentration ratio in the monkey of 0.8 and an unbound fraction in the plasma of 0.4 (10), this partition ratio provided an estimate of the unbound fraction of lidocaine in the liver of 0.65. To investigate the effect of altering such binding and, therefore, changing the effective volume of the liver, values of f_L ranging from 0.002 to 1.0 were also used. The values of V_T^R and f_T^R and V_T^S and f_T^S were arbitrarily selected to provide the appropriate effective tissue volumes according to preliminary conventional compartmental analysis based on the first-pass model described by Gibaldi and Feldman (11). This analysis also provided an estimate of the blood flow to the slowly equilibrating compartment. The estimate of free intrinsic clearance was based on the mean value reported by Perucca and Richens (8) in the control subjects after taking into account the extent of binding in the blood. Finally, to compare the simulations based on blood concentrations with the experimental serum concentration, the theoretical data was corrected by the blood–serum concentration of lidocaine using a value of 0.88 (8).

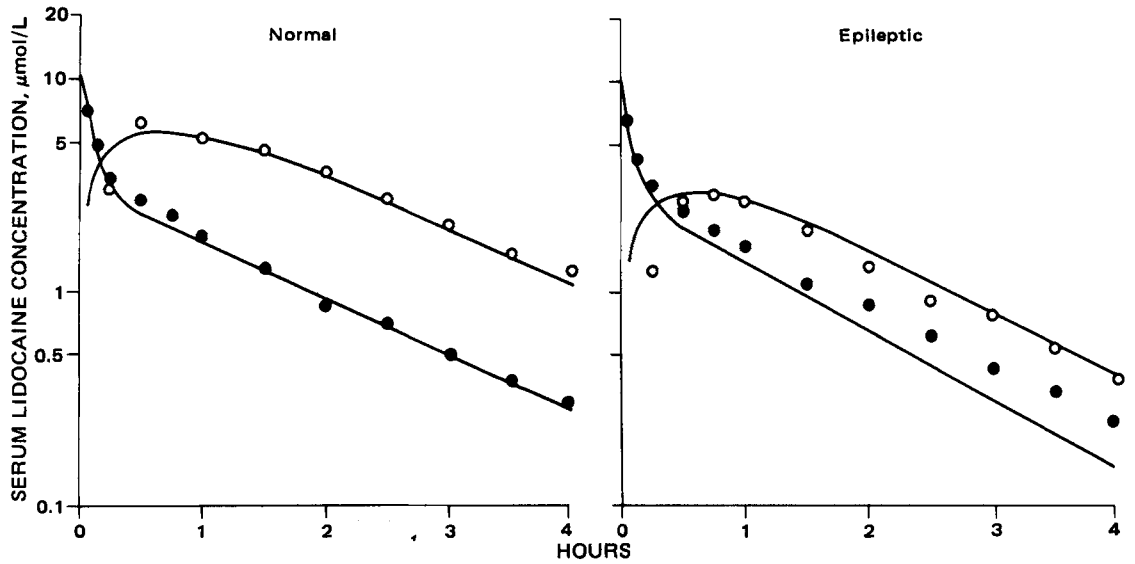

Figure 2—*Simulated and mean observed serum concentrations of lidocaine in normal subjects and epileptic patients following intravenous (●) and oral (○) doses of lidocaine. The solid lines represent the theoretical curves according to the model in Fig. 1 and parameter values in Table I; in the simulation of the epileptic patients only the free intrinsic clearance value was increased.*

Excellent agreement was obtained between the simulation using the parameter values in Table I and the experimental data from the normal subjects (Fig. 2). To test the hypothesis that the altered pharmacokinetics of lidocaine in the epileptic patients was solely due to an increase in hepatic drug-metabolizing ability, as suggested by Perucca and Richens (8), the value of free intrinsic clearance was increased from 390 to 930/h. Again, excellent agreement was obtained with the experimental observations (Fig. 2).

The effect of altering hepatic tissue binding on the oral disposition of lidocaine was examined by altering the unbound fraction over a 500-fold range (0.002–1.0) equivalent to changing the effective liver volume from 0.6 to 300 L. As shown in Fig. 3, this had essentially no effect on the serum concentration–time profile other than a small reduction in the peak serum level and a modest prolongation of the elimination half-life at very high levels of hepatic binding ($f_L < 0.01$). At such extreme values, about 20–70% of drug in the body during the terminal elimination phase would be present in the liver. Importantly, the changes in hepatic tissue binding had no effect on the total area under the oral serum concentration–time curve. Additional simulations indicated that these effects were independent of the value of the free intrinsic clearance, *i.e.*, they applied equally to low- and high-extraction drugs.

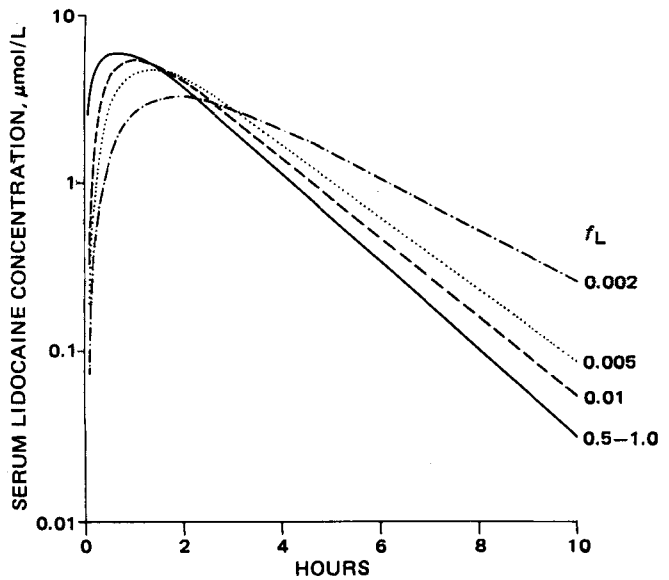

Figure 3—*The effects of the fraction of lidocaine not bound to liver tissue (f_L) on the serum concentrations of lidocaine following oral administration.*

The major experimental finding concerning the effect of chronic anticonvulsant therapy on the disposition of lidocaine was a reduction in the areas under the serum concentration–time curve to about 40% of that determined in subjects not receiving such medication. The elimination half-life and disposition profile following intravenous administration were, however, largely unaffected. It was concluded that these differences were consistent with enzyme induction leading to a two- to threefold increase in the hepatic drug metabolizing activity of a drug that is well extracted by the liver and, therefore, undergoes a large first-pass effect (8). The present analysis based on physiological modeling completely supports this conclusion using parameters consistent with the known disposition of lidocaine. Moreover, the simulations indicate that changes in hepatic tissue binding leading to alterations in the effective volume of the liver have no effect on oral clearance. This is not unexpected, since the total area under the curve following oral administration is equal to the ratio of the absorbed dose to the total intrinsic clearance (2). The major effects of increasing liver binding is to modestly reduce the peak serum concentration and prolong the elimination half-life, as would be predicted from the increased total volume of distribution of the drug.

Considerable insights have been obtained in recent years concerning the quantitative disposition of drugs and the factors controlling important processes such as elimination. In particular, the oral first-pass effect is well understood, especially under linear conditions. While hepatic

tissue binding contributes to the initial uptake and storage of drug in the liver, except in unusual situations, this is a reversible process, and such binding does not affect the irreversible removal of drug by the clearance processes. Accordingly, such a mechanism does not need to be invoked to explain the increased first-pass effect of drugs, including lidocaine, produced by the administration of enzyme-inducing agents.

Aspirin Prodrug Studies: Lack of Proper Literature Citation

I read with great interest the recent article by Hussain *et al.*, *J. Pharm. Sci.*, **72**, 1093 (1983), which contradicts the observations of Amidon *et al.*, *J. Pharm. Sci.*, **70**, 1299 (1981), concerning the question of aspirin phenylalanine ethyl ester as an aspirin prodrug.

Although the former article unequivocally demonstrates the inadequacies of the latter, it appears that both senior authors have been remiss in acknowledging the important contributions of other investigators in the development of aspirin prodrugs.

In particular, the aspirin triglyceride works of Paris *et al.*, *J. Med. Chem.*, **22**, 683 (1979) and *Agents and Actions*, **10**, 240 (1980) are never cited. More importantly, the only published article which describes the detection of aspirin in the plasma after *in vivo* administration of a prodrug of aspirin is conspicuously absent, Bodor *et al.*, *J. Pharm. Sci.*, **70**, 743 (1981).

The lack of proper literature citation by these authors is a poor reflection of the care taken by them in the preparation of their manuscripts, and is also a reflection on the quality of the reviewers who would allow such an obvious lack of citation to occur.

The Total Synthesis of Natural Products, Vol. 5. Edited by JOHN ApSIMON. John Wiley and Sons, One Wiley Drive, Somerset, NJ 08873. 1983. 550 pp. 15 × 23 cm. Price $60.00

Volume 5 of this series is devoted entirely to a review of sesquiterpene total synthesis from 1971 to 1979. Those familiar with the literature on synthesis will appreciate the enormity of this task. In Volume 2 a single chapter covered sesquiterpene synthesis through 1970; that an entire volume is now required attests to the explosion of research in this area during the past decade. The Heathcock group has assembled a lucid and readable account of modern sesquiterpene synthesis which can be heartily recommended to students and practicing chemists alike.

The authors have done a creditable job of organizing over 250 total syntheses. The volume is grouped into sesquiterpenes of increasing connective complexity (*i.e.*, acyclic, monocyclic, bicyclic) and includes a chapter on alkaloid sesquiterpenes. This organizational scheme facilitates the location of specific structural classes in addition to permitting the reader to digest the synthetic efforts toward a specific class of compounds in one sitting. A notable improvement over previous volumes is a closer correlation between the text and the reaction schemes, greatly improving the readability of the former. Each synthesis is accompanied by a detailed discussion, with special attention given to key steps. The syntheses of selected compounds are subjected to comparative analysis, including tabulated information on the number of steps, separations, and overall efficiency. The authors wisely refrain from the obvious temptation to use this interesting data to rate the individual syntheses. References to the isolation and activity of compounds are not included, but should be readily available through the papers on synthesis, making Volume 5 a useful reference to those involved in natural products chemistry. Practitioners of organic synthesis will find this volume of *The Total Synthesis of Natural Products* an enlightened and indispensable resource.

Deposition of Toxic Drugs and Chemicals in Man, 2nd Ed. By RANDALL C. BASELT. Biomedical Publications, P.O. Box 495, Davis, CA 95617. 1983. 795 pp. 15 × 23 cm. Price $49.50.

This compilation of important and useful information about common drugs and chemicals offers an excellent "one-stop" general reference for toxicologists, pharmacologists, and clinical chemists. This edition is organized in a format easier to read and contains considerably more information than the first edition.

Dr. Baselt devotes individual attention to 305 substances including drugs, pesticides, metals, and commonly used solvents to which humans are frequently exposed. He dedicates a section to each compound, showing the chemical structure and, when available, the volume of distribution, plasma protein binding, plasma half-life of drugs, and pK_a of compounds. Individual paragraphs describe concisely the drug as it relates to occurrence and usage, blood concentration, metabolism and excretion, toxicity, and analytical procedures. The references listed are plentiful in most cases, especially in each section on analytical methods.

In presenting data for the "metabolism and excretion" sections, the author made an effort to profile the metabolic process with both descriptive information and chemical structure. The reader should find this useful, considering the increased understanding of the role metabolites play in the human response to drugs. Each section on "toxicity" includes brief case histories and literature references of fatalities, relating the concentrations of the substance as found in blood and other body tissues.

With the overwhelming amount of information being generated on the fate of drugs and chemicals in the human body, it is almost a relief to see such data capsulized and presented in a useful source for the practicing scientist. This reference book certainly should have a spot reserved for it on the shelf of all analytical and clinical toxicologists who function in hospital laboratories.

Recent Advances in Clinical Therapeutics, Vol. II: Psychopharmacology, Neuropharmacology, and Gastrointestinal Therapeutics. Edited by JACK Z. YETIV and JOSEPH R. BIANCHINE. Grune and Stratton, Inc., 111 Fifth Avenue, New York, NY 10003. 1983. 290 pp. 16.5 × 24 cm. Price $32.50.

As the Preface states, this volume "is an outgrowth of a symposium held annually at the Ohio State University College of Medicine under the cosponsorship of the Departments of Pharmacology, Medicine, and Family Practice. The majority of the topics in this book were presented at the Fourth Annual Symposium on Recent Advances in Clinical Therapeutics held in September 1981. Several additional chapters were commissioned to round out the general focus of this volume." While fearing another random collection of disjointed lectures from 21 contributors, this volume was a pleasant surprise.

For each section, chapters are devoted to updates in general therapeutic principles as well as new drugs. Thus, the 25 newly approved or promising investigational drugs in this book are discussed in the context of their value in the overall management of the particular disease state. The table of contents is very detailed, and the index is more than adequate to help find desired information. Most chapters are well referenced.

The psychopharmacology section contains five chapters, covering neuroleptics, antidepressants, lithium, and phencyclidine. An excellent chapter on psychopharmacological classification of depressive disorders consolidates and clearly explains controversial and confusing literature. The lithium chapter focuses on new and important information, including renal effects and drug interaction concerns. The only chapter suffering from the 2½ year lag-time from presentation to publication is the chapter on antidepressants. So much has happened in the last 2½ years with newer antidepressants that this chapter is significantly out of date.

The neuropharmacology section contains chapters updating antiepileptic drugs, newer muscle-relaxant drugs, aging and neuropsychopharmacology, and the benzodiazepines. Each chapter is current and relevant. The aging and neuropsychopharmacology chapter is a concise summary of clinically useful information.

The gastrointestinal therapeutics section contains five very specific chapters. The histamine H_2-receptor antagonists chapter provides a useful discussion of cimetidine and ranitidine as well as their value for various indications. Other chapters include new therapeutics of reflux esophagitis, nonsteroidal anti-inflammatory drugs and the stomach, effects of GI and hepatic pathology on human drug responses, and chenodeoxycholic acid in the management of gallstones. The final miscellaneous section contains chapters on the treatment of sexually transmitted diseases, therapeutic use of marijuana derivatives, and management of bronchial asthma in the ambulatory patient.

For the pharmaceutical scientist interested in a concise update in clinical therapeutics, this volume will be helpful. It also provides some insight into the relative value of newly introduced drugs, as well as the remaining need for even better medicines.

As the Preface states, this volume "is an outgrowth of a symposium held annually at the Ohio State University College of Medicine under the cosponsorship of the Departments of Pharmacology, Medicine, and Family Practice. The majority of the topics in this book were presented at the Fourth Annual Symposium on Recent Advances in Clinical Therapeutics held in September 1981. Several additional chapters were commissioned to round out the general focus of this volume." While fearing another random collection of disjointed lectures from 21 contributors, this volume was a pleasant surprise.

For each section, chapters are devoted to updates in general therapeutic principles as well as new drugs. Thus, the 25 newly approved or promising investigational drugs in this book are discussed in the context of their value in the overall management of the particular disease state. The table of contents is very detailed, and the index is more than adequate to help find desired information. Most chapters are well referenced.

The psychopharmacology section contains five chapters, covering neuroleptics, antidepressants, lithium, and phencyclidine. An excellent chapter on psychopharmacological classification of depressive disorders consolidates and clearly explains controversial and confusing literature. The lithium chapter focuses on new and important information, including renal effects and drug interaction concerns. The only chapter suffering from the 2½ year lag-time from presentation to publication is the chapter on antidepressants. So much has happened in the last 2½ years with newer antidepressants that this chapter is significantly out of date.

The neuropharmacology section contains chapters updating antiepileptic drugs, newer muscle-relaxant drugs, aging and neuropsychopharmacology, and the benzodiazepines. Each chapter is current and relevant. The aging and neuropsychopharmacology chapter is a concise summary of clinically useful information.

The gastrointestinal therapeutics section contains five very specific chapters. The histamine H_2-receptor antagonists chapter provides a useful discussion of cimetidine and ranitidine as well as their value for various indications. Other chapters include new therapeutics of reflux esophagitis, nonsteroidal anti-inflammatory drugs and the stomach, effects of GI and hepatic pathology on human drug responses, and chenodeoxycholic acid in the management of gallstones. The final miscellaneous section contains chapters on the treatment of sexually transmitted diseases, therapeutic use of marijuana derivatives, and management of bronchial asthma in the ambulatory patient.

For the pharmaceutical scientist interested in a concise update in clinical therapeutics, this volume will be helpful. It also provides some insight into the relative value of newly introduced drugs, as well as the remaining need for even better medicines.

The Total Synthesis of Natural Products, Vol. 5. Edited by JOHN ApSIMON. John Wiley and Sons, One Wiley Drive, Somerset, NJ 08873. 1983. 550 pp. 15 × 23 cm. Price $60.00

Volume 5 of this series is devoted entirely to a review of sesquiterpene total synthesis from 1971 to 1979. Those familiar with the literature on synthesis will appreciate the enormity of this task. In Volume 2 a single chapter covered sesquiterpene synthesis through 1970; that an entire volume is now required attests to the explosion of research in this area during the past decade. The Heathcock group has assembled a lucid and readable account of modern sesquiterpene synthesis which can be heartily recommended to students and practicing chemists alike.

The authors have done a creditable job of organizing over 250 total syntheses. The volume is grouped into sesquiterpenes of increasing connective complexity (*i.e.*, acyclic, monocyclic, bicyclic) and includes a chapter on alkaloid sesquiterpenes. This organizational scheme facilitates the location of specific structural classes in addition to permitting the reader to digest the synthetic efforts toward a specific class of compounds in one sitting. A notable improvement over previous volumes is a closer correlation between the text and the reaction schemes, greatly improving the readability of the former. Each synthesis is accompanied by a detailed discussion, with special attention given to key steps. The syntheses of selected compounds are subjected to comparative analysis, including tabulated information on the number of steps, separations, and overall efficiency. The authors wisely refrain from the obvious temptation to use this interesting data to rate the individual syntheses. References to the isolation and activity of compounds are not included, but should be readily available through the papers on synthesis, making Volume 5 a useful reference to those involved in natural products chemistry. Practitioners of organic synthesis will find this volume of *The Total Synthesis of Natural Products* an enlightened and indispensable resource.

Deposition of Toxic Drugs and Chemicals in Man, 2nd Ed. By RANDALL C. BASELT. Biomedical Publications, P.O. Box 495, Davis, CA 95617. 1983. 795 pp. 15 × 23 cm. Price $49.50.

This compilation of important and useful information about common drugs and chemicals offers an excellent "one-stop" general reference for toxicologists, pharmacologists, and clinical chemists. This edition is organized in a format easier to read and contains considerably more information than the first edition.

Dr. Baselt devotes individual attention to 305 substances including drugs, pesticides, metals, and commonly used solvents to which humans are frequently exposed. He dedicates a section to each compound, showing the chemical structure and, when available, the volume of distribution, plasma protein binding, plasma half-life of drugs, and pK_a of compounds. Individual paragraphs describe concisely the drug as it relates to occurrence and usage, blood concentration, metabolism and excretion, toxicity, and analytical procedures. The references listed are plentiful in most cases, especially in each section on analytical methods.

In presenting data for the "metabolism and excretion" sections, the author made an effort to profile the metabolic process with both descriptive information and chemical structure. The reader should find this useful, considering the increased understanding of the role metabolites play in the human response to drugs. Each section on "toxicity" includes brief case histories and literature references of fatalities, relating the concentrations of the substance as found in blood and other body tissues.

With the overwhelming amount of information being generated on the fate of drugs and chemicals in the human body, it is almost a relief to see such data capsulized and presented in a useful source for the practicing scientist. This reference book certainly should have a spot reserved for it on the shelf of all analytical and clinical toxicologists who function in hospital laboratories.

Published monthly under the supervision of the Board of Trustees

Observations on the Selection of Our Professional Leaders

We are indebted to a fellow editor—who is also a current member of the APhA Academy of Pharmaceutical Science's Executive Committee—for the "idea germ" that triggered this month's editorial. We refer specifically to Professor Joseph R. Robinson of the School of Pharmacy, University of Wisconsin.

Among his many concurrent responsibilities, Dr. Robinson serves as Editor of the *Journal of Parenteral Science and Technology*, and he authors the editorial column that regularly appears in that bimonthly periodical.

His column—or more precisely, the "Editor's Page," as it is actually headed—in the January-February 1984 issue, is entitled "Leading Versus Managing." We recommend that the article be read in its entirety to get the benefit of Professor Robinson's full message. However, for our purposes here, we will briefly summarize his points as: (*a*) bringing out the important distinction between leadership and managership; (*b*) noting that a good manager is not necessarily a good leader, and in fact only rarely does a single individual possess both attributes; (*c*) observing that it is easier to be a good manager than it is to be a good leader; (*d*) pointing out that new executives often start out as good leaders but then gradually drift into an operating style wherein managing replaces leadership; and (*e*) concluding that the awareness of the value of, and the need for, leadership represents a vital first step in developing this very rare quality in one's self.

We would now like to take Professor Robinson's thoughts and observations a bit further.

Granted, virtually all of us profess to want leaders in our positions of authority, and we profess to want them to lead in a forceful and effective manner. But although we profess these desires, are they truly what we want or only what we have deluded ourselves into believing that we want?

These thoughts particularly come to mind as the American Pharmaceutical Association is currently in the throes of selecting a new President and chief executive officer. The criteria mentioned by all involved or in any way interested—from the APhA Board of Trustees, to the general membership, to the professional press—universally include "strong leadership" as a prime qualification for the person to be chosen for the office.

Certainly, the person who held the position for the past twenty-five years—the late William S. Apple—was unquestionably one of the strongest leaders that the entire health care community has ever produced. He was acknowledged by fan and critic alike as a dynamic, forceful personality who was able to achieve a level of success in his objectives far beyond normal expectations—and that this was primarily due to his strong leadership, his political astuteness, and his forceful personality.

Indeed, except perhaps for a few isolated criticisms in his later years, never did anyone fault either Dr. Apple or the organization he led, as being inactive, lethargic, unimaginative, or inflexible. When Dr. Apple took the reins at APhA, it had an image of being a conservative, outdated, and stodgy organization. He quickly reversed that perception, and by the early 1960s APhA was acknowledged as the frontrunner organization in pharmacy and among the forefront of all health care organizations.

But interestingly, criticism of Apple and APhA grew proportionately with their leadership influence. It appears that many members down deep really prefer the *status quo*. They want the appearance of activity, but they don't want change. The new APhA policy positions and initiatives were unpopular among many of the "rank and file" within the profession. Drug product selection, patient consultation, and clinical roles for the pharmacist were just some of the policies that APhA espoused first within organized pharmacy and which were vigorously resisted for a long time by much of the profession itself.

The role of APhA as an organizational "leader" for the profession—rather than simply a "protector" or "caretaker" for the profession—meant that, as an organization, it was out in front of the general membership and the profession as a whole. But the reaction of many pharmacists to APhA and Apple suggested that they didn't really want leadership. When they called for *a strong leader*, they really meant to say that they wanted *a dynamic manager*.

We see this same phenomenon repeated time-after-time in other areas. Journal subscribers and authors also profess to want a strong leader as the periodical's Editor. However, when changes are initiated, innovative approaches are established, or new policies are adopted, these developments are usually met with shocked disbelief if not outright resistance.

Scientific societies, including the APhA Academy of Pharmaceutical Sciences, almost universally will contend that they want an established, prominent scientist as their chief executive officer. Purportedly, this is so that the individual can serve with a high profile for the group in its dealings with other scientific organizations, with government agency officials, with the press, and with the general public.

But in contrast to industry and trade groups, experience shows that scientific societies and professional associations usually prefer to retain the leadership visability role for their chief elected officers or for some comparable elected officials.

Although the motivating reasons are natural and quite understandable, this sort of *modus operandi* is bound to impede the full exercise of the most effective leadership for the organization.

Consequently, we felt that Professor Robinson's observations have special relevance and application to the pharmaceutically related organizations, groups, and institutions with which we are involved or in which we participate.

If it is strong leadership that we truly want from those we select to staff and run those operations, then we must be prepared to accept the "fall-out" associated with new ideas, new directions, and new approaches. If we are not willing to do so, then let us be honest and admit candidly that what we really desire is simply good *managers*—and not good *leaders*.

Comparative Study of Lipophilicity *versus* Topological Molecular Descriptors in Biological Correlations

S. C. BASAK, D. K. HARRISS, and V. R. MAGNUSON ˣ

Received September 7, 1982, from the *Department of Chemistry, University of Minnesota-Duluth, Duluth, MN 55812.* Accepted for publication February 15, 1983

Abstract □ This paper analyzes the relative efficacies of lipophilicity *vis-à-vis* topological indices in the correlation of the biological properties of four groups of bioactive molecules: alcohols, barbiturates, triazinones, and ketobemidones. Wiener number (W), information-theoretic topological parameters (IC, SIC, CIC, I_D^w, and $\bar{I}_D^w$), and molecular connectivity indices ($^1\chi$, $^1\chi^v$) were used as the molecular descriptors. Results show that theoretical indices are comparable or superior to log P in biological correlations.

Keyphrases □ Lipophilicity—correlations with topological molecular descriptors, assessment of the biological activity of diverse molecules □ Biological activity—comparison of lipophilicity with topological molecular descriptors, diverse molecules □ Topology—molecular descriptors, comparison with lipophilicity, assessment of the biological activity of diverse molecules

In contemporary biomedicinal chemistry, quantum chemical (1–4), physicochemical (5–7), and topological (8–21) parameters have been extensively utilized in the prediction of biological activity of molecules. While quantum chemical descriptors provide the most accurate numerical information regarding molecular architecture, the complexity of many bioactive molecules precludes the possibility of the extensive use of these methods in drug design (8). The problem reaches a staggering dimension when one considers the enormous number of candidate structures derivable from a pharmacological "lead" by means of probable molecular manipulations (22).

To resolve this impasse attempts have been directed at developing methods that contribute reasonably accurate and practical information at a level less comprehensive than the quantum chemical treatment (8). The extrathermodynamic linear free energy relationship (LFER) approach, derived from physical organic chemistry, and topological indices defined on the chemical graph of the molecule, appear to provide convenient model systems in relating chemical structure to biological functions.

The LFER approach, usually termed Hansch analysis, relies on the basic premise that complex physicochemical interactions between pharmacological and biological targets under *in vitro* and *in vivo* conditions can be quantitatively expressed in terms of multiparametric regression models involving steric, electronic, hydrophobic, and other substituent constants (6, 7). The outcome of a large number of quantitative structure–activity relationship (QSAR) studies of the Hansch type indicates the predominant role of hydrophobicity (log P or π) in determining the action of a large variety of nonspecific bioactive molecules. On the other hand, stereoelectronic variables seem to be crucial for the physiological action of molecules that act *via* specialized enzyme or receptor systems (23). However, a number of studies show that steric, electronic, and hydrophobic factors have an appreciable degree of interdependence on each other. For a group of aromatic molecules, Rogers and Cammarata (24) found log P to be positively correlated with ΣS_r, the sum of the electrophilic superdelocalizabilities for the aryl atoms, and negatively correlated with $\Sigma|Q_r|$, the sum of the π-electron charge densities. Fujita (25) discussed the inherent difficulty in the complete separation of the hydrophobic and steric effects of substituents arising out of the internal correlation between these two classes of substituent constants. Van der Waals' volume (V_w), a steric factor, is well correlated with log P for a wide variety of compounds (26). Also, the different topological steric descriptors have appreciable correlation with log P (8, 15, 17, 20). These studies indicate that some common structural features affect the steric, electronic, and hydrophobic factors in an unknown manner. Moreover, it has been pointed out that although the Hansch approach is a valid QSAR model for the closely related congeners, it cannot account for the common biological properties of molecules with considerable structural diversity (27).

These considerations necessitated the development of substructural (27–29) and topological methods (8) to determine a direct relationship between chemical structure and biological action. In particular, QSAR literature of recent years shows

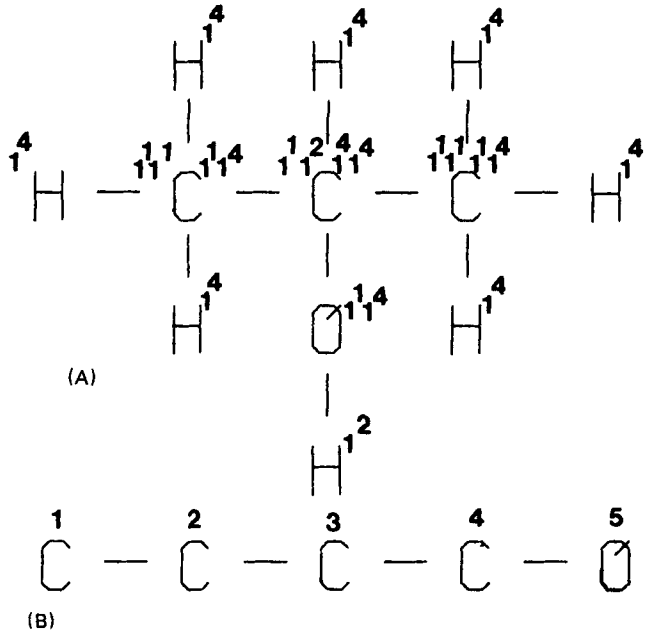

Figure 1—*(A) Coordinate-attached structure for 2-propanol. The coordinate notation $1^1 1^2 1^4 1^4$ for C-2 means that this carbon atom is singly bonded to four atoms whose valences are 1, 2, 4, and 4. (B) The labeled graph for 1-butanol.*

the progressive reliance on various topological indices as convenient structural parameters for correlational studies in chemistry (8, 30) and biology (8–21). Although a topological index is likely to be inherently steric in nature by virtue of being a numerical descriptor of molecular shape and size (8, 21), the most important progress in this area has been the development of topological structural parameters capable of expressing the electronic properties of molecules (31, 32).

One of the necessary preconditions of successful QSAR analysis is the availability of a set of parameters with minimum overlap profile (21, 33). Therefore, it seemed fitting to study the relative efficacies of lipophilicity *vis-à-vis* steric descriptors in rationalizing pharmacological and toxicological properties. With this purpose we have investigated the utility of log P (octanol-water), information-theoretic topological indices (IC, SIC, CIC, I_D^v, $\bar{I}_D^w$), Wiener number (W), and molecular connectivity indices ($^1\chi$, $^1\chi^v$) in the quantitative correlation of the toxicity of alcohols, the analgesic property of ketobemidones, Hill reaction inhibitory potencies of triazinones, and the anesthetic action of three different groups of barbiturates.

EXPERIMENTAL

Source of the Hydrophobic Parameter (log P, Octanol-Water)—Log P values for the various congeneric series were taken either from the literature or calculated according to the method of Hansch and Leo (34).

Table I—Partitioning and Calculation of Information Indices (IC, SIC, and CIC) for 2-Propanol [a]

Partition Class with Coordinate	Number of Atoms in the Partitioned Class[b] (n_i)	Probability ($p_i = n_i/n$)
I 1^4	7	7/12
II 1^2	1	1/12
III $1^1 1^4$	1	1/12
IV $1^1 1^1 1^1 1^4$	2	2/12
V $1^1 1^4 1^4 1^2$	1	1/12

[a] $IC = 7/12 \log_2(12/7) + 2/12 \log_2(12/2) + 3 \times 1/12 \log_2(12) = 1.7807$ bits; $SIC = IC/\log_2(12) = 0.4967$; $CIC = 1/12[7 \log_2(7) + 2 \log_2(2) + 1 \log_2(1)] = 1.8043$ bits. [b] Total number of atoms in the molecule (n) = 12.

Table II—Distance Matrix D(G) of the Hydrogen-Suppressed Graph G of 1-Butanol

Atom	1	2	3	4	5
1	0	1	2	3	4
2	1	0	1	2	3
3	2	1	0	1	2
4	3	2	1	0	1
5	4	3	2	1	0

Calculation of Molecular Connectivity ($^1\chi$)—To each atom of the hydrogen-suppressed molecular graph, a δ value is assigned corresponding to the number of nonhydrogen atoms bonded to it. A connectivity value for a bond C_k (connecting atoms i and j) is computed as follows (8):

$$C_k = (\delta_i \delta_j)^{-1/2} \qquad \text{(Eq. 1)}$$

And finally, $^1\chi$ is calculated as the sum of all the individual connectivity terms:

$$^1\chi = \sum_k C_k \qquad \text{(Eq. 2)}$$

Calculation of Valence Molecular Connectivity ($^1\chi^v$)—To each atom of the hydrogen-depleted molecular skeleton, a δ^v value is assigned according to the formulation:

$$\delta^v = Z_i^v - h_i \qquad \text{(Eq. 3)}$$

where Z_i^v represents the number of valence electrons and h_i denotes the number of bonded hydrogen atoms for the ith atom in the labeled graph. Thereafter, $^1\chi^v$ is calculated as in the case of $^1\chi$ by substituting δ^v for δ in Eq. 1.

Calculation of Information-Theoretic Indices from the Molecular Graph—The statistical treatment of chemical structure by means of information theory relies on the basic premise that each structure contains a finite set of elements (n) that could be decomposed into disjoint subsets n_i ($i = 1, 2, \ldots, k$) by means of selected equivalence relations defined on the set. A probability scheme may then be attached to this distribution:

$$\begin{pmatrix} n_1, n_2, \ldots, n_k \\ p_1, p_2, \ldots, p_k \end{pmatrix}$$

where $p_i = n_i/n$ is the probability that a randomly selected element will lie in the ith subset. The entropy (or complexity) of the probability distribution of the elements of the set (or structure) can then be computed by means of Shannon's formula (35):

$$\text{Information Content} = -\sum_i p_i \cdot \log_2 p_i \text{ bits} \qquad \text{(Eq. 4)}$$

where the logarithm is taken at a basis 2 in order to measure the information in bits. Following the pioneering studies of Rashevsky (36) and Trucco (37, 38) on the topological information content of chemical graphs, various authors have defined information-theoretic indices and applied them to structure-property (15, 30, 39, 40) and structure-activity (15–20, 40) correlations.

In the formalism developed by Sarker *et al.* (41), Basak *et al.* (19, 42), and Raychaudhury *et al.* (43) the total (nonhydrogen-suppressed) molecular graph is used to define the various topological indices, and the method is sufficiently general to include linear graphs as well as multigraphs. On the basis of a first-order topological neighborhood, Sarker *et al.* (41) defined an equivalence relation which decomposes the vertex set $\mathbf{X}(G)$ of the molecular graph G into disjoint subsets, whereby the information content (IC) of the graph is computed as:

$$IC(\mathbf{X}(G)) = -\sum_i p_i \cdot \log_2 p_i \text{ bits}$$

Subsequently, Basak *et al.* (42) defined another information-theoretic index, structural information content (SIC):

$$SIC(\mathbf{X}(G)) = IC/\log_2 n \qquad \text{(Eq. 5)}$$

where n is the cardinality of $\mathbf{X}(G)$. In continuation of this work Raychaudhury *et al.* (43) developed another information-theoretic topological index, *viz* complementary information content (CIC):

$$CIC(\mathbf{X}(G)) = \frac{1}{n}\sum_{i=1}^{k} n_i \cdot \log_2 n_i \text{ bits} \qquad \text{(Eq. 6)}$$

The equivalence relation is a relation (defined on a set) that has the property of being reflexive, symmetric, and transitive. Such a relation partitions a set into nonempty and disjoint subsets. The probability scheme attached to such

[a] In all cases the number of data points = 10.

decompositions of a set is, therefore, very much dependent on the nature of the equivalence relation. So, the information indices (IC, SIC, and CIC) of a chemical graph are not unique; rather the values of such indices are dependent on the mode of partition of the vertex set $\mathbf{X}(G)$ of the corresponding molecular graph G. In this paper we have computed IC, SIC, and CIC indices from the corresponding chemical graphs using an equivalence relation which is a slightly modified form of that used by Sarkar *et al.* (41). According to the equivalence relation used in this paper, two vertices of a chemical graph are said to be equivalent if they have similar edge multiplicity and the same number of first-order neighbors that have identical degrees (valence). If x represents an arbitrary element of the vertex set $\mathbf{X}(G)$ of a molecular graph G and r is a real number satisfying the relation $1 < r \leq 2$, then the open sphere $S(x,r)$ is given by:

$$S(x,r) = (x) \cup S_x^1 \qquad \text{(Eq. 7)}$$

where $S_x^1 = \{y \epsilon \mathbf{X}(G), d(x,y) = 1\}$ and (x) is the one-point set consisting of x only. If N be a set consisting of all such open spheres $S(x,r)$, where x runs over the whole set $\mathbf{X}(G)$, then N represents a collection of the first-order neighborhoods of all the vertices belonging to $\mathbf{X}(G)$.

Two vertices x and y of the vertex set $\mathbf{X}(G)$ will be called equivalent with respect to the first-order topological neighborhood if and only if:

1. $\mathbf{O}(S_x^1) = \mathbf{O}(S_y^1)$, where $\mathbf{O}(S_x^1)$ and $\mathbf{O}(S_y^1)$ represent the cardinalities of S_x^1 and S_y^1, respectively.
2. Corresponding to each element $x^i \epsilon S_x^1$ there exists an element $y^i \epsilon S_y^1$ such that $E[x,x^i] = E[y,y^i]$, where $E[x,x^i]$ denotes the number of edges connecting x and x^i, while $E[y,y^i]$ represents the number of edges of G connecting y and y^i; and
3. x^i and y^i have the same degrees (valence) for all i.

This theoretical scheme for the realization of the partition of atoms is exemplified along with the coordinate-attached structure of 2-propanol (Fig. 1A) and the calculation of its IC, SIC, and CIC indices (Table I) from the consideration of first-order topological neighborhood.

The Wiener number (W), proposed by Wiener (44), was the first topological index and represents the sum of all possible topological distances of a hydrogen-suppressed molecular graph. W can be conveniently calculated from the distance matrix $\mathbf{D}(G)$ of any graph G. It is a square $N \times N$ matrix, where N is the number of vertices in the hydrogen-depleted graph, the entries of the matrix being $d_{ij} = d_{ji}$, d_{ij} representing the number of bonds between vertices i and j by the shortest path. Table II shows the distance matrix of the labeled graph of 1-butanol (Fig. 1B). From the distance matrix, W is computed as:

$$W = \sum_{ij} d_{ij}/2 \qquad \text{(Eq. 8)}$$

The information indices from the distance matrix arise out of the statistical treatment of the topological distances of the chemical graph through the formalism of information theory (39). The index (I_D^w) is defined as:

$$I_D^w = W \cdot \log_2 W - \sum(k_d)(d \cdot \log_2 d) \qquad \text{(Eq. 9)}$$

where the distance d appears k_d times in the partition. The mean information index ($\bar{I}_D^w$) is calculated as:

$$\bar{I}_D^w = I_D^w / W \qquad \text{(Eq. 10)}$$

Statistical Analysis—Regression analysis was carried out according to the method of Nie *et al.* (45).

RESULTS AND DISCUSSION

Toxicity of Alcohols—The characteristic toxic action of aliphatic alcohols probably is narcosis (46). Veith *et al.* (47) reported that the aquatic toxicity (96 h LC_{50}) of alkanols in *Pimephales promelas* is highly correlated with log P (octanol-water) in terms of a bilinear model (48). However, Basak and Magnuson (19) showed that CIC can account for the toxicity of alcohols in a significant manner. It was of interest, therefore, to carry out a comparative study of log P *vis-à-vis* various structural parameters in the correlation of the LC_{50} of alcohols.

Table III shows the log LC_{50}, log P, IC, SIC, CIC, $^1\chi$, $^1\chi^v$, W, I_D^w, and $\bar{I}_D^w$ values for a series of 10 alkanols; the experimental log LC_{50} values were taken from Veith *et al.* (47). Table IIIa summarizes the results of the statistical analysis in an attempt to correlate log LC_{50} with log P and the different topological indices; r is the correlation coefficient, s the standard deviation, and F the F-ratio between the variances of observed and calculated values.

It appears from the results that a nonlinear fit shows significant improvement in the correlation coefficients as compared with the linear fits. The extent of fit of log LC_{50} values with log P and other structural parameters indicate that the topological indices (SIC, CIC, $^1\chi$, $^1\chi^v$, $\bar{I}_D^w$) are capable of explaining the properties of alcohols almost as efficiently as log P.

Analgesic Property of Ketobemidones—The opiate group of drugs is thought to bring about analgesia through the perturbation of certain types of specific receptors (49). The importance of lipophilicity for analgesic action is evident from the sharp decrease in the agonistic potency concomitant with quaterni-

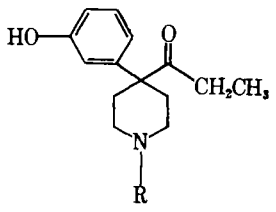
zation (50). It is proposed that hydrophobicity is critically important for the passage of opiates through the blood–brain barrier (51). In view of the fact that the mode of action for opiates is complicated by participation of various biogenic amine systems, different neuronal subpopulations, and multiple receptor types (52, 53), substituted ketobemidones (I) provide a convenient class of compounds for the study of the structure–activity relationships of opiates because the molecular manipulations within the group involve minimal alterations in the molecular electronic characteristics.



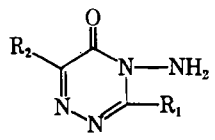
I

In an earlier study, Ray *et al.* (17) reported that SIC could correlate the analgesic potency (A-ED_{50}) of ketobemidones in mice. In view of the reportedly important role of lipophilicity in opiate pharmacology, we decided to study the relative efficacies of log P *vis-à-vis* other structural parameters in the correlation of the analgesic action of ketobemidones.

Table IV depicts the hot-plate analgesic potencies (A-ED_{50}) in mice, log P values, and the topological descriptors for a series of nine ketobemidones; the experimental A-ED_{50} values were taken from Wilson *et al.* (54). A look at the A-ED_{50} values indicates that there are two peaks of agonist activity in the series, namely when the side chain in the nitrogen atom is either methyl or amyl. Some of the higher homologues (hexyl, heptyl, and octyl) have measurable antagonist potencies (50), while the nonyl derivative has no analgesic property in the *in vivo* test. Under these circumstances we decided to delete the methyl and nonyl homologues of Table IV from the regression analysis. Table IVa represents the outcome of nonlinear regression analysis using log P as well as the topological indices. The linear correlations were not appreciable with any of the parameters. It is evident from the statistical analysis that the topological parameters IC, SIC, CIC, and $\bar{I}_D^w$ are superior to log P in the correlation of analgesic action while $^1\chi$ and $^1\chi^v$ appear to be as correlated as log P.

Herbicidal Action of Triazinones—Most herbicides are thought to exert their characteristic action through the blocking of the electron-transfer step in the oxygen-evolving photosynthesis process (55, 56). Therefore, in an attempt to design more effective herbicides, various authors have studied the effects of molecular manipulations on the Hill reaction inhibitory potencies of these compounds in isolated chloroplasts (55–59).

For a group of 1,2,4-triazinones, Hansch analysis revealed that lipophilicity (log P) alone was able to correlate the Hill reaction inhibitory potency (pI_{50}) in a significant manner (59). On the other hand, Ray *et al.* (17) reported that the information-theoretical topological index SIC could adequately account for the pI_{50} of triazinones. So it was deemed desirable to undertake a comparative study of log P and other theoretical parameters in the QSAR study of this class of herbicides.



II

The pI_{50}, log P, $^1\chi$, $^1\chi^v$, IC, SIC, CIC, W, I_D^w, and $\bar{I}_D^w$ values for a series of 11 triazinone derivatives (II) are presented in Table V; the log P and experimental pI_{50} values were taken from Draber *et al.* (59). Table Va reveals the outcome of statistical analysis in an attempt to correlate pI_{50} with log P and other descriptors. It is clear that all the parameters correlate significantly with experimental pI_{50} values. In all cases the parabolic relationship results in significant improvement in the fit with respect to the linear one. It is noteworthy that the theoretically derived indices IC, SIC, CIC, $^1\chi$, and $\bar{I}_D^w$ are almost as effective as log P in the correlation of pI_{50} values of the herbicides.

Narcotic Property of Barbiturates—Barbiturates are widely used in the treatment of several convulsive disorders (60). Although the precise mechanism of action of barbiturates is still not clear, attenuation of excitatory synaptic transmission (61, 62), potentiation of inhibitory synaptic transmission (61, 63), and blockage of electrically excitable membranes (64) are tentatively considered to be the causative factors behind the biological action of these compounds. Some recent studies, however, demonstrated the interaction of barbiturates with benzodiazepine receptors (65).

The high correlations of the physiological action of barbiturates with log P are the crucial factors for the assignment of a nonspecific mode of action to

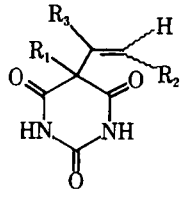
[a] Logarithm of the duration of anesthesia in hours after intraperitoneal injection at the AD_{100} dose level. [b] Logarithm of the induction time for anesthesia in minutes after intraperitoneal injection at the AD_{100} dose level.

this class of drugs (23, 66, 67). On the other hand, Kier and Hall (8) found the action of congeneric series of barbiturates to be well correlated with connectivity-type steric parameters. Raychaudhury *et al.* (68) reported significant linear correlations of the *in vivo* stability of barbiturates with IC and SIC indices. In a further study, Basak *et al.* (20) showed that steric parameters like V_w, CIC, $^1\chi^v$, and $\bar{I}_D^w$ are superior to log P in rationalizing the duration of physiological action of the barbiturate group of drugs. The above considerations necessitate a comparative study of lipophilic and steric parameters in the quantitative prediction of the phenomenology of barbiturate action.

To illustrate the relative efficacies of log P *vis-à-vis* topological descriptors in the analysis of the narcotic action of barbiturates, a QSAR study was carried out with three different groups of barbituric acid derivatives, where the structural variations in the side chains include elongation of the carbon skeleton, branching, and unsaturation. Table VI presents the duration of anesthesia (T in hours) and the logarithm of the induction time for anesthesia (t in minutes) after administration of the drugs at AD_{100} dose levels, log P, $^1\chi$, $^1\chi^v$, IC, SIC, CIC, W, I_D^w, and $\bar{I}_D^w$ values for a series of 14 barbiturates (III) with variously modified side chains. The experimental T and t values (determined after the intraperitoneal injection of the compounds to albino mice) were taken from Cope and Hancock (69), and the log P values were taken from Hansch (23).



III

Table VIa shows the correlations of log T values with lipophilicity and the theoretically computed descriptors. None of the parameters used show excellent correlations with the T values. However, $\bar{I}_D^w$, $^1\chi$, and CIC exhibit correlations comparable or superior to that with log P values. Table VIa depicts the correlation of the induction time for anesthesia (log t) with log P and other theoretical structural parameters. It is noteworthy that the correlations of log t

with I_D^w, $\bar{I}_D^w$, $^1\chi$, W, CIC, SIC, and IC are superior or comparable to that with log P (Table VIa).

Table VII summarizes the minimal anesthetic dose (MAD, log $1/c$) levels, log P, molecular connectivity, Wiener number, and the different information-theoretic indices for a series of 17 barbiturates (IV); the experimental MAD (log $1/c$) values were taken from Doran and Shoule (70). In an earlier study Hansch *et al.* (67) showed that log P correlates more or less satisfactorily with the experimental log $1/c$ values of this set of compounds. The results of regression analysis, depicted in Table VIIa, show that some of the topological descriptors (SIC, CIC, W, I_D^w, $\bar{I}_D^w$, $^1\chi$, and $^1\chi^v$) are superior to log P in the correlation of the anesthetic concentrations of this congeneric series of compounds.

Table VIII represents the anesthetic concentrations (AD_{50}, log $1/c$), log P,

[a] In each case, the number of data points = 13.

$^1\chi$, $^1\chi^v$, W, I_D^w, $\bar{I}_D^w$, IC, SIC, and CIC values) for a set of 13 barbiturates (V). The experimental log 1/c data were taken from the work of Cope *et al.* (71). The outcome of regression analysis indicates that log P and the various molecular descriptors correlate significantly with the AD_{50} values of this group of analogues (Table VIIIa). It is evident from the statistical analysis that IC, SIC, CIC, and $^1\chi$ are superior and I_D^w as well as $\bar{I}_D^w$ are slightly inferior to log P in accounting for the AD_{50} values of this group of barbiturates.

CONCLUSIONS

We have analyzed the relative roles of hydrophobicity (log P, octanol–water) *vis-à-vis* several topological parameters in the QSAR study of diverse sets of bioactive molecules that vary considerably with respect to chemical structure and physiological function. While alcohols and ketobemidones are simple homologous series, triazinones and barbiturates represent considerable structural diversity. At the biochemical level, alcohols and barbiturates are thought to be narcotic agents that act through nonspecific perturbation of cellular proteins or lipoprotein complexes (46, 47, 66, 72, 73). On the other hand, triazinones and ketobemidones act *via* specific mechanisms where well-defined biotargets are involved (54, 59). Yet it is interesting to note that certain graph theoretic invariants like CIC, $^1\chi$, $^1\chi^v$, W, and $\bar{I}_D^w$ could predict these dissimilar biological phenomena as efficiently as hydrophobicity.

From QSAR studies of different series of bioactive molecules, Hansch (23) pointed out that lipophilicity alone is sufficient to account for the action of

nonspecific bioactive molecules. On the other hand, stereoelectronic factors are deemed to be critical for molecules with specialized mechanism of action at the biochemical level (23, 74). However, the results of this paper indicate that topological steric parameters can correlate the action of both specific (triazinones and ketobemidones) and nonspecific (alcohol and barbiturates) bioactive agents. These findings could be rationalized in terms of the studies of Nemethy and Scheraga (75–77) where a "steric basis of hydrophobicity" is proposed on theoretical grounds. Alternatively, some recent studies highlight that certain so called "nonspecific" compounds may have specific physiological receptors (65, 78, 79) which could conceivably be sensitive to the steric factors associated with the effector molecule.

Finally, from the QSAR of these diverse series of bioactive molecules, the easily calculable molecular descriptors like CIC, $^1\chi$, $^1\chi^v$, W, and $\bar{I}_D^w$ appear to be as effective as log P in the rationalization of biological action. Of these five topological descriptors, only CIC and $\bar{I}_D^w$ are highly correlated with biological response for all six sets of compounds tested; accordingly, either CIC or $\bar{I}_D^w$ is the best single choice for a molecular descriptor.

Comparative Bioavailability of Two Furosemide Formulations in Humans

B. K. MARTIN *, M. UIHLEIN §, R. M. J. INGS ‡, L. A. STEVENS ‡, and J. McEWEN ‡x

Received September 8, 1980, from **BIOS (Consultancy and Contract Research) Ltd., Pinewood, College Ride, Bagshot, Surrey, GU19 5ER, England,* §*Pharma-Forschung, Hoechst AG, Postfach 80 03 20, D-6230 Frankfurt (Main) 80, West Germany, and* ‡*Hoechst UK, Walton Manor, Milton Keynes, Buckinghamshire, MK7-7AJ, England.* Accepted for publication February 10, 1983.

Abstract □ Twelve healthy male volunteers participated in a balanced crossover comparison of a brand-name and generic furosemide formulations. Each treatment was given as a single 40-mg tablet following an overnight fast. Furosemide concentrations in plasma and urine were determined up to 24 h after treatment; urine output and urinary sodium excretion were also measured. In comparison with the brand-name tablets, generic furosemide was significantly less bioavailable. Using a 95% confidence interval approach, generic furosemide gave up to 66% lower maximum furosemide plasma levels, up to 52% less area under the plasma level curve to infinite time, and up to 37% less urinary recovery of furosemide. Comparison of the effect of the two treatments was a less sensitive measurement of bioequivalence. Confidence intervals for differences in urinary output and sodium excretion over the period of maximum effect (0–4 h) were, however, asymmetrical, and pharmacodynamic differences between treatments were significant at the 10% level.

Keyphrases □ Furosemide—comparative bioavailability, brand-name and generic formulations, humans, plasma and urine □ Bioavailability—comparative, furosemide formulations in humans, plasma and urine □ Formulations—comparative bioavailability, brand-name and generic furosemide in humans, plasma and urine

During 1979, generic formulations of furosemide tablets which were not legally marketed became available to U.S. physicians. Shortly after these tablets were introduced, reports began to appear of diuretic ineffectiveness of some of the products. The Food and Drug Administration became aware of the problem and took steps to prevent further clinical use of unauthorized furosemide tablets (1).

With the above background in mind, it was felt that it would be useful to compare the relative bioavailability of the brand-name tablet formulation of furosemide available in the United States and one of the abovementioned generic furosemide tablets. This paper presents the results of a crossover study in healthy volunteers with comparative pharmacokinetic and pharmacodynamic measurements.

EXPERIMENTAL

Subjects—Twelve healthy male volunteers aged 18–42 years, within 10% of ideal body weight, received treatment on two occasions with 1-week between doses. A comprehensive checkup, including clinical examination, clinical chemistry/hematology evaluation, and urinalysis revealed no evidence of cardiac, respiratory, hepatic, or renal disease. The project was subject to ethics review, and each subject gave his signed informed consent.

Treatment—Furosemide (40 mg) was administered as a single tablet on two occasions 1 week apart to each subject, according to a balanced crossover design. Treatments were designated product I[1] and product II[2] respectively. Product I (the brand-name tablet) contained an average of 39.6 mg of furosemide/tablet; product II (the generic tablet) contained an average of 40.3 mg of furosemide/tablet. Therapy was given by mouth with 100 mL of water following an overnight fast, 1 h before a standard tea/toast breakfast. Oral fluid supplements (150 mL of water) were given at 1, 2, 3, 4, and 6 h after treatment.

Collection of Samples—Blood samples were taken by direct venipuncture at 0, 0.5, 1, 1.5 2, 2.5, 3, 4, 5, 6, 7, 8, 10, and 24 h and placed in heparinized tubes[3]. Following centrifugation, the plasma were stored in the deep-freeze until analyzed. A predose 24-h urine collection was made; after treatment complete urine samples were collected over the intervals of 0–1, 1–2, 2–3, 3–4, 4–6, 6–8, 8–10, and 10–24 h. The volume of each sample was recorded; aliquots were stored in the deep-freeze for electrolyte and drug assay. Urinary sodium was measured by flame photometry.

Furosemide Assay—Furosemide concentrations in plasma and urine were fluorometrically determined following HPLC separation. Urine was directly chromatographed after centrifugation. Following an initial 5-mL ether extraction of 0.25 mL of plasma plus 0.25 mL of phosphate buffer (pH 7.0) (with the ether layer discarded), the plasma was acidified with 50 μL of 5 M HCl and furosemide was extracted into 5 mL of ether. The ether layer was separated and evaporated under nitrogen; the residue was taken up with 0.1 mL of pH 7.0 phosphate buffer. An internal standard (100 ng of the phenyl analogue of furosemide) was simultaneously taken through the plasma procedure.

The chromatographic apparatus consisted of an automatic sampler[4], a solvent delivery pump[5], and a fluorometric detector with automatic overload reset[6]. The extracts were separated on a 12-cm × 4.3-mm column packed with 5-μm reverse-phase irregular organically modified silica[7]. The eluant was methanol–0.1 M H_3PO_4 (53:47). The excitation wavelength was 233 nm, and the emission wavelength was 370 nm (sharp-cut filter, with additional blue filter[8]).

The method was found to be linear over the concentration ranges of 10–1000 ng/mL for plasma and 0.5–10 μg/mL for urine. Assay precision for the plasma method was ± (7.7 + 0.039 C_p) ng/mL, where C_p is the plasma concentration; for urine, precision was ± (0.5 + 0.013 C_u) μg/mL, where C_u is urine concentration.

Pharmacokinetic Analysis—Initial estimates of furosemide elimination half-lives were calculated, using urinary data, by linear regression analysis of the logarithm of rate of urinary furosemide excretion against time (2). These estimates were employed as the starting values in an iterative least-squares curve-fitting program developed for a minicomputer[9], which generated a series of fitted coefficients and exponential constants. Most profiles fitted a model

with two elimination phases following absorption. The half-lives were calculated from each declining exponential term; the areas under the plasma level time curve to 10 h ($AUC_{0\ 10\ h}$) and to infinite time ($AUC_{0\ \infty}$) for each subject were calculated from the fitted equation by integration. Maximum plasma concentration (C_{max}) and time to maximum concentration (t_{max}) were taken directly from the observed data.

Statistical Analysis—Analysis of variance (ANOVA) was used to test for significant subject, treatment, or week differences (3) for each pharmacokinetic or pharmacodynamic parameter. Missing data were estimated using Yates' method (4). Before analysis, a normality test was carried out (5). If necessary, the results were logarithmically transformed to normalize the distribution of data and to stabilize the variance. The 95% confidence limits of Shirley (6) were applied to the mean treatment differences for each parameter. This gave a measure of precision and established whether the limits were symmetrical about a mean distribution of zero. The results for generic furosemide (product II) were expressed as a percentage of those for brand-name furosemide (product I).

The split-plot analysis of Westlake (7) was also used. This examined the data in two ways: (*a*) giving a measurement of quantitative differences in overall mean plasma concentrations for each treatment, and (*b*) giving an evaluation of the relative shapes of the plasma concentration-time profiles of the two treatments.

RESULTS

Table I shows the individual plasma levels of furosemide associated with each treatment. Mean plasma concentration with time is plotted in Fig. 1. Table II shows the amount of furosemide in each urine collection. The results of pharmacokinetic curve-fitting appear in Table III. Table IV gives the individual urine volumes, and Table V gives the individual urinary sodium data. The key pharmacokinetic and pharmacodynamic results are summarized in Table VI, and a summary of statistical analyses with 95% confidence limits is shown in Table VII.

Pharmacokinetics—For one individual (subject 9) following product II, the curve-fit was unacceptable (Table III, $r = 0.851$). In this case, derived pharmacokinetic values ($t_{1/2}$ and AUC terms) were estimated by Yates' method (5).

Following product I administration, the mean maximum plasma furosemide concentration (C_{max}) was 1658 ng/mL (range 550–2950 ng/mL). Following product II administration, the values were significantly lower ($p < 0.01$) with a mean C_{max} of 947 ng/mL (range 210–1800 ng/mL). There was no significant difference in time to maximum concentration (t_{max}), although there was a trend toward later values following product II treatment (*i.e.*, an asymmetrical confidence limit).

The overall bioavailability judged from AUC values followed the same trend as that shown by C_{max}, with a highly significant ($p < 0.01$) difference between treatments in values both to 10 h and to infinite time. Product I gave a mean $AUC_{0-\infty}$ of 3066 ng·h/mL (range 1362–5223 ng·h/mL), whereas product II gave a mean $AUC_{0-\infty}$ of 2098 ng·h/mL (range 891–3252 ng·h/mL). Figure 2 shows the individual $AUC_{0-\infty}$ values diagrammatically, and illustrates that despite some interindividual variability in plasma level profiles, subjects tended to keep a similar rank order of bioavailability following each preparation of furosemide.

Urinary elimination of unchanged furosemide accounted for between 17–50% of the administered dose. Again, a significant difference ($p = 0.02$) was observed between formulations in respect of the cumulative 0-24-h urinary furosemide, with product I giving a mean value of 13.6 mg (range 8.0–19.6 mg) and product II giving a mean value of 10.8 mg (range 4.9–17.0 mg).

Split-plot analysis showed highly significant ($p < 0.01$) differences between formulations both in the overall mean plasma values and in the treatment–time shape of the curves.

Pharmacodynamics—The missing values in the urinary tables reflect the fact that not all subjects were able to micturate on demand. Prior to statistical evaluation of pharmacodynamic data, estimates of the "missing" values were made by assuming that the urine eventually collected was actually produced at a constant rate over both "observed" and "missing" time periods.

The pharmacodynamic measurements presented for analysis in Tables VI and VII are those from the 0–4- and 0–24-h urine collection periods; the former covered the period of maximum diuresis (Tables IV and V) and was considered to be the most appropriate measure of meaningful pharmacodynamic effect. The mean 0–4-h urine volume following product I was 1460 mL (range 771–2010 mL); the equivalent mean result for product II was 1231 mL (range 590–2082 mL). The mean 0–4-h urine sodium output following product I was 181 mmol (range 95–296 mmol), and the mean 0–4-h urine sodium output following generic furosemide was 150 mmol (range 62–288 mmol). Most subjects showed less diuresis following product II; however, for the 0–4-h urine volume this trend was clearly reversed in subjects 9 and 10. With respect to urinary sodium, subject 10 again reversed the general trend toward diminished natriuresis following product II; subject 9 showed little difference between treatments in this respect.

Statistical analysis of these pharmacodynamic results (Table VII), in contrast with the corresponding analysis of pharmacokinetic data, did not show any significant differences between the effects of the two furosemide preparations. However, the 95% confidence intervals, especially for 0–4-h data, were asymmetrical with product II giving between −33% and 2% ($p = 0.07$) of the 0–4-h urine output of product I and between −38% and 4% ($p = 0.08$) of the 0–4-h sodium output of product I, reflecting the general trend for the generic formulation to show a diminished effect.

DISCUSSION

This study has shown statistically significant differences in the bioavailability of two furosemide formulations, the generic tablet giving up to 66% lower C_{max} values, up to 52% lower $AUC_{0-\infty}$ values, and up to 37% less urinary elimination of furosemide over 24 h. Although not statistically significant, there was also a trend toward later t_{max} values following the generic treatment. However, simultaneous analysis of drug effect did not give correspondingly significant differences in urine output and sodium excretion. Nevertheless,

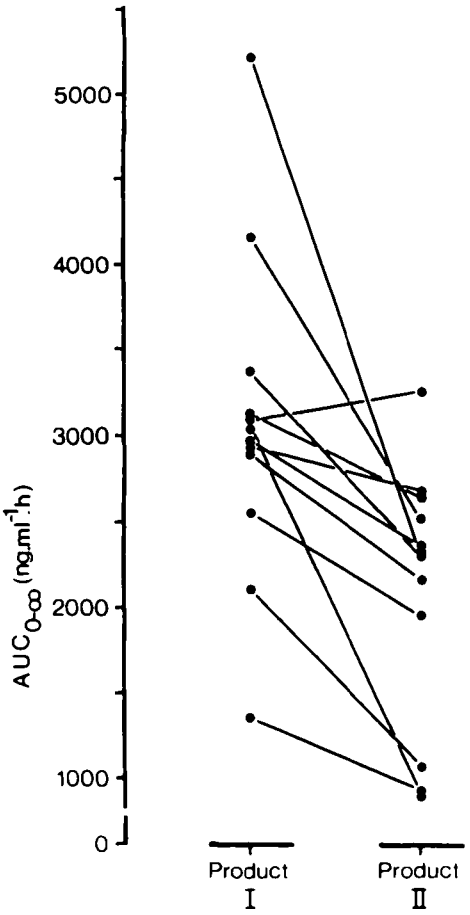

Figure 2—*Comparative bioavailability of the two furosemide formulations.*

pharmacodynamic differences between formulations over 0–4-h collection periods were significant at the 10% level, and the 95% confidence intervals were clearly asymmetrical; therefore, biological equivalence of these two formulations cannot be assumed.

The analysis of pharmacodynamic effects has concentrated on 0–4-h data rather than the complete collection interval of the experiment, since following acute diuresis and natriuresis in normal subjects, homeostatic mechanisms can result in compensatory "rebound" conservation of salt and water by 24 h. This tendency is shown by the diminished significance of 0–24-h statistical analysis in comparison with that for 0–4 h, especially with respect to urinary sodium excretion. The inherent logarithmic shape of the classical dose–response curve in pharmacology makes any pharmacodynamic measurement a less sensitive measure of formulation differences, since a given percentage change in drug concentration will give a smaller percentage change in drug effect: a linear change on the latter scale corresponds to a logarithmic change on the former scale.

This study supports the clinical observations of diuretic ineffectiveness which led to the withdrawal of this generic furosemide product. Since it has been reported that the absorption of furosemide is impaired in the presence of edema (8), it is possible that unequivalent furosemide formulations may show proportionately greater pharmacokinetic and pharmacodynamic differences in patients with cardiac failure than in normal subjects.

Kelly *et al.* (9) have previously shown that the bioavailability of brand-name furosemide tablets was similar to that of an aqueous solution. A comparative bioavailability study from Sweden (10) which included pharmacokinetic and pharmacodynamic observations revealed no significant differences between brand-name furosemide tablets and a generic tablet; however, a study from Israel (11) demonstrated statistically significant pharmacokinetic and pharmacodynamic differences between two other furosemide products. A preliminary observation from investigators in New Zealand (12) suggested that there may be clinically important differences in the response to brand-name and generic furosemide tablets, although a later more formal study (13) reported that the two furosemide products in question were in fact bioequivalent. However, it should be noted that this last study consisted only of urinary pharmacodynamic measurements, and our present investigation has shown that this may not be a sufficiently sensitive technique. Investigators in Australia (14) reported bioequivalence of yet another generic furosemide product basing their conclusions on measurements of urine volume and urine electrolytes.

Table VII—Summary of Statistical Results

Parameter	Overall Differences (ANOVA)[a] Subject Treatment Week 1	2	3	95% Confidence Interval (Generic as % of Standard)
C_{max}	NS	**	NS	−66% to −21%
t_{max}	NS	NS	NS	− 8% to +82%
$t_{1/2\alpha}$	NS	NS	NS	−18% to +21%
$t_{1/2\beta}$	NS	NS	•	−24% to +37%
$AUC_{0-10\ h}$	*	**	NS	−50% to −14%
$AUC_{0-\infty}$	•	**	NS	−52% to −15%
0–24 h urinary furosemide	NS	*	NS	−37% to − 5%
Urine volume				
0–4 h	NS	NS	NS	−33% to + 2%
0–24 h	NS	NS	NS	−15% to + 2%
Sodium output				
0–4 h	*	NS	NS	−38% to + 4%
0–24 h	**	NS	*	−19% to +10%

[a] Key: (NS) = not significant; (*) = significant at the 5% level; (**) = significant at the 1% level.

Furosemide can be used in clinical circumstances where a prompt diuresis is essential. While it is clear from the above discussion that some generic formulations are equivalent to brand-name tablets, it is also evident that other products may not be adequate. Alternative furosemide formulations should be carefully evaluated, preferably by means of full pharmacokinetic and pharmacodynamic investigations in humans.

In the absence of greater detail, it is difficult to comment on any pharmaceutical factors which may have contributed to inequivalence of these furosemide formulations. However, calcium and phosphate were detected in product II and not in product I following the application of standard National Formulary methods[10]. Residue analysis also showed differences in the amounts of inorganic excipients (4% for product I and 37% for product II)[10]. These observations appear to be in keeping with the findings of Rubinstein (15) who reported that the bioavailability of experimental batches of furosemide was considerably influenced by the choice of excipient. He also found a poor correlation between dissolution rate and drug bioavailability.

pK_a Determination of Verapamil by Liquid–Liquid Partition

JIRO HASEGAWA *x, TAKESHI FUJITA *, YAYOI HAYASHI ‡, KIKUO IWAMOTO ‡, and JUN WATANABE ‡

Received August 13, 1982, from the *Department of Drug Metabolism and Biopharmaceutics, Eisai Co. Ltd., 6-10, Koishikawa 4-chome, Bunkyo-ku, Tokyo 112, Japan and the ‡ Department of Biopharmaceutics, Faculty of Pharmaceutical Sciences, Nagoya City University, Mizuho-ku, Nagoya 467, Japan. Accepted for publication January 10, 1983.

Abstract □ The pK_a of verapamil was determined by measuring the partition coefficient of verapamil between *n*-heptane and aqueous buffer solution at various pH values. The magnitude of the effects of ionic strength or temperature on the pK_a of verapamil was in agreement with those reported previously. The estimated pK_a of verapamil in human plasma was 8.75. The pK_a of 2,4,6-trimethylpyridine measured by means of the present partition method was in good agreement with that determined by UV spectrophotometry.

Keyphrases □ Verapamil—pK_a determination, liquid–liquid partition coefficients, effects of ionic strength and temperature □ Partition coefficients—liquid–liquid, use in determining the pK_a of verapamil, effects of ionic strength and temperature □ Dissociation constants—verapamil, determination using liquid–liquid partition coefficients, effects of ionic strength and temperature

Verapamil, an effective antiarrhythmic agent, exerts its effect through selective inhibition of slow inward transport of calcium across cell membranes. Although the drug was first introduced in 1962 in Germany, no report on the pK_a value of verapamil, a weakly basic compound, has yet appeared. We required this information to analyze our results on the mechanism of salivary excretion of verapamil in humans and dogs.

Potentiometric or UV spectrophotometric methods are generally most useful for the accurate and reproducible determination of aqueous dissociation constants of organic compounds. However, these methods are not applicable for the determination of the pK_a of verapamil because the drug is insufficiently soluble in aqueous media to give a reliable titration curve and also because of the lack of a significant pH-dependent change in the absorption spectra. Several alternative methods exist for the determination of pK_a values of such compounds (1). For instance, mixed aqueous solvents can be used for the titration of sparingly soluble compounds.

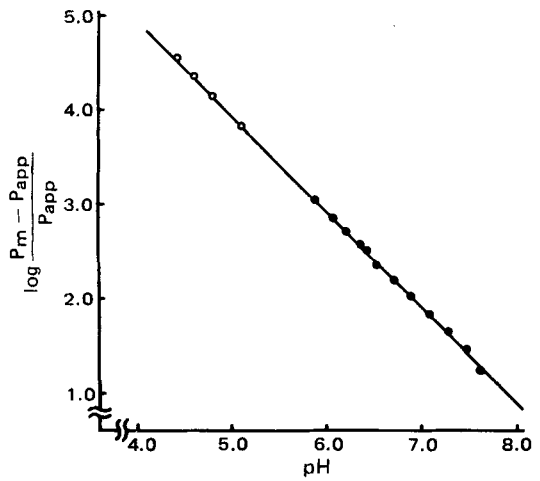

Figure 1—*Plot of log* $[(P_m - P_{app})/P_{app}]$ versus *pH. Initial concentration of verapamil in* n*-heptane, 0.003 M; ionic strength, 0.0315; temperature, 25°C. Key: (○) in phosphate buffer; (●) in acetate buffer.*

However, there is no completely satisfactory method for converting the results to the aqueous pK_a scale (2). The solubility (3, 4) and modified titration (5) methods are also unsuitable for verapamil, since it is difficult to determine the aqueous solubility of the un-ionized form of the compound with sufficient accuracy because of the extremely low solubility.

In the present study, we attempted to determine the pK_a of verapamil by a partition method based on measurement of the partition coefficient between water and an immiscible organic solvent at various pH values of the aqueous phase. Although this method was first proposed several decades ago (6, 7), it has not been generally recognized as a useful method for the pK_a determination of sparingly soluble compounds. Recently, Ezumi and Kubota extended this method to determine pK_a values of weak organic bifunctional acids and bases (8), but their proposed equation cannot be applied to the pK_a determination of verapamil because of the extremely high partition coefficient of this drug. To test the general applicability of the partition method, the effects of organic solvent, ionic strength, temperature, and concentration of verapamil on the pK_a value of verapamil were also studied. Furthermore, to confirm the validity of this method, the pK_a value of 2,4,6-trimethylpyridine was measured by means of both the partition and the UV spectrophotometric methods.

EXPERIMENTAL

Materials—Verapamil hydrochloride[1] and 2,4,6-trimethylpyridine were used as received. Organic solutions of the free base of verapamil or 2,4,6-trimethylpyridine were prepared by extracting alkaline solutions of these compounds (pH 11.0) with the appropriate organic solvent, followed by adjustment of the volume to 100 mL. *n*-Heptane[2], *n*-hexane[2], and carbon tetrachloride[2] were of spectroscopic grade, and other reagents[3] were of analytical grade.

Equipment—The pH values of aqueous buffer solutions were measured with a pH meter[4] with an accuracy of 0.01 pH unit. UV absorption measurements relevant to the determination of partition coefficients and the pK_a determination of 2,4,6-trimethylpyridine by the UV method were made using a spectrophotometer[5]. A spectrofluorophotometer[6] was used for the determination of verapamil in the low concentration range.

Determination of Partition Coefficient—Five milliliters of organic solvent containing verapamil or 2,4,6-trimethylpyridine and 5 mL of phosphate buffer or sodium hydroxide solution were added to a screw-capped vial and incubated for 2 h in a temperature-controlled incubator (±0.1°C) with occasional vigorous shaking by hand. The tube was centrifuged for 5 min at 3000 rpm, then immersed in the incubator again and allowed to stand for 30 min. Aliquots of both phases were withdrawn and subjected to analyses, and the pH of the aqueous phase was measured immediately.

Analytical Procedure—For verapamil, the concentration in the aqueous phase was determined either spectrophotometrically (λ_{max} = 277 nm) or spectrofluorophotometrically (excitation at 275 nm, emission at 339 nm) after appropriate dilution of the solution with 0.5 M HCl depending on the con-

Table II—Effect of Ion Species on P_m [a]

Salt[b]	pH[c]	P_m[d]
KCl	11.90	434 ± 21
NaCl	11.95	467 ± 6
Na_2SO_4	11.92	426 ± 6

[a] Organic solvent, *n*-heptane; initial concentration of verapamil in *n*-heptane, 0.001 M; temperature, 25°C. [b] Ionic strength was adjusted to 0.03 with the indicated salt. [c] Concentration of sodium hydroxide was 0.01 M. [d] Mean ± *SD* of three experiments.

centration of verapamil present. The organic phase was evaporated to dryness under a nitrogen stream at 40°C, and the residue was dissolved in 0.1 M HCl for spectrophotometric measurement. For 2,4,6-trimethylpyridine, concentrations in the aqueous and *n*-heptane phases were determined spectrophotometrically (λ_{max} = 266 nm and 263 nm, respectively) after appropriate dilution with 0.5 M HCl and *n*-heptane, respectively.

Preparation of Buffer Solution—All buffer solutions were prepared using monobasic potassium phosphate and dibasic sodium phosphate. The ionic strength of the aqueous phase after the partition experiment was calculated by means of the following:

$$I = \frac{1}{2}\left\{\frac{4[P]}{1 + 10^{7.21\text{-pH}}} + [P]\left(1 - \frac{1}{1 + 10^{7.21\text{-pH}}}\right) + [K] + [Na] + [V]\frac{1}{1 + P_{app}}\right\} \quad \text{(Eq. 1)}$$

where I is the ionic strength of the aqueous phase; [P], [V], [K], and [Na] are the molar concentrations of total phosphate, verapamil, potassium, and sodium, respectively; and P_{app} is the apparent partition coefficient of verapamil. The calculated ionic strength in the aqueous phase after partition varied appreciably with pH because of the differences in the concentration of verapamil in the aqueous solution. However, since deviations in ionic strength of this magnitude were estimated to change the pK_a value by no more than 0.01 pK_a unit, the variation of ionic strength with pH was disregarded and the ionic strength was expressed as the mean value.

Calculation of pK_a from Apparent Partition Coefficient—During partitioning of a weak base between organic and aqueous phases, the distribution of each species can be described by Scheme I: where, K_a and K_a' are the stoichiometric ionization constants of BH^+ in the aqueous and organic phases, respectively; P_m and P_i are the partition coefficients of un-ionized and ionized molecules, respectively; $[B]_o$ and $[B]_w$ are the molar concentrations of un-ionized molecules in the organic and aqueous phases, respectively; and $[BH^+]_o$ and $[BH^+]_w$ are the molar concentrations of ionized molecules in the organic and aqueous phases, respectively.

If the concentration of the ionized molecule is far less than that of the un-ionized molecule in the organic phase, that is $[BH^+]_o \ll [B]_o$, the apparent partition coefficient can be expressed by:

$$P_{app} = \frac{[B]_o}{[B]_w + [BH^+]_w} \quad \text{(Eq. 2)}$$

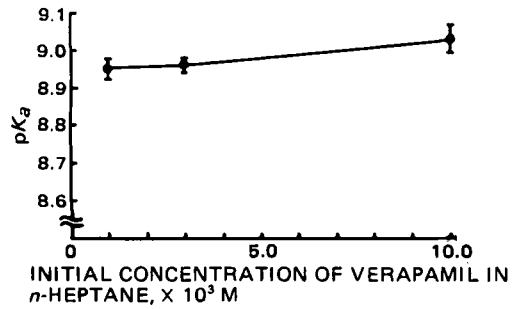

Figure 2—*Effect of concentration of verapamil on* pK_a. *Each point represents the mean* ± SD *of 10 experiments. Ionic strength, 0.1050–0.1005; temperature, 25°C.*

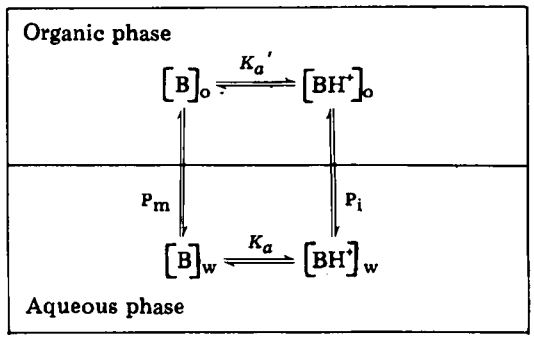

Scheme I

From the definition:

$$P_m = \frac{[B]_o}{[B]_w} \quad \text{(Eq. 3)}$$

$$K_a = \frac{[B]_w[H^+]}{[BH^+]_w} \quad \text{(Eq. 4)}$$

$$pK_a = pH + \log\frac{[BH^+]_w}{[B]_w} \quad \text{(Eq. 5)}$$

From Eqs. 2, 3, and 5:

$$pK_a = \log\frac{P_m - P_{app}}{P_{app}} + pH \quad \text{(Eq. 6)}$$

Equation 6 can be rearranged to:

$$P_{app} = P_m - \frac{1}{K_a}[H^+]\,P_{app} \quad \text{(Eq. 7)}$$

By plotting P_{app} *versus* $[H^+]\,P_{app}$, K_a, and P_m can be obtained simultaneously from the slope and the intercept of the plot, respectively. However, for a compound with a large P_m value, such as verapamil, this plot gives inaccurate results. Instead, by measuring P_m at a pH which is higher than the pK_a value of the compound by 2.0 pH units and P_{app} at a pH where the P_{app} value is ~1.0, the pK_a value can be calculated from Eq. 6.

Measurement of pK_a of 2,4,6-Trimethylpyridine by UV Spectrophotometry—The UV absorbances of 1×10^{-4} M 2,4,6-trimethylpyridine in phosphate buffer (from pH 6.98 to pH 7.57, I = 0.03), and in 0.1 M HCl and 0.1 M NaOH were measured at 266 nm and at 25°C. The pK_a value was calculated by using:

$$pK_a = pH + \log\frac{d - d_M}{d_I - d} \quad \text{(Eq. 8)}$$

where d, d_I, and d_M are the absorbances in buffer solution, 0.1 M HCl solution (where 2,4,6-trimethylpyridine exists predominantly as the ionized form), and 0.1 M NaOH solution (where it exists predominantly as the un-ionized form), respectively.

RESULTS AND DISCUSSION

Estimation of P_m—The present method inherently requires the measurement of the P_m value. Since the ion composition of the solution used for the measurement of P_m is inevitably different from that of the buffer solution used for the measurement of P_{app}, it is necessary to estimate the effect of ion species on the P_m value. As shown in Tables I and II, the observed P_m values change appreciably with change of pH or of the kind of neutral salts added to the solution. This discrepancy in P_m value results in a variation in the calculated

Table III—Effect of Organic Solvents on pK_a [a]

7.28	0.634	7.49
7.38	0.610	7.48
7.48	0.592	7.51
7.57	0.574	7.51
Mean ± *SD*		7.50 ± 0.01
0.1 M HCl	0.788	
0.1 M KOH	0.384	

[a] Concentration of 2,4,6-trimethylpyridine, 1×10^{-4} M; ionic strength, 0.03; temperature, 25°C. [b] Absorbance was measured at 266 nm. [c] $pK_a = pH + \log (d - d_M)/(d_I - d)$, where d, d_I, and d_M are the absorbances in solutions of the indicated pH, in 0.1 M HCl, and in 0.1 M KOH, respectively.

pK_a of up to 0.03 pK_a unit depending on the salt used; this possible deviation of the pK_a values obtained by the present method must be borne in mind. P_m measurements in the following experiments were carried out in 0.01 M NaOH solution whose ionic strength had been adjusted to 0.03 with sodium chloride.

Validity of Equation 6—To test the validity of Eq. 6 for the pK_a determination of verapamil, the apparent partition coefficients of verapamil between *n*-heptane and aqueous buffer solution at pH from 4.42 to 7.64 were obtained. The resultant log $[(P_m - P_{app})/P_{app}]$ *versus* pH plot was linear with a slope of −1.016 (r = 0.9999) (Fig. 1). This means that Eq. 6 is applicable to the calculation of pK_a from partition coefficients obtained under the proposed experimental conditions. There should be no appreciable effect of buffer composition on the resultant pK_a value, since the results obtained in acetate and phosphate buffers as the aqueous phase are essentially on the same regression line.

Effect of Verapamil Concentration—To determine the effect of verapamil concentration, pK_a values were measured at three different initial verapamil concentrations. As shown in Fig. 2, the obtained pK_a values increased slightly with increase of the verapamil concentration; in particular, the results at 0.01 M gave a significantly higher pK_a value than those at the lower concentrations.

One possible reason for this finding might be the self-association of verapamil in the solution, although extensive studies would be necessary to elucidate the actual reason. At the initial concentrations of 0.001 and 0.003 M, the obtained pK_a values were 8.95 and 8.96, respectively. These values are essentially identical, especially when the experimental error is taken into account. In the following experiment, the initial concentration of verapamil in *n*-heptane was fixed at 0.003 M.

Effect of Organic Solvent—If the theories and assumptions in the proposed method are valid, the pK_a values obtained by this method should be independent of the kind of organic solvent used for the determination of the partition coefficient. One possible source of error in determining the true pK_a value would be partial miscibility of the organic solvent with the aqueous phase during the partition experiment, which might interfere with the dissociation reaction in the aqueous phase. To minimize the extent of contamination of the aqueous phase with the organic solvent, paraffinic hydrocarbons were chosen as organic solvents for the partition experiment in view of their low water solubility. The pK_a values obtained with various organic solvents are presented in Table III. Three highly nonpolar solvents gave comparable pK_a values (*n*-heptane, 8.92; *n*-hexane, 8.89; and *n*-pentane, 8.93) even though they differ in water solubility by a factor of four (9, 10).

On the other hand, carbon tetrachloride gave a fairly low pK_a value compared with those obtained with paraffins. This result is consistent with those reported by Irving and Bell (7), who showed that the pK_a value of dithizone as determined by the partition method using carbon tetrachloride was smaller than that determined using cyclohexane by 0.4 pK_a unit. *n*-Heptane was chosen in the following experiments to minimize organic solvent contamination in the aqueous layer as well as to minimize evaporation, which may lead to volume loss of the organic phase during the partition experiment.

Table V—pK_a Values of 2,4,6-Trimethylpyridine Determined by the Partition Method

pH	P_{app}[a]	pK_a
5.88	0.276	7.53
6.08	0.433	7.53
6.20	0.579	7.51
6.38	0.835	7.53
6.42	0.929	7.52
6.55	1.165	7.54
6.71	1.718	7.51
Mean ± *SD*		7.52 ± 0.01
0.01 M NaOH	12.5[b]	

[a] Initial concentration of 2,4,6-trimethylpyridine in *n*-heptane, 0.003 M; ionic strength, 0.0315; temperature, 25°C. [b] Mean ± *SD* of three experiments.

Table VI—Temperature Dependency of pK_a^T of Verapamil

Temp.	Observed pK_a[a]	pK_a^T	
25°C	8.92[b]	8.84[c]	
31°C	8.79	8.71[c]	8.73[d]
37°C	8.68	8.60[c]	8.61[d]

[a] Initial concentration of verapamil in *n*-heptane, 0.003 M. [b] Mean of three experiments carried out on different days. [c] Calculated using Eq. 10 and the observed pK_a. [d] Calculated by the method of Albert and Sergent (14).

Comparison of the Partition Method with the UV Spectrophotometric Method—To confirm the reliability of the partition method, the pK_a value of 2,4,6-trimethylpyridine was determined by means of both the partition and UV spectrophotometric methods. As shown in Tables IV and V, the results obtained by the two methods were almost identical (7.52 and 7.50, respectively); the thermodynamic pK_a value (pK_a^T), calculated by subtracting the value of $-\log \gamma^{\pm}$ (*cf.*, Eq. 10) from the mean pK_a value to correct for the activity coefficient of the aqueous solvent, was 7.43, identical with the reported value (11). This result strongly supports the reliability of this method.

Effect of Ionic Strength—Methods to correct for ionic strength and obtain the pK_a^T value are well documented (1, 2). One method is to subtract the following log $\gamma^{\pm}$ value from the experimentally determined pK_a value:

$$-\log \gamma^{\pm} = \frac{AZ^+Z^-\sqrt{I}}{1 + Ba_i\sqrt{I}} \qquad \text{(Eq. 9)}$$

where I is the ionic strength of the solvent, $\gamma^{\pm}$ is the ionic activity coefficient, A and B are constants dependent on the dielectric constant of the solvent and the temperature, Z^+ and Z^- are the charge of the ion ($Z^+ = Z^- = 1$ for verapamil), and a_i is the ion size parameter. Since a_i for most electrolytes used in this experiment is equal to $3\text{–}4.5 \times 10^{-8}$ (12) and B changes only from 0.330×10^8 to 0.333×10^8 with the change of temperature from 25°C to 40°C, Eq. 9 can be simplified (13)[7]:

$$-\log \gamma^{\pm} = \frac{A\sqrt{I}}{1 + \sqrt{I}} \qquad \text{(Eq. 10)}$$

An alternative method is to determine pK_a at several different ionic strengths and then to plot pK_a *versus* $\sqrt{I}/(1 + \sqrt{I})$ and extrapolate the plot to infinite dilution (2). Figure 3 is the obtained pK_a *versus* $\sqrt{I}/(1 + \sqrt{I})$ plot for verapamil at 25°C. The intercept was 8.85 and is very close to the calculated value obtained from Eq. 10 (8.84). Although accurate and theoretically sound, this method is tedious. Therefore, since the two methods gave almost identical pK_a^T values at 25°C, Eq. 10 seems to be satisfactory for the determination of the pK_a^T of verapamil.

Temperature Dependency of pK_a^T—Determination of the pK_a is usually performed at 25°C. However, to interpret the absorption, distribution, metabolism, and excretion of drugs in terms of pK_a, one must obtain the pK_a value at 37°C experimentally or by calculation. Several equations have been proposed to express the variation of pK_a with temperature (1). Albert and Sergent proposed a temperature coefficient of pK_a of organic nitrogenous bases in the range of 0–40°C (14), but it is generally recognized that compounds vary somewhat in the sensitivity of their acidity constants to temperature changes. Therefore, the pK_a^T values of verapamil of 25°C, 31°C, and

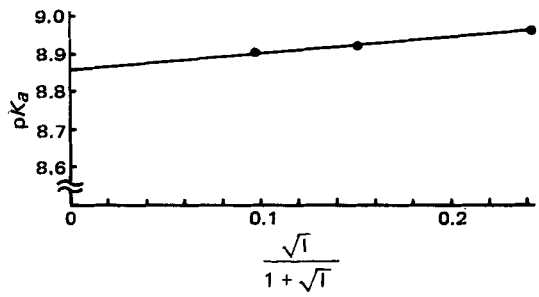

Figure 3—*Plot of* pK_a versus $\sqrt{I}/(1 + \sqrt{I})$. *Initial concentration of verapamil in organic solvent, 0.003 M; temperature, 25°C.*

[7] A = 0.488 at 0°C, 0.500 at 15°C, 0.509 at 25°C, 0.524 at 45°C.

Table VII—pK_a of Verapamil Under Various Conditions

Temp.	pK_a[a]				
	I = 0.00	I = 0.01	I = 0.03	I = 0.05	I = 0.10
5°C	9.28	9.32	9.35	9.37	9.40
10°C	9.16	9.21	9.23	9.25	9.28
15°C	9.05	9.10	9.12	9.14	9.17
20°C	8.94	8.99	9.01	9.03	9.06
25°C	8.84	8.89	8.92	8.93	8.96
30°C	8.74	8.79	8.82	8.83	8.86
37°C	8.60	8.65	8.68	8.70	8.73

[a] These values were calculated using Eqs. 10 and 12.

37°C were calculated, using Eq. 10, from the experimentally determined pK_a values at these temperatures. Experimentally obtained pK_a and pK_a^T values as well as pK_a^T values estimated using the temperature coefficients reported by Albert and Sergent are shown in Table VI.

Since the pK_a^T values calculated by the method of Albert and Sergent were close to the experimentally obtained values, their method seems to be applicable for the rough estimation of the pK_a^T of verapamil at various temperatures. On the other hand, the variation of pK_a^T with temperature can be expressed by (1):

$$pK_a^T = \frac{\Delta H^\circ}{2.303RT} - \frac{\Delta S^\circ}{2.303R} \qquad \text{(Eq. 11)}$$

where ΔH° is the enthalpy change under standard conditions, ΔS° is the entropy change under standard conditions, R is the gas constant, and T is the absolute temperature. As shown in Fig. 4, a plot of experimentally obtained pK_a^T values *versus* $1/T$ gave a straight line and could be expressed by Eq. 12. The pK_a^T values at arbitrary temperatures can be calculated by using:

$$pK_a^T = 1.833 \times 1/T \times 10^3 + 2.696 \qquad \text{(Eq. 12)}$$

CONCLUSIONS

The pK_a values of verapamil at various temperatures and ionic strengths can be estimated by means of Eqs. 10 and 12. The resultant values are presented in Table VII. On the assumption that sodium chloride is the main ionized component in plasma, the pK_a of verapamil in human plasma at 37°C can be calculated to be ~8.75.

Subject to the following restrictions, the present method should be applicable to the determination of pK_a of weak organic bases or acids[8], whose aqueous solubility is too low to give concentrations adequate for the determination of pK_a by the titration method:

1. A paraffinic hydrocarbon should be used as the organic solvent for the partition experiment to prevent the contamination of the aqueous phase with organic solvent.

[8] For acidic compounds, use $pK_a = \log [P_{app}/(P_m - P_{app})] + pH$ in place of Eq. 6 and add the $-\log \gamma^{\pm}$ value to the obtained pK_a in order to get pK_a^T.

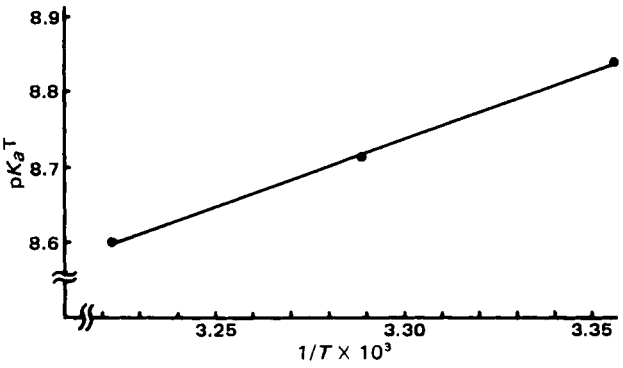

Figure 4—*Plot of* pK_a^T versus 1/T. *Initial concentration of verapamil in organic solvent, 0.003 M; temperature, 25°C; ionic strength, 0.0315.*

2. A P_m value of 1.0–1000 is advisable from the standpoint of accuracy.

3. The concentration of the drug in the partition experiment should be as low as possible.

4. Low buffer concentration is advisable to make the correction for the activity coefficient of ions simple. A swamping electrolyte such as sodium chloride should be added to adjust the ionic strength to a certain value (such as 0.05) to minimize the contribution of drug concentration change in the aqueous phase to the ionic strength.

Abstract □ An analytical method for the quantitation of nanogram to subnanogram amounts of dexamethasone is described. Dexamethasone was isolated from human plasma using a C_{18}-bonded reverse-phase cartridge, purified by subsequent normal-phase HPLC, and the corresponding trimethylsilyl derivative analyzed by gas chromatography–mass spectrometry (GC–MS). The quantitation by isotope-dilution MS was carried out by selected-ion monitoring on the $(M + 1)^+$ ion of the trimethylsilyl derivative of dexamethasone and its stable isotopically labeled diluent, [$^{13}C_6$,$^2H_3$]dexamethasone (681 and 690 *m/z*, respectively). Methane was used as the GC carrier gas and as the chemical-ionization reagent gas. The sensitivity of the method, judged from the lower limit of detection of the mass spectrometer, was at ~100 pg. The inter- and intraassay coefficients of variation (CV) determined at two different concentrations were 3.83 and 3.78% for 2 ng/mL and 2.64 and 1.29% for 5 ng/mL, respectively. Plasma concentration profiles for dexamethasone following a single 1-mg iv and a 2-mg oral dose of dexamethasone administered 24 h apart to two healthy volunteers are presented. The mass fragmentographic method described here is useful for bioavailability and pharmacokinetic studies of the synthetic glucocorticoid.

Keyphrases □ Dexamethasone—quantitative determination in human plasma, stable isotope dilution mass spectrometry □ Stable isotope mass spectrometry—quantitative determination of dexamethasone in human plasma

The assay of steroid hormones in biological fluids has been greatly simplified with the development of highly sensitive RIA techniques. RIA methods were developed for the estimation of plasma dexamethasone (1–3) and used to follow plasma levels of dexamethasone to determine the bioavailability of oral dexamethasone (4) and intravenous dexamethasone esters (5). Bioavailability studies of prednisone tablets have also been performed by an RIA method (6). There are often, however, serious restrictions to the use of RIA techniques in that cross-reactivity with other steroids is a serious problem in achieving acceptable specificity.

More specific and precise HPLC methods have been widely used in determining natural and synthetic corticosteroids in biological fluids. The methods have been applied to bioavailability and pharmacokinetic studies of synthetic corticosteroids such as prednisone, prednisolone (7, 8), and budesonide (9). A test method for determining content uniformity by HPLC has also been described for fludrocortisone acetate (10). The HPLC method offers the advantage that the corticosteroids can be analyzed without derivatization, unlike GC. However, the HPLC method lacks sensitivity and cannot be used to make accurate determinations of plasma concentrations in the nanogram-to-subnanogram range. Moreover, analytical methods such as RIA and HPLC do not have the advantage of the isotope dilution technique in that the correction for losses of a particular substance in various biological samples in the extraction and purification procedure cannot be easily made.

The use of gas chromatography–mass spectrometry (GC–MS) and isotopically labeled drugs as diluents has found broad application in pharmacological studies (11, 12). In this technique, stable isotopically labeled carriers serve as the ideal internal standard to correct for losses of a substance under study in the initial isolation procedures. Pharmacokinetic studies represent one field in which the sensitivity and specificity of GC–MS techniques offer an advantage. The present paper describes the development of an analytical method which involves stable isotope dilution mass spectrometry to follow plasma concentrations of dexamethasone after the administration of a therapeutic dose. The internal standard used was dexamethasone M+9 ([$^{13}C_6$,$^2H_3$]dexamethasone). The method has been applied to the bioavailability study of a commonly used tablet formulation of dexamethasone.

EXPERIMENTAL

Chemicals—Methanol[1] (HPLC grade), methylene dichloride[2] (distilled in glass), hexane[2] (UV grade, distilled in glass), and glacial acetic acid[3] (AR grade) were used without further purification. *N,O*-bis(Trimethylsilyl)trifluoroacetamide[4] (BSTFA) was commercially available, and dexamethasone[5] was a gift. Stable isotopically labeled dexamethasone, [1,2,3,4,10,19-$^{13}C_6$,19,19,19-$^2H_3$]dexamethaone, was synthesized under an FDA contract[6].

Mass Fragmentography—Mass fragmentographic determinations were made with a gas chromatograph–mass spectrometer fitted with a chemical-ionization source and a data system[7]. Methane was used as the GC carrier (15 mL/min) and as the chemical-ionization reagent gas. The chemical-ionization source pressure was maintained at ~0.21 torr, and electron energy of 70 eV. The trimethylsilyl derivatives were monitored at *m/z* values of 681 (nonlabeled dexamethasone) and 690 (labeled dexamethasone) by multiple-ion detection with an integration time of 0.839 s each.

GLC was performed on a glass column (60.96 cm × 2 mm i.d.) packed with 3% SP-2100[8] on Supelcoport[8] (80–100 mesh). The column temperature was 270°C and the temperature of the injector was 285°C. The temperature of the ion source was 270°C.

In the electron-impact mode of operation, the electron energy was set to 70 eV and the multiple-ion detection program was set to monitor the ions at *m/z* 680 and 689. The GC column was the same as described above. Helium (20 mL/min) was used as the carrier gas. The column temperature was 240°C, the injector was at 255°C, and the jet separator was at 250°C. The temperature of the ion source was 250°C.

Sample Preparation for Mass Fragmentography—To 1.0 mL of plasma was added 20 ng of dexamethasone M+9 dissolved in 10 μL of methanol, and the plasma was allowed to stand for 30 min. The plasma sample was applied to a C_{18} bonded reverse-phase cartridge[9]. The cartridge was washed with 4 mL of water and then eluted with 5 mL of methanol. The methanol eluate was evaporated to dryness under a stream of nitrogen. To the residue was added 100 μL of the HPLC solvent and the sample was injected with a syringe-loading sample injector[10] into a liquid chromatograph[11] equipped with a

UV-visible detector[12]. The normal-phase HPLC column[13] (0.25 m × 4.6 mm i.d.) was eluted with 30% methylene dichloride-4% methanol-0.2% acetic acid in *n*-hexane (13) at the rate of 2.5 mL/min, and the column effluent was monitored at 240 nm. Approximately 5 mL of HPLC eluate of the appropriate fraction was collected. The solvent was evaporated to dryness under a stream of nitrogen. The trimethylsilyl derivative was formed by reacting the residue with 30 μL of BSTFA in the presence of 10 μg of potassium acetate as a base catalyst (14, 15). The reaction was completed in 0.5–1 h at 80°C. Excess BSTFA was removed under a stream of nitrogen, and the residue was dissolved in 30 μL of *n*-hexane. A 5–10-μL volume of the above *n*-hexane solution was analyzed by GC–MS. In addition, a methoxime-trimethylsilyl (MO-TMS) derivative of dexamethasone was prepared for GC–MS analysis according to a reported method (16).

Preparation of Calibration Curve—To each of 10 standards containing 0.5–200 ng of dexamethasone in 10 μL of methanol was added 20 ng of dexamethasone M+9 in 10 μL of methanol and 10 μg of potassium acetate in 10 mL of methanol. After evaporation of the solvent to dryness under a stream of nitrogen, 30 μL of BSTFA was added to each sample to form the TMS (trimethylsilyl) derivative as described above. A 5–10-μL aliquot of the sample was subjected to GC–MS.

Determination of Accuracy—Dexamethasone in amounts of 2.02, 5.05, and 10.10 ng dissolved in 10 μL of methanol was added to 1.0-mL aliquots of pooled plasma. After preparation of the sample for mass fragmentography as described above, the observed area ratio of *m/z* 681 to *m/z* 690 was determined in triplicate.

Drug Administration—The two healthy adult male volunteers, 39 (subject 1) and 56 (subject 2) years old, weighed 64 and 77 kg, respectively. As a part of the experiment, a complete blood count, urinalysis, and screening blood chemistry battery (SMA) was performed. The laboratory results were found to be within normal limits. After an overnight fast, subjects 1 and 2 received three 0.75-mg dexamethasone tablets[14] orally with 250 mg of water and 1 mg of dexamethasone in its phosphate ester form[15] in 5 mL of saline intravenously over 5 min (1 mL/min), respectively, on the first day. No food was permitted for 4 h after drug administration. On the second day, the drug administration was repeated with each subject receiving the reverse treatment.

On the first day, 20-mL heparinized blood samples were taken from both subjects immediately before drug administration. At the end of injection and 5 min after injection, 10-mL heparinized blood samples were taken from subject 2. At 15, 30, 45, 60, 90, 120, 180, 240, 360, 480, 600, 1200, and 1420 min after dosing, 10-mL heparinized blood samples were taken from both subjects. On the second day, 5-mL blood samples were taken rather than 10 mL. The samples were centrifuged at 2000 rpm for 15 min. The plasma samples were placed in culture tubes with plastic caps and stored at −20°C until the time of assay.

RESULTS

Prerequisites for Mass Fragmentographic Analysis—*Derivative Formation*—In the electron-impact or chemical-ionization mass spectrum of dexamethasone, the relative abundance of the molecular or $(M+1)^+$ ion was very small and, unless derivatized, the ionization efficiency of the compound was not sufficient to make possible the analysis of nanogram amounts of dexamethasone. The 3,20-diMO-11β,17α,20-triTMS (MO-TMS) derivative (16) and 11β,17α,20,21-tetraTMS derivative (15) possessed good GC properties and were suitable for use in GC–MS analysis. The electron-impact mass spectra shown in Figs. 1 and 2 indicate that a much higher molecular ion intensity was observed for the tetra TMS derivative at *m/z* 680 than for the MO-TMS derivative at *m/z* 666. When the molecular ion of the tetra TMS derivative was monitored, the sensitivity limit of the assay by GC–MS (electron-impact) was found to be 10 ng of dexamethasone/sample for a standard solution with a signal-to-noise ratio of ~2.5.

Figure 3 shows the chemical-ionization mass spectrum of tetra TMS dexamethasone. An intense $(M+1)^+$ ion was observed at *m/z* 681, with three other predominant peaks in the high mass region >*m/z* 450. This was accomplished by using the chemical-ionization mode for MS analysis and methane as the GC carrier and chemical-ionization reagent gas. The GC effluent was introduced *via* the direct inlet of an MS interface. When the $(M+1)^+$ ion at *m/z* 681 was monitored, the sensitivity limit by GC–MS (chemical-ionization) was found to be 100 pg of dexamethasone for a standard

solution (equivalent to 300 pg/mL of plasma) when a signal-to-noise ratio of ≥2.5:1 was used as a criterion for a significant response.

Selective-ion recordings of tetra TMS dexamethasone showed that no contaminating byproducts with retention times close to that of the TMS derivative were present. After the initial purification procedures, there was no interference with the dexamethasone $(M+1)^+$ ion of the TMS derivative from endogenous compounds in the plasma extract.

Calibration Curve—Dexamethasone M+9 was used as the internal standard in the MS analysis of dexamethasone. The tetra TMS ether of dexamethasone M+9 gave the same fragmentation pattern as the TMS derivative of nonlabeled dexamethasone with the expected mass shifts of 9 amu (Fig. 4). Known mixtures of dexamethasone and dexamethasone M+9 were prepared so that the sample size (5–10 μL) injected into the GC–MS covered the dexamethasone calibrations range of 0.5–200 ng with a fixed amount (20 ng) of dexamethasone M+9. Each mixture was then anlayzed as the TMS derivative, monitoring the $(M+1)^+$ ions at *m/z* 681 for dexamethasone and *m/z* 690 for dexamethasone M+9. There was a good correlation between the mixed molar ratio and the observed peak area ratio. Least-squares analysis of the observed ratio gave a regression line with a slope coefficient of 0.9997.

Accuracy—The accuracy of measurements was determined for dexamethasone added to 1.0-mL aliquots of pooled plasma. The plasma samples contained 20 ng of the internal standard and different amounts (2.02, 5.05, and 10.10 ng) of dexamethasone. The amounts of dexamethasone were measured by the described GC–MS (chemical-ionization) method. The amounts of dexamethasone added were determined and were in good agreement with the amounts of the dexamethasone spiked, the relative error being <3% (Table I).

Precision—As determined by assaying in triplicate six 1.0-mL plasma samples with a dexamethasone concentration of either 2 or 5 ng/mL (Table II), the intraassay coefficients of variation were 3.78% for 2 ng/mL and 1.29% for 5 ng/mL. The interassay coefficients of variation at these two concentrations were 3.83% for 2 ng/mL and 2.64% for 5 ng/mL.

Pharmacokinetics and Bioavailability of Dexamethasone—A single oral dose of three 0.75-mg dexamethasone tablets and a single intravenous dose of 1 mg of dexamethasone in its phosphate ester form were administered 24 h apart to two healthy male volunteers (subjects 1 and 2). Time courses of dexamethasone concentrations in plasma were followed for 24 h by the present

method. Figure 5 shows a typical example of the selected-ion chromatogram for dexamethasone from the plasma sample.

Plasma concentrations of dexamethasone after intravenous administration appeared to decrease in a biexponential fashion (Fig. 6). The terminal phase of plasma concentrations of dexamethasone after oral administration paralleled that after intravenous administration in each subject. After oral administration the appearance of dexamethasone in the plasma was very rapid. The peak dexamethasone concentrations (15.4 ng/mL for subject 1 and 14.1 ng/mL for subject 2) were observed at 45 and 60 min, respectively, after a single oral dose of 2.25 mg. Semilogarithmic plots of the plasma concentration *versus* time (Fig. 6) indicate that after absorption, a distribution phase was observed in both subjects. The terminal decline phase was monoexponential at time points later than 2 h for subjects 1 and 2.

The observed set of plasma data was fitted to the polyexponential equation ($C_p = \Sigma C_i e^{-\lambda_i t}$) describing the plasma concentration–time curves and parameters characterizing the absorption and disposition of oral and intravenous dexamethasone were obtained *via* a computer[16] by a least-squares estimation using the steepest descent method. The estimate of the elimination half-life ($t_{1/2}$) was obtained from the terminal slope (λ_i): $t_{1/2} = 0.693/\lambda_i$. The total plasma clearance (CL_{pl}) was expressed as the intravenous dose divided by the area under the plasma concentration–time curve (AUC). The AUC from t = 0–10 h ($AUC_{10\ h}$) or t = 0 to infinity (AUC_∞) was measured by the trapezoidal rule. In the case of intravenous administration, the time point of 15 min was taken to be the first data point to measure the AUC. The AUC beyond the last detectable plasma dexamethasone concentration was calculated by dividing the last detectable plasma concentration (10-h point) by the terminal elimination rate constant, λ_i. The volume of distribution (Vd, area) was calculated by dividing the clearance by the terminal rate constant: Vd, area = CL_{pl}/λ_i. These pharmacokinetic parameters are summarized in Table III.

Bioavailability—The absolute bioavailability of oral dexamethasone was calculated from a comparison of dexamethasone concentrations after oral dexamethasone and intravenous dexamethasone-21-phosphate administration based on the AUC. It was assumed that after intravenous injection dexamethasone-21-phosphate rapidly and quantitatively hydrolyzed to its free alcohol (5). The calculated values for bioavailability were 54.7% ($AUC_{10\ h}$) and 54.9% (AUC_∞) for subject 1 and 71.7% ($AUC_{10\ h}$) and 71.2% (AUC_∞) for subject 2.

[16] CBM Model 2001-32.

DISCUSSION

The use of isotope dilution techniques coupled with isotope ratio determination by MS is rapidly becoming the method of choice in the analysis of steroids in biological samples (17–19). Since bioavailability and pharmacokinetic studies of synthetic corticosteroids require sensitive, specific, and reproducible analytical techniques, attempts were made in the present study to devise procedures that would allow analysis of nanogram-to-subnanogram amounts of dexamethasone in human blood by isotope dilution MS.

Generally, the MS analysis of corticosteroids in biological extracts is difficult due to their thermal instability and the problems associated with isolating sufficiently pure material for analysis. Recently, sample purification procedures using a C_{18} bonded reverse-phase cartridge for the quantitative analysis of corticosteroids in adrenal cell cultures by HPLC or GC–MS have been described (20). The present isotope-dilution MS method involves spiking the plasma sample with stable isotopically labeled dexamethasone M+9 and then purifying it by the use of a C_{18} bonded reverse-phase cartridge and normal-

phase HPLC. The steroid sample was then derivatized and analyzed by GC–MS. The absolute recovery of the purification procedures varied from 80 to 90%, and coextracted endogenous material did not present any problems in the final GC–MS analysis.

For each MS method developed, the choice of derivative and mode of MS analyses must be made to reduce the possibility of interferences and enhance the sensitivity. Several derivatives of corticosteroids for GC analysis have been introduced in the past (14, 21–24), and from a quantitative point of view the double MO-TMS derivative has been shown to be the most satisfactory (23). MO-TMS derivatives have been used for the quantitative determination of prednisolone and prednisone in human plasma using GC–MS (chemical-ionization) with methane as the chemical-ionization reagent gas (25).

It has also been suggested that in order to produce stable silylated derivatives of corticosteroids it is necessary first to protect the ketone groups at C-3 and C-20 (26–28). This step has now, however, been shown not to be necessary in the case of dexamethasone when the silylation reaction was carried out with BSTFA in the presence of a base catalyst such as anhydrous potassium or sodium acetate (15). In the present study potassium acetate was used as a base catalyst, the C-20 ketone group of dexamethasone was converted to an enol ether, and all hydroxyl groups were converted to TMS ether groups under reaction with BSTFA at 80°C for 0.5–1 h. A single product was obtained, and the tetra TMS derivative showed excellent thermal stability and good GC behavior. The MO-TMS derivative of dexamethasone was also thermally stable and suitable for GC analysis. This derivative was recently used for the qualitative determination of dexamethasone along with other synthetic corticosteroids in horse urine samples by combined HPLC-negative-ion chemical-ionization MS using ammonia as the reagent gas (29).

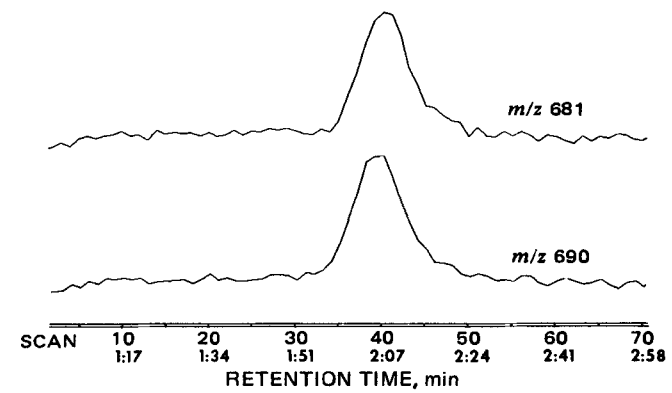

Figure 5—*Mass fragmentograms of tetra TMS dexamethasone and tetra TMS dexamethasone M+9 after processing from a plasma sample.*

Quantitation by MS requires the availability of isotopically labeled compounds to function as internal standards. It was expected that the molecular ion for tetra TMS dexamethasone would have a significant contribution to M+1, M+2, and M+3 because of the presence of four TMS groups. This multiplicity of the molecular ion imposes certain restrictions on the choice of a GC–MS internal standard. For a stable isotopically labeled dexamethasone to serve as an internal standard in the present study, it must be substituted with a large number of stable isotopes so that its molecular ion cluster will not overlap with the molecular ion cluster of nonlabeled dexamethasone.

Dexamethasone M+9, used as the internal standard, was suitable for the present purpose. The standard curve prepared by plotting the peak area ratio of the $(M+1)^+$ ions of the tetra TMS derivatives *versus* the amount of nonlabeled dexamethasone added to 20 ng of dexamethasone M+9 was linear at a concentration range of 0–200 ng, a concentration range commensurate with the clinical levels in the bioavailability study of dexamethasone. Furthermore, accuracy and precision provided by the present method were satisfactory.

The applicability of the method was shown by the determination of plasma dexamethasone levels in two healthy human volunteers after administration of a 2-mg oral or 1-mg iv dose of dexamethasone. This study indicated that most of orally administered dexamethasone was absorbed within 60 min. The terminal half-lives ($t_{1/2}$) calculated from plasma concentration data after oral and intravenous administration were in close agreement in both subjects. The half-life was somewhat short in subject 1 (~2 h) and was ~3.5 h in subject 2. These values were similar to results reported by other workers, who measured total plasma radioactivity after administering radiolabeled dexamethasone intravenously (30) or plasma levels by RIA (4).

An assumption was made that the total plasma clearance (CL_{pl}) was constant for each subject from oral to intravenous dose or *vice versa*, and the values for bioavailability of the oral preparation were estimated by a model-

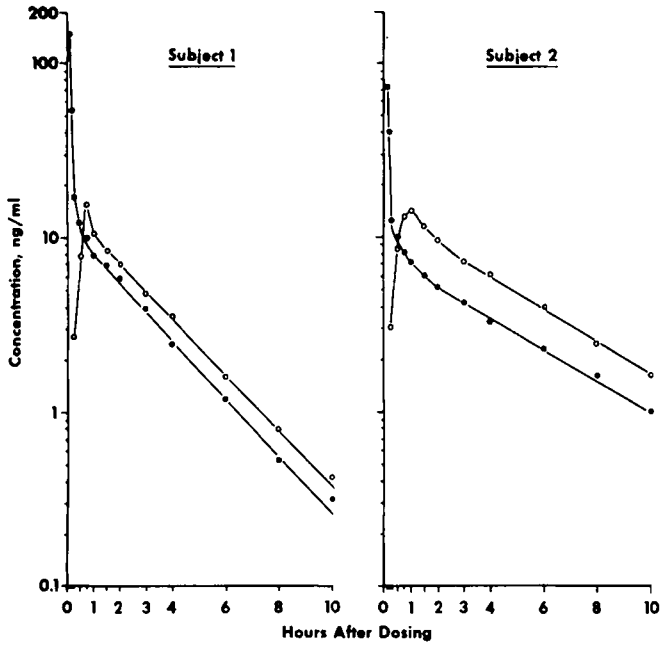

Figure 6—*Semilogarithmic plot of plasma concentrations of dexamethasone* versus *time after single 1-mg iv (●) and 2-mg oral (○) doses of dexamethasone.*

independent comparison of dexamethasone levels after oral and intravenous administration based on the $AUC_{10\ h}$ values of ~55 and 71% for subjects 1 and 2, respectively. A comparison of AUC_{∞} resulted in only a small difference in the bioavailability values from those obtained above.

CONCLUSION

The isotope dilution MS method described here afforded a sensitive and reliable technique to measure nanogram-to-subnanogram amounts of dexamethasone in plasma. Specificity was high because the GC–MS system was used to separate and to detect the specific compound in question after initial purification by a C_{18} bonded reverse-phase cartridge and normal-phase HPLC. It was possible to apply the present method for the accurate determination of low concentrations of dexamethasone in human plasma after administering only a few milligrams of the drug.

Comparative Disposition Kinetics of Two Diastereomeric Pairs of Cinchona Alkaloids in the Dog

ISAAC ABRAHAM * and CLARENCE T. UEDA ˣ

Received April 5, 1982, from the *Department of Pharmaceutics, College of Pharmacy, University of Nebraska Medical Center, Omaha, NE 68105.* Accepted for publication February 25, 1983. *Present Address: College of Pharmacy, Dalhousie University, Halifax, Nova Scotia.

ABSTRACT □ The comparative disposition kinetics of quinidine, quinine, cinchonine, and cinchonidine were investigated in five male, mongrel dogs after intravenous bolus injections of a 9.2-mmol/kg dose of each alkaloid base. Blood and plasma specimens were obtained at various times up to 6 h postdose and assayed for quinidine and quinine with a TLC–fluorometric procedure and for cinchonine and cinchonidine by HPLC. The plasma alkaloid concentration–time data were analyzed by weighted, nonlinear least-squares regression analysis to obtain the central compartment volume (V_c), disposition rate constants (α and β), and corresponding half-life values ($t_{1/2}$). Total body clearance (CL) and apparent volume of distribution (Vd) were estimated by nonparametric analysis. In this study, the highest plasma alkaloid concentrations were reached with quinidine and the lowest concentrations with the quinidine congener, cinchonine. The other congeneric pair, quinine and cinchonidine, exhibited plasma alkaloid concentrations that were comparable and intermediate to those of quinidine and cinchonine. With cinchonine and cinchonidine, the plasma and blood concentration–time curves were virtually superimposable. However, with quinidine and quinine, the plasma alkaloid concentrations of these diastereomers were approximately twice the corresponding blood concentrations. The total body clearance rate of quinidine was significantly slower than quinine and cinchonine clearance. No difference in clearance was observed between cinchonine and cinchonidine. The β and $t_{1/2\beta}$ for quinidine were significantly smaller and larger, respectively, than the corresponding values obtained with the other alkaloids. No significant differences in α or V_c and Vd were found between and within the two diastereomeric pairs of alkaloids. The differences in disposition kinetics observed in this study were attributable to an interaction of stereochemical and 6′-methoxy group substitution effects.

Keyphrases □ Quinine—comparative disposition kinetics in the dog, effects of stereochemistry and 6′-methoxy group substitution □ Quinidine—comparative disposition kinetics in the dog, effects of stereochemistry and 6′-methoxy group substitution □ Cinchonine—comparative disposition kinetics in the dog, effects of stereochemistry and 6′-methoxy group substitution □ Cinchonidine—comparative disposition kinetics in the dog, effects of stereochemistry and 6′-methoxy group substitution

Optical isomers as well as congeners of various drugs have been shown to exhibit different pharmacokinetic and/or pharmacological properties. Stereoselective behavior has been demonstrated for a number of drugs including disopyramide (1), fenfluramine (2), propoxyphene (3), propranolol (4, 5), quinidine/quinine (6–8), thyroxine (9), and warfarin (10). For optical isomers, the asymmetry in their molecular structure (and the resultant effects) clearly account for the differences in properties observed between isomers. Drug congeners, on the other hand, possess different properties because of the presence of different group substituents on the parent drug molecule. The various tetracycline, penicillin, and phenothiazine derivatives are well-known examples of drug congeners possessing different pharmacokinetic and pharmacological activities.

In this investigation, quinidine, quinine, cinchonine, and cinchonidine, two diastereomeric pairs of cinchona alkaloids, were used to evaluate the effects of stereochemistry and group substitution on drug disposition kinetics. Quinidine, quinine, cinchonine, and cinchonidine are the four principal naturally occurring alkaloids isolated from the bark of trees and shrubs of various species of the *Cinchona* and *Remijia* genera. Stereochemically, quinidine, quinine, cinchonine, and cinchonidine fall into two configurational and polarimetric groups. Cinchonine and its 6′-methoxy congener, quinidine, are dextrorotatory and have the same configuration at C-9. The other congeneric pair, cinchonidine and quinine, are levorotatory and have the opposite configuration at C-9 when compared with the dextrorotatory isomers.

The diastereomeric pairs, quinidine/quinine and cinchonine/cinchonidine, do not form racemates and are substances with distinct physicochemical properties (11) and therapeutic uses (7, 8). The purpose of this paper is to report our results on the disposition kinetics of quinidine, quinine, cinchonine, and cinchonidine in dogs.

EXPERIMENTAL

Materials—Quinine, cinchonine, and cinchonidine bases were obtained commercially[1] and used without further purification. Chromatographic analysis of these substances revealed the presence of trace amounts (<7%) of materials that were most likely the corresponding dihydro derivatives of these alkaloids. Quinidine, free of dihydroquinidine, was prepared from quinidine sulfate USP[2] according to the method of Thron and Dirscherl (12). The separated and purified dihydroquinidine was used as the internal standard for the assay of cinchonine and cinchonidine described below.

Drug solutions suitable for parenteral administration were prepared by dissolving the alkaloid base in dilute sulfuric acid (pH 4) and aseptically filtering each solution through a 0.45-μm membrane filter[3]. All other reagents and chemicals were analytical reagent grade.

Intravenous Drug Administration and Blood Sampling—Five male mongrel dogs (15–22 kg) were used in a crossover study with a 7–10-d washout period between drug treatments. During the study, the animals were housed in separate cages with free access to water and they were fed commercial dog food[4]. Food was withheld during the actual experiments.

After placing the dog in a sling support, vein infusion sets[5] with 19-gauge hypodermic needles were inserted into a leg vein of a fore- and hindlimb to facilitate intravenous drug administration and sampling of blood for drug analysis. Patency of the blood catheter was maintained by intermittent flushing with heparinized normal saline (100 IU/mL).

Prior to drug administration, 5 mL of blood was removed as a control sample and for the determination of the hematocrit. A 9.2-mmol/kg dose of alkaloid base was given by rapid intravenous injection *via* the infusion set. Each dose was followed by 3–5 mL of normal saline to ensure complete delivery of the intended dose.

Following drug administration, 3-mL blood samples for drug analysis were obtained at 5, 10, 15, 30, 60, 90, 120, 180, 240, 300, and 360 min, using the second infusion set, and placed in 10-mL heparinized tubes[6]. Approximately 1 mL of blood was reserved for the determination of drug concentrations in whole blood. The remaining sample was centrifuged to obtain the plasma fraction. The blood and plasma samples were stored at −10°C until analyzed.

Analysis of Alkaloids in Blood and Plasma—The concentrations of quinidine and quinine in blood and plasma were determined with the TLC-fluorometric method previously described for quinidine (13).

The samples containing cinchonine and cinchonidine were extracted with benzene in the same manner as quinidine and quinine and assayed using an adaptation of the liquid chromatographic procedure for quinidine described by Drayer and associates (14). After evaporating the benzene extract to

Peak 3 is the internal standard, dihydroquinidine.*

dryness under a stream of nitrogen, the residue was reconstituted with 25 μL of mobile phase containing 40 ng of dihydroquinidine as the internal standard. An aliquot of this solution was injected into a liquid chromatograph[7] equipped with a loop injector, a C_{18} reverse-phase μ-Bondapak column[8] (3.9 mm × 30 cm; 10-μm particles), and a variable-wavelength fluorescence detector[9]. The mobile phase consisted of 15% (v/v) acetonitrile in 2.5% acetic acid, which was delivered at a rate of 2 mL/min (~2000 psi), and monitored with an excitation wavelength of 315 nm using a 418-nm cutoff filter.

Figure 1 shows the chromatographic characteristics of cinchonine and cinchonidine, as well as the internal standard, obtained under various test conditions with the assay procedure used. As shown in this figure, excellent separation and resolution of the two cinchona alkaloid peaks were achieved. Cinchonine and cinchonidine both eluted with a retention time of 4.3 min. The

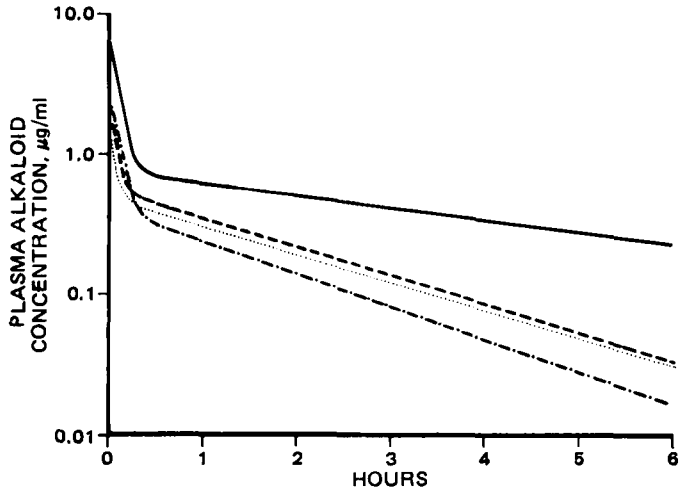

Figure 2—*Semilogarithmic graphs of the plasma alkaloid concentration–time curves for quinidine (—), quinine (· · · ·), cinchonine (- - - -), and cinchonidine (- · - · -) obtained after a 9.2 mmol/kg iv bolus dose of each alkaloid base in dog E. Each graph is the best-fit curve for each alkaloid obtained by nonlinear least-squares regression analysis of the experimental data.*

internal standard, dihydroquinidine, eluted in 8.1 min. The unidentified impurities in the drug samples eluted with an intermediate retention time of 6.0 min and, therefore, did not interfere with the assay for either drug.

Standard samples containing known concentrations of cinchonine and cinchonidine were prepared using blood obtained from untreated animals. They were processed concurrently with the plasma and blood samples to be analyzed and were used to prepare standard calibration curves using the peak height ratio of cinchonine or cinchonidine to internal standard. The unknown drug concentrations in plasma or blood were determined from the best-fit equation of the calibration curves obtained by linear regression analysis after blank correction. In all cases, the correlation coefficients were ≥0.995.

In the concentration range of 0.1–10 μg/mL for cinchonine and cinchonidine in blood and plasma, the relative standard deviations for the respective fluids were ≤7% and ≤5% for cinchonine and ≤8% and ≤5% for cinchonidine.

Data Analysis—The plasma drug concentration–time curves obtained with the bolus injections were fitted to a biexponential equation by weighted ($1/C^2$), nonlinear least-squares regression analysis using the NONLIN program (15):

$$C = Ae^{-\alpha t} + Be^{-\beta t} \qquad \text{(Eq. 1)}$$

Initial estimates of A, B, α, and β were obtained with the program CSTRIP (16); C is the plasma concentration of alkaloid at any time t, α, and β are first-order rate constants for the fast and slow disposition processes, respectively, and A and B are the corresponding ordinate intercepts for each exponential term.

Central compartment volumes (V_c) were estimated by:

$$V_c = \frac{\text{Dose}}{A + B} \qquad \text{(Eq. 2)}$$

The total body clearance rate (CL) was calculated for each alkaloid using:

$$CL = \frac{Dose}{\int_0^\infty C\,dt} \qquad \text{(Eq. 3)}$$

where $\int_0^\infty C\,dt$ is the total area under the plasma drug concentration–time curve, which was estimated by the trapezoidal rule to obtain the area up to the last measured concentration (C^*) and computing the area beyond C^* by dividing C^* by the terminal rate constant β.

The apparent volume of distribution (Vd) was determined by the relationship:

$$Vd = \frac{\text{Dose}}{\int_0^\infty C\,dt \cdot \beta} \qquad \text{(Eq. 4)}$$

Half-life values ($t_{1/2}$) were calculated as:

$$t_{1/2} = 0.693/\alpha \text{ or } \beta \qquad \text{(Eq. 5)}$$

Table I—Values for the Disposition Constants Obtained after a 9.2-mmol/kg iv Bolus Injection[a]

[a] Mean ± SEM; n = 5.

The two-way ANOVA test method was used to evaluate the significance of the differences observed between the four alkaloids in this study. This statistical procedure provided a means to evaluate the effects of stereochemistry, 6′-methoxy group substitution, and an interaction of both factors on drug disposition kinetics. A 0.05 significance level was used; the data are reported as the mean ±1 SE.

RESULTS AND DISCUSSION

A comparison of the plasma concentrations of quinidine, quinine, cinchonine, and cinchonidine obtained after intravenous administration of equimolar bolus doses is shown in Fig. 2 for a representative dog. In all dogs, the plasma concentration–time curves for each alkaloid declined biexponentially according to Eq. 1. A rapid distribution phase followed by a slower, terminal disposition phase was observed with all four alkaloids following the bolus injections. It was also noted in all animals studied that the highest plasma concentrations of alkaloid observed were achieved with quinidine. On the other hand, of the four alkaloids studied, the lowest plasma concentrations were always seen with the quinidine congener, cinchonine. The two remaining congeneric pair of alkaloids, quinine and cinchonidine, exhibited plasma concentrations that were comparable and intermediate between those of quinidine and cinchonine.

The rapid and brief distribution phase seen in this study in dogs with the four alkaloids ($t_{1/2\alpha} \simeq 5$ min) has also been observed for quinidine in rabbits (17, 18) and monkeys (19). Moreover, a similar distribution characteristic has been found with quinidine in humans (20–22).

Analysis of the plasma concentration-time data for each drug indicated that the relative differences in plasma alkaloid concentrations seen in this study were attributable to differences in total body clearance rates (CL) for the four alkaloids (Table I). Total body quinidine clearance (0.499 ± 0.111 L/h/kg) was significantly slower than the observed clearance rates of quinine and cinchonine of 1.435 ± 0.405 and 2.140 ± 0.436 L/h/kg, respectively. Interestingly, while there was a difference in CL between quinidine and quinine, it was observed that the cinchonine/cinchonidine diastereomers had similar clearance rates.

The terminal first-order elimination rate constant obtained for quinidine of 0.179 ± 0.014 h^{-1} was significantly smaller than the observed values for the remaining alkaloids ($p < 0.01$), which included the l-isomer of the diastereomeric pair, quinine (Table I). This finding indicated that the fractional removal rate of quinidine was the slowest of the four alkaloids studied. Further analysis of the results revealed that, while there was no difference in β between the cinchonine and cinchonidine diastereomers (0.500 ± 0.021 and 0.424 ± 0.024 h^{-1}), the terminal rate constants for this diastereomeric pair were significantly greater than the rate constant of quinine (0.311 ± 0.059 h^{-1}).

With the corresponding elimination half-life determinations (Table I), the cinchonine/cinchonidine pair were eliminated with similar $t_{1/2\beta}$ values of 1.40 ± 0.06 and 1.86 ± 0.20 h, respectively. On the other hand, the elimination half-lives of the quinidine/quinine diastereomers of 4.91 ± 0.95 and 2.24 ± 0.28 h, respectively, were significantly different ($p < 0.01$).

The results of the volume measurements are also summarized in Table I. In this study, no significant differences were observed between or within the two diastereomeric pairs of alkaloids in their central compartment volumes or overall apparent volumes of distribution.

In a recent investigation, Clohisy and Gibson (6) also observed that the total body clearance rate of quinidine was slower than the clearance rate of quinine in dogs. They found that the clearance of quinidine of 0.215 L/h/kg was about 44 or 56% slower than the quinine clearance rate of 0.487 L/h/kg. Although these clearance rates are less than the respective values observed in the present study, the results of the two studies are in agreement in that we observed a clearance rate of quinidine that was 63% slower than the corresponding rate of quinine clearance.

A possible explanation for these discrepancies could be the different dosages

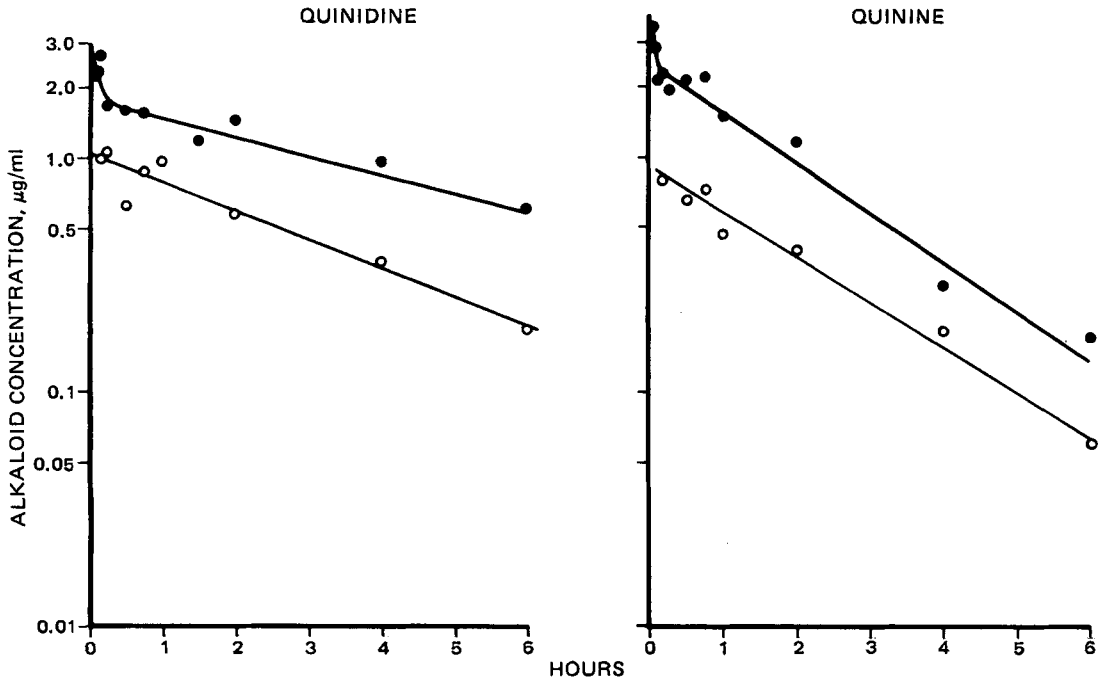

Figure 3—*Semilogarithmic graphs comparing the blood and plasma drug concentration–time curves of quinidine and quinine obtained after a 9.2 mmol/kg iv bolus dose of alkaloid base to dog C. The solid lines are the best-fit curves.*

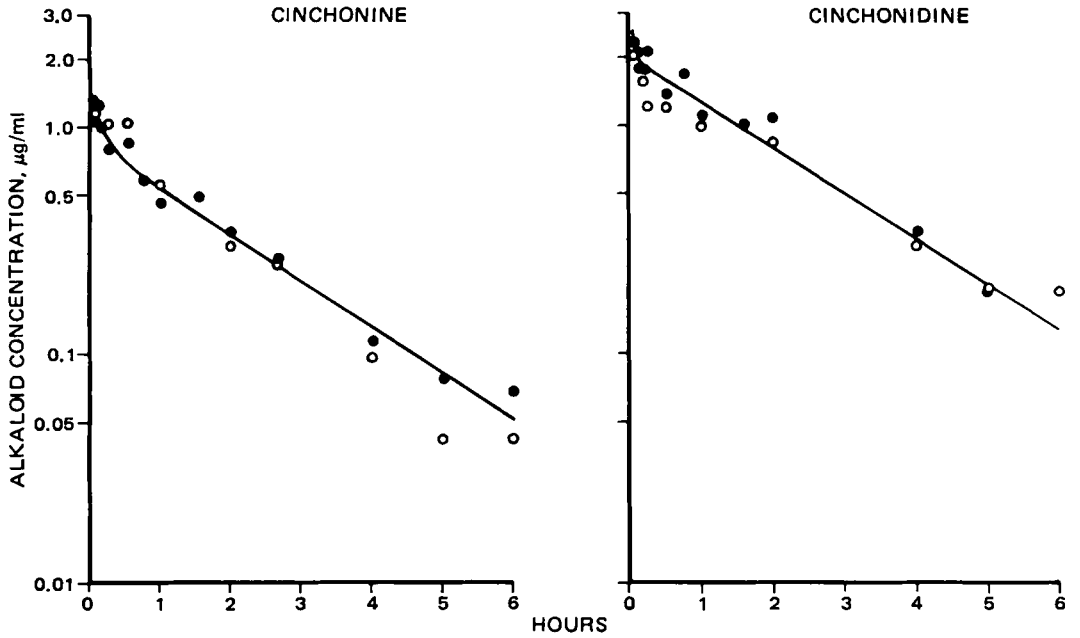

Figure 4—*Semilogarithmic graphs comparing the blood and plasma drug concentration-time curves of cinchonine and cinchonidine obtained after a 9.2 mmol/kg iv bolus dose of alkaloid base to dog C. The solid lines are the best-fit plasma curves.*

that were used in the two studies. In 1948, the findings of Taggart *et al.* (23) suggested that the disposition kinetics of all of the four alkaloids examined in this study were dose dependent. For quinidine, quinine, cinchonine, and cinchonidine, they reported that there was a disproportionate relationship between dose and mean plasma drug concentration attained. More recently, Bolme and Otto (24) also suggested that the pharmacokinetics of quinidine in humans is dose dependent. Thus, dose-dependent pharmacokinetics for quinidine and quinine in the dog is a distinct possibility. In this investigation, quinidine and quinine doses of 3 mg of alkaloid base/kg of body weight were given. Clohisy and Gibson (6) administered doses of the two alkaloids of 6.5 mg/kg. In support of the present findings, after the administration of a quinidine dose of 2.5 mg/kg, the estimated rate of quinidine clearance observed in dogs by Jellett *et al.* (25) was 0.435 L/h/kg (compared with 0.499 ± 0.111 L/h/kg in this study).

The observed difference in clearance between quinidine and quinine suggests that the disposition characteristics of these two diastereomers are stereoselective, as recently reported by Clohisy and Gibson (6). With the similarities in the apparent distribution volumes of these two alkaloids that were observed, these findings suggest that the stereoselective disposition behavior of quinidine and quinine is most likely associated with mechanisms for the metabolism and/or excretion of these drugs rather than a distribution process. In support of this conclusion, it was demonstrated in this study that the other diastereomers, cinchonine and cinchonidine, exhibited similar total body clearance rates. The two diastereomeric pair of alkaloids differ only in the 6′-position of the quinoline ring system, quinidine and quinine having a methoxy group in this position. Drayer *et al.* (26) have shown that a minor metabolite of quinidine in humans is the *o*-demethylated derivative of the drug. Therefore, the present data suggest that the 6′-position might be a site on the drug molecule that is involved in the stereoselective clearance of the quinidine/quinine diastereomers.

	R	
CINCHONINE	-H	CINCHONIDINE
QUINIDINE	$-OCH_3$	QUININE

With the observation that quinidine, quinine, cinchonine, and cinchonidine exhibited similar volumes of distribution, the differences in terminal rate constants and corresponding elimination half-lives found between quinidine and quinine were expressions of the differences in total body clearance rates that these diastereomers possess. A similar observation has been seen recently with the optical isomers of disopyramide (1) as well as by Clohisy and Gibson (6) in their study with quinidine and quinine.

In this study, there was no apparent effect of stereochemistry or the presence of the methoxy group in the 6′-position of the quinoline nucleus on the two measured volumes (V_c and Vd). *A priori*, this finding was quite unexpected since the 6′-methoxy group would have been expected to increase the volume of distribution by imparting greater lipid solubility to the parent drug molecule[10]. It is possible that the distribution volumes of the four alkaloids are similar because the stereochemical difference and 6′-methoxy substitution do not materially affect the manner and extent to which these alkaloids interact with tissue proteins.

In the present investigation, corresponding blood samples were collected and analyzed for their alkaloid content to evaluate the relative differences in drug concentrations between plasma and whole blood. It was reasoned that this information might give some insight into how the four drugs might differ in disposition in the body. With the quinidine/quinine diastereomers, after pseudodistribution equilibrium conditions were achieved, the blood concentrations of both diastereomers were demonstrably lower than the corresponding alkaloid concentrations in the plasma (Fig. 3). Nevertheless, the terminal disposition rate constants assessed with the blood and plasma data were similar for the respective isomers and, therefore, the blood and plasma elimination curves were parallel. For cinchonine and cinchonidine, the blood and plasma concentration-time curves were virtually superimposable after distribution equilibrium conditions were reached (Fig. 4).

In the plasma alkaloid concentration range of ~0–5 μg/mL, the overall plasma-to-blood concentration ratios observed for quinidine, quinine, cinchonine, and cinchonidine were 2.15 ± 0.26, 2.11 ± 0.28, 0.92 ± 0.10, and 1.26 ± 0.13, respectively. From these results and Fig. 4 it can be seen that the cinchonine/cinchonidine diastereomers are essentially distributed and cleared to the same extent whether assessed by measuring blood or plasma concentrations of these two alkaloids in the dog. On the other hand, the plasma-to-blood concentration ratios for quinidine and quinine suggest that these diastereomers are cleared twice as fast from the blood as from the plasma. In addition, based on blood quinidine and quinine concentration determinations, the apparent volumes of distribution for both of the diastereomers are twice as large as the corresponding plasma-estimated values.

Two possible explanations would account for the differences in plasma and blood concentrations observed for the two pairs of structurally related diastereomers in this investigation. First, quinidine and quinine may have had a higher affinity and/or capacity for binding to plasma proteins. In the vas-

[10] In three different solvent systems, 1-octanol, chloroform, and benzene–0.1 M phosphate buffer (pH 7.4), the partition coefficients of the methoxy diastereomers were significantly greater than the corresponding cinchonine/cinchonidine diastereomers in each of these systems (27).

cular system, a drug that is highly bound to plasma proteins will tend to remain in the plasma fraction. In separate *in vitro* experiments, the binding of quinidine, quinine, cinchonine and cinchonidine to bovine serum albumin was studied by equilibrium dialysis (28). In these studies, the bound fraction was highest for quinidine (followed by cinchonine > quinine > cinchonidine) when the plasma alkaloid concentrations were in the range of $0\text{-}25 \times 10^{-6}$ M. Moreover, the affinity constant (K_A) of quinidine for bovine serum albumin was three times greater than the K_A of quinine, and the affinity constants for the methoxy-substituted diastereomers were found to be 4–8 times larger than the corresponding unsubstituted diastereomers. It is possible that qualitatively similar conditions exist for the interactions of the four alkaloids to plasma proteins in the dog.

Alternatively, the differences in the relationship between blood and plasma alkaloid concentrations for the two diastereomeric pairs may have been due to differences in the binding to the red blood cell membrane and/or relative affinity for components within the erythrocytes (*e.g.*, hemoglobin). A lower affinity for erythrocytes could also result in a lower overall concentration of an alkaloid in the blood. The red blood cell/plasma ratios (K_r) were estimated for each alkaloid with the following expression:

$$K_r = \frac{K_b - (1 - H)}{H} \qquad \text{(Eq. 6)}$$

where K_b is the ratio of the concentration of drug in the blood to the corresponding plasma drug concentration and H is the hematocrit. According to Eq. 6, it was observed that the ratios of the cinchonine/cinchonidine diastereomers were significantly larger than the ratios obtained with the quinidine/quinine diastereomers.

Stereoselective drug disposition kinetics have been seen with a number of different optical isomers including disopyramide (1), propranolol (4,5), and warfarin (9). These differences in disposition kinetics undoubtedly affect the quantitative differences in pharmacological activities observed between isomers. In this study with the quinidine/quinine and cinchonine/cinchonidine diastereomers, the two-way ANOVA test method indicated that the disposition characteristics of these alkaloids were due to an interaction of stereochemical and 6′-methoxy group substitution effects and could not be attributed to a single effect. However, the stereochemical influences on the disposition kinetics of these four alkaloids appeared to be weaker than the effects contributed by the 6′-methoxy substitution.

Leucine Enkephalin Analogues Containing a Conformationally Restrained *N*-Terminal Amino Acid Residue

TREVOR DEEKS, PETER A. CROOKS *x, and ROGER D. WAIGH

Received December 2, 1982, from the *Department of Pharmacy, University of Manchester, Manchester, M13 9PL, UK.* Accepted for publication January 24, 1983. *Present address: Division of Medicinal Chemistry and Pharmacognosy College of Pharmacy, University of Kentucky, Lexington, KY 40506.

Abstract □ Three analogues of leucine enkephalin, in which the terminal tyrosine-1 residue has been replaced by conformationally restrained aromatic amino acids, have been synthesized by classical solution methods. Their opiate agonist potencies on electrically stimulated guinea pig ileum and mouse vas deferens preparations were determined and compared with morphine, Met enkephalin, and Leu enkephalin. None of these analogues had analgesic properties when evaluated on the above tissue preparations or when evaluated by the hot-plate test in mice after subcutaneous and intracerebroventricular administration.

Keyphrases □ Leucine enkephalin—conformationally restrained analogues, synthesis, analgesic activity □ Analgesics—evaluation of conformationally restrained leucine enkephalin derivatives, synthesis

A milestone in neurochemical research during the last decade has been the elucidation of the role of enkephalins as natural endogenous ligands for the opiate receptor (1, 2). Since this discovery, the synthesis of a multitiude of structural analogues of leucine and methionine enkephalins (Ig and Ih, respectively) have been reported (recent review, 3), some of which are more potent analgesics and/or possess greater *in vivo* stability than the natural opiate ligands. These synthetic analogues have resulted from modifications of the parent molecules, such as shortening or lengthening of the pentapeptide chain (4, 5), substitution of individual amino acids by other amino acids (5–11), and chemical modification of individual amino acids (12–14).

Preferred conformations of enkephalin molecules at analgesic receptors have been suggested, based on data from conformational studies involving both spectroscopic measurements and structure–activity considerations (15–33). These studies have attempted to relate the structure of the terminal tyrosine residue in the enkephalin molecule to the tyramine moiety present in the morphine molecule. Since morphine is a conformationally rigid molecule, this implies that the conformationally "loose" tyrosine residue in the enkephalin may interact at opiate receptors in a specific conformation which is related, stereochemically, to the rigid tyramine moiety present in the morphine molecule.

As part of a study designed to evaluate the importance of the tyrosine conformation in the enkephalins on analgesic activity and receptor recognition, we have initiated a preliminary investigation into the synthesis of Leu enkephalin derivatives in which the terminal tyrosine unit has been replaced by a variety of conformationally restrained aromatic amino acids and in which the terminal leucine-5 residue has been esterified to aid passage into the central nervous system. The investigations described in this report are restricted to the preparation of Leu enkephalin analogues containing a nonhydroxylated aromatic amino acid in place of the tyrosine-1 residue in order to initially determine the feasibility of preparing pentapeptides such as IIe–Ve, with a bulky terminal amino acid unit, *via* classical solution methods, before embarking on the preparation of the synthetically more difficult aromatic hydroxy derivatives IIf–Vf, which were regarded as the ultimate target compounds.

We now report the synthesis of the Leu enkephalin analogues IIe–IVe and their evaluation as analgesic agents on isolated guinea pig ileum myenteric plexus muscle, mouse vas deferens tissue, and by the hot-plate test in mice after subcutaneous and intracerebroventricular administration.

EXPERIMENTAL

Melting points were determined on a hot-stage microscope[1] and are uncorrected. Microanalyses were performed by the Micro-analytical Laboratory, Department of Chemistry, University of Manchester, analytical results obtained for all compounds were within ±0.4% of the theoretical value unless otherwise stated. ^{1}H-NMR spectra were recorded on a spectrometer[2] and are quoted in ppm on the δ scale. ^{13}C-NMR spectra were recorded on a spectrometer[3]. IR spectra were recorded as KCl disks, nujol mulls, or liquid films

on a spectrophotometer[4]. Mass spectra were determined on a spectrometer[5] operating at a probe temperature of 250°C. TLC separations were carried out on 0.25-mm silica gel[6]. 2-Aminoindan-2-carboxylic acid (34) and (±) 2-aminotetralin-2-carboxylic acid (35) were prepared by literature procedures. Amino acids and peptides with free amino functions were visualized by spraying with 1% ninhydrin in ethanol. *N*-Protected amino acids and peptides were visualized with 5% potassium dichromate in concentrated H_2SO_4; other compounds were visualized in iodine vapor. Hydrogenations were carried out on a hydrogenator[7] operating at atmospheric pressure and room temperature.

Ion-exchange chromatographic separations of *N*-deprotected pentapeptides were carried out on carboxymethylcellulose[8], prewashed with 0.5 M sulfuric acid followed by 0.2 M ammonium acetate buffer adjusted to pH 5.1 with 0.88 M ammonium hydroxide or glacial acetic acid and measured using a pH meter[9] fitted with a combined electrode[10]. Ion-exchange columns were run under slight pressure using a peristaltic pump set for an effluent output of 100 mL/h. Column effluents were monitored by UV spectrophotometry at 280 nm using a spectrophotometer[11] fitted with a 10-mm path length flow-through cell. Columns were eluted with 0.005–0.5 M gradient ammonium acetate buffer solutions at pH 5.1, and fractions were collected on an automatic fraction collector.

Amino acid analyses of peptides were performed on an amino acid analyzer[12] using ninhydrin as visualizer. The peptides were hydrolyzed in 6 M HCl at 110°C for 24 h in a sealed, evacuated tube.

Synthesis of *endo*-2-Aminobenzonorbornen-2-carboxylic Acid (IVa)—*Spiro[benzonorbornen-2,5′-hydantoin] (IVb)*—A solution of ammonium carbonate (28.6 g, 0.18 mol) in 50% aqueous ethanol (200 mL) was added to benzonorbornen-2-one (36) (11.1 g, 0.07 mol) in 50% aqueous ethanol (40 mL). The mixture was warmed to 50°C and a solution of potassium cyanide (4.6 g, 0.072 mol) in water (40 mL) was added in small portions over a 1-h period. The mixture was stirred at 58–60°C for 5 h. The ethanol was removed under reduced pressure, and the aqueous residue was extracted with ethyl acetate (3 × 200 mL). The combined organic extracts were dried, filtered, and evaporated to dryness, and the residue was triturated with ether to afford white crystals of IVb mp 225–229°C. The aqueous layer was acidified to pH 2 with concentrated sulfuric acid to afford an additional product for a total of 12.07 g 76%). This compound had identical spectrometric properties (IR, NMR) to an authentic sample recently prepared *via* a Strecker synthesis (48).

endo-*2-Aminobenzonorbornen-2-carboxylic Acid (IVa)*—A mixture of spiro[benzonorbornen-2,5′-hydantoin] (IVb) (6.63 g, 0.029 mol), barium hydroxide [$Ba(OH)_2{\cdot}8H_2O$, 17.6 g, 0.056 mol], and water (100 mL) was heated under reflux, in an atmosphere of nitrogen, for 70 h and then filtered while hot. The collected solid was washed with an equal volume of water, and the combined filtrate and washings were saturated with carbon dioxide, heated to boiling point, and refiltered. The filtrate (on cooling) afforded white crystals of IVb (140 mg, 2% recovery). The mother liquors were evaporated to ~50 mL to afford white crystals of IVa (4.69 g, 79%), mp 227.0–229.5°C [lit. (48) mp 227.5–229.5°C]. The hydrochloride salt was prepared from a portion of the product and had mp 228–231°C (dec.). ^{13}C-NMR (CH_3OH): 173.8 (s, CO_2H), 149.5 and 141.8 (2 × s, C-4a and C-8a), 129.5, 128.0, 125.2, and 123.1 (4 × d, ArC), 65.1 (s, C-2), 53.9 (d, C-4), 51.1 (d, C-1), 44.9 (t, C-9), and 39.8 (t, C-3); *m/z* 203 (M^+).

Preparation of *N*-Benzyloxycarbonyl Amino Acids—As a general method, the appropriate amino acid (0.011 mol) suspended in 2 M NaOH solution (100 mL) was heated on a steam bath to dissolve the amino acid and then cooled in an ice bath to 0–5°C, which caused the sodium salt of the amino acid to precipitate. Carbobenzyloxy chloride (2.11 g, 0.012 mol) was added in a dropwise manner to the cooled, stirred mixture over 40 min. The ice bath was then removed, and the mixture was stirred at room temperature for 30 h. The mixture was cooled to 0–5°C, and a further 2.11 g (0.012 mol) of carbobenzyloxy chloride added in a dropwise manner. After 60 h the mixture was carefully adjusted to pH 1 with 5 M HCl and extracted with ether (2 × 100 mL). The combined organic extracts were dried, filtered, and evaporated to dryness, and the residue was crystallized from ether–petroleum ether (bp 30–40°C) to afford the appropriate *N*-benzyloxycarbonyl amino acid.

2-Benzyloxycarbamidoindan-2-carboxylic acid (IIc)—This compound was prepared as described above from IIa in 32% yield, mp 46.5–53.0°C. IR (Nujol): 1748, 1663, 1545, and 1532 cm^{-1}; ^{1}H-NMR (DMSO-d_6): δ 3.48 (m, 4, C-1 and C-3 H), 5.04 (s, 2, benzyloxy CH_2), 7.05–7.45 (m, 9, ArH), 7.88 (s, 1, exchangeable with D_2O, NH), and 9.10 ppm (br s, 1, exchangeable with D_2O, COOH); *m/z* 311 (M^+).

Anal.—Calc. for $C_{18}H_{17}NO_4$: C, 69.5; H, 5.5; N, 4.5. Found: C, 69.9; H, 5.8; N, 4.2.

2-Benzyloxycarbamidotetralin-2-carboxylic Acid (IIIc)—Compound IIIc was prepared as described above from IIIa in 19% yield, mp 131.0–137.5°C. IR (KCl): 1772, 1728, 1688, 1680, 1580, and 1526 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 2.24 (m, 2, C-3 H), 2.80 (m, 2, C-4 H), 3.18 (m, 2, C-1 H), 5.05 (s, 2, benzyloxy CH_2), 5.30 (br s, 1, exchangeable with D_2O, NH), 6.90–7.50 (m, 9, ArH), and 10.32 (br s, 1, exchangeable with D_2O, COOH); *m/z* 325 (M^+).

Anal.—Calc. for $C_{19}H_{19}NO_4$: C, 70.2; H, 5.8; N, 4.3. Found: C, 70.1, H, 5.9, N, 4.0.

endo-*2-Benzyloxycarbamidobenzonorbornene-2-carboxylic Acid (IVc)*—This compound was prepared as described above from IVa in 27% yield, mp 90–93°C. IR (KCl): 1742, 1686, 1641, 1600, and 1582 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 1.28 (d of d, 1, J = 3 and 12 Hz, C-3 *endo*-H), 1.91 and 2.26 (2 × d, AB, J = 9 Hz, C-9 H), 2.95 (d of d, 1, J = 4 and 12 Hz, C-3 *exo*-H), 3.37 (m, 1, C-4 H), 3.84 (m, 1, C-1 H), 4.80 (br s, 1, exchangeable with D_2O, NH), 5.00 (d, 2, J = 4 Hz, benzyloxy CH_2), 6.95–7.50 (m, 9, ArH), and 11.05 ppm (s, 1, exchangeable with D_2O, COOH).

Anal.—Calc. for $C_{20}H_{25}NO_5$: C, 71.2; H, 5.6; N, 4.2. Found: C, 71.6; H, 5.8; N, 4.0.

Preparation of *N*-Protected Pentapeptides—As a general method, a solution of the appropriate *N*-benzyloxycarbonyl amino acid (1.9 mmol), glycylglycyl-L-phenylalanyl-L-leucine methyl ester (VI) (37) (1.9 mmol), and triethylamine (2.2 mmol) in CH_2Cl_2 (50 mL) was cooled in an ice bath, and 1-hydroxybenzotriazole (3.9 mol) in CH_2Cl_2 (10 mL) was added in a dropwise manner. The mixture was stirred for 5 min before adding *N,N′*-dicyclohexylcarbodiimide (2.1 mol) in CH_2Cl_2 (20 mL) in one portion. The ice bath was removed, the reaction was stirred at room temperature for 56 h, the precipitated dicyclohexylurea was removed by filtration, and the filtrate was evaporated to a volume of 10 mL and then refiltered. The resulting filtrate was evaporated to dryness, dissolved in ethyl acetate (50 mL) and washed with 1 M HCl (50 mL), saturated $NaHCO_3$ solution (50 mL), and finally water (50 mL). The organic layer was then dried, filtered, and evaporated to dryness. The resulting gummy residue was triturated with ether to afford the appropriate *N*-protected pentapeptide as a buff-colored, amorphous solid.

{[(*2 - Benzyloxycarbamido) -2- indanyl]carbonyl}glycylglycyl-L-phenylalanyl-L-leucine Methyl Ester (IId)*—Compound IId was prepared as above from IIc in 61% yield, mp 134–138°C. TLC (silica, ethyl acetate–methanol, 40:60): R_f 0.60; IR (KCl): 1726, 1675, 1665, 1650, 1595, 1532, and 1520 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 0.81 [d, 6, leucine δ-$(CH_3)_2$], 1.51 (m, 2, leucine β-CH_2), 1.78 (m, 1, leucine γ-CH), 3.07 (d of d, 4, indane 1- and 3-H), 3.09 (m, 2, phenylalanine β-CH_2), 3.55 and 3.57 (2 × s, 3, conformational forms of leucine OCH_3), 3.72 (m, 2, one of glycine α-CH_2's), 3.92 (m, 2, one of glycine α-CH_2's), 4.49 (m, 1, leucine α-CH), 4.71 (m, 1, phenylalanine α-CH), 4.99 (d, 2, $C_6H_5OCH_2$—O), 6.28 (d, 1, exchangeable with D_2O, NH), 7.03 (t, 2, exchangeable with D_2O, 2 × NH), 7.08–7.35 (m, 14, ArH), and 7.66 ppm (m, 2, exchangeable with D_2O, 2 × NH).

Anal.—Calc. for $C_{38}H_{45}N_5O_8$: C, 65.2; H, 6.2; N, 10.0. Found: C, 65.3; H, 6.2; N, 10.0.

{[(*2-Benzyloxycarbamido)-2-tetralyl]carbonyl} glycylglycyl-L-phenylalanyl-L-leucine Methyl Ester (IIId)*—This compound was prepared as above from IIIc in 91% yield, mp 86–90°C. TLC (silica, chloroform–methanol–acetic acid, 120:90:5): R_f 0.62; IR (KCl): 1740, 1725, 1704, 1690, 1675, 1660, 1564, and 1530 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 0.87 [d, 6, leucine δ-$CH_3)_2$], 1.55 (m, 2, leucine β-CH_2), 2.22 (m, 1, leucine γ-CH), 2.41 (m, 2, tetralin 3-H), 2.60–3.80 (m, 4, tetralin 1- and 4-H), 3.32 (m, 2, phenylalanine β-CH_2), 3.52 and 3.54 (2 × s, 3, leucine OCH_3's), 3.80 (m, 2, one of glycine α-CH_2's), 3.91 (m, 2, one of glycine α-CH_2's), 4.54 (m, 1, leucine α-CH), 4.73 (m, 1, phenylalanine α-CH), 5.02 (d, 2, benzyloxy CH_2), 6.78–7.70 (m, 14, ArH), 6.83 (d, 1, exchangeable with D_2O, NH), 7.16 (t, 2, exchangeable with D_2O, 2 × NH), 7.78 (m, 1, exchangeable with D_2O, NH), and 7.89 ppm (m, 1, exchangeable with D_2O, NH).

Anal.—Calc. for $C_{39}H_{47}N_5O_8$: C, 65.6; H, 6.6; N, 9.8. Found: C, 65.2; H, 6.7; N, 10.1.

{[(endo-*2-Benzyloxycarbamido) -2- benzonorbornenyl]carbonyl}glycylglycyl-L-phenylalanyl-L-leucine Methyl Ester (IVd)*—Compound IVd was prepared as above from IVc in 43% yield, mp 118–121°C. TLC (silica, chloroform–methanol–acetic acid, 120:90:5): R_f 0.72; IR (KCl): 1740, 1705, 1690, 1660, 1632, 1565, 1545, and 1520 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 0.84 [d, 6, leucine δ-$(CH_3)_2$], 1.30 (m, 1, benzonorbornenyl C-3 *exo*-H), 1.53 (m, 2, leucine β-CH_2), 1.94 (m, 1, leucine γ-CH), 1.98 (m, 2, benzonorbornenyl C-9 H), 2.64 (m, 1, benzonorbornenyl C-3 *endo*-H), 3.09 (m, 2, phenylalanine

β-CH_2), 3.62 (s, 3, leucine OCH_3), 3.63 (m, 2, benzonorbornenyl C-1 and C-4 H), 3.72 (m, 2, one of glycine α-CH_2's), 3.94 (m, 2, one of glycine α-CH_2's), 4.52 (m, 1, leucine α-CH), 4.69 (m, 1, phenylalanine α-CH), 5.17 (d, 2, benzyloxy CH_2), 6.38 (m, 1, exchangeable with D_2O, NH), 6.70–7.55 (m, 16, ArH and 2 exchangeable × NH), 7.60 (m, 1, exchangeable with D_2O, NH), and 7.70 ppm (m, 1, exchangeable with D_2O, NH).

Anal.—Calc. for $C_{40}H_{47}N_5O_8$: C, 66.2; H, 6.5, N, 9.2. Found: C, 65.8; H, 6.6; N, 8.9.

Synthesis of Unprotected Pentapeptides—As a general method, the appropriate *N*-protected pentapeptide (16 nmol) was dissolved in absolute ethanol (100 mL), 5% palladium-on-charcoal catalyst (0.5 g) was added, and the mixture was hydrogenated with stirring at room temperature and atmospheric pressure for 20 h. The catalyst was then removed by filtration, the filtrate evaporated to dryness, and the residue dissolved in ethyl acetate (50 mL). The organic solution was extracted with 1 M HCl (2 × 50 mL), followed by water (1 × 30 mL). The combined aqueous extracts were basified to pH 9 with solid sodium bicarbonate and back-extracted with ethyl acetate (2 × 50 mL). The combined ethyl acetate extracts were dried, filtered, and evaporated to dryness, and the residue was purified on a carboxymethylcellulose column, eluting with ammonium acetate buffer, as previously described, to afford the appropriate *N*-deprotected pentapeptide in buffer solution. The water and buffer salts were removed by freeze-drying, redissolving the residue in water (200 mL), and redrying on a freeze-drying apparatus[13] at 10^{-1}–10^{-2} torr.

[*(2-Aminoindanyl)carbonyl*]*glycylglycyl -L- phenylalanyl -L- leucine Methyl Ester (IIe)*—This compound was prepared as above from IId in 17% yield, mp 93–95°C. TLC (silica, chloroform–methanol–acetic acid, 120:90:5): R_f 0.69; IR (KCl): 1740, 1686, 1672, 1650, 1580, 1562, 1545, and 1525 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 0.85 and 0.93 [t and d, 6, leucine δ-$(CH_3)_2$], 1.60 (m, 2, leucine β-CH_2), 2.12 (m, 1, leucine γ-CH), 2.82 (d of d, 4, indane 1- and 3-H), 3.08, (m, 2, phenylalanine β-CH_2), 3.65 and 3.70 (2 × s, 3, leucine OCH_3), 3.81 (s, 2, exchangeable with D_2O, NH_2), 3.95 (d of d, 2, one of glycine α-CH_2's), 4.06 (d of d, 2, one of glycine α-CH_2's), 4.48 (m, 1, leucine α-CH), 4.92 (t, 1, phenylalanine α-CH), 7.00–7.31 (m, 9, ArH), 7.26 (d, 1, exchangeable with D_2O, NH), 7.49 (d, 1, exchangeable with D_2O, NH), 7.63 (m, 1, exchangeable with D_2O, NH), and 8.45 ppm (m, 1, exchangeable with D_2O, NH); amino acid analysis (after acidic hydrolysis): 2d 0.95, Gly 1.97, Phe 1.00, and Leu 1.01.

[*(2-Aminotetralyl)carbonyl*] *glycylglycyl -L- phenylalanyl -L- leucine Methyl Ester (IIIe)*—Compound IIIe was prepared as above from IIId in 11% yield, mp 165–170°C. TLC (silica, chloroform–methanol–acetic acid, 120:90:5): R_f 0.61; IR (KCl): 1740, 1690, 1678, 1655, 1550, and 1522 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 0.92 [m, 6, leucine δ-$(CH_3)_2$], 1.39 (m, 2, leucine β-CH_2), 1.58 (m, 2, tetralin 3-H), 1.82 (br s, 2, exchangeable with D_2O, NH_2), 1.92 (m, 1, leucine γ-CH), 3.01 (m, 4, tetralin 1- and 4-H), 3.38 (m, 2, phenylalanine β-CH_2), 3.70 and 3.72 (2 × s, 3, leucine OCH_3), 3.98 (m, 2, one of glycine α-CH_2's), 4.05 (m, 2, one of glycine α-CH_2's), 4.46 (m, 1, leucine α-CH), 4.82 (m, 1, phenylalanine α-CH), 6.88 (m, 1, exchangeable with D_2O, NH), 6.90–7.45 (m, 9, ArH), 7.54 (m, 1, exchangeable with D_2O, NH), 7.64 (m, 1, exchangeable with D_2O, NH), and 8.64 ppm (m, 1, exchangeable with D_2O, NH); amino acid analysis (after acidic hydrolysis): 3d 0.92, Gly 2.02, Phe 1.00, and Leu 1.12.

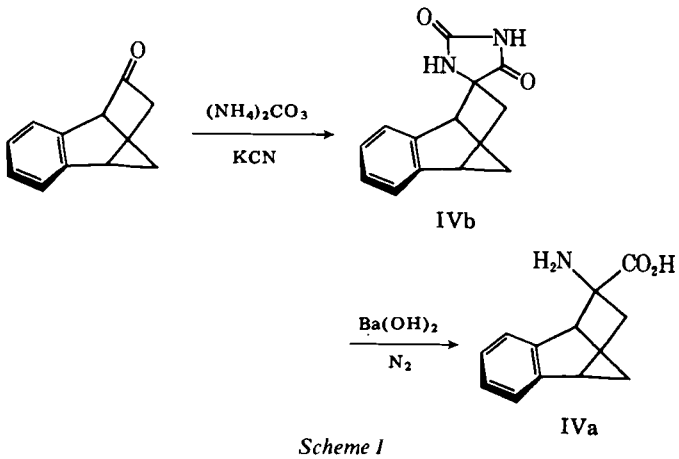
Anal.—Calc. for $C_{31}H_{41}N_5O_6 \cdot H_2O$: C, 62.3; H, 7.2; N, 11.7. Found: C, 62.8; H, 6.7; N, 11.2.

[(endo-*2-Aminobenzonorbornenyl)carbonyl*] *glycylglycyl -L- phenylalanyl-L-leucine Methyl Ester (IVe)*—This compound was prepared as above from IVd in 31% yield, mp 113–116°C. TLC (silica, chloroform–methanol–acetic acid, 120:90:5): R_f 0.78; IR (KCl): 1742, 1703, 1688, 1657, 1560, 1545, and 1520 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 0.85 [m, 6, leucine δ-$(CH_3)_2$], 1.32 (m, 2, leucine β-CH_2), 1.52 (d of d, 1, benzonorbornene C-3 *endo*-H), 1.60 (m, 1, leucine γ-CH), 1.70 (m, 2, benzonorbornene C-9 H), 1.92 (m, 2, benzonorbornene C-3 *exo*-H), 2.47 (m, 2, benzonorbornene 1- and 4-H), 3.08 (m, 2, phenylalanine β-CH_2), 3.34 (br s, 2, exchangeable with D_2O, NH_2), 3.65 (m, 3, leucine OCH_3), 3.90 (m, 2, one of glycine α-CH_2's), 4.04 (m, 2, one of glycine α-CH_2's), 4.52 (m, 1, leucine α-CH), 4.76 (m, 1, phenylalanine α-CH), 6.80–7.56 (m, 9, ArH), 7.02 (m, 1, exchangeable with D_2O, NH), 7.63 (m, 1, exchangeable with D_2O, NH), 7.77 (m, 1, exchangeable with D_2O, NH), and 8.70 ppm (m, 1, exchangeable with D_2O, NH); amino acid analysis (after acidic hydrolysis): 4d 0.91, Gly 2.4, Phe 1.00, and Leu 1.01.

Anal.—Calc. for $C_{32}H_{41}N_5O_6 \cdot H_2O$: C, 63.1; H, 7.1; N, 11.5. Found: C, 62.9; H, 7.4; N, 11.5.

Pharmacology—Compounds were evaluated for analgesic properties in albino mice (Tuck, TFW strain) by the following procedures. *In vitro* testing was carried out by measuring the inhibition of electronically stimulated contractions of the guinea pig ileum myenteric plexus muscle using the method of Kosterlitz and Watt (38) and by measuring the inhibition of mouse vas deferens tissue after stimulation with twin rectilinear pulses 10 ms apart (39). *In vivo* evaluation was carried out using the mouse hot-plate test (40).

[13] Model EF03; Edwards.



Scheme I

RESULTS

Chemistry—The amino acids IIa and IIIa were prepared by literature methods (34, 35). Synthetic routes to IVa and Va were designed based on the stereochemistry of the products that have been obtained from Strecker and Bucherer reactions on norbornane-2-one and related compounds (41–47). Reaction of benzonorbornen-2-one with ammonium carbonate and KCN afforded exclusively the expected spirohydantoin, IVb, which could be hydrolyzed with barium hydroxide to the *endo*-amino acid, IVa (Scheme I). The unequivocal structural assignment of IVa was determined from data obtained from ^{1}H- and ^{13}C-NMR spin-spin coupling data and from two-dimensional ^{1}H-NMR studies, both of which are reported by us elsewhere (48). Attempted synthesis of Va from benzonorbornen-2-one *via* a modified Strecker synthesis resulted in formation of only the *endo*-amino acid IVa (48).

The amino acids IIa, IIIa, and IVa were each *N*-protected with carbobenzoxy chloride in base and coupled with tetrapeptide VI (37) using the *N,N'*-dicyclohexylcarbodiimide-1-hydroxybenztriazole method. Hydrogenolysis of the protected pentapeptides IId, IIId, and IVd and purification of the resulting deprotected products by gradient buffer elution from carboxymethylcellulose at pH 5.1 afforded the pentapeptide methyl esters IIe, IIIe, and IVe.

Pharmacology—Compound IIe exhibited only weak analgesic properties when evaluated on electrically stimulated guinea pig ileum, showing an ID_{50} of 3.8 μm (ID_{50} values for morphine, Met enkephalin, and Leu enkephalin on the same preparation are 90.5, 86.8, and 450 nM, respectively), whereas compounds IIIe and IVe were inactive. None of the pentapeptides were active analgesics in the mouse vas deferens preparation or in the hot-plate test in mice after subcutaneous and intracerebroventricular injection.

CONCLUSIONS

This study has developed synthetic routes, based on classical solution techniques, which can be used to prepare Leu enkephalin derivatives in which the terminal tyrosine-1 residue has been replaced by a variety of conformationally restrained amino acid moieties, as represented in structures IIe, IIIe, and IVe. None of these pentapeptides possess any significant analgesic activity, both *in vitro* and *in vivo*, which is consistent with the observation that enkephalins lacking an aromatic *para*-hydroxy group in the tyrosine-1 moiety are inactive as analgesics (4, 7). The synthetic procedures developed in this study should be of value in the preparation of Leu enkephalin derivatives incorporating aromatic hydroxylated derivatives of IIa, IIIa, and IVa in place of the tyrosine-1 moiety.

Percutaneous Absorption: A New Physicochemical Predictive Model for Maximum Human *In Vivo* Penetration Rates

H. Y. ANDO [x], T. W. SCHULTZ, R. L. SCHNAARE, and E. T. SUGITA

Received December 18, 1981, from the *Department of Pharmacy, Philadelphia College of Pharmacy and Science, Philadelphia, PA 19104.* Accepted for publication February 7, 1983.

Abstract □ A diffusion model for stratum corneum-limited percutaneous absorption based on the interaction of the diffusate with the stratum corneum was derived. Two types of interactions were proposed, ion-dipole and lipid-lipid, based on current knowledge of the stratum corneum and on irreversible thermodynamic arguments. The resulting flux equations predict a linear dependence of flux on the dipole moment and ln X of the diffusates, where X is the mole fraction solubility. These flux equations were tested on 21 different diffusates whose human percutaneous absorption rates *in vivo* had been previously determined. A solubility method was used to classify the interaction pathway for each diffusate. Correlation of the maximum absorption rate for the lipid and polar pathways give correlation coefficients of 0.946 and 0.998, respectively. It is believed that these studies provide a starting point for the ultimate goal of percutaneous absorption research: to be able to bypass *in vivo* and *in vitro* studies and to predict absorption solely on the basis of the physicochemical properties of the diffusates.

Keyphrases □ Absorption, percutaneous—maximum *in vivo* penetration rates, humans, physicochemical predictive model □ Penetration rates—maximum, *in vivo* percutaneous absorption in humans, physicochemical predictive model □ Diffusion model—physicochemical, predictive, stratum corneum-limited percutaneous absorption, maximum *in vivo* penetration rates in humans

The ultimate goal of percutaneous penetration research is to predict the permeability of structurally unrelated compounds from physical properties, thereby eliminating the need for studies in humans or animals (1). Stoughton *et al.* (2) examined a series of nicotinic acid esters and correlated absorption with the oil-water partition coefficient of the molecules. Similar studies were carried out by Katz and Shaikh (3), Durrheim *et al.* (4), and Roberts *et al.* (5) for a series of corticosteroids, alcohols, and phenols, respectively. Lien and Tong (6) attempted to use multiple regression analysis to correlate absorption with steric factors, molar refraction, Taft's polar substituent constant, and molecular weight. In all of these studies, the correlation had to be limited to a series of closely related compounds. The goal of this study is to develop a model that can be used to predict human percutaneous absorption of any molecule from only its physicochemical properties.

THEORETICAL

Diffusion - In 1855, Fick (7) formulated a set of diffusion equations by direct analogy with the equations of heat conduction, which have come to be known as Fick's First and Second Laws, respectively:

$$J = -D \text{ grad } C \qquad \text{(Eq. 1)}$$

$$\partial C/\partial t = D \text{ div grad } C \qquad \text{(Eq. 2)}$$

where J is the flux in mol/cm^2/s, D is the diffusion coefficient in cm^2/s, and C is the molar concentration of the diffusate. Equations 1 and 2 only describe ideal diffusion. In most real systems, the driving force for diffusion is the gradient of the chemical potential, μ, and not the gradient of the concentration. Thus, the most general forms of the diffusion equations are (8):

$$J = -(C \cdot u/N) \text{ grad } \mu \qquad \text{(Eq. 3)}$$

$$\partial C/\partial t = \text{div } [(C \cdot u/N) \text{ grad } \mu] \qquad \text{(Eq. 4)}$$

where u is the mobility and N is Avogadro's number. Because Eqs. 2 and 4 are not invariant with respect to time inversion, one characteristic of diffusion so described is that it is an irreversible process in which chemical equilibrium is approached in such a way that free energy is minimized and entropy is maximized. Classical thermodynamics deals mainly with closed systems at equilibrium; irreversible thermodynamics copes with open systems that are not at equilibrium.

Irreversible Thermodynamics - This discipline is almost exclusively concerned with the analysis of entropy production, entropy flow, and the possible coupling of entropy production between different processes. In Fig. 1, a model irreversible system applied to percutaneous absorption is shown. System I is composed of the stratum corneum, which is generally considered the rate-limiting skin barrier for passive diffusion. System II contains system I and the applied drug, the rest of the organism, and its excretory products. In this model, system I is *open* to exchange mass with system II. The global system containing I and II is isolated.

For a continuous open system, such as system I, in which the only change in entropy is due to exchange of matter by diffusion, entropy is a function of the spatial coordinates. If s denotes entropy per unit volume for system I, then (9):

$$\partial s/\partial t = -\text{div } \Phi + \sigma \qquad \text{(Eq. 5)}$$

where Φ is the flow of entropy due to the interactions of system I with system II and σ is the entropy production per unit volume and time due to changes within system I. One of the fundamental postulates of irreversible thermodynamics is that:

$$\sigma > 0 \qquad \text{(Eq. 6)}$$

for irreversible processes like diffusion.

For a multicomponent system of γ elements with no temperature gradients, σ is given by (9):

$$\sigma = \sum_{\gamma} \sum_{i} \frac{1}{T}\left[F^i - T\frac{\partial \mu/T}{\partial x^i}\right] \rho_\gamma u_\gamma{}^i + \frac{A \cdot v}{T} \qquad \text{(Eq. 7)}$$

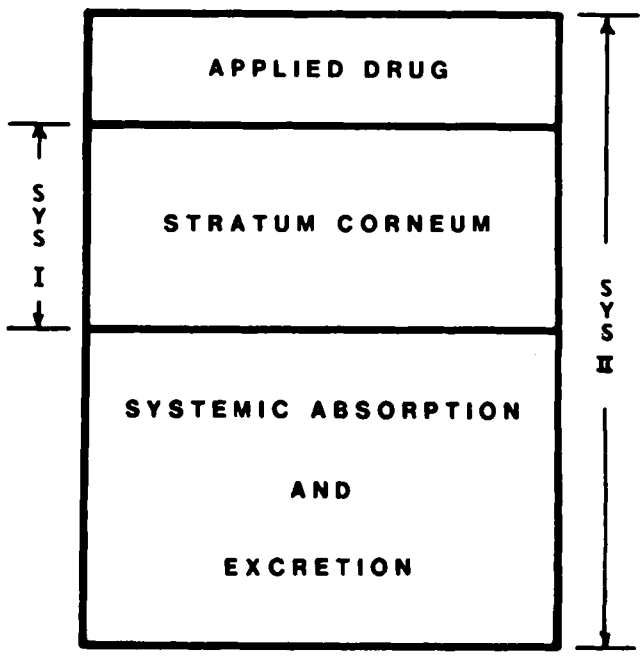

Figure 1—*A model thermodynamic system for percutaneous absorption.*

where F is the force/mass acting on the component γ; μ is the free energy/mass for the component γ; ρ_γ is the density of component γ; u_γ is the diffusion velocity of component γ; A is the affinity of chemical reaction; v is the rate of chemical reaction/unit volume; and i is the index for spacial coordinates. If consideration is limited to a two-component system in which a diffusing chemical ($\gamma = 2$) moves in the x direction through a stratum corneum ($\gamma = 1$) stationary with respect to the coordinate system, then σ becomes:

$$\sigma = (F_2 - \text{grad } \mu_2)\frac{\rho_2\Delta_2}{T} + \frac{A \cdot v}{T} \qquad \text{(Eq. 8)}$$

where Δ_2 is the diffusion velocity with respect to the velocity of the center of gravity. The first term represents the diffusion contribution to σ, the second, the chemical reaction.

When:

$$A \cdot v < 0, \textit{ i.e.}, \text{ an endothermic reaction} \qquad \text{(Eq. 9)}$$

$$A \cdot v > 0, \textit{ i.e.}, \text{ an exothermic reaction} \qquad \text{(Eq. 10)}$$

where A is the affinity of the reaction (9) and v is the rate of the reaction per unit volume. The chemical potential, μ_2, can be written as:

$$\mu_2 = \mu_2^\circ + RT \cdot ln\ \gamma_2^\circ C_2 \qquad \text{(Eq. 11)}$$

$$\mu_2 = RT \cdot \ln \gamma_2 C_2 \qquad \text{(Eq. 12)}$$

where:

$$RT \cdot \ln \gamma_2 = \mu_2^\circ + RT \cdot \ln \gamma_2^\circ \qquad \text{(Eq. 13)}$$

Using Eq. 12, we can rewrite Eq. 8 as:

$$\sigma = \sigma_d + \sigma_f + \sigma_i + \sigma_x \qquad \text{(Eq. 14)}$$

where:

$$\sigma_d = -(\rho_2\Delta_2/T)RT \text{ grad ln } C_2 \qquad \text{(Eq. 15)}$$

$$\sigma_f = (\rho_2\Delta_2 F_2)/T \qquad \text{(Eq. 16)}$$

$$\sigma_i = -(\rho_2\Delta_2/T)RT \text{ grad ln } \gamma_2 \qquad \text{(Eq. 17)}$$

$$\sigma_x = A \cdot v/T \qquad \text{(Eq. 18)}$$

Equation 14 expresses the fact that the local entropy production rate within system I can be attributed to at least four additive factors. The first factor is due to ideal diffusion as described by Fick's Law, while the third factor accounts for the interaction of the diffusate within the stratum corneum. These terms will be the subject of further discussion in the next section.

With regard to the σ_f and the σ_x terms, it is possible that under some circumstances they might be important in understanding *in vivo* percutaneous absorption. Since there is a sizable electric potential across the stratum corneum of ~−30 mV (10), certain highly polar diffusates might be affected by this force field; σ_f is the predicted manifestation of this effect. Such an effect would not be expected *in vitro* since the skin potential disappears when the animal dies. At this time, it is not clear how large or significant this effect might be. However, it was noted by Anjo *et al.* (11) that while the correlation between *in vivo* and *in vitro* penetration is good, any individual component may deviate significantly. With regard to σ_x, if a substance reacts within the stratum corneum, σ_x will be altered. There are many enzymes in the stratum corneum which might facilitate this process. This would affect σ_i and σ_d since the character of the diffusing substance would be changed.

The total entropy production rate, σ, must be positive in every macroscopic region of system I. This local formulation of the second law is the fundamental postulate of irreversible thermodynamics. This does not mean, however, that each individual term in Eq. 14 must be positive. Since the concentration gradient for passive diffusion is always negative, σ_d must always be positive. The other two terms that are of most interest are σ_i and σ_x. For σ_i, the gradient of the activity coefficient could be positive or negative; the same is true for σ_x. Therefore, the type of gradient and the kind of chemical reaction can influence whether these terms increase or decrease the total entropy production rate.

Physicochemical Predictive Model—Equation 1 has been used to confirm the passive diffusion properties of the stratum corneum (12). It implies, however, that the activity coefficient of the diffusate in the stratum corneum is unity. This is not likely. Higuchi (13) has written Eq. 1 in a form equivalent to:

$$J = -(D/\gamma) \text{ grad } a \qquad \text{(Eq. 19)}$$

where γ and a are the activity coefficient and the activity, respectively, in the stratum corneum. Although Eq. 18 formally appears more correct than Eq. 1, it is difficult to experimentally distinguish D from D/γ. This equation also assumes that grad γ is zero, *i.e.*, it is not a function of the space coordinates.

To account for the contribution of activity gradients in our model, Eq. 3 will be used as the description of diffusion in which the driving force is the gradient of the chemical potential, μ. The stationary component (stratum corneum) will be denoted by the subscript 1 in this model; the diffusate, by the subscript 2. Since Eq. 12 can be written as:

$$\mu_2 = RT \cdot \ln C_2 + RT \cdot \ln \gamma_2 \qquad \text{(Eq. 20)}$$

Eq. 3 can be written as:

$$J_2 = J_2^i - J_{21} \qquad \text{(Eq. 21)}$$

where:

$$J_2^i = -(C_2u_2/N)RT \text{ grad ln } C_2 \qquad \text{(Eq. 22)}$$

$$J_{21} = (C_2u_2/N)RT \text{ grad ln } \gamma_2 \qquad \text{(Eq. 23)}$$

and N is Avogadro's number.

Equation 21 is the fundamental equation in our model. It says that the flux of a diffusate through the stratum corneum is dependent on two terms. The first term, J_2^i, is a restatement of Fick's Law for ideal diffusion since Eq. 22 is identical to Eq. 1 where:

$$D = u_2RT/N \qquad \text{(Eq. 24)}$$

The second term, J_{21}, depends on the interaction between the stratum corneum and the diffusing molecules. This interaction is expressed in the γ_2 factor. If biological gradients exist in the stratum corneum with respect to keratin hydration of the fixed amino acid ions and with respect to lipid composition, γ_2 would be expected to be a function of the spacial coordinate in the direction of diffusion, chosen here to be x.

Polar Gradients—Consider first the interaction of the fixed ions of the amino acids in the stratum corneum keratin with *polar* diffusants: ln γ_2 can be expressed as (14):

$$\ln \gamma_2 = (A/RT)(w_{11} + w_{22} - 2w_{21}) \qquad \text{(Eq. 25)}$$

where A is constant, w_{11} and w_{22} are the cohesive energies of the stratum corneum and the diffusate, respectively, and w_{21} is the interaction energy of the stratum corneum and the diffusate.

The simplest interpretation of w_{11} and w_{22} is in terms of the solubility parameters δ_1 and δ_2 (15) where $\delta_1 = (w_{11})^{1/2}$ and $\delta_2 = (w_{22})^{1/2}$. For the lipoidal barrier model, in the absence of a gradient, the closer δ_2 matches δ_1, the faster the diffusate permeates through the membrane (16). The gradient of w_{21} accounts for a deviation from this ideality. The interpretation of δ_1 for the ion–dipole interaction could be made in terms of cross-linkings of keratin by disulfide and ϵ-(γ-glutamyl)lysine bonds (17).

If constant cohesive energies are assumed, then Eq. 23 can be written as:

$$J_{21} = -L_{21} \text{ grad } w_{21} \qquad \text{(Eq. 26)}$$

where $L_{21} = 2C_2u_2A/N$. For the percutaneous absorption, the positive x coordinate direction will be chosen as increasing from the skin surface into the deeper layers of the skin.

Water gradients in fixed-charge systems of proteins have been proposed by Ling (18, 19) as a mechanism for the selective permeability of nonelectrolytes into the cells. Such multilayer gradients can exist when fixed negative charges alternate with positive charges in a checkerboard-like arrangement of the right dimension (19). More recently, Flagg-Newton and Loewenstein (20) have argued that the directional "permselectivity" channels that they found between asymmetric cell junctions of two different cell types could only result from an interaction of the permeating species with the channel. The effects of the interaction of the stratum corneum with a diffusate in terms of irreversible thermodynamics have been discussed. For a continuous system, the total entropy production per unit volume per unit time is given by Eq. 14. The importance of activity gradients can be seen from Eq. 17.

From skin resistance data, a linear hydration gradient of the stratum corneum keratin with respect to depth has been shown to exist, the innermost layer being the most hydrated (21). Water adsorption occurs at the polarized amino acid fixed ions of the polypeptide chain in keratin, which are then surrounded by a maximum of four water molecules (22). A linear increase of the dielectric isotherm up to 8% water suggests that there is a well-defined contribution for each newly added water molecule to the total polarization. For increasing positive values of x, such a reduction of the effective charge of the z_ith ion due to increasing hydration with depth can be expressed as $Z_{ix}e = Z_ie(1 - x/b)$,

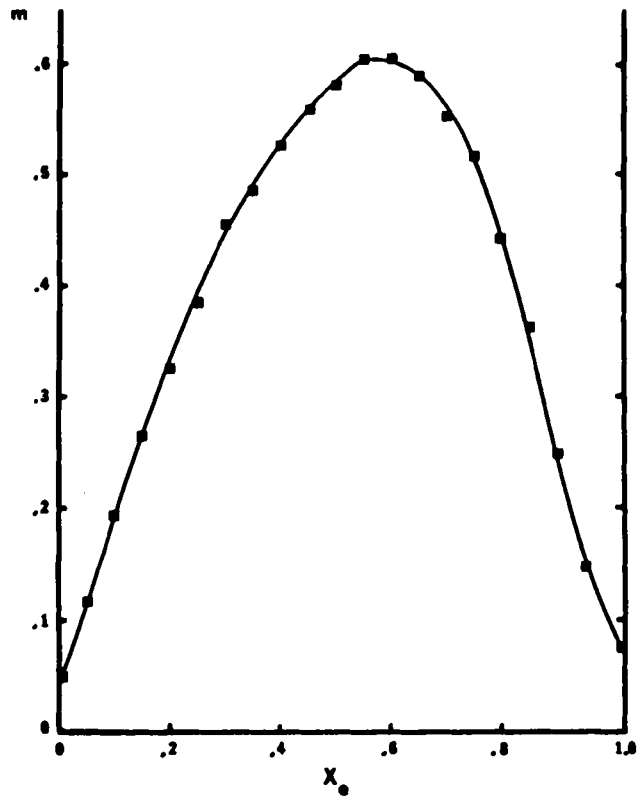

Figure 2—*Determination of the maximum solubility for cholesterol in the* n-*heptane-ethanol cosolvent system. Key:* (m) *molal solubility;* (X_e) *mole fraction ethanol.* m_{max} *occurs at* $X_e = 0.575$.

where b is the thickness of the stratum corneum. Therefore, replacing $Z_i e$ by $Z_{ix} e$ in the ion-dipole interaction energy expression (23) gives:

$$w_{21} = \sum_i (Z_i e \cos\theta\, \mu_2 / r_i^2)(1/D_s - (x/b)/D_s) \qquad \text{(Eq. 27)}$$

for $x \leq b$, where $Z_i e$ is the charge on the ions in the stratum corneum a distance r_i from the diffusate of dipole moment μ_2, D_s is the aqueous dielectric saturation value (24, 25), and b is the asymptotic value of r_i when the dielectric constant equals that of liquid water. Equation 26 can now be written as:

$$J_{21} = \Delta_p \mu_2 \qquad \text{(Eq. 28)}$$

where:

$$\Delta_p = L_{21} \sum_i (Z_i e \cos\theta)/(D_s b \cdot r_i^2) \qquad \text{(Eq. 29)}$$

Using Eq. 28, Eq. 21 can be written for ion-dipole interactions as:

$$J_2 = J_2^i - \Delta_2 \mu_2 \qquad \text{(Eq. 30)}$$

For the polar diffusing species in our study, it will be shown that a plot of J_2 *versus* μ_2 is linear.

Lipid Gradients—Recent freeze-fracture electron microscopic studies by Elias *et al.* (26) have shown that within the stratum corneum there is a gradient of lipid coalescence from the innermost layer to the surface. Odland bodies (membrane-coating granules), which are extruded into the intercellular spaces of the stratum granulosum, aggregate in the lower reaches of the stratum corneum. However, in the middle and upper reaches, all membrane-associated particles are absent. Studies with essential fatty acid-deficient mice (27) have shown that when these particles fail to coalesce into normal neutral lipid-rich sheets in the upper stratum corneum, a defective barrier results. Recent studies in humans stress the importance of these lipids as a major determinant of percutaneous absorption (28). Onken and Moyer made similar observations many years ago (29).

At this time, the exact profile of the lipid gradient is not known. However, it is likely that it will have exponential character for the following reasons. For phospholipid membranes, like the Odland bodies, the bimolecular leaflet is thermodynamically the most stable configuration (30, 31). Such membranes do not coalesce under normal conditions; according to Lucy (32), coalescence will only occur when two adjoining membranes both take on micellar character. In the micellar configuration, coalescence can occur when adjacent micelles mutually interdigitate.

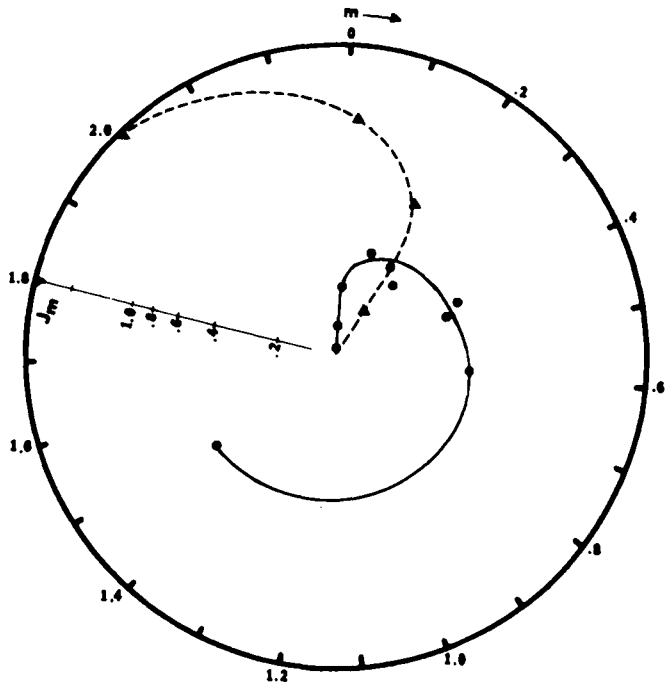

Figure 3—*Absorption patterns for proposed dipole and lipid pathway. Key:* (J_m) *maximum percutaneous absorption rate (%/h) (46);* (m) *molal solubility in the* n-*heptane-ethanol cosolvent,* $X_e = 0.575$; *(---) proposed polar pathway for* ▲ *diffusates; (—) proposed lipid pathway for* ● *diffusates.*

Certain agents cause micellar configurations in membranes, including the biologically significant lysolecithin (33). In the stratum corneum, lysolecithin is released when the phospholipase A enzymes decompose phospholipids (34). This byproduct of enzyme metabolism is an excellent detergent (35), which, because of its wedge shape, easily forms micelles (32). Studies have shown that treatment of whole cells with lysolecithin causes membrane fusion and disintegration (33). The action of phospholipase A on red blood cells (36) and rat liver cells (37) *in vitro* is the same as its action on lipid extracts, except higher concentrations of the enzyme are required for extracts (37). Evidently, surface phospholipids are more available to the enzyme. Whole cells, therefore, have a higher effective enzyme/phospholipid molar ratio. For the release of lysolecithin in the stratum corneum from the Odland bodies, this means that enzyme kinetics is most likely carried out in the linear Michaelis-Menten region. Since the release of lysolecithin would be expected to be the rate-limiting step in initiating coalescence of the Odland bodies, coalescence would be expected to have an exponential time dependence. The gradient would also be expected to have an exponential dependence, since the stratum corneum squames are shed at a uniform rate from the innermost layer to the surface (38, 39).

For diffusates with lipid-like character, interaction with the lipid stratum corneum gradient would be expected to occur through dispersion or van der Waals forces (40). Using Hildebrand's thermodynamic interpretation of such interactions in terms of solubility parameters (40), Khalil and Martin (41) have argued that permeation is optimal when the solubility parameter of the diffusate, δ_2, is as close to the solubility parameter of the lipid barrier, δ_1. Therefore, ln γ_2 in Eq. 25 would be expressed as (14):

$$-\ln \gamma_2 = (A/RT)(\delta_1 - \delta_2)^2 \qquad \text{(Eq. 31)}$$

where δ_1 and δ_2 are the solubility parameters of the barrier and the diffusate, respectively. Therefore:

$$\text{grad} \ln \gamma_2 = -(2A/RT)(\delta_1 - \delta_2)\, \text{grad}\, (\delta_1 - \delta_2) \qquad \text{(Eq. 32)}$$

From our discussion above, if the lipid gradient has the general exponential character:

$$\delta_1 - \delta_2 = E\text{-}\exp\,(g_{np} x) \qquad \text{(Eq. 33)}$$

then:

$$\text{grad} \ln \gamma_2 = 2g_{np}(A/RT)(\delta_1 - \delta_2)^2 \qquad \text{(Eq. 34)}$$

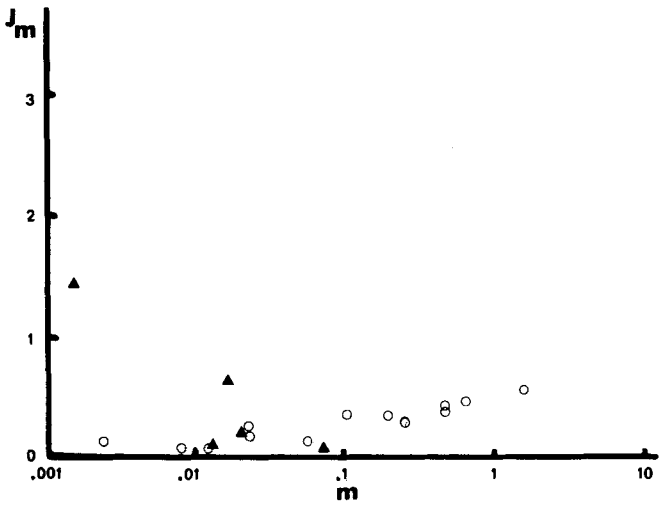

Figure 4—*Log-linear plot of absorption patterns for proposed dipole and lipid pathway. Key: (J_m) maximum percutaneous absorption rate (%/h) (46); (m) molal solubility in the* n*-heptane–ethanol cosolvent, X_e = 0.575; (▲) proposed polar pathway diffusates; (○) proposed lipid pathway diffusates.*

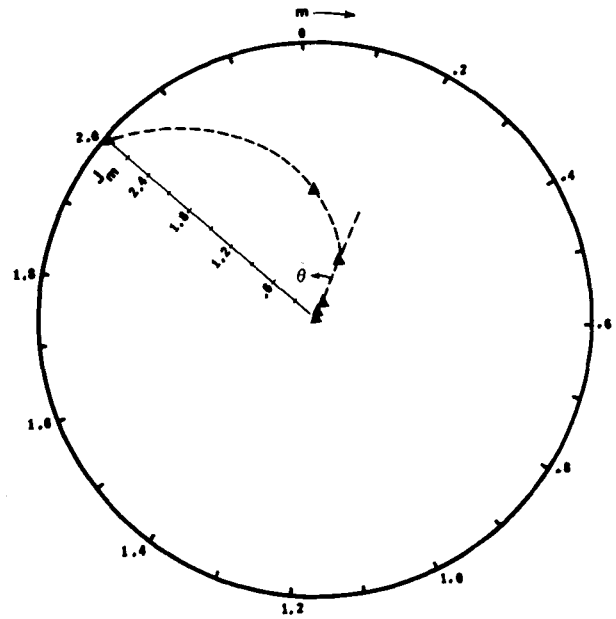

Figure 5—*Absorption pattern for proposed dipole pathway. But from regular solution theory (13):

$$(A/RT)(\delta_1 - \delta_2)^2 = ln\, X_2^i - \ln X_2 \qquad \text{(Eq. 35)}$$

where X_2^i and X_2 are the ideal and the measured solubilities of the diffusates. Therefore, Eq. 21 can be expressed as:

$$J_2 = J_2^i - \Delta_{np}(\ln X_2^i - \ln X_2) \qquad \text{(Eq. 36)}$$

where $\Delta_{np} = 2C_2u_2RTg_{np}/N_2$ and the ideal solubility, X_2^i, can be determined from (18):

$$\ln X_2^i = (\Delta H_f/RT)[(T_m - T)/T_m] \qquad \text{(Eq. 37)}$$

where ΔH_f is the molar heat of fusion of the diffusate and T_m is the melting point in degrees Kelvin. Equation 36 is the lipid–lipid interactional diffusion equation that is analogous to Eq. 30 for the polar gradient. This equation can also be expressed as:

$$J_2 = J_2^i - \frac{\Delta_{np} \cdot A}{RT}(\delta_1 - \delta_2)^2 \qquad \text{(Eq. 38)}$$

Resolution of Diffusional Pathways—In the stratum corneum, both lipid and protein interactional pathways have been hypothesized by Higuchi (13) and Scheuplein (42). The nonideal portion of Eq. 21 (Eq. 23) has, therefore, been expressed in a form which reflects such pathways. Equation 30 is based on an ion–dipole interaction, Eq. 36, on van der Waals interaction. To experimentally identify those solutes that might interact with the stratum corneum lipids by van der Waals forces during diffusion, a plot of flux *versus* the molal solubility of the diffusate in a cosolvent system in which the polarity could be varied over a wide range was proposed. Since the cholesterol/phospholipid (C/P) molar ratio increases 1700-fold from the basal layer to the stratum corneum (43) due to the near complete catabolism of the phospholipids, cholesterol was hypothesized to be the major lipid which interacts with the diffusing solutes. The proposed composition of the cosolvent, therefore, was chosen to be that in which cholesterol has a maximum solubility. At this composition, $w_{11} = w_{22}$, *i.e.* the difference in solubility parameters of the solvent and the lipid approaches zero (44, 45).

EXPERIMENTAL

Solutes—The following solutes were used as provided by the manufacturer: acetylsalicylic acid[1], androstenedione[1], benzoic acid[1], caffeine[1], corticosterone[1], cortisone[1], dehydroepiandrosterone[1], estradiol[1], hydrocortisone[1], hydrocortisone acetate[1], nicotinamide[1], *p*-aminobenzoic acid[1], progesterone[1], testosterone[1], testosterone acetate[1], testosterone propionate[1], salicylic acid[1], thiourea[1], urea[1], 17-hydroxyprogesterone[2], deoxycorticosterone[2], and cholesterol[3].

Solubility Determination—All solubility determinations were carried out in cosolvent mixtures of absolute ethanol[4] and *n*-heptane[3], which were miscible in all proportions. To obtain a saturated solution, 5 mL of solvent was added to a 7-mL liquid scintillation vial[5] containing an excess amount of solute and a 6-mm glass bead. The bead ensured good mixing of the solute and the solvent when the vials were placed on a linear reciprocating agitator[6]. A temperature of 27°C was maintained during agitation by placing a plastic heating pad[7] underneath the vial holders. Dissolution studies showed that agitation at 180 cpm for 48 h was sufficient to ensure that a saturated solution was formed for the most insoluble solute–solvent combinations: that of caffeine or thiourea in *n*-heptane. These agitation conditions, therefore, were used for all solutes.

After agitation, the vials were centrifuged in a clinical centrifuge[8] at 4000 rpm for 5 min. During this centrifugation, a hair dryer[9] was used to maintain the temperature of the vials >27°C. The vials were then allowed to equilibrate at 25°C in a water bath for 24 h before solubility determinations of the saturated supernatant were carried out gravimetrically in aluminum foil planchets[10]

RESULTS

Diffusional Pathways—The molal solubility of cholesterol in an *n*-heptane–ethanol cosolvent system is shown in Fig. 2. These data show that the maximum solubility occurs at an ethanol mole fraction (X_e) of 0.575. Since cholesterol was chosen as our model stratum corneum interactional lipid, all subsequent solubility determinations were carried out at X_e = 0.575. Such data were used, first, to discriminate the lipid and polar pathways.

In Fig. 3, the molal solubilities of the solutes that were studied are plotted as the azimuthal coordinate in a polar coordinate system. The maximum percutaneous absorption rates, J_m, for these solutes determined by Feldmann and Maibach (1, 46) are plotted as the radial coordinate on a logarithmic scale. Two distinct trends for these data are depicted by the dotted and solid lines. The dotted line describes a curve that spirals out from the origin in the positive azimuthal direction (counterclockwise) from the initial ray, m = 0.19. The solid line, on the other hand, describes a curve that spirals out from the initial ray, m = 0, in the negative azimuthal direction. In the strictest sense, these logarithmic curves are not true spirals. However, it will be shown presently that each curve, plotted with respect to a rectilinear radial coordinate, can

be represented by a modified Archimedean spiral[11] and that each spiral is consistent with one of the proposed mechanisms. Figure 4 shows how a similar pathway designation on a log-linear plot would be much more difficult to ascertain for the solid triangles. These points are the same as the triangles on the counterclockwise spiral in Fig. 3.

Polar Mechanism—In Fig. 5, J_m for the diffusates along the dotted line of Fig. 3 are plotted on a rectilinear scale. The diffusates lie on a path described by a modified Archimedean spiral:

$$J_m = J_i + a \cdot \theta \qquad \text{(Eq. 39)}$$

where the initial ray is defined by:

$$J_i = 1.1; \qquad m = 0.16 \qquad \text{(Eq. 40)}$$

θ is the angular molal increment in the positive azimuthal direction from the initial ray, and the slope a is given by:

$$a = 8.3 \qquad \text{(Eq. 41)}$$

This spiral is defined as a modified Archimedean spiral since some of the diffusates lie on the initial ray before θ evolves. Thus, for $\theta = 0$, thiourea, urea, nicotinamide, and *p*-aminobenzoic acid (from the origin outward) lie on the initial ray. For increasing values of θ (counterclockwise direction), the radial component of each diffusing species is located on the spiral by adding a times θ to J_i. Caffeine and then benzoic acid lie on the spiral as θ increases.

Figure 6 shows a plot of J_m *versus* μ_2, the dipole moment of the diffusates (47–52) in Fig. 4. The first four points agree with the linear relationship

[11] Archimedes described in his book *On Spirals* a plane spiral as the locus of points described by the polar coordinate equation $\rho = a \cdot \theta$, where θ = angular (azimuthal) coordinate and ρ = radial coordinate. Such a spiral could be formed, mechanically, in the following way. Imagine a machine that could move a pen along a straight line at a uniform rate. If the pen were placed at the center of a rotating turntable and pulled outward along this line, the curve that would be traced out on the turntable would be an Archimedean spiral. The line would be called the initial line; the center, the origin. The modified Archimedean spiral we defined spirals out from some point along the initial line rather than from the origin.

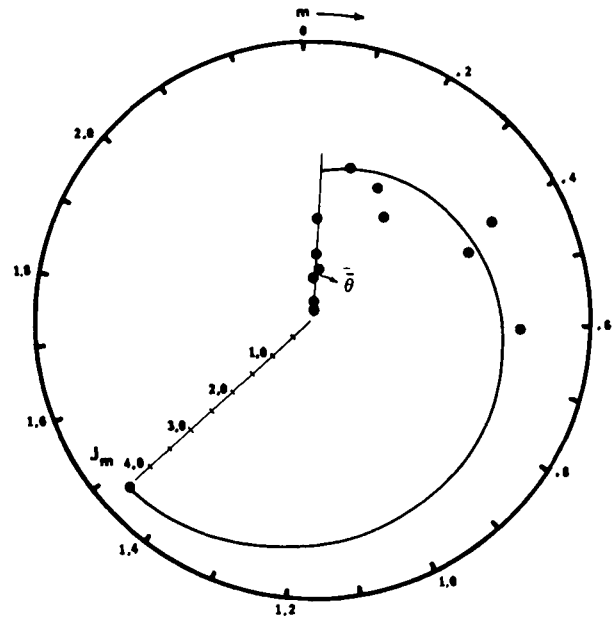

Figure 7—*Absorption pattern for proposed lipid pathway. predicted by the polar pathway of Eq. 30. The linear regression equation for J_m *versus* μ_2 is:

$$J_m = 4.25 - 1.18 \cdot \mu_2 \qquad \text{(Eq. 42)}$$

with a linear regression coefficient of −0.998. It is also evident from Fig. 6 that there is a limit beyond which further increases in the dipole moment, μ_2, cannot continue to cause a linear reduction in J_m. This, evidently, is the situation with urea and thiourea.

Nonpolar Mechanism—The data along the solid line spiral are plotted in Fig. 7 on a rectilinear radial scale. This modified Archimedean spiral can be described by:

$$J_m = J_i + a \cdot \bar{\theta} \qquad \text{(Eq. 43)}$$

where the initial ray is defined as:

$$J_i = 2.7; \qquad m = 0.3, \qquad \text{(Eq. 44)}$$

$\bar{\theta}$ is the angular molal increment in the negative azimuthal direction from the initial ray, and the slope a is given by:

$$a = 1.22 \qquad \text{(Eq. 45)}$$

Along the initial ray of this spiral, from the origin outward, are hydrocortisone, cortisone, hydrocortisone acetate, estradiol, corticosterone, and 17-hydroxyprogesterone. For increasing values of $\bar{\theta}$ (clockwise direction), androstenedione, deoxycorticosterone, progesterone, acetylsalicylic acid, testosterone, dehydroepiandrosterone, and salicylic acid are found on the spiral. In Fig. 8, J_m *versus* $-\ln X$ is plotted assuming that the nonpolar mechanism of Eq. 36 would describe this spiral, since all of the diffusates are steroids except for salicylic acid. The linear regression equation for this plot is:

$$J_m = 0.73 + (9.3 \times 10^{-2}) \cdot \ln X_2 \qquad \text{(Eq. 46)}$$

with a linear regression coefficient of −0.945.

DISCUSSION

The existence of gradients in the stratum corneum were suspected over 17 years ago. Kligman (53) argued that even though the stratum corneum appears to be a homogeneous structure from its innermost layer to its outer surface, there must be a stratification of the keratinization process within the structure, at least at the chemical level. Believing that biochemical and biophysical events of this magnitude could take place so abruptly, in Kligman's opinion, is tantamount to believing in a biological miracle. It has been only recently, however, that experimental evidence for such gradients has been

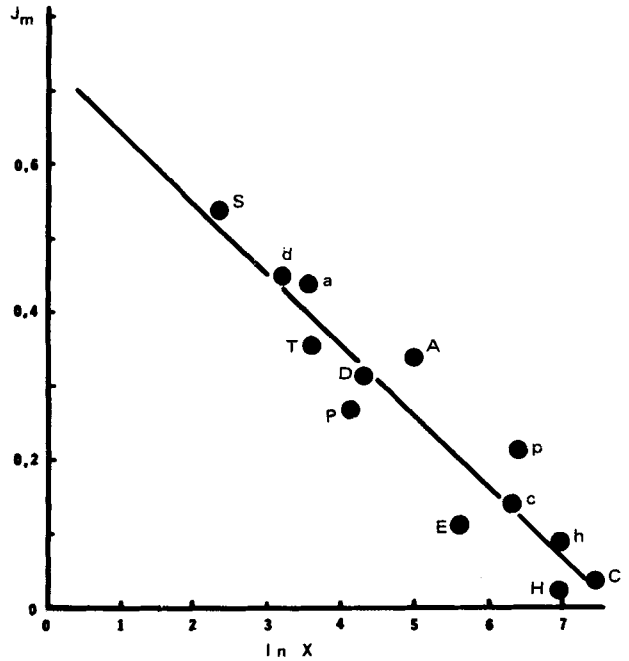

Figure 8—*Regression of ln* X versus *absorption rate. Key: (X) mole fraction solubility; (J_m) maximum absorption rate (%/h.) confirmed. Elias *et al.* (26) have demonstrated a lipid gradient of coalescence and Tagami *et al.* (21, 54), a hydration gradient of the stratum corneum keratin. Based on reasonable physical assumptions concerning the mathematical form of these gradients, a physical model predicting the dependence of solute transport through the stratum corneum on the dipole moment, μ_2, and the logarithm of the mole fraction solubility, ln X_2, have been derived.

To test this model, a solubility method, using a polar coordinate plot, has been developed to separate those diffusates that would be most affected by the lipophilicity of the stratum corneum from those that would be more affected by its ionic components. However, it is not clear what the "effective" lipophilicity of the stratum corneum might be. Most likely it is different between different animal species. This may be the reason why human penetration data often differ from animal data, even after corrections are made for the stratum corneum thickness (55).

Classically, the oil–water partition coefficient has been used as a measure of lipophilicity. The relationship of octanol–water partition coefficients to biological activity has proven to be of value in predicting quantitative structure–activity relationships (56). However, application of this approach to percutaneous absorption has not been completely successful, we believe, because lipophilicity differs from tissue to tissue depending on the relative composition of neutral to polar lipids. One reason diffusion in nervous tissue is slower than in liver tissue is because the cholesterol/phospholipid molar ratio of nerve cell plasma membranes is much higher than in liver cells. Mammalian cells appear to control membrane permeability by varying the relative amounts of cholesterol and phospholipids in their membranes (57, 58).

For these reasons, use of 1-octanol which has a solubility parameter of 10.3 and the 1-octanol–water partition coefficient may not accurately represent the lipophilicity of the stratum corneum. In these studies, an *n*-heptane–ethanol cosolvent system that spans a solubility parameter range from 7.5 to 13 was used. Since cholesterol is one of the dominant neutral lipids in the stratum corneum (59), the cosolvent composition (or solubility parameter) at which cholesterol had an optimum was chosen to represent the lipophilicity of the stratum corneum, other lipids such as ceramide not being readily available in sufficient quantities. In this sense, then, these studies should be viewed only as a first attempt to evaluate stratum corneum lipophilicity. Conceptually a distribution function, $X(\delta)$, could be determined for each compound by determining its mole fraction solubility, X, over a range of solvent polarities. Chertkoff and Martin (44) and others have shown that $X(\delta)$ will have a maximum value when δ for the solute equals δ for the cosolvent. Experimental data for these bell-shaped distribution functions could then be fitted by nonlinear regression to a mathematical function so that for each solute $X_j(\delta_i)$ for any δ_i could be generated. For a given δ_i, ln X_j for all of the diffusates in the van der Waal group could then be determined. The linear regression coefficient r_i for the regression over j of ln X *versus* the percutaneous absorption rate for the jth drug, J_j, would then be possible. δ_i could then be varied to optimize r_i. The value of δ, δ_{pa}, which corresponds to the largest value of r_i might then be designated the "effective" lipophilicity for percutaneous absorption. If such studies should come to pass, it is possible that separate δ_{pa} values for humans and animals could be determined, thus providing a quantitative parameter for human–animal correlations.

The penetration data of Feldmann and Maibach (1, 46) was used because these data represent the most complete set of human *in vivo* studies ever attempted using a common methodology and have provided the human *in vivo* comparison for most animal models (60–63). Maximum absorption rates were chosen because they are the only unique characteristics of these absorption curves, since half-lives or absorption constants could not be determined due to the sampling intervals.

A classification based on modified Archimedean spiral pattern formation was used to determine which regression expression should be used. To date, 21 different diffusates have been studied. Nineteen of these solutes correlate with one of the two mechanisms developed in the *Theoretical* section. The permeability of two solutes, testosterone acetate and testosterone propionate, cannot be explained on the basis of either mechanism. Parenthetically, these solutes were not predicted to correlate with either mechanism, *i.e.*, they did not fall on either the polar or nonpolar spirals. On the other hand, it was extremely gratifying that the percutaneous absorption of diffusates of such differing structure could be explained in terms of two physical properties.

Since the net flux in Eq. 21 is a function of the ideal flux and the interaction flux, the good correlation between the net flux and μ_2 or ln X_2 may indicate that the ideal fluxes of the different solutes within the stratum corneum are of the same order of magnitude. This would differ from diffusion in liquids, where the mobility is a function of the reciprocal of the frictional resistance, which is in turn a function of the viscosity of the media and the size of the molecule (64). In the stratum corneum, specific physical interactions may control diffusion.

Finally, this physicochemical model does not attempt to explain percutaneous absorption in terms of different structural components of the epidermis. Michaels *et al.* (65) have described one such model in which the stratum corneum is conceived of as proteinaceous bricks held together by interstitial lipid mortar. For the model developed here, only the properties of the physical components are accounted for, because it is extremely difficult to unambiguously discriminate structural pathways. On the other hand, the parameters that have been chosen are open to future verification. If on further testing, deviations from the predicted model expressions are found, an analysis can be carried out to determine whether the form of the gradient or the polarity of the solvent system that has been chosen to represent the stratum corneum can explain this deviation. In some situations, neither approach may suffice because the stratum corneum may not be rate limiting. In summary, the physicochemical model presented here is only meant to represent the current state of knowledge; it may need modifications in the future based on new evidence. It is hoped, however, that it provides a measurable framework for the future testing of its validity.

Viscosity of Xanthan Gum Solutions at Low Shear Rates

JOEL L. ZATZ ˣ and STEVEN KNAPP

Received September 3, 1982, from the *Rutgers College of Pharmacy, Piscataway, NJ 08854.* Accepted for publication November 30, 1982.

Abstract □ The viscosity of xanthan gum solutions in the low shear region was investigated with the aid of a Couette instrument. All solutions were highly pseudoplastic. Solutions containing 0.3–0.5% of the gum exhibited a highly ordered phase at very low shear. Viscosity, the degree of pseudoplasticity, and the value of the transition from soft gel to pseudoplastic behavior were directly related to gum concentration. The effect of the addition of a salt on viscosity depended on the xanthan gum concentration. The viscosity of a 0.3% xanthan gum solution was practically unaffected by the salts. Higher gum concentrations exhibited a viscosity increase when salt was present. Concentrations <0.3% exhibited a viscosity decrease in the presence of a salt. All viscosity effects seemed to reach limiting values at $\sim 10^{-3}$ to 3.3×10^{-3} *N* salt. No major differences were observed between sodium chloride, calcium chloride, and sodium citrate in their influence on xanthan gum viscosity.

Keyphrases □ Viscosity—xanthan gum in aqueous solutions, low shear rates, effect of added salts □ Xanthan gum—aqueous solutions, viscosity at low shear rates, effect of added salts □ Shear rate—low range, viscosity of xanthan gum in aqueous solutions, effect of added salts

Xanthan gum, an extracellular polysaccharide of the bacterium *Xanthamonas campestris* which was originally isolated and characterized by Jeanes and coworkers (1), has a wide variety of uses in the pharmaceutical, cosmetic, oil, and food industries. The polymer is an efficient thickening agent whose aqueous solutions are shear thinning (2, 3).

Examination of the molecular structure of xanthan gum offers insight into the basis for much of the physicochemical behavior of the substance in solution. Xanthan gum is structurally very complex. As proposed by Jansson and coworkers (4), the backbone of the molecule is a cellulose chain composed of [β(1→4)-D-glucose]. Every second residue of the chain has a β(1→3) substituted trisaccharide side chain of the [β-D-mannopyranosyl - (1→4)-α-D-glucopyranosyl-(1→2)-β-D-mannopyranoside-6-*O*-acetate] variety. Further, pyruvic acid substitution on the terminal mannose residue of the side chain (to the degree of 25–50%) has been reported and probably plays a key role in the molecular properties of xanthan gum in solution (5). The proposed structure of xanthan gum also suggests that the substituted trisaccharide side chains may lie close to the cellulose backbone at room temperature in some ordered, rod-like conformation held together loosely by short range van der Waals forces (6). At elevated temperatures, however, it has been shown, *via* NMR relaxation procedures and optical methods such as circular dichroism and optical rotation, that there is a temperature-induced rearrangement within the molecular structure of the gum (7). It has been suggested that "chain melting" occurs, and the ordered, rod-like helix may become more flexible at elevated temperatures, with the trisaccharide side chains extending outward from the cellulose backbone. This structural change may be responsible for a sudden drop in viscosity of a 1% aqueous xanthan gum solution at elevated temperature (7).

The addition of salt to a water solution of purified xanthan gum raises the temperature at which structural rearrangement takes place, as shown by optical rotation and viscosity measurements (8). Calcium chloride was effective in much lower concentrations than sodium chloride, suggesting that stabilization of the helical, rod-like confirmation was due to reduction in charge repulsion between the backbone and the side chains (8). The response of xanthan gum to variations of ionic strength is unlike that of most other polyelectrolytes. Normally, polyelectrolytes exhibit an expanded structure under conditions of low ionic strength as the result of neighboring group electrostatic charge repulsion. The addition of a salt results in a screening of the neighboring group repulsive forces and causes the molecule to collapse into a compact coil. Studies of the effects of salts on xanthan gum viscosity have produced somewhat contradictory results. In one case, the viscosity of a dilute xanthan gum solution was increased in the presence of sodium chloride (3). Another report shows a moderate decrease in viscosity under similar conditions (9), although the extent of viscosity reduction was not as pronounced as for typical polyelectrolytes. Symes (10) showed that the effect of 0.1 M KCl on xanthan gum solution viscosity depended on the gum concentration. At gum concentrations <0.25%, viscosity of aqueous solutions without added salt were higher than those containing potassium chloride. The reverse was true for solu-

tions containing >0.25% xanthan gum. The relative stability of viscosity of xanthan gum solutions to ionic strength, temperature, and pH variation (11) has been ascribed to the rod-like shape of the molecule and the importance of hydrogen bonding in intermolecular interaction (12).

In considering the application of xanthan gum as a suspending agent and emulsion stabilizer, viscosity characteristics in the very low shear region are of great importance. The only previous investigation in which very low shear viscosity was studied (2, 3) utilized a purified xanthan gum preparation. In the present study, a new instrument based on the Couette principle and capable of measurements at very low shear was utilized to investigate the rheological behavior of solutions prepared from commercial food-grade xanthan gum. The influence of several salts on solutions containing various xanthan gum concentrations was also studied.

EXPERIMENTAL

Xanthan gum[1] was utilized as received. All salts and preservatives were reagent or USP grade. Deionized water was used in the preparation of solutions.

Xanthan gum solutions (2%) containing 0.1% methylparaben and 0.03% propylparaben served as a stock preparation of the gum. Desired electrolyte

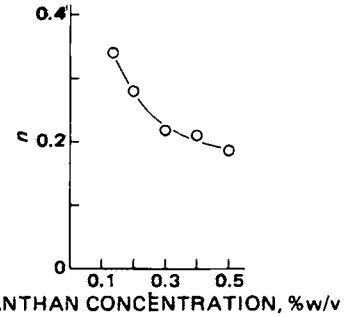

Figure 5—*Power low constant, n, as a function of xanthan gum concentration in aqueous solution.*

concentrations were obtained by dilution of 0.1 *N* stock solutions containing the parabens. Dilutions were made with deionized water containing methyl- and propylparabens. The diluted solutions were mixed using a low-torque mixer until they were homogeneous. Several samples were taken at various locations in the solution and examined rheologically to assure homogeneity of the mixed solutions. It was found that a 2-min mixing time, even at the highest concentration of xanthan gum used, was sufficient to ensure solution homogeneity.

Rheological measurements were made with a commercial instrument[2] that utilizes the Couette principle, with an air bearing to maintain the position of an inner cylinder while the outer cylinder rotates. The torque on the inner cylinder is measured. Both shear rate and shear stress are determined with high precision and plotted automatically as a flow curve (shear stress *versus* shear rate) while the properties of the sample are explored. Sensitivity and scaling factors are adjustable to cover a wide range of shear rates and material characteristics. Sample properties can be measured by increasing shear rate, decreasing shear rate, or cycling back and forth, and the time period during which these measurements are made may be selected from within a wide range.

RESULTS AND DISCUSSION

Flow curves for aqueous solutions containing three xanthan gum concentrations are presented in Fig. 1. To obtain these curves the instrument was set so that scanning of the shear rates covered (0–30 s^{-1}) took 4 min. The curve for 0.133% xanthan gum solution exhibited continuous curvature with no evidence of a yield point or discontinuity. The pseudoplastic behavior of the solution is evident. At 0.3% xanthan gum the flow curve rises steeply at first, reaches a peak, drops sharply, and then rises smoothly again. The abrupt change in slope signals a different type of behavior than that observed at lower concentrations. At shear values beyond the discontinuity, the 0.3% solution exhibits typical pseudoplastic behavior. Shear stress values for the 0.5% xanthan gum solution fall above that of the 0.3% solution, indicating that the apparent viscosity is higher at all values of shear rate. However, the flow curves for the 0.3 and 0.5% solutions are qualitatively similar.

The effect of changing the direction of shear rate change and of a second shearing cycle on the flow curve of a 0.5% xanthan gum solution are shown in Fig. 2. A complete shear cycle consists of having the shear rate increase from zero to a preset value (in this case, 3 s^{-1}) and then decrease again to zero. Arrows in Fig. 2 indicate whether a curve was generated from left to right (increasing shear rate) or right to left (decreasing shear rate). The instrument was programmed so that each complete cycle was executed during 8 min. A 1-min rest period separated the onset of the second shearing cycle (cycle 2 in Fig. 2) from completion of the initial cycle (cycle 1). The initial scan (cycle 1 going from 0 to 3 s^{-1}) was not retraced by the return curve (cycle 1 from 3 to 0 s^{-1}). Also, when the sample was sheared a second time (cycle 2) only the return curve coincided with that from the first shearing cycle. The curve generated by increasing the shear rate during cycle 2 fell between that of the initial trace in the same direction and the return curves, although closer to the latter. The behavior of 0.3% xanthan gum solutions was similar to that of the 0.5% solution, but the difference in magnitude between the various curves was smaller.

Several conclusions may be drawn from the data in Fig. 2 and similar data for 0.3% solutions:

1. Initial disturbance of a sample encounters high resistance. This is shown by the high slope found in the flow curve when shear is first applied.
2. A transition in behavior is found when the shear rate is increased to slightly higher values (but the shear rate at which this transition occurs is still quite small).

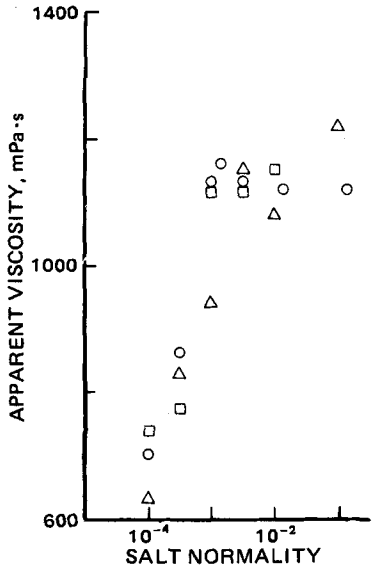

Figure 6—*Effect of various salts on the apparent viscosity of 0.5% solutions of xanthan gum at a shear rate of 3.0 s^{-1}. Key: (○) calcium chloride; (△) sodium chloride; (□) sodium citrate.*

3. Viscosity in the low shear region is dependent on the recent history of the sample. In other words, some thixotropy is evident.

Figure 3 shows results for a single shearing cycle of a 0.5% xanthan gum solution in which the low shear rates were scanned at a rate equal to 1/15 that used in the previous experiments. Comparison of the curve in Fig. 3 arising from increasing the shear rate with that of the corresponding curve for cycle 1 in Fig. 2 shows that although there are some differences in magnitude in the very low shear rate area, the same general pattern is found. After a sharp increase in shear stress, the curve in Fig. 3 peaks, drops, and then follows the pattern of a psuedoplastic material as the shear rate rises. The return curve (3 to 0 s^{-1}) in Fig. 3 does not coincide with the initial tracing. In fact it is identical to the return curves obtained at the faster scan rate (Fig. 2).

Using the same scan rate as for the work in Fig. 3, the discontinuity in the flow curve of a 0.4% xanthan gum solution was still quite marked. With a 0.3% solution it was not so sharp, but still discernable. Reducing the rate of change of the shear rate increased the extent to which the structural architecture could adjust in response to changing shear conditions. Although the difference in magnitude between the two curves that comprise a complete shear cycle was reduced at the slower scan rate, the existence of a structural change at very low shear was still evident.

The viscosity behavior of xanthan gum solutions must be described in terms of intermolecular networks formed by the extremely long, rigid, highly asymmetric polymer molecules (10). At concentrations of 0.3–0.5% (in aqueous solution), network formation results in a system that may be described as a "soft gel" which persists as long as the system is not disturbed. At extremely low shear stress, particles of gel are the unit of flow, and the resistance

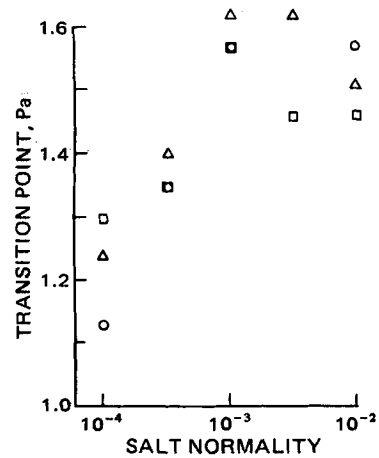

Figure 7—*Effect of various salts on the gel transition point of 0.5% solutions of xanthan gum. Key: (○) calcium chloride; (△) sodium chloride; (□) sodium citrate.*

Table I—Effect of Salts on the Apparent Viscosity of Xanthan Gum Solutions at a Shear Rate of 3.0 s^{-1}

Xanthan Gum Concentration, % w/v	Apparent Viscosity, mPa·s					
	No Added Salt	10^{-4} M NaCl	10^{-3} M NaCl	10^{-2} M NaCl	10^{-3} M $CaCl_2$	10^{-2} M $CaCl_2$
0.133	186	—	—	80	83	76
0.2	340	265	210	220	—	—
0.3	414	460	430	450	415	410
0.4	580	670	670	740	—	—
0.5	620	630	940	1080	1160	1120

to deformation is very high. After the transition point, structure within the gel particles is affected. Partial breakdown of intermolecular linkages and spatial rearrangement of the polymer molecules accounts for the pseudplastic behavior at shear rates higher than that at which the transition occurs. From the breaks in the consistency curves, the transition shear stress was estimated to be 1.1 Pa for the 0.5% solution, 0.9 Pa for the 0.4% solution, and 0.4 Pa for the 0.3% solution.

At xanthan gum concentrations >0.5%, gel strength would be expected to increase. A yield value was reported for a 1% xanthan gum solution, but not for lower concentrations (2, 3). At concentrations < ~0.3%, measurements in our laboratory failed to show a definite gel-like region and then a transition to a less-ordered state.

Apparent viscosity (shear stress/shear rate) was calculated for the xanthan gum solutions from first cycle flow curves using fresh solutions. Flow curves in which the maximum shear rate scanned was 3.0 s^{-1} were used to calculate apparent viscosity for shear rates ranging from 0.3 to 3.0 s^{-1}. All values calculated were for shear rates higher than those at which the transition from a gel state took place. Apparent viscosity for shear rates from 3.0 to 30 s^{-1} were obtained from flow curves for which the maximum shear rate setting was 30 s^{-1}. The logarithm of apparent viscosity is plotted as a function of the logarithm of shear rate in Fig. 4. These plots are linear for the 0.3 and 0.5% xanthan gum solutions; the 0.133% solution also exhibits a linear relationship except for the lowest shear rate values. The curves in Fig. 4, which follow the same general pattern as plots shown previously for other xanthan gum concentrations (2), indicate that the power law equation is applicable:

$$\eta = KD^{(n-1)}$$

where η is apparent viscosity, D is shear rate, K is the viscosity at 1 s^{-1}, and n is a constant that indicates the degree of pseudoplasticity. The minimum possible value of n, corresponding to the highest degree of pseudoplasticity, is zero (13). Values of n, calculated from the linear portion of log viscosity–log shear rate relations, are plotted as a function of xanthan gum concentration in Fig. 5. From Figs. 4 and 5, it is evident that an increase in xanthan gum concentration results in an increase in both viscosity and the degree of pseudoplasticity.

The addition of various salts to a 0.5% xanthan gum solution brought about an increase in apparent viscosity. Results for one shear rate, 3.0 s^{-1}, are shown in Fig. 6. Similar relationships were found by making comparisons at other shear rate values. The increase in viscosity reached a limiting value with increasing salt concentration, which was about the same for the three salts studied. Furthermore, the three salts appeared to be nearly equally effective. A concentration of 10^{-3} N $CaCl_2$ or NaCl brought viscosity to the plateau level. Sodium citrate required a concentration of 3.3×10^{-3} N to reach the same viscosity.

These salts also increased the magnitude of the shear stress at which the low shear transition from a gel state took place (Fig. 7). Transition points were estimated from the low shear range flow curves obtained under the same conditions as those shown in Fig. 3. The error in reading the transition points from the graphs was ~0.1 Pa. The addition of a salt increases the magnitude of shear stress at which the transition from a gel occurs, and, as with the effect on viscosity, the transition shear stress reaches a limiting value with increasing salt concentration. All salts appear to be equally effective, reaching maximal shear stress at a concentration of 10^{-3} N.

Although the most extensive salt studies were performed on 0.5% xanthan gum solutions, some data were obtained with lower gum concentrations (Table I). The dependence of apparent viscosity on salt concentration varied with the xanthan gum concentrations. In a 0.5% xanthan gum solution, the addition of a salt nearly doubled the viscosity. The viscosity of a 0.4% xanthan gum solution was also increased by salt, but to a smaller extent. The viscosity of a 0.3% xanthan gum solution was hardly affected by salt, while solutions containing ≤0.2% of the gum showed a decrease in viscosity. The decrease in viscosity was more pronounced at the lower xanthan gum concentration (0.133%). Sodium chloride and calcium chloride seemed to have equal effect on viscosity at all xanthan gum concentrations, suggesting that reduction of

intramolecular charge repulsion is not a primary factor in these salt effects on viscosity. However, interpretation of these results is complicated by the fact that xanthan gum, as supplied by the manufacturer, contains some cellular material and ions. Typically, monovalent cations, (principally sodium and potassium) amount to 3–6% (w/w) of the finished product[3]. Divalent cations, principally calcium and magnesium, make up ~0.15–0.35% by weight of the commercial polymer[3]. For the same reason, it is difficult to compare results of this study with many previous reports for which purified gum was utilized.

The utility of xanthan gum as a stabilizer of aqueous suspensions and other disperse systems is due, in part, to the pseudoplastic nature of gum solutions. At high shear the viscosity is quite low, permitting shaking, pouring, and pumping without high resistance. On the other hand, the high viscosity augmented by existence of a gel-like state at very low shear accounts for the high resistance to particle sedimentation. Viscosity, the degree of pseudoplasticity, and the value of the transition from gel-like to pseudoplastic behavior are dependent on xanthan gum concentration. The effect of addition of a salt on viscosity of xanthan gum solutions is complex. A 0.3% xanthan gum solution exhibits negligible viscosity changes when a salt is added. Higher concentrations of xanthan gum show increased viscosity, and lower xanthan gum concentrations undergo a reduction in viscosity. All of these effects seem to reach limiting values at $\sim 10^{-3}$ *N* to 3.3×10^{-3} *N* salt concentration. Based on the small number of salts studied, viscosity changes appear to be independent of the salt. However, certain ions in particular pH ranges exhibit more specific effects on viscosity (11).

Syntheses and Evaluation of Some Mannich Bases Derived from Acetophenones Against P388 Lymphocytic Leukemia and Toxicological Assessment of 3-Dimethylamino-2-dimethylaminomethyl-1-(4-methoxyphenyl)-1-Propanone Dihydrochloride in Rats

J. R. DIMMOCK *[x], K. SHYAM *, B. M. LOGAN *, P. J. SMITH [‡], and B. M. CROSS [§]

Received September 7, 1982, from the **College of Pharmacy*, [‡]*Department of Chemistry, College of Arts and Science* and [§]*Department of Veterinary Pathology, Western College of Veterinary Medicine, University of Saskatchewan, Saskatoon, Saskatchewan S7N 0W0 Canada.* Accepted for publication January 18, 1983.

Abstract □ A number of analogues of 3-dimethylamino-2-dimethylaminomethyl-1-(4-methoxyphenyl)-1-propanone dihydrochloride (IIa) and related compounds which showed activity against P388 lymphocytic leukemia were prepared, and of the 16 analogues, three met the criterion for activity in this screen. The toxicity of IIa was examined in rats and either a single dose of 25 mg/kg or nine daily doses of 12.5 mg/kg administered by the intraperitoneal route produced marked irritation and damage to the tissue with which it came into contact. Compound IIa did not show significant activity against eight other tumor systems.

Keyphrases □ Mannich bases—derived from acetophenones, antileukemic activity in the P388 screen, toxicological assessment in rats □ Antileukemic agents—potential, Mannich bases derived from acetophenones, P388 screen, toxicological assessment in rats □ 3-Dimethylamino-2-dimethylaminomethyl-1-(4-methoxyphenyl)-1-propanone dihydrochloride—synthesis, antileukemic activity in the P388 screen, toxicological assessment in rats

A number of Mannich bases have been synthesized and evaluated against murine P388 lymphocytic leukemia (1–3). Under certain conditions, Mannich bases undergo elimination leading to the formation of the corresponding α,β-unsaturated ketones (4, 5), which have a marked affinity for nucleophiles (6, 7). This property may account for certain of the biological properties of Mannich bases (8, 9).

Series I was recently evaluated against P388 leukemia in mice and shown to be inactive (10). However, if a second dimethylaminomethyl group is inserted into the molecule, as in IIa, the deamination product would retain a dimethylaminomethyl function attached to the olefinic carbon atom α to the carbonyl group. Since, on occasions, the pH of tumor cells has been claimed to be more acidic than normal cells (11–13), deamination of IIa could give rise, possibly preferentially in malignant tissue, to a compound bearing a protonated nitrogen atom. Hence nucleophilic attack by cellular macromolecules would be enhanced since the intermediate formed as a result of Michael addition would be stabilized by two electron-withdrawing functions, namely the carbonyl group and the positively charged nitrogen atom.

A representative compound, IIa, was synthesized and shown to increase the median survival time in mice with P388 lymphocytic leukemia by 28 and 24% at dose levels of 25 and 12.5 mg/kg, respectively. A comparison of the bioactivities of IIb–f

A number of Mannich bases have been synthesized and evaluated against murine P388 lymphocytic leukemia (1–3). Under certain conditions, Mannich bases undergo elimination leading to the formation of the corresponding α,β-unsaturated ketones (4, 5), which have a marked affinity for nucleophiles (6, 7). This property may account for certain of the biological properties of Mannich bases (8, 9).

Series I was recently evaluated against P388 leukemia in mice and shown to be inactive (10). However, if a second dimethylaminomethyl group is inserted into the molecule, as in IIa, the deamination product would retain a dimethylaminomethyl function attached to the olefinic carbon atom α to the carbonyl group. Since, on occasions, the pH of tumor cells has been claimed to be more acidic than normal cells (11–13), deamination of IIa could give rise, possibly preferentially in malignant tissue, to a compound bearing a protonated nitrogen atom. Hence nucleophilic attack by cellular macromolecules would be enhanced since the intermediate formed as a result of Michael addition would be stabilized by two electron-withdrawing functions, namely the carbonyl group and the positively charged nitrogen atom.

A representative compound, IIa, was synthesized and shown to increase the median survival time in mice with P388 lymphocytic leukemia by 28 and 24% at dose levels of 25 and 12.5 mg/kg, respectively. A comparison of the bioactivities of IIb–f

© 1984, American Pharmaceutical Association

with Ia–e was made in order to explore the generality of this molecular modification on antileukemic activity. It was found that IIb–f increased the median survival time by 36, 38, 17, 16, and 8%, respectively, and this gradation in biological activity followed, in general, the values of the Hammett σ constants of −0.27, −0.17, 0.00, 0.23, and 0.60 for the nuclear substituents of IIb–f, respectively (10). The stabilities of representative compounds in I and II which possessed extremes of Hammett σ values (Ia,e and IIb,f) were examined under simulated physiological conditions (phosphate buffer, pH 7.4, at 37°C). While I was stable for at least 1.5 h, IIb and f broke down to the corresponding olefinic ketones at rates which seemed to suggest that elimination was favored by electron-withdrawing substituents on the aromatic ring. It was considered possible that an optimal rate of breakdown was associated with anticancer activity, *i.e.*, if decomposition was too rapid (as in the case of IIf), then the α,β-unsaturated ketone generated was sequestered prior to interaction with leukemia cells, whereas if it was too slow or even refractory to deamination (as suggested by the data for I), there would be insufficient α,β-unsaturated ketone present for presumed nucleophilic attack.

The aims of the present investigation were twofold. First, since the promising lead compounds IIa–c possessed nuclear methoxyl and methyl groups with Hammett σ values of $\sim$−0.2, it was proposed to synthesize III, which principally contained these groups and in which the Hammett σ value for the substituents on the aromatic ring for IIIa–f were +0.12, −0.15, −0.03, −0.37, −0.07, and −0.24, respectively. Thus, the rate of release of the α,β-unsaturated ketone would be expected to vary, and the validity of the rate of breakdown of III with antileukemic activity could be explored further. However, the rate of release of the conjugated styryl ketones *in vivo* could also be influenced by the pK_a of the basic group and, hence, the preparation of IV was envisaged. The pK_a values for dimethylamine, pyrrolidine, piperidine, morpholine, and trimethylamine are 10.77, 11.27, 11.22, 8.70, and 9.80, respectively (14), and thus the rate of decomposition predicted is IVd > IVe > IVa > IVb,c. Since the dibasic compounds in II were, in general, more active *versus* P388 lymphocytic leukemia than I, a comparison of the antineoplastic activities of III and IV with the monobasic derivatives V and VI was deemed profitable to shed more light on the generality of this observation. Second, IIa has been designated a Selected Agent Compound by the National Cancer Institute, and it seemed of importance, therefore, to explore the toxicity of IIa in order to further evaluate its potential as a candidate anticancer drug.

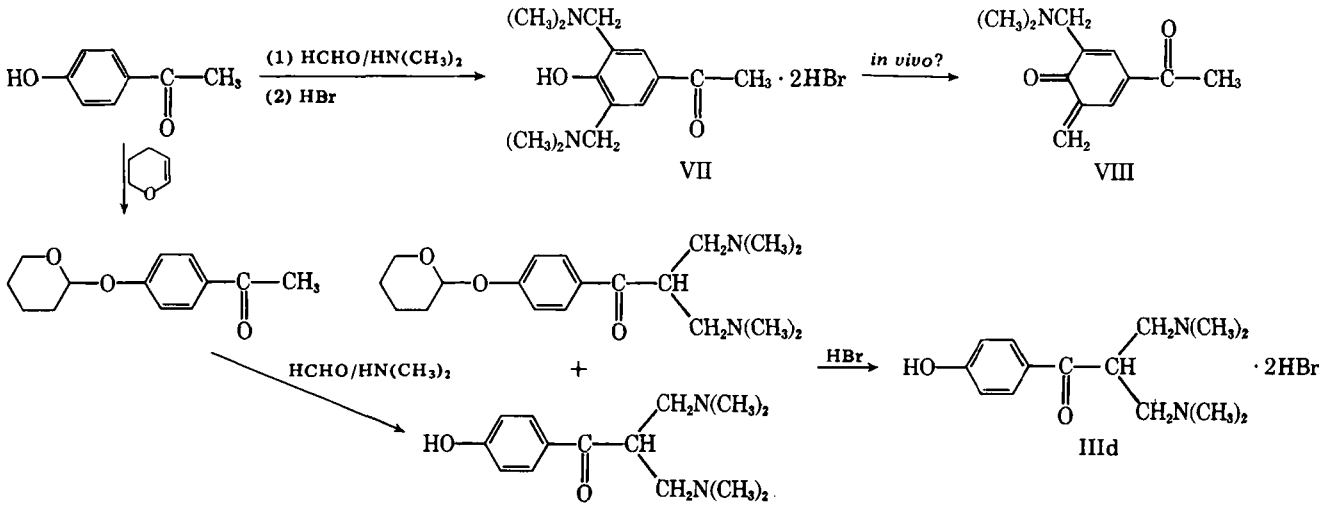
RESULTS AND DISCUSSION

Compounds IIa, IIIa–c, e, f, and IVb–d were prepared by treating acetophenone or a substituted acetophenone with an excess of formaldehyde and amine and converting the products into the corresponding dihydrohalide salts. Utilization of this general procedure in attempting to prepare IIId gave rise to the nuclear bis(aminomethyl) product, VII (Scheme I). To obtain exclusively side chain aminomethylation, the nuclear hydroxyl group of *p*-hydroxyacetophenone was protected by a tetrahydropyranyl function (15), and TLC of the product of a Mannich reaction with this ketone showed a mixture of diamines was formed in which both protected and free hydroxyl groups were present. The mixture was then treated with hydrogen bromide to give the desired product IIId (Scheme I).

The mass spectrum of this compound was of interest insofar as the base peak



Scheme I

differed from four related compounds IIb and d–f, although common fragmentation pathways were found in all five compounds (Table I; Scheme II). The peak due to the dimethyl(methylene)ammonium ion (f, *m/z* 58) is the base peak except for IIId, in which case it is the acylium ion (g) *m/z* 121. Stabilization of the positive charge in the acylium ion by the powerful electron-releasing mesomeric effect of the hydroxyl group ($\sigma_p^+ = -0.85$) (16) could account for this phenomenon (Scheme III). It is of interest to note that a major ion in the fragmentation pattern of IIb is *m/z* 135, due to the related *p*-methoxy acylium ion. Other observations of interest from Scheme II are as follows.

1. The radical ion of the free diamine (a) which could be formed is absent in all five cases. On the other hand, each spectrum shows peaks of equal intensity at *m/z* 80 and 82 due to $[HBr]^+$ and also at *m/z* 79 and 81 due to Br^+.

2. The peak due to the radical ion of 1-aryl-2-dimethylaminomethyl-2-propen-1-one (b), which could arise from loss of dimethylamine from a, is also absent. This pathway, however, cannot be ruled out since the data obtained suggest that ion b is formed, but is of low intensity because of its fragmentation to give c, *m/z* 84.

3. The carbocation (d) may account for the peak having the highest mass-charge ratio in each case. Homolytic fission of the bond γ to the carbonyl function in d gives the radical ion of the acrylophenone (e).

Compound IVa was prepared by Mannich condensation of Ic with pyrrolidine and formaldehyde, and quaternization of the free base of IId and Ic with methyl bromide gave IVe and VId, respectively. The remaining compounds in series V and VI were prepared essentially by the method of Maxwell (17). The physical data of IIa and III–VII and the efficacy of most of the compounds against P388 lymphocytic leukemia are given in Table II.

Compounds IIIb, d, and f, like the active diamines IIb and c, have nuclear substituents with an average Hammett σ value of ~−0.25, and both IIIb and f are active against P388 lymphocytic leukemia while IIId possesses marginal activity. It is conceivable that facile *O*-glucuronidation minimizes the antileukemic efficacy of IIId. The remaining three compounds IIIa, c, and e, with an average nuclear Hammett σ value of 0.02, were inactive. There was slightly higher activity in the case of IIIa, d, and e (average T/C% = 115) than with their monobasic counterparts Va–c (average T/C% = 105). No correlation between the predicted ease of breakdown in series IV with anticancer activity was apparent, and compounds VIa, b, and d were inactive. However, two

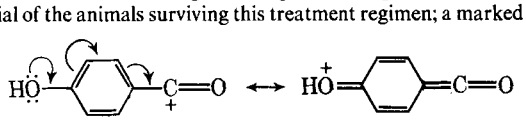
compounds (IVa and d) increased the median survival time in mice with P388 lymphocytic leukemia by ~20%. It was hoped that VII would give rise to the *ortho* quinone VIII *in vivo* (Scheme I), but the lack of both antineoplastic activity and marked murine toxicity suggested that this pathway did not materialize. The screening results observed in this study reveal a continuation of a trend observed earlier (10) that, in general, higher anticancer activity is found among dibasic derivatives of substituted acetophenones than with the corresponding monobasic analogues.

The second phase of this investigation was to examine the disposition of IIa. As mentioned earlier, significant antineoplastic activity was found at dose levels of 12.5 and 25 mg/kg. During the first trial with IIa, a single 12.5-mg/kg ip injection was administered to rats. Three test and one control rats were killed 2, 4, 6, 8, 10, and 15 d postinjection. During the second trial, three rats were given a single 25-mg/kg injection of IIa. The rats were closely observed, and one rat was killed 5, and two others at 30, and 48 h postinjection, Following this, a single 12.5-mg/kg injection of IIa was repeated in three animals. One of the test rats and one control were killed 24, 48, and 84 after the injection. In the final trial, it was proposed to give nine daily injections of IIa (12.5 mg/kg) to nine rats and to examine the animals 3, 8, and 15 after the ninth injection.

The results obtained were as follows. On both occasions a single 12.5-mg/kg injection of IIa produced no gross or microscopic lesions in the rats. After the single 25-mg/kg injection of IIa, the rats appeared very depressed, were reluctant to move and were "hunched over." One rat (no. 1) was killed 5 h after injection. Twenty-four hours after injection, the remaining rats (nos. 2 and 3) were depressed and reluctant to move. Porphyrin stained the forelimbs, faces, and heads; the hair coats were rough and spiky. The abdomen of one animal was tense and contracted.

At necropsy, all three rats were observed to have hydroperitoneum. The proximal intestine was flaccid, dilated, and fluid filled. The contents of the distal jejunum, ileum, and large intestine were very dry. Numerous white opaque areas of coagulation necrosis and saponification were scattered throughout the abdominal fat and the fat associated with the spermatic cords in rats 2 and 3. The cecal wall of rat 1 was edematous and contained a perforated ulcer at the distal end. Microscopic examination revealed interlobular pancreatic edema and edema of the colonic muscularis. Rat 2 was killed 30 h after the injection. Opaque areas present in the pancreas represented acute necrosis of the peripheral lobules. The subserosal longitudinal muscle of the stomach, small intestine, and colon had also undergone acute necrosis. The myonecrosis ranged from focal to diffuse; in places it extended through the circular muscle into the submucosa and was accompanied by hemorrhage. The walls of the seminal vesicles and coagulating glands were similarly affected, with the necrosis extended through the entire wall in areas. Rat 3 was killed 48 h after injection. A fibrinous peritonitis was present with fibrinous adhesions joining the liver to the diaphragm and the pancreas to the stomach, and fibrin coated the seminal vesicles, coagulating glands, and the mesentery. Petechial hemorrhages were visible on the serosa of the cecum, colon, and rectum. The histopathological lesions were similar to those of rat 2. The necrosis and hemorrhage in the wall of the stomach and intestine were more diffuse and often extended into the lamina propria. Small ulcers were present in the squamous portion of the stomach.

Table III indicates the changes in weight resulting from the multiple-injection trial of the animals surviving this treatment regimen; a marked weight



Scheme III

Table II—Physical Data on the Mannich Bases IIa and III–VII and Activity Against P388 Lymphocytic Leukemia in Mice

Compound	Yield, %	Melting Point, °C	Formula[a]	Maximum C%[b]	Toxicity in mice[c]
IIa	31	175–177	$C_{15}H_{26}Cl_2N_2O_2$	128(25)	0/6(100), 2/6(50), 6/6(25)
IIIa	21	161–163	$C_{15}H_{26}Cl_2N_2O_2$	114(12.5)	0/6(50), 6/6(25)

[a] Elemental analyses for C, H, and N were conducted for all compounds. Unless otherwise noted, all values were within ±0.4% of the theoretical values. [b] Ratios of the survival time of the treated (T) to control (C) animals expressed as a percentage. Compounds were initially screened at 200, 100, and 50 mg/kg; if mortalities occurred at these doses, they were reduced to nonlethal levels. A compound should increase the median survival time by at least 20% to be considered active. The dose in mg/kg is in parentheses. [c] Numbers of survivors 5 d after commencement of the dosage schedule of nine daily doses, except for IIIb–f, IVb, IVe (50-mg/kg dose), and VII in which cases five daily doses were administered. [d] Calc. for C, 40.79; found, 39.96. [e] Calc. for C, 48.23; found 47.77. [f] Calc. for C, 45.30; found 44.88. [g] Lit. (18) mp 197.0–197.5°C. [h] Lit. (19) mp 189.5–190.5°C. [i] Lit. (20) mp 238°C.

loss was observed after completing the injection schedule, although 15 d after the last injection, some weight gain was noted (rats 5 and 6).

Four animals (nos. 4 and 7–9) died before the termination of the multiple-injection trial. Porphyrin staining of the faces was marked in all the rats. Necropsy revealed mild hydroperitoneum, a dilated fluid-filled proximal small intestine, and a large intestine filled with dry ingesta. Rat 7 was killed after it had received its second 12.5-mg/kg injection of IIa. The animal was very quiet, reluctant to move, had a tense contracted abdomen and a spiky coat. Histopathological examination revealed acute degeneration and necrosis of the subcapsular muscle fibers of the seminal vesicles with infiltration by granulocytes. The bladder wall was edematous, and the subserosal myofibers had undergone acute necrosis. The intestinal serosal mesothelium was hypertrophied.

A second rat (no. 8) died after it had received its second injection. In addition to those necropsy findings previously mentioned, all serosal blood vessels were very congested. Areas of necrosis were scattered throughout the abdominal fat and the fat associated with the reproductive organs. Numerous small ulcers extended into the submucosa of the squamous stomach. Throughout the intestine and bladder there was necrosis of subserosal muscle. Fibers were eosinophilic and shrunken. Nuclei were absent, pycnotic, and karyorrhectic. Peripheral pancreatic acini had undergone acute necrosis, and granulocytes had infiltrated the affected areas.

A third test rat (no. 9) died after receiving its fifth injection of IIa. Hematuria had been reported on the previous day. In addition to heavy porphyrin staining of the face and forepaws, blood stained the fur around the prepuce.

Table III—Weight Changes of Male Wistar Rats after Intraperitoneal Injection of IIa and Saline for Nine Consecutive Days

Rat[a]	Day 1	Day 2	Day 3	Day 4	Day 5	Day 6	Day 7	Day 8	Day 9	Weight Difference Between Days 1 and 9, g	Weight, g Day 12	Day 17	Day 24	Weight Difference Between Day 1 Day of Examination, g
1	350	340	330	325	320	305	290	300	295	−55	295			−55

Control 3	355	340	330	315	320	335	340	345	340	−15			375	+20

[a] Rats 1-9 were injected with IIa at 12.5 mg/kg, while controls 1-3 were injected with 0.9% NaCl (saline). [b] Rat 4 died on Day 14. [c] Rat 7 was killed after receiving a second injection. [d] Rat 8 died after receiving a second injection. [e] Rat 9 died after a fifth injection.

The fluid contained in the stomach, duodenum, and jejunum was blood stained. There were areas of hemorrhage and necrosis in the pancreas, circular hemorrhages in the cecal mucosa, and blood in the urinary bladder. Histopathological examination revealed an acute diffuse peritonitis, characterized by the presence of fibrin and granulocytes on the intestinal serosa and in the connective tissue and fat associated with the seminal vesicles, coagulating glands, and the right spermatic cord. The duodenal serosa was coated with granulocytes, which extended through the edematous muscularis in some areas to the submucosa. Acute myonecrosis was noted in the duodenal wall. Similar lesions were scattered throughout the wall of the intestine and bladder. An ulcerative cystitis consisted of areas of mucosal necrosis, granulocyte infiltration into an edematous submucosa, and necrosis of single mucosal cells which sloughed into a blood-filled lumen.

The fourth animal (no. 4) died 5 d after the ninth injection of IIa. The animal was autolyzed; however, a large area of necrosis bounded by hemorrhage was noticed in the right inguinal subcutis and body wall.

Two test animals (nos. 1 and 2) and one control (no. 1) were killed 3 d after the ninth injection. One of the test animals was lame in the right hind limb. In both test animals, fibrous adhesions joined large areas of the subcutaneous tissue and body wall in the right inguinal region. In each rat, an area of necrosis, 1-1.5 cm in diameter, in the body wall was bounded by a distinct red line; grossly, the viscera appeared normal. The coagulation necrosis extended through the body wall to the peritoneum. Many of the necrotic muscle fibers were calcified. Granulation tissue has replaced much of the necrotic tissue, and muscle fibers bordering the areas of necrosis showed signs of regeneration with very long, plump nuclei and multinucleate areas. The necrotic subcutaneous fat had been replaced with granulation tissue. In the intestine and bladder, areas of the serosa and outermost muscularis had been replaced by regenerating muscle fibers, fibroblasts, and capillaries. The orientation of the regenerating fibers was irregular. Areas of mesenteric fat necrosis had been replaced by granulation tissue and lymphocytes.

One rat (no. 3) was killed 8 d after the last injection. This rat was also lame in the right hind limb. During necropsy, a large area of necrosis was found in the subcutis of the right inguinal area. A severe chronic peritonitis was present; all intestine loops were tightly adhered to each other, the bladder, seminal vesicles, and sublumbar musculature. The intestines were dilated and contained fluid. Normal fecal pellets were present in the rectum. Areas of the intestinal wall were thickened; however, the intestine was patent although the lumen was greatly reduced. A mass 1.5 cm in diameter occupied a position in the dorsal body wall midway between the right kidney and the bladder. The mass had a fibrous wall, was filled with clear fluid, and involved the right ureter and sublumbar muscles. The right ureter proximal to the mass was dilated with clear fluid. There was hydronephrosis of an enlarged right kidney. The right seminal vesicle was shrunken; atrophy of the right testis was seen during microscopic examination. Few spermatogonia were present in the seminal tubules; however, spermatozoa were present in the epididymal tubules. The walls of the intestines, seminal vesicles, and coagulating glands were thickened with a layer of granulation tissue. Areas of abdominal fat necrosis had been walled off with fibrous tissue; many of these areas had calcified. Fibrous tissue thickened the pancreatic capsule and extended between acini. Gastric ulcers extended into the muscularis mucosa. Beneath the ulcers, the muscularis and submucosa were infiltrated by fibroblasts, angioblasts, and numerous eosinophils. The medulla of the right kidney was compressed, and there was perivascular and cortical edema.

The thick fibrous wall of the fluid-filled mass extended into the adipose tissue and the muscles of the dorsal abdominal wall. It surrounded blood vessels, nerves, and sublumbar lymph nodes. Areas of mineralizing necrotic muscle were present in the mass; lymphocytes and multinucleate giant cells were prominently associated with these areas. Thrombosed blood vessels and areas of fat necrosis were also trapped in the mass. The central cavity appeared to be lined by fibroblasts.

The last two test animals (nos. 5 and 6) were sacrificed 15 d after the ninth injection. Hematuria had been reported in one of these animals after the eighth and ninth injections. Diarrhea was reported at the same time for the other rat. An ulcer 1 cm long was present in one animal in the skin fold between the right stifle and right inguinal area. Further examination revealed ulceration, necrosis, and replacement with granulation tissue that extended through the dermis and subcutis and into the body wall. Fibrous adhesions between abdominal viscera were extensive in both rats; adhesions trapped the right testes, epididymes, and spermatic cords in the scrotal sacs. The right testis from one rat was extremely small and lacked spermatogonia. The seminal vesicles and bladder were adhered together. Areas of necrotic seminal vesicle had undergone mineralization. Epididymal fibrosis was prominent in the rat no. 6; no spermatozoa were present in the epididymal or seminal tubules. Large numbers of abnormal cells, including multinucleate giant cells, were present in the seminal tubules. Sertoli cells were very prominent.

One may summarize these disposition studies by noting that when the rats received a single 25-mg/kg injection of IIa, it appeared that any portion of the abdominal viscera coming into contact with the substance underwent necrosis. Adynamic ileus, produced by peritonitis and pain, resulted in a large volume of fluid pooling in the anterior intestine and probably caused severe electrolyte imbalance. Acute gastric ulceration was probably also a manifestation of the stress produced by abdominal pain. Although a single dose of 12.5 mg/kg produced no gross or light microscopic lesions, nine daily doses at the same level resulted in severe myonecrosis and peritonitis. Throughout the series of injections, the rats exhibited behavioral manifestations of stress and pain and lost a significant amount of weight. After cessation of injections there was tissue healing; however, the permanent damage produced would interfere with intestinal, reproductive, and (in one instance) renal function. It must be concluded that the compound, at a single 25-mg/kg dose or a series of 12.5-mg/kg doses, is very irritating and severely damages any tissue with which it comes into contact.

Finally, the screening of the Selected Agent Compound IIa *versus* a number of tumors (21) was undertaken (Table IV). In tumor systems 3-8 inclusive, IIa was inactive and although some reduction in tumor weight was found in the colon and lung xenografts, it was insufficient to meet the criteria for activity.

EXPERIMENTAL

Melting points are uncorrected. Elemental analyses were undertaken locally[1], and organic extracts were dried with anhydrous magnesium sulfate. TLC was carried out using sheets of silica gel with fluorescent indicator[2] and a solvent mixture of toluene–methanol (9:1). Mass spectra[3] were run at 70 eV, and the 60-MHz NMR spectra[4] were determined in deuterochloroform or deuterium oxide using internal standards of tetramethylsilane and sodium 2,2-dimethyl-2-silapentane-5-sulfonate, respectively.

Syntheses of Compounds—*1-Aryl-3-dimethylamino-2-dimethylamino-*

Table IV—Evaluation of IIa Against Various Tumors in Mice

Tumor	Treatment Schedule	Maximum T/C%[a]	Toxicity[b]
CX-1 Colon xenograft	Four daily injections	38(25)	0/6(100), 3/6(50), 6/6(25)
LX-1 Lung xenograft	One injection every 4 d; total of three injections	64(50)	0/6(100), 6/6(50)
MX-1 Breast xenograft	One injection every 4 d; total of four injections	101(12.5)	0/6(100), 5/6(50), 6/6(25)
$CD8F_1$ Mammary tumor	One injection	103(7.81)	1/10(125), 3/10(62.5), 10/10(31.25)
Colon 38	One injection every 7 d; total of two injections	102(25)	0/10(100), 1/10(50), 10/10(25)
B16 Melanocarcinoma	Nine daily injections	102(25)	0/10(50), 10/10(25)
L 1210 Lymphoid leukemia	Nine daily injections	110(25)	1/6(50), 6/6(25)
Lewis lung carcinoma	Nine daily injections	105(12.5)	1/10(50), 10/10(25)
P388 Lymphocytic leukemia	Nine daily injections	128(25)	0/6(100), 2/6(50), 6/6(25)

[a] Figures for tumors 1–5 are the weight differences of the treated animals compared with controls expressed as a percentage. A value of <20 for the first four tumors indicates activity; values of <42 in the case of the colon 38 tumor are considered active. The figures for tumors 6–9 are the ratios of the median survival time of treated animals compared with controls expressed as a percentage. A compound should increase the survival time by 25, 25, 40, and 20%, respectively, to be considered active. Doses in mg/kg are in parentheses. [b] At day 5; doses are in parentheses.

methyl-1-propanone Dihydrohalides (*IIa*, *IIIa–c,e,f*)—A mixture of the substituted acetophenone (0.05 mol), aqueous solutions of formaldehyde (37% w/v, 0.15 mol) and dimethylamine (25% w/v, 0.15 mol), and ethanol (25 mL) was heated under reflux for 3 h (IIa, IIIa,e), 24 h (IIIb,f), or 30 h (IIIc). The solvent was removed *in vacuo*, and the mixture was extracted with ether (3 × 20 mL). The combined ethereal extracts were washed with water, dried, and then the solvent was removed under reduced pressure to give the Mannich base, which was dissolved in acetone and treated with either hydrogen chloride or hydrogen bromide. The colorless solid which precipitated was removed by filtration, dried, and recrystallized from methanol to give the desired Mannich base salts.

3-Dimethylamino-2-dimethylaminomethyl-1-(4-hydroxyphenyl)-1-propanone Dihydrobromide (*IIId*)—A mixture of 4-hydroxyacetophenone (13.6 g, 0.1 mol), 2,3-dihydro-4*H*-pyran (10.4 g, 0.12 mol), an acidic ion-exchange resin[5] (1.5 g), and benzene (125 mL) was stirred vigorously at room temperature for 24 h. The reaction was monitored by following the disappearance of 4-hydroxyacetophenone (R_f 0.65) using TLC. After removal of the resin by filtration, the mixture was passed through a column of silica gel (60–200 mesh, benzene). The resultant yellow solution was washed with aqueous sodium hydroxide solution (10% w/v, 3 × 20 mL) and then with water (4 × 20 mL). After drying, the benzene was removed *in vacuo* to give a yellow solid, which was recrystallized from *n*-hexane to give 4-(2-tetrahydropyranyloxy)-acetophenone (15.6 g, 71%) as yellow crystals, mp 84–86°C [lit. (22) mp 89.5–91.0°C]; R_f 0.82; ^{1}H-NMR ($CDCl_3$): δ 7.82 (d, 2, ArH at C_2 and C_6), 7.00 (d, 2, ArH at C_3 and C_5), 5.45 (t, 1, tetrahydropyranyl H at C_2), 3.68 (m, 2, tetrahydropyranyl H at C_6), 2.54 (s, 3, CH_3), and 2.20–1.40 ppm (m, 6, tetrahydropyranyl H at C_3, C_4, and C_5).

A mixture of 4-(2-tetrahydropyranyloxy)-acetophenone (2.2 g, 0.01 mol), an aqueous solution of formaldehyde (37% w/v, 2.4 mL, 0.03 mol), dimethylamine (25% w/v, 4.5 mL, 0.025 mol), and ethanol (10 mL) was heated at reflux for 30 h. The ethanol was removed *in vacuo*, the mixture was extracted with ether (2 × 10 mL), and the combined organic extracts were washed with water (3 × 5 mL) and dried. After filtration, an additional quantity of anhydrous ether (10 mL) was added, and the solution was treated with hydrogen bromide to give a light-yellow solid, which was recrystallized from methanolic hydrogen bromide (1% w/v) and then from methanol to give IIId (1.4 g) as a bright-yellow solid. ^{1}H-NMR (D_2O): δ 8.04 (d, 2, ArH at C_2 and C_6), 7.04 (d, 2, ArH at C_3 and C_5), 4.04–3.20 [m, 5, $C_2H(CH_2)_2$], and 2.95 ppm [s, 12, $2N(CH_3)_2$]. The yield is based on the use of 4-(2-tetrahydropyranyloxy)-acetophenone as the starting material.

3-Dimethylamino-1-phenyl-2-(1-pyrrolidinylmethyl)-1-propanone Dihydrobromide (*IVa*)—A mixture of 3-dimethylamino-1-phenyl-1-propanone hydrochloride (5.35 g, 0.025 mol) (17), an aqueous solution of formaldehyde (37% w/v, 24 mL, 0.03 mol), pyrrolidine (2.5 mL, 0.03 mol), and ethanol (35 mL) was heated at reflux for 3 h. The solvent was removed *in vacuo*, and water (40 mL) followed by excess aqueous sodium hydroxide (40% w/v) were added to the crude mixture; the aqueous phase was then extracted with ether (50 mL). The organic extract was dried, and removal of the ether gave an oil, which was dissolved in acetone and treated with hydrogen bromide. The resultant crude dihydrobromide salt was recrystallized from ethanol to give IVa as colorless prisms (4.3 g). The yield was based on the use of 3-dimethylamino-1-phenyl-1-propanone hydrochloride as starting material.

3-Amino-2-aminomethyl-1-phenyl-1-propanone Dihydrobromides (*IVb–d*)—These compounds were prepared using the general procedure described for the synthesis of IIa, IIIa–c, e, and f *vide supra*. In the synthesis of IVb–d, the time of heating at reflux in ethanol was 24, 3, and 24 h, respectively.

3-Dimethylamino-2-dimethylaminomethyl-1-phenyl-1-propanone Dimethobromide (*IVe*)—3-Dimethylamino-2-dimethylaminomethyl-1-phenyl-1-propanone dihydrochloride was prepared as colorless crystals, mp 163–164°C [lit. (23) mp 164–165°C] in 20% yield by a reported procedure (10), except that hydrogen chloride was passed through a solution of the free base in acetone and not hydrogen bromide. An aqueous solution of the diamine dihydrochloride (5.8 g, 0.02 mol) was cooled to 5°C and rendered basic to litmus with triethylamine. The mixture was stirred with ice-cooling for 15 min and extracted with ether (3 × 15 mL). The combined organic extracts were washed with water (3 × 10 mL) and dried, and then the solvent was removed under reduced pressure to give a pale-yellow oil, which was dissolved in dry acetone and treated with excess methyl bromide. The solid was removed by filtration, washed with dry acetone, dried, and recrystallized from acetone–methanol to give IVe as a colorless solid (5.4 g).

3-Dimethylamino-1-aryl-1-propanone Hydrobromides (*V*)—The substituted 1-propanone hydrochlorides were prepared by a literature method (17) and then converted into the hydrobromide salts by a reported procedure (10). The crude hydrobromides were recrystallized from acetone–methanol (Va and c) or methanol (Vb). The percentage yields listed in Table II are based on syntheses from the appropriate substituted acetophenone and not from the crude hydrochloride.

3-Amino-1-phenyl-1-propanone Hydrobromides (*VIa–c*)—The appropriate 1-propanone hydrochlorides were prepared essentially by a literature method (17) using the required amine hydrochloride in place of dimethylamine hydrochloride. The times of heating the reactants at reflux were 2 h (VIa and c) and 3 h (VIb). The hydrobromides were obtained from the hydrochloride salts by a literature method (10) and purified by recrystallization from acetone–methanol. The percentage yields in Table II are based on the quantity of acetophenone used.

3-Dimethylamino-1-phenyl-1-propanone Methobromide (*VId*)—Aqueous sodium carbonate solution (10% w/v) was added to an aqueous solution of crude 3-dimethylamino-1-phenyl-1-propanone hydrochloride (17) (4.27 g, 0.02 mol) in water until basic to litmus, and the mixture was extracted with chloroform (4 × 15 mL). After the combined organic extracts were washed with water (3 × 5 mL) and dried, the chloroform was removed *in vacuo* to give a pale-yellow oil, which was dissolved in anhydrous ether (15 mL) and treated with methyl bromide (1.6 mL, 2.77 g, 0.029 mol). The solution was cooled to −4°C for 3 h, and the precipitate was removed by filtration, washed with dry ether, dried, and recrystallized from methanol–acetone (4:1) to give VId as colorless crystals. The yield recorded in Table II was based on the quantity of acetophenone used.

3,5-Bis(dimethylaminomethyl)-4-hydroxyacetophenone Dihydrobromide (*VII*)—A mixture of *p*-hydroxyacetophenone (6.8 g, 0.05 mol), an aqueous solution of formaldehyde (37% w/v, 8.9 mL, 0.11 mol), dimethylamine (5.0 g, 0.11 mol), and ethanol (50 mL) was heated at reflux for 20 h. After removal of the ethanol and water *in vacuo*, the resultant viscous oil was dissolved in acetone and treated with hydrogen bromide. The precipitate was removed by filtration, washed with acetone, dried, and recrystallized from methanol to give VII as colorless prisms (8.8 g). ^{1}H-NMR (D_2O): δ 8.00 (s, 2, ArH at C_2 and C_6), 4.45 (s, 4, 2 × CH_2N), 2.98 [s, 12, 2 × $N(CH_3)_2$], and 2.62 ppm (s, 3, $COCH_3$).

Biological Evaluations—*Screening of Compounds*—The antineoplastic evaluation of the compounds described herein was undertaken by the National Cancer Institute, Bethesda, Maryland, using their protocols (24). The compounds listed in Table II were injected by the intraperitoneal route into male or female Swiss, $B_6D_2F_1$, or CD_2F_1 mice. The derivatives were dissolved in saline prior to injection, except for IVe and VId which were administered in hydroxypropyl cellulose; VIb was injected in both saline and saline containing polysorbate 80[6]. Compounds IVc and VI had been previously assessed by the

[5] Amberlyst H-15; Rohm and Haas, Philadelphia, Pa.

[6] Tween 80; Atlas Chemical Industries.

National Cancer Institute, although not against P388 lymphocytic leukemia.

The data in Table IV was generated as follows. Compound IIa was dissolved in saline and administered to mice hosting tumors 1–3 by the subcutaneous route and intraperitoneally in the remaining cases. The xenografts (tumors 1–3) were inoculated into NU/NU athymic Swiss mice by subcutaneous injection. The activity recorded is the mean tumor weight change between day 0 and the final evaluation days which were 15, 11, and 11 d, respectively. The $CD8F_1$ mammary and colon 38 tumors in $CD8F_1$ and $B_6C_3F_1$ mice, respectively, were evaluated after 34 and 20 d. The activity noted for the $CD8F_1$ mammary tumor was the median tumor weight change, and for the colon 38 tumor, the median tumor weight was estimated from the diameter of the tumor. The B16 melanocarcinoma was injected intraperitoneally into $B_6C_3F_1$ mice and evaluated on day 60. Both L1210 and P388 leukemias were injected by the intraperitoneal route into CD_2F_1 mice and evaluated on day 30. The Lewis lung carcinoma was injected intravenously into $B_6C_3F_1$ mice and evaluated on day 60. The activity of the last four tumors is expressed as the effect on median survival time. The toxicity of IIa *versus* the nine tumors listed in Table IV was evaluated on days 15, 11, 11, 34, 20, 5, 5, 5, and 5, respectively.

Disposition Studies with IIa—Dosed male Wistar rats, weighing 220–250 g (first trial), 285–300 g (second trial), and 240–250 g (third trial) were injected with IIa dissolved in sterile saline (0.9% w/v) by the intraperitoneal route, while control animals received sterile saline (0.9% w/v). All animals were necropsied after sacrifice, and the following tissues were fixed in 10% buffered formalin: lung, heart, thymus, trachea, thyroid, liver, spleen, pancreas, kidney, adrenal, stomach, duodenum, jejunum, ileum, cecum, colon, rectum, lymph nodes, bladder, and reproductive organs. Tissues were processed routinely, sectioned at 5 μm, and stained with hematoxylin and eosin.

Tack Behavior of Coating Solutions II

S. K. CHOPRA and R. TAWASHI ˣ

Received November 17, 1982, *from the Faculty of Pharmacy, University of Montreal, Case Postale 6128, Succursale "A", Montreal, Quebec, H3C 3J7 Canada.* Accepted for publication March 9, 1983.

Abstract □ The tackiness of coating solutions containing high concentrations of polymers was determined using a parallel plate technique. Kinematics of the film-splitting process was also investigated using a high-speed movie camera. The results showed that the impulse required to split a liquid film of highly concentrated polymer solution (semisolid), in contrast to a dilute solution is related not to viscosity, but to the internal structures of the system. Evidence has been found that the materials that are considered to be tacky in practice, display "delayed elastic effects" and require far larger impulses than nontacky materials.

Keyphrases □ Film-coating solutions—tablets, tack behavior, viscosity, concentrated polymer solutions □ Viscosity—film-coating solvents for tablets, tack behavior, concentrated polymer solutions □ Polymers—concentrated solutions, viscosity, tack behavior, film-coating of tablets

The technique of film-coating solid dosage forms has grown at an accelerating rate, employing a wide variety of materials and coating systems (1–3). One of the factors affecting the tablet-coating process is the tackiness of the coating formulations. The concentration of the film formers used in these coating formulations depends on the molecular weight, grade, and chemical structure of the polymers (4). Generally, the concentration of a polymer used in a film-coating formulation ranges from 2 to 10% (5). During the drying phase of the coating process, evaporation of the solvent occurs. Consequently, the concentration of the polymer increases, giving rise to increasing tackiness until the deposited film is essentially

National Cancer Institute, although not against P388 lymphocytic leukemia.

The data in Table IV was generated as follows. Compound IIa was dissolved in saline and administered to mice hosting tumors 1–3 by the subcutaneous route and intraperitoneally in the remaining cases. The xenografts (tumors 1–3) were inoculated into NU/NU athymic Swiss mice by subcutaneous injection. The activity recorded is the mean tumor weight change between day 0 and the final evaluation days which were 15, 11, and 11 d, respectively. The $CD8F_1$ mammary and colon 38 tumors in $CD8F_1$ and $B_6C_3F_1$ mice, respectively, were evaluated after 34 and 20 d. The activity noted for the $CD8F_1$ mammary tumor was the median tumor weight change, and for the colon 38 tumor, the median tumor weight was estimated from the diameter of the tumor. The B16 melanocarcinoma was injected intraperitoneally into $B_6C_3F_1$ mice and evaluated on day 60. Both L1210 and P388 leukemias were injected by the intraperitoneal route into CD_2F_1 mice and evaluated on day 30. The Lewis lung carcinoma was injected intravenously into $B_6C_3F_1$ mice and evaluated on day 60. The activity of the last four tumors is expressed as the effect on median survival time. The toxicity of IIa *versus* the nine tumors listed in Table IV was evaluated on days 15, 11, 11, 34, 20, 5, 5, 5, and 5, respectively.

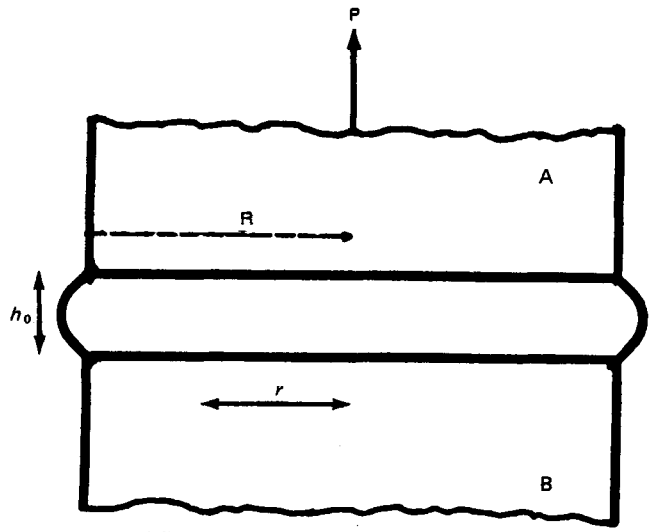

Figure 1—*Liquid flow between parallel plates.*

free of solvent (6). The tackiness of various coating solutions containing relatively low concentrations of polymers has been measured using a parallel-plate technique (7). The present study quantifies the tackiness of coating solutions containing high concentrations of polymers, *i.e.*, high-viscosity solutions.

BACKGROUND

In a previous communication (7), it was suggested that the relationship between tackiness and viscosity of coating solutions is nonlinear, and the following modified Stefan equation was proposed:

$$ft = \frac{3}{4} r^2 k' \eta^{0.67} \left[\frac{1}{h_1^2} - \frac{1}{h_2^2}\right] \qquad \text{(Eq. 1)}$$

where ft (tack) is the impulse per unit area required to separate two planes, initially in contact, through an intervening liquid; η is the viscosity (in poises) of the liquid; r is the radius (in centimeters) of the plates; h_1 and h_2 are the initial and final thickness (in centimeters) of the liquid film; and k' is the instrumental factor.

The above relationship was found to be satisfactory, provided that the rate of separation of plates joined with a liquid of given viscosity was below a certain limit. The upper limit of the speed of separation beyond which the experimental tack values obtained are lower than those predicted by Eq. 1 decreases with increase in the viscosity of a solution. An earlier study (8) on the tackiness of inks suggested that a rapid film separation does not occur by liquid flow, but is the result of a viscoelastic response of the liquid, which may react as a solid towards rapidly applied stress. This theory was later supported by another study performed on the kinematics of liquid film separation (9). Other studies (10, 11) acknowledged the existence of limits beyond which obedience to:

$$F = \frac{3\pi\eta r^4}{4t} \left[\frac{1}{h_1^2} - \frac{1}{h_2^2}\right] \qquad \text{(Eq. 2)}$$

by Stefan may not be expected, but the authors rejected the basic tenets of the viscoelastic theory in their explanation of film splitting at high rates of separation. These authors suggested that at high rates of separation, the flow conditions consistant with the above equation are upset by the onset of cavitation, which sets upper limits to the force of separation. On this basis the limiting force should be independent of the liquid and the initial distance between the plates. This is contrary to the results obtained experimentally. In the present study, an attempt is made to clarify the aforementioned discrepancies.

Consider two flat circular plates of radius R arranged parallel to each other

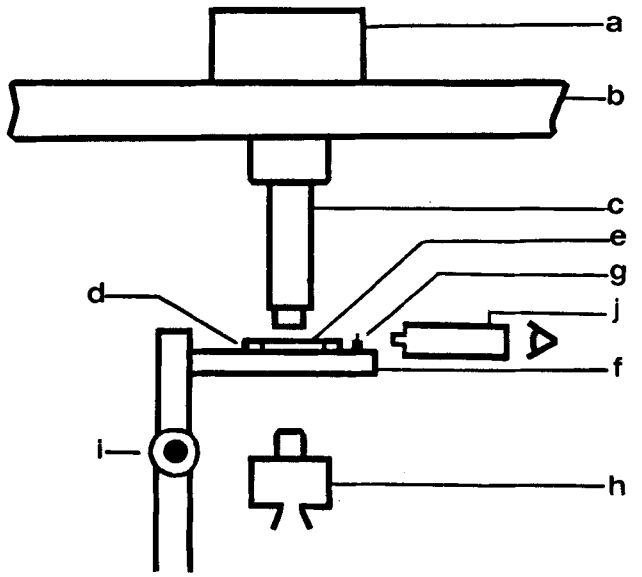

Figure 2—*Schematic diagram of tack measuring assembly in conjunction with a high-speed movie camera. Figure 5—*Stress-time oscillograms at various rates of separation for lecithin. Key: (a) 3.33×10^{-3} cm/s; (b) 8.33×10^{-3} cm/s; (c) 1.66×10^{-2} cm/s; (d) 3.33×10^{-2} cm/s; (e) 8.33×10^{-2} cm/s; (f) 1.66×10^{-1} cm/s.*

and initially in contact through an interlayer of liquid of thickness h_0 (Fig. 1). When the plates are separated, the liquid from the periphery moves toward the center of the plates. This centripetal flow of the liquid is directly caused by the pressure difference between the peripheral and the central portion of the liquid layer (12).

When the distance h_0 between the plates increases by dh_0 in dt seconds, the volume of an imaginary cylinder of a radius r between the plates, increases by $\pi r^2 dh_0$. This volume increase is equal to the volume of liquid that must flow from the periphery into the above cylindrical space within the same time interval. The viscous force acting on the above volume of liquid of viscosity η is given by $\eta \cdot d^2u/dh^2 \cdot 2\pi \cdot r dr \cdot dh$. Here u is the linear viscosity of flow at the point (r,h). Therefore, the force F needed to separate the plates must be equal to the above viscous force. If the volume of liquid flowing at time dt into the cylindrical space $\pi r^2 dh_0$ is less than the latter, then the force F needed to separate the plates will be a fraction of the theoretical value.

With the increase in the concentration of a polymer in solution due to evaporation of the solvent during the coating process, a transition from low-viscosity solution to high-viscosity solution, followed by highly viscous solutions (semisolids) occurs, until a solid state is reached. In other words, the fluidity of the solution decreases with the increase in the concentration of the polymer. Therefore, it may be difficult for highly concentrated solutions of polymers to flow into the cylindrical space between the parallel plates according to the conditions described earlier. Furthermore, it is also likely that no flow occurs at all in the case of semisolids. Therefore, for highly concentrated solutions, the film separation process may be different from the one described above for the tack equation. Based on these considerations, experiments were designed to study simultaneously the kinematics and dynamics of the film separation process.

EXPERIMENTAL

Materials—Polymers used in this study were hydroxypropyl methylcellulose (5 cps)[1], hydroxypropyl cellulose[2], and povidone[3]. Solutions of polymers were prepared in distilled water. Lecithin[4], a Newtonian liquid, and white petrolatum[5], a semisolid gel, were also used.

Preparation of Solutions—The solutions of hydroxypropyl methylcellulose (5 cps) and hydroxypropyl cellulose were prepared by first dispersing the polymers in distilled water at 70°C and 50°C, respectively, and then cooling the dispersions with ice-cold water to 25°C to obtain clear solutions. The solutions of povidone were prepared by simply dissolving the polymer in water at 70°C. All solutions were allowed to stand at 25°C until free of air bubbles.

Rate of Separation, cm/s	ft, g/cm/s: Aqueous Solution of Povidone, 30% (w/w) (η = 0.93 poise)	Aqueous Solution of Povidone, 60% (w/w) (Pseudoplastic)	Lecithin (η = 62 poises)
3.33×10^{-3}	-	9.02×10^5	3.88×10^5
8.33×10^{-3}	2.30×10^4	9.45×10^5	3.87×10^5
1.66×10^{-2}	2.40×10^4	8.40×10^5	3.86×10^5
3.33×10^{-2}	2.45×10^4	7.65×10^5	3.75×10^5
8.33×10^{-2}	2.35×10^4	5.32×10^5	2.65×10^5
1.66×10^{-1}	2.42×10^4	6.28×10^5	1.87×10^5

[a] h_1 = 0.00108 cm.

Measurement of Viscosity—All measurements were made on a rotational cup-and-bob viscometer[6] in conjunction with a strip-chart recorder[7]. The temperature of solutions was held constant at 25°C. The cup-and-bob geometry was varied according to the viscosity of the sample.

Tack Measurement Assembly—Tack measurements were made using a tensile testing machine[8]. A schematic diagram of the tack measurement assembly has been described in our previous report (7).

Assembly for Kinematic Study—Figure 2 illustrates the setup of a 16-mm high-speed motion picture camera[9] in conjunction with the tack measuring assembly. The movie camera is capable of taking 4000 frames/s. A mechanical switching device simultaneously starts the movie camera and the upward movement of the crosshead bar (b) of the tensile tester.

Measurement of Film Thickness and Tack—The method for measuring the thickness of the liquid film has been described in our previous report (7). After adjustment of the thickness of the test liquid, the crosshead bar was allowed to move upward at a specified speed. The film separation events were recorded on a storage-type oscilloscope[10], where the separation force (F) was displayed as a function of time. All measurements were made at 25°C, and a minimum of six measurements were taken for every test solution at each separation rate. The experimental tack values were within a margin of error of ±6%.

RESULTS AND DISCUSSION

Tack Behavior of Solutions Containing High Concentrations of Polymers (High-Viscosity Liquids)—Rheograms of 30 and 60% (w/w) aqueous solutions of povidone revealed the former to be Newtonian, whereas the latter is pseudoplastic in nature. The stress-time oscillograms obtained at various rates of separation of these solutions are shown in Figs. 3 and 4, respectively, and show that as the time of separation decreases, the peak force of separation increases. This response by the above liquids is similar to the one reported for the solutions containing relatively low concentration of various polymers (7). The oscillograms for the 60% solution of povidone at rates of separation $\leq 8.33 \times 10^{-3}$ cm/s, are similar in shape to those for the 30% povidone solution at all rates of separation studied in this investigation. However, the oscillograms obtained for the 60% polymer solution vary in shape when the rates of separation are $>8.33 \times 10^{-3}$ cm/s. This change in shape of the oscillograms at higher rates of separation was also observed in the case of lecithin, a high-viscosity Newtonian liquid. In this case, the upper limit of the rate of separation beyond which the oscillograms begin to vary in shape is 1.66×10^{-2} cm/s (Fig. 5).

The tack values of the above solutions are given in Table I. The tack was calculated by dividing the area under the curves of the stress-time oscillograms by the surface area of the probe. Table I shows that for a 30% (w/w) aqueous solution of povidone, tack is independent of the rate of separation. This is in agreement with Eq. 1. However, the tackiness of the 60% polymer solution decreased with an increase in separation rates at $>8.33 \times 10^{-3}$ cm/s. This decrease in tack values cannot be attributed solely to the pseudoplastic nature of the above solution, since the tackiness of lecithin, a Newtonian liquid, also decreased at rates of separation $>1.66 \times 10^{-2}$ cm/s (Table I).

The above results suggest that there is an upper limit to the rate of separation beyond which the shapes of the oscillograms begin to vary, regardless

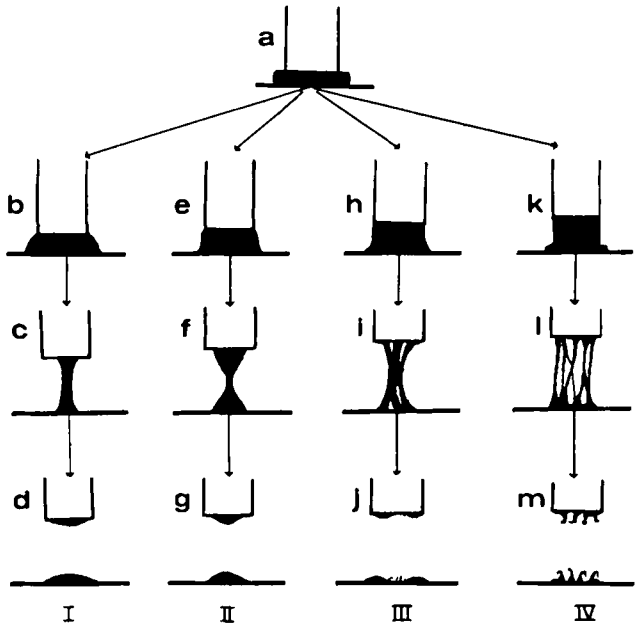

Figure 6—*Types of liquid flow patterns during film separation.*

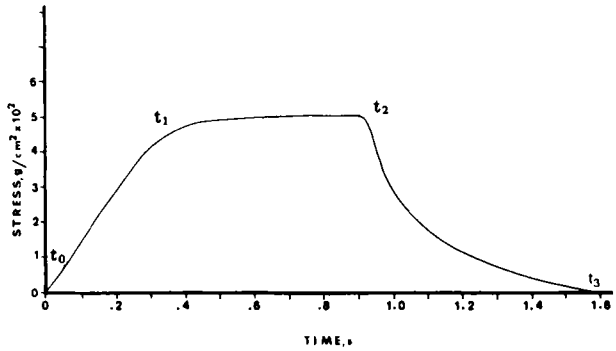

Figure 7—*Stress-time oscillogram at rate of separation of 8.33 × 10^{-2} cm for a 70% (w/w) aqueous solution of povidone;* h_1 = *0.00216 cm.*

of the flow behavior of the liquid. However, there is one noticeable difference between the shape of the oscillogram of lecithin and that of the 60% povidone solution obtained at a rate of separation of 1.66 × 10^{-1} cm/s. The slope of the ascending portion of the oscillogram (Fig. 5f) of lecithin is constant, whereas that for povidone solution (Fig. 4f) decreases gradually. The reason for this difference can be explained by simultaneously studying the kinematics and dynamics of the film-splitting process.

Kinematics of Film Splitting—The high-speed motion picture of the film separation process revealed four main patterns of liquid film splitting. The schematic diagrams of the film-splitting patterns as observed by projecting the high-speed movie are illustrated in Fig. 6.

Type I—Figure 6a–d represents the various stages of type I film-splitting pattern. The shapes of the oscillograms obtained for this pattern of film splitting are similar to those presented in Fig. 3. The first portion, *i.e.*, from t_0 to t_1 of the oscillogram (Fig. 3a), displays an increase in force which reaches a maximum. This is due to upward movement of the probe, which produces an increasing tension in the liquid until it begins to flow toward the center of the probe in order to relieve its strain (see Fig. 6b). The force required to maintain the centripetal flow is represented by the portion t_1 to t_2 of the oscillogram (Fig. 3a). This portion shows a gradual decrease in force from peak to zero. At t_2, the diameter of the base of the liquid column as seen from the bottom of the glass plate is at its minimum. Any further increase in the gap between the probe and the plate does not lead to further centripetal movement of the liquid, but rather to a necking-down of the column which eventually splits (see Fig. 6d). In cases such as above, the experimental *ft* is equal to that calculated using Eq. 1. Therefore, this pattern of liquid film splitting is in accordance with the theoretical consideration.

Type II—The various stages followed by the type II pattern of liquid film splitting are shown sequentially in Fig. 6e–g. The corresponding oscillogram is presented in Fig. 4c. The increase in force exhibited by the oscillogram from t_0 to t_1 is due to the increase in strain in the liquid before it begins to flow. The initial velocity of centripetal flow of the liquid is slower than the corresponding vertical movement of the probe. During this period a rapid decrease in force occurs. This is represented by the oscillogram (Fig. 4c) from t_1 to t_2. From t_2 to t_3, the velocity of the centripetal flow of the liquid increases, but does not keep pace with the rate of increase in the gap between the probe and the plate. During this time interval, the force gradually decreases to zero. At t_3, the diameter of the base of the liquid column is larger than that shown in Fig. 6f. The final separation takes place by necking-down of the hourglass column (Fig. 6g). The above observations clearly show that the centripetal flow of the liquid is not achieved within the time of creation of the cylindrical space between the probe and the plate. This means that the conditions described for the tack equation are not met. Therefore, in this type of film separation pattern, the value of experimental *ft* is less than that predicted by Eq. 1.

Type III—The oscillogram (Fig. 4d) corresponds to the film separation sequence shown in Figs. 6h–j. As soon as the tension in the liquid reaches its maximum, *i.e.*, at t_1 in Fig. 4d, the liquid begins to move centripetally but in irregular fashion. This type of movement leads to "channeling" of the liquid and produces a rapid decrease in force as shown by the portion t_1 to t_2 of the oscillogram. The liquid in channel form continues to move toward the a[x]is of the plate. This results in a gradually decreasing force as depicted by t[h]e portion t_2 to t_3 of the trace. The column arising out of the channeled liqu[id] is not cylindrical (Fig. 6i). The channel formation of the liquid (Fig. 6j) c[an] be seen even after film splitting. As in type II, the value of the experimen[tal] *ft* is lower than the predicted value.

Type IV—The oscillogram (Fig. 4f) corresponds to the film-splitting sequence shown in Figs. 6k–m. When the strain in the liquid is increased, a rapid linear increase in force from t_0 to t_1 is recorded. From t_1 to t_2, an increase in force continues but with decreasing slope. Since no centripetal flow occurs from t_0 to t_2, the decreasing slope of the increasing stress from t_1 to t_2 could be attributed to the orientation of polymer molecules toward the direction of flow, thereby reducing the internal resistance of the material until the flow begins (12). With the further increase in the gap between the probe and the plate, the liquid moves toward several points instead of moving toward the center of the plate. This eventually leads to the formation of several filaments (Fig. 6m). During this time, the separation force decreases, first rapidly and then gradually until it reaches zero, at t_3.

The increase in force with decreasing slope as shown by the portion t_1 to t_2 of the oscillogram for povidone (Fig. 4f) was also observed in the case of 30% (w/w) aqueous solution of hydroxypropyl methylcellulose (5 cps) and 30% (w/w) aqueous solution of hydroxypropyl cellulose. However, in the case of lecithin, the ascending portion of the oscillogram (Fig. 5) showed a linear increase in force at all rates of separation.

The results of this simultaneous kinematic and dynamic study of the film separation process suggest that the separation force reaches a maximum before the centripetal flow of the liquid takes place. The rate of increase in force during this time, remains constant if the resistance is purely viscous. A decrease in the rate of increase in force occurs in the case of highly concentrated polymer solutions and is probably due to the rearrangement of the internal structure of the system. The portion of the oscillogram representing maximum to zero separation force is dependent on the centripetal flow of the liquid during film separation. The shape of this region of the oscillogram changes with the change in pattern of the centripetal flow, which in turn is dependent on the viscosity of the liquid and the rate of film separation.

Tack Behavior of Highly Concentrated Polymer Solutions (Semisolids)—The stress-time oscillogram for a 70% (w/w) aqueous solution of povidone obtained at a rate of separation of 8.33 × 10^{-2} cm/s is shown in Fig. 7. The film separation process indicated that no centripetal movement of the liquid occurs and that film splitting proceeds by simple stretching and thinning-down of the filaments. Therefore, the film-separation process is different from that described for low- and high-viscosity solutions.

The stress-time oscillogram obtained is to a certain extent close to the stress-strain curve exhibited by the ductile response of plastics at high rates of separation (13). It can be divided into three regions. The first region represented by the portion t_0 to t_1 of the oscillogram (Fig. 7) is predominently due to the elastic forces of the liquid. In this region, the force first rises proportionally to the elongation and then rises less rapidly until it reaches "yield point" at t_1. In the second region following the "yield point," the specimen offers a pull resistance which is constant over a long period of time: t_1–t_2. Since no centripetal flow takes place during this time, the force is mainly due to the resistance to elongation of the filament beyond the elastic limit. This second region of the curve has been suggested to be due to the "delayed elastic deformation" effects (14). In the third region, t_2–t_3, "necking" and eventually splitting of the filaments occur. In Fig. 7, the *ft*, 9.80 × 10^4 g/cm/s for thinning and final rupture of the filament is only 20% of the total 4.81 × 10^5 g/cm/s required for the separation of the film. The bulk of the *ft*, 3.83 × 10^5 g/cm/s is devoted to the process of film elongation.

Tack experiments performed with petrolatum, a highly viscous semisolid did not show the region of "delayed elastic effects." This resulted in a rather short duration for filament elongation; hence the ft was relatively small.

The above observations suggest that the response of the concentrated polymer solutions (semisolids) to applied pull stress is a combination of viscous and elastic forces. The "delayed elastic effects" observed are the result of configurational elasticity, which is a process associated with orientation, alignment, and elongation by the uncurling of large chain molecules. Therefore, the ft required for the elongation of the filament will not only depend on the viscosity of the liquid, but also on the internal structure of the system.

Earlier investigators (10–12) suggested that tackiness is related to the geometry of the system and the rheological characteristics of the liquid. Therefore, according to this definition, lecithin, petrolatum, and even water added with high concentration of finely divided solids will be considered tacky, since these liquids or dispersions do offer resistance to flow. In actual practice, the above materials, unlike povidone solution, are not known to be tacky even though impulse for liquid film separation is required in both cases. Based on these observations, it can be concluded that a tacky material is one that displays "delayed elastic effects," and because of these effects it requires a long period of time for filament elongation. This provides a rather large impulse for a given force of separation.

Tack Effects in Tablet Coating—Coating solutions, when applied to the tablets during the coating process, are dilute solutions of polymers of low-viscosity grade. Separation of tablets stuck together by a freshly applied coating solution will occur by viscous flow. Therefore, the ft required will be equal for solutions of similar viscosity. As the solvent evaporates during the drying phase of the coating process, the solution will reach a semisolid state. At this point, resistance to filament elongation will depend on the molecular structure of the polymer.

Tablet coating solutions usually contain opacifier, plasticizers, and colorants to modify the physical characteristics and improve the film-forming properties of the polymers. The effect of these additives on the tack behavior of coating solutions is under investigation.

Phase Diagram and Aqueous Solubility of the Lidocaine–Prilocaine Binary System

A. BRODIN *x, A. NYQVIST-MAYER *, T. WADSTEN ‡, B. FORSLUND ‡, and F. BROBERG *

Received December 28, 1982, from the **Astra Läkemedel AB, Research and Development Laboratories, Pharmaceutics, S-151 85 Södertalje* and the ‡*Arrhenius Laboratory, University of Stockholm, Fack, S-106 91 Stockholm, Sweden.* Accepted for publication February 17, 1983.

Abstract □ The phase behavior of the lidocaine–prilocaine binary system has been studied by X-ray diffraction, differential thermal analysis, hot-stage microscopy, and IR spectrometry. No intermediate compounds or solid solubilities have been detected. The eutectic composition is close to 1:1, and the eutectic temperature is 18 ± 1°C. Aqueous solubility studies show that the lidocaine heat of solubility from the eutectic mixture is different from that of the pure drug, whereas it is the same for prilocaine. Investigations of various lidocaine–prilocaine ratios indicate that the two local anesthetics decrease the solubility of each other. The total solubility, however, is affected only to a minor extent.

Keyphrases □ Lidocaine—binary system with prilocaine, phase diagram and aqueous solubility □ Prilocaine—binary system with lidocaine, phase diagram and aqueous solubility □ Solubility—phase diagram of the lidocaine–prilocaine binary system in water □ Phase diagram—lidocaine–prilocaine binary system, aqueous solubility

Solid–solid interactions are of great interest in the development of pharmaceutical preparations. Dissolution rates, and thus bioavailability, of poorly soluble drugs can be enhanced by their fusion with water-soluble carriers such as urea or polyethylene glycol, which form solid solutions with drugs (1, 2). Eutectic mixtures may even be used to prevent freeze–thaw coagulation of suspensions (3). In powder technology, on the other hand, a eutectic interaction between substances may be considered as an incompatibility, making it necessary to use some auxiliary substance to inhibit adhesion of the powders (4). The physical state in which the drugs are present in such fused mixtures is debatable. The dispersion of phenylbutazone in urea represents a "plug compound" (5). Such solid dispersions are known to age (6, 7).

Studies on eutectic combinations of two drugs are rare (8). Recently, lidocaine and prilocaine have been reported to form a eutectic mixture (9). Since this mixture is liquid at room temperature, it has been possible to formulate an effective local anesthetic preparation for topical application. The purpose of this investigation is to characterize the lidocaine–prilocaine system from a physical point of view and to study its aqueous solubility.

EXPERIMENTAL

Materials—Lidocaine[1] and prilocaine[1] were used as obtained. To prepare the eutectic mixture (EMLA), 49.6% lidocaine and 50.4% prilocaine by weight were mixed and heated gently until liquefaction occurred.

X-Ray Diffraction—An X-ray powder diffraction camera[2] with a 50-mm diameter and strictly monochromatized Cu$K\alpha_1$ radiation was used. A small amount of the powder was spread out on the glue side of ordinary tape. The tape was attached to a thin metal plate, 30 mm in diameter, with an 8-mm

central hole. This hole was covered with the tape and sample, and the X-ray was passed through; the exposure time was ~45 min. To obtain very accurate diffraction data, an internal standard of potassium chloride was added to the specimens.

One exposure was performed at 4–5°C. The composition was 1:1, and the mixture was kept at 4–5°C for 10 d after having reacted at room temperature to form a viscous homogeneous mass. The material was spread out on extra-thin foil[3] covered with a thin layer of high-vacuum grease to avoid the influence of water. The sample holder was very rapidly transferred from the storing room to the camera. In this case, the internal standard was elemental silicon. No X-ray diffraction lines were registered from the grease-covered foil.

Differential Thermal Analysis (DTA)—A low-temperature instrument that covers the interval of 100–600 K (10) was used. Six different samples can be run simultaneously.

A rather unusual strategy was used to reach equilibrium, since a long time period was involved (several days). Different amounts of the components were weighed and mixed at room temperature in individual glass cups. After a few days, 20-mg portions were transferred to the DTA sample holders. These were

stored at 4–5°C for different periods of time. The temperature was chosen to avoid ice formation. Just before a specific registration was to take place, the whole DTA measuring head was also cooled to 4–5°C. The filled sample holders were then rapidly moved from refrigeration to the instrument, which was evacuated and further cooled to ~−20°C before the heating program (3°C/min) was started in dry air at atmospheric pressure.

The accuracy of the temperature reading is estimated to be ±1°C according to the calibrating procedure performed with standard samples[4]. The time to obtain equilibrium was found to be longer in the lidocaine-rich part of the system than in the prilocaine-rich part.

Hot-Stage Microscopy—*Nonequilibrium Conditions*—Weighed amounts of lidocaine and prilocaine in various ratios were mixed thoroughly and heated until melting occurred. The melts were cast on watch glasses and allowed to congeal at 5°C. The solidified mixtures were crushed and then homogenized with a mortar and pestle.

A binocular microscope with a hot stage and a control unit was used[5]. Phase transitions of the specimens were observed between crossed polars, both visually and by using a photoelectric sensor to record the changes in light transmission.

A proper amount of specimen was placed on a cooled slide. The specimen was observed from 5°C, with a heating rate of 1°C/min. The temperature at which the crystals just started to melt, or when using the photoelectric sensor the recorded curve started to change, was taken as the eutectic temperature. The temperature at which the whole field became dark was considered the melting point.

Equilibrium Conditions—To determine the liquidus curves of the lidocaine-prilocaine system and to supplement the results gained by the dynamic thermoanalytical methods, a number of equilibration experiments were undertaken. For these experiments, similar to those performed on ternary transition-metal oxide systems (11, 12), a simple microscope hot-stage device comprised of a copper reaction cell (Φ = 5 cm, height = 2 cm) and two 1-mm transparent quartz glass plates were used. The sample was held on the bottom plate, which was in direct contact with a copper block supporting the reaction cell, tempered by means of a circulating-water thermostat. Continuous observation of the sample with the help of a stereo microscope (40×) was made through the upper silica plate, and the temperature (5–75°C) of the sample was checked by a chromel-alumel thermocouple fixed in the copper block close to the sample. The melting temperatures of pure lidocaine, prilocaine, and ice (67°C, 37°C, and 0°C, respectively) served as calibration points in the temperature determinations. The gas-tight reaction cell was also provided with a gas inlet and outlet and a simple manipulator.

A typical run on this hot-stage was performed in the following way. A weighed mixture of lidocaine and prilocaine (in total ~5 mg) was kept at an appropriate temperature for enough time (~1 d) to get a homogeneous melt with a remaining solid phase centered in the droplet. The temperature during this primary stage must be low enough to preserve both kinds of crystals observed: thin platelets (lidocaine) and needles (prilocaine). When the coarse-grained original mixture finally was transformed into a more homogeneous crystalline mass of lidocaine or prilocaine, the temperature was raised in steps until very little solid phase was left in the melt droplet. During this second

[4] NBS-ICTA, Standard Reference Material 758.
[5] Mettler FP52 + FP5.

stage, lasting 1–2 d, checks for equilibrium attainment between solid and liquid were made by observing the growth-dissolution response of the crystals to small temperature changes. Finally, the highest temperature for a solid-liquid equilibrium, *i.e.*, the melting point, for the mixture was noted as that temperature at which the smallest solid residue to be observed in the microscope persisted and showed response to temperature changes.

For some mixtures the primary crystals were grown after the melting point determination by slow cooling and separated for subsequent X-ray analysis from the mother liquor by absorbing the liquor on a piece of porous filter paper. This was brought in contact with the melt by means of the manipulator. Albeit he equilibration experiments were performed in a dynamic atmosphere argon, ~10 mL/min) and lasted for long periods, no changes in size and color f the melt droplets were observed, thus indicating that evaporation losses were egligible.

IR Studies—The IR spectra of lidocaine, prilocaine, and EMLA were re-ɔrded using an IR spectrophotometer[6]. The EMLA samples were prepared : −6°C, and the resulting crystals were spread on potassium bromide disks. MLA was studied both in crystalline form at low temperatures and in liquid ɪrm at room temperature. The spectrum of each sample was recorded 3–4 mes in succession while its physical condition was observed.

Solubility Determination—The solubilities in 1 mM NaOH were deter-ıined for lidocaine, prilocaine, and EMLA at 25°C, 32°C, 37°C, and 45°C. ther combinations of lidocaine and prilocaine were studied in distilled water. quilibrated mixtures of the local anesthetics and water were filtered through ass wool and 0.1-μm polycarbonate filters[7]. The concentrations in the filtrate were determined by UV spectrophotometry[8] at 230 nm. The filtrate was analyzed at fixed time intervals until a constant concentration was obtained.

In the case of EMLA and the other combinations of lidocaine and prilocaine, HPLC was used to analyze the two concentrations separately. For the HPLC method, a 20-μL loop injection valve and a column (200 mm × 3.0 i.d.) packed with Lichrosorb RP-8 (10-μm particles) were connected to an 8-μL flow cell in a spectrophotometer[9]. The column was eluted at ambient temperature with a methanol-phosphate buffer (70:30 v/v, pH 8.0, I = 0.05) at a rate of 1 mL/min. The eluant was monitored at 246 mm with a recorder setting of 0.05 AUFS. Before injection, the samples were diluted with eluant to a concentration of 120 to 140 μg/mL of lidocaine and prilocaine. The peak heights were compared with those of standards chromatographed under similar conditions. Doubling the excess of a mixture did not affect the individual solubilities.

RESULTS AND DISCUSSION

Phase Diagram—The phase diagram for the lidocaine–prilocaine system obtained by hot-stage microscopy is shown in Fig. 1. In the extreme regions, <25% on both sides, visual observations were necessary to estimate the initial melting temperature, while the photoelectric sensor could be used in between. The results obtained with the two methods were in agreement. In the regions of the higher concentrations of lidocaine and prilocaine, respectively, the diagram indicates the existence of solid solutions.

To investigate this further, ~0–15% on both sides were analyzed by X-ray diffraction. A solid solubility may be observed as a shift in the line positions according to changes of the unit cell dimensions if the second component is located in the interstitial spaces of the crystal lattice of the first component. Different amounts of the starting materials were observed, and no interstitial solid solubility between the components could be detected. This may not exclude the existence of noncrystalline solid solutions in which the one component replaces molecules from the crystal lattice of the other component. The formation of substitutional solid solutions is favored if the molecular sizes of the two substances are similar.

Another complication in the phase diagram is the shape of the melting point curve in the 40–60% prilocaine range. Instead of coming to a distinctive eutectic point, the curve only approaches, without touching, the line representing the eutectic temperature. This and the relatively poor reproducibility of the curve on the lidocaine side, may be due to interactions between lidocaine and prilocaine and/or to a very slow process to obtain equilibrium between the melted and solid phases. The latter may also explain the discrepancy between the phase diagram and the X-ray diffraction data about the existence of solid solutions.

Comparing the IR spectrum of crystalline EMLA with those of the single components, no significant difference was detected, which indicates that no chemical interaction takes place between lidocaine and prilocaine. When EMLA melts, the absorbance of some bands are changed in the manner expected in the solid to fluid transition. The characteristic X-ray diffraction lines

obtained at low temperature showed that EMLA contained nothing but the two single components. By slowly raising the temperature to room level, all lines completely disappeared and only an amorphous liquid remained.

Since both IR spectrometry and X-ray diffraction indicated that no chemical interaction existed between lidocaine and prilocaine, the effects of prolonged equilibration times were investigated. As can be seen from Fig. 2, in the region of high prilocaine content, DTA of nonequilibrated samples only showed a single peak. After equilibration of the samples for 3 weeks at 5°C, another peak corresponding to the eutectic melting point appeared. It was also observed that when crystals from a lidocaine–prilocaine mixture (55:45) stored for a long time at 5°C were analyzed after being washed with cold water and dried, only lidocaine was found. The analysis was made by IR spectrometry and by melting point determination. This, plus the results from the DTA and X-ray diffraction studies, strongly suggests that no solid solutions exist on either side of the phase diagram. These regions seem to be due to the formation of a metastable product during the fusion process. Thus, in an equilibrated system, the eutectic consists of a mixture of the pure components, not a mixture of two solid solutions.

To locate more accurately the eutectic point, a set of lidocaine–prilocaine samples (~5 g) were kept for several weeks at temperatures below the liquidus. Results of the 19°C runs are shown in Fig. 3.

Hot-stage microscopy was also performed under equilibrium conditions. From these results, giving the liquidus curves, and the DTA information, mainly giving the eutectic temperature, we arrived at a tentative temperature-composition diagram (Fig. 3) very similar to that constructed on the basis of the nonequilibrium experiments (Fig. 1). The main differences are in the extreme regions and next to the eutectic composition.

Solubilities—Both lidocaine and prilocaine decrease the surface tension of water very little and do not form micelles (13). However, to determine the extent of interaction between the two local anesthetics in aqueous solution, equilibrium solubility experiments were conducted. As can be seen from Fig. 4, the temperature dependence is smaller for pure lidocaine [$\Delta H = -7.6 \pm 0.69$ (12) kJ/mol, $\pm SE$ (df)] than for pure prilocaine [$\Delta H = -17.5 \pm 0.58$ (13) kJ/mol]. The lidocaine solubilities are in agreement with those reported previously (14), $\Delta H = -8.9$ kJ/mol. The total solubility of lidocaine and prilocaine when equilibrating water with EMLA has a ΔH value of -18.2 ± 0.80 (10) kJ/mol.

Analyzing the water for lidocaine and prilocaine separately showed that lidocaine, in this case, had a slightly higher heat of solubility than prilocaine, -21.5 ± 1.25 (10) and -15.8 ± 0.78 (10) kJ/mol, respectively. The different ΔH value of lidocaine in the presence of prilocaine and the lower individual solubilities of the combined substances demonstrate that solute–solute–solvent interactions take place in the aqueous solution. These interactions are also seen when the solubilities are determined from different mixtures of the two local anesthetics (Fig. 5). In one series of experiments, solidified melts of lidocaine and prilocaine were studied. Enough mixture to assure saturation

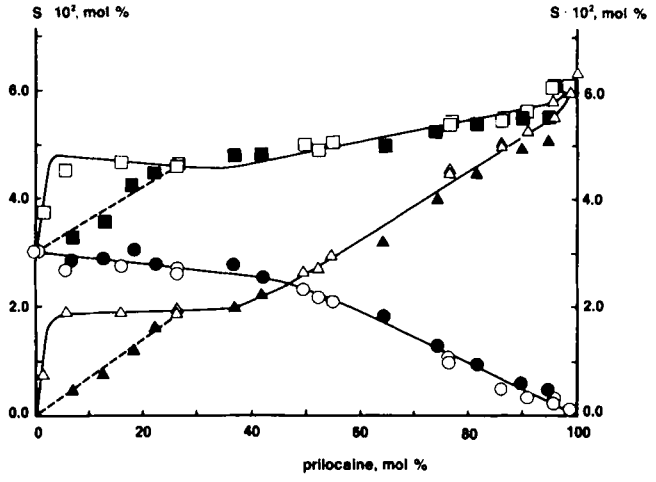

Figure 5—*Solubilities of lidocaine (○), prilocaine (△), and lidocaine plus prilocaine (□) from mixtures of the two local anesthetics at 25°C. Filled symbols represent experiments where the component with <50 mol% was initially dissolved in the water.*

with both components was used. After an initial increase due to a change in prilocaine solubility, the total solubility of the local anesthetics is affected very little compared with the solubilities of the individual substances when the molar ratio of the mixture is changed.

To obtain solutions saturated by only one of the substances, the substance with <50 mol% was dissolved in water before the other was added in excess. It was possible to make solutions where the prilocaine concentration did not reach its saturation level (Fig. 5). Due to the low saturation concentration and the relatively high molar ratio needed, this could not be achieved for lidocaine. In this case, the already dissolved lidocaine started to precipitate on the addition of prilocaine. The values for systems saturated with both substances simultaneously, *i.e.*, the first series of experiments, represent the highest obtainable solubilities. Concentrations lower than the solubility of prilocaine at <30 mol% in Fig. 5 do not influence the lidocaine solubility differently. Only the total amount of local anesthetics is changed. It can be noted that the total concentration of the local anesthetics only varies within 30% of the maximum concentration (that of pure prilocaine), in the range of 2–100 mol% prilocaine in the mixture.

Depending on the influence of additives, especially of salts, on the structure of water or their ability to compete with solvent water molecules, additives will affect the solubility of a solute. To quantify the effect of salts, the empirical Setschenov equation is convenient to use (15):

$$\ln (S_0/S) = k_s C$$

where S and S_0 are the solubilities with and without additive, respectively. The Setschenov coefficient, k_s, measures the sensitivity of the activity coefficient of the solute towards the additive. The concentration of additive, C, is expressed in moles per liter.

To illustrate the aqueous interactions between lidocaine and prilocaine further, the data were plotted according to the equation (Fig. 6). Data from both series of solubility experiments coincided. The Setschenov equation could be applied to prilocaine up to a lidocaine concentration of 0.013 M, with a k_s value of 0.68 obtained by linear regression through the origin. This corresponds to the linear part of Fig. 5 at >50 mol% prilocaine. As lidocaine approaches its highest value of saturation, ln (S_0/S) increases toward infinity. For lidocaine, k_s = 0.09; however, a second linear part with a slope of 1.88 seems to exist. The two linear parts correspond to those of lidocaine in Fig. 5. Since the intersection points in Fig. 5 at a prilocaine concentration of ~0.013 M do not coincide, an intermediate sensitivity of lidocaine to prilocaine might exist. This may also be the case for prilocaine. However, the experimental results do not permit any further evaluation of the intermediate regions using the simple Setschenov equation. As with prilocaine, ln (S_0/S) of lidocaine approaches infinity when the prilocaine concentration gets closer to the maximum saturation concentration. Other empirical expressions can be used to take this into account.

From a pharmaceutical point of view, the maximum aqueous total solubility of the local anesthetics is of interest. In nearly the entire range of lidocaine–prilocaine ratios studied, this solubility is ≥70% of that of pure prilocaine. Thus, the different pharmacological profiles of the two local anesthetics are more important than the aqueous solubility in selecting a suitable ratio for a pharmaceutical preparation. However, the eutectic mixture has the major advantage of being liquid at room temperature. For a preparation such as an oil-in-water cream for topical use, it is possible to emulsify the eutectic mixture directly without first dissolving the drugs in an inert oil.

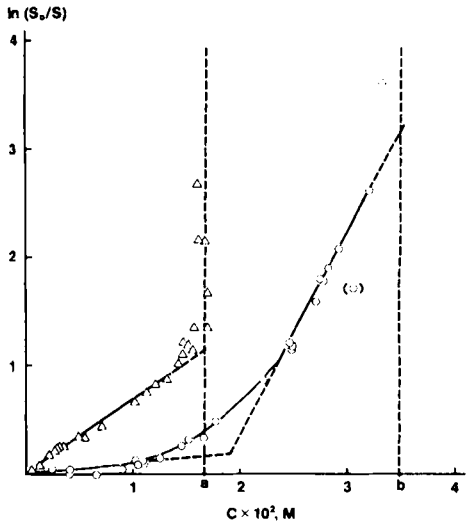

Figure 6—*Setschenov plots for lidocaine (○) and prilocaine (△) in solutic of the other component. Key: (a) solubility of lidocaine, 1.66 × 10⁻² M; solubility of prilocaine, 3.47 × 10⁻² M.*

CONCLUSION

The lidocaine–prilocaine binary system is a simple eutectic containing no intermediate compounds. The eutectic composition is close to 1:1, and the eutectic temperature is 18 ± 1°C. No solid solubility could be detected.

The temperature dependence of the individual solubilities of lidocaine and prilocaine from the eutectic mixture compared with that of the pure substances was higher for lidocaine and the same for prilocaine. For both substances, the individual solubilities from the mixture are lower than those obtained using the single components in the temperature range studied. This was also found for mixtures other than the eutectic. Complex aqueous interactions take place between lidocaine and prilocaine. These interactions depend on the initial ratio of the two drugs.

Absorption of Phenobarbital from Tablets and Elixir

MARVIN C. MEYER *x, ARTHUR B. STRAUGHN *, GURSHARAN RAGHOW *, WILLIAM L. SCHARY ‡§, and KEITH S. ROTENBERG ‡‖

Received November 19, 1982, from the *Department of Pharmaceutics, College of Pharmacy, University of Tennessee Center for the Health Sciences, Memphis, TN 38163 and the ‡Division of Biopharmaceutics, Food and Drug Administration, Rockville, MD 20857. Accepted for publication March 7, 1983. Present addresses: §Endo Pharmaceuticals, Inc., Du Pont Co., Wilmington, DE 19898 and ‖Pennwalt Corporation, Rochester, NY 14623.

Abstract □ A three-way crossover study was conducted with 24 healthy male volunteers to determine the relative bioavailability of four different 100-mg phenobarbital tablets compared with a reference elixir. Each subject received two of the tablets and the elixir at 30-d intervals. Blood samples were collected daily for 19 d after each dose. Plasma phenobarbital concentrations achieved with the five dosage forms differed by <20% within 2–3 h after dosing. The extent of absorption for all dosage forms, as determined from area under the plasma concentration-time profiles, were within 10% of each other. The peak plasma concentration was the greatest and the time to peak concentration was the shortest for the elixir. One of the tablets exhibited a time to peak concentration of 8.6 h, which was significantly longer than any of the other dosage forms. The time to peak concentration correlated with the percent of drug dissolved in 60 min, as determined in 0.1 M HCl, using the USP XX paddle method at 50 rpm.

Keyphrases □ Phenobarbital—relative bioavailability, tablets and elixir, pharmacokinetics in humans □ Bioavailability—relative, phenobarbital tablets and elixir, pharmacokinetics in humans □ Pharmacokinetics—phenobarbital tablets and elixir in humans, relative bioavailability

Phenobarbital, used as a sedative-hypnotic and as an anticonvulsant, has an aqueous solubility of only 1 mg/mL, and differences have been reported in the dissolution rates of different polymorphic forms of the drug (1). Because of its clinical indications and physicochemical properties, it is important to establish the bioavailability of dosage forms of phenobarbital. A recent brief clinical report indicated significantly different plasma phenobarbital concentrations in patients who were receiving 32-mg tablets from two manufacturers (2). However, a bioavailability study of a 30-mg tablet indicated better absorption from the tablet than from an intramuscular dose, which was only 80% absorbed (3). In another study (4) the absolute bioavailability of 60-mg tablets was determined, and the extent of absorption averaged 95%. In the most extensive study to date, five healthy subjects were given seven 100-mg tablets from different manufacturers (5). A noncrossover design was employed, and blood samples were obtained for only 64 h, although half-lives ranged from 41–220 h. Further, the doses were administered every 6 d, and no correction for residual drug from preceding doses was noted in the report. The time of maximum plasma concentration was the only parameter that exhibited statistically significant differences among the test products. There did not appear to be any correlation between the blood level-time profiles and the results of *in vitro* dissolution testing.

The present study employed 24 healthy subjects, four different 100-mg tablet dosage forms, and a reference elixir. Blood samples were obtained for 19 d following dose administration. Attempts were made to relate parameters obtained *in vivo* to those seen using an *in vitro* dissolution system.

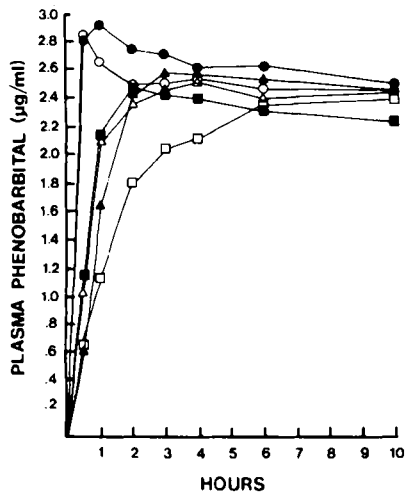

Figure 1—*Mean phenobarbital plasma concentrations during the initial 10 h after dosing* (n = 12). *Key: group I—product 1* (○); *product 2* (□); *product 3* (△); *group II—product 1* (●); *product 4* (■); *product 5* (▲).

EXPERIMENTAL

Dosage Forms—Four tablet products, containing between 97.2 and 100 mg of phenobarbital, were obtained from four manufacturers[1]. The products were selected from the numerous available sources on the basis of preliminary dissolution testing. An elixir[2] containing 100 mg of phenobarbital/25 mL was employed as a reference dosage form. Calculations were based on the labeled drug content of each of the five dosage forms.

Clinical Protocol—Twenty four male subjects (23–30 years, 53–100 kg) were randomly divided into two groups of 12. All subjects underwent urinalysis and hematological and blood chemistry[3] determinations, as well as a physical examination and an ECG, to ensure they were in good health. All subjects provided written informed consent. The subjects had not taken any known enzyme inducers for at least 3 months, any medication for 14 d, or any alcohol for 7 d prior to the start of the study.

Using a crossover design, group I received a 100-mg dose of the elixir (product 1) and two of the test tablets (products 2 and 3). The subjects in group II also received the elixir and the other two tablets (products 4 and 5). The three dosings were each separated by a 30-d period. The doses were administered after an overnight fast, along with 240 mL of water. No food or liquid

[a] Each value (μg/mL) represents the mean of the 12 subjects. The relative standard deviations are given in parentheses ($SD \times 100$/mean). [b] Percent difference = (100) (highest − lowest)/(highest).

other than water was permitted for 4 h following dosing. A standard meal[4] was provided 4 and 8 h after dosing. Ten-milliliter blood samples were obtained *via* a catheter or venipuncture just prior to the dose and 0.5, 1, 3, 4, 6, 10 h and 1, 2, 3, 5, 8, 12, 16, and 19 d after each dose using heparin as the anticoagulant. The blood samples were immediately centrifuged, and the plasma was stored frozen until the time of assay.

Plasma Assay—Plasma phenobarbital concentrations were determined using a slightly modified HPLC procedure previously employed in a study of ethotoin (6). A 1-μg/mL aqueous solution of phenytoin was used as the internal standard. The ether extraction of the plasma was adjusted to pH 11.2, and the chromatographic conditions were essentially as previously reported. The only modifications involved the reconstitution of the dried extract with 100 μL of mobile phase, the use of a 15-μL injection volume, and a mobile phase of 40% acetonitrile in 0.1 M sodium phosphate buffer (pH 7). Quantitation was accomplished with standard curves of peak height ratio (phenobarbital/phenytoin) *versus* phenobarbital concentration, prepared with pooled human plasma. The assay was linear over a concentration range of at least 0.25–3.0 μg/mL. The retention times for phenobarbital and phenytoin were 1.7 and 2.4 min, respectively. No interfering peaks were noted in blank plasma extracts. Duplicate determinations differed by <6% at the lowest standard concentration and by <3% at the highest value.

Data Analysis—The time of maximum plasma concentration (t_{max}) and maximum plasma concentration (C_{max}) were determined by inspection of individual subject data. The elimination rate constant (k) for each dose was determined by least-squares fitting of the postabsorption concentration–time data. The area under the plasma concentration–time curve (AUC) from 0 to 456 h was calculated using the trapezoidal method, while the $AUC_{0-\infty}$ was calculated by addition of the $AUC_{(456\ h-\infty)}$ to the $AUC_{(0-456\ h)}$. The $AUC_{(456\ h-\infty)}$ was determined by dividing the 456-h plasma concentration by k.

The statistical analysis was first performed separately on data from groups I and II. Analysis of variance was used to evaluate statistically significant differences ($p < 0.05$) at each sampling time, as well as values for t_{max}, C_{max}, and AUC. In cases where significant differences occurred, the Newman–Keuls *a posteriori* test was used to evaluate which subjects, treatment sequence, or dosage forms were different. To make comparisons of all four tablet formulations across both groups, a one-way analysis of variance and the Newman–Keuls *a posteriori* test were used to evaluate C_{max}, t_{max}, and relative $AUC_{(0-\infty)}$ for each tablet, adjusted for half-life differences. This latter value was determined as the product of the individual observed $AUC_{(0-\infty)}$ and k, divided by the product of $AUC_{(0-\infty)}$ and k for the elixir dose in each subject, to adjust for intrasubject differences in k. A power analysis (7) was used to evaluate the potential for statistical errors based on $\alpha = 0.05$ and $\beta = 0.2$. Because of an analytical failure, the data for one subject in group II (product 4) were lost. All concentrations and other parameters were estimated using a statistical method (8) based on the performance of the other two dosage forms in this subject and the data obtained for the other subjects within this group.

***In Vitro* Dissolution**—The dissolution of six tablets of each of the four tablet dosage forms was determined using the USP XX paddle method at 50 rpm. Deionized water and 0.1 M HCl at 37°C were employed as the dissolution media, using a volume of 1000 mL. Samples of the media were periodically withdrawn over a 90-min period.

[4] Content of each meal available on request.

RESULTS AND DISCUSSION

Although all subjects were instructed to avoid other drugs during the 3-month study, it was anticipated that some subjects might require minor medication. Thirteen of the subjects took at least one dose of some additional drug, with the majority of these being either acetaminophen for headache or antihistamines for rhinitis. Acetaminophen was previously shown not to interfere in the assay, and the basic antihistamines were not extracted during the assay. Further, inspection of time zero chromatograms and individual plasma concentration–time data did not reveal any effects of the other medications on the phenobarbital plasma concentration–time profiles.

Plasma Concentrations at Each Sampling Time—The mean plasma concentrations at each sampling time for both groups are summarized in Table I. The mean plasma concentrations at each sampling time from 0 to 10 h and from 24 to 456 h are illustrated in Figs. 1 and 2, respectively. Statistically significant differences among products in each study group are summarized in Table II. The rapidly absorbed elixir (product 1) resulted in the highest plasma phenobarbital concentrations for the first 6 h in group I and the highest concentrations at all but the 456-h time in group II. The actual difference among the products was <20% after the 2- and 1-h samples for the groups I and II studies, respectively. The intersubject variability, as reflected by the relative standard deviations, was much less for the elixir during the first hour, which is consistent with a rapidly absorbed dosage form.

The analysis of variance indicated that significant differences among the products occurred at 0.5, 1.0, 2.0, 3.0, and 4.0 h in group I and at 0.5 and 1.0 h in group II. In group I the Newman–Keuls *a posteriori* test (Table II) showed product 2 to have significantly lower concentrations than the elixir during the first 4 h. Product 2 was also significantly lower than product 3 in that group at 1, 3, and 4 h. Product 3 was significantly lower in concentration than the elixir at 0.5, 1, and 2 h. At the remainder of the sampling times product 2 had the lowest concentration at sampling times up to 48 h and slightly higher concentrations at the remainder of the sampling times.

In group II the Newman–Keuls *a posteriori* test indicated a significant difference among all the products at the 0.5-h sampling time, with product 5 having the lowest concentration and the elixir having the highest concentration. At 1 h the ranking of the products was identical to the ranking at 0.5 h, but the only significant difference was between the elixir and the two tablets. From 2 to 456 h no significant difference was observed among the three products.

[a] Each value represents the mean of the 12 subjects. The relative standard deviations are given in parentheses. [b] Percent difference = (100)(highest − lowest)/(highest).

Table III summarizes the mean values for the peak plasma concentration, time of peak concentration, $AUC_{(0-456\ h)}$, $AUC_{(0-\infty)}$, and the terminal elimination rate constant. The statistical analysis of differences among these values are given in Table II.

In group I the mean peak concentration (C_{max}) ranged from 3.01 μg/mL (product 1) to 2.44 μg/mL (product 2). This difference of 18.9% was significant ($p < 0.001$), and each product was significantly different from the other two products. The differences in C_{max} in group II was 18.4% with a range of 2.57 μg/mL (product 4) to 3.15 μg/mL (product 1). This difference was also significant ($p < 0.01$), with the elixir showing a higher concentration than the two tablets, which were not significantly different from each other.

The time of peak concentration (t_{max}) for the elixir (product 1) was 1 h in both groups. In group I, product 2 had a significantly longer t_{max} of 8.6 h compared with the elixir and product 3, which did not differ from each other. The significantly lower peak concentration and longer time to reach peak concentration for product 2 are indicative of a slower rate of absorption for this tablet. In group II, the elixir peaked sooner than the two tablets.

In group I the $AUC_{(0-456\ h)}$ ranged from 17.46 (product 3) to 17.66 μg·d/mL (product 2). This 1.1% difference was not significant. Extrapolation of the AUC to infinity resulted in AUC values ranging from 19.49 (product 1) to 19.80 μg·d/mL (product 3). Although extrapolation changed the ranking of the products, the 1.6% difference was not significant. The AUC values for the group II products were very similar to those in group I, with a range in $AUC_{(0-456\ h)}$ from 17.27 (product 4) to 19.17 μg·d/mL (product 1). The $AUC_{(0-\infty)}$ ranged from 20.53 (product 5) to 22.16 μg·d/mL (product 1). No significant differences in these values were noted ($p > 0.05$).

Sequence and Subject Differences—Significant differences among administration sequences (phases) were observed for several of the parameters. Generally, the ranking of the phases showed increases in plasma concentrations, with phase I < phase II < phase III. These differences were not significant ($p > 0.05$) for group II. Further, for group I the differences between phase I and phase III data were only ~10% for C_{max}, AUC, and k values. The slightly higher phenobarbital plasma concentrations obtained during phase III indicated that one dose per month did not result in any enzyme induction. Further, there was no progressive change in the apparent first-order elimination rate constant (k). Others have similarly found no apparent autoinduction of phenobarbital metabolism (4, 9). A decrease in the apparent volume of distribution over the 3-month testing period cannot be ruled out as a potential explanation for the slightly elevated plasma concentrations during phase III.

Significant subject differences were noted for all the parameters except the 0.5-h concentration and t_{max} in group I, and all but the 0.5-, 1.0-, 3.0-, 4.0- and 10.0-h concentrations and t_{max} in group II. Among the subjects, the C_{max} values ranged from 2.06 to 3.90 μg/mL and the mean $AUC_{(0-\infty)}$ ranged from 12.72 to 40.30 μg·d/mL. Mean terminal elimination rate constants for the subjects ranged from 0.0025 to 0.0064 h^{-1}, with an overall mean elimination rate constant for all dose administrations of 0.0050 h^{-1}.

Power Analysis—A power analysis (7) was also conducted utilizing an α level of 0.05 and a β level of 0.2. In group I, 12 subjects were sufficient to detect a 20% difference in products as being significant for the majority of the parameters. In those instances where >12 subjects were necessary, the actual difference in the products was greater than the percent difference required for significance to be detected. The statistical power for group II was not as great as in group I. However, it was sufficient to detect a 20% difference among the products in terms of 8 of the 15 sampling times, the C_{max}, and AUC values.

Comparisons Across Groups I and II—Table IV summarizes the one-way analysis of variance for comparison of products 2–5 in terms of C_{max}, t_{max}, and relative $AUC_{(0-\infty)}$. This table also includes the Newman–Keuls analysis of these parameters. The time of peak concentration ranged from 2.6 (product 3) to 8.6 h (product 2). Product 2 showed a significantly longer time to reach peak than the other three tablet products, which were not significantly different from each other. The peak plasma concentrations, which ranged from 2.44 to 2.70 μg/mL for the four tablet products, were not significantly different ($p > 0.05$). The relative $AUC_{(0-\infty)}$ ranged from 88 to 100% for the four tablets relative to the elixir. This difference among products was not significant ($p > 0.05$).

***In Vivo–In Vitro* Relationships**—Using the USP XIX basket method at 50 rpm, with pH 1.2 simulated gastric fluid as the dissolution media, Sylvestri

Table IV—Summary of Statistical Analysis Across Groups

Parameter	Mean Values: Product 2	Product 3	Product 4	Product 5	p Value
t_{max} (h)	8.60	2.60	3.20	4.20	<0.001
C_{max} (μg/mL)	2.44	2.70	2.57	2.69	0.532
Relative[a] $AUC_{(0-\infty)}$	1.01	0.98	0.88	0.95	0.515

Newman–Keuls Ranking[b]

Parameter	Product Ranking (Lowest to Highest)
t_{max}	3 4 5 2
C_{max}	2 4 5 3
Relative $AUC_{(0-\infty)}$	4 5 3 2

[a] See text for calculation. [b] Products underlined by a common line show no significant difference ($p > 0.05$).

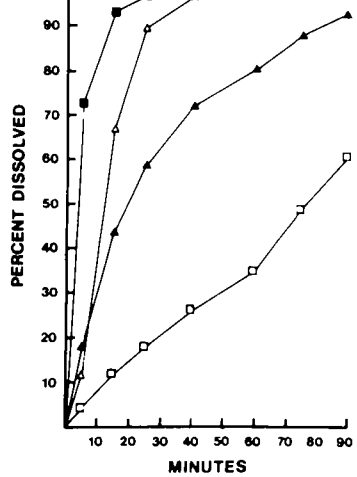

Figure 3—*Dissolution of four phenobarbital tablets in 0.1 M HCl using the USP XX paddle method at 50 rpm. Each value represents the mean of six determinations. Key: product 2 (□); product 3 (△); product 4 (■); product 5 (▲).*

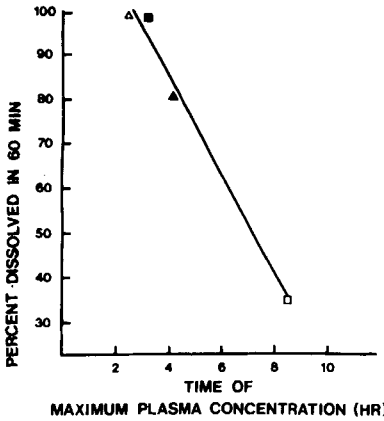

Figure 4—In vitro-in vivo *correlation for four phenobarbital tablets. Each* t_{max} *value represents the mean of 12 subjects and each* in vitro *value is the mean of six determinations. Key: product 2* (□); *product 3* (△); *product 4* (■); *product 5* (▲).

and Ueda (5) did not observe any correlation between the dissolution properties and the *in vivo* performance of seven different 100-mg phenobarbital tablets. Two of the products were different lots of products 2 and 4 employed in the present study. The results of the present study are shown in Fig. 3 for dissolution in 0.1 M HCl. Product 2 dissolved much slower than the other three tablets. The results were similar using deionized water, except for product 3 which dissolved slightly more slowly than product 5 in water. Since significant differences were noted among the products in terms of t_{max}, which reflects the rate of drug absorption, attempts were made to correlate the dissolution in acid with the mean values of t_{max} for the four tablets. Figure 4 illustrates the good relationship ($r = -0.995$) found between t_{max} and the percent of drug dissolved at 60 min. Whether the previously reported (5) lack of *in vitro–in vivo* correlation was due to differences between the two studies in the *in vivo* study design, in the *in vitro* methodology, and/or in the test tablets cannot be determined from the available data. In the present study there were no significant differences among the four tablets in terms of AUC, and the C_{max} values differed by <10%. Thus, it was not unexpected that the observed differences in dissolution rates could not be related to these *in vivo* parameters.

Clinical Implications—Since there were no significant differences in either C_{max} or AUC values, it can be concluded that the extent of absorption of phenobarbital was similar for the elixir and the four tablet products. However, there were significant differences among the tablet products in terms of rate of absorption, with product 2 showing the longest t_{max}. Because of the long half-life for phenobarbital in humans, differences in the rate of absorption should not have much effect on the steady-state phenobarbital plasma concentrations when the drug is employed on a chronic basis as an anticonvulsant. Projections of steady-state concentrations using a one-compartment model with first-order absorption suggest only minor differences in maximum and minimum plasma concentrations, comparing two dosage forms with an elimination half-life of 130 h and with absorption rate constants differing 10-fold. However if the drug is employed on an acute basis as a hypnotic, it is possible the onset of action could be delayed with product 2. In such an instance a patient could potentially ingest additional doses in an attempt to achieve the desired effect. Depending on the number of doses taken, there exists the possibility of excessive ingestion of the more slowly absorbed product resulting in undesirable side effects or toxicity. Thus, on the basis of rate of absorption, the four tablet products cannot be considered bioequivalent.

Use of Hexadeuterated Valproic Acid and Gas Chromatography–Mass Spectrometry to Determine the Pharmacokinetics of Valproic Acid

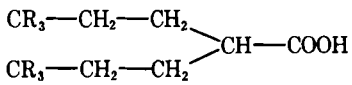
ANDREW A. ACHEAMPONG, FRANK S. ABBOTT ˣ, JAMES M. ORR, SHEILA M. FERGUSON, and ROLAND W. BURTON

Received July 19, 1982, from the *Faculty of Pharmaceutical Sciences, University of British Columbia, Vancouver, B.C., Canada V6T 1W5.* Accepted for publication February 18, 1983.

Abstract □ Di-([3,3,3-$^2H_3$]propyl)acetic acid, a hexadeuterated analogue of valproic acid, was synthesized and its pharmacokinetic properties compared with valproic acid. Concentrations of valproic acid and [^{2}H]valproic acid in serum and saliva were determined by GC–MS using selected-ion monitoring. Saliva drug levels were measured with good precision down to 0.1 μg/mL. Kinetic equivalence of valproic acid and [^{2}H]valproic acid was demonstrated in a single-dose study in a human volunteer. An isotope effect was observed for ω-oxidation, but the difference in metabolism was not sufficient to make [^{2}H]valproic acid biologically nonequivalent. The application of [^{2}H]valproic acid to determine the kinetics of valproic acid under steady-state concentrations was evaluated in the same volunteer. The kinetic data obtained with [^{2}H]valproic acid was consistent with previously reported values for valproic acid including kinetic differences observed between single-dose and steady-state experiments. Saliva levels of valproic acid were found to give a good correlation (r = 0.953) with total serum valproic acid under multiple-dose conditions. A concentration dependence was found for the ratio of saliva valproic acid to free valproic acid in serum, low ratios being observed at high serum concentrations of valproic acid.

Keyphrases □ Valproic acid—hexadeuterated analogue, gas chromatography–mass spectrometry, pharmacokinetics single- and multiple-dose regimes □ Pharmacokinetics—valproic acid, hexadeuterated, analogue, single- and multiple-dose regimens, gas chromatography–mass spectrometry

Valproic acid (I), an anticonvulsant drug that is effective in the treatment of absence seizures, is also used to treat primary and generalized tonic-clonic seizures (1, 2). The pharmacokinetics of valproic acid have been studied extensively in patients who also receive other antiepileptic drugs (3–6). As a consequence, little is known about the basic elimination kinetics of valproic acid during multiple dosing with valproic acid alone. Only a few studies have reported multiple-dose kinetics of valproic acid given as a single agent to normal volunteers (7–9).



I R = H
II R = ^{2}H

One method of determining changes in the kinetic parameters of a drug in patients on multiple-dose therapy is the use of a pulse-dose of a stable-isotope-labeled drug (10, 11). Application of this method to antiepileptic drug studies allows the elimination kinetics of the drug to be determined without discontinuing therapy and risking the exacerbation of seizures. The labeled-drug elimination phase can be followed for 3–4 half-lives during subsequent uninterrupted multiple dosing of unlabeled drug. This technique has been used by Von Unruh *et al.* (6) to study the elimination kinetics of valproic acid under steady-state conditions in patients on combined antiepileptic drug therapy using di-([2,3-$^2H_2$]propyl)acetic acid.

The purpose of this study was to synthesize a deuterium analogue of valproic acid, namely, di-([3,3,3-$^2H_3$]-propyl)-acetic acid (II) and to undertake a preliminary evaluation of its pharmacokinetics. The location of the deuterium atoms only on the terminal carbons of the propyl chains of II was thought to be ideal since ω-oxidation of valproic acid is a minor metabolic pathway (3).

To demonstrate the applicability of labeled valproic acid for determining the steady-state kinetics of valproic acid without interruption of drug administration, the pharmacokinetics of II were compared with I under both single- and multiple-dose situations in a healthy human volunteer. To achieve this, a selective and sensitive assay for II acid using GC–MS was required. The application of this technique to the measurement of salivary levels of valproic acid and [^{2}H]valproic acid was also investigated.

EXPERIMENTAL

Chemicals and Reagents—Valproic acid[1] and 1-bromo[3,3,3-$^2H_3$]propane[2] were obtained commercially. Octanoic acid[3] and diethyl malonate[4] were redistilled before use. Ethyl acetate[5], hexane[5], and methanol[5] were distilled-in-glass grade. All other chemicals were analytical grade.

Synthesis of Di-([3,3,3-$^2H_3$]propyl)acetic Acid (II)—Diethyl malonate (2.88 g, 0.018 mol) was added dropwise to a solution of sodium ethoxide (0.44 g of sodium in 11.0 mL of absolute ethanol). The mixture was heated at reflux for 20 min, cooled, and then 1-bromo[3,3,3-$^2H_3$]propane (2.5 g, 0.02 mol) was introduced in a dropwise manner. The mixture was stirred at reflux for 2 h. For the second alkylation step, the same amounts, of sodium ethoxide solution and 1-bromo[3,3,3-$^2H_3$]propane as used previously were added, and the reaction mixture was heated at reflux for an additional 3 h.

Sodium hydroxide solution (5.5 g in 16 mL of water) was added to the reaction mixture containing diethyl [$^2H_6$]dipropylmalonate and the mixture was refluxed for 8 h. After removing the ethanol by distillation at atmospheric pressure, the solution was diluted and cooled in an ice-water bath. A solution of 9 M sulfuric acid was added in a dropwise manner until the pH of the resulting solution fell to 2.5 (monitored with a pH meter[6]). A white precipitate of [^{2}H]dipropylmalonic acid was collected by filtration, washed with water, and dried *in vacuo* for 6 h (mp[7] 156–158°C). The [^{2}H]dipropylmalonic acid was heated at 190–200°C until evolution of carbon dioxide had ceased. The residue was distilled *in vacuo* to give 1.39 g of [^{2}H]valproic acid (50% yield based on diethyl malonate), bp 71–72°C, 0.5 mm Hg [lit. (12) bp 221°C, 760 mm Hg for valproic acid]. ^{1}H-NMR[8] ($CDCl_3$) relative to tetramethylsilane: δ 1.1–1.9 (m, 8), 2.2–2.5 (m, 1), and 10.5–11.5 ppm (br s, 1, COOH). The deuterium label was >97% as determined by GC–MS analysis of the *tert*-butyldimethylsilyl ester of the product as compared with derivatized unlabeled valproic acid.

Gas Chromatography–Mass Spectrometry— The instrument used for the ion-monitoring assay was a gas chromatograph[9] interfaced to a mass spec-

6.00	1.108 (1.45%)	
	Serum	
10	0.350 (1.75%)	$a^0 = -0.0349$
20	0.705 (2.68%)	
40	1.295 (0.77%)	$a_1 = 0.0358$
60	2.130 (0.57%)	
80	2.880 (0.31%)	$r^2 = 0.9981$
100	3.525 (0.44%)	

[a] $n = 4$. Peak area ratio is the ratio of *m/z* 207 of hexadeuterated valproic acid ester to *m/z* 201 of octanoic acid ester. [b] r^2 is the coefficient of determination, a_1 is the slope, and a^0 is the intercept. Equation for the line is $y = a_1x + a^0$ where y is the peak area ratio mean and x is drug concentration.

Single-Dose Study—A healthy male volunteer, 41 years of age (weight, 63.64 kg), who had not taken any drugs during the month prior to the experiment, participated in both the single- and multiple-dose studies. A single oral dose was prepared by dissolving 372 mg of valproic acid (I) and 182 mg of [²H]valproic acid (II) in 100 mL of water, and the pH of the resulting solution was adjusted to 7.4 using 1 M NaOH. The oral dose was taken in the morning after an overnight fast; food was not allowed until 3 h after dosing. Blood samples (5 mL) were taken at 0, 0.5, 1, 1.5, 2, 2.5, 3, 4, 5, 6, 7, 8, 12, 24, and 48 h, using an indwelling catheter (flushed with heparin solution) for the first 4 h and thereafter by venipuncture. Serum was prepared immediately after blood sampling. Saliva samples (2–5 mL) were obtained coincident to blood sample collections *via* expectoration into clean scintillation vials. Urine was collected at the following times: 0, 1, 2, 3, 4, 5, 6, 7, 8–12, 12–24, and 24–48 h after dosing. The serum, saliva, and urine samples were kept at −20°C until they were analyzed.

Multiple-Dose Study—A 600-mg oral dose of valproic acid syrup[14] (50 mg/mL) was given to the volunteer, who participated in both dosing studies, at 8 p.m. on day 1. The same dose of valproic acid was administered twice a day 12 h apart for the next 3 d. On day 5 (84 h after the initial dose) 600 mg of [²H]valproic acid dissolved in 100 mL of water (pH 7.4) was substituted for the valproic acid as the eighth dose. This dose was taken at the usual time in the morning after an overnight fast (all morning doses were following an

II	16.5	0.0420	0.88	20.9	10.66
(I + II)	13.1	0.0529	1.1	20.8	8.86

[a] Weight = 63.64 kg. [b] Oral bioavailability is assumed to be unity. [c] Parameters for II are calculated from $t = 0$–∞. [d] Parameters for (I + II) are calculated from steady-state I and II concentrations summed during the dosing interval of 12 h following the dose of II.

overnight fast). Thereafter, valproic acid syrup (600 mg) was administered every 12 h for a further period of 3 d.

During the multiple-dose study, blood samples (5 mL) were withdrawn periodically (usually at the trough levels) prior to the administration of the labeled valproic acid. Following the [^{2}H]valproic acid dose, blood samples were taken at various times. Serum was prepared from each sample, and the pH was measured immediately using a pH meter[6]. Serum samples were stored at −20°C until analyzed.

Saliva samples (2–5 mL) were obtained with and without stimulation with sucrose. For the correlation study of saliva and serum drug levels, unstimulated saliva samples were collected 5 min before each blood sampling time and a stimulated saliva sample was obtained 5 min following the blood sample collection. Saliva samples were also obtained at times not coincident with blood sampling times. The pH of the saliva sample was determined immediately following collection using a pH meter[6]. Saliva samples were stored at −20°C until analyzed.

Serum and Saliva Standards—The valproic acid assay used has been described previously in detail (13). Serum standards of labeled and unlabeled valproic acid were prepared by the addition of 0.1 mL of appropriate stock solutions in methanol into 5-mL volumetric flasks. Drug-free serum was added to the 5-mL mark to provide [^{2}H]valproic acid concentrations of 10, 20, 40, 60, 80, and 100 μg/mL and valproic acid concentrations of 20, 40, 60, 80, 100, and 120 μg/mL.

Saliva standards were prepared similarly, but with [^{2}H]valproic acid concentrations of 0.1, 0.25, 0.5, 1.0, 1.5, 3.0, and 6.0 μg/mL and valproic acid concentrations of 0.25, 0.5, 1.0, 1.5, 3.0, and 6.0 μg/mL.

Extraction and Derivatization—Serum standard or sample (50 μL) was pipetted into a 1.0-mL conical reaction vial[15]. Internal standard (200 μL of a solution of 10 mg/L octanoic acid in 1 M HCl) was added, followed by 200 μL of solvent (10% ethyl acetate in *n*-hexane), and the mixture was vortex mixed for 60 s. After centrifuging at 1000×*g* for 20 min, 150 μL of the solvent layer was transferred to a second vial and 7 μL of *tert*-butyldimethylchlorosilane reagent[16] was added. The mixture was vortex mixed for 30 s and then centrifuged for 5 min. A 5-μL aliquot of the organic layer was injected into the GC–MS system.

For saliva drug analysis, 200-μL saliva samples were treated in a manner similar to the serum samples, except that the internal standard concentration was 6.5 mg/L in 1 M HCl.

Selected-Ion Monitoring—Labeled and unlabeled valproic acids were quantitated in serum and saliva by selected-ion monitoring with the GC–MS system operated in the EI-mode. The very intense ions *m/z* 201 from the *tert*-butyldimethylsilyl derivatives of valproic acid and octanoic acid and the corresponding *m/z* 207 from the derivative of [^{2}H]valproic acid were monitored continuously. The retention times for the *tert*-butyldimethylsilyl derivatives of valproic acid (or [^{2}H]valproic acid) and octanoic acid on the Dexsil 300 column were 2.0 and 3.6 min, respectively.

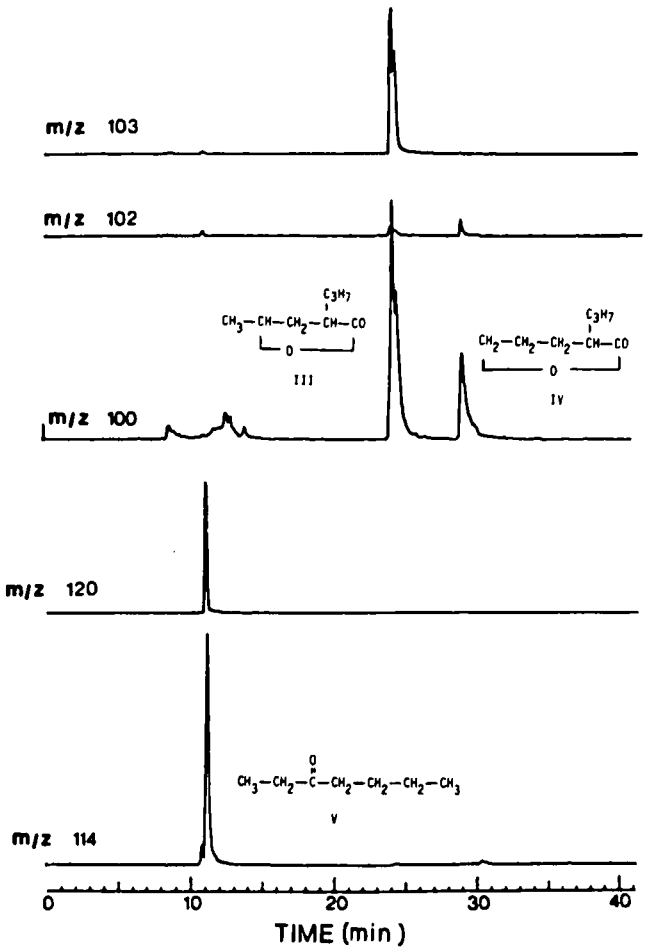

Figure 4—*Mass chromatograms of metabolites isolated from a urine sample following a single oral dose containing both valproic acid and [^{2}H]valproic acid. The* m/z *100 ion fragment peaks at 24 and 29 min are from the lactones of 4-hydroxyvalproic acid (III) and 5-hydroxyvalproic acid (IV), respectively. Corresponding peaks at* m/z *103 and* m/z *102 are the tri- and di- deuterated-analogues of the lactones. The lactones are formed during the acid extraction of the urine. Isomer separation is observed for the 4-hydroxyvalproic acid lactone (*m/z *100,* m/z *103 peaks);* m/z *114 and* m/z *120 peaks are 3-heptanone (V) and 3-[^{2}H]heptanone, respectively. The heptanone arises from acidic decarboxylation of 3-ketovalproic acid during the extraction.*

Calibration curves for valproic acid and [^{2}H]valproic acid were prepared by plotting the ion area ratios of drug to internal standard against the known drug concentrations. For valproic acid, the *m/z* 201 area ratios were used while the *m/z* 207 to *m/z* 201 area ratios were used for [^{2}H]valproic acid.

Plasma Protein Binding Studies—Free drug levels in serum were determined by equilibrium dialysis. The procedure has been described in a previous study (13). The serum and buffer samples from the two compartments were analyzed by GC–MS for free levels of valproic acid and [^{2}H]valproic acid. The extraction and derivatization procedures used were the same as for total drug quantitation in serum. The concentrations of free drug were determined using standard curves (1–10 μg/mL) prepared from buffer solutions to which valproic acid or [^{2}H]valproic acid had been added.

Pharmacokinetic Analysis—The elimination rate constants (K_E) of both valproic acid and [^{2}H]valproic acid were determined by least-squares regression analysis of the terminal log-linear part of the decay curves. The kinetic parameters, elimination half-life ($t_{1/2}$), area under the curve (AUC), total body clearance (CL), and apparent volume of distribution (Vd) were calculated by standard methods (14).

RESULTS AND DISCUSSION

Synthesis—[^{2}H]Valproic acid (II) was obtained *via* malonic ester synthesis according to the method of Adams and Kamm (15). The deuterated product had a high isotopic purity, as shown by comparison of the mass spectra of the

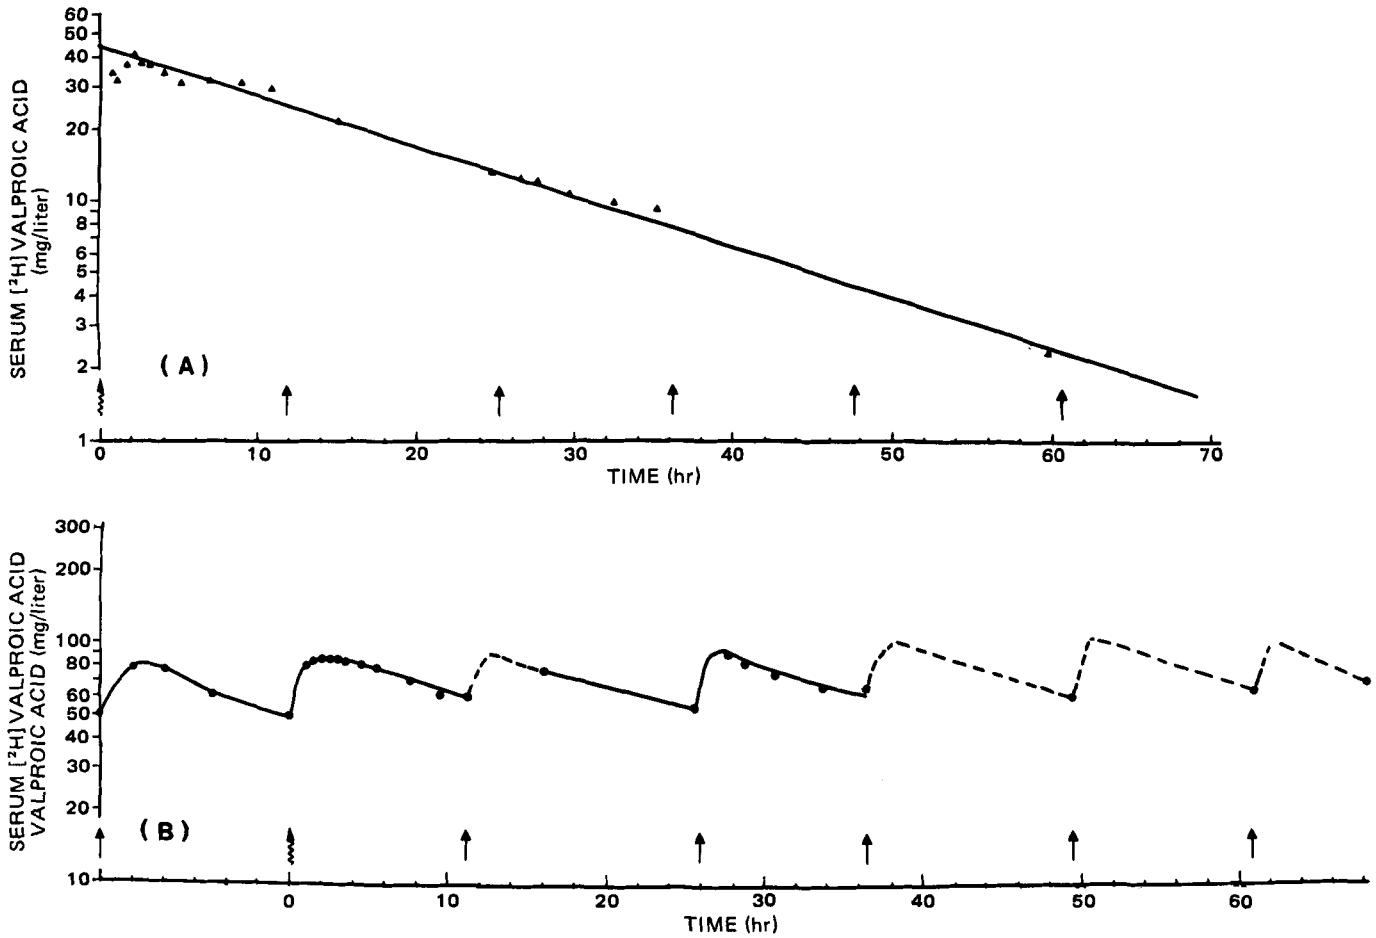

Figure 5—*(A) Time course of serum total [²H]valproic acid given as a substitute dose (600 mg) during multiple dosing with valproic acid. (B) Time course of serum total valproic acid + [²H]valproic acid beginning 12 h prior to and continuing for 60 h after the [²H]valproic acid dose. Key: (↕) time of dose of [²H]valproic acid; (↑) times when valproic acid (600 mg) was given.*

tert-butyldimethylsilyl derivatives of [²H]valproic acid and valproic acid (Fig. 1).

Assay—In this study it was imperative to develop a specific and sensitive assay to measure both valproic acid and [²H]valproic acid in serum and saliva. Quantitation was accomplished by monitoring the highly intense $[M-57]^+$ ions of the *tert*-butyldimethylsilyl derivatives (Fig. 1). The advantages of using the *tert*-butyldimethylsilyl derivatives compared with the trimethylsilyl and methyl esters of valproic acid have been discussed previously (13). The assay procedure used has resulted in clean mass chromatograms. Figure 2 shows a typical selected-ion chromatogram from a saliva sample. The recoveries of [²H]valproic acid from spiked serum and saliva samples were found to be 100%. The calibration curves constructed for valproic acid and [²H]valproic acid in serum and saliva were linear within the concentration ranges used and gave high correlation coefficients. Table I shows typical standard curves for [²H]valproic acid in serum and saliva. Calibration curves for valproic acid in serum and saliva were similar to that of a previous study (13). The relative standard deviations were generally <5%, attesting to the reproducibility of the assay.

Table III—Relationship of Saliva Concentrations of Valproic Acid and [²H]Valproic Acid and Serum Total or Serum Free Drug Levels in the Single- and Multiple-Dose Studies

Parameters[a]	Valproic Acid	[²H]Valproic Acid
Single-Dose Conditions		
Mean ratio, saliva/total serum	0.007	0.009
SD	0.001	0.001
r	0.926	0.901
Mean ratio, saliva/free serum	0.196	0.200
SD	0.027	0.033
r	0.863	0.850
Steady-State Conditions		
Mean ratio, saliva/total serum	0.009	0.011
SD	0.002	0.002
r	0.953	0.956
Mean ratio, saliva/free serum	0.112	0.138
SD	0.021	0.031
r	0.939	0.916

[a] Steady-state concentrations were measured during the first three dosing intervals following labeled-drug administration ($n = 17$); single-dose concentrations cover a period of 24 h ($n = 10$).

Pharmacokinetics of the Single- and Multiple-Dose Studies—Stable-isotope-labeled drugs have been used in different areas of pharmacokinetics including steady-state kinetics (10, 11), bioavailability studies (16), drug interaction studies (6), and drug metabolism studies (17). A stable-isotope-labeled drug which shows a significant biological isotope effect is not appropriate for use in a pharmacokinetic study. To examine the suitability of [²H]valproic acid for pharmacokinetic studies, (*i.e.*, lack of significant isotope effects), a single oral dose consisting of a 2:1 molar ratio of valproic acid to [²H]valproic acid was administered to a healthy human subject. The concentration–time curves of valproic acid and [²H]valproic acid for both serum and saliva describe the same constant 2:1 ratio of areas (Table II) as in the dose. The parallelism between the elimination phases of serum total valproic acid and serum total [²H]valproic acid (Fig. 3) strongly demonstrated that there was no significant isotope effect on the elimination kinetics of valproic acid after incorporation of six deuterium atoms onto the terminal carbon atoms of the propyl chains.

Additional evidence for the absence of a major isotope effect came from the analysis of urinary metabolites, where the major metabolites [valproic acid glucuronide, 3-ketovalproic acid, and 4-hydroxyvalproic acid (3)] showed the consistent 2:1 molar ratio of unlabeled to labeled metabolite (Fig. 4). An isotope effect was observed for the formation of the minor metabolite, 5-hydroxyvalproic acid. Because of the small proportion of 5-hydroxyvalproic acid relative to the other metabolites, a decrease in the formation of 5-hydroxy[$^2H_5$]valproic acid does not markedly affect the elimination kinetics of [²H]valproic acid.

The serum concentration–time curves of both valproic acid and [²H]valproic

acid after a single oral dose were biphasic, similar to those described by Gugler *et al.* (7) and as previously reported by Abbott *et al.* (13). Peak levels of valproic acid and [^{2}H]valproic acid were observed at 0.5 h in serum and saliva.

Following the dose of [^{2}H]valproic acid at steady state, absorption of this deuterated analogue was rapid with peak serum levels appearing within 2–3 h (Fig. 5). Biphasic elimination was not evident for either valproic acid in the 12-h dosing intervals or for [^{2}H]valproic acid as observed over 72 h. All decay curves appeared to be monoexponential.

Table II summarizes the pharmacokinetic data derived from the single-dose and steady-state experiments. The single-dose serum elimination half-life values observed for valproic acid and [^{2}H]valproic acid are practically identical and are comparable with the 15.9 ± 2.6 h value reported by Gugler *et al.* (7). Under multiple-dose conditions, the similar half-life values observed for serum total [^{2}H]valproic acid (14.3 h) and serum total valproic acid plus [^{2}H]valproic acid (13.5 h) was further evidence that [^{2}H]valproic acid is assimilated by the body in a manner identical to the unlabeled valproic acid. As an additional test, the serum total half-life values of valproic acid and valproic acid plus [^{2}H]valproic acid were compared over three consecutive days beginning the day prior to the deuterated dose. No significant change in half-life values was observed. Identical kinetic behavior of the two valproic acid species under multiple-dose conditions is also evident from the AUC data; the serum total $AUC_{0-\infty}$ for [^{2}H]valproic acid (900 mg·h/L) is essentially identical to the valproic acid plus [^{2}H]valproic acid $AUC_{\tau 1-\tau 2}$ (872 mg·h/L) as is expected from application of the principle of superposition where $AUC_{0-\infty}$ after first dose is equivalent to $AUC_{\tau 1-\tau 2}$ at steady state (14).

The elimination half-life of serum total [^{2}H]valproic acid of 14.3 h in this individual under multiple-dose conditions was shorter than the half-life observed in the single-dose study. The apparent volume of distribution of [^{2}H]valproic acid at steady state was not different from the single-dose value. However, the total body clearance of [^{2}H]valproic acid increased by 33% over the single-dose value. The observed increase in total body clearance may better reflect the change in valproic acid elimination kinetics from single- to multiple-dose conditions, since it is a parameter that is model independent (18). The change in total body clearance is not likely due to a reduction in the amount of drug absorbed, since the oral bioavailability is nearly 100% (19, 20). There is the possibility that the 33% increase in total body clearance is due to either an enzyme-inducing effect of valproic acid or a change in binding of valproic acid to serum proteins or both.

On the enzyme-inducing property of valproic acid, several investigators (21, 22) have reported that the half-life of antipyrine and D-glucaric acid urinary excretion in patients treated with sodium valproate were not different from those in drug-free controls. There has been one study (23) that reported that valproic acid increased D-glucaric acid urinary excretion significantly but not serum γ-glutamyltranspeptidase activity in epileptic children.

Valproic acid is cleared by metabolism and has a low extraction ratio (19); its rate of metabolism is proportional to the free serum concentrations. Total body clearance (CL_T) is a function of the free fraction of valproic acid (fu) and the intrinsic clearance (CL'_{int}) through the expression:

$$CL_T = CL'_{int} \cdot fu$$

where fu is the ratio of free drug to the total drug in serum and CL'_{int} is the inherent activity of the liver to metabolize unbound valproic acid (free clearance of valproic acid). In theory, a decrease in plasma protein binding (increase in fu) should increase total body clearance and decrease total serum concentrations of valproic acid or [^{2}H]valproic acid, but should have no effect on the free serum concentration of valproic acid or [^{2}H]valproic acid (18, 24).

In the present study total body clearance increased at steady state compared with the single-dose study (Table II), while the average free fraction in serum (fu) increased from 0.05 (±0.01 *SD*) under single-dose conditions to 0.09 (±0.01 *SD*) at steady-state serum total valproic acid plus [^{2}H]valproic acid concentrations of 50–100 μg/mL. Unless the liver enzyme activity was affected, one would not expect CL_{free} (CL'_{int}) to change between single-dose and steady-state conditions. The clearance of the free drug, however, was seen to decrease (*e.g.*, single dose for [^{2}H]valproic acid = 0.17 L/h/kg; steady state for [^{2}H]valproic acid = 0.12 L/h/kg; see Table II) under steady-state conditions, suggesting possible inhibition of metabolism of valproic acid or saturation of drug-metabolizing enzymes in this subject. Similar decreases in clearance of the free drug (CL_{free}) at steady state were observed by Bowdle *et al.* (8) for a group of normal volunteers on a multiple-dose schedule with valproic acid.

Saliva Valproic Acid Measurement—The saliva levels of valproic acid and [^{2}H]valproic acid were measured to determine if a significant correlation exists between serum total or serum free drug concentrations and saliva drug concentrations. The GC–MS method used here for measuring saliva valproic acid levels is highly sensitive and proved more than adequate to obtain precise data for the saliva concentrations in pharmacokinetic studies.

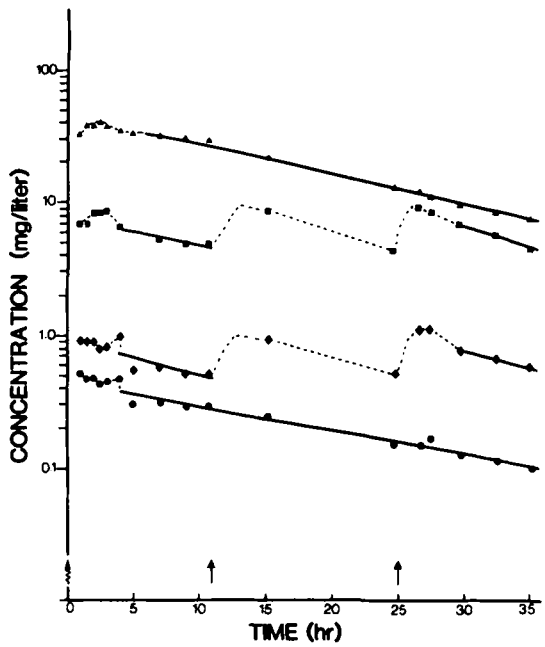

Figure 6—*Concentration–time curves of valproic acid (I) and [^{2}H]valproic acid (II) in serum and saliva following a 600-mg dose of II during the multiple-dose study. Key: (▲) serum total II; (■) serum free (I + II); (◆) saliva (I + II); (●) saliva II; (‡) time of dose of II; (↑) times when I (600 mg) was given.*

Sucrose-stimulated saliva samples had consistently lower pH (5.85 ± 0.48, n = 25) than unstimulated saliva samples (6.98 ± 0.29, n = 25) at similar sampling times. The greater variation in stimulated saliva pH may explain the greater fluctuations observed in the stimulated saliva drug concentrations compared with unstimulated saliva drug concentrations. Sucrose-stimulated saliva valproate levels during the multiple-dose study were higher (mean = 0.684 mg/L) than unstimulated saliva valproic acid levels (mean = 0.609 mg/L), and the difference was significant (pairwise t test, p = 0.013, n = 22).

The time course of unstimulated saliva valproic acid and [^{2}H]valproic acid concentrations at steady state are presented in Fig. 6 together with that of serum total [^{2}H]valproic acid concentrations and serum free valproic acid plus [^{2}H]valproic acid concentrations. Table III summarizes the relationship of drug levels found in saliva and serum.

The mean saliva to serum drug ratios are comparable with values obtained by Gugler *et al.* (7, 25). The correlation between saliva and serum total drug levels was fairly high (Table III) and is, in part, due to the precision of the assay (13). The low correlation values (0.11–0.64) reported in previous studies (9, 26, 27) may be due in part to the GC assays used in measuring saliva levels <1 μg/mL (7, 27). Another factor is the pooled human data analyzed in these studies, since interindividual variability is greater than intraindividual variability (7, 20).

The saliva levels of valproic acid were 20% of the serum free valproic acid concentration under single-dose conditions. Under a multiple-dose regimen, saliva valproate decreased to ~12% of the free serum drug concentrations (Table III). The increase in the serum free fraction under the multiple-dose conditions accounts for the observed decrease in the saliva to free serum valproate ratio.

Pharmacokinetics of Nicorandil, a New Coronary Vasodilator, in Dogs

TAKASHI ISHIZAKI *x, KAN CHIBA *, TOSHIYUKI SUGANUMA *, TOMIO SASAKI *, HIROSHI KAMIYAMA ‡, and HIDEKI NAKANO ‡

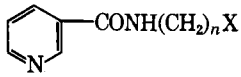
Received April 12, 1982, from the **Division of Clinical Pharmacology, Clinical Research Institute, National Medical Center, Toyama 1-21-2, Shinjuku-ku,* and the ‡*Central Research Institute, Chugai Pharmaceutical Co., Ltd., Tokyo, Japan.* Accepted for publication March 3, 1983.

Abstract □ The kinetic disposition of nicorandil, *N*-[2-(nitroxy)ethyl]-3-pyridinecarboxamide (I), and its main metabolic product, *N*-[2-(hydroxy)-ethyl]-3-pyridinecarboxamide (II), was studied after administering intravenous and oral doses (2.5 mg/kg) of nicorandil to the same beagle dogs. The plasma concentrations were measured using a high-performance liquid chromatographic method. The pharmacokinetic data derived from intravenous administration of nicorandil were: $t_{1/2}$, 0.73 ± 0.11 h; Vd_{area}, 0.67 ± 0.04 L/kg; and total plasma clearance, 13.50 ± 1.05 mL/min/kg. After oral administration, nicorandil was rapidly absorbed (t_{max}, 0.58 ± 0.11 h). The oral bioavailability was calculated as 0.72 ± 0.07. The metabolic formation of the corresponding alcohol after intravenous and oral administration of the parent compound appeared to occur quite efficiently, and its elimination half-life (3.09 ± 0.25 and 3.69 ± 0.88 h after intravenous and oral administration of nicorandil, respectively) was longer than that of the parent compound. Since the dose employed in this study was much higher than the expected therapeutic doses, whether such a good bioavailability after a lower dose of the drug would be obtained in humans remains unanswered.

Keyphrases □ Nicorandil—metabolism in dogs, pharmacokinetics, detection in plasma by HPLC □ Vasodilators, coronary—nicorandil, metabolism in dogs, pharmacokinetics, detection in plasma by HPLC □ Bioavailability—nicorandil in dogs, oral and intravenous administration, pharmacokinetics, detection in plasma by HPLC

Nicorandil[1] (*N*-[2-(nitroxy)ethyl]-3-pyridinecarboxamide, I) a new coronary vasodilator has been shown to produce a potent coronary vasodilating effect, virtually without affecting cardiac contraction, heart rate, or myocardial oxygen consumption in anesthetized dogs (1–3). The pharmacological profile appears to be somewhat similar to that of nitroglycerin (2–4). However, except for one study where the metabolic disposition of nicorandil was qualitatively examined in rats (5), the pharmacokinetics and bioavailability of this drug have not been investigated. The lack of a sensitive and specific method for measurement of nicorandil in the blood has precluded any quantitative pharmacokinetic analysis.

In this study we describe a high-performance liquid chromatographic (HPLC) method for determining nicorandil levels in canine plasma. Using this method, we attempted to study the kinetic disposition of nicorandil (I) administered intravenously and orally on two separate occasions in the same dogs. Some pharmacokinetic variables of *N*-[2-(hydroxy)-ethyl]-3-pyridinecarboxamide (II), a primary metabolite of nicorandil, were also estimated.



I X = ONO_2, n = 2
II X = OH, n = 2
III X = ONO_2, n = 3

EXPERIMENTAL

Materials and Procedures—Six adult beagle dogs weighing 8.2–9.9 kg were used for the study. They were fasted overnight; water was supplied *ad libitum*.

[1] The generic name was published in the *Supplement to WHO Chronicle*, **34**(9), 18 (1980). Lot R9B09, synthesized at the Organic Chemistry Research Laboratory, Chugai Pharmaceutical Co., Ltd., Tokyo, Japan, was used throughout.

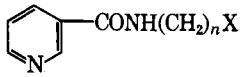
Since the dose employed in this study was much higher than the expected therapeutic doses, whether such a good bioavailability after a lower dose of the drug would be obtained in humans remains unanswered.

Keyphrases □ Nicorandil—metabolism in dogs, pharmacokinetics, detection in plasma by HPLC □ Vasodilators, coronary—nicorandil, metabolism in dogs, pharmacokinetics, detection in plasma by HPLC □ Bioavailability—nicorandil in dogs, oral and intravenous administration, pharmacokinetics, detection in plasma by HPLC

Nicorandil[1] (*N*-[2-(nitroxy)ethyl]-3-pyridinecarboxamide, I) a new coronary vasodilator has been shown to produce a potent coronary vasodilating effect, virtually without affecting cardiac contraction, heart rate, or myocardial oxygen consumption in anesthetized dogs (1–3). The pharmacological profile appears to be somewhat similar to that of nitroglycerin (2–4). However, except for one study where the metabolic disposition of nicorandil was qualitatively examined in rats (5), the pharmacokinetics and bioavailability of this drug have not been investigated. The lack of a sensitive and specific method for measurement of nicorandil in the blood has precluded any quantitative pharmacokinetic analysis.

In this study we describe a high-performance liquid chromatographic (HPLC) method for determining nicorandil levels in canine plasma. Using this method, we attempted to study the kinetic disposition of nicorandil (I) administered intravenously and orally on two separate occasions in the same dogs. Some pharmacokinetic variables of *N*-[2-(hydroxy)-ethyl]-3-pyridinecarboxamide (II), a primary metabolite of nicorandil, were also estimated.



I X = ONO_2, n = 2
II X = OH, n = 2
III X = ONO_2, n = 3

EXPERIMENTAL

Materials and Procedures—Six adult beagle dogs weighing 8.2–9.9 kg were used for the study. They were fasted overnight; water was supplied *ad libitum*.

[1] The generic name was published in the *Supplement to WHO Chronicle*, **34**(9), 18 (1980). Lot R9B09, synthesized at the Organic Chemistry Research Laboratory, Chugai Pharmaceutical Co., Ltd., Tokyo, Japan, was used throughout.

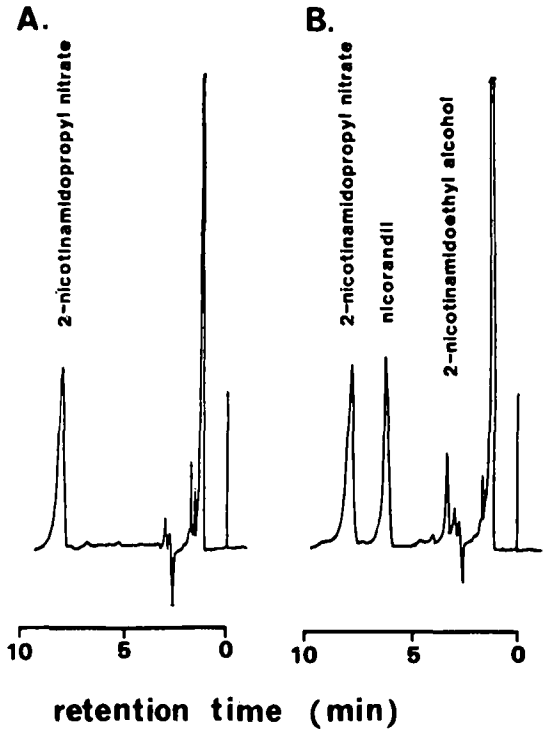

Figure 1—*Chromatograms of 10-μL canine plasma extracts. Key: (A) blank plasma spiked with 1.0 μg/mL of III (internal standard); (B) plasma spiked with 1 μg/mL of nicorandil and each of its analogues.*

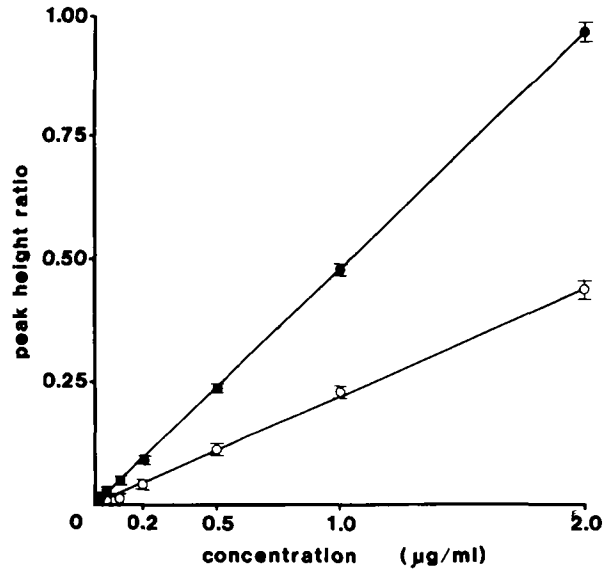

Figure 2—*Calibration curves for nicorandil and alcohol II in canine plasma. A four-point standard curve was prepared by plotting the ratio of the peak height of each compound to that of the internal standard, as mean ± SEM. Linear regression analysis of calibration curve data indicated no significant deviation from linearity for both compounds:* y = 0.4768x + 0.0031, r = 0.9997 *for nicorandil (●);* y = 0.2225x + 0.0006, r = 0.9970 *for alcohol II (○). In addition, intercept values did not significantly differ from zero.*

The dogs were examined during a 7-d acclimation period prior to the experiment, and showed no apparent hepatic or renal dysfunction. No anesthetic was administered during the experiments.

The dogs received 2.5 mg/kg of nicorandil (I) intravenously and orally on two occasions, separated by a 2-week wash-out period. The study was carried out in a randomized crossover fashion: three dogs received the intravenous dose first, while the oral dose was administered to the remaining three; the group given the intravenous dose in the first experiment was given the oral dose in the second and *vice versa*. Nicorandil was dissolved at a concentration of 10.0 mg/mL in 0.9% NaCl for intravenous injection (infused into the antebrachial vein over 30 s) or in distilled water for oral administration. The solutions were prepared just prior to administration. Oral dosing was accomplished with the aid of a rubber catheter (6.5 mm i.d., 9.5 mm o.d.) which was inserted ~40 cm through the mouth into the esophagus.

Blood samples (5 mL) for drug assay were withdrawn into heparinized syringes from the antebrachial vein opposite to where nicorandil was intravenously administered prior to and at 1, 2, 4, 10, 15, 20, 30, and 45 min and 1, 1.5, 2, 3, 4, 5, 6, 7, 8, 9, and 12 h after administration by either route. Immediately after blood collection, the plasma was separated and stored at −20°C until assayed.

Assay Method—The nitrate III[2] was used as the internal standard. Two milliliters of the plasma was transferred to a 15-mL stoppered conical-tip glass tube to which 1 mL of distilled water, 1 mL of internal standard solution (1 mL of distilled water contained 2.5 μg of internal standard III), two drops of 1 M NaOH, and 6.5 mL of ethyl acetate were added. The mixture was vigorously shaken in a mechanical shaker for 10 min. The upper ethyl acetate layer was removed after centrifugation at 3 × 10 rpm for 10 min, and the extraction procedure was repeated. The ethyl acetate layers were combined, transferred to a 30-mL pear-shaped glass flask, and evaporated to dryness. Immediately after evaporation, 0.5 mL of distilled water was added to dissolve the residue.

Ten-microliter samples were injected into an HPLC system[3] with a 30-cm × 4-mm i.d. stainless steel column[4]. The flow rate of the solvent, 25% methyl alcohol and 7% ethyl alcohol in distilled water, was 1.1 mL/min; the operating temperature was 25 ± 2°C. Successive eluates were checked by means of a UV absorption detector (254 nm with 0.01 AUFS) and recorded on a chart recorder at a rate of 0.5 cm/min. Under these conditions, the retention times were 6.0, 3.5, and 8.0 min for I, II, and III, respectively (Fig. 1).

Standard curves for nicorandil (I) and alcohol II in canine plasma were prepared as follows. One milliliter of a solution containing the equal amounts of both compounds in distilled water and 1 mL of a solution of III (2.5 μg) were added to the control canine plasma (2.0 mL) to give duplicate standards. An equal volume of distilled water was added to the control plasma (blank). The prepared standard plasma samples were treated in the same manner as the test samples.

The calibration curves (Fig. 2) were linear, passing through the origin, at concentrations ranging from 0.025 to 4.0 μg/mL for I and from 0.2 to 4.0 μg/mL for II. The coefficients of a linear regression analysis of the calibration values were found to be 0.9997 for I and 0.9970 for II. The reproducibility of the analysis, as determined by quadruplicate assays of plasma with known concentrations of both compounds, was examined on different days over a 3-week period. The coefficients of variation found at concentrations of 0.5 and 2.0 μg/mL were 5.7 and 2.7% for I and 4.2 and 2.0% for II, respectively. Within-day assays gave the following coefficient of variation values for both compounds: 3.3 and 1.8% at concentrations of 0.5 and 2.0 μg/mL for I, respectively, and 9.7 and 3.8% at concentrations of 0.5 and 2.0 μg/mL for II, respectively. The recovery rate for nicorandil was 92.0 ± 4.1 (mean ± *SD*), 91.3 ± 2.7, 99.5 ± 3.5, and 98.0 ± 3.6% at concentrations of 0.5, 1.0, 2.0, and 4.0 μg/mL of canine plasma (from 10 determinations at each concentration); the value for II was quite low, yielding 13.2 ± 2.6, 12.6 ± 2.3, 14.3 ± 1.6, and 14.6 ± 1.9%, respectively, at the same concentrations as for I. The sensitivity limits were ~0.025 μg/mL for I and ~0.2 μg/mL for II.

The stability of the test compounds in frozen plasma was also examined. Standard solutions containing 1, 2, and 4 μg of I, II, and III, respectively, were added to 2.0-mL aliquots of canine plasma, and the mixtures were stored at −20°C; the respective compounds were assayed on days 18 and 40 of storage. The mean ±*SD* recovery rates on day 18 relative to the same standard solutions freshly prepared were 101.5 ± 3.7% for I, 94.8 ± 2.6% for II, and 96.0 ± 3.5% for III; the respective values for the three compounds on day 40 were 95.0 ± 4.5, 94.0 ± 3.7, and 94.7 ± 3.5%. These compounds are considered to be stable in plasma kept at −20°C for a period of ≥40 d.

Concentrations of I and II reported in this study were the values measured within 20 d after the blood collection. Duplicate analyses were done on all samples with the average values reported.

Pharmacokinetic and Statistical Calculations—Model-independent pharmacokinetic parameters were estimated throughout the study. The terminal elimination rate constant of nicorandil (K) and its metabolite (K_{met}) was calculated from the least-squares regression slope of the terminal log-linear phase of the phase concentration–time data. The elimination half-life ($t_{1/2}$) was calculated as $t_{1/2}$ or $t_{1/2met} = 0.693/K$ or K_{met}.

The area under the curve against time (AUC) for nicorandil was estimated

[a] Each number of animals is the same as that given in Table I. [b] The mean ± *SEM* value is 1.01 ± 0.09 when dog 5 is excluded.

according to $AUC_0^\infty = AUC_0^T + C_p^T/K$. The AUC_0^T was calculated using the trapezoidal method, where T is the time of the last measured plasma concentration of nicorandil (C_p^T). The apparent volume of distribution (Vd_{area}) of nicorandil was obtained from the equation, Vd = intravenous dose/(intravenous $AUC_0^\infty \cdot K$). The apparent total body clearance (CL_{tot}) of nicorandil was calculated from CL_{tot} = intravenous dose/intravenous AUC_0^∞.

The absolute bioavailability of nicorandil (F) after oral administration was determined from F = oral AUC_0^∞/intravenous AUC_0^∞, where the oral AUC_0^∞ is defined as $AUC_0^T + C_p^T/K$. The maximal plasma nicorandil concentration (C_{max}) after oral administration and the time to peak concentration (t_{max}) were read from the concentration-time data of each animal.

We also predicted the theoretical value for oral bioavailability (F') of nicorandil using the following equation (6): F' = 1 − intravenous dose/(intravenous $AUC_0^\infty \cdot \lambda \cdot Q$), where Q is the liver blood flow of 41.0 mL/min/kg in the dog (7) and λ is the blood-plasma concentration ratio of nicorandil in the dog, which is known to be close to unity (1.01 ± 0.05, n = 10)[5]. This F' value was compared with the calculated value (F) for each dog.

Such pharmacokinetic variables as Vd_{area} and CL_{tot} were normalized for the body weight of the animal and expressed as liters per kilogram and milliliters per minute per kilogram, respectively. All average data are given as the mean ± *SEM*. All the pharmacokinetic and statistical calculations were done with a computer[6]. Statistical comparison of the data obtained using the two different routes of drug administration was made by a paired Student's t test, with a significance level of $p < 0.05$.

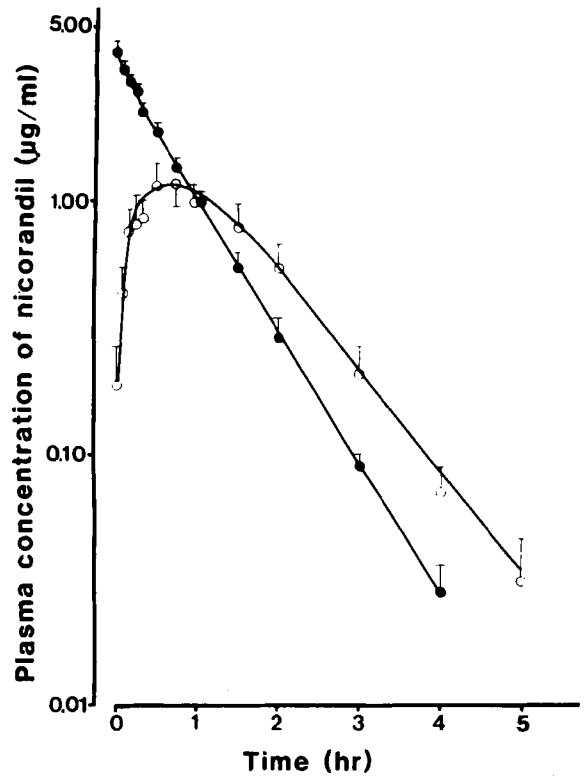

Figure 3—*Average concentration-time profile of nicorandil in plasma after intravenous (●) or oral (○) administration of a 2.5-mg/kg dose of nicorandil to six dogs, mean* ± SEM.

RESULTS

Semilogarithmic plots of nicorandil plasma concentrations against time after intravenous and oral administrations of the same dose of nicorandil (2.5 mg/kg) are shown in Fig. 3. Pharmacokinetic parameters of nicorandil related to intravenous and oral dosing are summarized in Tables I and II, respectively.

Following intravenous administration, the elimination phase had a $t_{1/2}$ of 0.73 ± 0.11 h. No nicorandil could be detected in the plasma 5 h after dosage with this HPLC method. The AUC_0^∞ values ranged from 2.35 to 4.19 μg·h/mL. The weight-normalized volume of distribution (Vd_{area}) and total body (plasma) clearance (CL_{tot}) was 0.67 ± 0.04 L/kg and 13.50 ± 1.05 mL/min/kg, respectively.

After oral administration, nicorandil in plasma was detected within 10 min of dosing and reached peak concentrations between 0.25 and 1.0 h (t_{max}, Table II). The mean peak plasma concentration (C_{max}) was 1.3 ± 0.2 μg/mL at ~0.58 h. After 6 h, no drug could be detected in the plasma with the HPLC method used. The interindividual variation in oral AUC_0^∞ (≃2.4-fold) was larger than that of intravenous AUC_0^∞ (≃1.8-fold) for the six dogs. The mean AUC_0^∞ was statistically different ($p < 0.02$) for the two different routes of nicorandil administration. The mean bioavailability (F), calculated from oral AUC_0^∞/intravenous AUC_0^∞, was 0.72 (Table II). The value (F') predicted the equation (6) was fairly consistent with that of F in all but one dog (no. 5). This dog showed the greatest C_{max} (2.1 μg/mL) with the shortest t_{max} (0.25 h), which may seemingly diminish the hepatic first-pass effect for orally administered nicorandil. Except for this dog, the ratio of F'/F ranged from 0.78 to 1.25 (mean = 1.01; Table II).

Semilogarithmic plots of plasma concentration-time data of alcohol II following intravenous and oral administration of nicorandil are shown in Fig. 4. The mean value for the oral AUC_0^∞ (13.0 ± 1.7 μg·h/mL) was identical with that for the intravenous AUC_0^∞ (13.5 ± 0.1 μg·h/mL). The mean terminal half-life of the metabolite (Table III) was much longer than that of the parent drug (Tables I and II).

DISCUSSION

The elimination half-life observed for nicorandil in this study appears to be longer than the respective values of conventional coronary vasodilators such as glyceryl trinitrate (nitroglycerin), isosorbide dinitrate, and pentaerythritol trinitrate, which are on the order of minutes in animals (including dogs) and humans (8–10). Previous workers (9) noted a plasma half-life for unchanged isosorbide dinitrate of ~7 min in dogs, while others (10) observed a plasma half-life for nitroglycerin of 4.4 min in normal volunteers. A preliminary clinical study (11) showed that the mean elimination half-life observed in 10 patients with heart disease after a single 20-mg oral administration of nicorandil was ~52 min (≃0.87 h).

It is noteworthy that the fraction available in the systemic circulation (*F*) for nicorandil, a mononitrate compound, was ~70% with a long elimination half-life (0.90 ± 0.07 h) after oral administration to dogs (Table II). This seems to be in marked contrast to the di- and trinitrate compounds in various animal species, including dogs (8, 9, 12). Studies conducted in animals (8, 9, 13–16) and humans (17) have suggested that the di- and trinitrates are rapidly and extensively degraded in the liver. On the other hand, isosorbide-5-mononitrate, a major metabolite of isosorbide dinitrate in dogs (9, 12) and humans (18–20), has recently been reported to be completely bioavailable after a single oral dose of 20 mg (21); the elimination half-life of isosorbide-5-mononitrate is ~8 times that of isosorbide dinitrate (20, 22).

We are tempted to speculate that the mononitrate forms of coronary vasodilators (*e.g.*, nicorandil) are resistant to metabolic breakdown and will attain higher plasma concentrations, resulting in greater bioavailability after oral administration. As our bioavailability data on nicorandil were obtained from only one species, however, it must be interpreted with caution. There are several other agents whose systemic availability is not proportional to the dose administered. For example, single-oral-dose studies using propranolol (23) have shown that as large doses of the drug are ingested, the hepatic extraction becomes saturated, allowing more of the drug to reach the systemic circulation. Since the oral dose of nicorandil administered to the dogs was ~3.3- to 10-fold greater than that recently tested (5–15 mg/d TID) in patients with angina pectoris (24), whether a similar bioavailability after a lower dose of nicorandil would have been obtained remains unanswered; a dose-ranging pharmacokinetic study would be required. It is likely that the degradation rate of nicorandil may vary from species to species, and that the bioavailability data from an animal species can not directly be translated into human terms.

Concerning the formation of the main metabolic product of nicorandil, the alcohol II, the low recovery of this metabolite from canine plasma using this HPLC method hampers discussion on its quantitative disposition. Bearing this limitation in mind, however, the formation of this metabolite appears to occur quite efficiently in dogs after both intravenous and oral administrations of the parent compound (Fig. 4). The metabolite has a longer half-life (Table III) compared with the parent compound (Tables I and II), and plasma concentrations were maintained at higher levels for a longer period of time following intravenous or oral administration of nicorandil (Fig. 4). One may question if the metabolite would affect the disposition of the parent compound, thereby modifying the cardiovascular effects of nicorandil. However, previous workers (1, 3, 5) have demonstrated that alcohol II is pharmacologically inactive and has no influence on the cardiovascular effects of nicorandil. Nevertheless, whether the alcohol can distort the disposition of nicorandil remains totally unknown.

Table III—Apparent Pharmacokinetic Parameters of Alcohol II Following a 2.5-mg/kg iv or Oral Dose of Nicorandil

Dog	Intravenous Study		Oral Study	
	K_{met}, h^{-1}	$t_{1/2met}$, h	K_{met}, h^{-1}	$t_{1/2met}$, h
1	0.18	3.76	0.26	2.68
2	0.28	2.50	0.23	3.05
3	0.20	3.43	0.34	2.05
4	0.22	3.15	0.10	6.93
5	0.31	2.18	0.36	1.94
6	0.20	3.50	0.14	4.90
Mean	0.23	3.09	0.24	3.60
SEM	±0.02	±0.25	±0.04	±0.80

In summary, nicorandil has a longer elimination half-life, and its oral bioavailability appears considerably greater than conventional nitrate compounds. However, before nicorandil becomes a therapeutic agent for the treatment of angina pectoris, its disposition and metabolic fate in the human body must be elucidated. Undoubtedly, this requires a more sensitive and specific assay method. Thus, the results reported herein using this HPLC method, which is sensitive enough to detect nicorandil only in the plasma of dogs administered a relatively large dose of nicorandil, should be viewed as a basis for further studies.

Abstract □ Piperacillin amide (IV) was successfully identified as the predominant impurity in commercial lots of piperacillin monohydrate (III). The impurity was isolated *via* a preparative liquid chromatographic scheme utilizing Florisil as the adsorbent and a mobile phase of water–acetonitrile (4:96, v/v). The isolated component had nearly the same reverse-phase HPLC properties as piperacillin and was chemically and thermally unstable. This labile impurity was spectroscopically identified by field desorption (FD), fast atom bombardment (FAB) with collision activation decomposition (CAD), and desorption chemical ionization (DCI) mass spectrometries, and NMR and IR spectrometries. Identity was confirmed on comparison of the chromatographic and spectrometric data of the impurity with an independently synthesized sample of piperacillin amide.

Keyphrases □ Piperacillin amide—impurity in piperacillin, isolation, identification using soft-ionization mass spectra, high-field NMR, and IR spectrometry □ Piperacillin—isolation of an amide impurity by column chromatography, identification using soft-ionization mass spectra, high-field NMR, and IR spectrometry, antibiotic activity

Piperacillin[1] is a third generation semisynthetic penicillin antibiotic with a broad spectrum of antimicrobial activity against both Gram-positive and Gram-negative organisms (1). As shown in Scheme I, piperacillin (III) is produced from the reaction of ampicillin (I) with 4-ethyl-2,3-dioxo-1-piperazinecarbonyl chloride (II). Five low-level components, each ≤0.6% w/w, were observed in the final piperacillin product. Two of these components were related to the starting materials: ampicillin and 1-ethyl-2,3-piperazinedione (2). Two components were expected process impurities: the β-lactam hydrolysis product of piperacillin (3) and the condensation product of piperacillin with ampicillin (2). The isolation and identification of the fifth component is the subject of this paper. This component, referred to as the "unknown piperacillin impurity," constituted the major impurity in commercial lots of piperacillin, 0.2–0.4% w/w[2]. This impurity proved to be difficult to isolate chromatographically and to characterize spectrometrically.

Two main factors which complicated the development of a reverse-phase HPLC method for isolating the unknown piperacillin impurity from piperacillin in quantities large enough for spectrometric analysis are:

1. the difficulty in resolving the major impurity from piperacillin because the impurity eluted as a shoulder on the high retention time side of piperacillin;
2. the chemical instability of the unknown material in normal HPLC reverse-phase solvents, *viz.*, methanol and aqueous media, at other than neutral pH for extended periods.

For these reasons, a unique preparative column chromatographic method using an isocratic normal phase was developed which was successful in resolving the unknown piperacillin impurity from piperacillin.

Identification of the isolated impurity was not routine, since it was highly polar and chemically and thermally unstable. The unknown impurity was characterized by mass spectrometry using soft-ionization conditions, *i.e.*, field desorption (FD) (4, 5), fast atom bombardment (FAB) (6, 7), and desorption chemical ionization (DCI) (8, 9). High-field NMR and Fourier transform IR spectrometries were also used to elucidate the structure of the unknown piperacillin impurity. The spectrometric data suggested that the unknown was piperacillin amide (IV). This hypothesis was confirmed by compar-

Abstract □ Piperacillin amide (IV) was successfully identified as the predominant impurity in commercial lots of piperacillin monohydrate (III). The impurity was isolated *via* a preparative liquid chromatographic scheme utilizing Florisil as the adsorbent and a mobile phase of water–acetonitrile (4:96, v/v). The isolated component had nearly the same reverse-phase HPLC properties as piperacillin and was chemically and thermally unstable. This labile impurity was spectroscopically identified by field desorption (FD), fast atom bombardment (FAB) with collision activation decomposition (CAD), and desorption chemical ionization (DCI) mass spectrometries, and NMR and IR spectrometries. Identity was confirmed on comparison of the chromatographic and spectrometric data of the impurity with an independently synthesized sample of piperacillin amide.

Keyphrases □ Piperacillin amide—impurity in piperacillin, isolation, identification using soft-ionization mass spectra, high-field NMR, and IR spectrometry □ Piperacillin—isolation of an amide impurity by column chromatography, identification using soft-ionization mass spectra, high-field NMR, and IR spectrometry, antibiotic activity

Piperacillin[1] is a third generation semisynthetic penicillin antibiotic with a broad spectrum of antimicrobial activity against both Gram-positive and Gram-negative organisms (1). As shown in Scheme I, piperacillin (III) is produced from the reaction of ampicillin (I) with 4-ethyl-2,3-dioxo-1-piperazinecarbonyl chloride (II). Five low-level components, each ≤0.6% w/w, were observed in the final piperacillin product. Two of these components were related to the starting materials: ampicillin and 1-ethyl-2,3-piperazinedione (2). Two components were expected process impurities: the β-lactam hydrolysis product of piperacillin (3) and the condensation product of piperacillin with ampicillin (2). The isolation and identification of the fifth component is the subject of this paper. This component, referred to as the "unknown piperacillin impurity," constituted the major impurity in commercial lots of piperacillin, 0.2–0.4% w/w[2]. This impurity proved to be difficult to isolate chromatographically and to characterize spectrometrically.

Two main factors which complicated the development of a reverse-phase HPLC method for isolating the unknown piperacillin impurity from piperacillin in quantities large enough for spectrometric analysis are:

1. the difficulty in resolving the major impurity from piperacillin because the impurity eluted as a shoulder on the high retention time side of piperacillin;
2. the chemical instability of the unknown material in normal HPLC reverse-phase solvents, *viz.*, methanol and aqueous media, at other than neutral pH for extended periods.

For these reasons, a unique preparative column chromatographic method using an isocratic normal phase was developed which was successful in resolving the unknown piperacillin impurity from piperacillin.

Identification of the isolated impurity was not routine, since it was highly polar and chemically and thermally unstable. The unknown impurity was characterized by mass spectrometry using soft-ionization conditions, *i.e.*, field desorption (FD) (4, 5), fast atom bombardment (FAB) (6, 7), and desorption chemical ionization (DCI) (8, 9). High-field NMR and Fourier transform IR spectrometries were also used to elucidate the structure of the unknown piperacillin impurity. The spectrometric data suggested that the unknown was piperacillin amide (IV). This hypothesis was confirmed by compar-

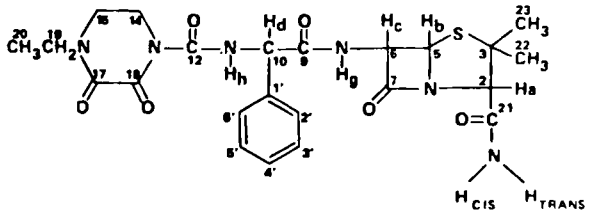
ison of the chromatographic and spectrometric data with that of an authentic piperacillin amide sample prepared in an unambiguous organic synthesis. These results demonstrate that the combination of soft-ionization mass spectral techniques, high-field NMR, and IR are exceptionally effective for identifying small amounts of nonvolatile components.



(IV)

EXPERIMENTAL

Chromatography—A column chromatographic procedure was followed for isolating the unknown piperacillin impurity. The chromatographic column was 80 × 5.2 cm and was packed with 1 kg of Florisil[3], 60–100 mesh. Twenty grams of bulk piperacillin monohydrate were dissolved in 200 mL of acetonitrile and loaded on to the column. The elution solvent consisted of acetonitrile–water (96:4, v/v) with a flow rate of 35 mL/min. The detector was a UV spectrophotometer[4] fitted with a variable-volume flow cell set to monitor at 220 nm. This system operated at ambient temperature. The elution volume of the piperacillin impurity was 2100–4000 mL. This experiment was repeated three times before discarding the column packing. The eluant containing the impurity from three runs was combined, distilled *in vacuo*, and freeze-dried to produce 84 mg of white solid.

Analytical reverse-phase HPLC[5] with UV detection[6] at 220 nm was used for the analysis of bulk piperacillin and the isolated impurity components. A 250 × 4.6-mm column packed with silica gel chemically bonded with octadecylchlorosilane[7] was maintained at 35°C. The mobile phase consisted of methanol–water–0.2 M Na_2HPO_4 (45:34:10, v/v/v) adjusted to pH 6.5 with 0.33 M phosphoric acid. The injection volume of samples was 20 μL, made up in the mobile phase.

Although dimethyl sulfoxide (Me_2SO) is the solvent of choice for the unknown piperacillin impurity, methanol was used even though the impurity underwent a chemical transformation when dissolved in the latter solvent for an extended period (>1 d) at room temperature. At elevated temperatures the reaction rate is enhanced considerably. However, by limiting the contact time to <30 min, this problem was circumvented.

Spectrometry—FD mass spectra were obtained with a double-focusing high-performance mass spectrometer[8]. The FD emitter consisted of a 10-μm tungsten wire with microneedles of pyrolytic carbon grown to a length of ~30 μm. The FD emitter was coated with a Me_2SO solution of the unknown piperacillin impurity sample. On application of the emitter current, very weak signals were observed due to a high sodium ion content contaminating the sample and emitter. The original sample was washed in the following fashion to remove inorganic salts. Approximately 20 mg of the trapped piperacillin impurity was partially dissolved in 5 mL of acetonitrile. On addition of 5 mL of distilled water a white precipitate formed, which was collected on a filter and washed with 1 mL of distilled water. The filtrate was then dried *in vacuo* and analyzed in the FD mode. The sodium signal of the washed sample was reduced considerably, and relatively intense FD signals were produced by the sample. Low-resolution FD data were acquired at a resolution of 1000.

Exact mass measurements in the FD mode were made at a resolution of 6000 in the following fashion. A reference peak in the electron-impact (EI) mode (PFK[9] fragment: $C_{13}F_{19}$, *m/z* 516.9697) was sequentially peak matched against the molecular ion of the unknown piperacillin impurity in the FD mode. The experimental mass difference between the FD and EI modes was measured with a known reference compound peak in both the field ionization (FI) and EI modes [tris(pentafluoroethyl)-*s*-triazine[9]: $C_9F_{15}N_3$, *m/z* 434.9853]. Using this mass difference, the exact mass of the unknown was corrected.

FAB spectra were obtained with a double-focusing high-performance mass spectrometer[8] and with a triple-stage quadrupole mass spectrometer[10]. Collision-activation decomposition (CAD) of selected FAB ions was performed on the latter instrument (10). The fast atom reagent gas was xenon, and the collision gas was argon. The samples for FAB ionization were either mixed directly with glycerol or dissolved in Me_2SO and then mixed with glycerol. FAB spectra of the unknown piperacillin impurity were obtained in both the positive- and negative-ionization modes. FAB/CAD spectra in the positive-ionization mode were obtained on the protonated molecular ion and the sodium adduct molecular ion of the unknown piperacillin impurity and synthetic piperacillin amide (neat and spiked with sodium chloride).

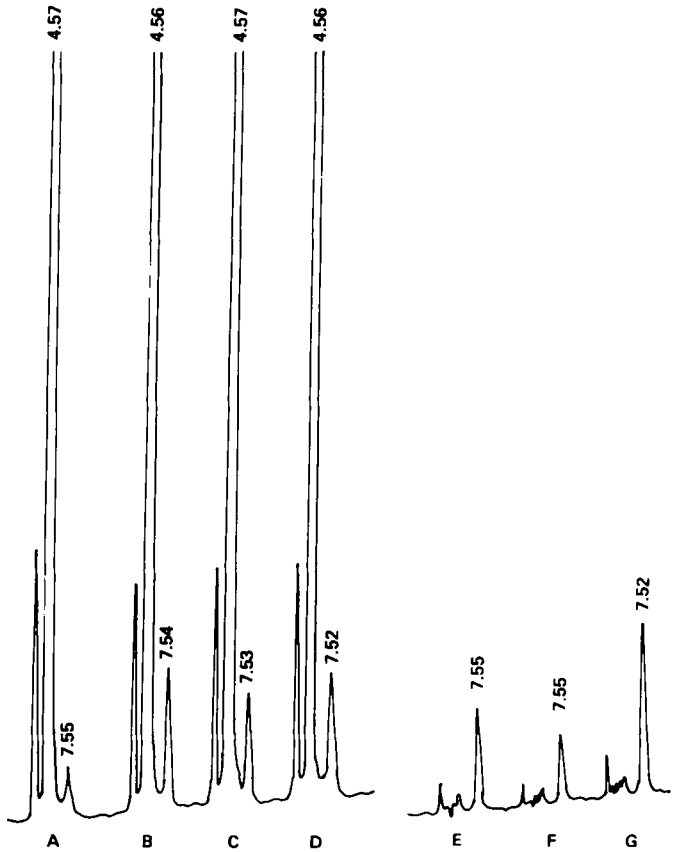


Figure 1—*HPLC chromatograms with retention times (min). Key: (A) bulk piperacillin; (B) bulk piperacillin spiked with unknown piperacillin impurity; (C) bulk piperacillin spiked with synthetic piperacillin amide; (D) bulk piperacillin spiked with unknown piperacillin impurity and synthetic piperacillin amide; (E) unknown piperacillin impurity; (F) synthetic piperacillin amide; (G) unknown piperacillin impurity spiked with synthetic piperacillin amide.*

Desorption chemical ionization (DCI) was performed on a quadrupole mass spectrometer[11] in the positive- and negative-ionization modes with methane and ammonia as the reagent gases. The sample was rubbed onto the surface of one end of a gold wire, ~1 cm long, and the other end was inserted into the tip of the direct insertion probe. This gold wire effectively extended the probe length so that the sample was inserted directly in the ion plasma region of the source. The thermal energy of the ion plasma and rapid heating of the probe gently desorbed the sample from the gold wire surface generating ions of diagnostic interest in the negative-ion mode. The DCI mass spectral data reported in this paper correspond to the first signal in the reconstructed total ion current profile, as the samples were rapidly heated.

The ^1H- and ^{13}C-NMR spectra were obtained on a high-field NMR spectrometer[12] operating in the pulsed Fourier transform mode at 250.13 and 62.89 MHz, respectively. The samples were dissolved in Me_2SO-d_6, and the spectra were referenced to tetramethylsilane. The IR spectra were recorded in 100 scans on a Fourier transform IR system[13] using samples pressed into potassium bromide pellets.

Preparation of Piperacillin Amide—To a solution of isobutyl chloroformate (13.6 g, 100 mmol) in chloroform (100 mL) at −30°C under argon was added a cold solution of piperacillin monohydrate (53.5 g, 100 mmol) in a mixture

of chloroform (500 mL) and triethylamine (10.1 g, 100 mmol, 14 mL) over a 40-min period. The mixture was stirred an additional 1.5 h at 0°C. Ammonia was bubbled through the mixture (a white precipitate formed immediately) in a steady stream for 25 min. The thick white suspension was diluted with 1 L of chloroform and then filtered. The white filter cake was washed with chloroform (2 × 200 mL) and dried *in vacuo* to afford 49 g of crude piperacillin amide, which contained a considerable amount of ammonium chloride.

The aforementioned crude product (30 g) was suspended in 150 mL of distilled water and stirred vigorously for 2 h. The white solid was filtered, washed with acetone (2 × 50 mL) and anhydrous ether (2 × 100 mL), and dried *in vacuo* to afford 24 g of piperacillin amide (78% yield), mp 217–220°C dec[14].

Spectral Data—All the spectral data listed below were identical for both the unknown piperacillin impurity and the synthetic piperacillin amide unless noted otherwise. FD-MS *m/z* (%) for the piperacillin impurity: 555, 539, 517, 516, 375, 374, 373, 143, 142, and 141; for piperacillin amide: 516(18), 375(18), 359(18), 274(12), 160(8), 159(14), 158(12), 144(20), 143(100), and 142(100). +FAB-MS *m/z* for the piperacillin impurity and amide spiked with sodium chloride: 539, 519, 518, 517, 397, 359, 333, 241, 159, and 143. −FAB-MS *m/z* for the piperacillin impurity: 517, 516, 515, and 373. +FAB/CAD(517)-MS *m/z* (%): 359(13), 274(12), 186(20), 175(3.5), 174(4), 159(100), 143(82), 132(4), 115(5), and 114(6). +FAB/CAD(539)-MS *m/z* (%): 475(11), 397(100), 181(2), and 165(20). +DCI-MS *m/z* (%): 375(15), 159(60), and 143(100). −DCI-MS *m/z* (%); 516(22), 374(100), 341(35), 331(35), 330(45), 233(85), 175(77), 174(62), 173(50), and 155(35). ^{1}H-NMR (Me_2SO-d_6): δ 1.18 (t, NCH_2CH_3, J = 7.5 Hz), 1.39 (s, CH_3), 1.53 (s, CH_3), 3.32 (q, NCH_2CH_3, J = 5.0 Hz), 3.56 (m, CH_2), 3.90 (m, CH_2), 4.10 (s, CH_a), 5.36 (d, CH_b, J = 3.5 Hz), 5.46 (dd, CH_c), 5.72 (d, CH_d, J = 7.0 Hz), 7.2–7.5 (m, 5 ArH; s, NH_{cis}), 7.58 (s, NH_{trans}), 9.35 (d, NH_g, J = 7.0 Hz), and 9.84 ppm (d, NH_h, J = 7.5 Hz). ^{13}C-NMR (Me_2SO-d_6): δ 11.9 (q, C-20), 26.5 (q, C-22), 30.0 (q, C-23), 40.3 (t, C-19), 41.6 (t, C-15), 42.8 (t, C-14), 56.5 (d, C-6), 57.7 (d, C-10), 63.9 (s, C-3), 66.7 (d, C-5), 70.6 (d, C-2), 126.5 (d, C-3′ and C-5′), 127.8 (d, C-4′), 128.3 (d, C-2′ and C-6′), 137.8 (s, C-1′), 151.8 (s, C-12), 155.3 (s, C-18), 159.4 (s, C-17), 168.8 (s, C-7), 169.3 (s, C-9), and 173.4 ppm (s, C-21).

RESULTS AND DISCUSSION

Florisil was chosen as the adsorbent because it almost irreversibly adsorbs acidic materials (11). Since this material should adsorb piperacillin acid irreversibly, it should be possible to elute the more chemically neutral piperacillin impurity selectively. The resolution of the two components on Florisil was accomplished using an elution solvent mixture containing an unusually high water concentration in acetonitrile, *i.e.*, water–acetonitrile (4:96, v/v). The high water content of the elution solvent did not degrade the Florisil adsorption properties for these very polar materials. Only very low levels of piperacillin were detected in the trapped piperacillin impurity sample using the analytical reverse-phase HPLC conditions described in the *Experimental* section.

Bulk piperacillin (monohydrate) and the trapped unknown piperacillin impurity component, when analyzed under the analytical HPLC conditions, produced the chromatograms illustrated in Fig. 1a and e, respectively. The components eluting at 4.57 and 7.55 min correspond to piperacillin and the unknown piperacillin impurity, respectively.

Similarly, the analytical HPLC chromatograms of the synthetic piperacillin amide and piperacillin spiked with the synthetic piperacillin amide are illustrated in Fig. 1f and c, respectively. In addition, experiments were performed in which piperacillin was spiked with the unknown piperacillin impurity (Fig. 1b) or both the unknown impurity and the synthetic piperacillin amide (Fig. 1d). In all cases, the retention times of the synthetic piperacillin amide and the unknown piperacillin impurity either individually or in the spiking experiments were identical, *i.e.*, within the experimental errors associated with the reproducibility of the HPLC experiment.

The mass spectral properties exhibited by the piperacillin impurity, even under soft-ionization conditions, included (*a*) the difficulty in generating intense molecular and fragment ions of long enough duration for accurate measurement and (*b*) the lability of the chemical bond between the piperazine moiety and the rest of the piperacillin molecule. These mass spectral properties of the piperacillin impurity were similar to those of piperacillin.

The FD mass spectra of the washed piperacillin impurity are illustrated in Fig. 2 as a function of increasing emitter current. At 16 mA (Fig. 2a) an intense ion cluster at *m/z* 516 appears, to which is added at 18 mA (Fig. 2b) an intense ion cluster at *m/z* 539 and a weak peak at *m/z* 555. The ion cluster at *m/z* 539 and the weak peak at *m/z* 555 correspond to the sodium and potassium adducts of the molecular ion, respectively, of the unknown piperacillin impurity. This confirms that *m/z* 516 is $M^{+\cdot}$ and not $[M + H]^+$.

The molecular ion of the unknown piperacillin impurity was peak-matched in the FD mode and had an exact mass of 516.1882. This value is within 9.1 millimass units of $C_{23}H_{28}N_6O_6S$ (516.1791), the corresponding elemental formula of piperacillin amide.

The FD mass spectrum of the synthetic piperacillin amide produced a relatively intense molecular ion as well as a number of fragment ions consistent with its structure. No sodium or potassium adduct molecular ions were observed due to the absence of the cations.

The molecular weight of 516 for the unknown piperacillin impurity as well as its identity as piperacillin amide were confirmed by positive and negative FAB ionization and DCI mass spectrometries. The FAB ionization mass spectra of the unknown piperacillin impurity contained the quasimolecular ions $[M + H]^+$, $[M + Na]^+$, and $[M - H]^-$ at *m/z* 517, 539, and 515, respectively. Weak fragment ions were produced as well and often were difficult to distinguish from the glycerol background spectrum. The identity of the impurity with that of piperacillin amide was confirmed on comparison of the nearly identical ions and intensities produced in the FAB/CAD spectra from the *m/z* 517 and 539 ions for the two materials.

Similarly, the positive and negative DCI spectra of the unknown piperacillin impurity and the synthetic piperacillin amide were identical. The positive DCI spectrum obtained no molecular ion and resembled the spectrum produced under electron-impact conditions. The negative DCI spectrum contained a molecular ion, $M^{-\cdot}$, and diagnostic ions characteristic of the molecule.

The ^{1}H-NMR spectrum of the unknown piperacillin impurity is nearly identical to that of piperacillin except for additional absorption observed in the aromatic proton region, which correspond to two additional protons. These two uncoupled nonequivalent protons correspond to the *cis* and *trans* amide protons of piperacillin amide. Synthetic piperacillin amide gave a NMR spectrum identical with that of the unknown impurity with the exception of the *trans* amide proton chemical shift, 7.58 ppm in piperacillin amide *versus*

[14] Melting points were determined on a Melt-Temp Melting Point Apparatus.

[15] Micro analytical elemental analyses were performed on a Model 240 Elemental Analyzer; Perkin-Elmer Corp., Norwalk, Conn.

[16] Karl Fisher analyses were performed on a Methohm Herisau-K.F. Automate E547 and Dosmat E535.

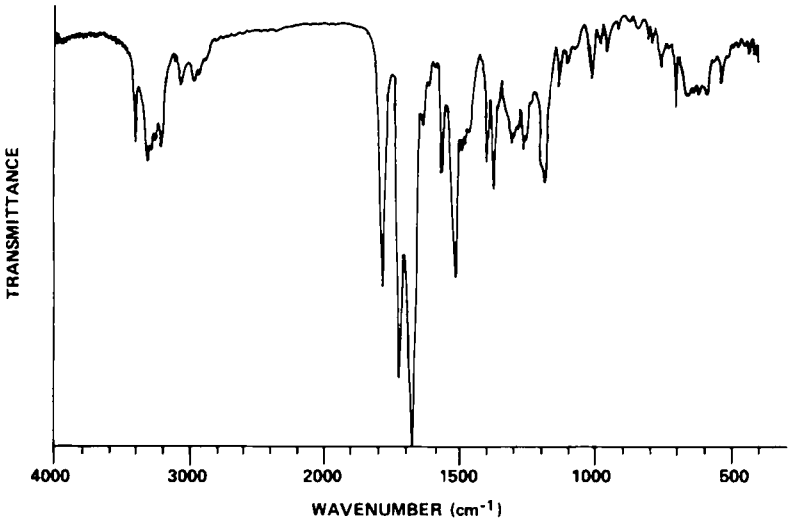

Figure 3—*IR spectrum of the unknown piperacillin impurity and synthetic piperacillin amide.*

7.72 ppm in the unknown piperacillin impurity. These differences in chemical shift, attributed to differences in concentration between the two samples, were verified in a NMR spiking experiment of synthetic piperacillin amide into the piperacillin impurity. Chemical shifts of amide protons undergo large variations when the hydrogen bonding interactions are modified by concentration, pH, temperature, and solvent changes.

The ^{13}C-NMR spectrum of the unknown piperacillin impurity is identical (within experimental error) to that of piperacillin; hence, piperacillin and the unknown impurity have identical carbon backbone structures. The ^{13}C-NMR chemical shifts and intensities of the synthetic piperacillin amide were identical to that of the unknown impurity.

The IR spectrum of the unknown piperacillin impurity and that of the synthetic piperacillin amide were identical (Fig. 3). The characteristic absorption band assigned to the carbonyl stretching mode of the β-lactam ring is at 1780 cm^{-1}.

The unknown piperacillin impurity is structurally very similar to piperacillin, *viz.*, the β-lactam group is intact (IR) and the major NMR absorptions of piperacillin and the piperacillin impurity are nearly identical, with the exception of two proton resonances at 7.72 and ~7.3 ppm. The MS data indicate that the unknown structure has a molecular weight of 516, one mass unit less than piperacillin, and based on this even mass has an elemental composition of an even number of nitrogen atoms. The unknown piperacillin impurity has been shown, based on the comparison of liquid chromatographic and MS, NMR, and IR spectrometric data, to be identical with *bona fide* piperacillin amide. The origin of the piperacillin amide is unknown.

Piperacillin amide was tested for biological activity in an *in vitro* spectrum assay against 27 bacteria. It lacked antimicrobial activity.

Excretion, Distribution, and Metabolism of Primaquine in Rats

ALICE M. CLARK *x, JOHN K. BAKER ‡, and JAMES D. McCHESNEY *

Received April 4, 1982, from the *Department of Pharmacognosy and the ‡Department of Medicinal Chemistry, School of Pharmacy, The University of Mississippi, University, MS 38677. Accepted for publication February 7, 1983.

Abstract □ The metabolism of the 8-aminoquinoline antimalarial drug, primaquine (I) was studied using rats. The drug was administered intravenously, intraperitoneally, and orally, and blood samples were collected at various time intervals. Primaquine was metabolized by oxidative deamination to give 8-(3-carboxy-1-methylpropylamino)-6-methoxyquinoline (III). The plasma levels of both primaquine and its metabolite were determined by HPLC. The tissue distributions of radioactive primaquine after intravenous, intraperitoneal, and oral administrations were also determined. Significant concentrations of radioactivity were found in the lungs, adrenal glands, and liver. In addition, a significant portion of the dose was found to be excreted in the feces within 24 h after administration of the drug by either of the three routes.

Keyphrases □ Primaquine—excretion, distribution, and metabolism in rats □ 8-(3-Carboxy-1-methylpropylamino)-6-methoxyquinoline—primaquine metabolite, excretion and distribution in rats □ Metabolism—primaquine in rats, excretion and distribution

Primaquine (I), an 8-amino-6-methoxyquinoline derivative used for the treatment of malaria, is active against the exoerythrocytic forms of *Plasmodium vivax* and *Plasmodium ovale* and against the gametocytes of *Plasmodium falciparum*, thus inhibiting sporogony (1). Primaquine has a low chemotherapeutic index, therefore greatly limiting its prophylactic and therapeutic applications. It is known to induce hemolytic lesions in patients suffering from a deficiency in glucose 6-phosphate dehydrogenase, a genetic condition most common among inhabitants of regions in which malaria is endemic.

Although earlier workers suggested that one or more metabolites of primaquine may be responsible for its toxicity and/or antimalarial activity, very little has actually been accomplished in identifying the metabolite(s) of primaquine. Studies with other 8-aminoquinolines such as pamaquine and pentaquine have indicated that these drugs are metabolized very rapidly (2–6); it was speculated that primaquine might undergo a similar fate. Based on earlier work with pentaquine (6) and pamaquine (7), it was proposed that primaquine underwent metabolic degradation by *O*-demethylation of the 6-methoxy group followed by hydroxylation at the 5-position and oxidation to give a 5,6-quinone derivative. It was further speculated that this product was capable of oxidation–reduction activity and, therefore, may account for the hemolytic activity of primaquine (8). None of these proposed metabolites have actually been characterized from humans or animals; however, 6-methoxy-8-aminoquinoline (II) was identified as a metabolite of primaquine in the urine of humans (9).

We have recently reported the identification of 8-(3-carboxy-1-methylpropylamino)-6-methoxyquinoline (III) as the major metabolite of primaquine in rat plasma after intravenous injection (10); this is also the major metabolite in several species of fungi (11). We report herein further studies on the metabolism and distribution of primaquine after intravenous, intraperitoneal, and oral administrations.

EXPERIMENTAL

Source of Compounds—Commercially available primaquine diphosphate (I) was used as received[1]. [2,4-^{14}C]Primaquine diphosphate[2] had a specific activity of 1.55 mCi/mmol. 8-(3-Carboxy-1-methylpropylamino)-6-methoxyquinoline (III) was prepared by microbial transformation of primaquine as previously described (11).

Determination of Plasma Levels of Primaquine and Its Metabolite—Male Wistar rats (200–300 g) were anesthetized with sodium pentobarbital (30 mg/kg ip). Primaquine diphosphate was administered either intravenously (10 or 20 mg/kg), intraperitoneally (20 mg/kg), or orally (20 mg/kg) as an aqueous solution in distilled water (40 mg/mL). Multiple blood samples were collected from the intraorbital sinus vein in two 50-μL heparanized capillary tubes at 1, 3, 15, 30 min, and 1, 3, 6, 12, and 24 h after dosing.

After centrifugation in a hematocrit centrifuge for 2 min, the plasma was analyzed using an HPLC procedure shown to be specific for III and primaquine (10). HPLC analyses utilized a C_{18} reverse-phase column[3] (10 μm) with a mobile phase consisting of 6.6 g of K_2HPO_4, 8.4 g of KH_2PO_4, 2.4 L of methanol, 1.6 L of water, and 4 g of *N,N*-dimethyloctylamine (flow rate = 1 mL/min) (10). The sample size consisted of 20 μL of plasma, and detection was accomplished using a dual-wavelength UV detector (254 and 280 nm). For pharmacokinetic studies, the carboxylic acid metabolite (III) was injected at a dosage of 12 mg/kg iv, the molar equivalent to the primaquine diphosphate dosage of 20 mg/kg. Blood samples were collected from the intraorbital sinus vein at 1, 3, 15, 30 min, and 1, 3, 6, 12, and 24 h postadministration. After centrifugation, the plasma samples (20 μL) were analyzed directly by HPLC.

Tissue Distribution of [2,4-^{14}C]Primaquine Diphosphate—Fifty-four male Wistar rats (200–300 g) were anesthetized with sodium pentobarbital (30 mg/kg of body weight ip). An aqueous solution consisting of a 9:1 mixture of primaquine diphosphate and [^{14}C]primaquine diphosphate was administered intravenously (10 mg/kg), intraperitoneally (20 mg/kg), and orally (20

mg/kg). The rats were sacrificed at 1, 3, 15, 30 min, and 1, 3, 6, 12, and 24 h after administration; two rats were used for the determination of each time point for each route of administration. A blood sample was collected by cardiac puncture and the following organs and tissues were removed: lungs, kidneys, adrenal glands, heart, liver, spleen, pancreas, brain, abdominal muscle, abdominal fat, small intestine, large intestine, testes, and stomach. After the total wet weight of each organ was determined, a portion (100–200 mg) was taken for combustion. The tissue samples were burned in a sample oxidizer[4] and the [^{14}C]carbon dioxide was trapped with a carbon dioxide absorber[5]. The trapped [^{14}C]carbon dioxide was diluted in an organic scintillation cocktail[6], and the radioactivity of each sample was measured in a liquid scintillation counter[7]. Radioactivity in the various tissues was expressed as

the relative concentration (12), defined as (counts of radioactivity in an organ/total radioactivity dose) × (weight of animal/weight of organ).

Determination of Radioactivity in Plasma After Administration of [^{14}C]-Primaquine Diphosphate—[^{14}C]Primaquine diphosphate (1.55 mCi/mmol) was injected intravenously into a single rat at a dose of 10 mg/kg. After 3 h, a blood sample was collected by cardiac puncture, and the rat was sacrificed. The blood was centrifuged, and a portion of the plasma (20 μL) was injected into the HPLC. A total of 16 fractions (1 mL each) were collected, and each fraction was diluted with 15 mL of scintillation cocktail[8]. The radioactivity of each fraction was measured using a liquid scintillation counter[7]. To determine the total radioactivity, a 20-μL portion of the plasma was also diluted with 1 mL of the HPLC mobile phase and 15 mL of scintillation cocktail, and the radioactivity was measured.

RESULTS AND DISCUSSION

Primaquine diphosphate was administered intravenously, intraperitoneally, and orally to male rats, blood was collected at various time intervals, and the plasma was analyzed by HPLC for primaquine (I) and its metabolite (III). After intravenous injection of primaquine diphosphate, the drug disappeared very rapidly from the blood ($t_{1/2} \sim 1$ min). Within 1 min after administration of the dose, the plasma concentration was only 1–5% of the value one would expect if there were an even distribution of the drug in the blood (Fig. 1). This extremely rapid fall in plasma concentration was also observed using ^{14}C-labeled primaquine, where at 1 min after intravenous administration, the relative concentration in blood was 0.22 and in the lung a value of 4.90 was observed. These observations were consistent with the observations of other workers (13, 14) using structurally related drugs, who found that if a given drug contained a basic aliphatic amino group ($pK_a > 8.5$) that was joined to a lipophilic aromatic ring system, the drug would rapidly ($t_{1/2} < 3$ min) accumulate in the lung tissue. Primaquine also contains an aliphatic amine side chain ($pK_a = 10.39$) with a very lipophilic aromatic ring system, which probably accounted for its rapid disappearance from plasma and accumulation in the lung tissue.

After intravenous administration of primaquine diphosphate (20 mg/kg), an initial rapid drop in plasma concentration of primaquine was observed, followed by a considerably slower fall in the plasma level ($t_{1/2} = 2.24 \pm 0.82$ h). When the animals were dosed at a lower level (10 mg/kg), essentially the same half-life was observed ($t_{1/2} = 1.88 \pm 0.35$ h). After intraperitoneal administration of primaquine diphosphate, the plasma levels of primaquine reached a maximum ~30 min (Fig. 1) after administration of the dose, then began to fall at about the same rate that was observed for the intraveneous dose. Following oral administration of primaquine diphosphate (20 mg/kg), the plasma level of primaquine (Fig. 1) never rose above 1.0 μg/mL. From

a comparison of the area under the primaquine concentration *versus* time curves of the oral and intravenous routes of administration (Table I), it was found that only 25% (range 8–56%) of the primaquine diphosphate was available to the central compartment.

Following intravenous or intraperitoneal administration of primaquine diphosphate (20 mg/kg), the plasma level of the carboxylic acid metabolite (III) was found to increase very rapidly, and after 1 h the concentration of metabolite III was far greater than that of primaquine (Fig. 2). When a pure sample of III was given at a dose equivalent on a molar basis to 20 mg/kg of primaquine diphosphate, the initial concentration of III was much greater (Fig. 3) than had been observed for primaquine. Therefore, it would appear that once the basic amino group is metabolically removed from the side chain of primaquine, the metabolite no longer has a high affinity for the lung and other tissues. In addition, the half-life of III ($t_{1/2} = 4.38 \pm 0.26$ h) was found to be twice as long as that of primaquine itself. The very high plasma concentration of the metabolite compared with primaquine (Figs. 1 and 2) could be a result of the much lower tissue affinity and longer half-life of the metabolite compared with that of the parent drug.

Following intravenous administration of primaquine diphosphate (20 mg/kg, Table II) it was found that 22% (range 5.63–63.6%) of the dose was converted to the metabolite (III). When the dose was reduced by half, essentially the same extent of conversion was observed (mean 17.1%; range 15.5–19.6%). When the primaquine diphosphate was administered intraperitoneally, the percent conversion to the metabolite was slightly higher (mean 45%, range 21.6–73.9%); however, the difference was not statistically significant at the 95% level.

Following oral administration of primaquine diphosphate (20 mg/kg, Table II), it was found that the percent of metabolite III that ultimately reached the plasma (mean 4.2%, range 2.71–6.88%) was significantly lower than that seen in the other routes of administration. Since only 25% of the primaquine that was administered orally actually reached the plasma, it would also be anticipated that the amount of the metabolite formed would be correspondingly lower if the primaquine was poorly absorbed or if the primaquine was being excreted in the bile following a first pass through the liver.

From a comparison of the HPLC analyses of the plasma of primaquine-treated animals and plasma blanks, only metabolite III and primaquine were

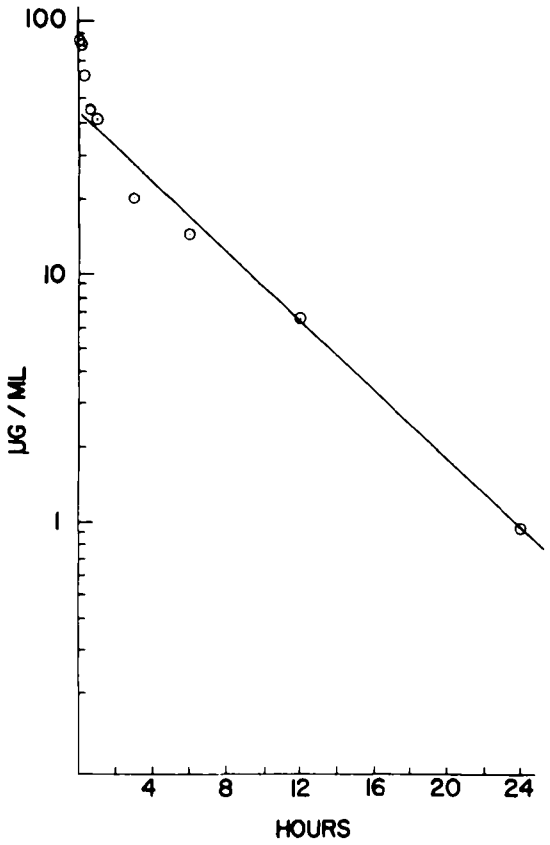

Figure 3—*Plasma concentration of 8-(3-carboxy-1-methylpropylamino)-6-methoxyquinoline (III) after an intravenous injection of III. Each value represents the average of three animals. Metabolite III showed a half-life of 4.38 ± 0.26 h.*

detected. To determine if other metabolites might have gone undetected in the plasma, a rat was administered [^{14}C]primaquine diphosphate (10 mg/kg iv; 1.55 mCi/mmol). The rat was sacrificed 3 h after administration of the labeled primaquine, and a blood sample was taken by cardiac puncture. A portion of the plasma was injected into the HPLC, and 1-mL fractions were collected. Each of the fractions was diluted with scintillation cocktail and the radioactivity was measured. It was found that 59% of the total radioactivity in the plasma could be accounted for in fractions containing the carboxylic acid metabolite (III) and 5% as unchanged primaquine.

An investigation of the tissue distribution of primaquine in rats was undertaken using ^{14}C-labeled primaquine diphosphate. While this work was in progress, Holbrook *et al.* reported on the tissue distribution of labeled primaquine in rats using [6-*O*-methyl-^{3}H]primaquine (15). In that report, the distribution of primaquine was measured in seven rat tissues (lung, liver, kidney, spleen, heart, brain, and blood) at 15–180 min after intraperitoneal administration (15). We report herein the distribution of primaquine in 15

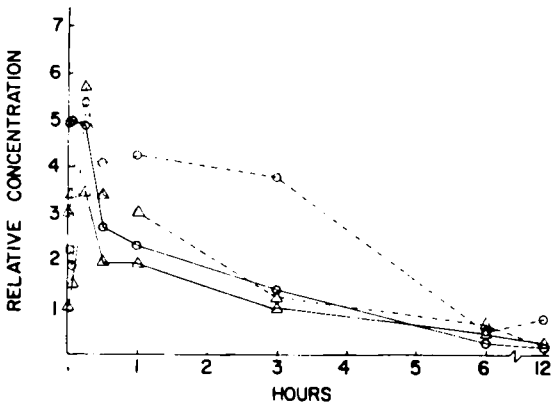

Figure 4—*Relative concentration of radioactivity in the lung (○) and liver (△) after intravenous (—) and intraperitoneal (---) administrations of [^{14}C]primaquine diphosphate. Each value represents the average of two animals.*

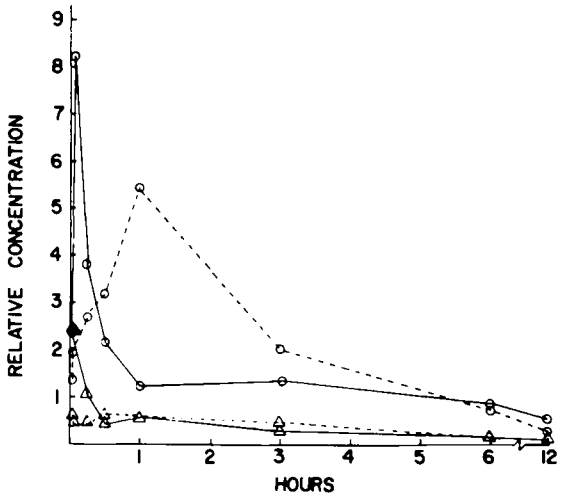

Figure 5—*Relative concentration of radioactivity in the adrenal gland (○) and heart (△) after intravenous (—) and intraperitoneal (---) administrations of [^{14}C]primaquine diphosphate. Each value represents the average of two animals.*

tissues at nine intervals from 1 min to 24 h after intravenous, intraperitoneal, and oral administration using ring-labeled [^{14}C]primaquine rather than the methyl-labeled [^{3}H]primaquine previously used. Although there appears to be wide distribution of primaquine throughout the body tissues, it is apparent that the radioactivity is concentrated in certain tissues, as determined by relative concentration (12).

At 1 min after intravenous administration of [^{14}C]primaquine diphosphate, the lungs contained the highest concentration of radioactivity (relative concentration = 4.90; Table III). Radioactivity was also concentrated in the heart, adrenal glands, kidneys, and liver. The adrenal glands and lungs contained the highest concentrations of radioactivity until 3 h after injection, when the contents of the small intestine showed the highest concentration of radioactivity. The contents of both the small and large intestines continued to contain the highest relative amount of radioactivity at 6, 12, and 24 h after injection. It appears, therefore, that there is extensive recirculation of radiolabeled material through the intestinal system after intravenous injection.

Following intraperitoneal administration of labeled primaquine, a number of tissues showed a selective concentration of the radioactivity (Table IV). Significant uptake was observed for the lung (Fig. 4), liver (Fig. 4), adrenal (Fig. 5), and spleen (Fig. 6) tissues. Large quantities of the radioactivity were also found in the contents of the large and small intestines in the later time periods following the intraperitoneal dosage (Fig. 7). Although the time course of the intraperitoneal and intravenous routes were different, there were no significant differences in the tissue distribution.

Following oral administration of labeled primaquine, a significantly different distribution of the radioactivity was observed (Table V). The areas under the curves (AUC) for the lung, adrenal, spleen, kidney, heart, blood, and pancreas tissues were found to be only 22 ± 4% (range 19–29%) of the dose-adjusted AUC values obtained after intravenous administration. However, the AUC for the liver was found to be 45% of that obtained after intravenous administration. These findings suggest that a major portion of the primaquine reaches the liver; however, metabolism and excretion into the bile prevents the major portion of the dose from reaching the plasma and other tissues.

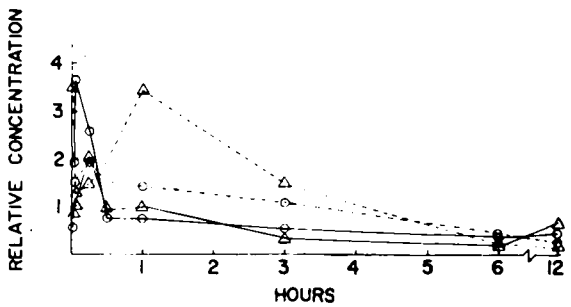

Figure 6—*Relative concentration of radioactivity in kidney (○) and spleen (△) after intravenous (—) and intraperitoneal (---) administrations of [^{14}C]primaquine diphosphate. Each value represents the average of two animals.*

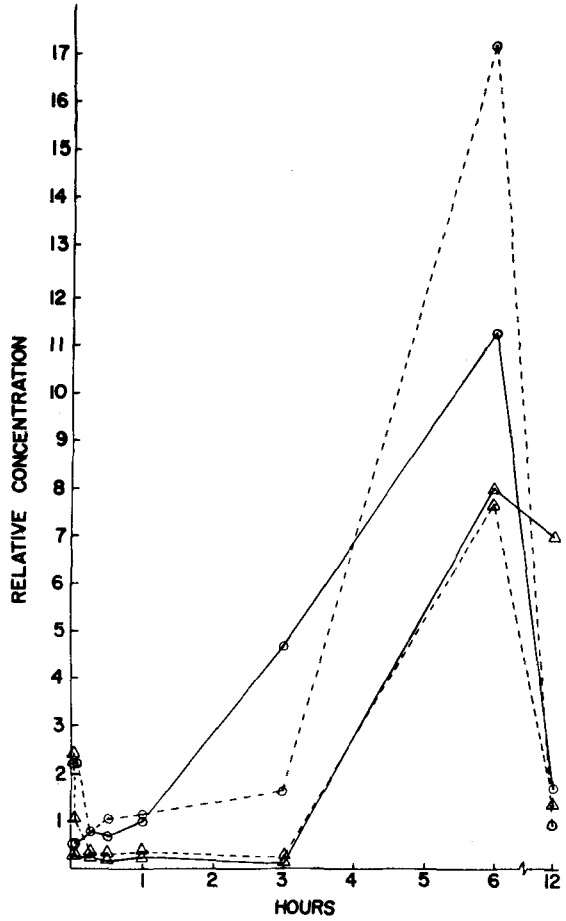

Figure 7—*Relative concentration of radioactivity in the contents of the small intestine (○) and large intestine (△) after intravenous (—) and intraperitoneal (---) administrations of [^{14}C]primaquine diphosphate. Each value represents the average of two animals.*

Consistent with these findings was the observation that a significant portion of the radioactivity was found in the feces following intravenous or intraperitoneal administrations (Table VI). Since the percentages of the dose found in the feces after intravenous, intraperitoneal, and oral administrations are all nearly the same, it would appear that primaquine is fairly well absorbed when given orally, but that only a small portion (25% by HPLC analysis) of the primaquine actually reaches the plasma because of first-pass metabolism and enterohepatic circulation.

CONCLUSIONS

The results of these studies show that primaquine was rapidly metabolized after intravenous and intraperitoneal injection and a major metabolite (mean 28%, range 5.6–74%) was found to be the carboxylic acid product (III) resulting from oxidative deamination. At 3 h after administration of the dose, this metabolite accounted for almost 60% of the total radioactivity in rat plasma, as shown by HPLC fractionation of radioactive blood samples. These findings were consistent with those of Holbrook *et al.* (15), which indicated that the majority of the radioactivity in the blood samples was not extractable into heptane under alkaline conditions.

A significant finding of the current distribution studies was that a large portion of the carbon-14 was found in the intestinal tract and feces following intravenous or intraperitoneal administration. Of the label excreted during the first 24 h following intravenous or intraperitoneal administration, approximately one-third was found in the feces, which would suggest that enterohepatic circulation may be involved in the distribution and metabolism of primaquine.

When primaquine was given orally, only 25% (range 5–56%) of the dose ultimately reached the plasma, while 18% of the dose was excreted in the feces during the first 24 h. These observations would suggest that first-pass metabolism and enterohepatic circulation may be involved in the systemic availability of primaquine following oral dosing. When labeled primaquine was administered intravenously, the major portion of the dose was found in highly perfused tissues such as the lungs, adrenal glands, liver, spleen, and heart, while little remained in the plasma. This rapid uptake by lung tissue has also been reported for similar aromatic compounds containing a very basic aliphatic amino group (13, 14).

When the labeled primaquine was administered orally, the tissue distribution was found to be significantly different because of enterohepatic recirculation and first-pass metabolism. Following oral administration, the amount of label reaching most tissues was reduced to 22% of that obtained after intravenous administration. However, the amount reaching the liver remained fairly high following oral administration, which was significant considering that primaquine is normally administered orally to suppress the malaria organisms residing in the liver.

Table VI—Percentage of Radioactive Dose Excreted in Urine and Feces after Intravenous, Intraperitoneal, and Oral Administrations of [^{14}C]-Primaquine Diphosphate [a]

Route of Administration	Radioactive Dose Recovered, %	
	Urine (0–24 h)	Feces (0–24 h)
Intravenous	26%	18%
Intraperitoneal	37%	14%

Characterization of Microenvironments of 2-(4′-Hydroxyphenylazo)benzoic Acid Bound to Bovine Serum Albumin by Studying the Solvent Effects

TAMIKO SAKURAI ˣ **and SEISHI TSUCHIYA**

Received September 10, 1982, from the *Tokyo College of Pharmacy, 1432-1, Horinouchi, Hachioji, Tokyo, Japan.* Accepted for publication February 11, 1983.

Abstract □ The binding and thermodynamic parameters of the two binding forms of 2-(4′-hydroxyphenylazo)benzoic acid to bovine serum albumin were estimated. The number of the binding sites of the azo form was 3.2 and that of the hydrazone form was 0.7. The binding of the hydrazone form was affected only by enthalpy changes, in contrast to that of the azo form which was affected by both enthalpy and entropy changes. To estimate the complex microenvironments of 2-(4′-hydroxyphenylazo)benzoic acid molecules on bovine serum albumin, the solvent effects were studied. The 2-carboxyl group of 2-(4′-hydroxyphenylazo)benzoic acid participates in the azo–hydrazone tautomerism. The 2-carboxylate ion forms an ion pair with triethylamine in ethylene dichloride, chloroform, and benzene, resulting in the appearance of the hydrazone form. The hydrazone formation in the system of 2-(4′-hydroxyphenylazo)benzoic acid–triethylamine (1:1) in chloroform was affected only by enthalpy changes, in the same manner as in the system of 2-(4′-hydroxyphenylazo)benzoic acid–bovine serum albumin. We speculate the presence of the two kinds of ion pairs on the basis of the changes of the azo–hydrazone tautomerism in chloroform, and that the azo form takes the contact ion pair and the hydrazone form takes the solvent-separated ion pair. A new possible model for the interaction of the azo and hydrazone forms and bovine serum albumin is proposed.

Keyphrases □ Microenvironments—2-(4′-hydroxyphenylazo)benzoic acid bound to bovine serum albumin, solvent effects, characterization □ 2-(4′-Hydroxyphenylazo)benzoic acid—binding to bovine serum albumin, solvent effects, characterization of microenvironments □ Protein binding—microenvironments of 2-(4′-hydroxyphenylazo)benzoic acid bound to bovine serum albumin, solvent effects

In a previous paper (1), it was shown that 2-(4′-hydroxyphenylazo)benzoic acid binds to two different classes of binding sites on bovine serum albumin. This binding can be distinguished spectrally since it involves the preferential binding of either the azo or hydrazone forms of this molecule to these sites. 2-(4′-Hydroxyphenylazo)benzoic acid has therefore become a useful probe when studying drug affinities and competitive binding of drugs at the two classes of binding sites (2).

To investigate the circumstances of the two classes of binding sites, the thermodynamic parameters of the azo and the hydrazone forms bound to bovine serum albumin in pH 7.40 phosphate buffer were sought. It was found that the binding of the hydrazone form was affected by the contribution of enthalpy changes only ($\Delta H°$), in contrast with that of the azo form which was affected by both enthalpy ($\Delta H°$) and entropy ($\Delta S°$) changes.

We attempted to simulate the situation leading to the hydrazone stabilization in the binding sites by measuring the changes of the azo–hydrazone tautomerism in various solvents with different dielectric constants. Baxter (3) observed the spectral change of 2-(4′-hydroxyphenylazo)benzoic acid in some organic solvents containing small amounts of the aqueous solution or in the cationic detergent. His observation has been taken to suggest the importance of the hydrophobic environments in development of the hydrazone form. However, this interpretation obscures the explanation of the thermodynamic parameters mentioned above. This paper reveals the participation of the 2-carboxyl group of 2-(4′-hydroxyphenylazo)-benzoic acid, rather than of the dielectric constant of the solvent, to the azo–hydrazone tautomerism and discusses a new possible model for the interaction of the azo and hydrazone forms in two classes of binding sites on bovine serum albumin.

EXPERIMENTAL

Materials—Bovine serum albumin (fraction V[1]) was used without further purification. 2-(4′-Hydroxyphenylazo)benzoic acid was recrystallized. Methanol, ethanol, and isopropyl alcohol were dried with molecular sieves and distilled. *tert*-Butyl alcohol, benzene, chloroform, and ethylene dichloride were refluxed over calcium hydride and distilled. Dimethyl sulfoxide and dimethylformamide were dried with molecular sieves, followed by distillation under nitrogen and reduced pressure. *n*-Butyl alcohol and isobutyl alcohol were redistilled. Triethylamine dried with calcium hydride was distilled under nitrogen and reduced pressure.

Apparatus—The visible[2], UV[2], and IR spectra[3] were obtained by spectrophotometers. Conductivity measurements[4] were made at 25°C (cell constant, 1 mho/cm).

Binding Constants of the Azo and Hydrazone Forms—Five milliliters of the solution containing 2-(4′-hydroxyphenylazo)benzoic acid (0.2×10^{-4} M–4.0×10^{-4} M) and 0.3% bovine serum albumin was dialyzed against 15 mL of the buffer solution, (0.067 M phosphate buffer, pH 7.40) for 20 h at 20°C or 37°C. After equilibration, the concentration of the total bound 2-(4′-hydroxyphenylazo)benzoic acid was determined by analyzing the free concentration in 15 mL of buffer solution. The analysis of the concentration of the azo and hydrazone forms has been described previously (1). The binding of the azo form, the hydrazone form, and total 2-(4′-hydroxyphenylazo)-benzoic acid was drawn in Scatchard plots; the binding constants were obtained from the slopes of these plots.

Equilibrium Constants of Azo–Hydrazone Tautomerism—2-(4′-Hydroxyphenylazo)benzoic acid and triethylamine were mixed at the same concentration (0.5×10^{-4} M) in the solvent, and the absorption spectra were measured at 0°C, 10°C, 20°C, and 30°C. The equilibrium constant (K) of the azo–hydrazone tautomerism is obtained by the concentration ratio (4):

$$K = \frac{(\text{hydrazone})}{(\text{azo})} = \frac{A_h/E_h}{A_a/E_a} = \frac{A_h}{A_a} \cdot \frac{E_a}{E_h} \qquad \text{(Eq. 1)}$$

where A_h, A_a, E_h, and E_a are the absorbances of the hydrazone form at 480 nm, that of the azo form at 350 nm, the molar extinction coefficient of the hydrazone form, and that of the azo form, respectively. The decrease of the concentration of the azo form, $\Delta A_a/E_a$, equals the increase of that of the hydrazone form, $\Delta A_h/E_h$. Therefore:

$$\Delta A_a/E_a = \Delta A_h/E_h \qquad \text{(Eq. 2)}$$

$$E_a/E_h = \Delta A_a/\Delta A_h \qquad \text{(Eq. 3)}$$

As E_a/E_h was 0.5 by Eq. 3 in this experiment, K was obtained by substituting this value and A_h/A_a at each temperature into Eq. 1.

pK_a of the 2-Carboxyl Group by Conductivity Measurements—The conductivity water was obtained by passing water through ion-exchange resin, followed by distillation (relative conductivity $< 1 \times 10^{-6}$ mho/cm). As the first step, 1×10^{-4} M 2-(4′-hydroxyphenylazo)benzoic acid solution was prepared under nitrogen, and the equivalent conductances ($\Lambda_{I(C)}$) at the acid

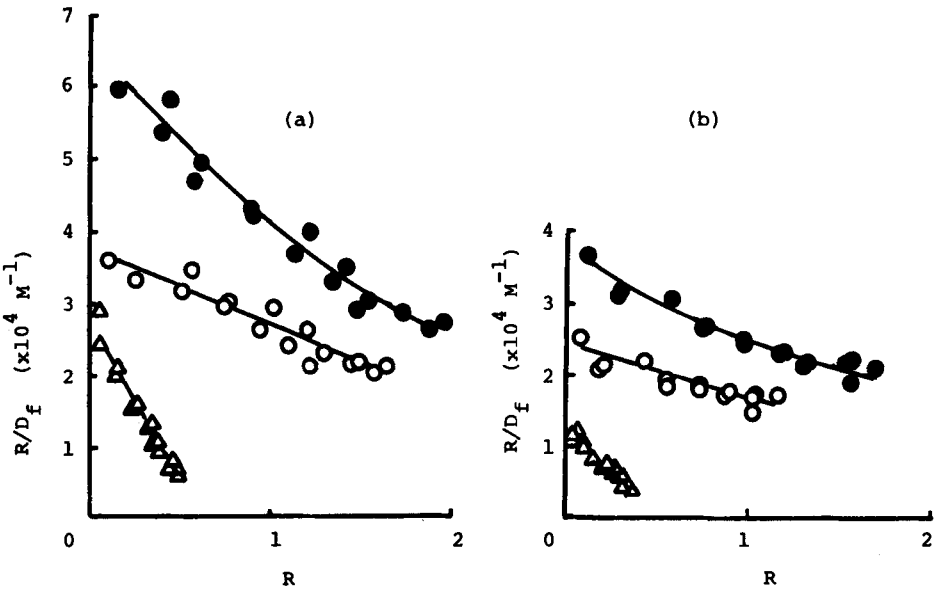

Figure 1—*Scatchard plots of the binding of the azo form (○), hydrazone form (△), and total (●) 2-(4′-hydroxyphenylazo)benzoic acid to 0.3% bovine serum albumin at 20°C (a) and 37°C (b). R represents the molar ratio of the bound form to bovine serum albumin; D_f is the concentration of the free form.*

concentrations (C) of 0.9×10^{-4}, 1.05×10^{-4}, 1.2×10^{-4}, 1.35×10^{-4}, and 1.5×10^{-4} M were measured twice. As the second step, the limiting conductance of 2-(4′-hydroxyphenylazo)benzoic acid ($\mathring{\Lambda}_I$) was obtained as follows. A solution of the sodium salt of 2-(4′-hydroxyphenylazo)benzoic acid (5×10^{-3} M) was prepared by dissolving the acid in 0.005 M NaOH ($f = 0.98$), and the equivalent conductances of the sodium salt of 2-(4′-hydroxyphenylazo)benzoic acid ($\Lambda_{I\text{-}Na}$) were measured twice for each concentration using the diluted solution (0.2×10^{-3}–5×10^{-3} M). The limiting conductance of the sodium salt of the acid ($\mathring{\Lambda}_{I\text{-}NA}$) was graphically estimated by plotting $\Lambda_{I\text{-}Na}$ against the square root of the concentration of the sodium salt of 2-(4′-hydroxyphenylazo)benzoic acid and was found to be 70.3. $\mathring{\Lambda}_I$ was then calculated as 370.3, taking the limiting conductance of Na^+ and that of H^+ as 50 and 350, respectively (5).

The degree of ionization (α) is equal to $(\Lambda_{I(C)})/(\mathring{\Lambda}_I)$, and the ionization constant (K_a) can be obtained by the following Ostwald's equation, taking C as the concentration of 2-(4′-hydroxyphenylazo)benzoic acid:

$$K_a = \frac{\alpha^2 \cdot C}{1 - \alpha}$$

The pK_a value of the 2-carboxyl group of 2-(4′-hydroxyphenylazo)benzoic acid was estimated to be 3.66 at 25°C by averaging the values obtained from the aforementioned five concentrations.

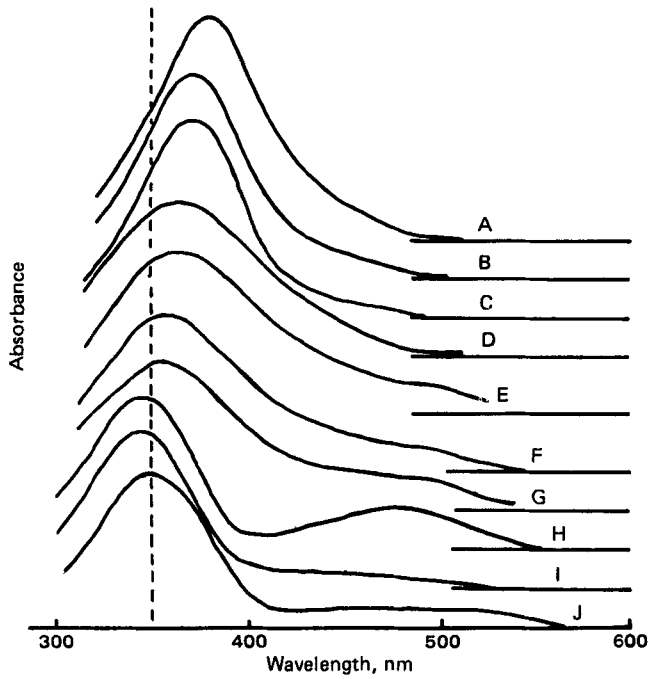

Figure 2—*Absorption spectra of 2-(4′-hydroxyphenylazo)benzoic acid (0.5×10^{-4} M) in various solvents. The ordinate is arbitrary; the broken line represents 350 nm; the solid lines to the right of the diagram are the baselines for each solvent. Key for solvents (dielectric constant): (A) chloroform (4.8 at 20°C); (B) ethylene dichloride (9.1 at 20°C); (C) benzene (2.3 at 20°C); (D) tert-butyl alcohol (10.9 at 30°C); (E) n-butyl alcohol (17.1 at 25°C); (F) isopropyl alcohol (18.3 at 25°C); (G) isobutyl alcohol (17.7 at 25°C); (H) ethanol (24.3 at 25°C); (I) methanol (32.6 at 25°C); (J) dimethyl sulfoxide (48.9 at 20°C).*

RESULTS AND DISCUSSION

Thermodynamics of the Azo and Hydrazone Forms—Figure 1 shows the Scatchard plots of the binding of the azo form, the hydrazone form, and total 2-(4′-hydroxyphenylazo)benzoic acid with bovine serum albumin at 20°C and 37°C. In this concentration range, the plots of both the azo and hydrazone forms showed straight lines and were extrapolated to 3.2 and 0.7 on the x-axis, respectively, which corresponds to the number of the binding sites. On the other hand, the binding of total 2-(4′-hydroxyphenylazo)benzoic acid showed a curvature; this binding curve satisfactorily corresponded to the line obtained by the graphical summation of the plots of the azo and hydrazone forms according to the method described by Rosenthal (6).

The thermodynamic parameters are shown in Table I. The binding of both forms shows an exothermic reaction, as has been reported for many protein bindings. However, the negative value of free energy changes ($\Delta G°$) of the hydrazone form was derived from the contribution of $\Delta H°$ only, in contrast with the concentration of both $\Delta H°$ and $\Delta S°$ in that of the azo form. Therefore, the binding of the hydrazone form is entropically unstable, but energetically stable. On the other hand, the binding of the azo form is stable both entropically and energetically. These facts show that two different microenvironments of 2-(4′-hydroxyphenylazo)benzoic acid molecules produced two binding forms, the azo and the hydrazone.

Solvent Effects of the Azo–Hydrazone Tautomerism—To consider the situation leading to the hydrazone stabilization, the solvent effects of the azo–hydrazone tautomerism were investigated. Figure 2 shows the absorption spectra of 2-(4′-hydroxyphenylazo)benzoic acid in various solvents. In

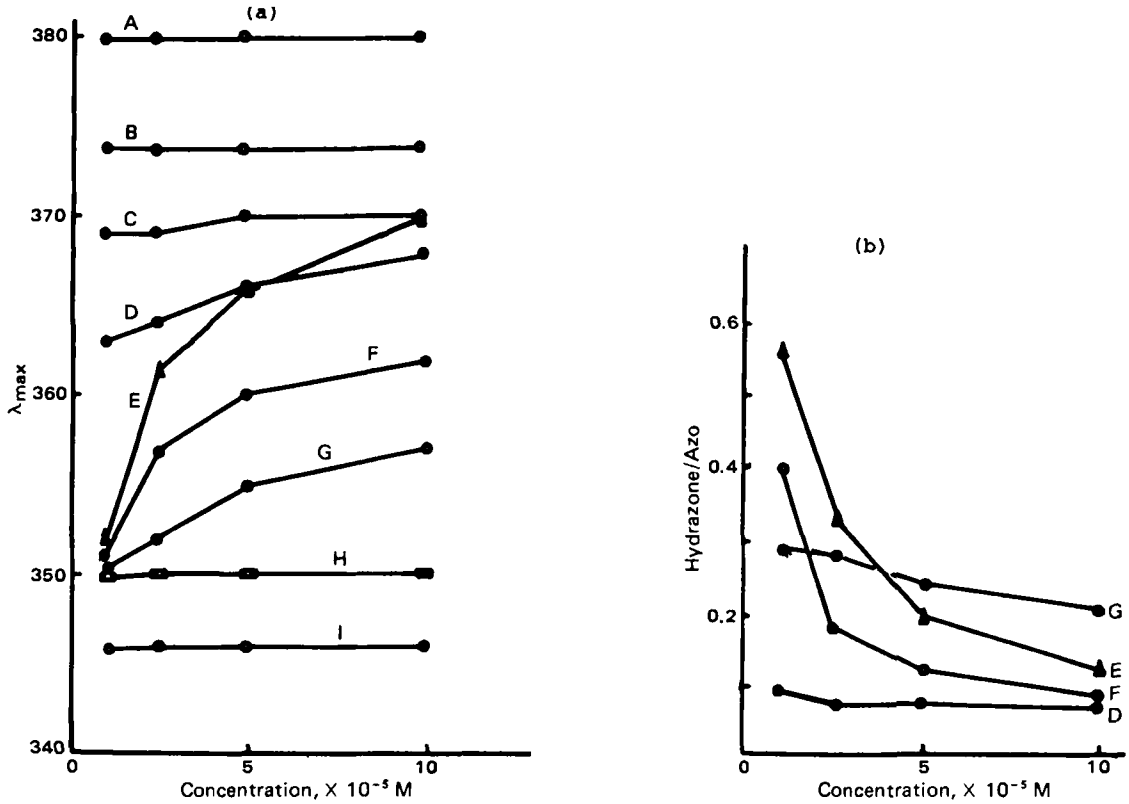

Figure 3—*Concentration dependence of the absorption spectra of 2-(4′-hydroxyphenylazo)benzoic acid utilizing λ_{max} (a) and the expedient concentration ratio of hydrazone to azo forms (b). Key: (A) chloroform; (B) ethylene dichloride; (C) benzene; (D)* tert*-butyl alcohol; (E)* n*-butyl alcohol; (F) isopropyl alcohol; (G) isobutyl alcohol; (H) dimethyl sulfoxide; (I) methanol and ethanol.*

methanol, ethanol, isopropyl alcohol, *n*-butyl alcohol, and isobutyl alcohol, λ_{max} was observed at ~350 nm with the shoulder or broad peak at ~500 nm; in *tert*-butyl alcohol λ_{max} was at 365 nm without a shoulder.

According to the calculation by means of Hückel molecular orbital by Moriguchi (7), $\pi \rightarrow \pi^*$ transition of the azo and the hydrazone forms of 4-hydroxyazobenzene shows λ_{max} at 350 and 458 nm, respectively. Terada *et al.* (8) reported that the absorption spectra with λ_{max} at ~350 nm and at ~480 nm in the aqueous solutions of 2-(4′-hydroxyphenylazo)benzoic acid under the different conditions are the azo and hydrazone forms on the basis of the resonance Raman spectra. We considered the λ_{max} values at ~350 nm and the broad peak at ~500 nm observed in the solvents as the azo and hydrazone forms, respectively.

In the solvents with low dielectric constants (ethylene dichloride, chloroform, and benzene), λ_{max} was observed at 374, 380, and 370 nm, shifting to a longer wavelength than in alcoholic solvents with higher dielectric constants. As a general rule, the absorption spectrum due to the $\pi \rightarrow \pi^*$ transition shifts to the shorter wavelength in the solvent with the lower polarity. To determine which of the absorption spectra in the solvents with low dielectric constants are assigned to the azo and hydrazone forms respectively, the IR spectra were measured. In the IR spectra of 2-(4′-hydroxyphenylazo)benzoic acid in eth-

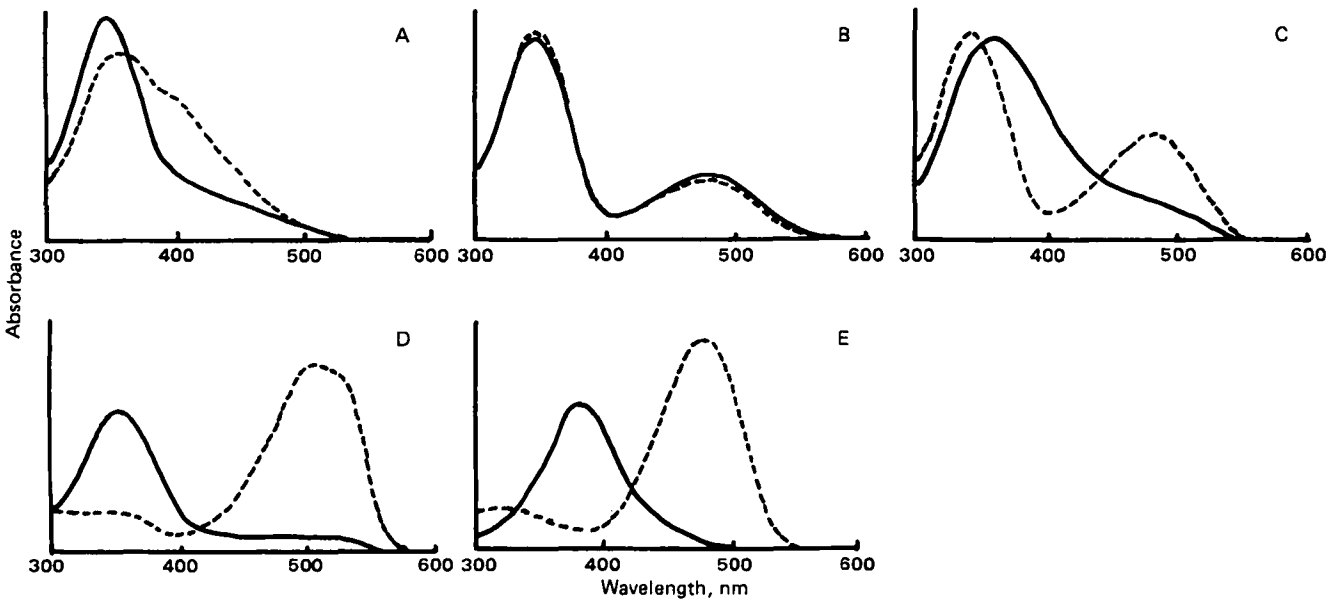

Figure 4—*Absorption spectra of 2-(4′-hydroxyphenylazo)benzoic acid in solvents with (----) or without (—) 0.1 M triethylamine. Key: (A) methanol; (B) ethanol; (C) isopropyl alcohol; (similar change observed with* n*-butyl and isobutyl alcohols); (D) dimethylformamide (similar change observed with dimethyl sulfoxide); (E) chloroform (similar change observed with ethylene dichloride and benzene).*

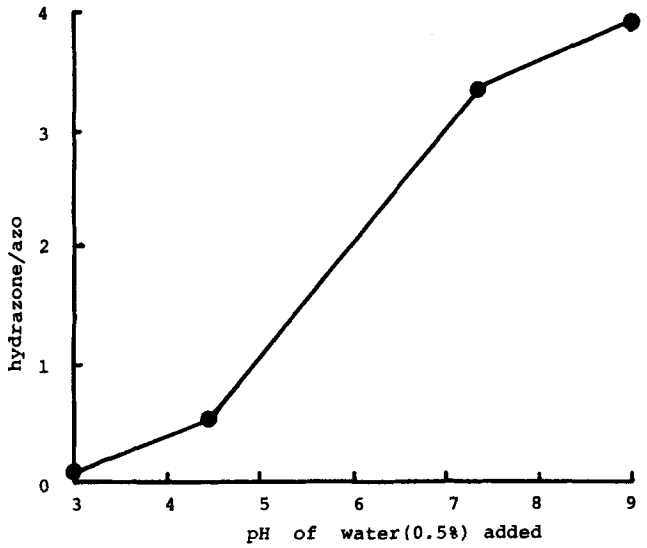

Figure 5—*Effects of the pH of water added to dimethylformamide on hydrazone formation. The ordinate was obtained as the ratio of the absorbance at 510 nm to that at 350 nm.*

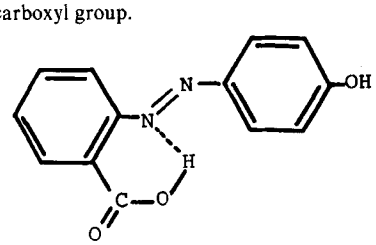
ylene dichloride and chloroform, there was an absorption maximum at 3670 cm^{-1} due to ν_{OH} of the 4′-hydroxy group monomer, but no appearance of a peak at ~1660 cm^{-1} due to $\nu_{C=O}$ of the conjugated ketone group. Therefore, 2-(4′-hydroxyphenylazo)benzoic acid takes the azo form in ethylene dichloride and chloroform. As the solvent effects of the absorption spectra of 4-hydroxyazobenzene obeyed the ordinary rule in this experiment, it seems that the 2-carboxyl group in the 2-(4′-hydroxyphenylazo)benzoic acid molecule takes part in the unusual spectral shift to the longer wavelength in the solvents with lower dielectric constants.

So, to investigate the intra- or intermolecular interaction, the effects of the concentration of 2-(4′-hydroxyphenylazo)benzoic acid on the absorption spectra were examined. As shown in Fig. 3a λ_{max} shifted to the longer wavelength with the increase of the concentrations of 2-(4′-hydroxyphenylazo)-benzoic acid in isobutyl, isopropyl, *n*-butyl, and *tert*-butyl alcohols, indicating the presence of the intermolecular interaction (9), while no shift was observed in chloroform, ethylene dichloride, benzene, dimethyl sulfoxide, ethanol, and methanol.

It seems that dimethyl sulfoxide, ethanol, and methanol with relatively high dielectric constants can solvate the hydroxy moiety of the 2-carboxyl group easily. On the other hand, chloroform, ethylene dichloride, and benzene could not solvate the hydroxy moiety of the 2-carboxyl group easily. Therefore, it is suggested that in these solvents the intramolecular interaction stabilizes the azo form (I). Figure 3b shows the concentration dependence of the ratio of the maximum absorbance at ~500 nm to that at ~350 nm, which expediently corresponds to the concentration ratio of the hydrazone form to the azo form. The increase of the intermolecular interaction in isobutyl, isopropyl, *n*-butyl, and *tert*-butyl alcohols with the increase of the concentration of 2-(4′-hydroxyphenylazo)benzoic acid resulted in the decrease in the hydrazone form. This may indicate the stabilization of the azo form due to the dimerization of the 2-carboxyl group.



I

Solvent Effects on the 2-Carboxylate Ion—As mentioned above, the formation of the hydrazone form in various solvents cannot be estimated only from the dielectric constants of the solvents, but depends on their solvation to 2-(4′-hydroxyphenylazo)benzoic acid molecules and the intra- or intermolecular interaction of the 2-carboxyl group.

As the 2-carboxyl group dissociates in the pH 7.40 phosphate buffer used in the study of the binding of 2-(4′-hydroxyphenylazo)benzoic acid with bovine serum albumin, the participation of the 2-carboxylate ion in the azo–hydrazone tautomerism in various solvents was investigated. Figure 4 shows the absorption spectra at the addition of 0.1 M triethylamine to 2-(4′-hydroxyphenylazo)benzoic acid in some solvents. In the IR spectra, the addition of triethylamine to 2-(4′-hydroxyphenylazo)benzoic acid in all the solvents caused the disappearance of the peak at ~1700 cm^{-1} due to the carboxyl group and the appearance of the peak at ~1600 cm^{-1} due to the carboxylate ion, indicating the dissociation of the 2-carboxyl group. The absorption spectra in methanol showed the spectrum similar to that in the alkaline aqueous solution assigned to the azo form (10), and in ethanol the spectral change was not observed. In dimethylformamide, with a high dielectric constant, the hydrazone form predominated. On the other hand, in chloroform, with a low dielectric constant, the same change was observed as in dimethylformamide. However, the addition of 0.1 M triethylamine to 4-hydroxyazobenzene did not cause the spectral change in any solvent.

Table II—Direct Conductivity Measurements of 2-(4′-Hydroxyphenylazo)-benzoic Acid–Triethylamine (1×10^{-3}M:0.1 M) at 25°C

Solvent	0.1 M Triethylamine, μmho/cm[a]	2-(4′-Hydroxyphenylazo)benzoic Acid–Triethylamine System, μmho/cm
Dimethyl sulfoxide	1.2[b]	17.6
Methanol	49.7[b]	123.5
Ethanol	8.0[b]	24.7
Isopropyl alcohol	<1	2.3
tert-Butyl alcohol	<1	<1
Ethylene dichloride	<1	<1
Chloroform	<1	<1
Benzene	<1	<1

[a] Triethylamine only was added to the solvent. [b] This indicates the ionization of triethylamine.

Moreover, to estimate the participation of the 2-carboxylate ion in the formation of the hydrazone form, aqueous solutions at four pH values were all added to dimethylformamide at a concentration of 0.5% (Fig. 5). According to the principle of the specific sorting of solvents, a component with a stronger solvating power in the mixtures of solvents selectively solvates the solute. So, in the dimethylformamide–water mixtures, water solvates the 2-carboxyl group. Therefore, the pH of a small quantity of water may significantly affect the ionization of the 2-carboxyl group. With pH >3.66 (the pK_a value obtained by conductivity measurements), the ratio of the hydrazone form increased. These facts show that the ionization of the 2-carboxyl group resulted in the accelerated formation of the hydrazone form.

Next, conductivity measurements were carried out on the system of 1×10^{-3} M 2-(4′-hydroxyphenylazo)benzoic acid–0.1 M triethylamine in some solvents (Table II). In the 2-(4′-hydroxyphenylazo)benzoic acid–triethylamine system, the conductivity was not observed in *tert*-butyl alcohol, ethylene dichloride, chloroform, and benzene. This observation indicates that 2-carboxylate ion exists as an ion pair with a triethylammonium ion exclusively in these solvents. In the other solvents, the free ions and ion pair are in equilibrium. Therefore, the predominant appearance of the hydrazone form in such solvents as ethylene dichloride, chloroform, and benzene after the addition of triethylamine (Fig. 4) is attributed to the formation of ion pairs.

Table III shows the thermodynamic parameters for hydrazone formation in the system of 2-(4′-hydroxyphenylazo)benzoic acid–amines (1:1) in chloroform. When the temperature was lowered, the hydrazone form increased. Only $\Delta H°$ contributed to the hydrazone formation (−4130 cal·M^{-1} in triethylamine and −5880 cal·M^{-1} in diethylamine), in the same manner as in the system of 2-(4′-hydroxyphenylazo)benzoic acid–bovine serum albumin (Table I). The same result was obtained in ethylene dichloride and benzene. It seems that this change of the azo–hydrazone tautomerism depending on temperature reflects the presence of two species of ion pairs. One ion pair takes the azo form and the other the hydrazone form. Hogen-Esch and Smid (11) presented evidence for two kinds of ion pairs for 9-fluorenyl-alkali metal, *viz.*, the contact ion pair and the solvent-separated ion pair, which were distin-

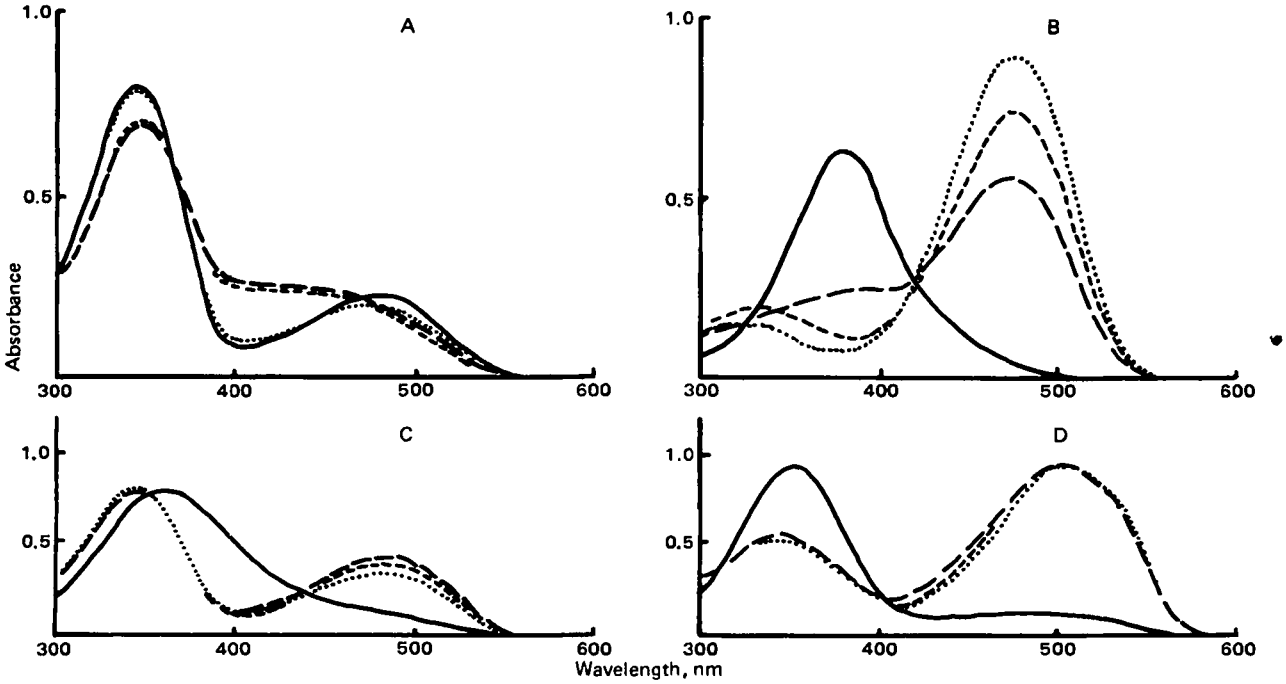

Figure 6—*Effects of* n*-butylamine (—), diethylamine (---), piperidine (---), and triethylamine (·····) on the absorption spectra of 2-(4′-hydroxyphenylazo)benzoic acid (0.5 × 10⁻⁴ M). Piperidine induced the same change as diethylamine. The solid line represents no addition of amines. Key: (A) ethanol; (B) chloroform; (C) isopropyl alcohol; (D) dimethyl sulfoxide.*

guishable by the absorption spectra. The relative amounts of these two kinds of ion pairs were found to be the sensitive functions for the solvating power, temperature of the medium, and for the types of anion and cation. In the same solvent, an ion pair of any ion with a counterion with a larger molecular volume is likely to take the form of the solvent-separated ion pair (12). According to Grunwald's description (13), the distance between a cation and an anion is ~3 Å for a contact ion pair and ~6 Å for a solvent-separated ion pair.

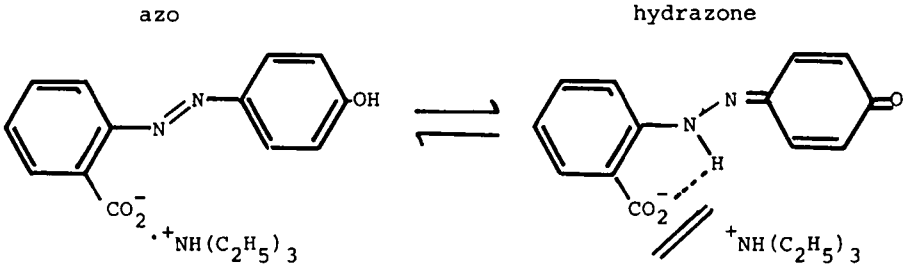
Investigation was carried out on the effects of some amines, which dissociated the 2-carboxyl group of 2-(4′-hydroxyphenylazo)benzoic acid in methanol, ethanol, isopropyl alcohol, dimethyl sulfoxide, benzene, ethylene dichloride, and chloroform, but are considered to have different steric hindrances in forming ion pairs. Figure 6 shows the absorption spectra of 2-(4′-hydroxyphenylazo)benzoic acid with four amines. Among the solvents investigated, triethylamine, with a larger molecular volume, induced the hydrazone formation more strongly than the other amines only in ethylene dichloride, chloroform, and benzene.

Solvent-separated ion pairs become stable when the temperature is lowered due to the large gain of solvation enthalpy (11). Therefore, the hydrazone formation in chloroform (Table III) is attributed to the solvent-separated ion pairs. At the same temperature, as diethylamine more easily introduces the contact ion pairs than triethylamine because of a small steric hindrance, the hydrazone formation decreases (Table III). From these considerations, the origin of the hydrazone formation is speculated to be the formation of the solvent-separated ion pairs, in which the 2-carboxylate ion may take an energetically stable form due to the intramolecular hydrogen bond (Scheme I).

It seems that the accelerated formation of the hydrazone form was not observed (Fig. 4) in methanol and ethanol, because of the easy solvation of 2-carboxylate ion. These facts imply that 2-(4′-hydroxyphenylazo)benzoic acid molecules do not take the hydrazone form in the solvents in which the contact ion pairs can be formed or the free ions can solvate easily.

On the other hand, that the hydrazone form predominated in dimethyl sulfoxide or dimethylformamide (Fig. 4) in spite of the high dielectric constants of these solvents can be interpreted by the solvating power of these solvents. Because these solvents are powerful solvating agents to a cation, but not to an anion (14), no contact ion pairs may be formed. The fact that no difference was observed among the four amines in their effects in dimethyl sulfoxide (Fig. 6) may prove the predominant presence of the solvent-separated ion pairs.

Thomas and Merlin (15) inferred from their resonance Raman spectroscopic study that hydrazone formation on protein binding is stabilized by the intermolecular hydrogen bond between the —NH— group of the hydrazone form and the carboxylate of a suitable amino acid residue in the binding sites. Unlike that of Thomas and Merlin, another possible model can be proposed for the 2-(4′-hydroxyphenylazo)benzoic acid–bovine serum albumin interaction. The 2-carboxyl group of the 2-(4′-hydroxyphenylazo)benzoic acid dissociated at pH 7.40 may be attracted by a long-range electrostatic force due to the arginine or lysine residues in the proposed binding sites (16) of Brown's model (17). At the binding sites of the azo form, 2-(4′-hydroxyphenylazo)benzoic acid may be able to form contact ion pairs with the basic amino acid residues. On the other hand, at the binding sites of the hydrazone form, the microenvironment of 2-(4′-hydroxyphenylazo)benzoic acid molecules may structurally restrict the proximity of the 2-carboxylate ion to the amino acid residues, resulting in no formation of the contact ion pairs. Consequently, the distance between the 2-carboxylate ion and the basic amino acid residue may be similar to that between the two counterions of the solvent-separated ion pair, *viz.*, 6 Å. This speculation may be corroborated by the fact that the binding capacity of bovine serum albumin to the hydrazone



Scheme I

form is smaller than that to the azo form (Fig. 1); *i.e.*, the number of the binding sites of the former is 0.7, although that of the latter is 3.2. Moreover, as was shown previously (18), the circular dichroism spectra of the azo form induced by bovine serum albumin was larger than that of the hydrazone form. Taking into consideration this result and the theory of Takenaka *et al.* (19) that the contact ion pair formation between unchiral benzoic acid derivatives and chiral amines introduces the larger circular dichroism, the azo form may be present as the contact ion pairs in the 2-(4′-hydroxyphenylazo)benzoic acid–bovine serum albumin interaction.

Polymorphism of Butyrophenones Related to Haloperidol

M. AZIBI, M. DRAGUET-BRUGHMANS ˣ, and R. BOUCHE

Received June 28, 1982, from the *Laboratoire d'Analyse des Médicaments, Université Catholique de Louvain, BP 7340 1200 Bruxelles, Belgium.* Accepted for publication March 31, 1983.

Abstract □ A comparison of X-ray powder diffraction patterns, IR spectra, and crystal structures of structurally related compounds belonging to the butyrophenone family has been undertaken to obtain information about the elements of chemical structure which predispose a substance to exhibit polymorphism. Five butyrophenones, differing by the nature of only one substituent, were selected. After crystallization from 15 solvents, it appears that two compounds of the group exhibit more than one crystalline form. An explanation of the absence of polymorphism in the other compounds of the group is proposed and discussed.

Keyphrases □ Polymorphism—disubstituted butyrophenones, comparison of IR spectra, X-ray diffraction patterns, and crystal structures □ Haloperidol—polymorphism, comparison of IR spectra, X-ray diffraction patterns, and crystal structures □ Moperone—polymorphism, comparison of IR spectra, X-ray diffraction patterns, and crystal structures □ Bromperidol—polymorphism, comparison of IR spectra, X-ray diffraction patterns, and crystal structures

Many papers have been published in the past 10 years about drug polymorphism, generally describing the way of obtaining the polymorphs of a given substance (1–3); their IR spectra (2, 4, 5), thermal behaviors (6–8), and X-ray diffraction patterns (3, 8, 9); their dissolution and solubility profiles (2, 8, 10, 11); and more rarely their *in vivo* rates of release (12–15). Studies of polymorphism are thus often empirical. Few studies attempted to determine what structural characteristics predispose an organic compound to exhibit polymorphism; in a paper concerning the polymorphism of sulfamides, Yang and Guillory (16) investigated that problem.

This work was undertaken to study the polymorphism of closely related compounds belonging to the butyrophenone family; to compare their IR spectra, X-ray diffraction patterns, and crystal structures; and to correlate, if possible, the frequency of polymorphism occurrence and chemical structure. The substances were chosen because of their therapeutic importance, structural simplicity, and crystalline nature (17–21).

BROMPERIDOL: R = Br
I: R = F
II: R = H
MOPERONE: R = CH_3

EXPERIMENTAL

Materials—Five butyrophenones were selected for study: haloperidol[1], bromperidol[2], 4-[4-hydroxy-4-(4-fluorophenyl)-1-piperidinyl]-1-(4-fluorophenyl)-1-butanone[3] (I), moperone[4], and 4-(hydroxy-4-phenyl-1-piperidinyl)-1-(4-fluorophenyl)-1-butanone[5] (II). The difference between these substances lies only in the nature of the substituent at the 26 position.

[1] Haloperidol: 4-[4-(4-chlorophenyl)-4-hydroxy-1-piperidinyl]-1-(4-fluorophenyl)-1-butanone.

[2] Bromperidol: 4-[4-(4-bromophenyl)-4-hydroxy-1-piperidinyl]-1-(-4-fluorophenyl)-1-butanone.

[3] I: 4-[4-(4-fluorophenyl)-4-hydroxy-1-piperidinyl]-1-(4-fluorophenyl)-1-butanone (no generic name).

[4] Moperone: 4′-fluoro-4(4-hydroxy-4-*p*-tolylpiperidino)butyrophenone.

[5] II: 4-(4-hydroxy-4-phenyl-1-piperidinyl)-1-(4-fluorophenyl)-1-butanone (no generic name).

Thermal Analysis—Thermal behavior was studied on a differential scanning calorimeter[6] (DSC) at a heating rate of 4°C/min. Temperatures of fusion were measured at the onset point of each peak. A thermogravimetric analyzer[7] (TGA) was used for distinguishing between polymorphs and solvates and for determining the stoichiometry of the solvates.

Infrared Spectrometry[8]—IR spectra were recorded in potassium bromide[9] pellets (0.5 % w/w) and in *n*-hexane or carbon tetrachloride solution[10] (1 mg/mL).

X-ray Diffraction[11]—X-ray powder diffraction patterns were recorded using a powder camera. The incident beam was CuKα with λ = 1.5406 Å. The interplanar spacing (d values) were obtained by direct measurement on the films, and the corresponding intensities were estimated using a densitometer[12].

Crystallizations—Crystallizations of the five selected compounds were performed in analytical-grade[13] acetone, benzene, 1-butanol, carbon tetrachloride, chloroform, cyclohexane, dichloromethane, ether, dimethyl sulfoxide, ethanol, *n*-heptane, *n*-hexane, isopropyl alcohol, methanol, and petroleum ether either by slow evaporation at room temperature or by slow cooling of hot saturated solutions.

RESULTS AND DISCUSSION

Three polymorphic forms of moperone, including a monohydrated form, were observed and characterized. At ~70°C, the hydrated form undergoes dehydration, which generates polymorph III. This form melts at 96°C; it is very unstable and cannot be isolated. Forms I and II are stable. Form II undergoes a solid–solid transition to form I at 110°C; form I melts at 124°C. X-ray powder diffraction patterns (Table I) and IR spectra in potassium bromide pellets (Table II) exhibit significative differences between the three forms. In the spectrum of form II, only one —OH stretching vibration band appears at 3180 cm^{-1}. The IR spectrum of form I presents two —OH stretching vibration bands: a large one at 3100 cm^{-1} and a narrow and very strong one at 3560 cm^{-1}. Comparison with spectra obtained in carbon tetrachloride solution allows assignment of the 3560 cm^{-1} band to the vibration of weakly bonded —OH group; the 3180 and 31,000 cm^{-1} bands correspond to hydrogen-bonded hydroxyl groups (22).

Two polymorphs of II were obtained by recrystallization. They are easily identified by DSC (Fig. 1): form II melts at 112°C (ΔH_{fusion} = 35 kJ/mol) and form I melts at 140°C (ΔH_{fusion} = 43 kJ/mol). The data from X-ray diffraction patterns show great differences between the two forms (Table III). The IR spectra in potassium bromide pellets also have obvious differences, especially in the region of the —OH, —CH, and CO stretching vibrations (Table IV). The band of the —OH stretching appears as at 3180 cm^{-1} in the two spectra, but it is broader for form II. As the —OH stretching frequency of II in carbon tetrachloride solution is observed at 3620 cm^{-1}, it can be concluded that the two polymorphs are hydrogen bonded. The stability of form II is poor.

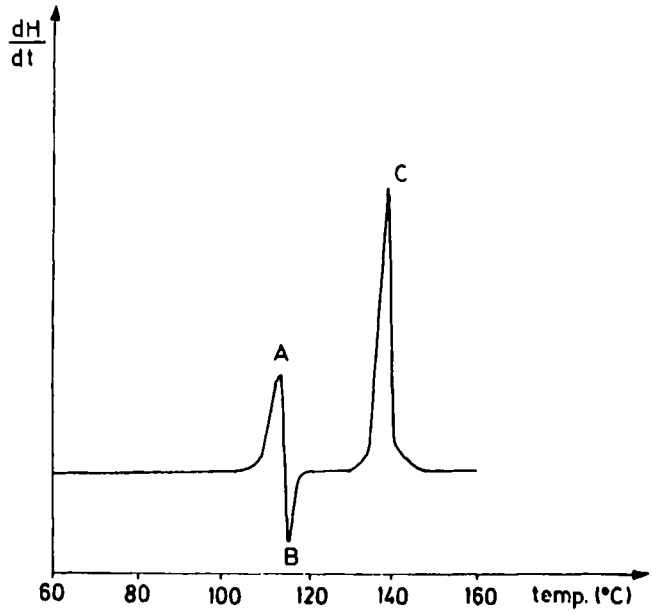

Figure 1—*Thermogram of a mixture of two polymorphs of II. Key: (A) melting of form II; (B) recrystallization of form I from the melt; (C) melting of form I.*

Despite repeated crystallizations from 15 solvents at room temperature and in a water bath, we find no evidence of polymorphism in haloperidol, bromperidol, and I. All crystallization batchs give the same X-ray powder diffraction patterns, the same DSC thermograms, and the same spectra (Table V). Temperatures and heats of fusion of haloperidol, bromperidol, and I are, respectively, 150°C and 48 kJ/mol, 158°C and 51 kJ/mol, 123°C and 34 kJ/mol. Thus, it appears that the three dihalosubstituted compounds do not exhibit polymorphism, whereas moperone and II occur as two or more polymorphs or pseudopolymorphs.

To obtain a better understanding of the phenomenon of polymorphism and to confirm the influence of the substituent on the occurrence of polymorphism in this family, the crystal structure of each polymorph must be investigated. Instability of moperone form II and II form II produces poor quality monocrystals and did not allow determination of their crystal structures. Nevertheless, considering the crystal structure of polymorph I and using the data of the IR spectra of form II of both compounds, the solid structures of moperone form II and II form II can be approached.

The main differences between the crystal structures of haloperidol, bromperidol, I, and moperone forms I and II lie in the nature and strength of the intermolecular hydrogen bonds and in intermolecular van der Waals contacts. Crystal structures show that haloperidol, bromperidol, and I are isomorphs (2-4). Their molecules are bonded together by a strong intermolecular O(19)—N(1) hydrogen bond. The length of that bond is, respectively, 2.84, 2.86, and 2.84 Å (Table VI). The energy of the hydroxyl group stretching vibrations in the IR spectra is in good agreement with these data. The intermolecular van der Waals contacts are the same in the three substances. Dipole–dipole F(18)—C(15) interactions and R(26)—R(26) contacts hold the molecules end to end (Table VII).

Molecules of II form I are also held together by a O(19)—N(1) bond, but in this case the bond is longer (2.94 Å) (Table VI). The position of the —OH stretching vibration band at 3180 cm^{-1} indicates a bond weaker than in the first group of substances. An F(18)—C(19) van der Waals contact stabilizes the crystal lattice (Table VII).

The crystal structure of II form II was not resolved. Meanwhile, considering the crystallographic data of form I, the enlargement of the νOH band and the lowering (15 cm^{-1}) of the νCO band in form II (Table IV) can be attributed to the existence of a O(19)—O(11) bond. Hydrogen bonding is thus different between the two forms.

Moperone form I presents a very peculiar crystal structure: its asymmetric unit is made up by two independent molecules, A and B (Table VI). Molecules of type A are held together by a short O(10)—N(1) hydrogen bond. The two absorption bands at 3100 and 3560 cm^{-1} can now be explained (Table II): the first arises from the strong O(19)—N(1) hydrogen bond, and the second can be attributed to the stretching of a hydroxyl group included in a cyclic dimeric structure. The narrowness of the band at 3560 cm^{-1} supports this interpretation. The van der Waals contacts between molecules A and B con-

tribute to the building of the crystal lattice. The main intermolecular contacts are F(18)—C(2) and F(18A—C26)B. Knowing the crystal structure of moperone form I and the IR spectra of moperone form II, it is possible to infer the existence of only one type of hydrogen bond, O(19)—N(1), in moperone form II (Tables II and VI).

Comparison of the crystallographic data of haloperidol, bromperidol, I, moperone form I, and II form I shows differences of molecular conformation in the crystal lattices (17–21). The side chain of the three dihalosubstituted compounds is in a TTGT conformation, while it is in a TTTT conformation in moperone form I and II form I. The latter is the most frequent among the five isoenergetic confirmations showed by PCILO calculations (25). The piperidine ring is in the usual chair form encountered in the butyrophenones, the hydroxyl group is axial, and the phenyl ring equatorial. The torsion angle along the C(4)—C(20) bond takes a relatively constant value, except in molecule B of moperone form I (17–21).

The three dihalosubstituted substances (haloperidol, bromperidol, and I) are thus isomorphs. Their crystals are monoclinic, with a $P2_1/C$ spatial grouping and four molecules per unit cell. The molecules are packed into parallel layers, which are built up by the intermolecular van der Waals contacts between the R-26 substituents of two molecules put end to end and by dipole–dipole F(18)—C(15) contacts. The layers are linked together by the strong O(19)—N(1) hydrogen bond, and they generate areas of high halogen concentration. From these observations, it is apparent that electrostatic forces, caused by the presence of the halogens and acting at the extremities of each molecule, play a significant role in the building of the crystal structure. In the process of crystal growth, a molecule reaching the surface of a crystal is influenced predominantly by the halogens of the molecule extremities located on the faces of the growing crystal. Bernstein *et al.* (26–28), working on dihalosubstituted substances, have made the same observations. The van der Waals contacts and the hydrogen bonds give a great stability to the crystal building. The observed crystal packing therefore depicts the highest probabilities of occurrence, which elucidate the absence of polymorphism of haloperidol, bromperidol, and I.

Moperone and II exhibit polymorphism. Moreover, they present a very different crystalline structure from the other three substances. In II form II and molecule B of moperone form I, peculiar hydrogen bonds appear: O(19)—O(11) and O(19)—C(22). The absence of halogen in the R-26 position leads to more disordered crystal structures, and the linear packing of haloperidol, bromperidol, and I disappears. During the crystallization, the

molecules have a greater freedom and several crystal structures are possible; this explains why moperone and II exhibit more than one crystalline form. In this limited group of butyrophenones, it can be concluded that the substituent at the 26 position predominantly influences the occurrence or absence of polymorphism.

Gas Chromatographic Determination of Quazepam and Two Major Metabolites in Human Plasma

JAMES M. HILBERT ˣ, JAMES M. NING, GREGORY MURPHY, ANGEL JIMENEZ, and NICOLA ZAMPAGLIONE

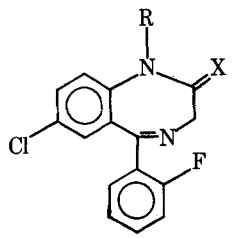
Received January 7, 1983, from *Schering Corporation, Bloomfield, NJ 07003.* Accepted for publication March 29, 1983.

Abstract □ Two rapid, sensitive, and specific gas chromatographic (GC) methods for the quantitative determination of quazepam (I), 7-chloro-5-(2-fluorophenyl-1,3-dihydro-1-(2,2,2-trifluoroethyl)- 2*H* -1,4-benzodiazepine-2-thione, and its major active plasma metabolites, the 2-oxo compound (II) and the dealkylated oxo compound (III), have been developed; the first measures I and II and the second measures III. The compounds are extracted from plasma with toluene and quantitated by electron-capture detection using the internal standard method. The methods are capable of quantitating plasma levels of I and II as low as 0.75 ng/mL and plasma levels of III as low as 1.5 ng/mL. Correlation coefficients of standard curves were >0.9995 for all compounds. Precision of the methods was measured at two different concentrations for each compound; the *CV* values were 3–6% for all three compounds. The recovery of all compounds was >80%, and the ratio of recovery of each compound to that of its internal standard did not vary at different concentrations, indicating appropriate internal standards have been selected for the methods. Quazepam metabolites, other benzodiazepines, and drugs which are potential comedication do not interfere with either method. The methods were shown to be suitable for investigating the bioavailability and pharmacokinetics of quazepam at therapeutic doses.

Keyphrases □ Quazepam—gas chromatography two major metabolites, human plasma □ Gas chromatography—quazepam and two major metabolites in human plasma □ Metabolites—quazepam, human plasma, gas chromatography

Quazepam, 7-chloro-5-(2-fluorophenyl)-1,3-dihydro-1-(2,2,2-trifluoroethyl)-2*H*-1,4-benzodiazepine-2-thione, a novel benzodiazepine which has been reported to have good sedative and hypnotic activity (1, 2), is extensively metabolized in humans. Two major active metabolites have been identified in plasma (Scheme I), the 2-oxo compound II [7-chloro-5-(2-fluorophenyl) -1,3-dihydro-1-(2,2,2-trifluoroethyl)-2*H*-1,4-benzodiazepin-2-one] and III [7-chloro-5-(2-fluorophenyl)-1,3-dihydro-2*H*-1,4-benzodiazepin-2-one] (2). To fully evaluate the bioavailability and pharmacokinetics of quazepam, two sensitive and specific gas chromatographic (GC) assays have been developed to measure the unchanged drug and the two major metabolites in plasma; one method measures I and II, and the other measures III.

Polarographic (3) and GC methods (4–6) have been published for III. However, these methods either lack sensitivity or involve derivatization. The methods described in this report require simple extraction procedures, no derivatization, and are more sensitive than previously reported chromatographic assays.



I: X = S, R = —CH_2CF_3
II: X = O, R = —CH_2CF_3
III: X = O, R = H

EXPERIMENTAL

Chemicals and Reagents—Quazepam[1] (I), II[1], 7,9-dibromo-1,3-dihydro-5-phenyl-2*H*-1,4-benzodiazepin-2-one (IV)[1] (the internal standard for the assay of III), III[2], and diazepam[2] (the internal standard for the assay for I and II) were used. A stock solution of I and II (0.75 mg/mL) was prepared by accurately weighing 75 mg each of I and II into a 100-mL volumetric flask and dissolving them in toluene. The standard solution of the two compounds (1.5 μg/mL) was prepared by diluting 0.20 mL of the stock solution to 100 mL with toluene. A stock solution of III (1 mg/mL) was prepared by weighing accurately 10 mg of III into a 10-mL volumetric flask and dissolving the compound in toluene. The standard solution of III (1.5 μg/mL) was prepared by diluting 0.15 mL of the stock solution to 100 mL with toluene.

Both standard solutions of the internal standards (diazepam and IV) were prepared by accurately weighing 10 mg of each compound, dissolving it in 10 mL with toluene, and diluting 1 mL of the resulting stock solution to 100 mL of toluene. Toluene[3] and cyclohexane[3] were glass distilled.

Chromatographic Conditions for the Assay of I and II—The chromatograph[4] was equipped with a ^{63}Ni pulse-modulated electron-capture detector, an automatic injector[5], and a data system for measuring peak heights and calculating concentrations[6]. The coiled glass column (1.83 m × 2 mm i.d.) was silanized[7] and then packed with 3% OV-25 on 80–100 mesh Supelcoport[8]. The temperatures of the column, injector, and detector were maintained at 220°C, 280°C, and 350°C, respectively. Ultra-high purity nitrogen was used as the carrier gas with a flow rate of 28 mL/min.

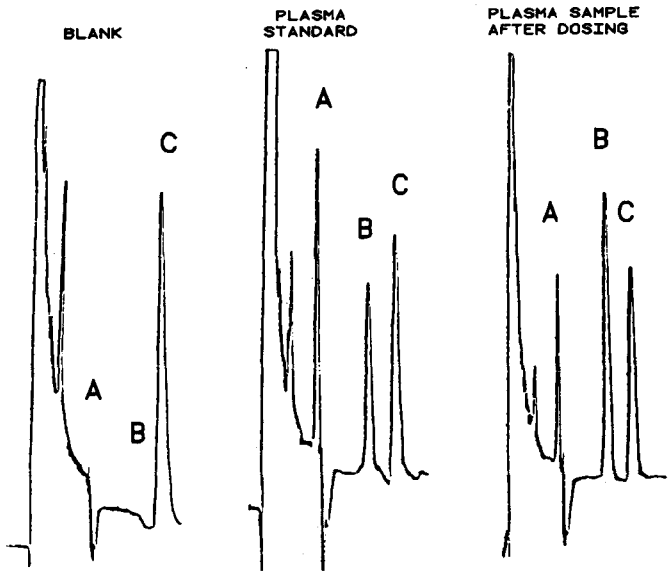


Figure 1—*Typical gas chromatograms of blank plasma, a standard concentration of 12 ng/mL of quazepam and II plasma, and human plasma withdrawn at 1.5 h after an oral dose of 15 mg of quazepam. Chromatography was on OV-25 at 220°C with electron-capture detection. Key: (A) II; (B) quazepam; (C) diazepam.*

[a] Values are the average of duplicate determinations.

Sample Preparation for the Assay of I and II—Aliquots (0.5 mL) of plasma samples were pipetted in a glass centrifuge tube, mixed with 6 μL of the 10-μg/mL solution of diazepam, and extracted with 0.5 mL of toluene. Following centrifugation[9] at 1500 rpm, 1.0 μL of the toluene extract was injected into the gas chromatograph.

Chromatographic Conditions for the Assay of III—The chromatograph[4] was equipped with a ^{63}Ni pulse-modulated electron-capture detector, an automatic injector[5], and a data system for measuring peak heights and calculating concentrations[6]. The coiled glass column (1.83 m × 2 mm i.d.) was silanized[7] and then packed with 3% SP-2250 DB on 100–120 mesh Supelcoport[8]. The temperature of the column, injector, and detector were maintained at 235°C, 250°C, and 350°C, respectively. Ultra-high purity nitrogen was used as the carrier gas with a flow rate of 43 mL/min.

Sample Preparation for the Assay of III—Aliquots (0.25 mL) of plasma samples were prepared in a glass centrifuge tube and extracted twice with 0.25 mL of cyclohexane. The cyclohexane layer was discarded; 0.2 mL of the extracted plasma was transferred to a centrifuge tube and mixed with 0.25 mL of toluene and 6 μL of the 10-μg/mL toluene solution of IV. Following centrifugation at 1500 rpm for 5 min, 3 μL of the toluene extract was injected into the gas chromatograph.

[a] Used for the assay of I and II. [b] Used for the assay of III. [c] No peak observed for the compound. [d] 3-Chloro-10,11-dihydro- *N*,*N*-dimethyl-5*H*-dibenz[6,*F*]azepine-5-propanamine.

Standard Curves, Reproducibility, and Recovery Studies—A standard curve was prepared for each compound by adding aliquots of each stock solution to a series of control human plasma samples. A set of standard plasma concentrations were made for each of these compounds ranging from 0.75 to 96 ng/mL for I and II and from 1.5 to 96 ng/mL for III. The samples were carried through the respective assay procedures, and the concentration values obtained from the data system were plotted against the actual concentrations.

To demonstrate the precision and accuracy of I–II assay, 10 plasma samples were spiked with I and II, five samples at 1.5 ng/mL and five samples at 12 ng/mL. Similarly five plasma samples were spiked with III at 3 ng/mL and five samples at 24 ng/mL. Then, the plasma samples were carried through the respective assay procedures, and the means, standard deviations, and coefficients of variation calculated.

For determination of recoveries from plasma, the peak heights of extracted standards of each compound at 3 and 48 ng/mL were compared with those of the respective unextracted standards. The unextracted standards were made

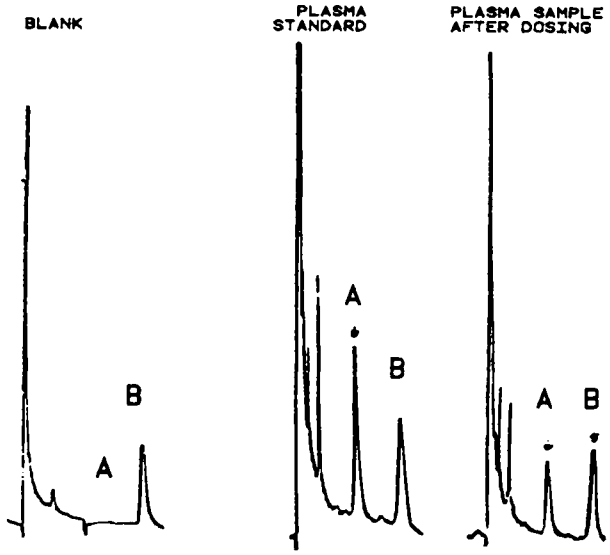

Figure 2—*Typical gas chromatograms of blank plasma, a standard concentration of 24 ng/mL of III in human plasma, and human plasma withdrawn 48 h after an oral dose of 15 mg of quazepam. Chromatography was on SP-2250 DB at 235°C with electron-capture detection. Key: (A) III; (B) IV.*

by adding the compounds to toluene which had been previously extracted with an equal volume of plasma.

RESULTS AND DISCUSSION

As shown in Fig. 1, I, II, and the internal standard (diazepam) were well separated from one another on the OV-25 stationary phase. The respective retention times of I, II, and diazepam were 6.8, 3.5, and 8.7 min.

Compound III could not be analyzed under the conditions used for I and II due to poor sensitivity and excessive tailing of its peaks on OV-25 and similar stationary phases. It was found that III could be analyzed on SP-2250 DB, a stationary phase deactivated for bases. This packing gave excellent symmetrical peak shapes (Fig. 2) and much higher sensitivity. Compound III and the internal standard IV had retention times of 5.9 and 10.3 min, respectively, on the SP-2250 DB column.

Table I shows that the standard curves were linear for quazepam and both metabolites ($r^2 > 0.9995$) throughout the entire range investigated. The smallest concentration of each compound used in the standard curves, 0.75 ng/mL for I and II and 1.5 ng/mL for III, exhibited acceptable chromatographic peaks which were clearly within the linear range of the GC response. Therefore, the assays are sensitive enough to detect and quantitate concentrations of 0.75 ng/mL for I and II and 1.5 ng/mL for III.

The results of replicate analyses indicate that the methods have a high degree of accuracy, since the mean concentration values determined were very close to known concentrations. The coefficient of variation was 3–6% for the three compounds at each concentration, indicating the assays are very precise (Table II).

To determine the specificity of the methods, possible interferences from two other quazepam metabolites, the 3-hydroxy derivative of II, and the 3-hydroxy derivative of III (7), other benzodiazepines, and drugs that might be used as comedication were checked by chromatographing solutions of pure standards. None of these compounds (with the exception of halazepam, which was not completely resolved from II) had a retention time similar to those compounds being analyzed in either system (Table III). Thus, the assays are specific for quazepam and its two metabolites, II and III, in the presence of these compounds. Furthermore, the assays should be specific for quazepam and its metabolites in the presence of compounds which do not contain a nitro or halogen moiety, since these compounds do not respond to electron-capture detection.

Both assays are rapid, since, unlike the extraction procedures in previous assays of III and benzodiazepines similar to I and II (3–6, 8–12), no buffering of the plasma is needed to extract all the compounds with recoveries >80% (Table IV). However, in the assay of III, it is necessary to first wash the plasma with cyclohexane to selectively remove an unidentified plasma constituent which gives a chromatographic peak that interferes with the peak of III.

In addition to good recoveries, the data in Table IV show that the ratio of recoveries of I, II, and III to the respective internal standards were very similar at each concentration examined, indicating that appropriate internal standards have been selected for the methods.

The application of these methods is shown in the mean plasma level–time profile of quazepam and its two metabolites in 12 subjects following administration of a 15-mg quazepam tablet (Fig. 3). Clearly, the described methods are suitable for investigating the bioavailability and pharmacokinetics of quazepam at therapeutic doses.

In summary, rapid, sensitive, specific, and reproducible methods for quazepam and its two metabolites have been developed. The methods are capable of quantitating plasma levels of I and II as low as 0.75 ng/mL and plasma levels of III as low as 1.5 ng/mL. Pharmacokinetic studies which have been conducted utilizing these methods will be reported elsewhere.

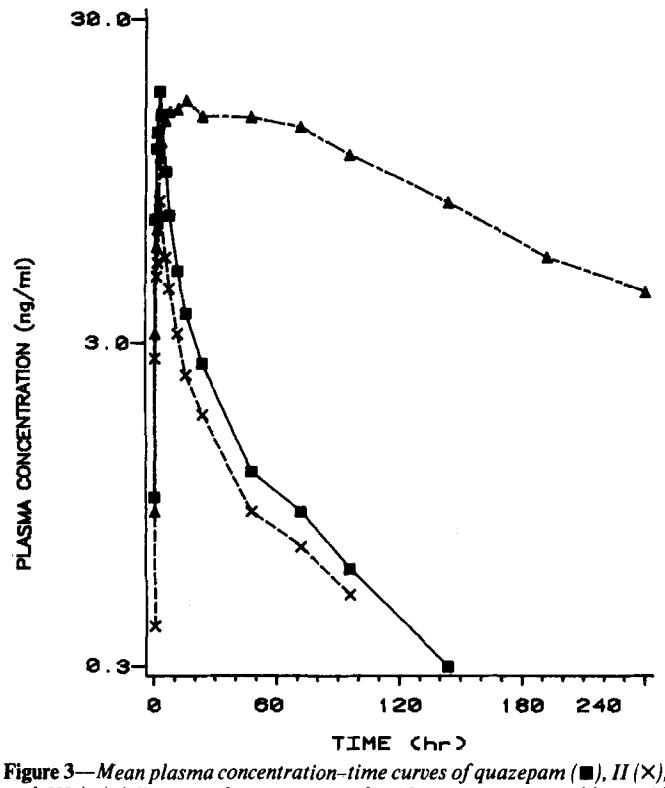

Figure 3—*Mean plasma concentration–time curves of quazepam (■), II (×), and III (▲) following administration of a 15-mg quazepam tablet to 12 subjects.*

Abstract □ The possibility that the fluorescence probe, 1-anilino-8-naphthalenesulfonate (I), might be used for predicting the interindividual differences in the plasma protein binding of acidic drugs was examined. The interindividual differences in the free fraction of I (f_I) were found not to be due to corresponding differences in plasma albumin concentration, but to those differences in binding constant. The binding constant of I to the plasma of 18 individual rats ranged from 1.75×10^6 M^{-1} to 2.3×10^7 M^{-1}. The free fraction of I had a highly significant statistical correlation with plasma concentration of free fatty acids, but had no significant correlation with the infinite fluorescence of I or the degree of the polarization of I. Each free fraction of five acidic drugs (warfarin, phenylbutazone, salicylic acid, indomethacin, and sulfaphenazole) was correlated with f_I with high statistical significance. Therefore, the simple and convenient method using I may predict the interindividual differences in the plasma protein binding of acidic drugs in rats.

Keyphrases □ 1-Anilino-8-naphthalenesulfonate—fluorescence probe, prediction of interindividual differences in plasma protein binding, acidic drugs, rats □ Fluorescence probe—1-anilino-8-naphthalenesulfonate, prediction of interindividual differences in plasma protein binding, acidic drugs, rats □ Binding, plasma protein—1-anilino-8-naphthalenesulfonate, prediction of interindividual differences, acidic drugs, rats

Serum (or plasma) protein binding can have pronounced effects on the pharmacodynamic and toxicological actions of drugs, as well as on their elimination kinetics. This effect is particularly striking with respect to the elimination of the extensively serum protein-bound drugs such as anticoagulants (warfarin, dicoumarol) by rats and humans, since there are pronounced interindividual differences in the free fraction of these drugs (1, 2). Minor interindividual changes in the degree of binding of such highly protein-bound drugs can produce significant changes in the amount of unbound drug. Differences in the structure of albumin or in the plasma concentration of endogenous inhibitory agents were suggested to be alternative reasons for such pronounced interindividual differences in the free fraction of these drugs (1); however, the details are, as yet, unresolved. Based on these facts, Levy and Yacobi (3) suggested that *in vitro* plasma protein binding tests with blood samples prior to drug administration might be useful for predicting quantitatively unusual distribution, elimination, and pharmacological effect characteristics of certain highly plasma protein-bound drugs.

It was previously reported that there are pronounced interindividual differences in binding of the anionic fluorescence probe 1-anilino-8-naphthalenesulfonate (I) to rat plasma (4). Free fatty acids were found to be one of the endogenous inhibitors, and there was a highly significant correlation between the free fractions of I and phenylbutazone (4).

In the present study, we investigated further the correlation between the free fraction of I and those of various acidic drugs extensively bound to plasma protein, and suggested the possibility that I might be used clinically for predicting the interindividual differences in the plasma protein binding of acidic drugs. Furthermore, we tried to examine whether or not differences in the structure of albumin are associated with differences in the free fraction of I.

EXPERIMENTAL

Materials—The following analytical-grade materials were used: 1-anilino-8-naphthalenesulfonate (I) as the sodium salt[1], warfarin[2], indomethacin[3], sulfaphenazole[4], sodium salicylate[5], sodium laurate[6], sodium palmitate[6], sodium stearate[6], sodium oleate[6], and rat serum albumin (fraction V)[7]. The rat serum albumin was defatted by the method of Chen (5).

Plasma Preparation—Adult male Wistar rats, weighing 290–340 g, were used. Approximately 10 min after heparinizing, blood was collected from the carotid artery under light ether anesthesia, and the plasma was obtained by centrifugation (3000 rpm for 10 min). Prepared plasma (2.5 mL) was used on the same day for measuring the bindings of drugs, and the remaining plasma (2 mL) was divided into the three aliquots, which were stored at −40°C and used within 1 week for the measurements of the concentrations of albumin, free fatty acids, and total bilirubin.

Equilibrium Dialysis—The 2-mL fresh plasma sample was diluted to 25% by the addition of 6 mL of Tris-HCl buffer (50 mM, pH 7.4). The bindings of four acidic drugs (sulfaphenazole, salicylic acid, indomethacin, and phenylbutazone) to the dilute plasma were measured by equilibrium dialysis (25°C). The details of the equilibrium dialysis techniques were described previously (4, 6).

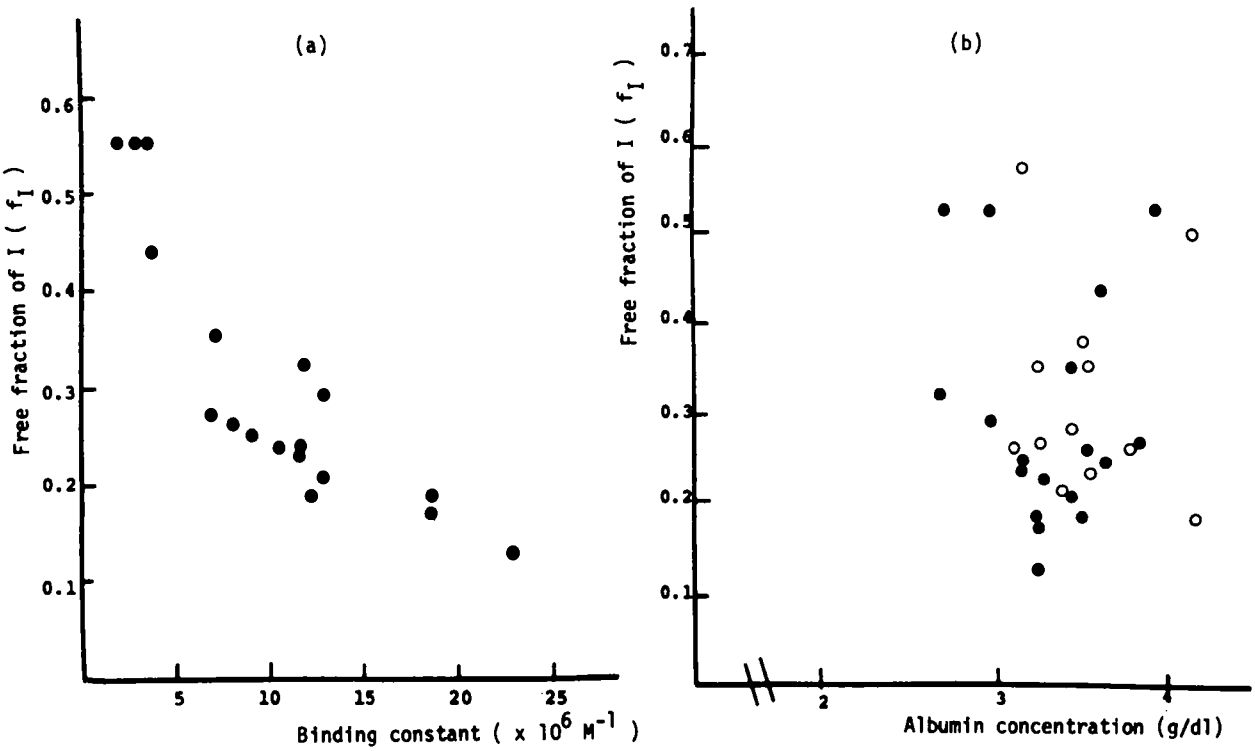

Figure 1—*Relationship between the free fraction of I and the binding constant (a) and albumin concentration (b) in the plasma of individual rats. Rat plasma diluted to 0.2% was used for the determination of f_I at a I concentration of 1 μM using the fluorescence method as described in the text. Correlation coefficient for the binding constant = −0.858, $p < 0.001$. Correlation coefficient for the albumin concentration = −0.072 (not significant). Key: (●) rats 1–18; (○) rats 19–32.*

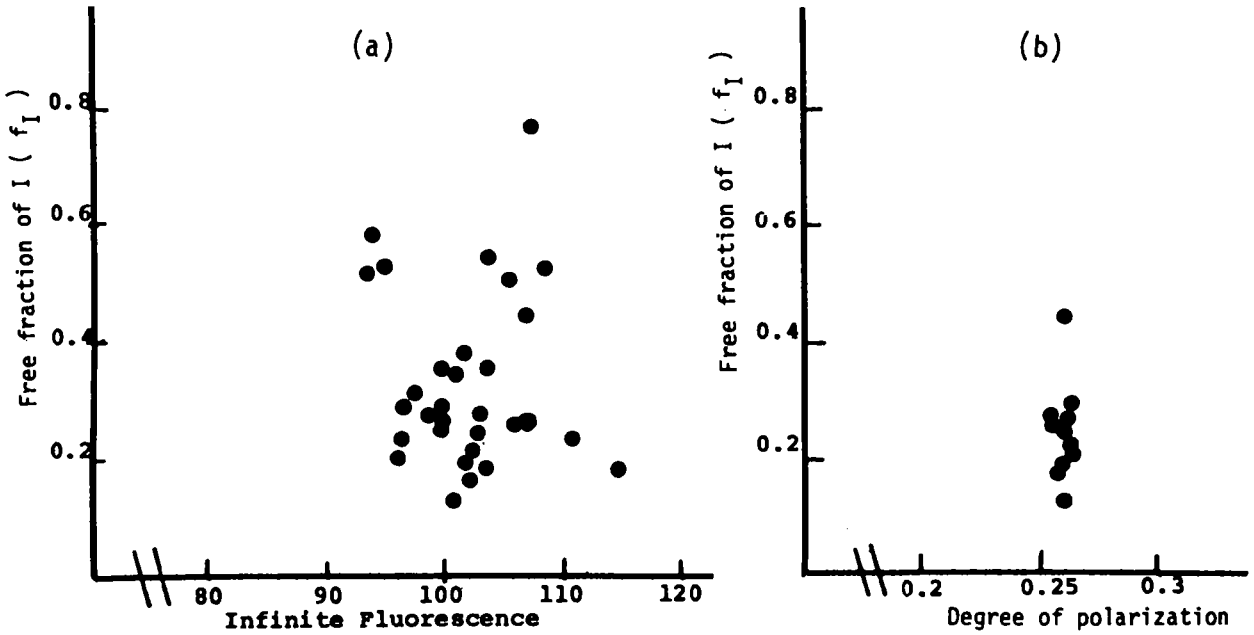

Figure 2—*Relationship between f_I and the infinite fluorescence of I (a) and the degree of polarization (b) in the plasma of individual rats. (See text for details.) Correlation coefficient for infinite fluorescence = −0.368 (not significant), using rats 1–32; correlation coefficient for degree of polarization = 0.258 (not significant), using rats 8–18.*

Fluorescence Measurement—Fluorometric measurements[8] were performed in the same buffer as above at room temperature (19–23°C). The bindings of I and warfarin to plasma were measured by the fluorescence method.

Binding of I.—The excitation and emission wavelengths were 400 and 480 nm, respectively. Titration of 1 μM of I with plasma was used to determine the infinite fluorescence when this concentration of I was completely bound. The infinite fluorescence thus obtained shows the fluorescence quantum yield of bound I and may reflect the changes in the environment at the binding site.

A reverse titration of 0.3% plasma with I was then carried out to obtain the binding parameters. Details of this titration procedure have been described previously (4, 6). The bound fraction of I (X_1) was given by:

$$X_1 = F_{obs}/F_{bound} \quad \text{(Eq. 1)}$$

where F_{obs} is the observed fluorescence and F_{bound} is the infinite fluorescence when a given concentration of I is completely bound. The free fraction of I (f_I) was then calculated by:

$$f_I = 1 - X_I \quad \text{(Eq. 2)}$$

[8] Hitachi MPF-4 fluorescence spectrometer.

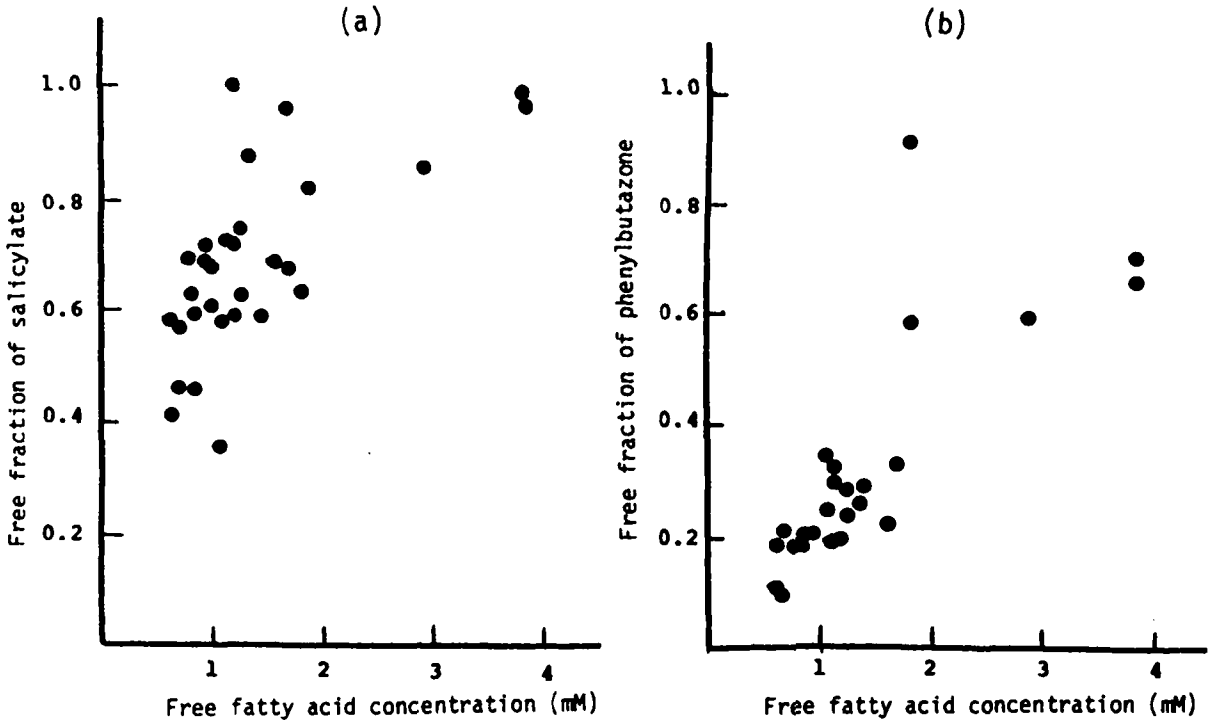

Figure 3—*Relationship between free fatty acid concentration and the free fractions of salicylate (a) and phenylbutazone (b) in the plasma of individual rats, determined by equilibrium dialysis using rat plasma diluted to 25% and initial drug concentrations of 0.1 mM. Correlation coefficient for salicylate = 0.661 ($p < 0.001$) using rats 3–32; correlation coefficient for phenylbutazone = 0.761 ($p < 0.001$) using rats 8–32.*

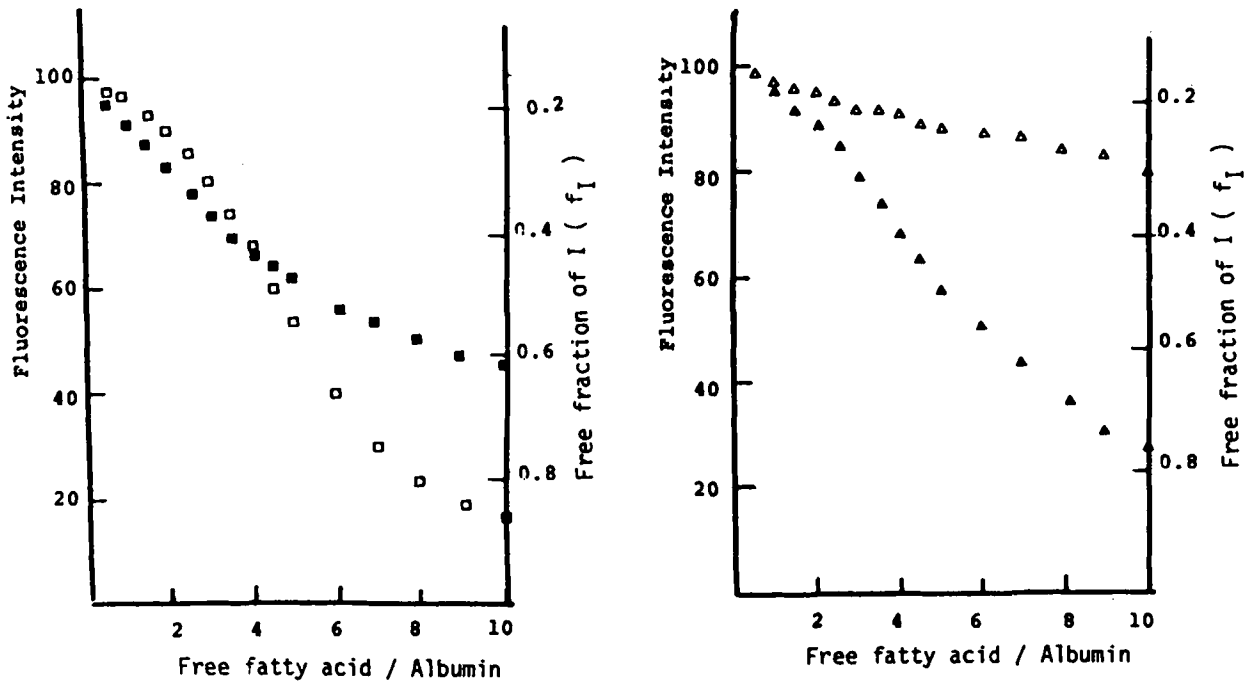

Figure 4—*Effect of various free fatty acids on the fluorescence of I with 1 μM defatted rat albumin and 1 μM of I. The fluorescence intensity in the absence of free fatty acids was set at 100 U. Fluorescence intensities (left ordinate) were converted to free fractions of I (right ordinate). Key: (□) oleic acid; (■) lauric acid; (△) stearic acid; (▲) palmitic acid.*

To study the conformational changes in the structure of plasma proteins, the polarization of the fluorescence of I bound to plasma proteins (mainly albumin) was measured using excitation and emission wavelengths of 380 and 480 nm, respectively. The degree of polarization, P, was calculated as:

$$P = (F_{par} - hF_{per})/(F_{par} - hF_{per}) \quad \text{(Eq. 3)}$$

where F_{par} and F_{per} refer to the intensity of the fluorescence light polarized parallel and perpendicular to the exciting light, respectively, and h is a correction factor which accounts for the selective transmission of the monochromatic light and the selective reflection of the sample tubes. Two film-type polarizers were used for the polarization measurements.

Warfarin Binding—The binding of warfarin to plasma was also measured by the fluorescence method previously adopted by Chakrabarti *et al.* (7, 8). The excitation and emission wavelengths were 320 and 390 nm, respectively. The bound fraction of warfarin (X_{II}) was calculated as:

$$X_{II} = (F_{obs} - F_{free})/(F_{bound} - F_{free}) \quad \text{(Eq. 4)}$$

where F_{obs} is the observed fluorescence corrected for the protein blank, F_{free}

Table I—Correlation Coefficients Between Free Fatty Acid Concentration and the Free Fractions of Various Acidic Drugs in Rat Plasma

Drug	n	Correlation Coefficient[a] (r)	Free Fatty Acid Level	
			Mean, mM	Range, mM
1-Anilino-8-naphthalenesulfonate (I)	32	0.609*[b]	1.35	0.43–3.78
Warfarin (II)	21	0.609**	1.14	0.62–1.80
Phenylbutazone (III)	25	0.761*[c]	1.14	0.62–3.78
Salicylate (IV)	30	0.661*[c]	1.39	0.62–3.78
Sulfaphenazole (V)	30	0.551** (0.687)*[d]	1.39	0.62–3.78
Indomethacin (VI)	15	0.536***	1.72	0.62–3.78

[a] Key for statistical significance: (*) $p < 0.001$; (**) $p < 0.01$; (***) $p < 0.05$. [b] Previously reported in Ref. 4. [c] Experimental data are shown in Fig. 3. [d] Among the 30 rats studied, one (rat 28) showed an abnormal free fraction (0.773), as indicated by an asterisk in Fig. 6. The correlation coefficient in parentheses was calculated excluding this abnormal datum point.

is the fluorescence of warfarin in the buffer at a given concentration, and F_{bound} is the fluorescence in the presence of a large excess of plasma proteins. The X_{II} value was obtained using 10 μM warfarin and 2% plasma, which corresponded to ~10 μM albumin.

Analytical Method—In the equilibrium dialysis experiments, the determination of drug at the buffer side was carried out spectrofluorometrically[8] or spectrophotometrically[9].

Indomethacin—The concentration was directly measured spectrophotometrically (λ_1 = 370 nm, λ_2 = 320 nm). The blank value which came from the membrane-permeable components was subtracted.

Phenylbutazone—After addition of 0.5 mL of 1 M HCl to 0.5 mL of sample, the mixture was extracted with 4 mL of *n*-heptane, and the 2.5-mL organic layer was reextracted with 2 mL of 4% sodium carbonate. The sodium carbonate layer was measured spectrophotometrically (λ_1 = 330 nm, λ_2 = 270 nm).

Salicylic Acid—After addition of 0.5 mL of 1 M HCl to 0.5 mL of sample, the mixture was extracted with 6 mL of dichloroethane, and the 4-mL organic layer was reextracted with 4 mL of 4% sodium carbonate. The drug concentration of the aqueous layer was measured spectrofluorometrically (λ_{ex} = 300 nm, λ_{em} = 410 nm) using a 390-nm cut-off filter at the emission side.

Sulfaphenazole—The concentration was determined colorimetrically (λ_1 = 650 nm, λ_2 = 550 nm) according to the method of Tsuda and Matsunaga (9). The determinations of free fatty acids[10], total bilirubin[11] (conjugated plus unconjugated), and albumin[12] in the plasma were performed using kits.

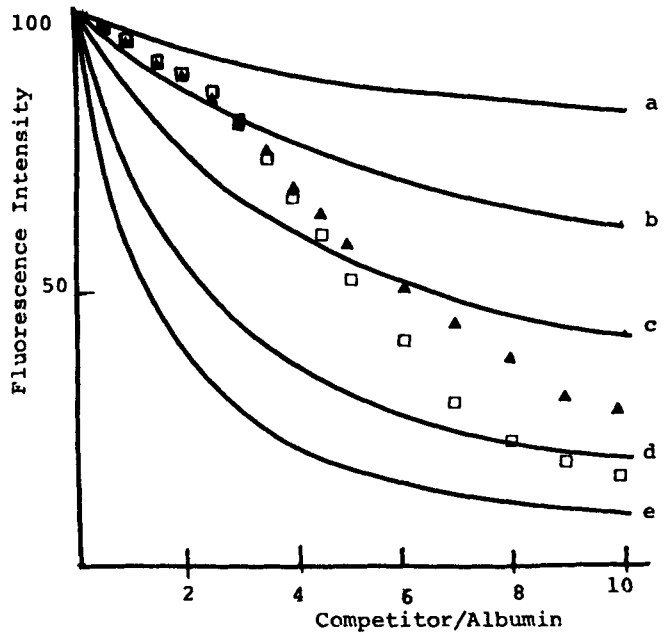

Figure 5—*Simulation of inhibition of the binding of I to rat albumin based on the assumption of simple competition. The solid lines were calculated with Eq. 5, using* $T_A = 1\ \mu M$, $P = 1\ \mu M$, $n = 1$, $K_A = 2.2 \times 10^7\ M^{-1}$, *and* K_B: *(a)* $0.3 \times 10^6\ M^{-1}$, *(b)* $1 \times 10^6\ M^{-1}$, *(c)* $3 \times 10^6\ M^{-1}$, *(d)* $10 \times 10^6\ M^{-1}$, *and (e)* $30 \times 10^6\ M^{-1}$. *(See text for details.) Data for oleic (□) and palmitic (▲) acids from Fig. 4 are shown for comparison.*

RESULTS AND DISCUSSION

Interindividual Differences in the Plasma Binding of I—It was previously reported that the free fraction of I (f_I) showed pronounced interindividual differences ranging from 0.126 to 0.777 (4). To determine whether these interindividual differences were due to differences in the binding constant or to those in albumin concentration, the correlations between f_I and these two factors were examined. Using plasma of 18 rats, binding kinetics with changing concentration of I were examined. Although the binding constant for the high-affinity site shows some interindividual differences (ranging from $1.75 \times 10^6\ M^{-1}$ to $2.3 \times 10^7\ M^{-1}$), the number of binding sites on albumin gives values $\simeq 1$. As shown in Fig. 1a, there is a highly statistically significant negative correlation between f_I and the binding constant for the high-affinity site ($r = -0.858$, $p < 0.001$); no significant correlation between f_I and the albumin concentration was seen (Fig. 1b). Figure 2 shows the correlation between f_I and the infinite fluorescence of I and the degree of polarization, both of which have been used as indices of the conformational changes of plasma albumin (7, 10, 11). No significant correlation was observed in either case. Consequently, the conformational changes of albumin might not be associated with the interindividual differences in f_I. On the other hand, it was previously found that there was a significant positive correlation between f_I and free fatty acid concentration in plasma, which was considered to be one of the endogenous displacing agents (4). However, the correlation coefficient was not so high ($r = 0.609$) that the interindividual differences could be explained only by free fatty acids (4).

Correlation Between the Free Fractions of Various Acidic Drugs and the Free Fatty Acid Concentration—Correlations between the free fatty acid concentrations in rat plasma and the free fractions of five acidic drugs (warfarin, phenylbutazone, salicylic acid, sulfaphenazole, and indomethacin) were investigated. Results in the case of phenylbutazone and salicylic acid are shown in Fig. 3; the correlation coefficients obtained are listed in Table I. Statistically significant positive correlations were observed between the free fatty acid concentration and the free fractions of all the drugs.

Plasma albumin is generally thought to play a major role in the binding of acidic drugs to plasma. To evaluate the extent of the potency of various free fatty acids to inhibit the binding of I to albumin, the titrations of the mixture of I (1 μM) and defatted rat albumin (1 μM) with various free fatty acids were carried out (Fig. 4). If it is assumed that the quantum yield of bound I (infinite fluorescence) is not altered by the binding of free fatty acid to albumin, the decrease in the fluorescence would represent the decrease in the concentration of bound I (see Eq. 1). The free fraction of I in the absence of free fatty acids under this condition was calculated to be 0.14 using Eq. 1. This value was essentially the same as the smallest free fraction of I (0.126) among those obtained using rat plasma.

Table II—Matrix of the Correlation Coefficients Between the Free Fractions of Six Acidic Drugs[a]

Drug	I	II	III	IV	V	VI
I		0.944*[b]	0.896*[c]	0.701*[b]	0.548**[b] (0.715*)[d]	0.808*[b]
II			0.911*	0.641*	0.422[ns] (0.561**)[d]	0.797*
III				0.732*	0.721* (0.655*)[d]	0.830*
IV					0.405*** (0.638*)[d]	0.605**
V						0.810* (0.775*)[d]

[a] Key for statistical significance: (*) $p < 0.001$; (**) $p < 0.01$; (***) $p < 0.05$; (ns) not significant ($p > 0.05$). [b] Experimental data are shown in Fig. 6. [c] Previously reported in Ref. 4. [d] The explanation for the values in parentheses is given in Table I, footnote *d*.

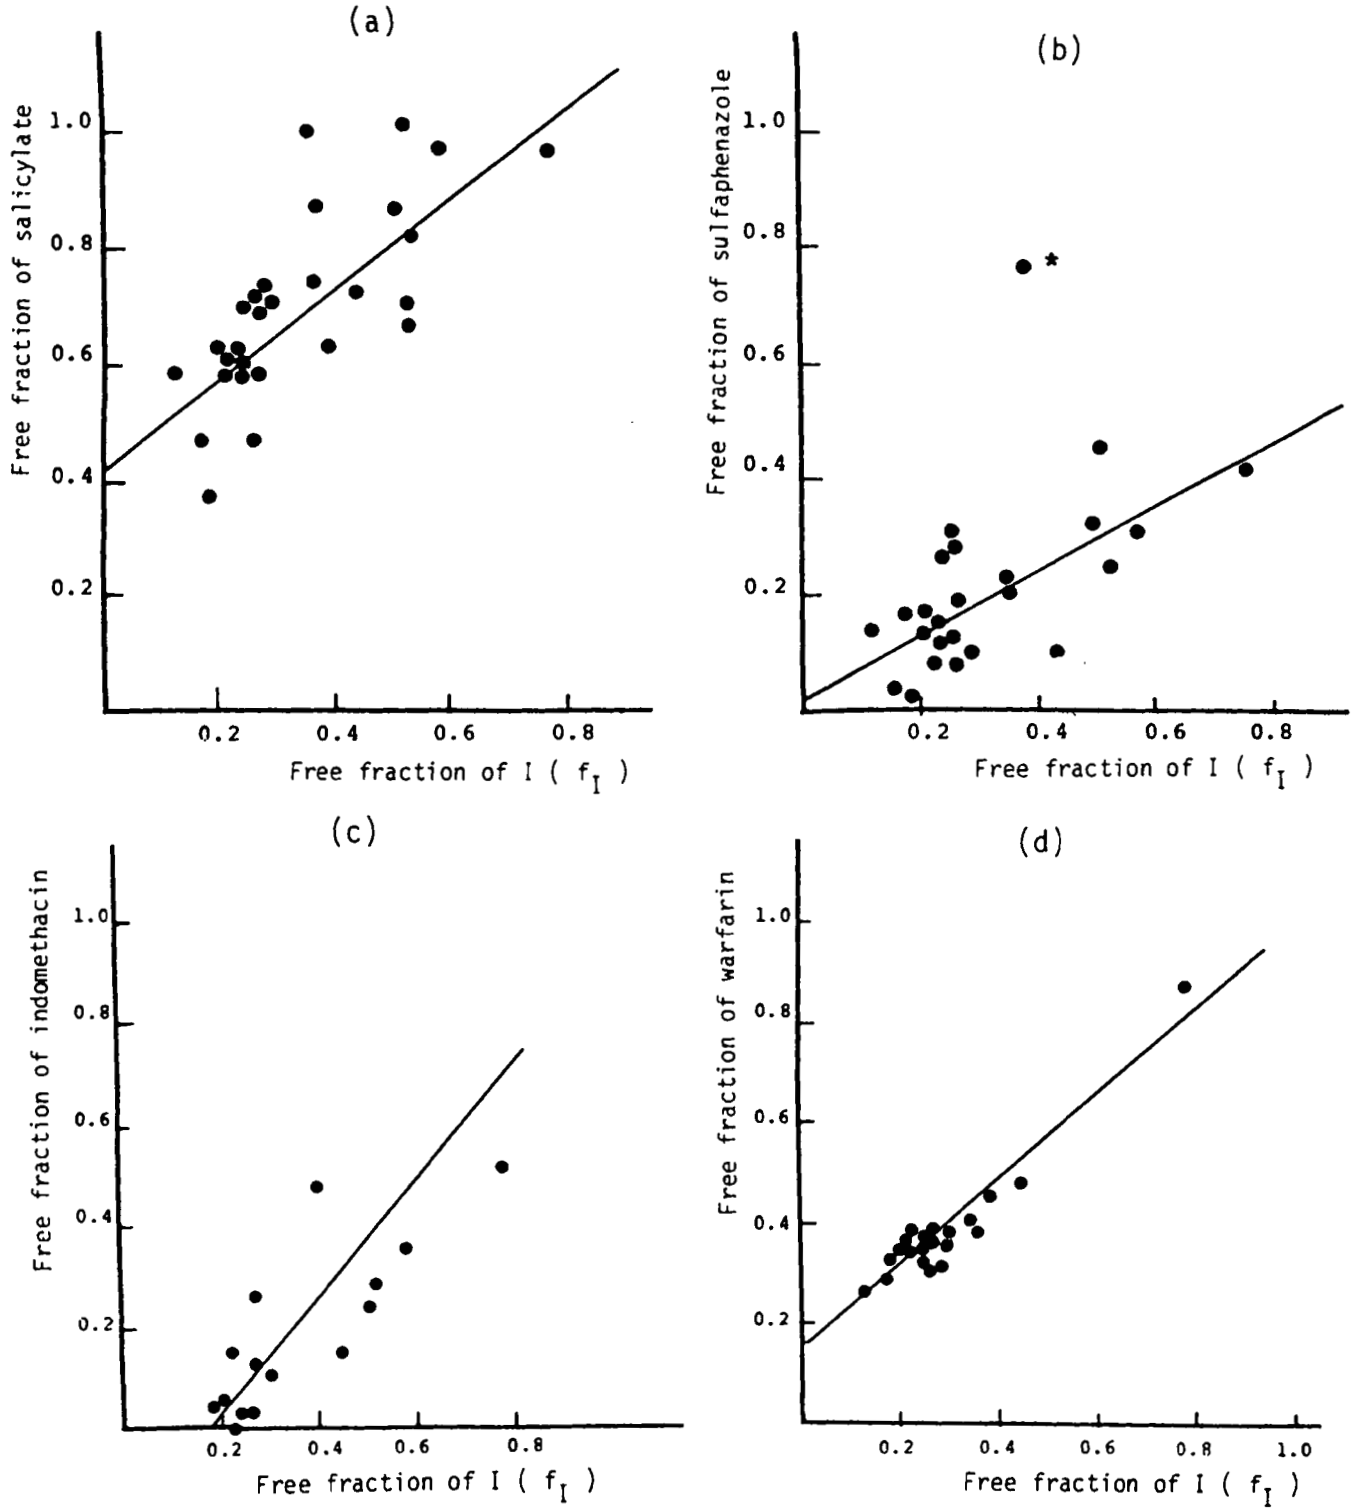

Figure 6—*Relationship between* f_I *and the free fractions of salicylate (a), sulfaphenazole (b), indomethacin (c), and warfarin (d) in the plasma of individual rats. Least-squares fits of the data yielded the solid lines. The experimental conditions are the same as described in Fig 3, and the correlation coefficients were summarized in Table II.*

Among the four free fatty acids studied, stearic acid is a weak inhibitor, while oleic acid and palmitic acid are relatively strong inhibitors. The latter acids have a similar pattern of inhibition, in which the fluorescence decrease is slow up to a free fatty acid/albumin ratio of 2 and faster thereafter. If simple competition by two ligands (I and free fatty acid in this case) for equal and independing binding sites is assumed, the following equation holds (12):

$$T_B = \left[n - r_A - \frac{r_A}{(T_A - P \cdot r_A)K_A}\right] \times \left[P + \frac{K_A(T_A - P \cdot r_A)}{r_A \cdot K_B}\right] \quad \text{(Eq. 5)}$$

where T_A and T_B are the total concentrations of I and the competitor (free fatty acid), respectively, P is the albumin concentration, r_A is the number of I molecules bound per mole of albumin, n is the number of binding sites, and K_A and K_B are the binding constants of I and competitor, respectively. In the present case, parameters used in this calculation are $T_A = 1\ \mu M$, $P = 1\ \mu M$, $n = 1$, $K_A = 2.2 \times 10^7\ M^{-1}$ (4).

Since the fluorescence intensity (F) of I is proportional to r_A, F can be calculated as a function of T_B using Eq. 5, when K_B is given. Figure 5 shows the simulation curves thus calculated. The simulation curve at any K_B value never reproduces the anomalous patterns obtained in the titration with oleic

and palmitic acids. Therefore, the slow fluorescence decrease up to the free fatty acid/albumin ratio of ~2 and the faster decrease after that could not be explained by the simple competition. Santons and Spector (13, 14) investigated the effects of free fatty acids on the binding of I to human or bovine serum albumin. They found that the fluorescence of I was enhanced when ≤2 mol of palmitate were added to 1 mol of human albumin, but larger amounts of palmitate produced a reduction in the fluorescence of I; with bovine and rabbit albumins, palmitate in all concentrations only reduced the fluorescence of I. The present result with rat albumin is similar to those with bovine and rabbit albumin.

Correlation Between the Free Fraction of I and those of Various Acidic Drugs—Figure 6 shows the correlation between f_I and the free fractions of various acidic drugs. There are highly statistically significant positive correlations in all cases. Warfarin and phenylbutazone were especially well correlated with I, $r \geq 0.9$. Such high correlations are reasonable when considering that warfarin and phenylbutazone reportedly competitively inhibit the binding of I to bovine serum albumin (15). The correlation coefficients between the free fractions of all drugs are listed in Table II; there is a statistically significant positive correlation between the free fraction of any pair of drugs.

This finding suggests that we can probably estimate the degree of plasma binding of such acidic drugs by knowing that of I. However, it must be kept in mind that the free fractions of various drugs obtained in the present study using dilute plasma samples do not necessarily represent the *in vivo* free fraction. To be able to employ this method using I as a clinical test, therefore, it would be necessary to determine the plasma bindings of various drugs using undiluted human plasma and examine the correlations between the free fractions of these drugs and that of I. However, the fluorescence method using I, which we have presented herein, has the advantages that it takes a short time (5–10 min) and needs a very small amount of plasma (<0.1 mL) to measure the free fraction of I.

Note added in proof: Heparin was used to prepare rat plasma in this study. The effect of heparin injection on plasma protein binding of I was subsequently studied and was reported (16).

Interaction of Doxorubicin with Nuclei Isolated from Rat Liver and Kidney

TETSUYA TERASAKI, TATSUJI IGA ˣ, YUICHI SUGIYAMA, and MANABU HANANO

Received April 1, 1982, from the *Faculty of Pharmaceutical Sciences, University of Tokyo, Hongo, Bunky-ku, Tokyo, 113, Japan.* Accepted for publication March 24, 1983.

Abstract □ The interaction of doxorubicin with nuclei isolated from rat liver and kidney was studied by fluorospectrometry. The nuclei had at least two different types of binding sites for the drug. Both Mg^{2+} and Ca^{2+} competitively inhibited the binding of doxorubicin to the nuclei, which showed a remarkable temperature dependency. No significant difference was observed between the numbers of binding sites ($n = 6.70 \times 10^{-2}$ mol/mol of DNA for liver; 6.41×10^{-2} mol/mol of DNA for kidney) or the affinity constants ($K_a = 4.85 \times 10^5$ M^{-1} for liver; 5.41×10^5 M^{-1} for kidney) under quasi-physiological conditions. These results obtained from *in vitro* binding experiments support previous suggestions that the differences in the *in vivo* distribution of doxorubicin among tissues are not due to differences in the nuclear binding of the drug. The amount of nuclei per gram of tissue is the primary determinant of the characteristic tissue distribution of doxorubicin.

Keyphrases □ Doxorubicin—interaction with nuclei isolated from rat liver and kidney, binding, distribution □ Binding—interaction of doxorubicin with nuclei isolated from rat liver and kidney, distribution □ Nuclei, liver and kidney—interaction with doxorubicin, rats, binding, distribution □ Distribution—interaction of doxorubicin with nuclei isolated from rat liver and kidney, binding

Doxorubicin, an anthracycline antibiotic, has cytotoxic and antineoplastic activities and inhibits both enzymatic RNA and DNA synthesis by intercalating with DNA (1). The tissue distribution of doxorubicin has been studied extensively in humans and laboratory animals, but the mechanism of its distribution in such tissues as liver, kidney, and muscle has not been elucidated (2–6). The tissue distribution of this drug is generally thought to be related to the affinity for the tissue binder, the concentration of binder, and the permeability across the plasma membrane.

The interaction of doxorubicin and other derivatives with DNA or chromatins isolated from tumor cells, calf thymus, and cultured lung cells has been studied by several methods (7–10). Although the binding of the drug to native DNA has been extensively studied, little information has been obtained on its intercalation with nuclei isolated from normal tissues. Moreover, it has been suggested that doxorubicin also interacts strongly with the negatively charged phospholipid, cardiolipin (11). In addition, it was revealed that tumor cells may have a carrier-mediated influx system and an active efflux mechanism (12). Previously, a good correlation between the *in vivo* tissue-to-plasma partition coefficients for doxorubicin in several tissues and the amounts of nuclei per gram of tissue in rats and rabbits was demonstrated, suggesting that there is little or no difference in the nuclear binding of the drug among tissues (13).

The purpose of this study was to determine the *in vitro* binding characteristics of doxorubicin with isolated nuclei from rat liver and kidney in an attempt to elucidate the mechanisms by which the *in vivo* tissue distribution of the drug occurs.

and palmitic acids. Therefore, the slow fluorescence decrease up to the free fatty acid/albumin ratio of ~2 and the faster decrease after that could not be explained by the simple competition. Santons and Spector (13, 14) investigated the effects of free fatty acids on the binding of I to human or bovine serum albumin. They found that the fluorescence of I was enhanced when ≤2 mol of palmitate were added to 1 mol of human albumin, but larger amounts of palmitate produced a reduction in the fluorescence of I; with bovine and rabbit albumins, palmitate in all concentrations only reduced the fluorescence of I. The present result with rat albumin is similar to those with bovine and rabbit albumin.

Correlation Between the Free Fraction of I and those of Various Acidic Drugs—Figure 6 shows the correlation between f_I and the free fractions of various acidic drugs. There are highly statistically significant positive correlations in all cases. Warfarin and phenylbutazone were especially well correlated with I, $r \geq 0.9$. Such high correlations are reasonable when considering that warfarin and phenylbutazone reportedly competitively inhibit the binding of I to bovine serum albumin (15). The correlation coefficients between the free fractions of all drugs are listed in Table II; there is a statistically significant positive correlation between the free fraction of any pair of drugs.

This finding suggests that we can probably estimate the degree of plasma binding of such acidic drugs by knowing that of I. However, it must be kept in mind that the free fractions of various drugs obtained in the present study using dilute plasma samples do not necessarily represent the *in vivo* free fraction. To be able to employ this method using I as a clinical test, therefore, it would be necessary to determine the plasma bindings of various drugs using undiluted human plasma and examine the correlations between the free fractions of these drugs and that of I. However, the fluorescence method using I, which we have presented herein, has the advantages that it takes a short time (5–10 min) and needs a very small amount of plasma (<0.1 mL) to measure the free fraction of I.

Note added in proof: Heparin was used to prepare rat plasma in this study. The effect of heparin injection on plasma protein binding of I was subsequently studied and was reported (16).

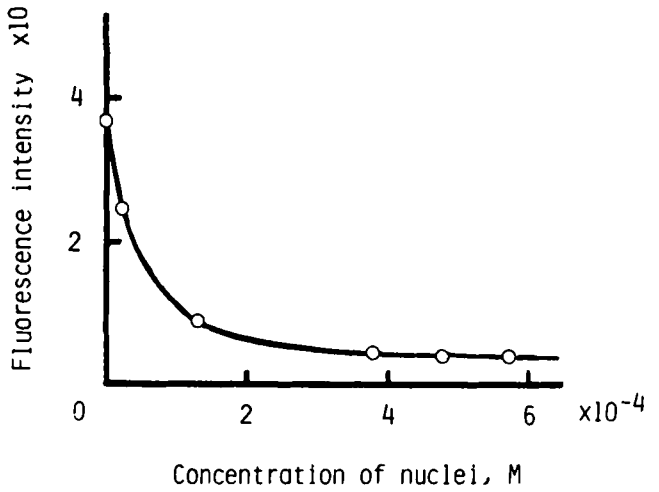

Figure 1—*Effect of nuclear binding on the fluorescence intensity of doxorubicin. The concentration of nuclei is expressed in terms of a nucleotide. A nucleotide molecular weight of 330.9 was used to determine DNA concentration (as nucleotide) as the sodium salt.*

EXPERIMENTAL

Materials—Doxorubicin hydrochloride[1] was stored in the dark in a desiccator at 4°C. Solutions of the drug (2×10^{-6}–5×10^{-4} M) in 405 mM sucrose were freshly prepared immediately before use. Calf thymus DNA[2] and yeast RNA[2] (type XI) were used as standards for the determination of DNA and RNA concentrations in the tissue and nuclei. Micrococcal nuclease[3] was used for the preparation of chromatin. All other reagents were commercial products of analytical grade.

Preparation of Nuclei and Chromatin—Male Wistar rats[4], weighing 250–270 g, were used as liver and kidney donors. Nuclei and chromatin were prepared essentially according to the procedure of Sugano *et al.* (14), except that 1 mM magnesium chloride was added to the isolation buffer to prevent the aggregation of nuclei. No detergent was added to the buffer. The resulting nuclear pellet was suspended in buffer (pH 7.4) containing 340 mM sucrose, 60 mM potassium chloride, 15 mM Tris, 15 mM 2-mercaptoethanol, 1 mM calcium chloride, 1 mM magnesium chloride, and 0.1 mM α-toluenesulfonyl fluoride. The integrity of isolated nuclei was examined microscopically after staining with 1.0% orcein-45% acetic acid solution. The yield of nuclei was 20–30%.

Binding Experiments—The binding studies of doxorubicin to nuclei were performed by spectrofluorometric titration in a fluorospectrometer[5]. Aliquots (2–10 μL) of freshly prepared doxorubicin stock solution (2×10^{-6}–5×10^{-4} M), up to a 150-μL total sample volume, were added to the cuvette filled with 3 mL of nuclei (2×10^{-5}–5×10^{-5} M as DNA) in a quasi-physiological buffer (pH 7.0) solution containing 135 mM sucrose (which was added to inhibit the swelling of nuclei), 20 mM Tris, 50 mM sodium chloride, 100 mM potassium chloride, 1 mM magnesium chloride, and 1 mM calcium chloride (15, 16). The solution was stirred with a glass rod after each addition, and the fluorescence was measured at 590 nm (excitation at 500 nm) at 10 min (at 37°C) or 30 min (at 7°C) after the addition of the drug. The fluorescence intensity of doxorubicin decreased with increasing amount of nuclei added (Fig. 1), as reported for the interaction of anthracycline antibiotics with DNA and chromatins (7), and the fluorescence intensity (I) of the drug binding to the nuclei can be expressed by:

$$I = q_f C_f + q_b C_b \qquad \text{(Eq. 1)}$$

Table I—Characterization of Nuclei Isolated from Rat Liver and Kidney

	Liver			Kidney		
	Homogenate	Nuclei[a]	Ratio of Nuclei/ Homogenate	Homogenate	Nuclei[a]	Ratio of Nuclei/ Homogenate
RNA[b]/DNA[c]	7.36	0.289	0.039	3.04	0.132	0.043
Protein[d]/DNA[c]	108.0	2.95	0.027	68.0	1.93	0.028
Yield (%)		25.8			21.6	

[a] Obtained from four independent experiments. [b] RNA was extracted by the method of Schneider (17) and determined by the orcinol method (19). [c] DNA was extracted in the same manner as described for RNA and determined by the method of Burton (18). [d] Protein was determined according to Lowry *et al.* (20) with bovine serum albumin (Fraction V) as the standard.

where q_f and q_b are the quantum yields of free and bound doxorubicin and C_f and C_b are the concentrations of free and bound drug, respectively. The total concentration (C_t) of doxorubicin is given by:

$$C_t = C_f + C_b \quad \text{(Eq. 2)}$$

The procedure for estimating the quantum yield of drug bound to nuclei is presented in the *Appendix*. Representative calibration curves, determined for each experiment, are shown in Fig. 2.

The apparent binding constants were calculated by means of the following equation using C_f and C_b obtained from Eqs. 1 and 2:

$$(C_b/C_N)/C_f = nK_a - K_a(C_b/C_N) \quad \text{(Eq. 3)}$$

where C_N is the concentration of nuclei as DNA, n is the number of binding sites, and K_a is the affinity constant. To check the degradation of doxorubicin during the binding experiments, the amount of drug in the nuclear suspension before and after incubation was determined by TLC scanning, as reported previously (13).

Analytical Methods—The concentration of nuclei was expressed as that of nucleotide. The molecular weight of 330.9 (the average molecular weight for a nucleotide) was used to determine DNA concentration as the sodium salt. DNA in the tissue and isolated nuclei was extracted according to the procedure of Schneider (17) and determined colorimetrically by the method of Burton (18). RNA was extracted in the same manner as described for DNA and was determined by the orcinol method (19). Protein was determined according to the procedure of Lowry *et al.* (20) with bovine serum albumin[6] as the standard.

Data Analysis—The data were analyzed by a least-squares method using a digital computer[7]. The SALS program (21) was used for the calibration curves and the calculation of the binding parameters of the Scatchard plots.

RESULTS

Characterization of Isolated Nuclei—From microscopic observations of nuclei prepared from the liver and kidney, both preparations were confirmed to be unaffected by the isolation procedure, and only slight cytoplasmic contamination was observed. The RNA/DNA and protein/DNA ratios of tissue homogenate and isolated nuclei were compared (Table I). Since no significant metabolism of doxorubicin was observed during the period of the spectrophotometric study, contamination of nuclei with microsomal and/or cytoplasmic enzymes appeared to be negligible.

Scatchard Analysis of Doxorubicin Binding to Liver Nuclei—A Scatchard plot of doxorubicin binding to liver nuclei based on three independent experiments is shown in Fig. 3; reproducibility was good. The curvature of the plot suggests the existence of at least two classes of binding sites. The binding parameters for the high-affinity sites obtained in the lower drug concentration range (9×10^{-8}–4×10^{-6} M) by the least-squares method were $K_a = 4.85 \times 10^5\ M^{-1}$ and $n = 6.70 \times 10^{-2}$ mol/mol of DNA. However, it was difficult to calculate meaningful binding parameters for the low-affinity sites, since the high inner filter effect of doxorubicin made it difficult to use higher drug concentrations in the binding experiments. The number of high-affinity binding sites is comparable to the value of 8×10^{-2} for the binding of daunomycin to chromatin prepared from Ehrlich ascites tumor cells, as reported by Sabeur *et al.* (7). However, the affinity constant obtained for nuclei showed a large difference from their value ($5 \times 10^6\ M^{-1}$) (2), which might be due to differences in both temperature and buffer composition.

Effect of Temperature—Figure 4 shows Scatchard plots of the temperature dependency of doxorubicin binding to nuclei. The calculated binding constant at 7°C was $K_a = 2.76 \times 10^6\ M^{-1}$, and the number of binding sites was $n = 5.97 \times 10^{-2}$ mol/mol of DNA. This number of binding sites is similar to that observed at 37°C (6.70×10^{-2}), but there appeared to be a remarkable temperature dependency of the affinity constant, K_a. The calculated enthalpy change was −10 kcal/mol.

Effect of Magnesium and Calcium Ions—To examine the effect of divalent metal ions on doxorubicin binding to liver nuclei, the binding was studied in the absence of 1 mM Mg^{2+} or Ca^{2+} in the buffer. The Scatchard plots of doxorubicin binding to liver nuclei are shown in Fig. 5a for Mg^{2+} and in Fig. 5b for Ca^{2+}. Both divalent metal ions decreased the affinity constant, but did not change the number of binding sites. The affinity constant and the number of binding sites, calculated by the least-squares method, for the high-affinity binding sites in divalent metal ion-free buffer were $K_a = 8.39 \times 10^5\ M^{-1}$ and $n = 6.03 \times 10^{-2}$ mol/mol of DNA, respectively, without Mg^{2+}, and $K_a = 6.67 \times 10^5\ M^{-1}$ and $n = 6.44 \times 10^{-2}$ mol/mol of DNA, respectively, without Ca^{2+}. No remarkable decrease in K_a was observed at two- or threefold higher concentrations of these divalent ions.

Effect of pH—Since different intracellular pH values (pH 6.8–7.4) among various tissues have been reported (22), the effect of the buffer pH on doxorubicin binding to liver nuclei was studied over the pH range of 6.4–8.0. As shown in Fig. 6, a small difference appears to exist, but this may not be significant.

Comparison of Doxorubicin Binding to Nuclei and Chromatin Isolated from Liver—Figure 7 shows the Scatchard plots of drug binding to nuclei and chromatin prepared from the liver nuclei. The affinity constant for chromatin in 10 mM Tris buffer at 37°C (pH 7.0) was $2.65 \times 10^6\ M^{-1}$, and the number of binding sites was 7.59×10^{-2} mol/mol of DNA. The numbers of binding sites to nuclei (Fig. 3) and to chromatin (Fig. 7) are very similar. When doxorubicin binding to chromatin was examined under the same conditions as employed for nuclei (Fig. 3), aggregations of chromatin occurred which might be caused by the high cation concentration (23). Since a homogenous dispersion of chromatin could not be obtained in the physiological buffer, the Tris buffer was used. However, there seemed to be little difference in the binding characteristics of the drug between nuclei and chromatin.

Comparison of Doxorubicin Binding to Nuclei Isolated from Liver and Kidney—To determine whether the binding characteristics of doxorubicin to nuclei are different among different tissues, the binding of the drug to nuclei isolated from kidney, as well as liver, was examined. The results of the antibiotic binding to kidney nuclei are shown in Fig. 8. The calculated affinity constant was $5.41 \times 10^5\ M^{-1}$, and the number of binding sites was 6.41×10^{-2} mol/mol of DNA. Little difference was observed in these parameters between nuclei isolated from the liver ($K_a = 4.85 \times 10^5\ M^{-1}$, $n = 6.70 \times 10^{-2}$ mol/mol of DNA; Fig. 3) and kidney under the same conditions.

DISCUSSION

It is well known that the concentrations of doxorubicin after intravenous administration show large differences among tissues (2–6). We have studied the mechanisms of this characteristic tissue distribution on the basis of the working hypothesis that the amount of nuclei per gram of tissue is the predominant factor and, therefore, the differences in the binding characteristics among tissues are probably negligible (13). In this study, the *in vitro* binding characteristics of doxorubicin to nuclei isolated from the rat liver and kidney were examined in an attempt to prove that these assumptions are valid.

Both the integrity and purity of nuclei are known to be important determinants of the *in vitro* binding of doxorubicin. In this study, the ratios of RNA/DNA and protein/DNA (Table I) are comparable to those reported for liver chromatin by Spelsberg and Hnilica (RNA/DNA ratio = 0.1; protein/DNA ratio = 2.2) (24), and no significant aggregation of the isolated nuclei was observed by microscopic examination. Thus, the nuclei prepared in this study were thought to be suitable for the binding study of doxorubicin. Moreover, the chromosomal proteins, which were suggested to inhibit the interaction of homidium bromide and dactinomycin, bind tightly to DNA (25, 26). Therefore, the release of those important proteins might be negligible in this mild isolation procedure. Since nuclei are the dominant organelles

associated with the intracellular localization of doxorubicin (27), slight contamination by cytoplasm might not affect the binding parameters.

The results obtained from the nuclei and chromatin binding studies (Figs. 3–8), suggest that both the temperature and buffer contents are more important determinants than is the medium pH. Two binding sites have been reported for daunomycin binding to DNA; one site is a hydrophobic site which binds the antibiotic aglycone with successive base pairs of the double helix, the other site binds daunomycin by an electrostatic interaction involving the DNA phosphate groups and the daunomycin amino group. Data in Fig. 3 also support the existence of at least two binding sites. Another possible interaction by means of hydrogen bonding has also been proposed (28). It has been reported that divalent cations such as Mg^{2+} and Ca^{2+} interact with the phosphate groups of DNA (29). In this study, typical competitive inhibition by both Mg^{2+} and Ca^{2+} was observed in the nuclear binding of doxorubicin (Fig. 5). Accordingly, the present results support the proposed mechanism that the drug binds predominantly to DNA by an electrostatic interaction with phosphate groups.

No significant pH dependency of doxorubicin binding to nuclei was observed over the pH range studied (pH 6.4–8.0) (Fig. 6), which might be due to the complete ionization of the primary phosphate groups of DNA over this pH range. This result is in agreement with the finding that Ca^{2+} showed a constant binding to DNA over the pH range of 5.0–9.5 (29). Consequently, it is considered that doxorubicin binding to nuclei might not be affected by the tissue differences of intracellular pH in the physiological region (22).

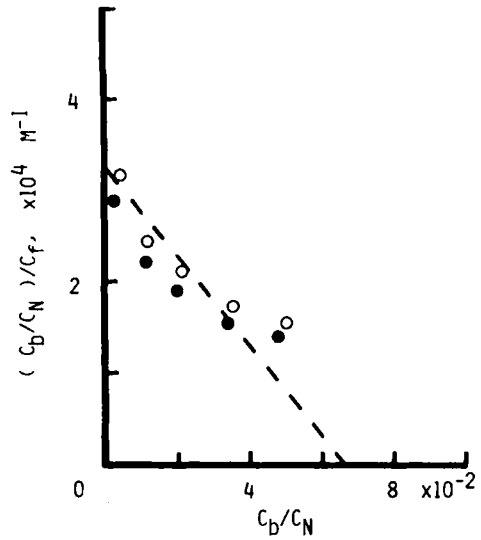

Figure 6—*Scatchard plots of the effect of pH on the binding of doxorubicin to nuclei isolated from the rat liver. The binding study was performed at 37°C in quasi-physiological buffer. The concentration of nuclei was 4.6 × 10^{-5} M as DNA in each study. Key: (○) pH 8.0; (●) pH 6.4; (---) pH 7.0, taken from Fig. 3 for comparison.*

A previous study (13) demonstrated that the *in vivo* tissue-to-plasma partition coefficient of the kidney was 1.5 times greater than that of the liver. However, in the current study no significant difference was observed between the numbers of binding sites (n = 6.70 × 10^{-2} mol/mol of DNA for liver, 6.41 × 10^{-2} mol/mol of DNA for the kidney) or the affinity constants (K_a = 4.85 × 10^5 M^{-1} for the liver, 5.41 × 10^5 M^{-1} for the kidney). Thus, the working hypothesis that the binding of doxorubicin per nuclei is constant among various tissues is supported.

As shown in Fig. 7, the degree of drug binding was similar to nuclei and chromatin. Since chromatin prepared by the procedure employed in this study had a negligible amount of nuclear membrane (14), it is probable that the binding to nuclei reflects the binding characteristics to nuclear DNA rather than to nuclear membranes. Furthermore, the nuclear membrane has numerous nuclear pores (average diameter, 90 nm) (30), so it is unlikely that the membrane permeability is an important determinant of doxorubicin binding either *in vivo* or *in vitro*, in view of the molecular weight of the drug.

A quasi-physiological buffer, which has been proposed to provide the best possible conditions on the basis of morphological examination of isolated nuclei and the intracellular concentrations of ions (15, 16), was used as the buffer for the binding study. Thus, the values of nuclear binding parameters (Figs.

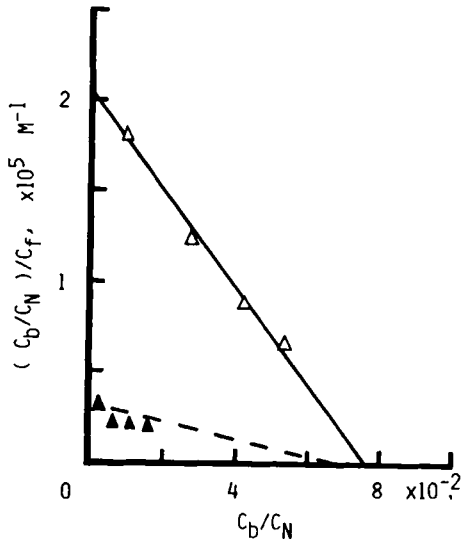

Figure 7—*Scatchard plots for the binding of doxorubicin to nuclei and chromatin prepared from rat liver nuclei. The binding was studied in two different concentrations of buffer at 37°C. Key: (△) 10 mM Tris (pH 7.0, concentration of nuclei was 2.2 × 10^{-5} M as DNA); (▲) 135 mM sucrose, 10 mM Tris, 50 mM sodium chloride, 100 mM potassium chloride, 1 mM magnesium chloride, and 1 mM calcium chloride (concentration of nuclei was 6.5 × 10^{-5} as DNA); (---) binding curve for liver nuclei, taken from Fig. 3.*

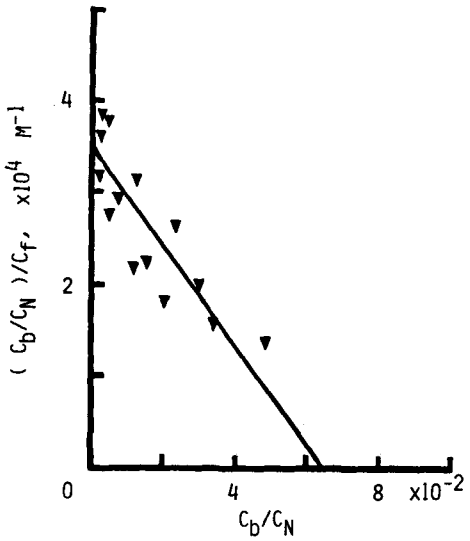

Figure 8—*Scatchard plot of data for the binding of doxorubicin to nuclei isolated from the rat kidney. The concentration of nuclei was 3.7 × 10^{-5} M as DNA. The line was fitted by the SALS method using a digital computer.*

3 and 8) obtained in this *in vitro* study might be comparable with those under *in vivo* conditions. However, further detailed study would be necessary to elucidate whether these results on *in vitro* nuclei actually reflect the *in vivo* binding.

In conclusion, no difference in the nuclear binding of doxorubicin was demonstrated between the liver and kidney, suggesting that the amount of nuclei per gram of tissue is the primary determinant of the characteristic tissue distribution of this drug.

APPENDIX: Estimation of Quantum Yield of Doxorubicin Binding to Nuclei

Rearranging Eq. 3 gives:

$$(C_b/C_f) = nK_aC_N/(1 + K_aC_f) \quad \text{(Eq. 4)}$$

According to Eq. 4, in the presence of an excess amount of nuclei doxorubicin is bound completely to nuclei.

Since the fluorescence intensity (I) of doxorubicin decreases with increasing amount of nuclei added, I gives the minimum value (I_{min}) when the drug is bound completely to nuclei, and the maximum value (I_{max}) is obtained in the absence of nuclei. The quantum yields of free (q_f) and bound (q_b) drug are defined as:

$$q_f = I_{max}/C_t \quad \text{(Eq. 5)}$$

$$q_b = I_{min}/C_t \quad \text{(Eq. 6)}$$

where C_t is the total concentration of doxorubicin. Substituting Eqs. 5 and 6 into Eq. 1 gives:

$$I = (I_{max}C_f + I_{min}C_b)/C_t \quad \text{(Eq. 7)}$$

When $K_aC_f \ll 1$, Eq. 4 is reduced to:

$$(C_b/C_f) = nK_aC_N \quad \text{(Eq. 8)}$$

Substituting Eqs. 2 and 8 into Eq. 7 gives:

$$I = (I_{max} + I_{min}nK_aC_N)/(1 + nK_aC_N) \quad \text{(Eq. 9)}$$

Thus, rearranging Eq. 9 gives:

$$I = I_{min} + (1/nK_a) \times (I_{max} - I)/C_N \quad \text{(Eq. 10)}$$

A plot of I *versus* $(I_{max} - I)/C_N$ should yield a straight line. The intercept of the ordinate gives I_{min}, and the reciprocal of the slope gives nK_a. Accordingly, the quantum yield of bound doxorubicin (q_b) can be calculated from Eq. 6.

Abstract □ Among ligands that bind to the α- and β-adrenoceptors and to the muscarinic acetylcholine receptor (m-AChR), those that bind to the latter have the best properties for external detection of receptor sites by gamma-camera imaging. To develop the optimal radiotracer, nonradioactive analogues of 3-quinuclidinyl benzilate (I) were tested in *in vivo* displacement studies with (−)-[^{3}H]I to determine their ability to compete with (−)-[^{3}H]I for the muscarinic acetylcholine receptor. There is a linear correlation between the ability to compete with (−)-[^{3}H]I for the m-AChR and the affinity constant of the analogue as determined by *in vitro* assay, suggesting that the test is a valid indicator of *in vivo* distribution. One radioiodinated analogue, 3-quinuclidinyl *p*-iodobenzilate, bound to m-AChR in the heart and brain of rats.

Keyphrases □ 3-Quinuclidinyl benzilate—analogues, binding to α- and β-adrenoceptors and the muscarinic acetylcholine receptor, gamma-camera imaging □ Radioligand binding—3-quinuclidinyl benzilate analogues to the muscarinic acetylcholine receptor, gamma-camera imaging □ Radiotracers—development of 3-quinuclidinyl benzilate analogues for gamma-camera imaging, binding to α- and β-adrenoceptors and muscarinic acetylcholine receptor

We have attempted to develop an effective strategy for the design, synthesis, *in vitro* analysis, animal distribution studies, and clinical evaluation of receptor binding radiotracers. Because of the special requirements for receptor binding radiotracers (high effective specific activity, high chemical and radiochemical purity, low nonreceptor binding, and low rate of metabolism) the choice is crucial (1). A large investment of research effort is needed to produce a radiolabeled receptor-binding ligand; only one receptor-binding radiotracer, 16α-[^{77}Br]bromoestradiol, is presently in the clinical trial phase (2)*.

To prepare a gamma-emitting receptor-binding radiotracer we have investigated several tritium-labeled compounds that bind to the α- and β-adrenoceptor and to the muscarinic acetylcholine receptor (m-AChR). The results, both *in vitro* and *in vivo*, using the tritium-labeled compounds led us to synthesize a number of nonradioactive derivatives of I substituted with stable isotopes of the routinely used gamma-emitting radionuclides iodine-123, bromine-77 and -75, and fluorine-18 (3). These stable halogenated derivatives of I were used in *in vivo* competition studies with (−)-[^{3}H]I to determine their ability to compete with the parent structure for m-AChR and, thus, give an indication of their own distribution.

Because making each derivative with iodine-123, bromine-77, or fluorine-18 would be an overwhelming task given the requirements mentioned previously, we thought that this approach—*in vivo* competition studies—would be an efficient strategy to determine which radiotracer to pursue. We also prepared and tested a number of other receptor-binding ligands to determine the structural requirements for binding to the receptor.

EXPERIMENTAL

Radioligands—(−)-3-[^{3}H]Quinuclidinyl benzilate (I)[1], (±)-4-(3-*tert*-butylamino-2-hydroxypropoxy)-1-*H*-2-cyano-3-[^{125}I]iodoindole (II)[2], and [^{3}H]prazosin (III)[1] were used without further purification. (±)-4-(3-*tert*-Butylamino-2-hydroxypropoxy)-1-*H*-3-[^{125}I]iodoindole (IV) was prepared according to the method of Barovsky and Brooker (4). Each was determined to be >95% radiochemically pure.

Preparation of Nonradioactive Compounds—*N*-Methyl scopolamine (V)[3], scopolamine (VI)[3], benactyzine (VII)[4], α-(hydroxymethyl) 4-bromobenzeneacetic acid 8-methyl-8-azabicyclo[3.2.1]oct-3-yl ester (4-bromoatropine; VIII)[5], benztropine (IX)[6], carbetapentane (X)[7], carazolol (XI)[8], phentolamine (XII)[9], propranolol (XIII)[10], and pindolol (XIV)[11] were obtained commercially. Other compounds were prepared and purified as previously published (3). Each derivative (3 μmol) was dissolved in 3 mL of EtOH without heat. At the time of use, 3 mL of saline was added, and 2 mL of this solution was mixed with 0.075–0.100 mL of (−)-[^{3}H]I at a final concentration of 37–50 μCi/mL. A 0.1-mL aliquot was injected per animal. Each compound was analyzed by HPLC before and after use by published techniques (3) and found to be chemically pure. Each analogue of I is a mixture of the four diastereomers.

Animal Studies—The *in vivo* distribution was determined in male Sprague–Dawley rats weighing 250–300 g at the time of study. The thyroid was not blocked. Under light halothane anesthesia, 0.1 mL of radiopharmaceutical solution (3–5 μCi in 50% ethanol) was injected into an exposed femoral vein. At selected times after the injection, the animals were killed and samples of blood, ventricular muscle, lung, liver, pancreas, midbrain, and cerebellum tissues were taken. The midbrain included the corpus striatum and hippocampus along with a portion of the brain stem. No cerebral cortex or pineal gland tissue was sampled. Small samples of solid tissue (100–200 mg) and blood (25 μL) were processed overnight in tissue solubilizer and then counted after the addition of liquid scintillation cocktail. Replicate counts separated by 24 h were taken to verify the absence of chemiluminescence. The results are expressed as the percentage of the injected dose per gram of wet tissue with 95% confidence limits. This allows direct comparison to determine if differences are significant at the 95% level.

RESULTS AND DISCUSSION

From our previous survey of various receptor systems in the heart such as the α- and β-adrenoceptors and the muscarinic acetylcholine receptor (m-AChR), it became obvious that the m-AChR system has the greatest potential. From a simple biomolecular model (5) and from distribution studies using commercially available tritium-labeled ligands, 3-quinuclidinyl benzilate (I) appeared to be the best radioligand (6).

Distribution of α- and β-Adrenoceptor Binding Radiotracer—The high-affinity β-adrenoceptor ligand XI and the high affinity α-adrenoceptor ligand III showed displaceable binding in the rat heart and lung, but XI gave

[a] Amount of nonradioactive compound coinjected per animal, six animals per group.

heart-to-blood (H/B) ratios of <5 (Table I) and III was not displaceable in guinea pig and rabbit (6). (±)-[^{3}H]I showed H/B ratios of >25 and displaceable binding in two species (6, 7).

Recently, three iodinated β-adrenoceptor ligands became available commercially. The first, iodohydroxybenzylpindolol (XV) gave low H/B ratios but displaceable binding in the lung (6). Two other compounds, II and IV, have also been prepared (8). Compound IV does not give high H/B ratios in the rat, but II does and also shows displaceable binding in the heart and lung (Table I). This compound appears to be useful for studying the change in concentration of β-adrenoceptors in both the heart and lung.

Very little uptake in the midbrain is observed so that this interesting location of α- and β-adrenoceptors cannot be studied with these agents (Table I). (−)-[^{3}H]I, on the other hand, shows not only high displaceable binding in the heart but also in the striatum (9). There is, therefore, an opportunity to study the change in m-AChR in these tissues if an appropriate gamma-emitting analogue of I can be prepared.

Proof of m-AChR Binding—The binding of (−)-[^{3}H]I to m-AChR in the heart and brain *in vitro* has been well documented. The burden of proof for m-AChR binding is based on the pharmacological profile whereby various agonists and antagonists are used in the *in vitro* assay, and the relative binding affinities are compared with physiological responses (10–13). We have added to this another test of binding to the m-AChR: stereospecificity. *In vitro*, the *R* and *S* isomers of I were shown to have affinity constants that differ by a factor of 58 in caudate putamen and 153 in ventricular muscle preparations (Table II). The evidence that (−)-[^{3}H]I is binding to the m-AChR *in vivo* is shown by the difference in competition of (−)-[^{3}H]I by the *R* and *S* isomers of I (Table III). The specific receptor binding relative to the nonreceptor binding can be determined in each case by comparing the concentration of (−)-[^{3}H]I in the presence and absence of an excess of competing nonradioactive ligand. Again the competition appeared to be stereoselective, with the more active isomer causing the greater displacement. We therefore conclude that we are studying binding to the m-AChR both *in vitro* and *in vivo*.

[a] Calculated from data in Refs. 3 and 11. The RBI is the affinity constant of each compound relative to that of (±)-I as determined by *in vitro* assay where (±)-I is 100.

Competitive Binding of Muscarinic Antagonist—Fifty nmole of each halogen analogue of I was coinjected with (−)-[^{3}H]I to determine the distribution of these nonradioactive derivatives indirectly. In the heart and midbrain the fluoro analogues are the most potent, followed by the bromo analogues, and finally the iodo analogues (Table III).

We also prepared a number of alkyl derivatives that contain a cyclohexyl, a cyclopentyl, or an *n*-butyl group in place of one aromatic ring (3) (Table IV). The cyclopentyl derivative has a higher affinity than I for the m-AChR in the heart, and this is reflected in the *in vivo* competition study (Fig. 1). This study shows that these structural changes do not adversely affect *in vivo* m-AChR binding and indicates alternate pathways to radiolabeling.

The remaining compounds are drugs that are thought to interact with the m-AChR (Table V). Compound VI is used for the relief of pylorospasm, peptic ulcer, and spastic colon. It is not as effective as I in inhibiting (−)-[^{3}H]I. The *N*-methyl quaternary derivative (V) is more potent than VI in *in vivo* displacement in the heart, but does not displace (−)-[^{3}H]I in the brain because the quaternary salt does not cross the blood–brain barrier. Compound VII is a mild antidepressant and anticholinergic agent; from the *in vivo* displacement studies it is indeed a weak displacer. Likewise VIII, a halogenated derivative of atropine, IX, an anticholinergic and antihistaminic derivative of tropine, and X, a sympathomimetic agent used in cough medicine, all are weak inhibitors of (−)-[^{3}H]I binding in all organs studied.

Correlation of *In Vitro* and *In Vivo* Results—These values for competitive blockade are in general agreement with the affinity constants determined by *in vitro* assay in our laboratory (Table II). The *in vitro* relative binding affinity was correlated with the *in vivo* displacement data using the logit–log plot (Fig. 1) (14). The logit–log plot was chosen because it uses experimental values, *i.e.*, B/B_0 (the amount of (−)-[^{3}H]I bound in the presence of nonradioactive inhibitor divided by the amount bound in the absence of inhibitor) and usually the log of the concentration of inhibitor (h):

$$\text{Logit } B/B_0 = -\log h - \log \frac{K_h}{1 + K_a L_0} \qquad \text{(Eq. 1)}$$

Since in our case the amount of (−)-[^{3}H]I injected (L_0), the affinity (K_a), and h are constant, we have chosen to plot the log of the relative binding index

Table III—Displacement of (−)-[^{3}H]I by I and Halogenated Derivatives at 2 h in the Rat

[a] 50 nmol of the antagonist per rat was coinjected with 3.5 to 5 μCi (−)-[^{3}H]I [15–20 μCi/kg]; six rats per group.

(RBI). The RBI is defined as the affinity of the analogue (K_h) relative to that of (±)-I as determined by *in vitro* assay, where (±)-I is 100 (Table II). Another advantage of the logit plot is the linear relationship between the logit B/B_0 and the log RBI; this linear relationship allows easier statistical analysis.

Although 50 nmol of each nonradioactive compound (h) was coinjected with the (−)-[^{3}H]I, the actual concentration of material at the receptor site is unknown. The uptake of I in the target tissues is rapid (Table VI), and therefore coinjection of the displacer with the radioligand should allow competitive binding without complications due to differing pharmacokinetics (15). This competition has been demonstrated independently by Maziere *et al.* (16) who showed that atropine could increase the washout of ^{11}C-labeled *N*-methyl-I. If irreversible binding occurred or excretion was faster than rebinding, then these results would not be possible (17). If the concentration of inhibitor is similar, the various compounds should compete with (−)-[^{3}H]I in relation to their affinities for the m-AChR provided that receptor binding is the dominant factor controlling the *in vivo* distribution.

The linear correlation equation for the heart is logit $y = 1.28 - 0.777$ ln RBI ($r^2 = 0.70$) and for the midbrain, logit $y = 3.54 - 0.679$ ln RBI ($r^2 = 0.60$), where logit y is ln $[(B/B_0)/(1 - B/B_0)]$. The correlations are reasonably good

Table VI—Pharmacokinetics of (−)-[^{3}H]I [a]

[a] Six rats per group.

considering the assumptions of uniform pharmacokinetics. We suggest that these results, therefore, imply the validity of these assumptions. The *p*-iodo derivative is not as potent as it ought to be based on the correlation in the midbrain (not shown in Fig. 1B, $B/B_0 = 1.07$). This suggests that iodinated I is not as available as the other derivatives for receptor binding in the brain. In general, all iodinated and brominated derivatives lie above the correlation line, indicating that they are not as readily transported to the receptor. However, the high correlation in both the heart and brain indicate that the major factor controlling the *in vivo* distribution in the target organs is the affinity for the m-AChR.

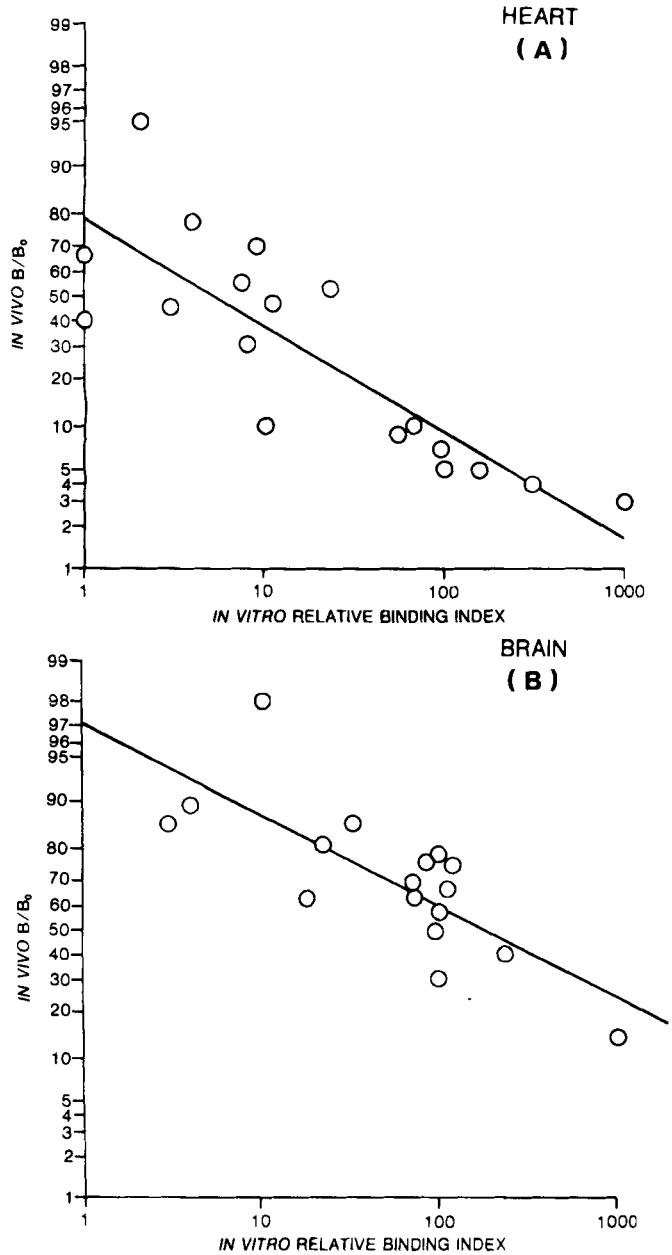

Figure 1—*Plot of logit* B/B_0 *calculated from the ratio of the percent of dose/g bound in the heart (A) and brain (B) in the presence of 50 nmol of nonradioactive analogue per animal to the percent of dose/g bound in the absence of the analogue* versus *the relative bonding index (RBI) determined by* in vitro *assay.*

Relative Displacement in the Heart and Brain—At the same concentration of nonradioactive I, more (−)-[^{3}H]I binding is inhibited in the heart than in the striatum. This could be due to either a higher concentration of m-AChR in the midbrain compared with the heart or to a decreased concentration of nonradioactive compound in the midbrain compared with the heart. From the pharmacokinetic data in Table VI, it is clear that a higher concentration (percent of dose/g) of I is obtained in the heart than in the midbrain by a factor of ≥10 despite the fact that the receptor concentration is considered greater in the striatum (12). Since amines such as I are only transported across the blood–brain barrier as the uncharged species, the differences in uptake between the heart and midbrain could be expected.

The heart-to-blood ratios for (−)-[^{3}H]I (Table VI) are significantly higher than those published for (±)-[^{3}H]I (6, 7). This shows the importance of using the highest affinity stereoisomer of the receptor ligand.

Relative Competition in the Midbrain and Cerebellum—The effect of a difference in m-AChR concentration can best be investigated by comparing the uptake of (−)-[^{3}H]I in the cerebellum and the midbrain (Table III). At maximum specific activity for (−)-[^{3}H]I (33 Ci/mmol), the uptake in the midbrain (MB) and cerebellum (C) is 0.67 and 0.48% of the dose/g, respectively, for a MB/C ratio of 1.40. As the specific activity is decreased by coinjection of I, the percent of dose/g is decreased more rapidly in the cerebellum than in the midbrain. This has the effect of producing higher MB/C ratios as the specific activity is decreased. Finally, with coinjection of 500 nmol of I the ratio is again reduced to 1.2. This can be explained by the cubic equation describing displacement (18):

$$R^2 + R(1 + K^*p^* - K^*q) - K^*q + \frac{hK_h(R+1)R}{(K_h/K^*)R + 1} = 0 \quad \text{(Eq. 2)}$$

where R is the bound/free ratio, K^* is the equilibrium affinity constant of p^*, p^* is the total concentration of radioligand, K_h is the equilibrium affinity constant of h, h is the total concentration of displacer, and q is the total concentration of receptor, provided that the midbrain contains more m-ACh receptor than the cerebellum as the *in vitro* data indicate (12). Examples of the effect of the change in conditions on the bound/free ratio are given in Table VII. It is interesting to note that Yamamura *et al.* (10) using 15 nmol of (±)-[^{3}H]I at 5 Ci/mmol suggested that the MB/C ratio of tritium was indicative of the receptor concentration, but it appears to be fortuitous that the MB/C ratio of 6 approximated the receptor concentration in their experiments. The relative displacement from the two organs appears to be a better explanation than distribution based on receptor concentration. The 2-h distribution of (−)-[^{3}H]I appears to be unrelated to receptor concentration at high specific activity of (−)-[^{3}H]I.

Distribution of Radioiodinated 3-Quinuclidinyl *p*-Iodobenzilate (XVI)—The distribution of XVI labeled with iodine-125 was studied to determine the correlation between the *in vivo* competition study and radiolabeled distribution studies (Table VIII). Four distribution studies at slightly different specific activities show that XVI does give reasonable heart-to-brain (H/B) ratios, but high lung concentration is also evident. The radioactivity is inhibited in the heart and striatum by 50 nmol of I, indicating that XVI is binding to receptor at least in part in these organs. The specific activities were determined by comparing (−)-[^{3}H]I and [^{125}I]XVI binding curves. Setting the receptor concentration equal for both curves permits the calculation of the specific activity of [^{125}I]XVI (19). Another method (20, 21) of adding nonradioactive XII (p) to [^{125}I]XII (p^*) was not sensitive to changes in the specific activity. It is only useful for low specific activity radioligands when the concentration of p and p^* are similar at receptor saturation.

Table VII—Effect of Receptor, Radioligand, and Inhibitor Concentrations on the Bound to Free Drug Ratio (B/F)

	Effect of Concentration on Calculated B/F[a]							
p^*	1.4 nM	1.4 pM	1.4 pM	1.4 nM	1.4 nM	1.4 pM	1.4 pM	1.4 nM
h	25 nM	25 nM	2.5 nM	2.5 nM	25 nM	25 nM	2.5 nM	2.5 nM
q	10 nM	10 nM	10 nM	10 nM	100 nM	100 nM	100 nM	100 nM
B/F								
Calculated	≤1	≤1	96	79	921	938	121	1201
Maximum[b]	125	125	125	125	1250	1250	1250	1250

[a] Calculated from the Cubic Equation (18) using $K^* = 12.5 \times 10^9 M^{-1}$, $K_h = 12.5 \times 10^9 M^{-1}$ for I displacing [^{3}H]I at a typical concentration of p^* (1.4 pM for iodine-125 and 1.4 nM for tritium, h, and q). [b] Calculated from $B/F = K^*q$ (5).

[a] Mixture of four diastereomers. [b] 50 nmol of I per animal coinjected with [^{125}I]XVI; six rats per group.

The higher lipophilicity of XVI when compared with (−)-[^{3}H]I causes higher lung concentration and greater nonreceptor binding to tissue. This may be the cause of the lower displacing power of the nonradioactive compound in the brain. It is also of interest that XVI gives a MB/C ratio of ≥4 at high specific activity. Although it appears that XVI is distributed according to receptor concentration in the brain, recent studies suggest that the ratio is the result of more rapid washout from the cerebellum (9). Using ^{123}I-labeled XVI we were able to visualize the heart and cerebrum of the dog (22). Just as increased uptake in the receptor-containing organs was observed when we used (−)-[^{3}H]I instead of (±)-[^{3}H]I, we also expect in the case of XVI (a mixture of four disastereomers) that the percent of the dose in the receptor-containing organ will increase when the highest affinity isomer is used.

CONCLUSIONS

The *in vivo* displacement experiments show that the relative uptake is correlated with the affinity constant of all derivatives except the *p*-iodo derivative in the brain. The *m*-fluoro derivative is more potent than the *p*-fluoro derivative *in vitro* and *in vivo*. Both bromo derivatives are equally weak receptor binders *in vitro* and *in vivo*. Because of its increased concentration in nontarget organs such as the lung, the *p*-iodo derivative does not inhibit (−)-[^{3}H]I from the midbrain to the same extent as derivatives with comparable m-AChR affinities. Nevertheless, ^{125}I-labeled XVI is taken up by the m-AChR in the heart and brain, although to a lesser extent than (−)-[^{3}H]I. Images of the dog heart and midbrain have been obtained using ^{123}I-labeled XVI (22).

It appears that radioiodinated derivatives are now available for the imaging of β-adrenoceptors in the heart and lung (II) and for the imaging of m-AChR in the heart and brain (XVI). With these agents, changes in receptor concentration as a function of disease may be evaluated *in vivo* (23).

Percutaneous Absorption of Alkanoic Acids I: A Study of Operational Conditions

ZVI LIRON and SASSON COHEN ˣ

Received December 27, 1982, from the *Department of Physiology and Pharmacology, Tel Aviv University, Sackler School of Medicine and Institute for Biological Research, Ness Ziona, Israel.* Accepted for publication October 11, 1983.

Abstract □ The rate of penetration of propionic and butyric acids through excised porcine skin was determined *in vitro* in specific apparatus allowing optimal control of operational conditions. In one technique, the rate was followed by continuous pH-stat titration of acid appearing in the perfusate, in another, by periodic monitoring of [^{14}C]propionic acid in the perfusate. With the assumption that Fick's equation applies to the process of penetration, it was found that the permeability coefficient, K_p, increases with increasing mass of neat penetrant applied per unit area to the donor side, increases with increasing concentration of penetrant in *n*-heptane as vehicle, increases with increasing temperature, E_a = 11.4 kcal/mol, and decreases with decreasing perfusion rate of the acceptor side when this rate is smaller than 60 mL/h.

Keyphrases □ Absorption, percutaneous—alkanoic acids *in vitro*, porcine skin, permeability coefficients, operational conditions □ Alkanoic acids—percutaneous absorption *in vitro*, porcine skin, permeability coefficients, operational conditions □ Permeability coefficients—alkanoic acids through porcine skin, *in vitro* percutaneous absorption, operational conditions

The process of transdermal drug absorption is a subject of current interest in the areas of pharmaceutics, applied pharmacology, and toxicology. For passage through the skin, the penetrating molecule must move first through the stratum corneum, then into the viable epidermis, the papillary dermis, and the capillary walls into the bloodstream. Scheuplein and Blank (1) analyzed the diffusional resistance of the different skin layers, and it was shown clearly that the stratum corneum is overwhelmingly dominant.

This and the passive nature of the stratum corneum enabled application of Fick's equation to the transport process across the skin. A passive system has two main characteristics: (*a*) a delay period following contact of the penetrant with the surface, during which time the membrane itself becomes charged with the penetrant and (*b*) flow across the bulk of the membrane barrier at a steady rate, which lasts as long as the penetrant remains in adequate supply on one side and is being removed from the other. The steady-state flux of penetration, J_s, is given by:

$$J_s = \frac{K_m D(C_I - C_{II})}{X} = K_p \Delta C_s \qquad \text{(Eq. 1)}$$

where $K_p = K_m D/X$. K_p is the permeability coefficient, D is the diffusion coefficient, K_m is the membrane–solution partition coefficient, and X is the thickness of the membrane. ΔC_s expresses the concentration difference under steady-state conditions between the two phases at either side of the membrane. The permeability coefficient, K_p, is physically equivalent to the solute permeability coefficient at zero-volume flow, ω, as shown by Kedem and Katchalsky (2); the relationship is given by $K_p = RT\omega$. It was shown by many workers (1) that Fick's law holds fairly well for skin whether the penetrating substance is a gas, an ion, or a nonelectrolyte.

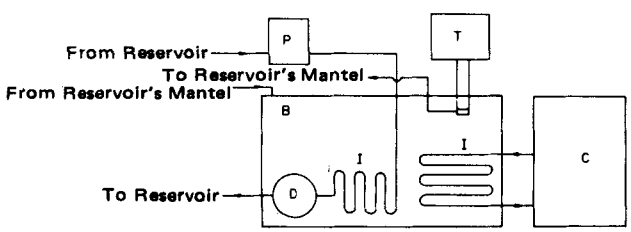

Figure 1—*Schematic representation of the pH-stat assembly. Key: (B) bath; (C) cooler; (D) diffusion cell; (I) immersion coil; (P) peristaltic pump; (T) thermostat.*

For optimal control of operational conditions, the penetration process is usually studied *in vitro*. Excised skin is used in diffusion cells in which a barrier of animal or human skin is interposed between two compartments, and the passage of compounds is measured from the epidermal surface on one side into a bathing fluid on the other side.

The present work is a pilot study of operational factors that affect the percutaneous absorption of propionic and butyric acids through excised porcine skin *in vitro*. Its main objective has been the generation of adequate knowledge to allow a systematic investigation of the permeation process by these and other members of this class of compounds. Concern with the alkanoic acids stems from an interest in the applicability of regular solution theory (3) to pharmaceutical sciences in general and to percutaneous drug application in particular. Recent accurate data (4) on the solubility parameter and molal volumes of a wide range of alkanoic acids suggested their use as candidates of choice in such a study, in preference to other potential permeating species, such as the series of alcohols used by Scheuplein (5). Compliance of the alkanoic acids with this theory is being presented in the second paper of this series (6).

The methodology used in this study is a modified extension of procedures that had been adequately described by earlier workers in this field, notably Ainsworth (7), Blank (8, 9), Wurster and Kramer (10), Scheuplein (5), Polano and Ponec

Bartsch of Boehringer Mannheim for carazolol; and Dr. D. J. Marshall of Ayerst for propranolol. We would also like to thank G. Rosen for preparing the manuscript.

Percutaneous Absorption of Alkanoic Acids I: A Study of Operational Conditions

ZVI LIRON and SASSON COHEN ˣ

Received December 27, 1982, from the *Department of Physiology and Pharmacology, Tel Aviv University, Sackler School of Medicine and Institute for Biological Research, Ness Ziona, Israel.* Accepted for publication October 11, 1983.

Abstract □ The rate of penetration of propionic and butyric acids through excised porcine skin was determined *in vitro* in specific apparatus allowing optimal control of operational conditions. In one technique, the rate was followed by continuous pH-stat titration of acid appearing in the perfusate, in another, by periodic monitoring of [^{14}C]propionic acid in the perfusate. With the assumption that Fick's equation applies to the process of penetration, it was found that the permeability coefficient, K_p, increases with increasing mass of neat penetrant applied per unit area to the donor side, increases with increasing concentration of penetrant in *n*-heptane as vehicle, increases with increasing temperature, E_a = 11.4 kcal/mol, and decreases with decreasing perfusion rate of the acceptor side when this rate is smaller than 60 mL/h.

Keyphrases □ Absorption, percutaneous—alkanoic acids *in vitro*, porcine skin, permeability coefficients, operational conditions □ Alkanoic acids—percutaneous absorption *in vitro*, porcine skin, permeability coefficients, operational conditions □ Permeability coefficients—alkanoic acids through porcine skin, *in vitro* percutaneous absorption, operational conditions

The process of transdermal drug absorption is a subject of current interest in the areas of pharmaceutics, applied pharmacology, and toxicology. For passage through the skin, the penetrating molecule must move first through the stratum corneum, then into the viable epidermis, the papillary dermis, and the capillary walls into the bloodstream. Scheuplein and Blank (1) analyzed the diffusional resistance of the different skin layers, and it was shown clearly that the stratum corneum is overwhelmingly dominant.

This and the passive nature of the stratum corneum enabled application of Fick's equation to the transport process across the skin. A passive system has two main characteristics: (*a*) a delay period following contact of the penetrant with the surface, during which time the membrane itself becomes charged with the penetrant and (*b*) flow across the bulk of the membrane barrier at a steady rate, which lasts as long as the penetrant remains in adequate supply on one side and is being removed from the other. The steady-state flux of penetration, J_s, is given by:

$$J_s = \frac{K_m D(C_I - C_{II})}{X} = K_p \Delta C_s \qquad \text{(Eq. 1)}$$

where $K_p = K_m D/X$. K_p is the permeability coefficient, D is the diffusion coefficient, K_m is the membrane–solution partition coefficient, and X is the thickness of the membrane. ΔC_s expresses the concentration difference under steady-state conditions between the two phases at either side of the membrane. The permeability coefficient, K_p, is physically equivalent to the solute permeability coefficient at zero-volume flow, ω, as shown by Kedem and Katchalsky (2); the relationship is given by $K_p = RT\omega$. It was shown by many workers (1) that Fick's law holds fairly well for skin whether the penetrating substance is a gas, an ion, or a nonelectrolyte.

(11), and others (12). The main improvements over earlier procedures consisted in the design of the diffusion cells, which allowed much flexibility in the choice of experimental conditions, and in the automation of the perfusate sampling procedure, which was based on either of two independent methods: pH-stat titration of acid or the monitoring of isotope-labeled acid in the perfusate. Occasionally, both sampling procedures were used jointly, with remarkable agreement.

EXPERIMENTAL

Apparatus—Two procedures were used in the skin penetration studies. In one the penetration process could be followed directly by recording the titration of the acid appearing in the perfusate over a given period. This procedure however, was limited to relatively high concentrations of penetrants and to one diffusion cell at a time. In the automatic sampling system, using a radioisotope-labeled penetrant, one could use four diffusion cells in parallel and much lower concentrations of penetrant. The diffusion cells used in either procedure were almost identical, differing only in some external features.

pH-Stat System—This consisted of the diffusion cell assembly and the analyzing or titration assembly. The diffusion cell assembly is schematically shown in Fig. 1. The diffusion cell (D) was immersed in a thermostatic bath (B). The perfusate was made to flow in a closed circuit, being continuously sucked from the reservoir by a peristaltic pump (P), through an immersion coil (I), into the lower entrance of the diffusion cell, and through the exit of the diffusion cell, back to the reservoir. The flow rate in all these experiments

was 1 mL/min. The temperature of the bath was controlled by a thermostat (T), equipped with a pump which was connected to the heating mantle of the reservoir. In cases where the room temperature was higher than the working temperature, a cooler (C) was used. The temperature in the bath was measured with a Brand thermometer, 0.1°C scale division.

The titration assembly was used in its pH-stat mode of operation. At that mode, the apparatus recorded the supply of the corresponding base required to keep the reservoir at a constant pH as a function of time. The equipment[1] included the following parts: recorder, pH meter, titrator, autoburet, stirring motor, and a reservoir equipped with a heating mantle and a combined microelectrode[2]. Nitrogen was bubbled into the reservoir to minimize access to atmospheric carbon dioxide.

The diffusion cell was of polytef and consisted of two parts assembled together to hold the skin sample. The lower part had a cylindrical hollow 1-cm² cross-circular area and 1-mL volume. Two stainless steel pipes of 1 mm i.d. entered the hollow, one at the bottom and one at the upper edge of the cylinder. Buffered solution flowing from the reservoir entered the diffusion cell through the lower pipe and left the cell, now with penetrant, through the upper pipe and back to the reservoir for titration. The skin to be tested was mounted on needle tips so that it constituted a tight barrier between the two compartments of the diffusion cell. The upper part of the diffusion cell contained suitable holes through which the needles passed, leading metal pins for convenience and accurate closing of the cell, and three screws for tightening the two parts of the cell to each other. The upper part was equipped also with a screw cap and a neoprene O-ring which enabled water-tight closure and immersion of the whole diffusion cell in the thermostatic bath.

Automatic Radioisotope Sampling System—A diagram of this system is shown in Fig. 2. The perfusate was contained in the reservoir (R) at a constant temperature maintained by the thermostat (T). When working at lower temperatures, the cooler (C) was used. The perfusate was sucked in parallel through four channels by the peristaltic pump and it was delivered into the lower entrance of each of the four diffusion cells. The perfusate containing the penetrant left each cell through the upper exit tube into the proper collecting vial. When working at high perfusate flow rates, the effluent from each diffusion cell was divided by a T-valve, electro-pneumatic actuated in a predetermined time cycle so that the proper amounts were in the vials and the rest was discarded. The 4-mL collecting vials were held in a special tray, in four rows of 24 vials each. The tray was shifted to each of its 24 positions, according to a predetermined time cycle. The tray shifting was activated by an electro-pneumatic system composed of a solenoid valve, a feeder, and two synchronic motors of 1 and 2 rph. When the tray reached its last position the whole system, including the peristaltic pump, was automatically switched off.

This experimental system was planned to work also at low perfusate flow rates and it became important to shorten, as much as possible, the distance from the exit of the diffusion cell to the sampling vial. This requirement could not be fulfilled when the cells had to be dipped into a thermostated bath. Therefore, it was decided to use diffusion cells of similar construction and design, but also equipped with a jacket for temperature control. To achieve good heat transfer, and yet work with noninteracting materials, the diffusion cells were made of stainless steel. In principle, each of the two parts of the diffusion cell could be temperature controlled independently, simulating the condition of the skin *in vivo*. In experiments in which the whole cell was kept at a single temperature, the jackets of the two parts of the diffusion cell were connected in series. The thermostatic fluid flowing through two diffusion cells was driven by the pump of the thermostat (T). The two other cells got their thermostatic fluid through the pump (M). The four diffusion cells were placed on a special tray, over and near the sampling vials tray.

Skin Samples—Intact porcine skin was used in all the experiments. Skin was clipped from the backs of male minipigs (Kibbutz Lahav strain) weighing

~15 kg each. The skin was fastened to a hard board, enclosed in a plastic bag, and stored at ~−20°C until used. In preliminary tests, it was found that storage under these conditions for 2 months did not affect the penetration rate of propionic acid through the skin. The fat was carefully removed with a scalpel just before the skin sample was fastened in the diffusion cell. All samples of new skin were standardized before use by running a penetration experiment with 1 M propionic acid in *n*-heptane and by measuring the thickness of the stratum corneum, using the frozen-section technique (13).

Materials—All the compounds used in this study were of the highest analytical grade available commercially. The specific activity of [^{14}C]propionic acid was about 55 mCi/mmol; as a marker, it was diluted with "cold" propionic acid, to suitable working concentrations. The scintillation medium was prepared by mixing the following reagents, all scintillation grade: xylene (1 L), triton X-100 (0.5 L), 2,5-diphenyloxazole (6 g), and 1,4-bis-2-(4-methyl-5-phenyloxazolyl)benzene (0.15 g). The perfusate medium was phosphate buffer, pH 7.4, composed of 140 mM NaCl, 0.4 mM KH_2PO_4, and 2 mM K_2HPO_4.

Operating Procedure—At the beginning of each experiment the titration assembly was calibrated with two buffer solutions, pH 7.0 and 4.0. A 25.0-mL volume of the corresponding phosphate buffer solution was introduced into the reservoir, and *via* the peristaltic pump the buffer solution flowed into the open diffusion cell and created a dome over the cylindrical hollow. The skin was mounted on the needles, pressed by the upper part of the diffusion cell, and fastened by screws into the proper position. In mounting the skin into the diffusion cell, care was taken to exclude air bubbles. The diffusion cell was then closed by its screw cap, dipped into the thermostatic bath, and preconditioned for 2 h to wash away the intrinsic acidity of the skin. This point, when reached, could be inspected easily from the trace of the recorder. In general, during the last half-hour of the preconditioning time no acid entered the perfusate.

After the preconditioning period, the diffusion cell was taken out of the bath, the cap was removed, and the proper amount of penetrant was applied to the skin. In all experiments except those in which the influence of the neat acid was studied, the penetrating medium was applied in a volume of 0.3 mL. The cap was replaced and the diffusion cell was returned to the thermostatic bath. As the penetrating acid entered the titration reservoir, it was automatically measured by titration with base. This allowed for direct recording of the penetration curve. In experiments where titration and radioactive analysis were simultaneously performed as a cross-check, 100-μL samples were taken from the reservoir at half-hour intervals. A 3-mL volume of scintillation medium was added, and the samples were counted in a scintillation counter. Triplicate runs were made for a given set of penetration conditions.

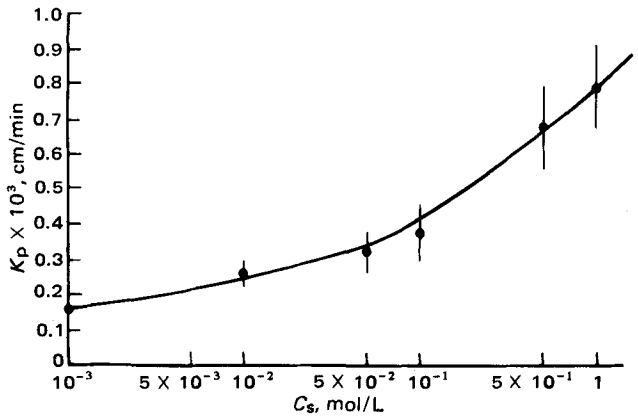

Figure 4—*Penetration of propionic acid from* n*-heptane solution through porcine skin at 25°C and at a perfusate flow rate of 3 mL/h by the radioisotope and pH-stat procedures, showing concentration effect. Points and bars are mean and* SE *from 3–5 runs.*

In the automatic sampling system the main procedure was essentially similar. The four diffusion cells were connected to the perfusate reservoir and the thermostatic fluid *via* flexible tygon tubing. The skin samples were mounted into the diffusion cell, the system was equilibrated for 2 h, and the penetrant was added to each of the diffusion cells. At the end of the penetration process the sampling vials were removed, and their contents were mixed with scintillation medium and counted. A 10-mL aliquot of scintillation liquid was added to 3 mL of sample; these proportions were found to give reproducible counting efficiencies. The first two samples were used as blanks for background counting immediately after the preconditioning period and before application of the penetrant.

The two techniques gave almost identical penetration curves and were complementary to each other. The titration assembly offered the advantage of direct recording of a continuous breakthrough curve and the convenience of following the penetration process in "real time." The system was simple to operate, but required use of relatively high donor phase concentrations.

In the automatic sampling system, use of radiolabeled penetrant increased the sensitivity of detection and estimation, making possible operation at low concentrations of the penetrant in the donor medium. But in this case, penetration analysis was not a continuous process as in the titration method. Samples of the perfusate were taken at distinct time intervals for analysis, the cumulative penetrating mass was calculated, and the penetration curve was drawn accordingly.

RESULTS AND DISCUSSION

Applied Mass Effect—The influence of the applied mass of the neat acid on the penetration characteristics was tested with butyric acid at 37°C. Experiments were done with 10, 20, 40, and 80 μL applied to the upper part of the skin; the corresponding penetration curves are shown in Fig. 3. The rates of penetration at steady state (J_s) and the corresponding permeability coefficients (K_p) are given in Table I; the values of K_p were calculated from Eq. 1 setting ΔC_s equal to the reciprocal molal volume of the neat acid. Breakthrough time was defined as the period taken for the first detectable penetrating molecules to appear in the perfusate.

With penetrating agents that do not interact with the skin membrane, it would be reasonable to assume that as long as the exposed skin area in the diffusion cell was covered with penetrant, the amount applied would not change the penetration curve. However, if the penetration rate depended on the amount of penetrant, as was indeed observed, then it could be reasoned that there occurred an interaction between the stratum corneum and the penetrant. From Fig. 3 it can be clearly seen that, in the early phase of penetration, the breakthrough time was similar for all amounts of acid applied. But as the process of penetration advanced further, the rate of penetration appeared to increase with the amount applied to the donor side. It is conceivable that butyric acid eventually affected the integrity of the stratum corneum barrier, which became less resistant as a barrier to the flow of the penetrant. The present finding agrees with those of Allenby *et al.* (14) who measured skin impedance changes after applying neat acids. Changes in impedance were found for neat acids, but almost no change was found for formic acid aqueous solutions (<80%).

Further insight into the effect of neat acid may be sought from a careful

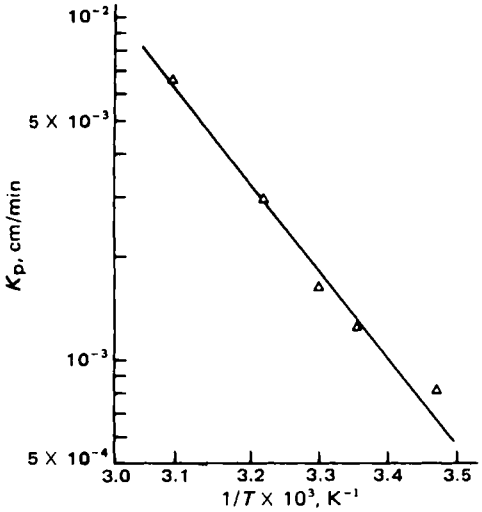

Figure 6—*Arrhenius plot of the dependence on temperature of the penetration of propionic acid (1 M n-heptane solution) through porcine skin: log* $K_p = 6.69 - 2.87 \times 10^3/T$ *(r = 0.99).*

consideration of the penetration curves (Fig. 3). There is first an exponential transient region, followed by a steady-state region, then an exponential decay region. The relative length of time for each region appears to depend on the amount of applied acid.

From the recovered fraction of the amount applied at the end of the steady-state region, it is conceivable that the eventual decline in penetration rate was due to the combined effect of depletion and a water back-diffusion process through which the acid on the donor side had become diluted to an extent that decreased its penetration. Such a process could also explain the apparent dependence of the penetration curves on the amount of compound applied, because it is expected to have a greater effect for smaller amounts of applied penetrant.

Concentration Effect—The effect of concentration was studied in the automatic sampling system using labeled propionic acid. The experiments were done at 25°C and at a perfusate flow rate of 3 mL/h; *n*-heptane solutions in the range of 0.001–1 M were used. Typical penetration curves were obtained, and the permeability coefficients, K_p, were calculated and plotted as a function of the penetrant concentration (Fig. 4). For convenience, the concentrations were drawn on a log scale. It can be seen that there is a smooth increase in the permeability coefficient as the concentration is increased. The increase in the permeability coefficient over a concentration range of three orders of magnitude is ~4.5.

The effect of concentration has been reported in many papers, but not much fundamental work has been done. It is generally taken as obvious that as the concentration increases, the flux also increases. Scheuplein and Blank (1) measured the penetration of butanol from aqueous solutions, in a concentration range of 0.01–0.3 M, and their results are consistant with the present findings; namely, there was a slight but continuous increase in the permeability coefficient as the penetrant concentration in the donor phase increased. The rate of change in K_p was larger for the higher concentrations. This change could be ascribed to altered barrier function as presumed to occur with large amounts of applied acid.

Temperature Effect—The effect of temperature on skin penetrations was studied for 1 M propionic acid in *n*-heptane. The experiments were carried out at 15°C, 25°C, 30°C, 37°C, and 50°C. The corresponding permeability coefficients are listed in Table II, and the penetration curves at these temperatures are shown in Fig. 5. A plot of log permeability coefficients against the absolute temperature reciprocal (Fig. 6) gave a straight line, the slope of which was used to derive the corresponding Arrhenius activation energy. The activation energy for propionic acid was found to be 11.4 kcal/mol. For comparison, Scheuplein and Blank (1) found values of 16.5 and 10 kcal/mol for the polar and nonpolar alcohols, respectively. It should be recalled that

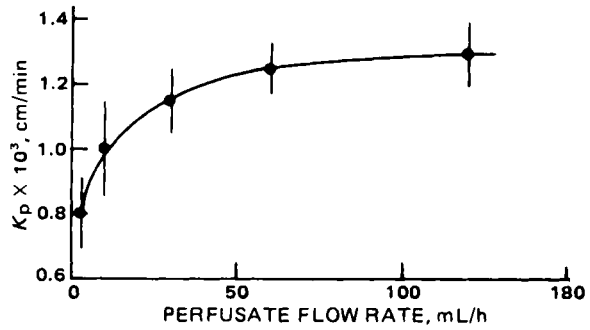

Figure 7—*Penetration of propionic acid (1 M n-heptane solutions) through porcine skin at 25°C by the pH-stat procedure, showing the effect of perfusion flow rate. Points and bars represent the mean and* SE *of 3–5 runs.*

they used a single membrane for the whole range of temperatures studied, in a procedure that took as long as 2 weeks to perform. In the present procedure, use was made of new skin samples for each experiment. The fit of results to a straight line (Fig. 6) is very good ($r = 0.99$).

This relationship, while useful, does not allow direct extrapolation to conditions that occur *in vivo*, where there is a temperature gradient across the skin. The sharp dependence of K_p on temperature implies a corresponding dependence of either K_m or D or both (Eq. 1) on the same variable. A temperature rise (or drop) across the skin may have a differential effect on each of the partitioning and diffusion steps in the overall permeation process.

Perfusate Flow Rate Effect—The perfusate flow rate is an operational factor which must be considered, especially if one intends to extrapolate from *in vitro* to *in vivo* conditions and also for a proper comparison of experimental data obtained from different sources. In a transport process where the diffusion through the membrane is the rate-limiting factor, it would be reasonable to assume that the penetration profile would not be affected by a change in the perfusate flow rate. But this would be true only for a certain range; the situation would change when the perfusate flow rate approaches zero, especially for the fast penetrants. In view of this, the effect of perfusate flow rate was considered in more detail. Accordingly, a study was made of the effect of the perfusate flow rate in the range of 3–120 mL/h, on the penetration rate of propionic acid (1 M in *n*-heptane). The results are shown in Fig. 7. As expected, the effect was pronounced at the lower perfusate flow rates, but at a flow rate of ~60 mL/h there was no further effect on permeability. Similar results were obtained by Tregear (15) for the penetration of tri-*n*-butyl phosphate through perfused porcine skin.

Percutaneous Absorption of Alkanoic Acids II: Application of Regular Solution Theory

ZVI LIRON and SASSON COHEN ˣ

Received December 27, 1982, from the *Department of Physiology and Pharmacology, Tel Aviv University, Sackler School of Medicine and Institute for Biological Research, Ness Ziona, Israel.* Accepted for publication February 10, 1983.

Abstract □ The permeability coefficient, K_p, of pure unbranched alkanoic acids (C_2-C_7) applied to isolated porcine skin, reached a maximum in the solubility parameter (δ_2) range of 9.7–10 $cal^{1/2}/cm^{3/2}$. When these and other penetrants were delivered from a solvent vehicle, the following linear relationships could be demonstrated: (*a*) between log K_p and the molar attraction constant of the penetrant [$\delta_2 v_2$ or $(-Ev)^{1/2}$] for six unbranched and six branched acids delivered from 1 M solution in *n*-heptane; (*b*) between K_p and the partial molal volume difference in *n*-heptane ($\bar{v}_2 - v_2^0$) for the unbranched acids; and (*c*) between K_p and ($\bar{v}_2 - v_2^0$) for propionic acid delivered from 1 M solutions in nine solvents having δ_1 values in the range 7.4–12.7 $cal^{1/2}/cm^{3/2}$. Drug penetrability in a given series could be assessed from knowledge of the excess free energy of the penetrant in the delivery system used.

Keyphrases □ Absorption, percutaneous—alkanoic acids *in vitro*, porcine skin, permeability coefficients, application of regular solution theory □ Alkanoic acids—percutaneous absorption *in vitro*, porcine skin, permeability coefficients, application of regular solution theory □ Permeability coefficients—alkanoic acids through porcine skin, *in vitro* percutaneous absorption, application of regular solution theory

Percutaneous absorption is determined by two major processes: dissolution and diffusion. The contribution of each of these in the overall process is expressed in Fick's equation in terms of the partition coefficient and the diffusion coefficient (1). Both of these factors are affected by the molecular characteristics of the penetrant, such as solubility, size, and shape.

Solubility is dominant in skin penetration. Its importance was recognized early when it was found that compounds with both lipid and water solubilities penetrate better than substances with either high water or high lipid solubility. This led many workers to seek a correlation between skin penetrability and the partition coefficient of the penetrating compound between two reference solvents, such as ether–water (2), olive oil–water (3), benzene–water (4), and others. Later, it was recognized (3) that such partition coefficients may be misleading, since none represent the true partitioning between the penetrant and the stratum corneum.

The situation is even more complex when a vehicle is used. To ensure penetration from a vehicle, one approach utilizes the differences in thermodynamic activities of the penetrant between the vehicle and membrane phases. Ideally, such vehicles or formulations "push" the drug into the skin without causing detectable injury to the skin membrane. Intuitively, one would choose a vehicle that does not bind the incorporated drug too strongly; *i.e.*, the thermodynamic activity of the active ingredient in the vehicle should be relatively high. On the other hand, the flux is proportional to the drug concentration, and these two opposing factors lead to the conclusion that for each drug an optimal delivery system could be designed through a judicious combination of vehicle and concentration. Poulsen (5) analyzed vehicle effects for some theoretical cases in which one vehicle system, composed of two components, was used. The change in flux, related to the change in the partition coefficient and the drug concentration, was illustrated as a function of the change in the vehicle composition. The use of such an analysis in an experimental system is laborious and difficult to apply to practical problems. Thus, a more straightforward measure of vehicle effect on drug penetrability seems necessary.

Little is known about the effect of molecular size and shape on penetration through skin. An inverse relationship appears to exist between absorption rate and molecular weight (6). Small molecules penetrate more rapidly than large molecules, but within a narrow range of molecular size, there is little correlation between size and penetration rate. It has not been easy to separate the contribution of the size factor in the overall process when there is also a simultaneous change in solubility. For example, in a study of the percutaneous absorption of closely related compounds in human skin, Feldman and Maibach (7) found wide differences in penetration which could not be explained on a strict basis.

The present work deals with the application of regular so-

lution theory (8) to the percutaneous absorption of alkanoic acids as model penetrants. This theory provides for the contribution of both solubility and size in the dissolution process.

THEORETICAL

Solubility and Molal Volume—Fick's equation was originally formulated using penetrant concentrations within the membrane:

$$J_s = \frac{D_m \Delta C_m}{X} \qquad \text{(Eq. 1)}$$

where the subscript m refers to the membrane. In the extreme case where the solubility of the penetrant in the membrane is nil, $\Delta C_m = 0$, and the flux (J_s) must vanish. The concentrations within the membrane can be related to the concentrations in the donor and receptor phases using the partition coefficient term. Fick's law is then expressed in its more familiar form; hence, knowledge of D_m and K_m should allow the prediction of drug penetrability, but these two constants are usually not accessible.

Scheuplein and Blank (3) studied the penetrability of straight-chain alcohols, members of an homologous series. They found that homologues from methanol to octanol had almost the same diffusion coefficient. Therefore, any change in the permeability coefficient could be related directly to the change in the partition coefficient or the solubility of a particular homologue. In view of this, one expects to find for members of an homologous series a correlation between the permeability coefficient K_p and K_m or its equivalent in terms of regular solution. A necessary oversimplification is the consideration of the admittedly complex structure of the skin as an homogenous phase. Such an approach would be justified if the analysis of skin penetration data could be simplified, or at least correlated with parameters predicted from regular solution theory. In this theory, the heat of mixing ΔH^M was given by Hildebrand *et al.* (9) as:

$$\Delta H^M = (X_1 v_1 + X_2 v_2)(\delta_1 - \delta_2)^2 \phi_1 \phi_2 \qquad \text{(Eq. 2)}$$

where X is the mole fraction, ϕ is the volume fraction, v is the molal volume,

3	3.00	−2.52	2.90	0.75
4	1.00	−3.00	1.94	0.89
5	0.25	−3.60	0.84	1.04
6	0.08	−4.10	0.72	1.19
7	0.03	−4.52	0.05	1.35

[a] Determined by the titrimetric procedure using 300 μL of 1 M solutions in *n*-heptane.

and subscripts 1 and 2 relate to the solute and solvent, respectively[1]. The Gibbs free energy change in the mixing process is given by:

$$\Delta F^M = \Delta H^M - T\Delta S^M \qquad \text{(Eq. 3)}$$

The smaller ΔF^M the more compatible the elements being mixed. This means that the best mixing conditions will be achieved when δ_2 approaches δ_1. If we consider the stratum corneum membrane as a solvent having an average solubility parameter δ_1, different molecules will dissolve and penetrate through this medium in accordance with their specific solubility parameter, δ_2.

Davis (10) expressed the relationship between solubility parameter and partition coefficient, and later Srebrenik and Cohen (11) developed a more refined expression that takes into account partial molal volume changes. The partition coefficient was given by:

$$\ln K_m = \frac{-2\delta_1\delta_2}{RT} v_2 + \frac{\delta_1^2}{RT}\bar{v}_{21} - \frac{\bar{v}_{21}}{v_1} - \left(-2\frac{\delta_3\delta_2}{RT} v_2 + \frac{\delta_3^2}{RT}\bar{v}_{23} - \frac{\bar{v}_{23}}{v_3}\right) \qquad \text{(Eq. 4)}$$

where K_m is the partition coefficient, subscript 2 refers to solute which partitions between two phases (subscripts 1 and 3), and $\bar{v}_{21}$ and $\bar{v}_{23}$ are the partial molal volumes of solute 2 in phase 1 and phase 3, respectively. The application of Eq. 4 to skin transport analysis is not straightforward, but nevertheless it could be used with approximation, as will be shown later. A dissolution process is accompanied by a change in the molal volume of the solute. The degree of this change depends on the similarity between the solute-solvent pair; for low solute concentrations it is given by:

$$\frac{\bar{v}_2 - v_2^0}{v_2^0} = \frac{(\delta_1 - \delta_2)^2}{(\partial E/\partial v)_T} \qquad \text{(Eq. 5)}$$

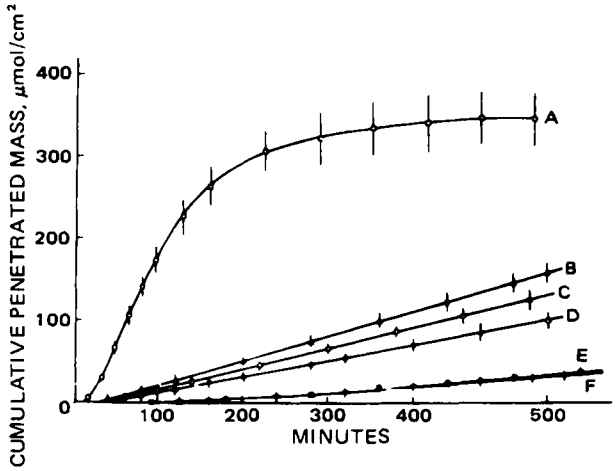

Figure 4—*Penetration of branched alkanoic acids (300 μL of 1 M solutions in* n*-heptane) through porcine skin at 37°C, determined by titrimetry. Key: (A) Cyclopropane carboxylic; (B) 3-methylbutyric; (C) 2-methylbutyric; (D) pivalic; (E) 3,3-dimethylbutyric; (F) 2-ethylbutyric, superimposed on (E).*

[1] For the sake of consistency with previous publications and throughout this article, the subscript 2 refers only to solute or penetrant, subscripts 1 or 3 refer to solvents or biophase.

[a] Determined by the titrimetric procedure using 300 μL of 1 M solutions in *n*-heptane. [b] From Ref. 14.

For solutions obeying regular solution theory, the solute excess free energy is directly proportional to the change in the solute partial molal volume (12):

$$\Delta F_2^{ex} = (\bar{v}_2 - v_2^0)(\partial E/\partial v)_T \qquad \text{(Eq. 6)}$$

The excess free energy of the solute in the donor phase is an important parameter that may be considered as the driving force for the penetration process through the skin membrane. Since the value of the excess free energy is higher, the flux (and hence the permeability coefficient) is increased. In principle, knowledge of δ_2 and v_2^0 of a particular homologue in a given series should allow the prediction of its relative penetrability through a common membrane, in this case the stratum corneum.

EXPERIMENTAL

The experimental system used has been described in detail in the previous paper (1). All skin penetration experiments were done on excised porcine skin maintained at 37.0°C or 25.0°C on either side of the membrane. Pure penetrants were applied to the donor side in a constant mass. Solutions of penetrants in *n*-heptane (1 M) were applied in a constant volume. The total penetrated mass over time was determined either by automatic titration of acid appearing in the perfusate or by scintillation counting of the carbon-14 radioisotope label added to the penetrant (1).

The effect on the skin of the pure solvent as vehicle was studied by simulating penetration experiments in diffusion cells with no penetrant added. The skin was removed after 5 and 20 h, and the condition and thickness of the stratum corneum were examined using the paraffin and frozen-section techniques (13). No significant changes were observed from untreated skin.

Partial molal volumes of penetrants ($\bar{v}_2$) at high dilution in a given solvent were determined by a previously described densitometric procedure (14). All

chemicals and solvents were of the highest analytical grade available commercially.

RESULTS AND DISCUSSION

Pure Straight-Chain Alkanoic Acids—The donor phase consisted of 430 μmol of each tested compound. The acids may be classified into two main groups according to the rate of penetration (Fig. 1; Table I). The faster penetrants were the acetic–butyric acids; the slower ones were hexanoic–octanoic acids; valeric acid had an intermediate penetration rate. The slower penetrants showed a steady penetration rate over the entire experimental period, whereas the more rapid penetrants showed a characteristic curve (1) with a lag phase region, a steady-state region, and a decay region. The latter could be due to the decline in penetrant mass at the donor side or its dilution with water through back-diffusion. Propionic acid, rather than acetic acid, had the highest rate of penetration. A plot of the permeability coefficients of these acids as a function of their solubility parameter (Fig. 2), shows a maximum at $\delta_2 = 9.7 - 10.0$ cal$^{1/2}$/cm$^{3/2}$. This range could be taken to represent the solubility parameter of the stratum corneum, but with the reservation that the lower acids could considerably alter this parameter with increasing applied mass, as observed earlier for butyric acid (1).

Straight and Branched-Chain Alkanoic Acids—*n-Heptane Solution Experiments*—The problem encountered in the use of the pure penetrants could be minimized by studying penetration rates from dilute solutions in a relatively "inert" solvent, in this case *n*-heptane. The penetration of the straight-chain alkanoic acids, delivered from 300 μL of 1 M solutions in this solvent, is shown in Fig. 3. From the penetration curves thus obtained, the permeability coefficients were calculated and tabulated with the corresponding values of the partial molal volume differences, ($\bar{v}_2 - v_2^0$ determined at 25°C) and the values of the square root of the volume–cohesive energy product or $\delta_2 v_2^0$ (Table II). The value ($\bar{v}_2 - v_2^0$) is proportional to excess free energy ΔF_2^{ex} at infinite dilution in *n*-heptane (Eq. 6); $\delta_2 v_2^0$ is the molar attraction constant of the penetrant, irrespective of vehicle used. On theoretical grounds (Eq. 4), there should exist a correlation between K_m (and hence K_p) and each of these parameters. The penetration data of some branched alkanoic acids are given separately (Fig. 4, Table III). Cyclopropane carboxylic acid was the fastest penetrant, whereas the isomeric 3,3-dimethylbutyric and 2-ethylbutyric acids were the slowest, both showing a similar penetration profile.

From Fig. 5, the correlation between log K_p and the number of carbon atoms in the molecule of unbranched acids is very good ($r = 1.00$). A similar result was obtained by Scheuplein and Blank (3) for normal alcohols in aqueous solution.

In view of the linear relationship between the number of carbon atoms in the molecule and log K_p on the one hand, and the number of carbon atoms and the square root of the volume–cohesive energy product $(-Ev)^{1/2}$ or $\delta_2 v_2^0$ (14) on the other, one expects to find a linear relationship between $(-Ev)^{1/2}$ and log K_p. Such a plot is shown in Fig. 6 where K_p had been derived from data at 37°C, but $(-Ev)^{1/2}$ from data at 25°C. The linearity of the plot should not be affected by this difference in temperature since it can be demonstrated (15) that in related compounds with an almost common thermal expansion coefficient:

$$(\delta v)_T = (\delta v)_{T^0} \cdot \text{constant} \qquad \text{(Eq. 7)}$$

Remarkably, the branched-chain homologues follow the same relationship. The fit to a straight line [$\log K_p = -0.16 - 3.26(-Ev)^{1/2}$] is very good ($r =$

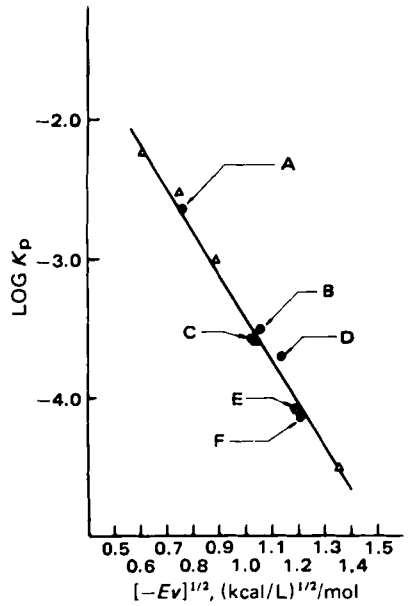

Figure 6—*Penetration of alkanoic acids through porcine skin at 37°C. Permeability coefficient as a function of the square root of the volume cohesive energy product: log* $K_p = -0.16 - 3.26(-Ev)^{1/2}$, (r = 0.99). *See Fig. 4 for key; Δ refers to straight-chain acids.*

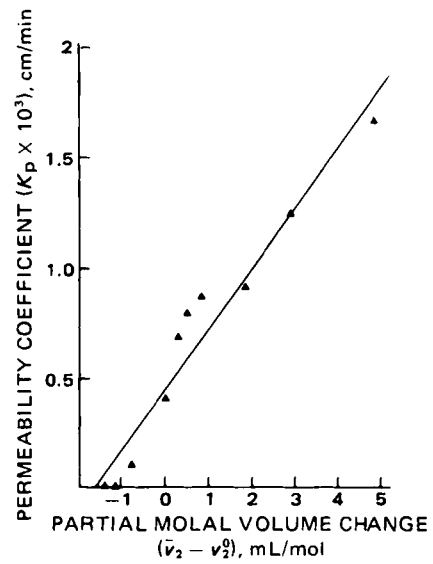

Figure 7—*Penetration of propionic acid from 1 M solutions through porcine skin at 25°C showing vehicle effect.* $K_p = 4.57 \times 10^{-4} + 2.75 \times 10^{-4}(\bar{v}_2 - v_2^0)$.

0.99). This relationship is important because it enables one to evaluate the permeability coefficient of an untested acid from its solubility parameter (δ_2) and molal volume (v_2^0). In this context, there is some analogy between the present findings and the demonstration by Ostrenga (16) of the relationship between the molal attraction constant and the relative degree of drug-receptor interaction for several different groups of structurally related compounds.

From Fig. 6 and Eq. 4 one can derive the following empirical relationship (see the *Appendix*):

$$\ln K_p \simeq \frac{-2(\delta_1 - \delta_3)}{RT}\delta_2 v_2^0 + b \qquad \text{(Eq. 8)}$$

where $\delta_1 = \delta_m$, the solubility parameter of the stratum corneum; $\delta_3 = 7.4$, the solubility parameter of *n*-heptane; and *b* (constant) = −0.16. From the slope (−3.26), temperature (310 K), and any given value of $\delta_2 v_2^0$, it can be shown that $\delta_1 \simeq 9.7$. This value is compatible with the rapid penetration rates found for pure propionic and butyric acids (Figs. 1 and 2), which have comparable δ_2 values.

In an alternative approach, a plot of K_p at 37°C as a function of the net molal expansion ($\bar{v}_2 - v_2^0$), at infinite dilution in *n*-heptane at 25°C (Table II) gave a straight line (not shown) with an acceptable correlation coefficient ($r = 0.97$) for this type of experiment. This means that permeability could be related to excess free energy (Eq. 6). As this last function becomes larger for a given solvent-solute system the permeability coefficient of the penetrant through the skin should increase.

Vehicle Effect—The vehicle effect was studied for 1 M propionic acid solutions in the solvents listed in Table IV. The penetration experiments with *n*-heptane through bromonaphthalene were done in the titration assembly system, whereas those with nitroethane through nitromethane were done in the automatic radioisotope sampling system. Experiments with *n*-heptane were also carried out in the last system as a cross-check.

If regular solution behavior were to hold throughout the whole range of solvents used, Eqs. 5 and 6 predict a parabolic relationship between K_p and δ_1, with a minimum in penetration rate for the solvent having the closest solubility parameter to that of propionic acid. However, the experimental data show a steady decrease in K_p as one moves from *n*-heptane to nitromethane (a monotonous increase in the solubility parameter). The reason for this phenomenon might be due to the breakdown of regular solution behavior beyond a certain polarity ($\delta_1 > 10$).

Irrespective of this apparent discrepancy it is still possible to analyze the vehicle effect by use of the excess free energy approach. Figure 7 is a plot of the permeability coefficient K_p as a function of the partial molal volume change; the fit, over this wide range, is very good ($r = 0.97$). This function also accounts for the higher permeability coefficient of the penetrant in cyclohexane ($\delta_1 = 8.2$) relative to *n*-heptane ($\delta_1 = 7.4$). Negative values of $\bar{v}_2 - v_2^0$ for nitroethane, acetonitrile, and nitromethane are also well correlated with the change in the permeability coefficient. The excess free energy is a measure of the force driving the penetrant molecule from its solution in a given vehicle. The determination of the partial molal volume of the penetrant in a given solvent affords an excellent means for the assessment of its delivery into the skin.

APPENDIX

The following applies to penetrants that are members of an homologous series delivered from a common solvent vehicle into a common skin sample. Under these conditions, δ_1, δ_3, v_1, and v_3 become constant and Eq. 4 can be written:

$$\ln K_m = \frac{-2(\delta_1 - \delta_3)}{RT}\delta_2 v_2^0 + \bar{v}_{21}a_1 - \bar{v}_{23}a_2 \qquad \text{(Eq. 9)}$$

where a_1 and a_2 are constants.

If the differences between the partial molal volumes of the solute in each of the three phases considered is negligible, then:

$$v_2^0 \simeq \bar{v}_{21} \simeq \bar{v}_{23} \qquad \text{(Eq. 10)}$$

For an homologous series:

$$v_2^0 = a_3 + a_4 \cdot n \qquad \text{(Eq. 11)}$$

where a_3 and a_4 are constants and $n = 0,1,2,3\ldots$ Eq. 9 now becomes:

$$\ln K_m = \frac{-2(\delta_1 - \delta_3)}{RT}\delta_2 v_2^0 + (a_1 - a_2)(a_3 + a_4 \cdot n) \qquad \text{(Eq. 12)}$$

For low *n* values $a_3 > a_4 \cdot n$, and the expression $(a_1 - a_2)(a_3 + a_4 \cdot n)$ is practically constant. Even at $n = 5$ (equivalent to heptanoic acid), the change in the value $(a_1 - a_2)(a_3 + a_4 \cdot n)$ is still small compared with the value of $-2(\delta_1 - \delta_3)/RT\ \delta_2 v_2^0$, so that:

$$\ln K_m \simeq \frac{-2(\delta_1 - \delta_3)}{RT}\delta_2 v_2^0 + a_5 \qquad \text{(Eq. 13)}$$

where a_5 is a constant.

In an homologous series, D_m is almost constant, therefore:

$$\ln K_p \simeq \ln K_m + \text{constant} \qquad \text{(Eq. 14)}$$

or

$$\ln K_p \simeq \frac{-2(\delta_1 - \delta_3)}{RT}\delta_2 v_2^0 + \text{constant} \qquad \text{(Eq. 8)}$$

Quantitative Analysis of Trimethobenzamide Hydrochloride by Ion-Pair Column Chromatography and Semiquantitative Analysis of 3,4,5-Trimethoxybenzoic Acid by Thin-Layer Chromatography

HELEN NAVIASKY

Received November 23, 1982, from the *Food and Drug Administration, Baltimore, MD 21201.* *Accepted for publication March 29, 1983.*

Abstract □ An ion-pair column chromatographic/UV spectrophotometric method for assaying trimethobenzamide hydrochloride in capsules and injections is presented, as well as a method for the detection of 3,4,5-trimethoxybenzoic acid in trimethobenzamide hydrochloride bulk drug and dosage forms. Results obtained by the USP XX, Pharmacopeial Forum, and ion-pair column assay procedures are compared, and results of a collaborative study of the proposed assay and impurity detection methods are presented.

Keyphrases □ Trimethobenzamide hydrochloride—quantitative analysis by ion-pair column chromatography, semiquantitative analysis of 3,4,5-trimethoxybenzoic acid □ 3,4,5-Trimethoxybenzoic acid—semiquantitative analysis by thin-layer chromatography, quantitative analysis of trimethobenzamide hydrochloride □ Ion-pair column chromatography—quantitative analysis of trimethobenzamide hydrochloride, semiquantitative analysis of 3,4,5-trimethoxybenzoic acid by thin-layer chromatography

Monographs (1, 2) for trimethobenzamide hydrochloride (I) in capsules and injections have several shortcomings. The USP (1) assay method for the capsules involves direct dilution in 0.1 M HCl and UV spectrometric comparison with the USP reference standard. This procedure does not separate possible impurities, such as 3,4,5-trimethoxybenzoic acid (II), or interfering excipients. The *Pharmacopeial Forum* (PF) assay for injection preparations (2) also involves a UV assay which has several shortcomings.

This paper describes an ion-pair column chromatographic assay procedure, in which I is quantitatively removed from an aqueous acidic chloride column with a chlorinated organic solvent. Ether is used to remove phenolic ingredients and breakdown products prior to the elution of I.

Also, a TLC procedure is reported for the detection of II in amounts as low as 0.25% of the weight of I. Compound II is both a synthetic precursor and a breakdown product of I and could be encountered as a contaminant in drug preparations.

Table I—Recovery Data for I using the Proposed Ion-Pair, USP, and PF Injection Assay Methods

	Column Ion Pair	USP Injection	PF Injection
I, mg	8	200	200

SD	0.81	0.91	0.68
CV, %	0.82	0.94	0.70

EXPERIMENTAL

Reagents—Trimethobenzamide hydrochloride USP reference standard[1] was dried at 105°C for 4 h prior to use. Methylene chloride[2], pentane[2], and ether[2] were commercial distilled-in-glass grade. Compounds I[3] and II[3], chromatographic diatomaceous earth[4], glass wool, and the other reagents were used as received.

Apparatus—An ultrasonic bath, chromatographic tubes[5], a tamping rod[5], commercial TLC plates coated with a 250-μm layer of silica gel with a fluorescent indicator, a suitable TLC developing chamber, and a recording UV spectrophotometer were used.

Standard Preparation—Approximately 10 mg of trimethobenzamide hydrochloride USP reference standard was accurately weighed and transferred to a 100-mL volumetric flask. Methylene chloride (70 mL) was added, and the mixture was sonicated. The resulting solution was diluted to volume with methylene chloride. A 20-μg/mL solution was obtained by diluting quantitatively and stepwise with methylene chloride.

Chromatographic Column—A pledget of fine glass wool was packed in the base of a chromatographic column. A flexible spatula was used to mix 1 g of chromatographic diatomaceous earth with 500-μL of 1 M HCl in a 50-mL beaker. The mixture was transferred to a column and tamped.

Capsule Assay Preparation—The contents of ≥20 capsules were transferred to a tared container, and the average weight/capsule was determined. The

Quantitative Analysis of Trimethobenzamide Hydrochloride by Ion-Pair Column Chromatography and Semiquantitative Analysis of 3,4,5-Trimethoxybenzoic Acid by Thin-Layer Chromatography

HELEN NAVIASKY

Received November 23, 1982, from the *Food and Drug Administration, Baltimore, MD 21201.* *Accepted for publication March 29, 1983.*

Abstract □ An ion-pair column chromatographic/UV spectrophotometric method for assaying trimethobenzamide hydrochloride in capsules and injections is presented, as well as a method for the detection of 3,4,5-trimethoxybenzoic acid in trimethobenzamide hydrochloride bulk drug and dosage forms. Results obtained by the USP XX, Pharmacopeial Forum, and ion-pair column assay procedures are compared, and results of a collaborative study of the proposed assay and impurity detection methods are presented.

Keyphrases □ Trimethobenzamide hydrochloride—quantitative analysis by ion-pair column chromatography, semiquantitative analysis of 3,4,5-trimethoxybenzoic acid □ 3,4,5-Trimethoxybenzoic acid—semiquantitative analysis by thin-layer chromatography, quantitative analysis of trimethobenzamide hydrochloride □ Ion-pair column chromatography—quantitative analysis of trimethobenzamide hydrochloride, semiquantitative analysis of 3,4,5-trimethoxybenzoic acid by thin-layer chromatography

Monographs (1, 2) for trimethobenzamide hydrochloride (I) in capsules and injections have several shortcomings. The USP (1) assay method for the capsules involves direct dilution in 0.1 M HCl and UV spectrometric comparison with the USP reference standard. This procedure does not separate possible impurities, such as 3,4,5-trimethoxybenzoic acid (II), or interfering excipients. The *Pharmacopeial Forum* (PF) assay for injection preparations (2) also involves a UV assay which has several shortcomings.

This paper describes an ion-pair column chromatographic assay procedure, in which I is quantitatively removed from an aqueous acidic chloride column with a chlorinated organic solvent. Ether is used to remove phenolic ingredients and breakdown products prior to the elution of I.

Also, a TLC procedure is reported for the detection of II in amounts as low as 0.25% of the weight of I. Compound II is both a synthetic precursor and a breakdown product of I and could be encountered as a contaminant in drug preparations.

EXPERIMENTAL

Reagents—Trimethobenzamide hydrochloride USP reference standard[1] was dried at 105°C for 4 h prior to use. Methylene chloride[2], pentane[2], and ether[2] were commercial distilled-in-glass grade. Compounds I[3] and II[3], chromatographic diatomaceous earth[4], glass wool, and the other reagents were used as received.

Apparatus—An ultrasonic bath, chromatographic tubes[5], a tamping rod[5], commercial TLC plates coated with a 250-μm layer of silica gel with a fluorescent indicator, a suitable TLC developing chamber, and a recording UV spectrophotometer were used.

Standard Preparation—Approximately 10 mg of trimethobenzamide hydrochloride USP reference standard was accurately weighed and transferred to a 100-mL volumetric flask. Methylene chloride (70 mL) was added, and the mixture was sonicated. The resulting solution was diluted to volume with methylene chloride. A 20-μg/mL solution was obtained by diluting quantitatively and stepwise with methylene chloride.

Chromatographic Column—A pledget of fine glass wool was packed in the base of a chromatographic column. A flexible spatula was used to mix 1 g of chromatographic diatomaceous earth with 500-μL of 1 M HCl in a 50-mL beaker. The mixture was transferred to a column and tamped.

Capsule Assay Preparation—The contents of ≥20 capsules were transferred to a tared container, and the average weight/capsule was determined. The

contents were finely powdered and mixed, and an accurately weighed portion of powder equivalent to 200 mg of I was transferred to a 50-mL volumetric flask. Thirty milliliters of water was added, the mixture was shaken mechanically for 10 min, and then diluted to volume with water. The mixture was filtered (the first 10 mL was discarded).

Injection Assay Preparation—An accurately measured volume of injection solution, equivalent to 200 mg of I, was transferred to a 50-mL volumetric flask, then diluted to volume with water.

Procedure—Assay preparation (2 mL) was tranferred to a 100-mL beaker, 200 μL of hydrochloric acid was added, and the mixture was swirled gently. Three grams of chromatographic diatomaceous earth was added, mixed well with a flexible spatula, and transferred to the column. The beaker was scrubbed with 1 g of diatomaceous earth, which was added to the column, and tamped with a pledget of glass wool. Fifty milliliters of water-saturated ether then four 50-mL portions of water-saturated methylene chloride were passed through the column. The methylene chloride eluants were combined; a 25 mL portion was diluted to 50 mL with methylene chloride.

The absorbance of this solution and the standard preparation were concomitantly determined in 1-cm cells at the wavelength of maximum absorbance, 261 nm, with a spectrophotometer, using methylene chloride as the blank. The quantity (in mg) of I in the portion of the capsules was calculated by $10C(A_u/A_s)$. The quantity (in mg) of I/mL of injection taken was calculated by $(10C/V)(A_u/A_s)$. C is the exact concentration in μg/mL) of I in the standard preparation; V is the volume (in mL) of the injection solution; and A_u and A_s are the absorbances of the sample solution and the standard preparation, respectively.

Assay for 3,4,5-Trimethoxybenzoic Acid (4)—The standard solution was prepared by diluting 25 mg of 3,4,5-trimethoxybenzoic acid to 50 mL with methanol. The bulk drug samples were prepared by transferring 400 mg of I, accurately weighed, to a 10-mL volumetric flask. Methanol was added to volume, and the contents were mixed until a solution was obtained.

Capsule Sample Preparation—An accurately weighed portion of the capsule contents equivalent to 400 mg of I was transferred to a 10-mL volumetric flask. Methanol (~7 mL) was added, and the flask was shaken for ~5 min. The solution was diluted to volume with methanol, mixed, and centrifuged or let stand until the precipitate settled.

Injection Sample Preparation—An accurately measured volume of injection solution equivalent to 200 mg of I was transferred to a separator containing 5 mL of water and 3 mL of 1 M HCl and extracted with two 20-mL portions of ether. The ether extracts were combined and extracted with 10 mL of water. The aqueous layer was discarded, the ether layer was filtered through cotton premoistened with ether into a small glass-stoppered flask and evaporated under a stream of nitrogen, and the residue was dissolved in 2.0 mL of methanol.

Procedure—A 25.0-μL aliquot of bulk drug or capsule sample preparation, or 10.0 μL of injection sample preparation, and 10.0 μL of standard prepa-

ration were applied ~2.5 cm from the bottom of a TLC plate coated with a 250-μm layer of fluorescent silica gel. The plate was developed in a mixture of pentane–acetic acid (88:12) in a suitable unlined chamber until the solvent had ascended 10 cm above the spotting line. The plate was removed, dried in air, and observed under short-wavelength UV light. The R_f value of II is ~0.3; I remains on the spotting line.

RESULTS AND DISCUSSION

Assay Method—The compositing method herein includes a "finely powder" step not usually included for capsules. This was necessary because the varying particle sizes of the components caused stratification of the composite, resulting in nonuniform sample portions.

Methylene chloride was chosen as the eluting solvent rather than chloroform, even though the solubility of I is over fourfold greater in chloroform than in methylene chloride[6]. Because the UV cutoff of $CHCl_3$ is at ~245 nm, it is a poor solvent for the UV determination of I, whose maximum and minimum are at 261 and 240 nm, respectively. If chloroform were used as an eluting solvent and then evaporated so that the residue could be dissolved in methanol or 0.1 M HCl, breakdown could occur during heating and evaporating, catalyzed by traces of HCl eluting from the column with the $CHCl_3$. The UV cutoff of CH_2Cl_2 is ~230 nm, and by using it as the eluant, the evaporation and redissolution steps are eliminated, as is the opportunity for decomposition. The FDA Compendial Monograph Evaluation and Development (CMED) program guidelines require that at least 95% of the drug be eluted in the first half of the eluate when column chromatography is used. Analysis of fractions of eluate of bulk I taken through the column ion-pair elution show that methylene chloride is a satisfactory solvent for meeting this requirement.

Statistical results comparing replicate recoveries of bulk I using the column ion-pair, PF, and the USP injection assay procedures are shown in Table I. Recoveries average 99.4% for the column ion-pair procedure, which is ~2–3% higher than recoveries by the PF and USP methods. Linearity of the column ion-pair and PF techniques are shown in Table II. Both methods were found to be equally linear throughout the ranges tested, *i.e.*, 4–12 mg for the column ion-pair and 122–284 mg for the PF methods. Assay results for commercial capsules are shown in Table III, with statistical comparison of the proposed and USP methods. Results are higher using the USP method, but since this is a direct dilution with no cleanup other than filtration, it was expected. Table IV shows results of injection preparation assays by the ion-pair, USP, and PF methods. Both the column ion-pair and PF results are higher than those for the USP method for all lots tested, indicating improved recoveries.

Collaborative Study—All samples for the study were distributed as coded, blind duplicates. Capsule samples were sent to the collaborators as powders. Capsule sample A was prepared by finely powdering and blending 240 commercial I capsules[7] labeled to contain 250 mg of I/capsule. Capsule sample B was composited by finely powdering and blending the contents of 390 capsules[7] of I labeled to contain 100 mg of I/capsule. Capsule sample C was an "authentic" mixture prepared by finely powdering and blending I with the

[a] Labeled as containing 200 mg of I/2 mL. [b] Authentic sample, composite A. [c] Commercial sample, composite B. [d] Commercial sample, composite C.

manufacturer's designated excipients to achieve a concentration of ~450 mg of I/g and an amount of II equal to 0.25% of the weight of I. Injection solution sample A was an authentic mixture simulating the ampule formulation of I plus II equal to 0.25% of the weight of I. Injection solution samples B and C were composites of 22 20-mL vials[7] and 168 2-mL disposable syringes[7], respectively, each labeled to contain 100 mg of I/mL. Bulk drug samples contained I with 0.8% of added II, I with 0.25% of II, or I alone.

Collaborative assay results are presented in Tables V and VI. Average results for both capsules and injection solutions ranged from 97.7 to 102.4% (recovered or of theoretical) with coefficients of variation of ≤2.07%, indicating good recovery and reproducibility.

None of the commercial lots of the bulk drug, capsules, or injection preparations of I were found to contain II, but the TLC impurity test was developed and included in the collaborative study because it is a rapid and sensitive method for detecting degradation of I. Collaborators reported results on a basis of ≥0.5% of the amount of I, <0.5% of the amount of I, and no II. One collaborator reported incorrectly that one of the 0.8% bulk drug samples was <0.5% and another analyst incorrectly reported that both authentic injection samples had ≥0.5%. Otherwise, the results correlated well.

CONCLUSIONS

The back-extraction method was studied by the author prior to its publication in PF and was found to be a definite improvement over the USP injection assay method. However, a method was desired that would be specific and stability indicating for I, be applicable to assays of capsule as well as injection formulations, and eliminate the problems inherent in separator extractions with ether. The ion-pair chromatography method has been demonstrated by both statistical and collaborative studies to have achieved these purposes. In addition, the proposed TLC procedure has been shown to be a rapid, sensitive, and reliable method for detecting the presence of II, an impurity of I, in bulk drug and formulations.

Bromperidol Radioimmunoassay: Human Plasma Levels

JOHN TISCHIO ˣ, NANCY HETYEI, and JAMES PATRICK *

Received July 6, 1982, from the *Research Laboratories, Ortho Pharmaceutical Corporation, Raritan, NJ 08869.* Accepted for publication March 9, 1983. *Present address: Schering Corporation, Bloomfield, NJ 07003.

Abstract □ A sensitive radioimmunoassay (RIA) procedure was developed to assay for bromperidol levels in human plasma after therapeutic drug administration. The antisera used in the RIA procedure was generated in rabbits against a haloperidol–bovine serum albumin conjugate. Tritiated haloperidol was used as the radioligand in the assay. A single ether extraction of alkalinized plasma was used to separate bromperidol from its more polar metabolites and to reduce assay variability encountered with a direct plasma assay. The lower limit of detection was ~0.5 ng/mL of parent drug in plasma. The assay exhibited within- and between-assay variabilities of ~9 and 14%, respectively. A 103–106% recovery of bromperidol from quality control plasma samples was observed over the concentration range of 1–150 ng/mL. A correlation coefficient of 0.9999 with respect to measured *versus* expected bromperidol content in the quality control plasma samples was exhibited. Cross-reactivity characteristics of the antisera indicated that dehydrobromperidol could significantly interfere (~25% cross-reactivity) with the RIA procedure. However, biotransformation studies have not suggested this compound as a metabolite of bromperidol. Predose (C_{min}) plasma levels of bromperidol in schizophrenic patients maintained on drug therapy are also reported.

Keyphrases □ Bromperidol—radioimmunoassay, human plasma levels, haloperidol-bovine serum albumin conjugate □ Radioimmunoassay—bromperidol, human plasma levels, haloperidol-bovine serum albumin conjugate

Bromperidol (I), 4-[4-(*p*-bromophenyl)-4-hydroxypiperidino]-4′-fluorobutyrophenone, the bromo analogue of haloperidol (II), is a potent neuroleptic agent which has been under clinical investigation for the treatment of psychoses such as schizophrenia. The bioavailability and pharmacokinetics of this drug in dogs under steady-state conditions following multiple-dose oral administration have been reported (1). A limited study comparing preliminary pharmacokinetic results from dogs and humans was also reported (2). In general, relating pharmacokinetics of the psychotropic agents with effective treatment of psychiatric disorders is difficult partly due to the lack of a sensitive and reliable analytical methodology. This problem can be aggravated by the different neuroleptic plasma levels observed in patients receiving concurrent medication (3).

A radioimmunoassay (RIA) method was developed in our laboratory and was used to measure levels of bromperidol in human plasma (4, 5). With this methodology the bioavailability and pharmacokinetics of bromperidol in patients chronically receiving drug therapy was studied (5). This paper describes the RIA procedure used to measure bromperidol plasma levels in schizophrenic patients. Also reported are mean C_{min} drug plasma levels from 15 schizophrenic patients maintained on various drug regimens.

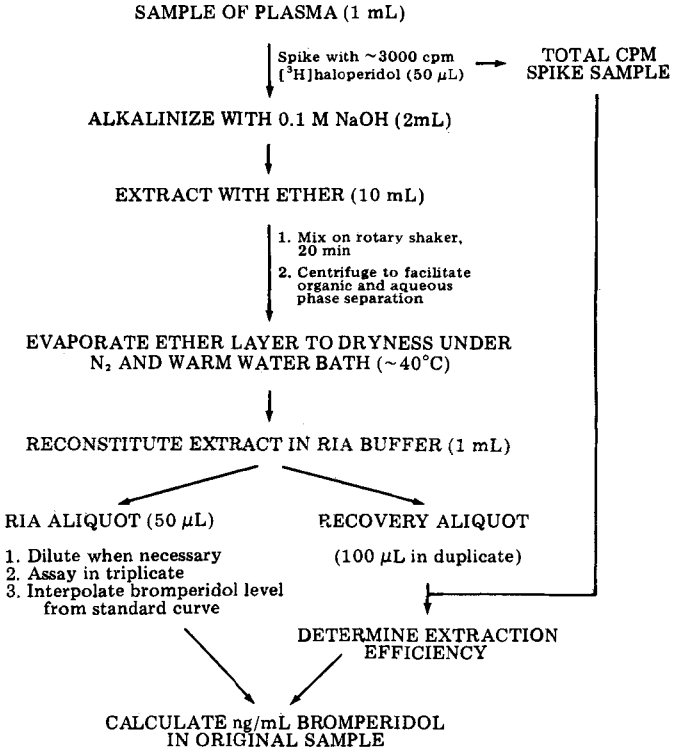
EXPERIMENTAL

Materials—Antisera[1] used in the RIA procedure was generated in rabbits against a haloperidol hapten chemically linked to bovine serum albumin *via* the tertiary alcohol functional group. Tritiated haloperidol[1], specific activity ~14 Ci/mmol, was used as the radioligand in the RIA procedure and to determine extraction efficiencies of drug material in the biological sample extraction procedure.

Radioimmunoassay—A bromperidol standard RIA curve was routinely generated from a series of test tubes (12 × 75 mm) prepared to contain an extract of control plasma sample (50 μL), unlabeled competitor (bromperidol, 0.02–10.0 ng in 50 μL of buffer), [^{3}H]haloperidol (50 μL containing ~6600 cpm), haloperidol antisera (50 μL, final antisera dilution of 1:1800), and RIA buffer (0.1 M sodium phosphate, 0.9% NaCl, 0.1% bovine IgG, and 0.1% sodium azide, pH 7.0) to achieve a final volume of 600 μL/tube. The contents were then mixed and incubated[2] at room temperature (~21°C) for ~18 h. (Note that this incubation period was chosen for convenience, since equilibrium of the radioligand binding to the antisera was demonstrated for an incubation period of 6 h.) Bound and free [^{3}H]haloperidol were separated by adsorption of free radioligand using dextran-coated charcoal (200 μL of a suspension containing 1 g of charcoal[2] and 100 mg of dextran[3] in 50 mL of RIA buffer). The charcoal suspension was incubated for 1.5 h, at room temperature. Centrifugation at ~330×*g* for 15 min adequately separated the charcoal-adsorbed material from that bound to the antisera. The supernatants were decanted into scintillation vials containing 15 mL of liquid scintillation cocktail[4] and 600 μL of water to aid dissolution of the sample. Bound radioactivity for each sample was determined using a liquid scintillation counter[5].

Quality control plasma samples were prepared to contain known amounts of bromperidol ranging from 1 to 150 ng/mL. These samples were prepared at the start of the study, stored at ~−20°C, and assayed throughout the study period (~6 months). Data from these analyses provided a measure of the drug stability in the biological matrix, as well as information from which assay statistics were calculated.

Patient plasma samples and quality control plasma samples were extracted according to the procedure outlined in Scheme I. This extraction procedure



Scheme I—Plasma sample extraction procedure and assay protocol for the bromperidol RIA.

Table I—Compounds Examined for Cross-Reactivity Characteristics

Compound	Structure	D_{50}[a], ng	Relative Percent Cross-Reactivity[b]
I		0.26	100.0%
II		0.28	92.9%
III		277.4	0.1%
IV		1.07	24.3%
V		>1000	N.D.I.[c]
VI		>1000	N.D.I.
VII		5.76	4.5%
VIII		>1000	N.D.I.
IX		>1000	N.D.I.
X		>1000	N.D.I.

[a] D_{50} is the amount of compound required to depress the radioligand binding to the antisera 50%. [b] (D_{50} bromperidol/D_{50} competitor) × 100. [c] No detectable interference.

was required in order to remove potential interferences (presumably conjugates of bromperidol). The reconstituted extracts, or dilutions thereof, were assayed in replicate (3 × 50-μL aliquots) for drug content as described for the standard curve.

Data Processing—The standard curve and plasma bromperidol levels were determined using the logit-log computer program of Frazier and Rodbard (6).

Antisera Selectivity—The cross-reactivity of the compounds in Table I was determined by competing the individual substances, over a range of 0.05–1000 ng, with a fixed amount of radioligand and antisera. A 50% displacement value (D_{50}, amount of compound required to displace the radioligand binding to the antisera by 50%) was determined for each compound. The ratio of D_{50} observed for bromperidol to the D_{50} observed for the other compounds was used to determine a relative percent cross-reactivity.

Patient Samples—Schizophrenic patients (n = 15) were maintained on bromperidol therapy given in tablet form[6] once daily. Whole blood samples were collected by venipuncture using heparinized evacuated blood collection tubes (10–15 mL) prior to medication over a period of several days (n = 4–10, Table II). Each whole blood sample was centrifuged (~500×g for 10 min at 4°C), and the plasma was separated and frozen. At an appropriate time the plasma samples were thawed, and aliquots (1 mL) were transferred to test tubes and sealed with a polytef screw cap. The aliquots were refrozen and maintained at ~ −20°C until analysis could be performed (usually within 4 weeks) by the RIA procedure. Duplicate 1-mL aliquots of selected plasma samples were assayed in parallel to estimate between-sample variability.

RESULTS AND DISCUSSION

A history of standard curve parameters for the bromperidol RIA was compiled. The mean (±SD) B_0 value[7], slope, intercept, D_{50}, and minimal detectable amount, as described by the data handling computer program (6) calculated from 10 assays, were 39.8% (5.1%), −1.06 (0.06), −1.13 (0.19), 0.35 ng (0.06 ng), and 0.03 ng (0.01 ng), respectively. The mean extraction efficiency for the quality control plasma samples (n = 227) assayed in the 10 assays was 84.6 ± 7.3%. This sample extraction step was necessary to reduce the variability observed when the plasma sample was assayed directly and to separate bromperidol from its polar metabolites. A similar extraction procedure was used by Van den Eeckhout *et al.* (2) to eliminate interfering plasma constituents.

[a] Administered once a day in tablet form. [b] Determined from plasma samples collected prior to dose administration (C_{min}). [c] Determined as follows: 100 × (SD/mean). [d] Number of days C_{min} blood samples were collected.

The RIA procedure for the measurement of bromperidol levels in human plasma was demonstrated by investigating the following criteria: (*a*) accuracy—correlating measured bromperidol in human plasma samples (quality control plasma samples) containing known amounts of drug (*i.e.*, 1, 5, 10, 25, 50, 100, and 150 ng/mL of bromperidol; (*b*) precision—determining replicate, within-assay, and between-assay variability statistics; and (*c*) selectivity—determining cross-reactivity characteristics of several structurally related compounds and potential metabolites of bromperidol. Table III summarizes the results obtained from the analysis of approximately five samples of each quality control human plasma specimen in several different assays performed over a 6-month period. (Note that not all quality control plasma concentrations were analyzed in every assay.) The mean values of the observed bromperidol content and between-assay variation, as well as the within-assay and replicate variations for each of the quality control plasma samples, are shown.

The quality control plasma sample concentrations of 1–50 ng/mL (reported in Table III) were compared with the expected (theoretical) values. Linear regression of the observed *versus* expected data yielded $y = 1.026x + 1.317$, with a correlation coefficient of 0.9994. If the 100- and 150-ng/mL quality control plasma results were included in this correlation, linear regression yielded $y = 1.051x + 0.889$, with a correlation coefficient of 0.9999. (Note that there were a limited number of assays, n = 3 and 2, which included the 100- and 150-ng/mL samples, respectively.)

The mean coefficient of variation [CV = 100 × (SD/mean)] observed between sample replicates (triplicate) for the seven quality control plasma concentrations ranged from 6 to 9.6%. Likewise, the mean CV observed between samples within an assay ranged from 5.4 to 12.4%, and the CV between assays ranged from 2.1 to 21.4% for the seven quality control plasma concentrations. In both instances, the within- and between-assay precision was greatest at the higher bromperidol concentrations and lowest at the 1-ng/mL concentration. These results demonstrate the stability of bromperidol in the biological matrix under the storage conditions and reasonable reproducibility of the RIA throughout the study.

The selectivity of the RIA for bromperidol is summarized in Table I, which lists the compounds examined for cross-reactivity characteristics with the haloperidol antisera. As can be seen, bromperidol (I) and haloperidol (II) show almost identical cross-reactivity characteristics with the antisera. Of the remaining compounds examined, only dehydrobromperidol (IV) showed appreciable cross-reactivity with the antisera (~25%). However, interference of dehydrobromperidol with the analysis of bromperidol in plasma is not likely to occur since there is no suggestion that this compound is a metabolite of bromperidol[8].

[8] Bromperidol is extensively metabolized in humans with the major metabolite being an *O*-glucuronide conjugate of the intact drug. Oxidative-*N*-dealkylation does not appear to be a major metabolic pathway of the drug in humans. These results have been presented at the 23rd Annual American Society of Pharmacognosy Meeting in Pittsburgh, Pa., August 1982.

[a] Quality control plasma samples were reconstituted to original sample volume (1 mL) with RIA buffer and assayed directly by RIA method. [b] Quality control plasma samples were diluted 1:2 after reconstitution with RIA buffer prior to being assayed by RIA method. [c] Quality control plasma samples were diluted either 1:2, 1:3, or 1:9 after reconstitution with RIA buffer prior to being assayed by RIA method. [d] The mean (±*SD*) and CV of the bromperidol concentration was calculated averaging the mean bromperidol concentration of each assay for each quality control plasma concentration. [e] The mean ± *SD* of the CV observed between samples within an assay was calculated averaging the mean CV between samples of each assay for each quality control plasma concentration. [f] The mean ± *SD* of the CV of the replicates of all samples assayed for each quality control plasma concentration.

Bromperidol levels (C_{min}) determined in the patient plasma samples are summarized in Table II. These data represent the mean bromperidol concentrations determined in samples collected immediately before the daily medication (n = 4–10 d) was administered. The patient plasma samples generally demonstrated the same degree of precision described for the quality control plasma samples with regard to replicate and within-assay variability. These variabilities (*CV*) were 7.1 ± 3.9 (n = 101) and 6.6 ± 4.6 (n = 45), respectively. However, intrasubject variability, the variability observed between the C_{min} values of an individual, ranged from 4.6 to 58.5% with no apparent correlation between the *CV* and the level of drug measured (Table II). In addition, comparison of the mean C_{min} drug levels from subjects receiving approximately the same dose per body weight demonstrated substantial intersubject variability. Specifically, patients A and C (dose, 0.14–0.15 mg/kg) had mean C_{min} levels of 3.73 and 6.67 ng/mL, respectively; patients K and M (dose, 0.55 mg/kg) had mean C_{min} levels of 9.20 and 20.24 ng/mL, respectively; and patients L, N, and O (dose, 0.91–1.00 mg/kg) had mean C_{min} levels of 10.72, 55.13, and 32.23, respectively. Realistically, this intra- and interindividual variability observed in mean C_{min} bromperidol levels cannot be explained solely by assay variability. Rather a combination of metabolism, elimination, and possibly concurrent medication may significantly influence the scatter in these single time point determinations.

In conclusion, this report describes an RIA procedure used to assay the bromperidol content of human plasma samples. Predose plasma samples, obtained from schizophrenic patients chronically receiving bromperidol therapy, were assayed using this RIA method. Substantial intra- and intersubject variabilities in the C_{min} drug levels were demonstrated. The bioavailability and pharmacokinetic information of bromperidol in schizophrenic patients will be reported elsewhere.

Novel Concept for a Mucosal Adhesive Ointment

K.-D. BREMECKER *[x], H. STREMPEL [‡], and G. KLEIN [‡]

Received December 14, 1982, from the *Institut für Pharmazeutische Technologie der Philipps Universität Marburg/Lahn, Ketzerbach 63, 3550 Marburg*, and the [‡]*Hautabteilung des Luisen-Hospitals, Aachen, West Germany.* Accepted for publication March 8, 1983.

Abstract □ Conventional adhesive ointments cause irritation to the mucous membranes. Therefore, a novel mucosal adhesive ointment based partly on neutralized polymethacrylic acid methyl ester was formulated. The flow curves of the ointment vehicle showed pseudoplastic properties. The rheological behavior as well as the adhesion on the mucosal membrane could be varied by the type and concentration of the polymer used and the base used for neutralization. During clinical studies, the ointment vehicle as well as a tretinoin (vitamin A acid) preparation for the treatment of lichen planus did not cause any local irritation or systemic side effects. Both vehicle and preparation were found to be pleasant for the patients to use. The new system of the mucosal adhesive ointment is not limited to the incorporation of tretinoin as the active agent; combined with other drugs the system could be applied to all types of mucosal membranes.

Keyphrases □ Adhesive ointment, mucosal—tretinoin, irritation-free formulation, clinical assessment □ Lichen ruber planus—treatment with tretinoin, irritation-free formulation, mucosal adhesive ointment □ Tretinoin—mucosal adhesive ointment, irritation-free formulation, clinical testing for lichen ruber planus

Ointments employed for the treatment of the mucous membranes of the mouth must be suited to the special conditions pertaining to that particular site of application. The flow of saliva and the mechanical stress generated by the continuous movements of the buccal cavity prevent any long-term adhesion of the ointment subsequent to its application. The quantity

of saliva produced each day ranges from 0.5 to 1.5 L (1, 2); with suitable stimulation, transient flow rates of up to 10 mL/min have been found (3, 4). On the one hand, therefore, mucosal adhesive ointments should be sufficiently hydrophilic to permit intimate contact with and adhesion to the skin surface; on the other hand, they should include a lipophilic component to prevent the ointment base from being washed away, or at least to delay this process. It is for this reason that such ointments frequently contain a hydrogel constituent suspended in a lipophilic base, which swells and exhibits its adhesive characteristics only after contact with mucous membranes and saliva. Typical ointments that have been developed in this way are a polyacrylate[1]-calcium carbonate–liquid paraffin suspension (5) and a sodium carboxymethylcellulose, pectin, and gelatin combination in a polyethylene–paraffin base[2]. In some cases, highly viscous solutions or hydrogels with no lipophilic admixtures are also used for this purpose, in which case natural and synthetic macromolecular compounds such as tragacanth alginates, pectin, methylcellulose, and polyacrylate[1] are incorporated.

The intended objective, apart from good mucosal adhesion over as long a period as possible, is for the ointment base to be as free from mechanical, physical, and chemical irritant properties as is practical, depending on the indication. Any

irritation of the oral mucosa should be strictly avoided, as it is extremely sensitive. This whole problem has to be faced, for example, in developing a mucosal adhesive ointment for the treatment of lichen planus mucosae oris with tretinoin (vitamin A acid). Tretinoin, described by Günther (6) in 1972 in the treatment of lichen ruber planus, has been employed with great success by many clinicians. However a number of patients have complained of reddening of the mucosa, pain, burning sensations, and maceration (7–10); the ointment bases were considered to have caused irritation to the sensitized oral mucosa. Therefore, there has been a need to formulate a nonirritating mucosal adhesive ointment containing tretinoin.

Polymethyl methacrylate[3] would seem to be a logical candidate for these tests, as it is a polymer with lipophilic methyl groups and hydrophilic carboxyl and ester groups. Both of these components were mentioned earlier as being essential for a mucosal adhesive ointment. The solubility of this polymer in water and its adhesiveness and viscidity can be varied, within certain limits, by using different degrees of neutralization (11). However, as polymethyl methacrylate has not previously been used as a mucosal adhesive ointment, the drug-free ointment base was first clinically investigated in volunteers. For dermatological reasons, no preservations, surfactants, stabilizers, or taste adjusters were added either to the ointment base or to the final tretinoin preparation, because of their potential irritant and allergenic effects.

EXPERIMENTAL

Production of the Polymethyl Methacrylate Base—Dilute polymethyl methacrylate salt solutions (<10%) were produced from concentrated master batches (≥10%) and, following the neutralization reaction (~1 h), made up to the required end concentration with water. For the master batch, polymethyl methacrylate was steeped for 10 min in 3–4 times its volume of cold water (20°C), and the amount of base required for neutralization was added cold with the remaining water (20°C) with continuous stirring. A 7.5-mmol volume of base/g of polymethyl methacrylate is needed for complete neutralization

Table 1—Tretinoin Grain Size Distribution as a Function of Storage Temperature and Time

Storage Temp.	Particle Size, μm	Storage Time		
		Nil	3 months	6 months
8°C	10	97%	98%	97%
	10-20	2.8%	1.7%	2.7%
	20	0.2%	0.2%	0.3%
25°C	10	98%	97%	98%
	10-20	1.8%	2.7%	1.7%
	20	0.2%	0.3%	0.3%

(Fig. 1). It was possible to accelerate the reaction by heating the mixture to ~ 60°C *in vacuo*. A detailed procedure has been described previously (11). The final stage in preparing the ointment base involved its sterilization for 20 min at 121°C in a steam autoclave.

Production of the Adhesive Ointment Base—The following quantities were used to prepare a 1-kg batch: 50 g of polymethyl methacrylate in 200 g of water and 12 g of NaOH in 238 g of water. The sterilized polymethyl methacrylate ointment base was produced from the above ingredients, into which the following components were incorporated under aseptic conditions: 1 g of tretinoin[4], 200 g of glycerol (85%)[5], and 299 g of water. The tretinoin was micronized with the aid of a high-efficiency mill[6] and a three-roller mill[7]. The ointment was placed into 20-g tubes for the clinical tests.

Flow Characteristics—The flow characteristics of the aqueous polymethyl methacrylate solutions were investigated with a rotational viscometer[8] at 25°C. The number of rpm was changed by 25 s^{-1}. The pH value was measured with a digital pH meter[9].

Tretinoin Determination—The tretinoin content in the finished preparation was determined with a UV-visual spectrophotometer at 351 nm ($E^{1\%}_{1cm}$ = 1500). For this purpose, 1 g of ointment was dissolved in 50 mL of water, brought to 100 mL with isopropyl alcohol, and measured against a blank made from drug-free ointment base, water, and isopropyl alcohol. This complies essentially with the requirement described in the USP XX (12). The particle size of the active agent in the ointment was determined microscopically immediately after manufacture and after 3 and 6 months of storage at room temperature and at 8°C. The drug content was also checked after storage.

Clinical Testing—Clinical testing was carried out in three sections: study

of the ointment base on (A) skin and (B) mucous membranes and (C) application of the tretinoin adhesive ointment.

Section A: Patch Testing of the Polymethyl Methacrylate Ointment Base—A nonallergenic test patch[10] to which the ointment base under investigation had been applied was affixed to the flexor surface of the right forearm of each of 16 subjects, aged 17 to 43 years (10 females and 6 males), with no skin or mucosal disorders. The patch was removed after 24 h. The skin reaction was read after 24, 48, and 72 h and once again after 1 week, in accordance with the procedure of Bandmann and Dohn (13).

Section B: Application of the Polymethyl Methacrylate Ointment Base to the Oral Mucosa—The same ointment base was then tested on the oral mucosa of the same 16 subjects. The test was carried out over a period of 14 d in each case. The subjects were each provided with a 20-g tube of ointment base and were instructed to apply the ointment four times daily to the same area of the oral mucosa. They were reexamined and questioned after 1 and 2 weeks. Fifteen of the subjects completed the study; one dropped out prematurely due to a recurrence of perlèche, which was apparently associated with poorly fitting dentures.

Section C: Application of the Tretinoin Adhesive Ointment to the Oral Mucosa—A total of 18 patients (7 females and 11 males) with lichen ruber planus, confirmed histologically in each case, were treated over a nearly 2-year period. The changes in the mucous membranes had first appeared on the average 20.8 months earlier and had been treated, unsuccessfully, with adhesive ointments and lozenges containing such active ingredients as cortisone, psychopharmacological drugs, external agents with a local anesthetic action, and antimycotics. The condition affecting 17 of the patients was a striate or reticular form of lichen ruber planus, while one patient had lichen planus annularis of the mucosa, which manifested the same kind of changes found on the skin. No erosive or verrucose lesions were observed. While two patients were found to have eruptions on the tongue in addition to buccal changes, only the upper surface of the tongue was affected in two others.

RESULTS AND DISCUSSION

One of the most important criteria in assessing the consistency of ointments is the flow behavior. Among other factors the rheological behavior of aqueous polymethyl methacrylate preparations was influenced by the degree of the neutralization. Strong bases such as sodium hydroxide produced a sharp rise in the pH at the end point corresponding to 7.5 mmol of base/g of the polymer. Weaker bases produced a flatter curve (Fig. 1). The neutralization characteristics of polymethyl methacrylate were similar to those of a weak acid. Maximal viscosity was achieved on the stoichiometric neutralization (100% S) of the carboxyl groups (Fig. 2).

[10] Fin Chambers on Scanpor; Hermal Chemie, Hamburg, West Germany.

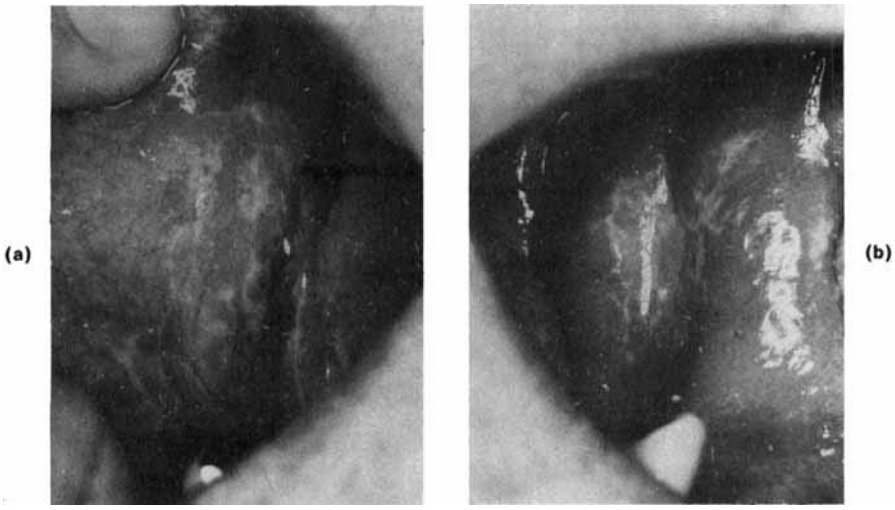

Figure 6—*Buccal mucosa of a patient with lichen planus mucosae oris, right (a) and left (b) sides.*

Admittedly, rheological measurements of polymethyl methacrylate had already been carried out by various researchers (14–16), but these were mainly discontinuous measurements which had lent themselves to widely differing interpretations. To obtain some unequivocal evidence, therefore, it would seem advisable to repeat an investigation of the flow characteristics of the polymethyl methacrylate preparations with a modern rotational viscometer. For this purpose the three standardly marketed types of polymethyl methacrylate (nv, low; mv, medium; hv, high viscidity) were investigated as 5% solutions neutralized with sodium hydroxide. Viscous texture flow curves typical of macromolecular disperse systems were obtained.

The flow characteristics were pseudoplastic; no pronounced thixotropic effect was observed. The highest viscosity was found with polymethyl methacrylate hv (Fig. 3), in line with the molecular weight which, according to the type, varied between 5×10^5 and 2×10^6 (17). In addition to the molecular weight, the solvation status of the polymer coil is also a significant factor in the viscosity of the solution.

The type and concentration of the base (degree of neutralization) can influence the viscosity of the polymer solution. This influence exerted by the base was investigated with sodium tetraborate, sodium hydroxide, triethanolamine, and diisopropanolamine. Relatively small cations, such as sodium ions, afforded relatively low viscosities; sterically expansive cations such as those of the amines, afforded higher viscosities (Fig. 4).

Different concentrations of the base influenced the viscosity of the polymer solution equally (Fig. 5). Fully neutralized carboxyl groups, corresponding to a 100% S (100% saturation) degree of neutralization, resulted in a high viscosity. A probable explanation of this behavior may be the degree of solvation of the polymer. Polymethyl methacrylate as a weak acid is badly dissociated and insoluble in aqueous systems (11). After neutralization of the polymer it can be assumed that nearly all acid groups are dissociated and the polymer is completely solvated, resulting in a viscous solution. Partly neutralized preparations as well as those with an excess of base were less viscous; in the first case, not all the carboxyl groups were completely solvated, and in the second, free cations interfered with complete solvation.

The polymethyl methacrylate preparations became increasingly tacky as the degree of neutralization was reduced, which is a desirable feature for good mucosal adhesion. Since saliva is weakly acidic—the values quoted in the literature vary between pH 5.8 and 7.8 (18–20), with average normal saliva at pH 6.4—only partly neutralized polymethyl methacrylate (80% S) was used for the mucosal adhesive ointment. The resulting ointment was free of irritation due to isohydria and had good mucosal adhesion, due to partial neutralization. The active substance, tretinoin, is stable in the weakly acidic milieu afforded by the ointment base.

Solubilizers and organic solvents such as those in tretinoin preparations for external application (21) should not be used to incorporate the active substances for mucosal ointments. Consequently, the micronized drug could only be suspended in the ointment base. Hence, there is a possibility of sedimentation due to the base lacking any thixotropic effect; in addition, crystal growth is possible and had to be tested for. To that end, the fineness and degree of dispersion of the active substance were determined as a function of storage conditions. The majority of the particles were <10 μm. Larger particles up to 60 μm were observed sporadically. Table I shows that there is no appreciable recrystallization as judged by the grain size distribution as a function of storage time.

If due allowance is made for the variations that occur with the analytical method, it will be seen that the drug content was practically constant over the observation period (Table II). Neither sedimentation nor any loss of active substance occurred during storage. These qualities go far beyond the requirements of the USP XX with regard to tretinoin ointments, which allow contents to vary between 90 and 130% (12). For the clinical tests, the ointment was supplied to the patients in 20-g tubes. This was at most a 2-week supply.

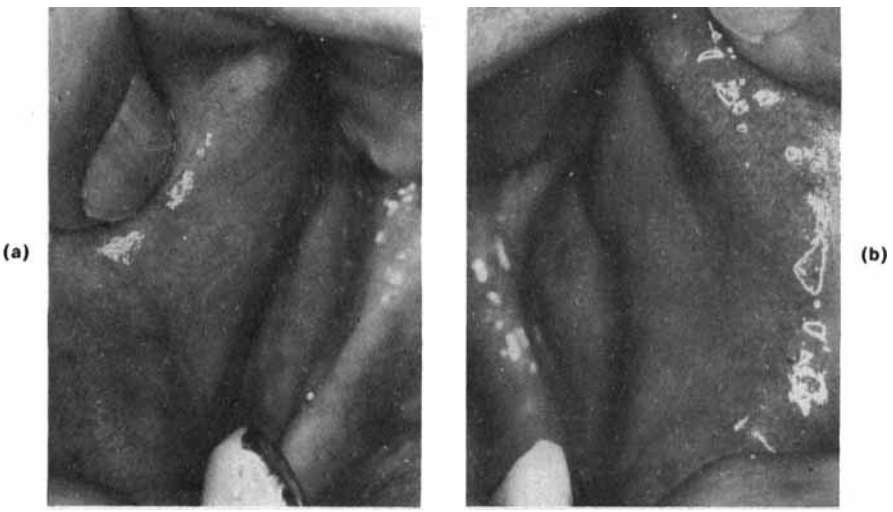

Figure 7—*Buccal mucosa of the same patient after treatment with the tretinoin adhesive ointment, right (a) and left (b) sides.*

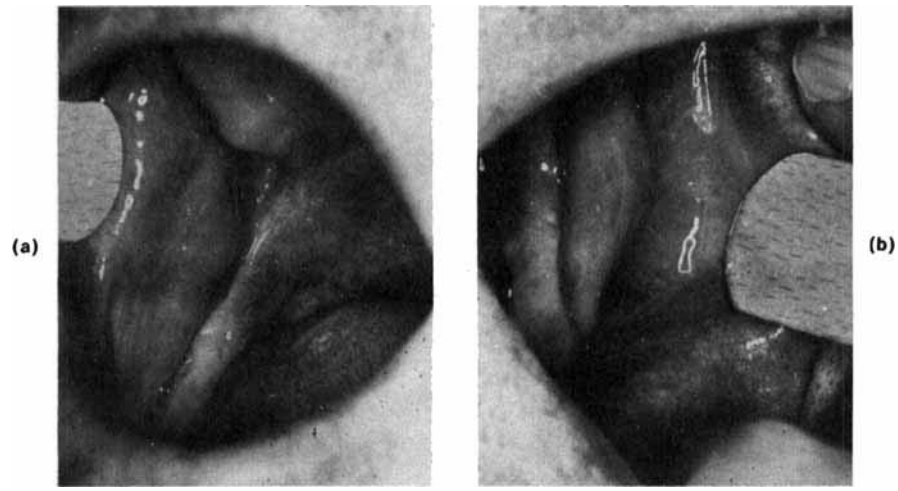

Figure 8—*Buccal mucosa of the same patient 20 months after completing a 3-week course of treatment with the tretinoin adhesive ointment, right (a) and left (b) sides.*

The use of this package size reduced to a low level the risk of any secondary contamination of the ointment.

No positive skin reaction was found in any of the subjects when the patch test was evaluated. No observable objective changes in either the treated or untreated areas were found when the oral mucosa of the subjects remaining in the trial were examined macroscopically with illumination of the buccal cavity. Subjectively, a feeling of "numbness" or of "stickiness" at the site of application lasting some 10–15 min after application of the ointment was reported.

With twice-daily treatment with tretinoin mucosal adhesive ointment, the macroscopic lesions disappeared after an average of 3.12 weeks in 15 of 18 patients (Figs. 6 and 7). This observation was also in accordance with the histological findings in two patients who agreed to an exploratory excision of tissue after completing therapy. To examine the long-term effect, the patients returned for a checkup 11.4 months (on average) after discontinuing therapy; this revealed that none had suffered a relapse (Fig. 8). The two patients who had lesions on the tongue only were among the three subjects in whom therapy was unsuccessful. The tongue lesions of one patient who had buccal changes as well also failed to respond to treatment. However, other authors have also reported that tongue changes in lichen ruber planus exhibit similar resistance to therapy (22). No undesirable side effects of the oral mucosa occurred in any of our cases. The ointment caused no unpleasant sensations and had good adhesive qualities.

As a novel concept, aqueous polymethyl methacrylate preparations can be employed as extremely well-tolerated ointment bases for use in mucous membranes. These ointment bases are characterized by an excellent adhesion. A description of a model for the determination of the adhesive time of mucosal adhesive ointments *in vitro* will be published elsewhere. The preparation of the polymethyl methacrylate ointment base as well as the incorporation of the active agent is easily carried out. The system can be utilized for other drugs, other symptoms, and all mucous membranes, with possible application to oral and vaginal mycoses, herpes labialis, pyoderma, and aphthosis.

Table II—Percentage of Tretinoin in Polymethyl Methacrylate Mucosal Adhesive Ointment as a Function of Storage Temperature and Time

Storage Temp.	Storage Time

Examination of the Interrelationship Between Aliphatic Group Dipole Moment and Polar Substituent Constants

WEN-YEN LI, ')NG-RU GUO, and ERIC J. LIEN ˣ

Received February 1 83, from the *Section of Biomedicinal Chemistry, School of Pharmacy, University of Southern California, Los Angeles, CA 90033.* Acceptec ublication March 29, 1983.

Abstract □ The relationships between 210 aliphatic group dipole moments (μ) and Taft polar constants (σ^*) are explored, and they are shown to be correlated by a general equation: $\mu = -a\cdot\sigma^* - b\cdot n' - c$, where a, b, and c are constants. The value n' is a parameter reflecting the attenuating factor due to the number and electronic nature of the interval atoms between the most electronegative atom and the first atom connected to the acetate in the measurement of σ^*. The μ and σ^* values of over 214 aliphatic substituents are compiled for future correlation studies. Comparative examples using σ^* and μ in quantitative structure-activity relationships are presented.

Keyphrases □ Dipole moment—aliphatic group, correlation with Taft polar substituent constants, quantitative structure-activity relationships □ Taft polar substituent constants—correlation with aliphatic group dipole moment, quantitative structure-activity relationships □ Quantitative structure-activity relationships—interrelationships between aliphatic group dipole moment and Taft polar substituent constants, applications

In addition to the electronic parameters like the Hammett σ constant and Taft polar constant (σ^*), the group dipole moment, a free energy-related parameter, has been used to study drug-receptor interactions and quantitative structure-activity relationships, especially if σ or other electronic parameters fail to give meaningful correlations (1). It has been reported (1) that the correlation between the aromatic group dipole moment (μ) and σ_m or σ_p varies drastically, or fails completely, if noncongeneric groups are pooled together.

The Taft polar constant (σ^*), which describes mainly the magnitude of inductive electron-withdrawing power of the substituent in the aliphatic system X—CH_2COOR on the reactive center, is defined by (1):

$$\sigma^* = (1/2.48)[\log (K_X/K_0)_B - \log (K_X/K_0)_A] \quad \text{(Eq. 1)}$$

in which B and A designate base- and acid-catalyzed hydrolyses of the ester with the substituent α to the carbonyl group. Although there are problems associated with the definition of σ^*, it is a reasonably accurate measure of the inductive effect, *i.e.*, the inductive electron-withdrawing power of an atom or group of atoms in a molecule. One may expect a better correlation between the aliphatic dipole moment μ, a measure of the charge separation in the group, and σ^* than that of μ and σ_m or σ_p. There have been some reports about the correlation of σ^* values with dipole moments (2), but they mainly involve some limited congeneric series of substituents. The present report attempts to make a wider exploration of the problem and to compile a table of aliphatic group dipole moments and σ^* for future use in correlation studies.

EXPERIMENTAL

A total of 214 substituent groups (for which both μ and σ^* were available) were analyzed to examine the relationship between μ and σ^*. Taft polar constants (σ^*) were taken from Hansch and Leo (3) and Perrin (4). The aliphatic group dipole moments (μ) were taken from the corresponding aliphatic molecular dipole moments (5), where the group is attached to an alkyl group, $CH_3(CH_2)_n$ — X (n = 0–6), assuming the dipole moment value of the alkyl group to be zero. The sign is assigned by comparison of the electronegativities between the substituent and the alkyl group to which the substituent group is connected. A negative sign indicates an electron-withdrawing group. All the regression lines were derived by a computer[1] *via* the method of nonweighted least-squares fit.

RESULTS AND DISCUSSION

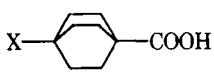
Equation 2 shows the overall correlation between σ^* and μ of 214 substituent groups:

$$\mu = -0.676\sigma^* - 1.055$$

$$n = 214 \quad r = 0.583 \quad s = 1.031 \quad \text{(Eq. 2)}$$

It is obvious that the correlation is not good, and only 34% ($r^2 = 0.34$) of the variance in the data can be explained by this equation. Since the exact number of n in $CH_3(CH_2)_nR$ will not affect the dipole moment, but will affect the σ^* value of such an $R(CH_2)_n$ group attached to an acetate used in the acid- and base-catalyzed hydrolyses, the attenuated polar effect due to different n values needs to be corrected.

According to an alternative approach to the definition of localized effect, a new parameter σ' was proposed by Roberts and Moreland (6) using the pK_a of 4-substituted bicyclo[2.2.2]octane-1-carboxylic acids:



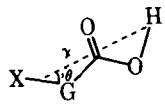
where

$$\sigma'X = \frac{-pK_X + pK_H}{\rho'} \quad \text{(Eq. 3)}$$

Kirkwood and Westheimer used Eq. 4 to describe the effect of the substituent on the acid strength of a series of XG—COOH (7):

$$\log K_X/K_H = \frac{c\mu_x\cdot\cos\theta}{2.303\cdot RTD\cdot r^2} \quad \text{(Eq. 4)}$$

where e is the electric charge on the proton, μ_x is the moment of the X—G bond, r is the distance between the proton and the center of the dipole, θ is the angle made by the distance r and the X—G bond, and D is the dielectric constant.



Combining Eq. 4 with the Hammett equation, one obtains (7):

$$\rho'\cdot\sigma_x = \frac{c\mu_x\cdot\cos\theta}{2.303\cdot RTD\cdot r^2} \quad \text{(Eq. 5)}$$

Equation 5 indicates that the localized effect of the constituent group is not only dependent on its dipole moment, but also inversely proportional to the square of the distance from the center of the dipole to the reaction site. Accurately determining the distance and the electrical effect of G between X and the reaction site is not easy. The polar effect of the substituent group is some combination of the inductive (through a bond) and field (through space) effects; therefore, the interval atom number between the most electronegative atom (where the negative inductive effect predominates) and the first atom of the group connecting the reaction site in the measurement of σ^*, as well as their electronic character, need to be considerd to fully reflect the effect of G on the magnitude of σ^*. This requires the addition of an attenuating parameter in correlating μ with σ^*.

Each interval atom exerts a shielding effect to transmit the inductive electron-withdrawing power as measured by σ^*. The higher the interval atom number (n), the greater will be the total shielding effect. When going over three —CH_2— the inductive effect of the group becomes insignificant.

0.217	0.905		2.481	18	0.814	0.175		23
0.226	0.861	0.118	2.863	18	0.946	0.102	$F_{1,14} = 30.8$	24

[a] $F_{1,16;0.95} = 4.49$; $F_{1,14;0.95} = 4.60$; $F_{1,16;0.99} = 8.53$; $F_{1,14;0.99} = 8.86$.

However, different types or locations of the interval atom will have different electronic environments which may produce different shielding effects. Thus, n' as an attenuating parameter reflecting the environmental factor of G should not only be the atom number, but be determined on the basis of its contribution to the electron-withdrawing power. Among the environmental factors contributing appreciably to the electron-withdrawing power, the intrinsic electronegativity of the atoms is the most important. If the interval atoms are such that their electronegativity is higher than an sp^3-hybrid carbon atom (—CH_2—) such as O, N, S, sp^2-, sp-hybrid carbon atom, or the sp^3-carbon atom attached by two electronegative atoms (—CCl_2—, —CBr_2—) or groups like NO_2, —C_6H_5, their shielding effect is smaller than that of —CH_2—. This is not only due to electron delocalization of p or d orbitals formed for transmission of inductive action, but also the additive inductive effect on their neighboring atom. Generally, this effect can be shown by causing a downfield shift in NMR spectrum of the proton attached to these atoms. Daily and Shoolery (8) have proposed a scale of electronegativity of substituent groups obtained from shifts in the NMR spectra of ethyl and methyl derivatives; it was strikingly demonstrated that the electronegativities obtained in this manner are essentially equal to the electronegativities of the Pauling scale of the first atom in the group.

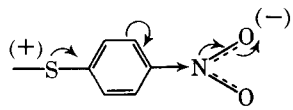
For the reasons mentioned above, the following rough rules are suggested as an initial premise to determine the n' values introduced into the regression analysis as a parameter:

1. For each —CH_2— and other atom that has less electronegativity than a carbon atom, $n' = 1$.

2. For N, S, —CH=CH—, —C≡C—, =C=O, and carbon atoms to which two halogen atoms or electronegative groups are attached simultaneously, $n' = 0.5$ each. For the conjugated system —C_6H_4—, —CH=CH—CH=CH—, and —CH=CH—, $n' = 1$.

3. Carbon or other atoms to which three or more oxygen or halogen atoms are attached are assigned $n' = 0$, for example, —CCl_3, —SO_3R.

The above method is employed to determine the n' values of each group. For example, with a *p*-nitrophenyl sulfide group, the —NO_2 withdraws electrons from all atoms, the negative pole of this group is toward oxygen atoms, the interval atoms include one sulfur atom ($n' = 0.5$), one benzine ring ($n' = 1$), and a nitrogen atom ($n' = 0.5$); therefore, the total $n' = 0.5 + 1 + 0.5 = 2.0$.



By introducing the n' into the regression analysis together with σ^* values, Eq. 6 was obtained:

$$\mu = -0.853\sigma^* - 1.045n' - 0.160$$
$$n = 214 \quad \gamma = 0.801 \quad s = 0.762 \qquad \text{(Eq. 6)}$$

Comparison with Eq. 2 shows that the correlation coefficient is markedly improved. An *F*-test indicates that the interval atom factor n' is statistically highly significant ($F_{1,211} = 171$) for studying the relationship between σ^* and μ.

By deleting those groups which deviate greater than 2 *SD* from this regression and by dividing the 210 substituents into two subgroups, the following equations were obtained. For subgroup I:

$$\mu = -0.687\sigma^* - 0.760$$
$$n = 177 \quad r = 0.686 \quad s = 0.755 \qquad \text{(Eq. 7)}$$
$$\mu = -0.853\sigma^* - 0.942n' - 0.028$$
$$n = 177 \quad r = 0.921 \quad s = 0.406 \qquad \text{(Eq. 8)}$$

[a] Taken from Ref. 12. [b] Calculated from Eq. 31.

For subgroup II:

$$\mu = -0.635\sigma^* - 2.666$$

$$n = 33 \quad r = 0.787 \quad s = 0.648 \qquad \text{(Eq. 9)}$$

$$\mu = -0.763\sigma^* - 0.853n' - 1.820$$

$$n = 33 \quad r = 0.940 \quad s = 0.366 \qquad \text{(Eq. 10)}$$

The first subgroup includes 180 substituent groups of no distinct structural relationship, but the second subgroup includes 33 substituent groups characterized structurally as amido, sulfonyl, sulfone, nitrophenyl, and amino groups.

All the equations have very similar slopes, and n' shows similar contribution to the overall correlation. Thus, the relationship between the dipole moment and polar substituent constant σ^* may be presented by the following:

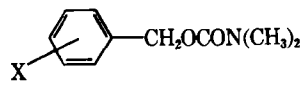
$$\mu = -a\cdot\sigma^* - b\cdot n' - c \qquad \text{(Eq. 11)}$$

n' is a complex factor including the number and electronic nature of the interval atoms. Whether n' can be expressed more accurately by the chemical shift values of these atoms in ^{1}H- or ^{13}C-NMR remains to be studied. Careful examination of the data shows that for practical application of the equation, the range of the value of n' is limited to 0–2.5, and the total value of n' generally should not be greater than the value of σ^* or μ to obtain a reasonable result (*Appendix*).

In Eq. 11, c is a constant representing the types of substituent groups. Substituents in the second subgroup, like amido, sulfonyl, sulfone, amino, and nitrophenyl groups, have considerably larger μ values with relatively small σ^* values. For amines and amides this may be due to the lone pair electron on the nitrogen atom decreasing the inductive electron-withdrawing power of C=O and SO_2—, while at the same time increasing the dipole moment through its resonance effect. For sulfonyl and sulfone groups, the relatively large dipole moment values may be due to presence of much larger mesomeric moments (9, 10).

On the basis of the correlations obtained, σ^* expresses the total electronic effect of the substituent, including the X and G in the group. Thus if interaction between drug and receptor is controlled by the total electronic nature (X + G) of the substituent through transmission toward the reactive site, σ^* constants may be a suitable descriptor of electronic effects for QSAR. If, on the other hand, the interaction is intermolecular in nature and is controlled directly by the electronic nature of the X portion of the substituent, then dipole moment μ as a measure of the charge separation in the group may give a more meaningful correlation.

For instance, Eqs. 12–24 (Table I) show the QSAR between the anticonvulsant activity and physicochemical parameters (Table II) of substituted benzyl *N*,*N*-dimethyl carbamates reported by Yamauea *et al.* (11):



Equations 13 and 15 were obtained by using simultaneously Hammett σ constant and Hansch's π, but in Eqs. 16 and 18, the aromatic group dipole moment μ_{ph} was used as an electronic parameter instead of σ. When the substituted benzene is regarded as an aliphatic substituent group of CH_3—$OCON(CH_3)_2$, Eqs. 19 and 21, and 22 and 24 are obtained by using the Taft polar constant σ^* and aliphatic group dipole moment μ as the electronic parameters, respectively.

According to the correlation coefficient and *F*-test, the dipole moment (whether aromatic group moment μ_{ph} or aliphatic group moment μ) gives a statistically more significant correlation than the Hammett σ or Taft σ^*. Among these electronic parameters used, the aliphatic group dipole moment seems to be the best, giving the highest degree of correlation in the case examined (Eq. 24).

Takayama *et al.* (12) reported the QSAR of antifungal 1-(3,5-dichlorophenyl)-2,5-pyrrolidinediones and 3-(3,5-dichlorophenyl)-2,4-oxazolidinediones and showed that the activity becomes greater with the increasing hydrophobicity of the substituents on the imido ring, independent of the electronic (σ^*) and steric effects (E_s) (Table III). Reexamination with aliphatic group dipole moment μ as an electronic parameter and log MW as a measure of bulk is shown by Eqs. 25–31 (Table IV). The correlation with μ or log p alone is statistically significant, although the improvement in regression with log p by introducing μ or log MW is generally not very significant ($F_{1,25}$ = 2.58 or 0.25, respectively) because of considerable covariance between log p and μ or μ and log MW. Among the two parameter equations, the combination of log MW and μ gives the highest correlation (Eq. 31), and the combination of log p and μ gives a slightly lower correlation (Eq. 30). The addition of log MW is statistically significant at the 99.9% level, as indicated by an *F*-test ($F_{1,25}$ = 21.80). This suggests that both the size of the molecule (13) and the dipole moment of the substituent group are important in determining the antifungal activity of the compounds examined.

The existence of the covariance among log p, log MW, and μ is shown in the following squared correlation matrix:

	log MW	log p	μ
log MW	1	0.13	0.50
log p		1	0.81
μ			1

Use of these three parameters simultaneously or the addition of $(\log p)^2$ does not result in a further improvement in correlation.

Synthesis and Evaluation of *N*-Alkanoyl-*S*-benzyl-L-cysteinylglutamic Acid Esters as Glyoxalase I Inhibitors and Anticancer Agents

WILLIAM O. FOYE ˣ and CHAUR-MING JAN ‡

Received October 14, 1982, from the *Samuel M. Best Research Laboratory, Massachusetts College of Pharmacy and Allied Health Sciences, Boston, MA 02115.* Accepted for publication February 3, 1983. ‡ Present address: G. D. Searle and Company, Chicago, IL 60680.

Abstract □ Esters of several glutathione analogues have been synthesized in which the glycine moiety was replaced by straight-chain fatty acids and the mercapto group was benzylated. Two of the derivatives (sufficiently water-soluble for the assay) were found to inhibit glyoxalase I to a greater extent than did *S*-methylglutathione. The two glyoxalase I inhibitors did not inhibit P388 lymphocytic leukemia in mice, however.

Keyphrases □ *N*-Alkanoyl-*S*-benzyl-L-cysteinylglutamic acid esters—synthesis, anticancer activity in the P388 leukemia screen, glyoxalase I inhibition □ Anticancer agents—potential, *N*-alkanoyl-*S*-benzyl-L-cysteinylglutamic acid esters, activity in the P388 leukemia screen, glyoxalase I inhibition

S-Alkyl and *S*-aryl glutathiones are potent competitive inhibitors of glyoxalase (1). The glyoxalase enzyme system converts methylglyoxal to lactic acid in the presence of the cofactor glutathione (2). Since methylglyoxal and other α-keto aldehydes are known to be carcinostatic (3), it was suggested that inhibitors of the glyoxalase system may create a build-up of methylglyoxal in the cells and thus inhibit cellular growth (4). The fact that glutathione concentration in the cells is rapidly increased (5) just prior to cell division suggests that the glyoxalase system is involved in the regulation of cell growth by maintaining a proper concentration of methylglyoxal (1). The high concentration of lactic acid (6) and deficiency of methylglyoxal (7) in cancer cells suggests further that such cells, having lost the ability to maintain the necessary balance of methylglyoxal, continue to grow at an uncontrolled rate. Inhibitors of the glyoxalase system that result in a build-up of cellular methylglyoxal could, therefore, function as anticancer agents. To some extent this has been realized. Some of the *S*-alkyl and *S*-aryl glutathione inhibitors of the glyoxalase system exhibited cytotoxic activity against L1210 leukemia and KB cells in tissue culture (8). However, α-hydroxy thiol esters of glutathione inhibited glyoxalase I but lacked antileukemic activity against L1210 lymphoid leukemia (9).

The rapid metabolism of *S*-substituted glutathiones by glutathionase rendered the *S*-alkyl and *S*-aryl glutathiones inactive when tested *in vivo* (10). Glutathione and *S*-substituted derivatives are rapidly hydrolyzed by two enzymes, glutathionase and cysteinylglycinase (11). In an attempt to find glutathione analogues that might be resistant to enzymatic hydrolysis, a series of analogues (I) having the glycine residue replaced by a fatty acid was synthesized. The diester function was not successfully converted to the carboxyl function, however. It was also considered possible that such a derivative would have greater lipophilicity and possibly provide a more strongly bound enzyme-inhibitor complex. A series of *S*-(ω-phthalimidoalkyl)glutathiones and *S*-(ω-aminoalkyl)-glutathiones, for instance, showed greater inhibition of glyoxalase I with greater lipophilicity (12).

Table I—Physical Properties of the *N*-Alkanoyl-*S*-benzyl-L-cysteines [a]

R	Formula	Reaction Time, h	Yield, %	Melting Point, °C
C_2H_5	$C_{13}H_{17}NO_3S$	30	69	86.0–86.5
C_3H_7	$C_{14}H_{19}NO_3S$	40	63	115–116
C_5H_{11}	$C_{16}H_{23}NO_3S$	96	52	83–84
C_8H_{17}	$C_{18}H_{27}NO_3S$	96	51	88–89

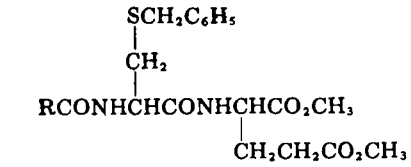
Dimethyl *N*-Alkanoyl-*S*-benzyl-L-cysteinylglutamates (I)				
C_2H_5	$C_{20}H_{28}N_2O_6S$	2	61	113–114
C_3H_7	$C_{21}H_{30}N_2O_6S$	2	59	93–94
C_8H_{17}	$C_{25}H_{38}N_2O_6S$	2	50	107–108

[a] Elemental analyses for C, H, N, and S were within ± 0.4% of the theoretical values for all compounds. [b] Recrystallized from *n*-hexane.



I: R = C_3H_7—$C_{10}H_{21}$

DISCUSSION

Chemistry—*S*-Benzyl-L-cysteine was readily converted to fatty acid amides (11) by reaction of the pyridinium salt of *S*-benzyl-L-cysteine with the fatty acid chloride in excess pyridine at 0°C. Yields of 18–69% were realized, with chain lengths ranging from 3 to 10 carbons with the longer chain acids giving progressively lower yields. Physical properties of the *N*-alkanoyl-*S*-benzyl-L-cysteines are recorded in Table I.

Condensation of the *N*-alkanoyl-*S*-benzyl-L-cysteines with dimethyl glutamate was carried out by conversion of the cysteine moiety to a mixed anhydride with isobutyl chlorocarbonate in the presence of *N*-methylmorpholine. Condensation with dimethyl glutamate hydrochloride in the presence of triethylamine took place readily at −10–0°C giving reasonable yields (50–61%) of I, in the case of the propanoyl, butanoyl, and octanoyl derivatives. Attempts to hydrolyze the methyl ester functions were unsuccessful. The reaction sequence is shown in Scheme I, and physical properties of I are listed in Table I.

Biological Testing—The method of Racker (13) for measuring inhibition of glyoxalase I was used. This was based on the formation of *S*-lactoylglutathione, catalyzed by glyoxalase I, which has high optical density at 240 nm. The rate of increase in absorption at 240 nm was measured, and the ratio of inhibitor concentration to substrate concentration at 50% inhibition was used to compare relative inhibitory properties of the compounds. To determine the concentration of inhibitor required for 50% inhibition, a plot of v_0/v_i *versus*

Table II—Inhibition of Glyoxalase I

Compound	ID_{50}, mM	$[I/S]_{50}$[a]
S-Methylglutathione	6.10	9.84
Dimethyl *N*-propanoyl-*S*-benzyl-L-cysteinylglutamate	1.95	3.15
Dimethyl *N*-butanoyl-*S*-benzyl-L-cysteinylglutamate	1.90	3.06

[a] Ratio of inhibitor concentration to substrate concentration at 50% inhibition.

Table III—Antileukemic Activities in Mice[a]

Compound	Dose, mg/kg[b]	Weight Difference (T − C)	Median Survival Time (T/C), %[c]
Dimethyl *N*-propanoyl-*S*-benzyl-L-cysteinylglutamate	200	0.8	97
	100	0.3	100
	50	−0.2	110
Dimethyl *N*-butanoyl-*S*-benzyl-L-cysteinylglutamate	200	−0.2	96
	100	1.4	104
	50	1.1	104

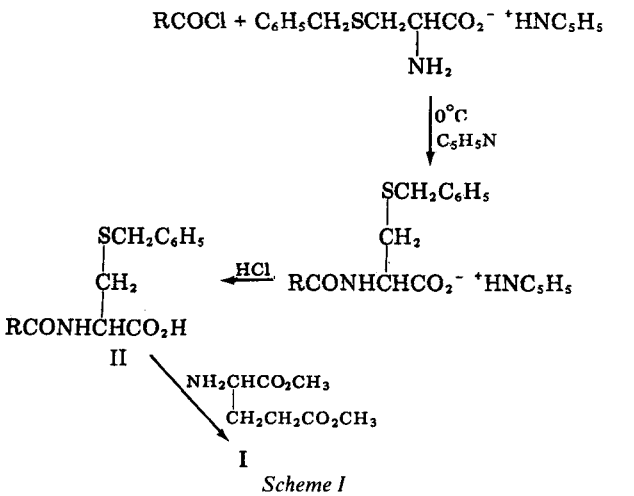
[a] CDF_1 mice were inoculated (5×10^6 cells) with P388 lymphocytic leukemia. [b] Drugs were administered intraperitoneally daily for 9 d; observations were continued for 30 d. [c] A T/C% value of >125 is considered a positive result.

[I] was made, where v_0 is the initial velocity of the uninhibited enzymatic reaction and v_I is the initial velocity of the inhibited reaction at various concentrations of inhibitor (Table II). The *N*-propanoyl- and *N*-butanoyl-*S*-benzyl-L-cysteinylglutamic acid esters both showed better inhibitory activities than did *S*-methylglutathione. The longer-chain amide proved to be too insoluble in water to be measured by this method.

Antileukemia testing[1] of the propanoyl and butanoyl amides was carried out in mice against P388 lymphocytic leukemia, according to the NCI protocol (14). Details regarding dose and survival times are listed in Table III. Neither of the compounds showed positive activity in this screen.

EXPERIMENTAL[2]

S-Benzyl-L-cysteine—L-(+)-Cysteine hydrochloride (36.0 g, 0.229 mol) was dissolved in a small amount of water, and 27.5 g (0.687 mol) of sodium hydroxide was added. Benzyl bromide (38.9 g, 0.229 mol) was added in a dropwise manner to the solution, and the mixture was shaken vigorously for 1 h. The unreacted benzyl bromide and benzyl alcohol were extracted with ether. The aqueous solution was acidified with 20% acetic acid, and the white crystals were collected and recrystallized from water, yielding 36.5 g (75%); mp 215–217°C [lit. (15) mp 213–214°C].



Scheme I

***N*-Alkanoyl-*S*-benzyl-L-cysteines**[3]—*S*-Benzyl-L-cysteine (31.65 g, 0.15 mol) in 180 mL of pyridine was cooled to 0°C. After 30 min, 13.02 mL (0.15 mol) of propanoyl chloride was added in a dropwise manner with vigorous shaking and ice cooling during 30 min. The mixture was shaken mechanically for 30 h at room temperature, and the excess pyridine was removed under reduced pressure. The syrupy residue was acidified with 10% HCl (Congo Red endpoint), and the oily product was extracted three times with ethyl acetate. The extract was dried (Na_2SO_4) and concentrated to a small volume using a rotary evaporator. The residual solution was treated with petroleum ether and stored at 0°C; recrystallization of the product from benzene gave 27.6 g (69%) of white needles, mp 86.0–86.5°C; IR(KBr): 3380 (N—H), 1735 (C=O), 1600 (C=O), and 1525 cm^{-1} (CNH).

***N*-Alkanoyl-*S*-benzyl-L-cysteinylglutamic Acid Dimethyl Esters**[3]—A solution of 5.35 g (0.02 mol) of *N*-propanoyl-*S*-benzyl-L-cysteine in 60 mL of dry tetrahydrofuran containing 2.20 mL (0.02 mol) of *N*-methylmorpholine was cooled to −15°C, and 2.80 mL (0.021 mol) of isobutyl chlorocarbonate was added with stirring. After 15 min, 4.66 g (0.022 mol) of L-glutamic acid dimethyl ester hydrochloride was added, followed by 3.0 mL (0.021 mol) of triethylamine in 60 mL of cold tetrahydrofuran. Stirring was continued at −10–0°C for 30 min and at 0°C for 1.5 h. The reaction mixture was diluted with 300 mL of cold water, and a yellow-green oil separated and was extracted three times with ethyl acetate. The extract was dried (Na_2SO_4) and concentrated to a small volume using a rotary evaporator. Crystallization resulted on storage at 0°C, and recrystallization from absolute ethanol gave 5.2 g (61% yield) of white crystals, mp 113–114°C; IR (KBr): 3300 (N—H), 1755 (C=O), 1735 (C=O), 1660 (C=O), 1640 (C=O), and 1545 cm^{-1} (CNH).

Inhibition of Glyoxalase I—The enzymatic reactions were carried out at room temperature in 0.05 M phosphate buffer, pH 6.6. A fresh solution of glutathione in distilled water was made before each assay. For each assay, the spectrophotometer cell contained a total volume of 3.0 mL, which was 5.0 mM in methylglyoxal and 0.869 mM in glutathione.

A commercial 40% (w/v) solution (10 mL) of methylglyoxal was diluted to 50 mL with distilled water, and the acidic components were removed by a Dowex 1-X8 (200–400 mesh, carbonate form) column. The solution was standardized by the method of Friedemann (16). Glyoxalase I was diluted to a concentration of 40 μg of protein/mL with 0.05 M phosphate buffer (pH 6.6) containing 0.1% bovine serum albumin.

Sufficient amounts of glyoxalase I were employed to give an easily measurable initial rate, which was followed by increase in absorption at 240 nm. Methylglyoxal, glutathione, and buffer were added to the cell and allowed to equilibrate for exactly 6 min before addition of the enzyme. The ratio of the inhibitor concentration to that of the substrate for 50% inhibition, $[I/S]_{50}$ was determined for each compound measured. To determine the concentration of inhibitor required for 50% inhibition (ID_{50}), a plot of v_0/v_I *versus* [I] was made, where v_0 is the initial velocity of the uninhibited reaction and v_I is the initial velocity of the inhibited reaction at various inhibitor (I) concentrations (17). At least two of the points on the plot were in the 30–70% inhibition range. Initial velocity measurements were determined by the change in absorbance, ΔO.D./time with readings at 1-min intervals for 3 min.

Simple Radioligand Binding Assay for the Determination of Urinary Scopolamine

M. SCHEURLEN *x, H. BITTIGER ‡, and BIRGIT AMMANN *

Received November 2, 1982, from the **Human Pharmacology Institute, Ciba-Geigy, Tübingen, Federal Republic of Germany* and the ‡*Research Department of the Pharmaceutical Division, Ciba-Geigy, Basel, Switzerland.* Accepted for publication March 29, 1983.

Abstract □ A sensitive radioligand binding assay is described for the determination of scopolamine in human urine. As a measure for the drug concentration, the quantitative displacement of scopolamine of tritiated quinuclidinyl benzylate from rat brain receptors was used. The assay is sensitive to concentrations as low as 1.2 ng/mL, surpassed only by GC–MS techniques. It can be performed easily and quickly and does not include extraction procedures. Scopoline and scopine, possible metabolites of scopolamine, do not interfere with the assay. After transdermal administration of scopolamine, 34% of the drug is found in the urine. Of the total scopolamine excreted, 79% is conjugated to glucuronic and/or sulfuric acid and 21% is excreted in the unbound form.

Keyphrases □ Scopolamine—urinary determination, radioligand binding assay, □ Radioligand binding—simple assay, determination of urinary scopolamine □ Excretion, urinary—scopolamine, determination by radioligand binding assay

The lack of suitable methods for measuring low concentrations of scopolamine and other strongly acting parasympatholytic substances in biological fluids after therapeutic dosages in humans makes it difficult to obtain exact pharmacokinetic data on these drugs. Several methods exist for the determination of scopolamine, but these do not allow a rapid and sensitive measurement of low drug concentrations. GC (1) or acid–dye techniques (2) are not sensitive enough, while a GC–MS method (3) is not specific and involves difficult extraction procedures.

The development of radioligand binding techniques for studies of drug interactions with cholinergic receptors, using tritiated quinuclidinyl benzylate (I) as the radioligand (4), allows (analogous to RIA) the measurement of drugs having strong affinity to muscarinic receptors. Using tritiated I we developed a radioligand binding assay for the determination of the very low urinary concentrations of scopolamine that are found after transdermal administration of the drug.

EXPERIMENTAL

Preparation of Rat brain Homogenate—Male rats (Tif RAI f SPF) of 150–250-g body weight were used. After being sacrificed by decapitation, the brains were removed and the cerebral cortices dissected on ice and homogenized[1] for 30 s, at position 5, in 20 volumes of ice-cold 50 mM Tris-HCl buffer (pH 7.3). The homogenate was centrifuged at 26,000×*g* for 10 min, and the pellet was resuspended in the same volume of fresh buffer; this step was repeated three times. All procedures were performed at 4°C. The final pellet was suspended in 20 volumes of Tris-HCl and divided into 1-mL aliquots, which were rapidly frozen in liquid propane (~−160°C) and stored at −30°C. (After storage at −30°C for up to 3 months no loss of binding capacity was observed.) For the radioreceptor assay, the 1-mL aliquots were thawed for 5 min in a water bath (37°C) and diluted 17-fold by addition of ice-cold Tris-HCl. Membrane suspensions were not used in the assay for longer than 12 h after thawing.

Radioligand Binding Assay—The radioreceptor assay was performed at room temperature in 5-mL polystyrene tubes in a total volume of 2 mL of Tris-HCl containing brain membranes [~100 μg of protein as determined according to Lowry *et al.* (5)], 0.2 nM [^{3}H]-I[2] (33 Ci/mmol), and a 50-μL urine sample.

After 30 min, the incubation was terminated by filtration through a glass-fiber filter (2.4 cm diameter[3]) under reduced pressure. The filters were rinsed twice with 5-mL ice-cold Tris-HCl. After incubation of the filters for 30 min with 1-mL of tissue solubilizer[4] (diluted 1:1 with propanol), 10 mL of acidified scintillation fluid[5] was added and the radioactivity was determined in a liquid scintillation counter[6]. Nonspecific binding was defined by 10^{-7} M unlabeled I[7]. Scopolamine hydrobromide trihydrate[8] was used as a standard.

For the calibration curve, different concentrations of scopolamine were added to blank urine and tested as described above. The displacement (in percent) of ^{3}H-QNB from the muscarinic receptors in the brain homogenate was plotted on logit–log scale against the scopolamine concentration. Unknown urinary scopolamine concentrations were calculated from the calibration curve. To determine the total scopolamine (conjugated and free drug), urine samples were incubated at 37°C for 3 h with an equal volume of 1 M acetate buffer (pH 4.75) and 7.5 μL of β-glucuronidase–sulfatase[9]/mL of the mixture. The pH was adjusted to 7.3 with NaOH before the binding assay was performed.

Scopolamine Medication and Collection of Urine—Scopolamine was administered transdermally to nine healthy volunteers as a transdermal therapeutic system with scopolamine[10]. The drug system was applied on the skin surface behind the ear. Each system contains 1.5 mg of scopolamine base and can deliver ~0.5 mg of drug over 72 h. The system is programmed to release 0.15 mg as a loading dose during the first few hours; afterward, ~5 μg of scopolamine/h pass through the skin into the blood circulation. The drug system was applied for 64 h, delivering ~0.45 mg of scopolamine. Urine was collected in plastic bottles before the medication, in 12-h periods during the application, and for 8 × 6 h after removal of the drug. Aliquots were stored at −20°C in plastic tubes until assayed. For each subject, an individual urine blank for the calibration of the assay was collected before the medication.

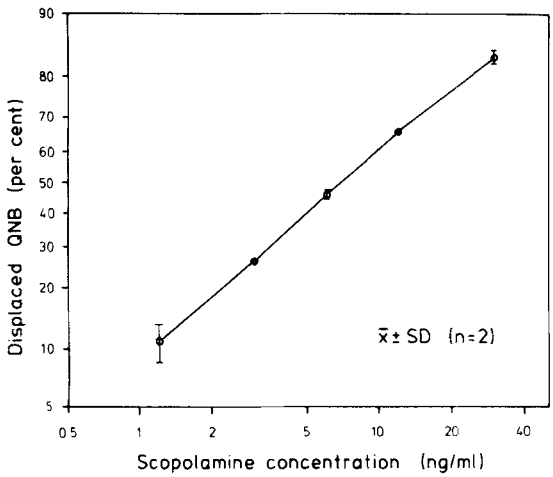

Figure 1—*Displacement of tritiated quinuclidinyl benzylate (QNB) from rat brain membranes by scopolamine (logit-log scale). Different concentrations of scopolamine were added to blank urine. The displacement of the labeled I from rat brain membranes was determined under the assay conditions described in* Experimental. *The values are means* ±SD *of two measurements.*

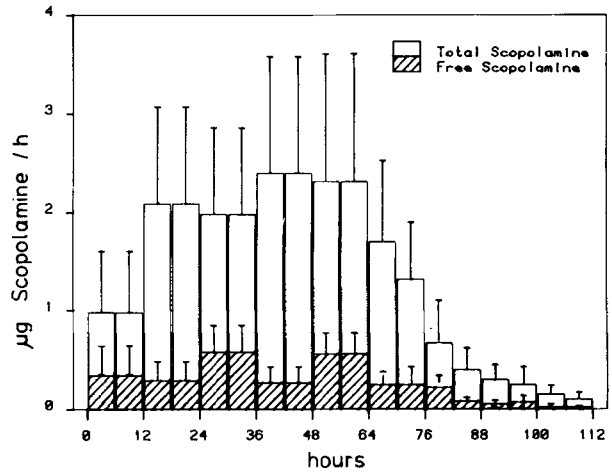

Figure 2—*Urinary excretion of scopolamine after transdermal administration. Application time was 64 h. Urine was collected as described under* Experimental. *The values are means* ±SD *from nine volunteers.*

RESULTS AND DISCUSSION

Under the test conditions selected, there was a linear correlation on logit-log scale between inhibition of [^{3}H]-I binding and scopolamine concentration in the range of 10^{-10}–2.5×10^{-9} M. This corresponds to a 1.2–30-ng/mL scopolamine concentration in 0.05-mL urine samples (Fig. 1). The IC_{50} value was 4.7×10^{-10} M.

To test the intra- and interassay reproducibility of the binding assay, blank urine samples containing 2, 10, and 25 ng/mL of scopolamine, respectively, were assayed repeatedly on a single day or different days. The results of these measurements are shown in Table I.

To exclude interference of the radioligand binding assay by scopoline and scopine, possible degradation products of scopolamine, these two substances were added to the urine blank in different concentrations (10^{-10}, 10^{-9}, and 10^{-8} M in the incubation mixture). Under these conditions, no displacement of [^{3}H]-I from brain membranes was observed.

The radioligand binding assay was used to measure the urinary excretion of scopolamine after administration of the transdermal system for 64 h. During the time of medication and 48 h thereafter, a total urinary excretion of 156 µg (80–276 µg) of scopolamine was observed (mean of nine volunteers). Steady state was reached after ~12 h of medication, lasting until the removal of the drug system (Fig. 2).

Scopolamine is excreted mainly in its conjugated form (79% *versus* 21% in unbound form), as determined after β-glucuronidase–sulfatase incubation. Assuming a total delivery of 0.45 mg of scopolamine to the circulatory system, an average of 34% (17–60%) of the administered scopolamine can be detected in the urine. Scopolamine, in very small amounts, was recovered from the urine even in the last collection period [42–48 h after the removal of the system (Fig. 2].

The use of radioligand binding techniques was originally established for studies of drug–receptor interactions *in vitro*. Radioreceptor assays were also exploited to measure concentrations of hormones (6), neurotransmitters (7, 8), or drugs (9) in biological fluids (10). Recently, such an assay for the measurement of atropine in plasma was published (11).

Table I—Intra- and Interassay Reproducibility of the Radioligand Binding Assay [a]

n	Conc. Given, ng/mL	Conc. Found, ng/mL	CV, %	Recovery, %
		Within Day		
10	2	2.3	13.7	113
10	5	5.5	5.0	109
10	10	11.7	8.0	117
10	25	27.8	7.9	111
		Day-to-Day		
11	2	2.3	32.1	114
10	5	5.7	11.3	115
20	10	10.3	12.1	103
21	25	25.6	12.6	103

[a] Scopolamine was added to the urine blank in different concentrations (2, 5, 10, and 25 ng/mL). The samples were assayed as described in the text either in one series or on different days.

The method described here was developed to determine the very low amounts of scopolamine excreted in the urine after transdermal administration of the drug. In spite of similar detection limits with this method (1.2 ng/mL) and that of Metcalfe (0.9 ng/mL) (11), scopolamine concentrations in plasma could not be measured after application of a transdermal delivery system. This could be explained by the different amounts of drug administered. While Metcalfe injected 2 mg im of atropine, the transdermal system only delivers 0.5 µg of drug/h to the blood.
