Pharmacokinetic Considerations in Obesity

ROBERT A. BLOUIN* AND GRAHAM W. WARREN

Contribution from *Division of Pharmaceutical Sciences, College of Pharmacy and Graduate Center for Toxicology, University of Kentucky, Lexington, Kentucky 40536-0082.*

Received April 22, 1998. Final revised manuscript received October 26, 1998.
Accepted for publication October 28, 1998.

Introduction

Obesity is a disease characterized as a condition resulting from the excess accumulation of body fat. In conjunction with increased stores of body fat, obesity has also been associated with increased mortality influenced by increased incidence of hypertension, atherosclerosis and coronary artery disease, diabetes, cancers of the breast, colon, prostate, endometrium, ovary, and cervix, and decreased overall survivability when compared with nonobese counterparts.[1−5] As a consequence, obese individuals generally require more therapeutic intervention earlier in life than nonobese individuals. A very important consideration for pharmacological treatment of obese individuals is the possible discrepancies between obese and nonobese individuals in pharmacokinetic and/or pharmacodynamic activities of a drug. Changes in pharmacokinetic parameters such as volume of distribution or clearance can significantly alter the pharmacologic impact of a drug; therefore, it is important to characterize the properties of drugs in obese individuals.

The direct causes of obesity are difficult to discern due to the plethora of physiological changes associated with obesity. Furthermore, characterizing metabolic and genetic differences between obese and nonobese individuals has proven complex resulting in broad scale attempts to study genetic and nutritional models of obesity in animals. These animal models can be used to help determine the possible causes and effects of obesity in humans resulting in possible agents to attenuate the causes and effects of obesity.

There have been several references reviewing the causes and pharmacological implications of obesity.[6−12] These show the effects of obesity on the pharmacokinetics of drugs in obese subjects; however, there have been considerable advances in the understanding of obesity, particularly in the genetic causes and changes in genetic expression asssociated with obesity. This article will attempt to comprehensively review current knowledge regarding obesity ranging from genetic and nutritional animal studies to pharmacokinetic studies of specific drugs in humans.

Obesity and Drug Absorption

The effects of obesity on absorption and overall bioavailability is poorly understood. In contrast to expected decreases in bioavailability associated with increased splanchnic blood flow in obesity,[23] the bioavailability of midazolam[13] and propanolol,[14] two compounds with moderate to high hepatic extraction, was shown not to be significantly different between obese and lean individuals. Body weight was shown to have no effect on the bioavailability of cyclosporine in renal transplant recipients.[15] No statistically significant difference in the bioavailability of dexfenfluramine could be established between obese and normalweight individuals.[16] Overall, studies indicate no significant difference in absorption between obese and lean subjects.

Obesity and Drug Distribution

The volume of distribution of a drug is dependent on a number of factors including tissue size, tissue permeability, plasma protein binding, and the affinity of drugs for a tissue compartment.[17] These factors can be affected by the

Published on Web 12/03/1998

physical and chemical properties of a drug in addition to the presence of many disease states. Obesity is a disease state associated with changes in plasma protein binding constituents[18,19] and increases in adipose tissue mass and lean body mass,[20] organ mass,[21,22] cardiac output,[23,24,25] cardiac size and blood volume,[23,24] and splanchnic blood flow[23] relative to normal-weight individuals.

A general trend has been observed for predicting changes in volume of distribution in obese subjects. Increasingly lipophilic substances, based upon the octanol/water lipid partitioning coefficients (LPC), are generally increasingly affected by obesity. Less lipophilic compounds, with lower LPCs, generally have little to no change in volume of distribution with obesity. There are exceptions to this generalization: cyclosporine, a highly lipophilic compound with a relatively large volume of distribution, has been shown in separate experiments to have comparable absolute volumes of distribution (V_{dss}) in both obese and normal-weight individuals.[15,26]

The effect of high lipid partition coefficients in barbiturates was demonstrated by Cheymol[8] when increasing LPC were correlated with increases in distribution into adipose tissue. Thiopental[27] and diazepam,[11,28] with corresponding LPC values of 676[29] and 309,[30] show significant increases in volume of distribution (V_{dss}) for obese individuals relative to normal-weight individuals. In both cases, the volume of distribution increased for both absolute volume of distribution and when normalized for total body weight. However, the absolute distribution (V_{dss}) of digoxin[31] and procainamide[32] has been shown to remain relatively consistent between obese and normal-weight individuals despite relatively high LPC values,[29,33] and the distribution of digoxin decreased in obese individuals when normalized to actual body weight.[31] Others have shown that digoxin does not have extensive distribution into adipose tissue.[34] These results are supportive of the explanation by Christoff et al.[32] that the high LPC values are too low to enhance distribution into adipose tissue. Ritschell and Kahl[33] have developed equations based upon several parameters (i.e., LPC, plasma protein binding, ionization, normal-weight volume of distribution, and body weight parameters) to help determine volume of distribution in obese individuals, but there has been little further experimental support of these equations.

Polar compounds have been shown to have several different relationships between body weight and volume of distribution. Theophylline, shown not to correlate well with ideal body weight (IBW) or total body weight (TBW),[35,36] was shown to adhere well to the following power equation suggested by Rizzo et al.:[37]

$$V_d \text{ (in liters)} = 1.29\text{TBW}^{0.74}$$

Several authors[38,39] agree that a better relationship between aminoglycoside volume of distribution and body weight is given in the following equation proposed by Bauer et al.:[40]

$$V_d \text{ (in liters)} = (0.26 \text{ L/kg})[\text{IBW} + (\text{CF} \times \text{AW})]$$

where CF is a correction factor between 0.2 and 0.5 and AW = TBW − IBW (adipose weight).

Neuromuscular agents are another group of generally polar compounds. The best method of calculating dosing strategies might be to base calculations on IBW. In one study, it was shown that the absolute volume of distribution (V_{dss}) of atracurium is unchanged in obese individuals.[41] At the same time, the volume of distribution corrected for TBW decreased. Some lipophilic substances, such as the β-adrenergic receptor blockers bisoprolol and nebivolol, also have volumes of distribution that decrease when corrected for TBW.[42,43] These decreased volumes of distribution when corrected for TBW indicate that these drugs distribute less into excess adipose tissue. Bisoprolol was shown to have an increased apparent volume of distribution but decreased volume when corrected for TBW. The authors concluded that these parameters indicated that bisoprolol distributed primarily into excess lean body mass relative to excess adipose tissue.

Plasma protein binding is an important determinant of a drugs pharmacokinetics. Changes in the concentrations of plasma binding proteins or alterations in the affinity of plasma proteins for substrate could affect the movement of drug into tissue compartments. The major plasma proteins are albumin, primarily responsible for binding acidic drugs, α_1-acid glycoprotein (AAG), primarily responsible for binding basic drugs, and lipoproteins. Studies have shown that drugs primarily bound by albumin (e.g., thiopental[27] and phenytoin[18,19,44]) show no significant changes in protein binding in obese individuals; however, the binding of drugs to AAG have been shown to increase and decrease in obesity. Benedek et al.[19] showed a significant increase in AAG concentrations in obese individuals with concomitant decreases in the free fractions of propanolol, principally bound by AAG. Cheymol et al.[45] showed no significant differences in AAG between obese and lean individuals; however, a decrease in volume of distribution of propanolol was observed which was more consistent with increased plasma protein binding. Derry et al.[46] also observed an increase in AAG with no change in the plasma free fraction of triazolam, a drug principally bound by AAG. These results indicate the possibility that plasma protein binding affinity may change in obesity without changes in protein concentrations. The plasma protein binding of verapamil, also associated with AAG binding, was unchanged between obese and nonobese individuals.[47] Due to higher triglyceride and cholesterol levels common in obesity, lipoprotein levels may be elevated in obese individuals; however the ramifications of elevated lipoprotein levels has been poorly studied and is not well understood to date.

The clearance of drugs can also be affected by obesity, though increases in clearance do not necessarily reflect changes in the half-life of a drug. The half-life of a drug can be related to both volume of distribution and clearance through the following relationship:

$$t_{1/2} = (V_d)(0.693)/\text{CL}$$

The half-life of a drug may increase without changes in clearance. Abernathy et al.[48] showed a significant increase in the plasma half-life of desmethyldiazepam without changes in clearance. Rather, the change in half-life was attributed to the increase in volume of distribution in obese individuals. LeJeunne et al.[42] demonstrated increased absolute volume of distribution (V_{dss}) and increased clearance of bisoprolol with no change in plasma half-life in obese versus nonobese individuals. These studies demonstrate the interrelationships between half-life, volume of distribution, and clearance as well as indicates the usefulness of volume of distribution and clearance over plasma half-life for a given drug.

Obesity and Drug Clearance

Changes in Metabolic Enzymes in Obese Humans—Measuring changes in hepatic metabolizing enzymes in humans is difficult due to the general lack of enzyme specific markers of metabolic activity. As a result, relationships are usually drawn between pharmacokinetic behavior

of a drug in humans and measured metabolic enzyme levels in animals. Important considerations are presented by the fact that fatty infiltration characterizes the livers of most individuals.[49] This fatty infiltration generally resembles mild alcoholic hepatitis in moderately obese individuals,[49] but morbidly obese individuals have markedly increased liver damage.[50] These factors could have a significant impact on the metabolic activity of the liver thereby dictating the importance of characterizing metabolism in obese individuals. There are some determinants of metabolic activity in humans that are generally considered as definitive markers for enzyme levels that have been used to show differences between obese and normal-weight individuals. These markers and the effects of obesity are discussed in the following paragraphs. Unless stated otherwise, clearance parameters are not normalized for body weight.

It was previously thought that hepatic oxidative metabolism was essentially unchanged in the obese individual when compared to a normal-weight individual. Caraco et al.[51] used obese and lean volunteers to evaluate the pharmacokinetics of antipyrine, a marker for hepatic oxidative metabolism. In the obese group, plasma half-life increased, apparent volume of distribution increased (but decreased when corrected for TBW), and the clearance remained unchanged. When volunteers were enrolled in a weight reduction program, obese individuals showed decreased half-life, decreased volume of distribution (increased when corrected for TBW), and a nonsignificant increase in clearance after losing weight. The nonsignificant changes in clearance indicate that the oxidative pathways employed by the liver for antipyrine metabolism remain unchanged between obese and normal-weight individuals; however, antipyrine undergoes extensive hepatic oxidative metabolism through multiple oxidative pathways, and a change in singular pathways would be difficult to assess.

Metabolism of chlorzoxazone to 6-hydroxychlorzoxazone has been used as a marker for hepatic cytochrome P450 (CYP) 2E1 activity in humans. O'Shea et al.[94] showed increased chlorzoxazone clearance in obese individuals as well as increased formation clearance of 6-hydroxychlorzoxazone from chlorzoxazone. The increase in chlorzoxazone clearance was attributed to increased CYP2E1 activity associated with obesity. The authors further stated that the increase in CYP2E1 activity may predispose obese individuals to CYP2E1-mediated toxicities associated with the production of toxic metabolites from environmental agents.

The formation of 6β-hydroxycortisol and *N*-methylerythromycin from cortisol and erythromycin has been shown to provide a general marker for cytochrome P450 3A activity in humans.[52,53] Hunt et al.[52] performed a study in volunteers to monitor the metabolism of cortisol and erythromycin to 6β-hydroxycortisol and *N*-methylerythromycin. Using these parameters as measures of CYP3A activity in humans, it was found that a negative correlation existed between percent IBW and *N*-methylerythromycin production. In contrast, cortisol metabolism showed no negative correlation between percent IBW and urinary 6β-hydroxycortisol/cortisol ratios. The authors thought that similar correlations should be drawn between percent IBW and *N*-methylerythromycin and percent IBW and 6β-hydroxycortisol/cortisol ratios. Another study by Hunt et al.[53] supported changes in CYP activity in humans by showing a negative correlation between erythromycin N-demethylation and percent IBW in elderly subjects. These contrasting studies demonstrate the difficulties associated with correlations between specific markers of drug metabolism and specific CYP isoform modulation.

Using drugs that are primarily transformed via Phase II conjugation pathways, glucuronidation and sulfation have been shown to increase in obese individuals. The clearance of oxazepam and lorazepam, benzodiazepines excreted primarily in the form of glucuronide conjugates, was shown to increase in obese individuals.[54] In another study, acetaminophen clearance was shown to increase with obesity,[55] though not as significantly as the increases shown with oxazepam and lorazepam.[54] It has been shown that acetaminophen is eliminated as both a glucuronide and sulfate conjugate in humans[56] whereas oxazepam and lorazepam are excreted primarily as glucuronide conjugates. It is likely that obesity affects different pathways through different mechanisms and levels: where glucuronidation might be significantly enhanced, sulfation may only be slightly to moderately enhanced due to obesity.

Other evidence supporting differential regulation of Phase II pathways are studies showing that the clearance of salicylate[57] and procainamide[32] is not significantly different between obese and lean individuals. Salicylate is conjugated to the glycine, phenolic, and acyl glucuronide, and procainamide is primarily acetylated. Together these results indicate that these pathways may not be significantly affected by obesity in humans.

Another interesting consideration in determining the metabolic activity of obese individuals is considering changes in metabolism in tissues other than the liver; specifically, due to the significant increase in adipose tissue in obese individuals, changes in metabolism within adipose tissue could be significant. Rafecas et al.,[58] using white adipose tissue from obese and lean patients, observed an increase in insulin cleavage in obese subjects relative to normal-weight subjects. In the absence of reduced glutathione, no insulin was cleaved, indicating that glutathione transhydrogenase, present in white adipose tissue, was likely the only enzyme responsible for insulin cleavage within white adipose tissue. The authors stated that hyperinsulinemia common in obesity may be offset by the substantial increase in adipose tissue possessing high intrinsic insulin cleaving activity. The results of this study point to the possibility that adipose tissue might play a significant role in energy regulation in obese individuals. Further evidence suggests that adipose tissue may play a role in the increased clearance of prednisolone in obese men.[59] The interconversion of prednisolone and prednisone is dependent on 11-hydroxysteroid dehydrogenase, an enzyme present in adipose tissue; therefore, the increase in adipose tissue may provide an alternative site of clearance for prednisolone.

In a series of studies, the pharmacokinetics of carbamazepine was evaluated in obese subjects before and after significant weight reduction[60] and in obese versus lean subjects.[61] In the first study, obese subjects were monitored to establish the pharmacokinetic parameters of carbamazepine, and then each subject was entered into a weight reduction program, regulating diet and exercise, after which the same pharmacokinetic parameters were assessed and compared for each individual. After significant weight reduction, the formerly obese individuals had a decreased plasma half-life, increased clearance, decreased absolute volume of distribution (Varea) with respect to bioavailability, and no significant change in Varea when normalized for total body weight. In the second study, relative to normal-weight individuals, obese individuals had increased absolute volume of distribution (Varea), increased plasma half-life, and unchanged clearance values. The disparity between changes in clearance remains unexplained, but it is important to note that obesity may be associated with changes in blood flow or metabolic activity. Further comparison between the two studies indicates that, for car-

bamazepine, the increased volume of distribution and half-life associated with obesity may involve reversible processes that may disappear following weight reduction.

Changes in Renal Function in Obese Humans

Elimination of a drug through the kidney can be accounted for by glomerular filtration, tubular secretion, and tubular reabsorption; however, there are several discrepancies regarding the influence of obesity on these functions. Davis et al.[62] and Stockholm et al.[63] have independently shown increases in glomerular filtration, measured using creatinine clearance, in obese women as compared to normal-weight women. Dionne et al.[64] has also shown increased creatinine clearance in obese subjects when compared to historical values of creatinine clearance; however, Ducharme et al.[65] showed decreased glomerular filtration via creatinine clearance in obese individuals from a patient population study of vancomycin pharmacokinetics. Reiss et al.[66] and Allard et al.[67] showed no significant difference between creatinine clearance in obese versus nonobese individuals. There are also discrepancies between studies of drug primarily excreted by glomerular filtration. Historical evidence has shown that the aminoglycoside antibiotics[68] including gentamicin[69,70] and vancomycin[71] are associated with increased clearance in obese individuals; however, recent evidence has shown that vancomycin clearance is unchanged in obese individuals greater than 1.3 times their IBW.[64] One possible explanation for these discrepancies might be due to the difference in extent of obesity and/or associated renal pathology.

Tubular function (i.e., tubular secretion and tubular reabsorption) in the kidney is often difficult to ascertain; thus, conclusions regarding tubular function are often indirect. Changes in tubular function have been indicated in several studies. The renal clearance of ciprofloxacin,[67] cimetidine,[72,73] procainamide,[32,45] and lithium[66] has been shown to increase in obese individuals. Since the renal excretion of ciprofloxacin,[92] cimetidine,[95] and procainamide[32] involves primarily glomerular filtration and tubular secretion, the increases in renal clearance of ciprofloxacin, cimetidine, and procainamide accompanied by a disproportionate increase in glomerular filtration supports increased tubular secretion in obese individuals. Renal clearance of lithium primarily involves glomerular filtration and tubular reabsorption;[93] consequently, the increase in the renal clearance of lithium with no increase in glomerular filtration[66] supports decreased tubular reabsorption in obese individuals.

Obesity and Drug Pharmacodynamics

A final but equally important consideration when developing a dosing strategy for an individual involves the consideration of drug efficacy. Obese subjects were shown to have increased sensitivity to triazolam as measured by a sedation score upon administration of a second dose.[46] The same dose of triazolam was used for both obese and nonobese individuals. Varin et al.[41] showed that even though obese individuals were exposed to significantly higher plasma concentrations of atracurium, no change was seen in the duration of neuromuscular blockade. The authors attributed this change in sensitivity to a combination of protein binding effects and desensitization of acetycholine receptors. Desensitization of acetylcholine receptors has been associated with chronic inactivity.[74,75] It is important to note that, with the plethora of probable genetic and nutritional changes associated with obesity, changes in receptor expression or affinity for ligand could be altered resulting in differential pharmacotherapeutic effects in obese individuals as compared to lean individuals.

Changes in Metabolic Enzymes in Obese Animals

The influence of pathophysiologic and morphologic changes associated with obesity on hepatic metabolism is not well understood. Before the late 1980s, studies correlating obesity-associated changes with either hepatic drug metabolizing enzymes (e.g., hepatic cytochrome P450) or drug markers (e.g., antipyrine) were nonexistent. In 1989, Corcoran et al.[12] showed no significant difference in CYP concentrations between obese and lean rats; however, total CYP increased per liver in the obese overfed rat. Beginning in the early 1990s, studies began showing changes in hepatic CYP resulting from obesity using both animal models and human markers. Studies dating as far back as the 1970s have indicated changes in Phase II metabolism pathways associated with obesity. The following paragraphs describe differences in Phase I and Phase II metabolism in obese animal models.

Research has been conducted to determine the effects of either genetically or nutritionally induced obesity in mice and rats. Irizar et al.[76] observed decreased total CYP expression in genetically obese (fa/fa) Zucker rats. When expressed as CYP activities per nmol of total CYP, CYP1A, CYP2B, CYP2E, CYP3A, and CYP4A were shown to increase in obese rats using specific substrates. Absolute CYP activities increased for CYP1A and CYP3A in obese rats whereas the increase in expression of other CYP isoforms resulted primarily due to the decrease in overall CYP levels. Anti-mouse CYP2D antibodies showed a decrease in apoprotein in obese rats when compared with normal rats. The investigators indicated the possibility that reduced growth hormone (reduced in obese male animals and shown to be partially responsible for the regulation of CYP3A expression) caused the increase in CYP3A activity. These results illustrate the possible ramifications of genetically induced obesity; however, parallels to humans are difficult to establish due to difficulty in characterizing the genetic causes of obesity in humans.

An alternative model of obesity uses nutritional modulation to induce obesity. Salazar et al.[79] previously reported an increase in CYP2E1 in obese overfed rats. Raucy et al.[77] used overfed Sprague Dawley rats to observe the effects of obesity on the expression of CYP2E1. Following 52 weeks of nutritional overfeeding, obese rats showed increased total CYP relative to control rats, unchanged CYP reductase and cytochrome b5, increased CYP2E1, and unchanged CYP2C11 and CYP3A. A strong correlation was also shown between CYP2E1 activity and CYP2E1 protein immunoblot staining thereby reducing the significance of posttranslational modifications common to CYP2E1. The authors further indicated that ketosis, often implicated as the mechanism by which CYP2E1 is increased, is likely not the primary mechanism of upregulation due to the fact that no significant increases were observed in CYP2B1 or CYP reductase activities also commonly associated with ketosis. Contrasting the genetic versus nutritional models, there appears to be a different mechanism of metabolic regulation influenced by either genetic expression or metabolic changes resulting in possible functional (i.e., enzymatic expression) and morphological (i.e., fatty infiltration in the liver associated with obesity) changes in obese rats. The importance of these factors could easily manifest itself by causing possible increases in toxicity following drug administration such as with the increased acetaminophen toxicity associated with obesity.[78]

Chaudhary et al.[80] provided evidence that glucuronidation increased and sulfation pathways were unaffected in

the genetically obese Zucker rat. Using acetaminophen as a substrate for glucuronidation and sulfation, the investigators observed no difference between urinary excretion of acetaminophen sulfate and increased urinary excretion of acetaminophen glucuronide in the genetically obese Zucker rat when compared to normal-weight rats. No change was observed for γ-glutamyl cysteine synthetase; however, total glutathione and UDPGT increased in obese rats relative to normal-weight rats. This is an important observation indicating that obese rats might have higher conjugation and detoxification pathways, but there is some discrepancy to this conclusion in that Barnett et al.[81] observed lower glutathione-S-transferase and total glutathione in genetically obese (ob/ob) mice indicating possibly higher susceptibility to toxicity in obese mice. The ob/ob mouse model associates noninsulin dependent diabetes with obesity which likely manifests differential enzymatic expression mechanisms than nondiabetes-associated obesity. Consequently, direct correlations between the two models is impossible, but the observation should be made that there are several presently unidentified mechanisms involved in obesity that could possibly result in the regulation and differential expression of many enzymes. An argument against the possibility that obese rats might have higher glutathione conjugation capacity is the fact that others have shown increased acetaminophen toxicity in obese rats indicative of depeted glutathione.[78]

Sastre et al.[82] used an overfed Wistar rat and Swiss mice model to demonstrate that overfed mice had lower levels of both reduced glutathione and oxidized glutathione than chow fed mice. This study seemed to parallel the study by Barnett et al.[81] using a genetically obese mouse model in that both models show a decreased propensity of obese mice for glutathione dependent conjugation and protection against cellular insult. The contrast mentioned before between obese Zucker rats and obese mice is also likely influenced by species specific differences in obesity, another complication in the elucidation and parallel application of obesity associated mechanisms involved in pharmacokinetic changes.

Contrasting the nutritional versus genetic models of obesity, differences can be seen between genetic obesity and nutritional obesity for both Phase I and Phase II enzymatic pathways. It should be noted that genetically induced obesity is targeted for a specific gene, but nutritional obesity can have effects on multiple genes that in turn can effect the expression of many other genes. Consequently, the pathways associated with nutritional obesity may be more variable and harder to elucidate. On the other hand, several current reviews[83–86] cover the genetic causes and effects of obesity should the reader be interested in broadening his/her knowledge of the genetic influences of obesity. Using genetic models, obesity has been linked to deficiencies in leptin, a hormone shown to be secreted by adipocytes[87] that reduces body weight and food intake in both obese and nonobese animals.[88] Research into the interactions of leptin with the body and the effects of obesity on leptin levels is generating volumes of new information into the molecular mechanisms of obesity and the possibilities that obesity might be under hormonal control. Several reviews[89,90] evaluate the current understanding of leptin and its relationship with the body.

Pharmacotherapeutic Toxicity in Obesity

The toxicity of substances can change with obesity. With possible increases in metabolism such as with the CYP system, drugs can be converted to toxic metabolites at higher rates; however, toxic drugs may also be converted to inactive metabolites at higher rates. Changes in the clearance, volume of distribution, bioavailability, or pharmacodynamics may affect the toxic potential of a drug. Additionally, changes in excretion mechanisms can alter the toxicity of a compound by either increasing exposure through decreased clearance or vice-versa. One study by Georgiadis et al.[91] observed the possible increases or decreases on the toxicity associated with the administration of a plethora of highly toxic chemotherapeutic agents to obese versus lean subjects with small-cell lung cancer. According to the study, no correlation could be established between obesity and increased toxicity for patients receiving cyclophosphamide, methotrexate, lomustine, etoposide, and cisplatin. Perhaps the most important conclusion to be drawn from the information presented in this article is that each drug behaves differently. Predicting toxicity associated with obesity is very difficult if not impossible. The best approach for pharmacotherapeutics in obese individuals is to use previous knowledge and be conservative. Careful monitoring of the obese patient is necessary when administering drugs with a small therapeutic index.

Summary

Using the parameters of volume of distribution and clearance, a therapeutic dosing strategy can be developed for a drug. Consequently, the effects of physiological disorders on these parameters is important for accurate pharmacotherapeutics. Regarding obesity, the volume of distribution has been shown to change in many situations. Generally, more lipophilic compounds are affected by obesity to a greater extent than hydrophilic compounds. More lipophilic compounds are associated with increases in volume of distribution in obesity; however, there are exceptions to this relationship. High LPC values did not correspond with markedly increased volumes of distribution for digoxin,[31] procainamide,[32] and cyclosporine.[15,26] Consequently, prior knowledge of the effects of obesity on specific drugs is essential for accurate dosing strategies based upon volume of distribution; generalizations among similar groups of drugs does not always result in proper physiologic responses between obese and lean individuals.

The clearance of a compound depends on the metabolic activity of characteristic enzymes that may be affected by obesity or diseases associated with obesity. Changes have been noted in both humans and animals for various CYP isozymes using either direct measurements (in animals) or through the use of metabolic markers (in humans) such as antipyrine or erythromycin. In addition, obesity has been associated with increased glucuronidation with questionable effects on sulfation. Changes between obese and lean subjects have also been observed for antioxidant systems including glutathione and catalase. It is important to note the variability in characterizing metabolic changes in obesity. Given the numerous possible genetic and environmental influences, predicting changes in metabolic activity can be difficult. Furthermore, there are possibilities that similar concentrations of a drug at its site of action may not elicit a similar response between obese and lean subjects, thereby making accurate therapeutic modifications more difficult for obese individuals.

Renal function, particularly glomerular filtration, has been shown to change with obesity. Increased glomerular filtration in some studies has been contradicted by decreases in glomerular filtration in other studies. These discrepancies illustrate the possible ramifications of different degrees of obesity, with morbidly obese individuals exhibiting different responses than moderately obese individuals. The effects of obesity on the toxicology of specific compounds is questionable depending upon not only the presence of enzymes that create toxic metabolites, but also

depending upon the presence of enzymes that remove toxic metabolites from the body. In conclusion, a safe therapeutic protocol for obese individuals should be based upon existing therapeutic information as well as careful monitoring of the patient during pharmacologic intervention.

Accepted for publication September 16, 1998.

Abstract □ The deamidation reactions of asparagine residues in α-helical and β-turn secondary structural environments of peptides and proteins are reviewed. Both kinds of secondary structure tend to stabilize asparagine residues against deamidation, although the effects are not large. The effect of β-sheet structures on asparagine stability is unclear, although simple considerations suggest a stabilization in this environment also.

Introduction

As peptides and proteins continue to enter the pharmaceutical marketplace, their stability becomes a pressing issue for the pharmaceutical sciences. One of the major routes of degradation of peptides and proteins that contain an asparagine (Asn) residue is the reaction illustrated in Figure 1, known as *deamidation*.[1] In deamidation, the NH center of the residue C-terminal to Asn attacks nucleophilically (with base catalysis) at the carbonyl center of the side-chain amide. Expulsion of ammonia produces a *cyclic imide* or *succinimide* derivative, which is activated toward hydrolysis. Hydrolysis occurs at both carbonyl centers, leading to a mixture of two products. Attack by water or water-derived species at the carbonyl center formed from the Asn side chain (the *β-carbonyl center*) produces a point-mutant peptide or protein in which Asn has been converted to aspartate (Asp), the *Asp product*. Attack at the carbonyl center derived from the backbone (the α-*carbonyl center*) produces a peptide or protein in which the un-natural amino acid iso-Asp has been incorporated into the backbone (the *iso-Asp product*). In some cases, the biological properties of the mutated proteins differ from those of the original material, and the degradation reaction is thus of pharmaceutical concern.

In the case of peptides or proteins that possess higher-order structure, the secondary, tertiary, or quaternary structural environment may affect the readiness with which deamidation can occur. Such an effect can arise in two different ways. First, the higher-order structure may place the Asn residue in spatial proximity to a functional group elsewhere in the primary sequence that is capable of accelerating or inhibiting the rate of deamidation. It is relatively difficult to generalize about effects of this kind, and they must be treated on a case-by-case basis. Second, the conformational properties of the Asn residue and the nearby peptide region containing it may be strongly conditioned by the nature of the structural environment that incorporates the residue. The work required to undergo the deamidation reaction, arising from such sources as strain energies that change on formation of the transition state(s) or vibrational entropy changes associated with the restriction of side-chain motions, may therefore vary substantially from one structural environment to another.

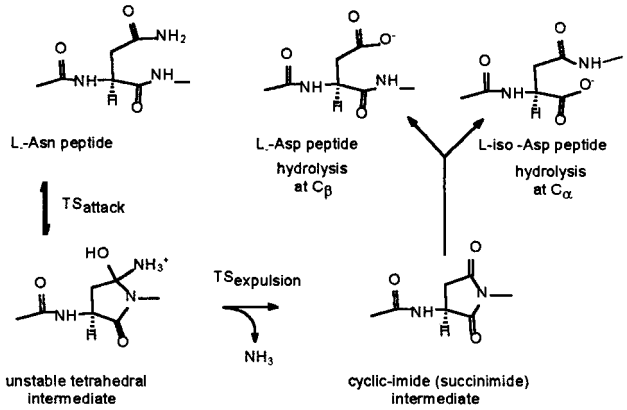

Figure 1—The mechanism of the Asn deamidation reaction at neutral and basic pH. The Asn-containing peptide (top left) undergoes base-catalyzed nucleophilic attack of the backbone NH center C-terminal to Asn on the side-chain amide carbonyl. This step, passing through the transition state TS_{attack}, leads to formation of the tetrahedral intermediate, an unstable species that never accumulates to observable concentrations. This unstable intermediate expels ammonia irreversibly in the transition state $TS_{expulsion}$ to generate the more stable cyclic imide intermediate at bottom right. This species accumulates to observable levels in the pH region 4–5, but decomposes as rapidly as it forms at higher pH. The cyclic imide undergoes hydrolytic attack at both carbonyl centers, leading to the Asp product and the iso-Asp product (upper right), the latter dominating in a ratio of 2:1 to 4:1. In addition to the reactions shown, racemization can occur by deprotonation of the chiral center in the ring, leading to racemized Asp product and iso-Asp product.

Examples of such effects have been provided by Kossiakoff,[2] who found that three of the 13 Asn residues of trypsin underwent relatively rapid deamidation. These residues (48, 95, 115) were characterized by a common conformation that favored the reaction and also by common hydrogen-bonding interactions with groups that could assist in the nucleophilic attack that occurs in deamidation. The conformation and the interactions were both results of the tertiary structure of trypsin.

In this minireview, we focus on secondary structural features and their role in governing deamidation rates. We further concentrate on experimental studies under highly defined conditions, omitting (with recognition of their great value) surveys of data collected under a range of conditions.[3,4]

Mechanism of Deamidation[5]

Figure 1 outlines the chief mechanistic features of the deamidation sequence as it occurs in the neutral and near-neutral pH regime (roughly pH 4−9). The cyclic imide intermediate is generated in a base-catalyzed reaction

involving deprotonation of the backbone NH center to generate a very small amount of the highly reactive conjugate base. Attack by this species at the side-chain amide function of Asn leads through the transition state labeled TS_{attack} to the tetrahedral intermediate shown. This species is very reactive and does not accumulate to observable levels. Instead, it decomposes either by return to reactant or by expulsion of ammonia to form the cyclic imide intermediate, the latter reaction occurring through the transition state labeled $TS_{expulsion}$. At the point when ammonia has been lost into the medium, return to the original reactant becomes very improbable, and the peptide or protein is committed to degradation.

Which of the two transition states is of higher free energy and thus governs the rate will depend on the pH and other factors, such as temperature and medium composition. The main form of the tetrahedral intermediate in the neutral region should be the cationic form because the pK_a of the ammonium-center is probably around 8.5 to 9. In this case, the choice of rate-limiting step is dictated by the relative ease of expulsion from the tetrahedral intermediate of the quite basic conjugate base of the backbone NH in competition with the less basic ammonia molecule. It is then likely that expulsion of ammonia is more rapid, and thus the rate-limiting transition state should be TS_{attack} for formation of the C−N bond.

The chemistry of decomposition of the cyclic imide intermediate to products is also mechanistically complex.[6] Unlike the tetrahedral intermediate, the cyclic imide accumulates to an observable extent under some conditions. Below and around pH 4, sizable concentrations of the cyclic intermediate may build up, and the material can often be isolated for independent study. At neutral and basic pH, base-catalyzed hydrolytic ring opening is rapid and precludes isolation or observation of the cyclic imide.

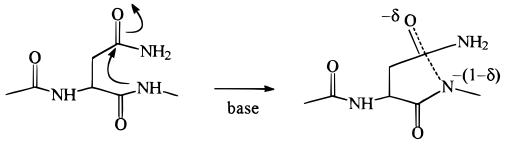
Hydrolytic attack occurs at both carbonyl centers of the cyclic imide, with attack at the (apparently) more sterically hindered C_α leading to the dominant iso-Asp product, and the less rapid attack at C_β leading to the Asp product. The ratio [iso-Asp]/[Asp] is quite generally around 4 in acidic solutions, tending toward 2.5−3 in more basic solutions. Very recent work[7] suggests that the determining feature in the regioselectivity is hydrogen bonding from the adjacent N-terminal NH, which promotes nucleophilic attack at C_α over that at C_β despite possible steric hindrance at C_α.

The roughly planar cyclic imide allows greater delocalization of electron density adjacent to C_α into the carbonyl group, rendering the C−H bond at the chiral center of the ring more acidic and more prone to removal by bases. Thus, conversion to a D-cyclic imide is possible. Hydrolysis of this species will lead to Asp and iso-Asp products of D configuration, and thus to partial or complete racemization.

Protein or peptide degradation becomes a certainty when formation of the cyclic imide intermediate, which is irreversible, is complete. The transition state TS_{attack} (Figure 1) is presumably rate-limiting in cylic-imide formation and it is therefore the effect of secondary protein structure on the free energy required to attain this transition state that determines how readily deamidation will occur in various protein or peptide secondary structural environments.

Structural Environment and Ring Formation

Prediction of the expected rate constant for deamidation under various circumstances remains a complex problem. The conversion of reactant state to TS_{attack}, as shown in eq 1, will require work equal to the free energy of activation ΔG^* and the rate constant will then be given by eq 2.



(1)

$$k = (kT/h)\exp\{-\Delta G^*/RT\} = (kT/h)\exp\{-\Delta H^*/RT + \Delta S^*/R\} \quad (2)$$

In eq 2, the free energy of activation (representing the total work of converting reactant state to transition state) is divided into its component parts ΔH^* and ΔS^*. The enthalpy of activation ΔH^*, measures such energetic quantities as the ring or conformational strain involved in formation of the new bond in eq 1, the energy requirement for partially breaking the amide carbonyl bond, the energy release for partial formation of the new C−N bond, the energy requirement for deprotonation of the backbone NH center, and any changes in solvation energies attendant upon conversion of reactant state to transition state. The entropy of activation ΔS^*, is a measure of the changes in molecular mobility or flexibility between reactant and transition states: loss of flexibility makes this quantity more negative, thus slowing the reaction, whereas increases of flexibility render the entropy of activation more positive, causing the reaction to proceed more rapidly. Clearly, the conformational flexibility of the molecule decreases on cyclization (loss of internal rotational entropy) but solvation changes, which will affect the translational mobility of the system, tend to be large and may contribute either positive or negative increments. The overall summation of effects contributing to ΔH^* and ΔS^* and thus to ΔG^*, thereby determining the rate constant of deamidation, is clearly a complicated matter about which generalization can be difficult.

Obviously, some of the features contributing to ΔH^* and ΔS^* will not be very sensitive to the secondary structural environment of an Asn residue in a peptide or protein. It is usually assumed that the energy changes associated with formation and fission of covalent bonds will be determined largely by the intrinsic chemistry of the nucleophilic reaction and will remain reasonably constant in various environments. On the other hand, the conformational contributions may be especially sensitive to the secondary structural environment.

Important Secondary Structural Elements

The complete enumeration of currently recognized elements of secondary structure in proteins and peptides would involve a large number of entries. A very useful summary has been given by Carter.[8] In this minireview, we will concentrate on the three most common secondary structural elements: the α-helix, the β-sheet, and the β-turn.

The α-helix consists of the right-handed coil in which every backbone carbonyl group is hydrogen-bonded to a backbone NH center of the fifth residue toward the C-terminus. All residues in an α-helix are conformationally equivalent in that their backbone dihedral angles are equal and all peptide bonds are in the trans configuration. Because all backbone NH centers of an α-helix are hydrogen-bonded, this factor alone might be expected to reduce the nucleophilic reactivity of the NH centers and thus the rate of deamidation of Asn residues in α-helices.

β-Sheets are structures obtained by alignment of fully extended peptide strands with all peptide bonds in the trans configuration so that all backbone carbonyl groups

of each strand are hydrogen-bonded to backbone NH centers in the adjacent strand, and vice-versa. The strands may be aligned either parallel to each other (C-terminus to C-terminus) or antiparallel (C-terminus to N-terminus). In either case, all NH centers are again hydrogen-bonded and will presumably exhibit reduced nucleophilic reactivity, and all residues are again conformationally equivalent.

The β-turns are present at points where strands of peptide reverse direction. Their defining feature is a hydrogen bond that unites the backbone carbonyl group of the first (N-terminal) residue of the turn to the backbone NH of the fourth residue (C-terminal) further on. The peptide bond between the second and third residues (the "middle peptide bond") defines a plane that is roughly perpendicular to the plane of the initial and final hydrogen-bonded peptide bonds. When the NH of the "middle peptide" is roughly trans to the side chain of the second residue, the β-turn is known as a Type I turn; when the configuration is roughly cis, the β-turn is known as a Type II turn. The simplest variants of these two types are Types I′ and II′ in which dihedral angles are reversed in sign while maintaining the other features unchanged. Other types of β-turns exist but are rare, and only Types I and II β-turns will be considered here. Each of the four residues involved in a β-turn is conformationally unique.

Clarke's Conjecture

Clarke[9] in 1987 noted that some generalizations about conformation and reactivity in deamidation are possible simply because, to react, the system must allow a juxtaposition of the nucleophilic backbone NH center and the electrophilic side-chain amide center of the Asn residue. The more difficult this juxtaposition, the slower deamidation should be, and the more readily the juxtaposition can be attained, the more rapid should deamidation become. Figure 2 illustrates this concept very schematically in terms of a *critical distance of approach* between nucleophile and electrophile for an Asn residue located in different secondary structural environments.

Clarke reasoned that secondary structural environments in which the conformation about the backbone bonds near an Asn residue favors a short critical distance of approach would be more likely to promote rapid deamidation than environments in which conformations favoring such an approach are not present. The side-chain conformation should also be important for deamidation but is unlikely to be affected systematically by the secondary structural environment. It is not certain how small the critical distance of approach actually must be at the deamidation transition state, but it is reasonable to expect that it is not greatly longer than the a typical C−N single bond (ca. 1.4−1.5 Å) because, according to Pauling's rule, a reduction in bond order by a factor of 2 corresponds to a lengthening of the bond by only 0.2 Å. Thus, a C−N bond of order 0.5 would be about 1.6−1.7 Å in length and a bond of order 0.25 would be about 1.8−1.9 Å in length. An Asn residue should, therefore, be protected with respect to deamidation in a structural environment that makes it hard to achieve critical distances of approach shorter than 2 Å.

In the most common types of secondary structure, the constraints imposed always predict a reduction in the rate of deamidation relative to the rate in a structurally unconstrained environment. Clarke's predictions suggest the following minimum critical distances of approach for different elements of secondary structure (see Figure 2 for schematic illustrations of these structures): α-helix, 2.5 Å; β-sheet (parallel or antiparallel), 3.5 Å; and β-turn (Type I or Type II), 3.1−3.3 Å. These distances are all so large as

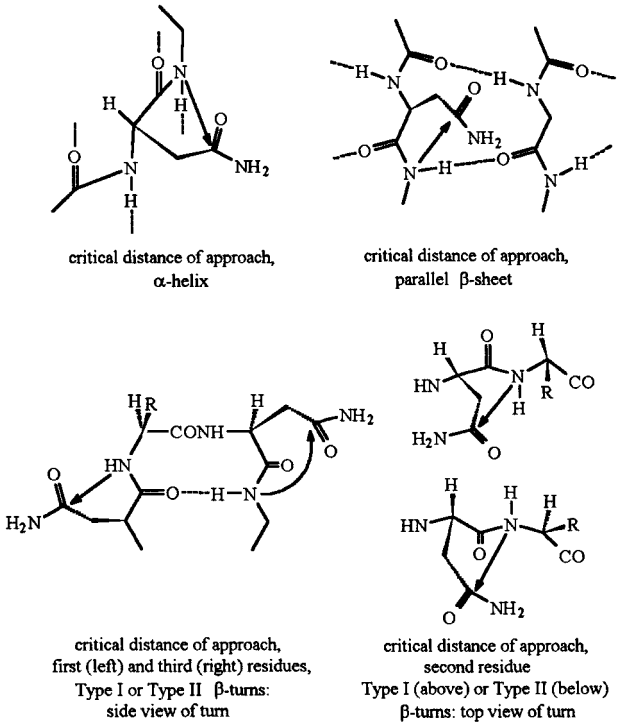


Figure 2—Schematic indications of the requisite directions of nucleophilic attack for Asn deamidation in various secondary structural environments. The arrows indicate the nucleophile–electrophile distance, which must be reduced to a critical value of less than about 2 Å to form the transition state TS_{attack}. Upper structures: α-helix (left) and β-sheet (right). The situation in the parallel β-sheet, which is shown, is not altered in the antiparallel sheet. Lower structures: β-turns. Left, first, and third residues of Type I or Type II β-turns, viewed from the side. Right, second residues of Type I (above) or Type II (below) β-turns.

to suggest that deamidation of Asn residues in any of these structural elements should occur less rapidly than for Asn residues in unstructured environments.

Clarke's estimates are based on the probability that the nucleophilic and electrophilic centers of an Asn residue in a particular secondary structural environment can reach the requisite critical distance of approach. It might be thought therefore that their origin should be in the entropy of activation ΔS^*. Despite the reasonable character of this idea, it is unlikely to be correct. Lightstone and Bruice[10] conducted an extensive investigation of the energetic factors involved in cyclic anhydride formation by intramolecular nucleophilic reaction of a carboxylate nucleophile with an ester electrophile. The conformation-dependent energetics of this reaction should be very similar to those in the deamidation reaction. Lightstone and Bruice showed that attainment of a "near-attack conformation," very similar to Clark's required critical distance between nucleophile and electrophile, requires both enthalpic and entropic contributions, and indeed the enthalpic components can be dominant. The same is almost surely true for deamidation.

Asparagine Deamidation in α-Helices

Asn is a somewhat infrequent residue in α-helices, being classified according to the Chou-Fasman rules[11,12] as a "weak helix-breaker." If the infrequency is caused by instability of Asn in the helical environment, the instability might suggest a more rapid rate of degradation. As already noted, the α-helical environment constrains the critical distance of approach to a quite long distance, which

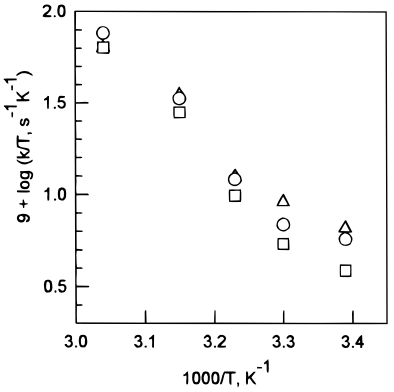

Figure 3—Eyring plot of deamidation rate constants determined by Bongers and co-workers[13] for deamidation at Asn-8 in the human growth-hormone releasing factor fragment hGRF(1–29) at pH 8 in aqueous solution at temperatures from 22 to 56 °C. The circles are for the wild-type (Thr-7 Gly-15), the triangles are for the Thr-7 Ala-15 mutant, and the squares are for the Pro-7 Gly-15 mutant.

suggests slow deamidation. Thus, from a general conceptual view, it is unclear what to expect.

Two experimental studies have been carried out in related model systems, and in fact have led to apparently contradictory results. Both make use of the structures derived from mammalian growth-hormone releasing factors (GRF), where Asn-8 is located in an α-helix. The helical region includes a glycine residue, Gly-15, which can be mutated to alanine (Ala), a helix enhancer, to increase the helical character or to proline (Pro), a helix breaker, to reduce the helical content. Alternatively, helical content may be reduced by mutation of threonine-7 to Pro.

Bongers and co-workers[13] obtained data that were interpreted as indicating that high helix content was associated with more rapid deamidation, and thus were contrary to the prediction of Clarke's conformational rule. They determined the deamidation rates at Asn-8 in aqueous buffers for the Ala-15 (high helix), Gly-15 (wild type), and Pro-7 (low helix) peptides (hGRF(1−29)NH_2) derived from human growth-hormone releasing factor, hGRF(1−44)NH_2. Data were obtained at five temperatures from 22 °C to 56 °C. Their findings are replotted as Eyring plots [log(k/T) versus (1/T)] in Figure 3.

The view of Bongers and co-workers is that the data for all three peptides fit a single temperature dependence at 37 °C and above. They attribute the roughly equal rates for the three to a proposed random-coil structure for all three peptides in this relatively high-temperature regime. The mutations at positions 7 and 15 were taken to have a minimal effect in the random-coil state on the deamidation of Asn-8. Bongers and co-workers then consider that the data disperse into three roughly parallel dependences in the low-temperature regime below 37 °C. The change in temperature dependences is postulated to be associated with a coil-to-α-helix transition occurring in the region around 37 °C.

In the low-temperature region, the Ala-15 peptide (assumed to have high helix content) reacts most rapidly, the Pro-7 peptide (assumed to have low helix content) reacts most slowly, and the Gly-15 peptide (assumed to have intermediate helix content) reacts at an intermediate rate. The structural assumptions were not confirmed by experiment. The low-temperature data thus, on this model, would indicate a fast reaction for the helix-enhancing mutant and a slow reaction for the helix-breaking mutant. This model suggests that presence in an α-helix renders an Asn residue *more labile*, rather than protecting it.

It is certainly clear that a single process is not at work throughout the temperature range represented in Figure 3: the plots for all three peptides are quite nonlinear. The *highest temperature* points suggest the following activation parameters for deamidation

$$\Delta H^* = \text{ca. } 10 \text{ kcal/mol (Ala-15)}$$
$$= \text{ca. } 14 \text{ kcal/mol (Gly-15 and Pro-7)}$$
$$\Delta S^* = \text{ca. } -50 \text{ eu (Ala-15)}$$
$$= \text{ca. } -35 \text{ eu (Gly-15 and Pro-7)}$$

The *lowest temperature* points suggest the following activation parameters

$$\Delta H^* = \text{ca. } 7.5 \text{ kcal/mol (Ala-15 and Pro-7)}$$
$$= \text{ca. } 4 \text{ kcal/mol (Gly-15)7}$$
$$\Delta S^* = \text{ca. } -60 \text{ eu (Ala-15 and Pro-7)}$$
$$= \text{ca. } -70 \text{ eu (Gly-15)}$$

Treated in this way, neither the high-temperature nor the low-temperature data support a systematic and simple interpretation: the similarities and differences in the rate constants (the largest range at any temperature is less than 2-fold) may arise from enthalpy−entropy compensation, although no credible claim in this direction is possible.

Some aspects of this study suggest that the break in the Eyring plots at around 37 °C may not arise from a thermal induction of helical structure. For example, the full-length GRF, hGRF(1−44)-NH_2, and the severely truncated peptide hGRF(1−29)-NH_2 exhibit equal rate constants for deamidation at the lowest temperature studied (22 °C, pH 8). This result is unexpected if helical character is present for the 29-mer but not for the 11-mer.

As Bongers and co-workers pointed out, the low-temperature data show a substantially lower enthalpy (or energy) of activation than is observed in many deamidation reactions. Further study must identify the anomaly that low temperatures are inducing in this particular case, although helical structure seems unlikely. One possibility is that aggregation of the peptides is occurring at the lower temperatures.

A later study gave results apparently in contrast to those of Bongers and co-workers, although the overlap between the two approaches is incomplete. Stevenson and co-workers[14] prepared the bovine GRF fragment [Leu^{27}]bGRF-(1−42)NH_2 with Gly, Ala, and Pro at position 15. Circular dichroism established that at 25 °C the overall helical content was 7.4% (Pro-15), 12.1% (Gly-15), and 17.7% (Ala-15). Addition of the helix-enhancing solvent methanol (MeOH) led to an increased helix content with preservation of the order seen in water: for 20% MeOH, the helical content was 16.3% (Pro-15), 28.6% (Gly-15), and 36.3% (Ala-15); and for 40% MeOH, the helical content reached 24.4% (Pro-15), 47.5% (Gly-15), and 52.5% (Ala-15).

For each of these circumstances, the deamidation rate constant for Asn-8 was determined at pH 10 in bicarbonate buffers (or the equivalent "pH" in aqueous methanol) at 37 °C. Figure 4 shows a plot in which the logarithm of the rate constant is related to the overall fractional helicity in the peptide. Although the errors are substantial, there is a discernible trend toward lower activity with greater helical character; the half-life times for deamidation increase from 6.9 h for the Pro-15 peptide in aqueous solution to 21.5 h for the Ala-15 peptide in 40% MeOH. Stevenson and co-workers therefore agree with the conclusion from Clarke's approach that presence in an α-helical environment protects Asn residues against deamidation, which stands in contrast to the interpretations put forward by Bongers and co-workers.

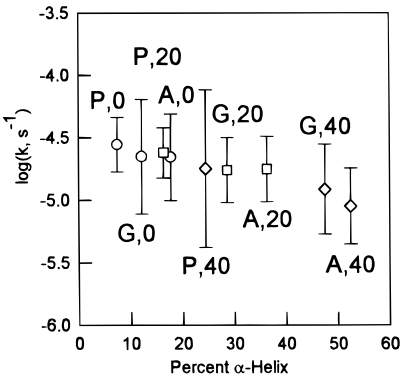

Figure 4—Plot of the logarithm of the rate constant determined by Stevenson and co-workers[14] for deamidation at Asn-8 in the bovine growth-hormone releasing fragment [Leu^{27}]bGRF(1–42)NH_2 at pH 10 in aqueous and aqueous–methanol solutions at 37 °C. Data are given for the wild-yype peptide Gly-15 (denoted by the letter G), for Ala-15 (denoted A), and for Pro-15 (denoted P). Each mutant was studied in three solvents: aqueous solution (circles; denoted by the number 0), 20% methanol/80% water (squares, denoted by 20), and 40% methanol/60% water (diamonds, denoted 40).

In neither of these studies are the rate effects attributed to α-helix incorporation large. Furthermore, in both studies, the methods used in attempting to control helix content may have given rise to other effects not connected with secondary structure. Bongers and co-workers introduced the presumed helix-breaking Pro at position 7, which is adjacent to Asn-8, the site of deamidation. This nearby structural change could have had effects on the rate not deriving from secondary structure. Stevenson and co-workers used methanol as a cosolvent to increase helix content. Brennan and Clarke,[15] however, have shown that the decreased dielectric constant in aqueous ethanol mixtures reduces the rate of deamidation; this effect will be at work in aqueous methanol solutions as well and will be superimposed on the conformational effect of the methanol. Bongers and co-workers attribute an acceleration of 1.8-fold in deamidation to the presence of Asn in an α-helix. In the work of Stevenson and co-workers, protection by a factor of 3 is attributed to presence of Asn in the α-helix. Thus without resolving the basis for the disagreement between these sets of results, one may tentatively conclude that deamidation rates are unlikely to vary by more than a factor of 10 on incorporation of an Asn residue into an α-helix.

Asparagine Deamidation in *β*-sheets

Clarke's approach indicates stabilization of Asn against deamidation when present in both parallel and antiparallel *β*-sheet structures, but no definitive study has yet been conducted to test this prediction experimentally.

One of the products of deamidation, the iso-Asp residue, does appear to induce *β*-sheet formation. The human *β*-amyloid protein undergoes deamidation at Asn-1 and Asn-7, giving rise in part to the iso-Asp residues at these positions.[16] Both polypeptides exhibit higher *β*-sheet content than does the native Asn polypeptide. This result suggests a lower free energy of the iso-Asp residue in the *β*-sheet than in other secondary structures, so that conversion of Asn to iso-Asp in *β*-sheet structures should be thermodynamically favored. For this thermodynamic effect to produce more rapid deamidation, the stabilization would have to be expressed in the deamidation transition state, which should occur only if this transition state resembled the iso-Asp structure. This effect is exceedingly unlikely because the rate-limiting transition state for deamidation must be one of those during irreversible formation of the cyclic imide intermediate, neither of which is related to the iso-Asp structure. Even in decomposition of the cyclic imide to the iso-Asp product, the transition state is more likely to resemble the ring structure than the open-chain structure. Thus the stabilization of the iso-Asp product by *β*-sheet structures is unlikely to be the cause of accelerated deamidation in *β*-sheets.

Asparagine Deamidation in *β*-Turns

Recent findings, described next, suggest that Asn located in any of the positions of a *β*-turn is stabilized against deamidation. This is also the prediction from the application of Clarke's conformational considerations (Figure 2). The same conclusion was reached for deamidation of Asn-12 in the HPr phosphocarrier protein,[17,18] a residue present in the third position of a Type I *β*-turn. This residue undergoes deamidation only under the very stringent condition of boiling water at basic pH. Furthermore, a number of proteins show faster deamidation in the unfolded form than in the native form for Asn residues located in *β*-turns of the native, folded structures or otherwise exhibit evidence of the stabilization of Asn or the related Asp residues in *β*-turn structures.[19–28]

In contrast, some crystallographic studies suggest that the transition state(s) for deamidation are stabilized in *β*-turns, and thus that deamidation should be accelerated in such structures. Capasso and co-workers[29] and Obrecht and co-workers[30] observed that structures containing a cyclic imide, such as Boc-L-Asu-Gly-OMe, exhibited a Type II′ *β*-turn in the crystal. The cyclic imide takes up the second position in the *β*-turn.

Because the cyclic imide structure is thus more stable when a *β*-turn is assumed, as shown by the preference for this structure in the solid state, it could be deduced that the presence of a *β*-turn would correspondingly favor conversion to a cyclic imide or to transition states resembling the cyclic imide. Because the transition state for deamidation is expected to resemble the cyclic imide, *β*-turns might well induce cyclization and deamidation. On the other hand, the adoption of the *β*-turn in the crystal structure might be conditioned by such features as crystal packing forces or the relatively nonaqueous environment of the crystal, and thus the conclusion derived from the crystal structure might not be accurate for proteins or peptides in solution.

In still unpublished work,[31] Asn-containing dipeptides were synthesized in cyclic forms, the N-terminus and C-terminus being united by the spacer, *ϵ*-aminocaproic acid. Such cyclic peptides assume a *β*-turn conformation, as was shown in these cases by nuclear magnetic resonance and circular dichroism spectroscopy. The deamidation rates of the cyclic *β*-turn mimics were compared with those of the open-chain analogues, which exhibited only random-coil structures. Universally, the *β*-turn structures showed slower deamidation rates than the random-coil structures. These results would suggest that *β*-turn structures indeed stabilize Asn residues against deamidation.

Summary

Two of the common forms of secondary structure (α-helices and *β*-turns) tend to stabilize Asn residues against deamidation. The effect is weak at best in α-helices, which may even destabilize Asn residues. Stabilization probably results at least in part from conformational restrictions, as deduced by Clarke, but may be additionally produced by the reduced nucleophilic reactivity of the backbone NH centers, which are hydrogen-bonded in α-helices and in all

except one position of the β-turns. Evidence is lacking for the third common form of secondary structure, β-sheets, but the prediction both from conformational considerations and from the reduced nucleophilicity of the backbone NH center is that stabilization would also be effected here.

Introduction

ADME (adsorption, distribution, metabolism, elimination) studies on new drug entities, toxicological studies on environmental contaminants, and evaluation of chemicals in the workplace all involve gathering similar types of information. Such studies rely on a combination of in vitro, ex vivo, and in vivo techniques. Among the in vitro and ex vivo systems are isolated enzymes, microsomes, cell cultures, tissue homogenates, tissue slices, and isolated organs. Information about the role of specific enzymes and tissues, types of intermediates formed, and pathways for xenobiotic biotransformation are gained through these types of studies. However, because they represent parts rather than the whole physiological system, the types of information gained do not reflect the entire scheme of biotransformation within the intact organism.

Traditional in vivo techniques include sampling blood and other biological fluids, analysis of elimination products to determine final disposition of the parent compound and metabolites, and tissue sampling requiring one or more animals per time point. These studies provide general information about the metabolism and final disposition of a compound, but do not offer details about specific enzymes, intermediates, or in vivo metabolic pathways. An overall limitation to traditional approaches is that results obtained in vitro sometimes do not correlate with those found in vivo.

Microdialysis sampling has several characteristics that complement traditional in vitro and in vivo pharmacokinetic and metabolism techniques. This approach is accomplished by implanting a probe consisting of a hollow fiber dialysis membrane into the organ or biological matrix of interest. The short length of hollow fiber is affixed to pieces of narrow bore tubing that serve as inlet and oulet conduits for the probe. A solution, termed the perfusate, is pumped slowly through the probe. The perfusate is an aqueous solution that closely matches the ionic composition of the extracellular fluid (ECF). When the perfusate is correctly matched to the ECF, there should be no net exchange of water or ions across the membrane. Low molecular weight compounds can diffuse into or out of the probe lumen in response to concentration gradients and are pumped to the analysis system.

A diagram of the process is shown in Figure 1. For clarity, the diagram shows only one analyte (A), although several compounds are typically sampled at the same time in a microdialysis experiment. Large molecules such as proteins (P) and small molecules bound to proteins (P-A) are excluded by the membrane. Those molecules entering the lumen of the membrane are swept along by the perfusate and exit the probe. The solution leaving the probe, termed the dialysate, is collected for analysis. The probe can be thought of as an artificial blood vessel in that it can both deliver and remove compounds from the local area. Delivery of the parent compound via the probe permits study of local metabolism without systemic involvement. Figure 2 shows a basic diagram of a microdialysis system for sampling from an awake, freely moving animal.

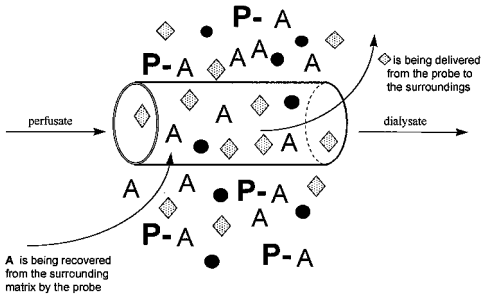

Figure 1—The microdialysis process.[37]

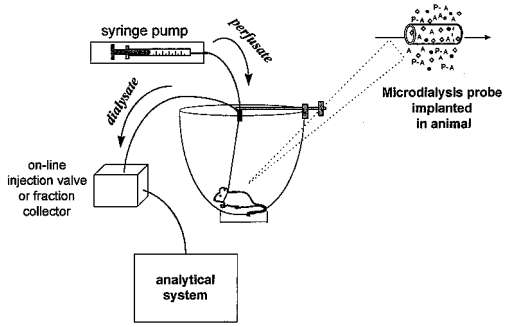

Figure 2—General diagram of microdialysis system for sampling from an awake, freely moving animal. The analysis may be performed on a variety of analytical systems, and coupling between the analytical and microdialysis systems may be on- or off-line.

Microdialysis is an established in vivo tool in the neurosciences and has been used in vitro and in peripheral tissues for a variety of applications of pharmacological and metabolic interest. Samples obtained by microdialysis represent a local profile of low molecular mass hydrophilic substances in the area surrounding the probe. For compounds of pharmaceutical interest, the dialysate reflects the free fraction of the compound of interest, which is the therapeutically active portion of the dose. Microdialysis sampling does not change the net fluid balance in the surrounding matrix or tissue, so higher temporal resolution can be achieved than with traditional techniques. Also, because there is no net fluid loss, samples can be collected continuously for hours or days from a single animal. Most importantly, each animal can serve as its own control, reducing the number of experimental animals needed.

Typically, sampling in vitro from various incubation mixtures or in vivo from blood or other fluids involves

manipulation of small volume samples and multiple step cleanup procedures, which produces poor temporal resolution relative to physiological or pharmacological events. Elimination products and tissue samples also require extensive sample cleanup prior to analysis. Because microdialysis sampling provides protein-free samples, loss of analyte during protein precipitation is avoided. Enzymes are also excluded from the dialysate sample; thus, there is no further enzymatic degradation of the sample.

Optimization of Microdialysis Sampling

Probe Design, Surgery, Tissue Response—The small size of the dialysis probe, nominally 300 μm o.d. with an active window in the range 4−10 mm in length, causes minimal perturbation to the tissue. Therefore, the technique can be used in awake, freely moving animals, and the integrity of tissues, organs, and systems is maintained. Several different probe geometries have been developed to facilitate in vivo sampling from various sites. Those commonly used are shown in Figure 3. The designs are of two general types: parallel and serial. Parallel perfusion probes are constructed of rigid or flexible cannula material and may have either a side-by-side or concentric arrangement. Probes with rigid cannulae are especially suited for intracerebral sampling, whereas those with flexible cannulae work well for venous sampling. Serial perfusion probes include linear and loop styles. They are typically used for sampling soft peripheral tissue such as skin, muscle, tumor, and liver. The shunt probe suspends a linear probe within a larger tube, allowing sampling from flowing fluids (such as bile or blood) without permanent diversion of the fluid.[1,2]

Several modified probe designs have also been reported, including a spinal loop dialysis catheter for use in sampling the spinal intrathecal space of unanesthetized rats[3,4] and a flexible intravenous probe for use with unanesthetized small animals.[5,6] In 1995, Kanthan et al.[7] described a method for microdialysis sampling in the human brain. This technique utilizes a Codman bolt kit, typically used to monitor intracranial pressures, and a custom-designed microdialysis probe with a probe sheath to accommodate variations in skull thickness. Using this system, five monoaminergic neurotransmitters[7] and glucose-induced decreases in glutamate levels[8] were monitored during acute focal ischemia.

Although the small size of the microdialysis probe causes minimal perturbation to the tissue, the surgery to implant the probe is invasive. Experimental animals are anesthetized during probe implantation, and the anatomical location of the target tissue dictates the duration of anesthesia and the severity of the surgical invasion. For example, probe implantation into the dermis or muscle is much less invasive to the animal than implantation in the liver or bile duct.

A few groups have examined tissue response to probe implantation and to indwelling probes. For intracerebral microdialysis, compromise of the blood−brain barrier (BBB) upon implantation of the guide cannula and/or probe must be considered. Benveniste and Hüttemeier[9] and deLange et al.[10] have reviewed the literature concerning BBB compromise and brain tissue response to probe implantation. One approach to evaluating the integrity of the BBB is to employ markers that do not normally cross the barrier. Several of these types of studies, which suggested that the BBB was generally intact within a short time after the surgery, are discussed in the reviews already mentioned. Other studies, however, have concluded that the BBB remains compromised for 24 h or longer after implantation takes place.[11−13] A second approach used to

assess changes in the BBB is to monitor alterations in the transport of a compound across the BBB after injection of compounds known to open the barrier. Again, conflicting results have been reported.[12,14] A study by Allen et al.[14] suggested that the rate of insertion of the probe into the tissue affects the amount of BBB damage and could account, to some extent, for the differing results.

Several publications from the laboratory of C. Lunte[15–17] have reported the responses of different tissues to the presence of a microdialysis probe over time. The tissues examined include dermis,[15] muscle and tumor,[16] and liver.[17] Dermis, muscle, and liver showed the expected acute inflammatory response, with the initial invasion of neutrophiles followed by macrophages. Tumor tissue showed little or no inflammatory response up to 72 h. Davies and Lunte[17] tested probes of various designs in liver tissue and found that using a 'needle' with a diameter smaller than that of the membrane minimized the extent of cell damage.

Quantitation Issues and Extraction Efficiency—Microdialysis sampling is not typically performed under equilibrium conditions, so the concentration of the analyte determined in the dialysate is some fraction of its actual concentration in the surrounding sample matrix. The relationship between the concentration of analyte in the dialysate and that of the sample matrix may be thought of as the extraction efficiency (EE) of the probe. Among the parameters that influence EE are temperature, perfusate flow rate, chemical and physical properties of the dialysis membrane, probe geometry, membrane surface area, and properties of the analyte. The diffusion rate of the analyte within the matrix also affects EE. In vivo uptake into cells, metabolic rate, extent of tissue vascularization, and blood flow will influence diffusion through the tissue.[18–20] Fortunately, under normal conditions of microdialysis sampling, these parameters remain constant; thus, a steady state is rapidly achieved although equilibrium is not established. Therefore, the EE of the probe for a given set of parameters is constant and the direction of net flux of the analyte across the membrane is determined by the concentration gradient of the analyte. In practice, the EE of the probe may be determined by recovery or delivery experiments.

Calibration of Microdialysis Probes—A major concern in the wider adoption of microdialysis sampling for pharmaceutical studies is the calibration of the microdialysis probes. Microdialysis is generally performed under nonequilibrium conditions where the recovery of a compound depends on many parameters. Recoveries ranging from <1% to >99% can be achieved. It is not always clear whether a high or low recovery is preferable. High recoveries are favored from the analytical perspective because higher concentrations are obtained. A high recovery also results in less depletion of the concentration around the probe because the situation is closer to equilibrium (i.e., the concentrations inside and outside the probe are the same). However, high recovery is typically achieved either using very slow perfusion rates or long dialysis membranes. Using a very slow perfusion rate leads to a loss of temporal resolution because of the relatively large sample volume requirement of most analytical methods. Higher recoveries can be obtained with large sampling windows; however, a loss of spatial resolution is the drawback. Low recoveries, on the other hand, result in less concentrated samples for analysis and a greater decrease in the analyte concentration around the microdialysis probe. However, these limitations may be offset by the fact that higher perfusion rates and shorter dialysis membranes can be used.

Although an in vitro determination of recovery provides a crude estimate of the behavior of a microdialysis probe with a given compound, extrapolating such a value to an in vivo experiment is impossible[21–24] because the nature of the tissue to be sampled and its interactions with the analyte affect the recovery. For many experiments, accurate calibration of the microdialysis probe is not necessary. For example, if the desired information is the relative change in concentration brought about by some experimental manipulation, only the concentration independence and stability of the recovery need be known. On the other hand, if a relative distribution of a compound to various sites is the information desired, then the behavior of each probe used must be normalized versus the other probes. Only when an absolute concentration is needed must each probe be calibrated for an accurate in vivo recovery. As this is often the most difficult step in a microdialysis experiment, careful experimental design should be practiced. If the desired information can be obtained from relative rather than absolute concentrations, the calibration issue is greatly simplified.

Calibration for Hydrodynamic Systems—Systems in which the sample is a flowing fluid, for example the blood and bile, present a special case for microdialysis sampling. Mass transfer in the sample is dominated by diffusion through the probe membrane rather than by diffusion through the surrounding tissue for such systems.[25] Diffusion must occur through a thin layer of stagnant fluid around the membrane. The thickness of this diffusion layer is a function of the velocity of the sample fluid. At low sample flow rates, the diffusion layer is thicker and diffusion through it is the rate-limiting step for microdialysis sampling. As the sample flow rate increases, the diffusion layer collapses and diffusion through the dialysis membrane begins to dominate. Eventually, diffusion through the dialysis membrane becomes the rate-limiting step, after which further increases in the sample flow rate do not affect the microdialysis process.

For hydrodynamic systems, an in vitro calibration can provide accurate recovery values if the perfusion flow rate and sample temperature are well controlled and the characteristics of the membrane do not change during the experiment. Because the membranes are hydrophilic and used in an aqueous environment, physical changes in the membrane are not likely. However, one must always be concerned that physiological responses to probe implantation may result in changes to the membrane environment. For example, there have been reports of the formation of clots around microdialysis probes implanted intravenously. Careful experimental design will usually prevent such problems, but one must always keep this possibility in mind.

Calibration in Tissues—A more difficult case is the use of microdialysis sampling in tissues, particularly those that are poorly perfused. It has been demonstrated that the recovery of a microdialysis probe depends on mass transport in three regions: the probe lumen, the dialysis membrane, and the sample medium.[18,23,24] The first two regions can be characterized in vitro and controlled. Mass transport in the probe lumen is limiting only when using very low perfusion rates, whereas transport through the dialysis fiber is limiting only when transport through the sample is rapid. Rapid transport through the sample occurs in most hydrodynamic systems as well as in highly perfused tissues. However, in most tissues, transport through the tissue determines the recovery of the microdialysis probes.[18,24] Under these conditions, calibration performed in vitro may not be valid in vivo. A number of approaches to the calibration of microdialysis probes in vivo have been described. The two most common methods involve (1) adding an internal standard to the perfusate, which is commonly known as "retrodialysis," or (2) estimating the equilibrium condition by adding varying concentrations of

analyte to the perfusate, which is known as the method of zero net flux. Alternatively, very slow perfusion rates can be employed, often circumventing the need for calibration.

Slow Perfusion—Justice et al.[26] have shown that at perfusion rates of <50 nL/min, recovery is >95% for compounds with molecular weights <500 Da. At such a slow perfusion rate, the error introduced by assuming 100% recovery is insignificant. One drawback to this approach is the difficulty in the collection and analysis of the dialysate sample. Off-line analysis generally requires at least 2 μL of sample. The use of on-line systems, such as microdialysis coupled to capillary electrophoresis or capillary liquid chromatography, makes it possible to analyze nanoliter volumes of sample.

Retrodialysis—In the retrodialysis method, an internal standard is added to the perfusate and the rate of delivery of this compound to the tissue is measured during microdialysis sampling.[27–30] The assumption is made that the recovery of the analyte is equal to the delivery of the internal standard. This method requires that the internal standard and the analyte behave in exactly the same manner. This requirement is usually met with regard to the diffusion coefficient of the two compounds, but is generally overlooked in terms of metabolism. Essentially, the internal standard and the analyte must be metabolized in an identical manner to provide a proper calibration of the probe. Of course, if this requirement were met, the internal standard could disrupt the experiment because it is being added to the system in relatively highly concentrations exactly at the site of sampling.

Method of Zero Net Flux—In the method of zero net flux, various concentrations of analyte are added successively to the perfusate.[31,32] The amount of analyte either lost or gained during dialysis is then determined. If the perfusion concentration is greater than the in vivo concentration, a loss has occurred; if the perfusate concentration is less than the in vivo concentration, there has been a gain. Only when the perfusate concentration and the in vivo concentration match has there been no net change in concentration because the system is at equilibrium. A plot of the change in concentration of dialysate versus the initial concentration of perfusate is made; this should result in a straight line. The slope of this line is the inverse of the concentration recovery and the y-intercept is the actual sample concentration. At this concentration, there is no net diffusion of the analyte into or out of the microdialysis probe, because the concentration in the sample and in the probe lumen is the same.

The method of zero net flux is more accurate than retrodialysis in that the actual compound of interest is used for calibration; however, it is a very time-consuming process. The precision of this method is highly dependent on the precision of the individual concentrations determined and the number of perfusion concentrations used. Several hours—up to 12 in some cases—are required to collect sufficient data at the various concentrations of standard added to the perfusate to provide an accurate estimate of the equilibrium state. During this time, the concentration of the analyte in the sample must remain constant. This requirement limits the use of the method to the determination of basal levels of endogenous compounds and steady-state concentrations of drugs during constant infusion experiments.

Delivery—Determining the delivery of the actual compound of interest is a variation of retrodialysis that overcomes the uncertainty introduced by using a standard to mimic the analyte.[15,33] First, the fact that the delivery is equal to the recovery is verified in vitro. This step serves to confirm the viability of the microdialysis probe. If the delivery and recovery are not equal for a given microdialysis probe, that probe is discarded. After the probe is implanted and the animal has recovered from surgery, the deliveries of the test compound and any other analytes of interest are determined prior to the start of the experiment. Finally, if possible, the deliveries are determined again after completion of the experiment. This procedure will verify any changes in the behavior of the probe during the course of the experiment. If the viability of the probe is tested prior to implantation, its behavior will not change during the course of the experiment within the constraints of tissue response, as was discussed previously. The shortcoming of this approach is that recovery changes resulting from the experiment are not detected. For example, administration of a vasodilator or constrictor can change recovery in a poorly perfused tissue by changing the blood flow. In general, changes in recovery as a result of experimental manipulation are more common when studying endogenous than exogenous compounds.

The various calibration methods are summarized in Table 1. Before undertaking in vivo calibration, the experimentalist should consider what information is desired from the microdialysis experiment. The need for in vivo calibration will generally fall into one of three categories. In the first, two states (such as basal versus excited or formulation A versus formulation B) are compared. In these cases, changes in analyte concentration usually provide sufficient information. Here, one does not need an exact EE value but, rather, a constant EE over the time course of the experiment. In this case, the behavior of the probe can be tracked using retrodialysis. In the second category, one needs to know only the order of magnitude of the analyte concentration in ECF. In other words, is the analyte present at 10 ng/mL or 100 ng/mL? In vitro calibration may be sufficient because it usually differs by not more than two or three times the in vivo value. If the EE is 60% in vitro and 30% in vivo, the concentration of analyte in the in vivo dialysate corrected for the in vitro EE will be within the order of magnitude of the analyte concentration in ECF. In the third category, where an accurate in vivo concentration is required, the in vivo EE must be determined for the analyte in the target tissue. The approaches that can be used to obtain this information include very low flow rates, zero net flux, and in vivo delivery of the analyte.

Analytical Considerations

Several features of microdialysis sampling are of considerable importance in the development of the analytical method. Because of the low flow rates employed, microdialysis typically results in small sample volumes of 1–10 μL. The process also inherently dilutes the samples as they are collected. Therefore, small volume samples, often with low analyte concentration (1 pM–1 μM), are typical and present a considerable challenge to the analyst.

From the analytical perspective, there are two primary considerations with respect to extraction efficiency. First, except in cases of local delivery via the probe, the dialysate concentration will be less than the actual tissue concentration of the analyte. Thus, the limit of detection must be less than the lowest in vivo concentration expected. Second, extraction efficiency increases as perfusion rate decreases. The slower the perfusion rate, the closer the dialysate concentration of the analyte will be to that in the sample matrix surrounding the probe.[34]

Increased temporal resolution is one of the advantages of microdialysis over blood sampling and traditional tissue sampling. For traditional blood sampling, the total fluid that can be withdrawn is limited, so the number of points that can be obtained is small. In traditional tissue sam-

Table 1—Approaches to In Vivo Calibration of Microdialysis Probes

method	description	considerations	reference
extrapolation to zero flow rate	An estimate of analyte concentration surrounding the probe is obtained by extrapolating to zero flow rate, where analyte concentration in the tissue and in the probe would presumably be in equilibrium.	Requires determining the recovery of the probe at several flow rates with the analyte at a steady-state concentration in the matrix throughout the determinations.	35
use of very low flow rate	This extension of the aforementioned method carries out microdialysis sampling at a flow rate (ca. 50 nL/min) where the probe recovery is >95% so that assuming 100% extraction efficiency introduces negligible error.	Practical considerations include long sampling intervals to collect sufficient volume for analysis and problems manipulating small-volume samples such as evaporation.	26
zero net flux	With the analyte at a steady-state concentration in the tissue, the probe is perfused with a succession of solutions containing known concentrations of the analyte. A plot of the change in perfusate concentration versus the initial perfusate concentration should be linear with the slope being the inverse of the probe recovery and the y-intercept being the point of zero net flux; that is, the concentration of the analyte in the tissue.	Tissue concentration of the analyte must remain at steady state, whereas the EE of the probe is determined for several different initial analyte concentrations in the perfusate.	31, 32
retrodialysis	Uses the in vivo delivery of an internal standard (usually an analog or mimic of the analyte) in the perfusate as the basis for probe calibration. The method assumes that the in vivo recovery of the analyte has a constant known relationship to the in vivo delivery of internal standard. In some cases that relationship is determined in vitro and assumed to hold in vivo.	The advantage of this method is convenience, especially in terms of time. The experimentalist should consider that, in a biologically active matrix, delivery of an internal standard that binds to receptors or is metabolized in the same way as the analyte will introduce unwanted perturbations in the tissue area being sampled.	27–30, 36
in vivo delivery of the analyte	A variation of retrodialysis that overcomes the uncertainty introduced when an analog is used as the internal standard. Essentially, the in vivo delivery of the analyte to the target tissue is determined before the actual experiment. If possible, the delivery is determined again after completion of the experiment to confirm that the probe behavior has not changed.	The method is simple, convenient, and has a minimal time requirement. This method assumes that the extraction efficiency of the probe in the tissue of interest is constant regardless of the direction of the concentration gradient of the analyte. The assumption should be validated for analytes and tissues of interest.	15, 37

pling, several animals must be sacrificed at each time point, and, thus, the frequency of time points is usually small to minimize the total number of animals used in each study. With microdialysis sampling, the same type of study can be conducted using only a few animals and, because there is no fluid loss or need to remove tissue, data can be collected continuously. The animal can also serve as its own control.

The temporal resolution of a microdialysis study is defined by the time interval at which the microdialysis samples are collected; it is dependent on the sensitivity and sample volume requirements of the analytical method as well as the recovery of the probe. Microdialysis provides a continuous flow of sample, whereas most analytical systems require discrete samples. Individual samples can be collected off-line with a fraction collector, but the sample volumes are very small due to the low perfusate flow rates used (typically 1 μL/min or less). If the analytical system requires a larger sample for injection or the method is not sensitive and requires a preconcentration step, larger volumes may be collected, albeit at the expense of temporal resolution. Overall, the analytical method with the lowest detection limit and smallest sample volume requirement affords the best temporal resolution for microdialysis experiments.

Another approach to overcoming problems associated with handling small volume samples is on-line coupling of the microdialysis system with the analytical system. This method minimizes the delay between sample collection and analysis and eliminates the problems of evaporation that can occur during any physical manipulation of small volume samples. Near real-time data on physiological events can be obtained, but the temporal resolution achieved by the coupled system will depend on the time needed for analysis (i.e., the analysis time must be less than the duration of the physiological event). Reviews of on-line coupling of microdialysis with LC and microseparation techniques are available.[38,39]

Three-Way Trade-Offs—When microdialysis sampling is applied in vivo, three previously independent systems become interlinked: the animal, the microdialysis sampling system, and the analytical system. The experimentalist must be aware that once these systems are linked, the conditions that were optimal for each element independently must now be considered in relation to the others. Frequently, the sample volume requirement of the analytical method necessitates increasing the microdialysis perfusion rate, which in turn lowers the extraction efficiency of the probe, thus providing samples with lower concentrations of analyte. Using a lower perfusion rate to increase probe efficiency and analyte concentration results in longer sampling times. Some degree of temporal resolution is lost through this compromise. In addition, the increased recovery may deplete compounds of low molecular mass in the tissue adjacent to the probe, in turn perturbing the biological system. The anatomical location and spatial resolution needed for obtaining the desired information influence the probe design and active window length. Although implantation of a microdialysis probe may cause little disruption of the target organ, the necessary anesthesia and extent of the surgical procedure also impact the biological system. The successful use of microdialysis sampling in vivo will depend on achieving a suitable balance among these systems.

The trade-offs among perfusate flow rate, concentration detection limit, and sample volume requirement will decide the temporal resolution that can be achieved for the experiment. A clear statement of the experimental question should dictate the balancing of the microdialysis sampling and analytical method parameters.

Analytical Methodologies

One of the main advantages of microdialysis sampling is that it can be used in conjunction with a wide range of analytical techniques. Non-separation-based methods can

be used to monitor one analyte at a time, and separation-based methods allow the detection of multiple analytes in each sample. This section will provide a brief overview of the considerations that must be heeded when coupling microdialysis sampling to various analytical techniques. Specific references will also be given in cases where the use of the analytical technique or the method of coupling to microdialysis sampling is novel.

Non-Separation-Based Sampling Approaches—In an attempt to further understand the complex nature of biological events, the idea of making real-time analytical measurements has attracted much attention. These types of measurements are achievable when using a continuous detection device, such as a biosensor. Microdialysis provides a possible alternative to implantable sensors. When on-line biosensors are used with microdialysis sampling, the apparatus typically consists of a syringe pump, a microdialysis probe, and a sensor or an enzyme reactor, followed by an electrochemical detector. The enzyme is present to provide specificity and to generate a redox-active species that can be detected electrochemically.

Although the response time of an on-line biosensor system coupled to microdialysis sampling is slower than that of an implantable modified microelectrode, the former is more quantitative and provides a higher conversion of analytes, a longer lifetime, and easier calibration. One disadvantage of biosensors is fouling of the electrode, usually by proteins. Coupling microdialysis sampling with a biosensor overcomes this problem because of the size-exclusion nature of the membrane. In vivo implantation of biosensors places size restraints on the dimensions of the electrode. Using a microdialysis probe in vivo reduces these restrictions on the biosensor.

One example of this methodology is the monitoring of extracellular L-glutamate with a microdialysis-based on-line biosensor subsequent to stimulation of cultured nerve cells.[40] A sensitivity of 24.3 nA/μM and a limit of detection of 7.2 nM for L-glutamate was reported with this system. In vivo levels of L-glutamate were also continuously monitored using microdialysis coupled to an enzyme-amperometric biosensor following cardiac arrest and K^+-induced local depolarization.[41] A limit of detection of 0.5 μmol/L was reported. In both of these examples, glutamate oxidase was employed to oxidize L-glutamate in the presence of oxygen, generating hydrogen peroxide, which was detected electrochemically. Similar sensors were applied to the real-time monitoring of lactate in the subcutaneous tissue of rabbits and humans through the use of microdialysis sampling and a lactate amperometric sensor;[42] glucose was monitored continuously with a glucose-oxidase-immobilized enzyme reactor.[43]

However, biosensors are not always used for continuous monitoring. Using injection valves, discrete microdialysis samples were injected into flow injection systems and analyzed with amperometric-based biosensors for L-lactate[44] and glucose.[45] A miniaturized flow injection thermal biosensor coupled with microdialysis sampling has been reported for the determination of glucose in subcutaneous fluid with a sampling rate of 42 samples/h.[46] Advantages of a flow injection analysis system are the ability to provide for on-line sample dilution, required when analyzing concentrated samples, and the capacity to periodically recalibrate the biosensor with standard solutions. Other non-separation-based methods without continuous monitoring have been reported, including immunoassays[47–49] and mass spectrometric analyses.[50,51] On-line interfacing of microdialysis and mass spectrometry (MS) has been reported for the analysis of tris(2-chloroethyl) phosphate in rat plasma,[52] along with the utilization of microdialysis for on-line sample cleanup of nucleic acid[53] and protein and peptide samples.[54]

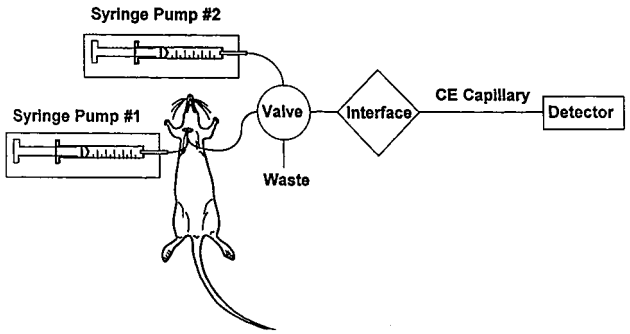

Figure 4—Schematic of the on-line microdialysis/capillary electrophoresis system used for the analysis of SR4233.[56]

Separation-Based Approaches—Microdialysates consist primarily of relatively small hydrophilic analytes in highly ionic aqueous samples. In general, these characteristics have made liquid chromatography (LC) the analytical method of choice to couple to microdialysis sampling. Reversed-phase or ion-exchange are the modes of liquid chromatography that are most compatible with direct injection of aqueous microdialysis samples. The mode of chromatography chosen for analysis is dependent on the physiochemical properties of the analyte. The type of column used (length, particle size, and internal diameter) is determined by the sampling interval desired and the required sensitivity. In a typical LC assay, 5–10 μL of sample are needed, which means that the temporal resolution is 5–10 min if a perfusion flow rate of 1 μL/min is employed. If lower microdialysate flow rates are used to increase recovery, temporal resolution is further decreased. Applications of on-line coupling of microdialysis with LC have been reviewed elsewhere.[38,39]

Capillary electrophoresis (CE) is another separation method that can be used for the analysis of microdialysis samples. The low sample volume requirement of CE is compatible with the small volumes generated by microdialysis sampling. Typical injection volumes in CE are 1–10 nL. However, 1–5-μL samples are generally required because of difficulties associated with the physical manipulation of submicroliter volumes, in particular, problems with surface tension and evaporation.

One disadvantage of CE is its incompatibility with high ionic strength samples. In CE the optimal procedure to achieve stacking, or compression of the injection zone, is to prepare the sample in an injection buffer that is 10-fold more dilute than the background electrolyte. The high ionic strength of the microdialysis sample causes anti-stacking and, therefore, lower detection sensitivity. In contrast, LC is amenable to high ionic strength samples.

There have been several reports of the on-line coupling of microdialysis and capillary electrophoresis with UV[55] and laser-induced fluorescence (LIF) detection.[56–58] The first reported coupling of microdialysis with CE and LIF detection involved the separation of an investigational antineoplastic, SR 4233, from its main metabolite, SR 4317.[55] Figure 4 shows a schematic of the on-line microdialysis/capillary electrophoresis system employed in this study. Resolution of the two compounds was achieved in <60 s, with an overall temporal resolution of 90 s. During the on-line study, a 4-mg/kg intravenous injection of SR 4233 was administered to the rat. A pharmacokinetic curve (Figure 5) was then constructed, and a 15.3 ± 1.0 min half-life of elimination and 1.1 ± 0.2 min half-life of distribution were determined for SR 4233. Another method of detection for use with the on-line coupling of microdialysis and CE that has been explored in our laboratory is electrochemical

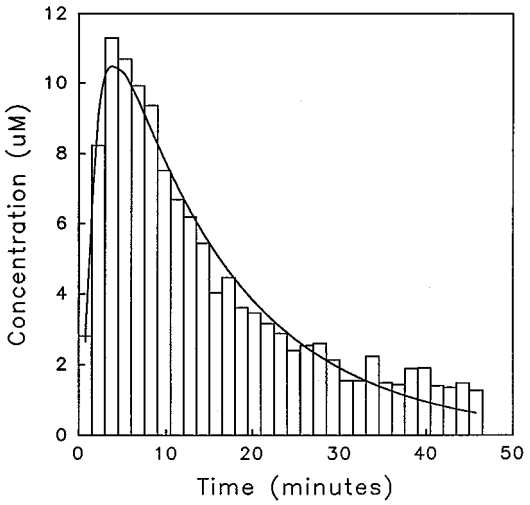

Figure 5—Pharmacokinetic curve following a 4-mg/kg ip dose of SR4233 obtained using an on-line microdialysis/capillary electrophoresis system.[56]

detection.[59] This detection system provides higher sensitivity than does ultraviolet (UV) detection and is comparable to LIF. Furthermore, the number of potential analytes that can be studied at high sensitivity is greatly increased because more compounds are electroactive than are naturally fluorescent.

Scope of Applications

As the number of research studies incorporating microdialysis sampling has continued to increase, secondary literature has appeared in the form of books[60] and review articles.[38,39,61–65] An exhaustive examination of the microdialysis literature is beyond the scope of this review. Many of these studies involve monitoring levels of endogenous compounds in response to the administration of drugs or other stimuli. Others report monitoring of the parent compound and/or metabolites in the dialysate. The small size and minimal invasiveness of microdialysis probes make the technique ideal for simultaneous monitoring in more than one organ or tissue. In the following overview of applications, we have focused on presenting a few examples to illustrate the breadth of possibilities for using microdialysis sampling in pharmacokinetic and metabolism studies.

In Vitro Studies

Microdialysis sampling does not change the net fluid balance of the surrounding sample matrix and provides clean samples in which analytes are separated from further enzymatic action. Thus, microdialysis is useful for in vitro drug development and evaluation applications. A series of reports on in vitro applications of microdialysis sampling has been published. These applications include tablet dissolution testing with both single and multiple vessel configurations,[66,67] erythrocyte membrane partitioning studies,[68] and enzyme kinetic studies.[69] Gunaratna and Kissinger[70] used microdialysis to follow metabolism kinetics in liver microsome incubations. In this application, an in vitro microdialysis system, shown in Figure 6, was used to monitor the metabolic profiles of three metabolites of diazepam following its incubation in liver microsomes (Figure 7). Several studies have been published in which microdialysis sampling was compared to traditional methods for determining drug binding to plasma proteins.[71–73] More recently, Yang and Elmquist[74] demonstrated the

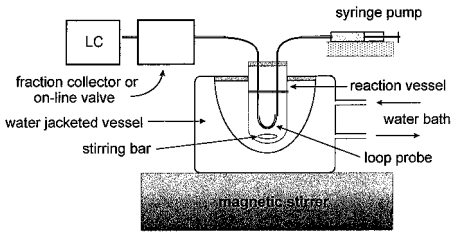

Figure 6—*In vitro* microdialysis sampling system for microsome or similar incubation process.[70]

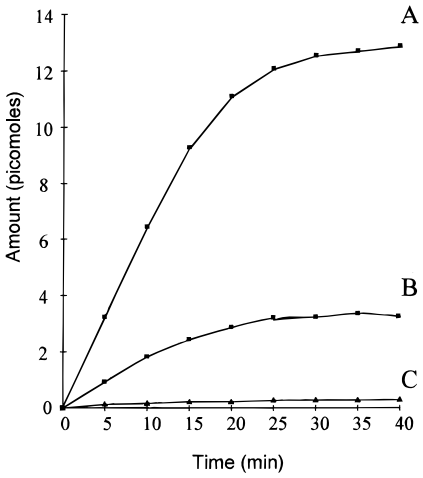

Figure 7—Metabolic profiles of diazapam metabolites sampled by microdialysis from liver microsome incubation mixture. Diazepam concentration was 145 M: (A) temazepam; (B) *N*-desmethyldiazepam; (C) oxazepam.[70]

feasibility of determining the plasma binding of a highly lipophilic drug, cyclosporin A, using microdialysis sampling.

Several researchers have employed in vitro microdialysis sampling to minimize sample preparation when monitoring fermentation and related bioprocesses. Mannino et al.[75] used an on-line microdialysis system to provide clean samples from milk products. They detected sugars amperometrically at a chemically modified electrode. Torto and co-workers[76] have demonstrated the utility of in situ microdialysis sampling for monitoring bioprocesses without perturbation of the process. Microdialysis sampling coupled on-line to LC with pulsed electrochemical detection was used to monitor an enzymatic hydrolysis that produced a mixture of oligosaccharides. Using the same system, Torto et al.[77] evaluated three microdialysis sampling modes with respect to their suitability for quantitative on-line monitoring of bioprocesses in small-volume (5 mL) bioreactors. They concluded that stopped-flow microdialysis modes were advantageous for small-volume reactors to avoid significant depletion of the analyte.

In Vivo Studies

Brain—Microdialysis sampling has been used to study a wide variety of endogenous and exogenous analytes in brain. The large number of papers published on this topic is beyond the scope of this review, so a brief overview of recent work from the laboratory of S. Lunte will be presented.

Tryptophan metabolism along the kynurenine pathway has been one area of interest in our research group. This pathway is responsible for approximately 90% of tryptophan metabolism in mammals and yields the formation of kynurenic acid, an endogenous glycine site NMDA receptor antagonist. Malone et al.[78] utilized CE with electrochemical detection for the determination of tryp-

tophan and kynurenine in brain microdialysates. In that study, an intraperitoneal injection of tryptophan was administered to an anaesthetized rat, and the levels of tryptophan and kynurenine in rat hippocampus were monitored for 6 h by microdialysis sampling. A three- to fourfold increase in dialysate tryptophan levels was observed, resulting in a maximum concentration of 2−3 μM tryptophan at approximately 90 min after ip administration. Sixty minutes after dosing, kynurenine was found to reach a maximum concentration of 1.3 μM. It was concluded that the high sensitivity and low volume requirements of CE with electrochemical detection allowed good temporal resolution and high recoveries to be realized. Kynurenic acid, however, cannot be effectively detected electrochemically; therefore, alternate methods for its determination were investigated. Capillary electrophoresis with LIF detection following zinc complexation was evaluated for monitoring the levels of kynurenic acid in brain microdialysis samples.[79] Kynurenic acid is essentially unable to penetrate the BBB; therefore, its presence in brain is dependent on its bioprecursor kynurenine, a major tryptophan metabolite. In this study, the increase in hippocampal kynurenic acid was monitored following a systemic injection of one of its bioprecursors, tryptophan or kynurenine. One of the greatest potential advantages of this methodology compared with those currently in use is its increased temporal resolution. Microdialysate samples could be analyzed every 10 min rather than the 30−60-min sampling intervals used with LC.

Another project involved the investigation of substance P metabolism in brain using microdialysis sampling followed by CE with postcolumn derivatization and laser-induced fluorescence detection.[80] A microdialysis probe implanted in the striatum of an anesthetized rat was perfused with substance P, and dialysate samples were analyzed for substance P and its metabolites. By introducing substance P into the brain via the microdialysis probe, metabolite formation in the immediate vicinity of the probe could be monitored.

Ocular—One of the major constraints in developing improved intraocular drug delivery systems has been the lack of information concerning the uptake, disposition, and elimination of drugs from the eye.[81] Ocular microdialysis is one technique that could provide such information; however, few studies using this method have been reported.

Continuous sampling of drugs in the vitreous humor of anesthetized rabbits has been reported.[81] This study involved the pharmacokinetic analysis of ganciclovir and acyclovir using a concentric microdialysis probe implanted in the vitreous humor. Ganciclovir is a purine nucleoside analog approved for the treatment of cytomegalovirus retinitis.

Ganciclovir or acyclovir was given as an intravitreal injection (100 mL) following implantation of the guide cannula. The microdialysis probe was then inserted into the guide cannula, and dialysates were collected every 20 min. It was found that the initial equilibration phase was over within the first 4 h, and that the microdialysis technique did not result in a breakdown of the blood−retinal barrier. The short vitreous half-lives of ganciclovir (2.62 ± 0.44 h) and acyclovir (2.98 ± 0.24 h) in albino rabbits suggest a transretinal mechanism of vitreous clearance for these compounds. In pigmented rabbits, however, the rate of elimination increased to 8.63 and 5.59 h for ganciclovir and acyclovir, respectively, as a result of binding to melanin. This research indicates that ocular microdialysis can be useful in assessing the vitreous concentrations of drugs and providing information on the uptake, disposition, and elimination of drugs from the eye.

Transdermal—Traditionally, transdermal drug delivery has been studied in vitro using isolated skin preparations; however, with the use of microdialysis sampling, in vivo studies can be performed.[15] In one such study, intradermal microdialysis was used to investigate the transdermal absorption of cyclosporin in rats.[82] Cyclosporin is an immunosuppressive agent that has been shown to be beneficial in treating several dermatological diseases. Due to the toxic effects found with systemic administration, topical application has been explored, but it is limited because of the poor ability of cyclosporin to penetrate the dermis. In this study, the use of an absorption enhancer, 1-[2-(decylthio)ethyl]azacyclopentan-2-one (HPE-101), and glycerin to increase the transdermal absorption of cyclosporin was evaluated. HPE-101 and glycerin were both found to significantly enhance the absorption of topically applied cyclosporin in rat skin. The authors concluded that utilizing an in vivo microdialysis method obviates the need for concern about hydration and microbial growth as with in vitro methods using excised skin.

Muscle—Two recent publications have focused on the use of microdialysis sampling correlated with traditional blood sampling to devise models for predicting the free concentration of drugs in muscle tissue from the plasma levels. Nolting and others[83] monitored piperacillin, a β-lactam antibiotic, in muscle tissue by microdialysis while collecting serial blood samples. They concluded that microdialysis sampling was suitable for determining concentrations of unbound drug in tissue. Kovar et al.[84] also used microdialysis sampling in muscle tissue to compare free tissue levels of ceftriazone, a highly bound drug, with free plasma levels determined from blood samples. Free levels were much higher in plasma than in muscle. To accurately predict free tissue levels of ceftriazone from plasma levels, the model required factors to account for nonlinear protein binding.

Adipose—Felländer and associates[85] examined the effect of α- and β-adrenoceptor blocking agents on lipolysis in human adipose tissue using microdialysis sampling during surgery. They found that in humans both α- and β-adrenogenic mechanisms modulated the response of adipose tissue to surgical trauma. In another study of lipolytic activity, Darimont et al.[86] used in vivo microdialysis sampling in rat adipose tissue. The effect of moxestrol, a potent estrogenic analog, on lipolysis was monitored by measuring extracellular glycerol in parametrial fat pads of estrus, diestrus, and ovariectomized animals.

Blood—The possibility of producing protein-free samples and conducting long-term continuous sampling without fluid loss is especially attractive for microdialysis sampling from blood vessels. In addition to commercially available venous probes, flexible probes for sampling from blood have been constructed by Telting-Diaz et al.[87] and Evrard et al.[5]

Nakashima and colleagues[88] applied microdialysis sampling to the study of in vivo plasma protein binding of valproate. Microdialysis probes were implanted in the femoral veins of rabbits prior to dosing the animals with valproate. Whole blood samples were collected simultaneously and prepared for analysis of the free fraction using ultrafiltration. No difference was found in the elimination half-lives determined from microdialysis and from blood sampling. Further, they found that in vivo dialysate concentrations could be corrected for probe efficiency using recovery values obtained from in vitro experiments performed in stirred rabbit plasma at 37 °C.

The monitoring of clinically relevant analytes in the blood of critically ill patients provides information vital to management and therapeutic decisions in their care. Rabenstein et al.[89] adapted the bile shunt probe introduced by Scott and Lunte[1] to obtain microdialysis samples from central vein catheters in greyhounds. The microdialysis

samples and blood samples were analyzed for glucose and lactate. In a related study, the same group used their probe system with a biosensor array to determine glucose and lactate.[2]

Tumor—The systemic concentration–time profile of a drug does not necessarily reflect its profile in the extracellular space of tissues. Antineoplastic drugs, because of their especially high cytotoxicity, and tumor tissue, being poorly perfused, are a case in point. A microdialysis probe implanted directly in tumor mass can monitor actual tissue levels of the drug and provide information concerning intumor metabolism, if any, of the drug. For example, Palsmeier and Lunte[16,33] applied microdialysis sampling to the investigation of the disposition and metabolism of SR-4233, a benzotriazine compound with preferential cytotoxicity for hypoxic tissue. They found that, using a systemic dose, much less drug reached the tumor than reached healthy muscle tissue. However, when the same amount of drug reached both tumor and muscle, which was accomplished by delivering the drug via a probe, the levels of reductive metabolites formed were significantly higher in tumor than in muscle.

Other oncological applications of microdialysis sampling include monitoring of carboplatin in cutaneous melanoma and in subcutaneous space to evaluate the portion of the dose reaching the cancerous tissue,[90] methotrexate transport in brain tumors,[91] and the influence of an angiogenesis inhibitor on the uptake of temozolomide.[92]

Transplacental—Ward and Pollack[93] used microdialysis sampling to monitor the effect of methanol on uteroplacental blood flow. The microdialysis probe was implanted through the uterine wall into the amniotic fluid of nearterm pregnant rats. Methanol was administered as an iv bolus dose or an iv infusion over several hours. In addition to producing data suggesting that maternal exposure to methanol may produce hypoxia in fetuses, their work demonstrated the value of microdialysis sampling as a tool for investigating the flux of compounds across placenta.

Bile—A shunt probe design introduced by Scott and Lunte[1] provides microdialysis samples from the bile duct of rats. Briefly, the microdialysis probe is suspended inside a tube that is implanted as a bile duct shunt. The shunt directs bile flow past the microdialysis membrane, then returns the bile to the duct prior to its entry into the small intestine. Because bile flow is maintained, continuous monitoring of compounds excreted into the bile is possible while maintaining enterohepatic circulation.

Scott and Lunte[1] monitored phenol and its metabolites in bile using the shunt probe. Hadwiger et al.[94] obtained pharmacokinetic profiles and parameters for tacrine and its hydroxylated metabolite in bile using the shunt probe design. Gunaratna and colleagues[95] demonstrated the use of this probe design in awake animals, choosing acetaminophen and its metabolites as the analytes.

Liver—Ischemia/reperfusion injury involves reactive oxidant species that are difficult to measure directly. Layton and colleagues[96] monitored two antioxidant species, uric acid and ascorbic acid, by microdialysis sampling in the liver of anesthetized rats during ischemia and reperfusion. As expected, the extracellular levels of both antioxidants decreased during and immediately following ischemia. High ascorbic acid levels were noted immediately after implantation of the microdialysis probe; however, this initially elevated level decreased to a stable basal level after 90 min.

Various drug delivery approaches are being evaluated for their ability to increase therapeutic effectiveness while reducing side effects associated with systemic doses. Sato et al.[97] found microdialysis sampling useful in evaluating microfibrous collagen sheets for local drug delivery. They studied the delivery of etoposide to liver tissues in rats in the presence and absence of cyclosporin A. Etoposide with or without cyclosporin A, a P-glycoprotein-mediated transport inhibitor, was incorporated in a microfibrous collagen sheet applied to the surface of the liver lobe over the site of the microdialysis probe. The microfibrous collagen sheet maintained drug concentrations in the liver with only low concentrations observed in plasma. Inclusion of cyclosporin A further prolonged the drug concentration in liver tissue.

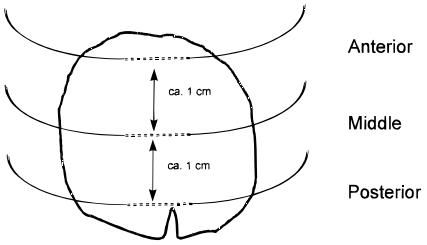

Figure 8—Placement of microdialysis probes implanted into the median lobe of the liver (viewed from the ventral surface) used to monitor phenol metabolism.[37]

Simultaneous Multiple-Probe Studies in the Same Organ—Malagié et al.[98] compared the effect of a combination treatment of WAY 100635 (a 5-HT_{1A} receptor antagonist) and fluoxetine (a 5-HT reuptake inhibitor) on two brain regions simultaneously. Microdialysis probes were implanted in the frontal cortex and ventral hippocampus prior to iv administration of either saline or WAY 100635, followed by ip administration of fluoxetine or saline. The 5-HT levels were monitored simultaneously in the cortex and hippocampus. Fluoxetine alone did not change the extracellular 5-HT levels in either region studied. When fluoxetine and WAY-100635 were coadministered, 5-HT levels in the frontal cortex but not the hippocampus increased by >200% compared with pre-dosing levels.

The spatial resolution of microdialysis sampling can provide information not readily accessible by other methods. Davies and Lunte[99] demonstrated this in a study of phenol metabolism in liver tissue. Three linear microdialysis probes placed in different regions (anterior, middle, and posterior) of the median lobe of rat livers revealed differences in metabolic profiles for the regions following iv administration of phenol (Figure 8). The levels of the conjugated metabolites phenol-glucuronide and glutathionyl-hydroquinone were significantly lower at the anterior position than at other positions, even though the levels of phenol reaching each region were the same (Figures 9 and 10).

Simultaneous Multiple-Probe Studies in Different Organs—Several studies have used simultaneous microdialysis sampling to study drug penetration of the BBB. Simultaneous microdialysis sampling from brain and blood was used by Malhortra et al.[100] to determine the penetration of an experimental NMDA antagonist into brain tissue. They found good agreement between the microdialysis-based pharmacokinetic parameters and those determined using conventional blood sampling. Nakashima et al.[101] evaluated simultaneous microdialysis sampling from blood and brain as a method for determining relative pharmacokinetics and metabolism of L-DOPA in the presence and absence of aromatic amino acid decarboxylase inhibitors. They found in vivo microdialysis to be a simple, reliable technique for the simultaneous determination of pharmacokinetics and metabolism in a target tissue and systemic circulation.

Other dual-site microdialysis sampling experiments have simultaneously examined L-DOPA in blood and muscle,[102,103] SDZ ICM 567 (a 5-HT_3 receptor antagonist) in blood and muscle,[104] lactate in muscle and adipose tissue in relation

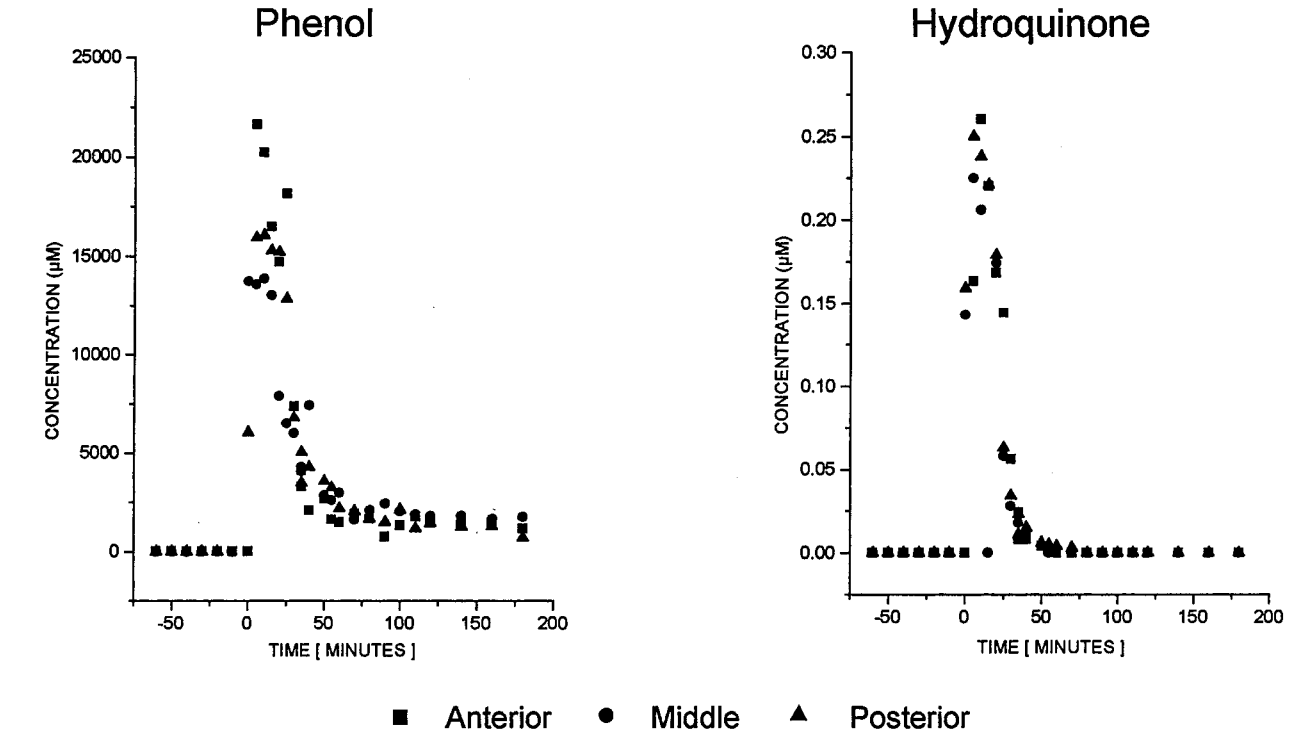

Figure 9—Typical concentration–time course for phenol (left) and hydroquinone (right) during and after a 20-min iv infusion of phenol (administration corresponding to 0–20 min).[37]

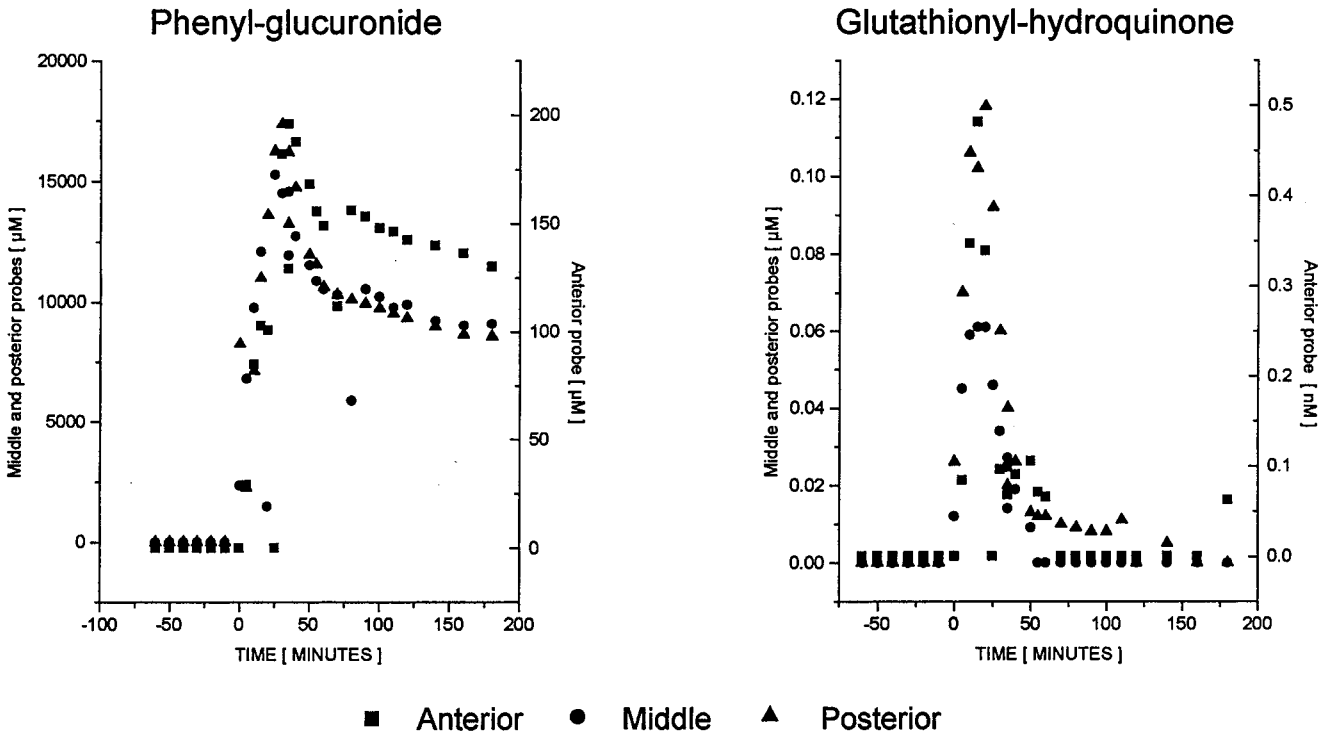

Figure 10—Typical concentration–time course for phenyl-glucuronide (left) and glutathionyl-hydroquinone (right) during and after a 20-min iv infusion of phenol (administration corresponding to 0–20 min). Note: scale for the anterior probe is the right-hand axis.[37]

to insulin action,[105] and antibiotics in human muscle and subcutaneous space.[106] Reports of simultaneous microdialysis sampling from three sites have also been published. These include disposition of phenol in bile, blood, and liver;[1] distribution kinetics of carbamazepine in brain, blood, and liver;[107] aluminum chelation by hydroxypyridinones in blood, liver, and brain;[108] methotrexate levels in kidney, liver, and muscle;[109,110] and lactate and xanthines in blood, liver, and small intestine during endotoxic shock.[111]

Multiple-site microdialysis sampling has proven useful in the investigation of pharmacokinetic drug–drug interactions.[112] Ekstrøm et al.[112] placed microdialysis probes in the blood, liver, and kidney of anesthetized rats to examine the interactions of methotrexate and the non-steroidal antiinflammatory drug (NSAID) naproxen. When animals were pretreated with naproxen, approximately a twofold increase in the areas under the curve (AUCs) of time versus concentration for methotrexate and 7-hydroxymethotrexate, the major metabolite, was found in all three tissues.

Conclusions

Quantitation or calibration of microdialysis probes and the challenge of analyzing the small volumes typical of microdialysis sampling are issues that must continue to be investigated. For microdialysis data to be quantitative, calibration of the probe is necessary. Approaches such as extrapolation to zero flow rates, the use of very low perfusion flow rates, and zero net flux tend to be time consuming. Retrodialysis and in vivo delivery are less time consuming; however, validation of these methods prior to initiation of the microdialysis study is necessary. In general, for applications where absolute tissue concentrations are required, the time involved in calibrating the probe can overshadow many of the other advantages of microdialysis sampling.

Another problem commonly encountered arises from the fact that the small sample volumes obtained from microdialysis sampling are usually less than that required for traditional analytical methodologies such as liquid chromatography. To obtain identical temporal resolution using standard separation methods, it is possible to increase the sample volume by increasing the microdialysis perfusion rate. However, this method decreases the concentration extraction efficiency of the probe. One solution to this problem has been the use of analytical systems with lower sample volume requirements, including microbore LC and capillary electrophoresis. Other approaches have employed preconcentration and stacking methods for LC and CE to overcome the problems of low concentration samples associated with using higher microdialysis perfusion flow rates.

Researchers have shown the feasibility of implanting microdialysis probes in a number of tissues; however, little has been published concerning the physiological response of the tissue to this probe implantation or the way in which tissue response may ultimately affect the pharmacokinetics or metabolic activity. Advances in probe design and dialysis membrane materials that result in less tissue damage as well as biocompatible materials for the construction of microdialysis probes continue to be of interest.

The simultaneous use of multiple probes is another area that has not yet been fully explored. This approach would permit investigations of tissue distribution in near real time while reducing the total number of animals necessary for a study in comparison with traditional methods. The challenge in multiple-probe experiments is preventing the tangling of numerous fluid lines. Multi-channel swivel systems exist for this purpose, but the channel volumes and resistance to turning increase with each additional channel. An alternative to multi-channel swivel systems is the use of a turntable to counter the animal's rotations.[113] These types of studies have become more practical with the commercial availability of swivel-free animal containment systems, such as the Raturn system from Bioanalytical Systems, Inc.

The capacity of microdialysis, performed in vivo, to provide continuous sampling over several days without detriment to the fluid volume of the animal, and the possibility of obtaining such samples simultaneously from multiple sites have the potential for significant reductions in the number of animals necessary for pharmacokinetic and distribution studies. When this technique is coupled on-line to a rapid LC or CE separation method, near real-time data can be obtained. Overall, the increasing application of microdialysis sampling to tissues other than brain, which has been demonstrated in the last decade, is likely to continue, especially as advances in analytical methods for small volume samples and suitable techniques for probe calibration are developed and refined.

MDCK (Madin–Darby Canine Kidney) Cells: A Tool for Membrane Permeability Screening

JENNIFER D. IRVINE,* LORI TAKAHASHI, KAREN LOCKHART, JONATHAN CHEONG, JOHN W. TOLAN, H. E. SELICK, AND J. RUSSELL GROVE

Contribution from *Affymax Research Institute (a Glaxo Wellcome Company), Santa Clara, California 95051.*

Received August 5, 1998. Accepted for publication October 2, 1998.

Abstract □ The goal of this work was to investigate the use of MDCK (Madin–Darby canine kidney) cells as a possible tool for assessing the membrane permeability properties of early drug discovery compounds. Apparent permeability (P_{app}) values of 55 compounds with known human absorption values were determined using MDCK cell monolayers. For comparison, P_{app} values of the same compounds were also determined using Caco-2 cells, a well-characterized in vitro model of intestinal drug absorption. Monolayers were grown on 0.4-μm Transwell-COL membrane culture inserts. MDCK cells were seeded at high density and cultured for 3 days, and Caco-2 cells were cultured under standard conditions for 21 to 25 days. Compounds were tested using 100 μM donor solutions in transport medium (pH 7.4) containing 1% DMSO. The P_{app} values in MDCK cells correlated well with those in Caco-2 cells ($r^2 = 0.79$). Spearman's rank correlation coefficient for MDCK P_{app} and human absorption was 0.58 compared with 0.54 for Caco-2 P_{app} and human absorption. These results indicate that MDCK cells may be a useful tool for rapid membrane permeability screening.

Introduction

The rise of combinatorial chemistry and other drug discovery technologies has vastly increased the number of new compounds to be evaluated as potential drug candidates. Accordingly, new high-throughput strategies are required to evaluate compound properties beyond potency and selectivity. A major focus in the pharmaceutical industry is to develop new drugs with good oral bioavailability. One essential factor of oral bioavailability is the ability of a compound to be well absorbed in the small intestine. Because of its inherent simplicity compared to in vivo and in situ studies, there has been significant interest in the in vitro Caco-2 cell model of human intestinal drug absorption.

When cultured on semipermeable membranes, Caco-2 cells, derived from a human colon adenocarcinoma, differentiate into a highly functionalized epithelial barrier with remarkable morphological and biochemical similarity to small intestinal columnar epithelium.[1−3] Fully differentiated cell monolayers can be used to assess the membrane transport properties of novel compounds.[4,5] In addition, the apparent permeability (P_{app}) values obtained from Caco-2 transport studies have been shown to correlate to human intestinal absorption.[6,7] As a consequence, the Caco-2 cell monolayer model has proven extremely useful not only as a tool for mechanistic studies of drug absorption but also as an absorption screening assay for preclinical drug selection.[8−10]

Though well-characterized and time-proven, the Caco-2 assay remains a relatively low throughput method, due in part to the limitations of its 3-week growth period and regular maintenance feeding requirements. Proprietary culture conditions that greatly accelerate the Caco-2 monolayer differentiation rate, and hence reduce the required culture time, are commercially available, but at additional expense.[11] To reduce the tissue culture time, cost, and effort required for permeability testing, we chose to investigate whether a faster-growing cell line might be suitable for absorption screening.

MDCK (Madin−Darby canine kidney) cells are a common model for studying cell growth regulation, metabolism, and transport mechanisms in distal renal epithelia.[12−17] Like Caco-2 cells, MDCK cells have been shown to differentiate into columnar epithelium and to form tight junctions when cultured on semipermeable membranes.[18,19] The use of the MDCK cell line as a model cellular barrier for assessing intestinal epithelial drug transport was discussed by Cho et al.[20,21] Ranaldi et al. published P_{app} results from MDCK and Caco-2 testing of antimicrobial compounds, showing similar P_{app} values with both cell lines.[22,23] Others have pointed out that MDCK cells are a good candidate for modeling simple epithelia.[24] We chose to study a large number of compounds in both MDCK and Caco-2 assays to evaluate the suitability of MDCK cells as a possible tool for assessing membrane permeability.

Materials and Methods

Materials—Cell culture media and buffer components were purchased from Gibco BRL (Gaithersburg, MD). Fetal bovine serum (FBS) was heat-treated at 56 °C for 30 min prior to use. Caco-2 and MDCK cells were obtained from the ATCC (American Type Culture Collection, Rockville, MD). Transwell-COL tissue culture inserts (6.5 mm diameter, 0.4 μm pore size, collagen-coated PTFE (poly(ethylene terephthalate)) were purchased from Costar Corporation (Cambridge, MA). An EndOhm volt-ohm meter and electrode were purchased from World Precision Instruments (Sarasota, FL). Amoxicillin was from Fluka (Ronkonkoma, NY). Cephalexin monohydrate and loracarbef-D monohydrate were from USP (Rockville, MD). Practolol was from Tocris Cookson (St. Louis, MO). Zidovudine (AZT) was from Aldrich Chemical Company (Milwaukee, WI). Compound 0311C90, acrivastine, fluparoxan, lamotrigine, netivudine, ondansetron, sumatriptan succinate, and trimethoprim were received from Glaxo-Wellcome (Research Triangle Park, NC). Gabapentin was from Parke-Davis (Ann Arbor,

MI). Olsalazine disodium was a gift from Pharmacia & Upjohn (Kalamazoo, MI). Sotalol hydrochloride was a gift from Irotec Labs (Little Island, Cork, Ireland). All other chemicals were from Sigma Chemical Company (St. Louis, MO).

Cell Culture—Caco-2 cells were maintained in Dulbecco's Modified Eagle Medium (DMEM) containing 10% FBS, 1% nonessential amino acids, and 2 mM fresh L-glutamine. Cells were cultured at 37 °C in an atmosphere of 5% CO_2 and 95% relative humidity. Cells were passaged at 80−90% confluence (every 3−4 days) using Trypsin-EDTA solution (Gibco #25300−047). Culture inserts were preincubated with culture medium (1 h, 37 °C) and then seeded with 63 000 cells per cm^2 (0.33 cm^2 per insert). Caco-2 monolayers were fed with fresh medium 24 h after seeding and then 3 times per week. Caco-2 monolayers were cultured for 21−25 days before use. Caco-2 cells were used at passage number 31 to 42, after receipt at passage 18 from ATCC.

MDCK cells were maintained in Minimal Essential Medium (MEM) containing 10% FBS and 2 mM fresh L-glutamine. MDCK cells were cultured and passaged in the same manner as Caco-2 cells. Culture inserts were preincubated with culture medium (1 h, 37 °C) and then seeded with 664 000 cells per cm^2 (0.33 cm^2 per insert). MDCK monolayers were washed and fed with fresh medium 1 h post-seeding and again 24 h post-seeding. MDCK monolayers were cultured for 3 days before use. MDCK cells were used at passage number 59 to 80, after receipt at passage 51 from ATCC.

Transport Assays—*Monolayer Screening*—Cell monolayers were fed with the appropriate culture medium on the day of assay. Two hours after feeding, monolayers were washed with transport medium (Hanks' Balanced Salt Solution (HBSS, Gibco #14025−092) + 10 mM Hepes, pH 7.4). Monolayers were equilibrated in transport medium for 30 min at 37 °C, in 95% humidity. The electrical resistance of each monolayer was measured at 37 °C at three locations using an STX-2 "chopstick" electrode and volt-ohm meter. The resistance of bare filter inserts was subtracted from monolayer resistance values. Monolayer resistance values were multiplied by the membrane area (0.33 cm^2) and averaged to calculate transepithelial electrical resistance (TEER ($\Omega \cdot cm^2$)) values for each monolayer. TEER values indicate the degree of monolayer confluence and tight junction development.

MDCK cells consistently showed lower TEER values than Caco-2 cells. Caco-2 monolayers with TEER values less than approximately 230 $\Omega \cdot cm^2$ were not used. MDCK monolayers with TEER values <90 $\Omega \cdot cm^2$ were not used. These cutoff values were determined to be the lower limit of the usual TEER value observed for each cell line. Typically, 70−90% of both MDCK and Caco-2 monolayers were acceptable for testing using this pre-screen procedure.

Transport Assay—Transport assay donor solutions consisted of 100 μM test compound in transport medium containing 100 μM lucifer yellow and 1% DMSO (pH 7.4). All test compounds were evaluated for suitable solubility and stability under assay conditions and a detection limit of ≤ 1 μM prior to assay. DMSO (1%) was used to increase the solubility of more hydrophobic compounds and was previously found to have no effect on Caco-2 paracellular or transcellular permeability of five test compounds. Ethanol and methanol were found to be unacceptable cosolvents for Caco-2 transport assays (unpublished results). Lucifer yellow, a fluorescent marker for the paracellular pathway, was used as an internal control in every test to verify tight junction integrity during the assay.

Transport assays were conducted using 0.3 mL of apical (AP) donor solution and 1 mL of basolateral (BL) acceptor solution (transport medium, pH 7.4). All compounds were tested in six replicate monolayers. Monolayers were incubated with donor and acceptor solutions for 60 min at 37 °C, 95% humidity, with 30 rpm reciprocal shaking. BL compartments were sampled at 15, 30, and 60 min. AP compartments were sampled at 60 min. The quality control compound set (a pool of propranolol, salicylic acid, cephalexin, vinblastine, and lucifer yellow) was assayed as a pool under the same conditions as the test compounds, using a donor solution containing 100 μM of each compound in transport medium (pH 7.4). Under these assay conditions, PEPT 1 dipeptide transporter activity was assumed to be minimal, because this transporter requires a pH gradient.

Most compounds, including the quality control compound set, were quantified by HPLC (Hewlett-Packard 1050 system) using a C18 column (YMC J'Sphere H80), variable wavelength detection (HP1050−VWD), and an acetonitrile/0.02 M ammonium formate, pH 3.7, mobile phase. Gabapentin was quantified via derivitization with dansyl chloride followed by fluorescence detection (Jasco 920 HPLC fluorescence detector; Ex = 352 nm, Em = 510 nm) using a Nucleosil C18 column and an acetonitrile/0.05M Tris HCl, pH 7.5, mobile phase. Mannitol was quantified by ion-exchange chromatography (Carbo-Pac PA10) with pulsed amperometry detection (Dionex ED40) using a gold electrode and a mobile phase of 52 mM NaOH. Sumatriptan was quantified using DC amperometry (Dionex ED40) with a carbon electrode and a Zorbax Elipse XDB−C8 column with a mobile phase of methanol/0.075 M phosphate (30:70) at pH 7.0. Lucifer yellow was quantified using a fluorescence 96-well plate reader (CytoFluor II (Biosearch, a subsidiary of Millipore)), Ex = 485 nm, Em = 530 nm.

Calculations—P_{app} (apparent permeability) values were calculated according to the following equation:

$$P_{app} = \left(\frac{dQ}{dt}\right) \times \frac{1}{C_0} \times \frac{1}{A} \quad (1)$$

where dQ/dt is the permeability rate, C_0 is the initial concentration in the donor compartment, and A is the surface area of the filter. Permeability rates were calculated by plotting the percent of initial AP drug mass (peak area) found in the BL compartment versus time and determining the slope of the line. The P_{app} values for most compounds were calculated from 15 min data to ensure that <10% of initial compound was found in the acceptor compartment. In some cases, no compound was detected in 15-min samples, so later timepoints were used. Loracarbef was detected in 30-min samples from both cell lines. Gabapentin was detected in 60-min samples from both cell lines. Olsalazine was detected in 30-min samples from MDCK cells and in 60-min samples from Caco-2 cells. Amoxicillin was detected in 60-min samples from Caco-2 cells.

Lucifer yellow (LY) results were used as an internal control for each monolayer to verify tight junction integrity during the entire assay period. Variations in tight junctions can significantly affect permeability results for compounds using the paracellular transport route. Accordingly, LY P_{app} values were quantified from 60-min basolateral samples after background subtraction. The normal range for LY permeability in Caco-2 monolayers observed in our study was approximately 1 to 7 nm/sec (1 nm/s = 1×10^{-7} cm/s). Results from Caco-2 monolayers with LY $P_{app} > 10$ nm/s were not used in compound P_{app} calculations. LY permeability in MDCK monolayers was unknown at the start of this study, though it was expected to be somewhat higher than in Caco-2 cells because of the lower resistance values observed for MDCK monolayers. Initially, results from MDCK monolayers with LY $P_{app} > 30$ nm/s were not used. Later in the study, the MDCK LY cutoff was adjusted to 15 nm/s.

Spearman's rank correlation coefficient, a measure of association between two separate rankings of n items, was calculated as follows:

$$r_s = 1 - \frac{6\sum d^2}{n^3 - n} \quad (2)$$

where d equals the difference between the two ranks that each item received, and n equals the number of items.[25] The value r_s is always between −1 and +1. Greater r_s values indicate greater positive association. Lower r_s values indicate less association.

Calculated log water:octanol partition coefficient (CLogP) values were calculated using Pcmodelsx, a hydrophobicity and polarizability prediction from Daylight Chemical Information Systems, Inc. (Mission Viejo, CA).

Quality Control—As a quality control measure to monitor the consistency of the cells during this experiment, a standard set of six compounds was tested at the beginning and end of the study with both cell lines. The standard set was composed of passive transcellular and paracellular compounds (propranolol HCl and LY), one dipeptide transporter substrate (cephalexin), and one *p*-glycoprotein substrate (vinblastine sulfate). Salicylic acid and cimetidine were also included, though the transport mechanisms of these compounds are somewhat more complex. The standard set was tested as a pool containing 100 μM each of the six compounds. The P_{app} of each compound in the pool was previously determined to be equivalent to the P_{app} of each compound tested

individually. The LY and TEER values were also monitored to ensure monolayer consistency during the study.

Results

Compound Test Set Assembly—To perform this study, a set of test compounds with known human absorption values (% absorption) and a broad range of physicochemical properties was assembled from literature references and Glaxo Wellcome data (Table 1). [6,7,26–33] Great care was taken to verify human intestinal absorption values by identifying primary references wherever possible. Primary references for most of the compounds tested here have been cited individually elsewhere.[33] Bioavailability data were not used. It was a challenge to identify compounds with low to intermediate levels of absorption (10 to 70%) because most compounds with known human absorption data have been successful as oral formulations. Compounds were not otherwise pre-selected in any manner that should bias the results of this study.

Compounds transported by more complicated transport mechanisms than passive diffusion were purposely retained in this set. Both Caco-2 and MDCK cell lines are known to express *p*-glycoprotein (Pgp) and dipeptide transporters, important mechanisms in the intestinal and renal barriers that retain nutrients while exporting xenobiotics. We were particularly interested to see how results for these compounds would compare between the two cell lines. Six compounds tested (amoxicillin, cefatrizine, cephalexin, gabapentin, lisinopril, and loracarbef) were reported dipeptide transport substrates. Three of the compounds tested (dexamethasone, ranitidine, and sulfasalazine) were reported efflux substrates.

MDCK and Caco-2 Monolayers—The formation of confluent MDCK monolayers with functional tight junctions was confirmed by microscopy, TEER values, and LY permeability results. The use of optically clear semipermeable membranes for culture (Costar Transwell-COL) allowed for visual examinations by microscopy. The TEER values provided a simple quick estimate of tight junction formation, which was then assessed more thoroughly by examining LY permeability. Results from a growth study showed evidence of tight junction maturation as TEER values increased and LY permeability decreased with time from zero to 3 days (Table 2). The average MDCK TEER value during this study was 173 $\Omega \cdot cm^2$ ($\pm$ 51). The average MDCK LY P_{app} value was 6.3 nm/s ($\pm$ 6.1).

As for MDCK cells, Caco-2 monolayer confluence and tight junction integrity were assessed by microscopy, TEER values, and LY permeability values. The average Caco-2 TEER value during this study was 280 $\Omega \cdot cm^2$ ($\pm$ 50). The average Caco-2 LY P_{app} value was 3.1 nm/s ($\pm$ 2.8).

Monolayer Quality Control—Quality control results with the standard set of six compounds indicated that both Caco-2 and MDCK cell lines produced similar permeability values at the beginning and end of the study (Table 4). The differences between the beginning and ending values were similar to the normal day-to-day variability for permeability values observed with these compounds.

MDCK P_{app} versus Caco-2 P_{app}—MDCK and Caco-2 permeability results are shown in Table 1. Values are reported as the average of replicates $\pm$ the standard deviation (SD). Included in the table are the reported human intestinal absorption values for the same compounds. When MDCK and Caco-2 P_{app} values were plotted against each other, a clear relationship was observed (Figure 1). The calculated r^2 value was 0.79, denoting a high level of correlation. Data for the known dipeptide transport and *p*-glycoprotein efflux substrates fit the Caco-2/MDCK correlation well. Greater deviation from the linear trend was seen among low P_{app} compounds. Some departure from linearity was noted for very high permeability compounds, where P_{app} values tended to be slightly greater in MDCK cells than in Caco-2 cells. The significance of this observation has not been determined.

Table 1—Permeability Results with MDCK and Caco-2 Monolayers

[a] Average P_{app} (nm/s) ± standard deviation.

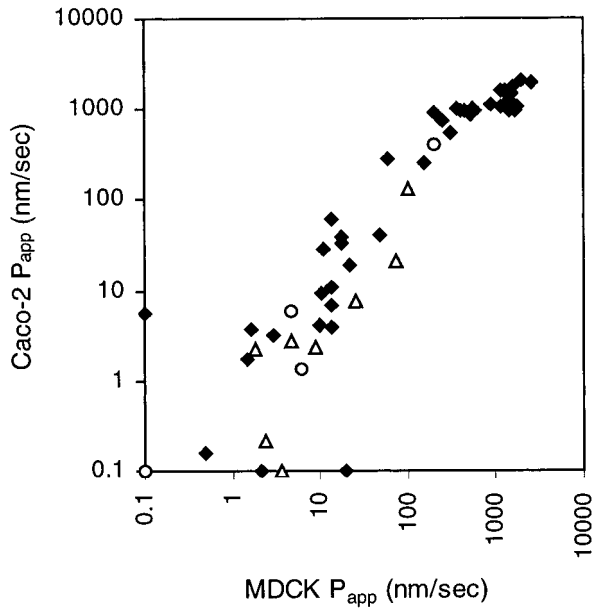

Figure 1—Correlation of MDCK and Caco-2 apparent permeability (P_{app}) values. P_{app} values plotted at 0.1 are actually ≤0.1, including zero for compounds not detected in the basolateral compartment. Key: (◆) = passive diffusion compounds; (△) active transport compounds; (○) efflux substrates.

absorbed compounds showed generally low P_{app} values. Some deviation from the sigmoidal trend was apparent with both cell lines, with somewhat greater deviation seen for Caco-2 data than for MDCK data. The compounds that fell out of the correlation were the same for both cell lines. Permeability values for amoxicillin, cephalexin, and loracarbef (three dipeptide transporter substrates) clearly underestimated their human absorption values of 94, 98, and 100%, respectively. Ranitidine (a *p*-glycoprotein efflux substrate) did not show detectable transport with either cell line, though it is reported to be 50% absorbed.

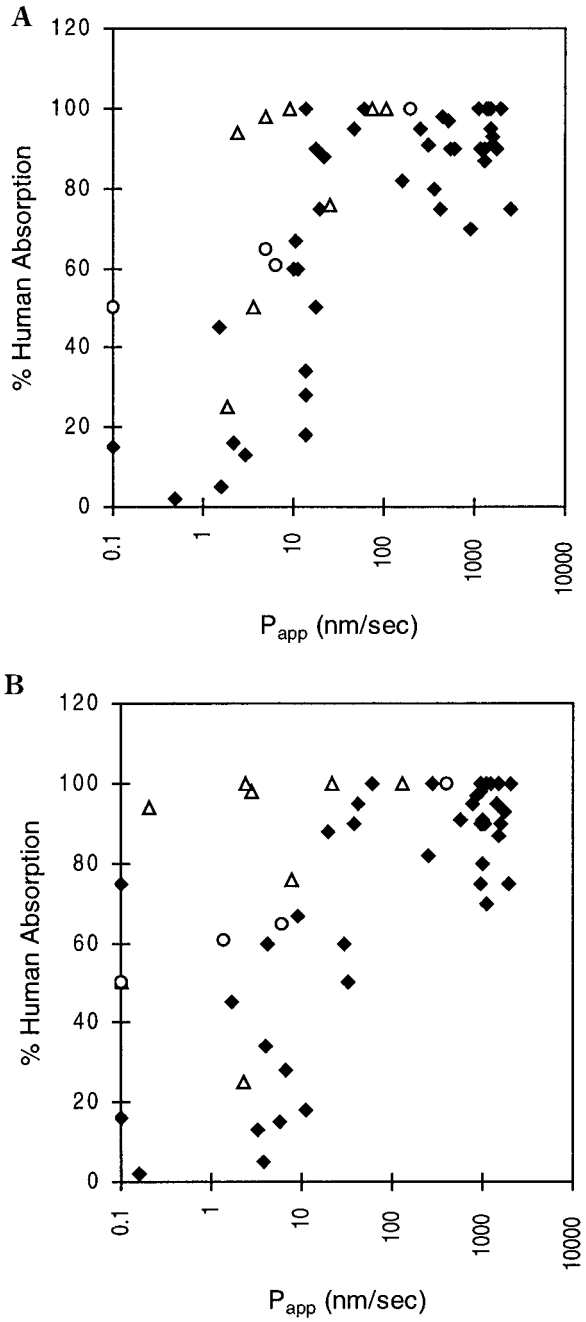

Figure 2—Correlation of apparent permeability (P_{app}) values and percent (%) human intestinal absorption. Figure 2A plots the relationship between MDCK P_{app} values and % absorption. Figure 2B plots the relationship between Caco-2 P_{app} values and % absorption. The P_{app} values plotted at 0.1 are actually ≤0.1, including zero for compounds not detected in the basolateral compartment. Key: (◆) passive diffusion compounds; (△) active transport compounds; (○) efflux substrates.

Rank Order—Because of the steep sigmoidal relationship between P_{app} values and human intestinal absorption and because of the variation in fit to the relationship, absolute absorption values are difficult to estimate from P_{app} data. In contrast, an estimate of rank order of absorption within a set of compounds, as measured by rank order of permeability, can be directly determined. Spearman's rank correlation coefficient was therefore calculated for MDCK and Caco-2 data to see how well either cell line modeled rank order of absorption (Table 3). The highest rank correlation was for MDCK P_{app} to Caco-2 P_{app} (0.93).

Rank correlations for MDCK P_{app} and Caco-2 P_{app} to human absorption were similar (0.58 and 0.54, respectively). In comparison, the rank correlation for cLogP to human absorption was 0.25. The rank correlation for human absorption to random number was calculated for perspective. For eight determinations, the average correlation was 0.0, however the value of one of the eight tests was 0.3.

Discussion

Although the MDCK cells are derived from dog kidney, whereas Caco-2 cells are derived from human colon, the two cell lines share many common epithelial cell characteristics.[15,17,34] That cells from such diverse origins could produce comparable transport results might seem surprising. Nonetheless, as a whole, we observed that permeability results from MDCK cells were similar to permeability results from Caco-2 cells. The r^2 value (0.79) for MDCK P_{app} versus Caco-2 P_{app} indicates the strength of that similarity, which is also visually evident in Figure 2. Because most of the compounds tested were passively absorbed, the good correlation between Caco-2 and MDCK P_{app} values suggests that the rules determining passive membrane permeability may be universal among cell types.

MDCK monolayers were seeded at a high density (664 000 cells/cm^2) to reduce tissue culture time. Similar high-density MDCK culture conditions have been reported by other labs.[14,34] MDCK TEER results in our studies (120−190 Ω·cm^2) were consistent with previously published data for cells seeded at a lower density and grown for 2−4 days.[20,24] Further studies in our lab have shown that the MDCK seeding density can be reduced by a factor of two or four without affecting assay performance (unpublished data). Caco-2 monolayers were seeded at a moderate density similar to those reported by other labs (63 000 cells/cm^2).[30,32] Caco-2 monolayers seeded at high density and assayed on day 3 showed high LY P_{app} values, which is evidence of poor tight junction integrity (unpublished results).

Permeability data from MDCK and Caco-2 monolayers correlated best for high P_{app} compounds. The weaker correlation observed for low P_{app} data may be partially due to greater variability in transport assay results for low permeability compounds and partially due to the magnification artifact of the log/log plot. We found permeability values of <10 tended to be poorly reproducible day to day. We therefore did not consider P_{app} results between 0.5 and 5.0 to be significantly different. Because of our interest in applying the permeation assay as a screening tool, that degree of error was tolerable.

Although most of the compounds tested here were absorbed by passive diffusion, to the best of our knowledge, some active transport compounds were included because oral absorption data was available. Caco-2 and MDCK P_{app} data for these active transport and efflux compounds appeared to correlate well. For the *p*-glycoprotein efflux substrates, the apical compound concentration may have been high enough to saturate the mechanism and negate any differences between the cells. For dipeptide transport substrates, both cell lines may have expressed roughly similar levels of transporters with roughly similar specificities. Caco-2 and MDCK permeability results for nonpassively absorbed compounds may not always correlate as well as observed here. This study was not designed to precisely examine and compare the permeability of active transport and efflux compounds in Caco-2 and MDCK cells. Although MDCK and Caco-2 cell lines have some active transport mechanisms in common, many transporters can affect drug permeability results.

The correlation between Caco-2 P_{app} values and human intestinal absorption that has been well-established by other laboratories was confirmed in these findings, and a similar correlation was observed for MDCK P_{app} values. In addition, both cell lines showed similar weaknesses with particular compounds. Thus, MDCK P_{app} values appear to function as well as Caco-2 cells when applied as a general absorption screen.

In conclusion, we have shown that drug permeability data from MDCK cells is similar to permeability data from Caco-2 cells, at least for passively absorbed compounds. We have found the fast-growing MDCK cell line can provide reliable results after only 3 days of culture, compared with the 21 days of culture required for Caco-2 testing. We suggest that it may be practical to use MDCK cells as a permeability screening tool to increase the throughput of membrane permeability screening in early drug discovery.

Abstract □ Niosomes are vesicles formed by the self-assembly of nonionic surfactants in aqueous dispersions. They can entrap drugs and have been used experimentally as sustained drug delivery systems. Apart from conventional spherical niosomes, various types of vesicle ultrastructures can be formed by varying the composition of the vesicle membrane. Hexadecyl diglycerol ether ($C_{16}G_2$), cholesterol, and poly-24-oxyethylene cholesteryl ether (Solulan C24) in the ratio 91:0:9 gave polyhedral niosomes, whereas spherical and tubular niosomes are produced at a composition ratio of 49:49:2. The mean size of both polyhedral and spherical/tubular niosomes were within the range of 6 to 9 μm. Both types of vesicle were visualized by cryo-scanning electron microscopy. The properties of the two forms of niosomes were studied using luteinizing hormone releasing hormone (LHRH) as a model peptide. Analysis by high-performance liquid chromatography demonstrated high entrapment of LHRH acetate in polyhedral niosomes when prepared by remote loading methods using pH or $(NH_4)_2SO_4$ gradients; in contrast, only low entrapment was achieved by passive loading methods (direct hydration at pH 7.4 or pH 3.0, dehydration–rehydration, and reversed-phase evaporation). In vitro studies demonstrated that both polyhedral and spherical/tubular niosomes were more stable in 5% rat skeletal muscle homogenate than in rat plasma. Also, polyhedral niosomes released more radiolabeled LHRH ([^{125}I]LHRH) than spherical/tubular niosomes in both muscle homogenate and plasma. In clearance experiments in the rat, following intramuscular injection, both polyhedral and spherical/tubular niosomes gradually released [^{125}I]LHRH into the blood, but some radioactivity remained at the injection site for 25 and 49 h, respectively. In contrast, [^{125}I]LHRH in phosphate buffered saline was completely cleared from the injection site at 2 h. The release of drug is sustained by both niosome formulations, but spherical/tubular niosomes possess more stable membranes than polyhedral niosomes due to the presence of cholesterol.

Introduction

Niosomes, analogues of liposomes, are nonphospholipid vesicles formed by the self-assembly of nonionic surfactants in aqueous dispersion and have been used experimentally as drug carriers.[1,2] Apart from conventional spherical vesicles, a range of niosome structures can be formed by varying the membrane composition of the vesicles. The properties of polyhedral, and spherical/tubular niosomes, formed by hexadecyl diglycerol ether ($C_{16}G_2$) cholesterol: poly-24-oxyethylene cholesteryl ether (Solulan C24) with molar ratios of 91:0:9 and 49:49:2, respectively, have been compared previously in relation to differences in ultrastructural morphology and membrane composition.[3,4] The irregular faceted shape of polyhedral niosomes results in a dispersion with a higher viscosity than that formed by their spherical/tubular counterparts.[3] Although polyhedral niosomes are less osmotically responsive in terms of size change in the presence of osmotic gradients, due to their rigid gel state membrane[5] and low curvature, they possess low cholesterol membranes that are very permeable to hydrophilic solutes such as carboxyfluorescein (CF).[4] However, we have found that the co-entrapment of sodium chloride with CF in polyhedral niosomes resulted in a very low CF release rate, regardless of the osmotic conditions.[4] It is believed that the dehydration of the polyoxyethylene chains of Solulan C24 in the membranes of polyhedral niosomes is responsible for this property.

In the present investigation we have studied the morphology of polyhedral and spherical/tubular niosomes using cryo-scanning electron microscopy. Luteinizing hormone releasing hormone (LHRH) was selected as a model peptide drug to investigate the possibility of using polyhedral and spherical/tubular niosomes and polyhedral niosomes prepared in the presence of NaCl as sustained drug delivery systems. A variety of preparation techniques were studied in an attempt to obtain a high level of LHRH entrapment in the vesicles.

Experimental Section

Materials—Hexadecyl diglycerol ether ($C_{16}G_2$) was a gift from L'Oreal (Paris, France), and poly-24-oxyethylene cholesteryl ether (Solulan C24) was donated by Ellis and Everald Anstead International (Essex, UK). Luteinizing hormone releasing hormone (LHRH) acetate salt, radiolabeled LHRH ([^{125}I]LHRH), and cholesterol were obtained from Sigma Chemical Company (Poole, UK). Sodium chloride, diethyl ether, and ammonium sulfate were supplied by BDH Laboratory Supplies (Poole, UK). Chloroform (HPLC grade) was purchased from Rathburn Chemicals (Walkerburn, UK). The water source was from an ultrahigh quality reverse osmosis water purifier (Elgastat UHQPS, Elga Ltd., Bucks, UK).

Methods—*Preparation of LHRH Acetate-Loaded Polyhedral Niosomes*—Six methods of preparation of LHRH loaded polyhedral niosomes, formed from $C_{16}G_2$:Solulan C24 (91:9) (60 μmol) and LHRH acetate (2 mg/mL), were investigated ($n = 3$).

Method A was direct hydration (hand-shaking) at pH 7.4. Dried surfactant film was hydrated with LHRH acetate prepared in pH 7.4 phosphate buffered saline (PBS) by mechanical shaking at 55 °C for 30 min.

Method B was direct hydration at pH 3.0. Dried surfactant film was hydrated with LHRH acetate prepared in pH 3.0 PBS at 55 °C for 30 min.

Method C was dehydration−rehydration of vesicles (DRV). Surfactant film was hydrated with 5 mL of water at 55 °C for 30 min before adding of 1 mL of LHRH acetate in water. The niosome dispersion was then freeze-dried overnight and rehydrated with 1 mL of pH 7.4 PBS.

Method D was reversed-phase evaporation of vesicles (REV). Surfactants were dissolved in 10 mL of $CHCl_3$:diethyl ether (1:1). Then, 1 mL of LHRH acetate in pH 7.4 PBS was injected into the dispersion, which was then bath sonicated for 2 min. Finally, the organic solvents were vacuum evaporated.

Method E was remote loading by $(NH_4)_2SO_4$ gradient. Surfactant film was hydrated with 1 mL of 120 mM $(NH_4)_2SO_4$ at 55 °C for 15 min. The dispersion was ultracentrifuged at 4 °C, and the pellets were redispersed with LHRH acetate in pH 7.4 PBS and shaken gently at 60 °C for 15 min.

Method F was remote loading by pH gradient. Dried surfactant film was hydrated with 1 mL of pH 3.0 PBS at 55 °C for 30 min. The dispersion was ultracentrifuged at 4 °C, and the pellets were redispersed with LHRH acetate in pH 7.4 PBS and shaken gently at 60 °C for 15 min.

The dispersions were washed twice with PBS pH 7.4 (or at pH 3.0) by ultracentrifugation at 4 °C. The entrapped LHRH acetate was analyzed by reversed-phase HPLC (μBondapak C18, 3.9 × 150 mm; mobile phase: 0.03 M CH_3COONH_4 :ACN, 70:30, flow rate, 0.6 mL/min, detection wavelength, 279 nm).

For the in vitro/in vivo evaluation, polyhedral and spherical/tubular niosomes prepared from $C_{16}G_2$:cholesterol: Solulan C24 (91:0:9) and (49:49:2), respectively, were loaded with [^{125}I]LHRH (1.67 μCi/mL in pH 7.4 PBS) using the pH gradient method described in Method F. To study the effect of NaCl, phosphate buffer at pH 7.4 prepared in 2 M NaCl was used instead of pH 7.4 PBS, except when the washed niosomes were redispersed prior to injection. Niosomes were sized using a laser diffraction method (MasterSizer X, Malvern Instruments Ltd., Worcestershire, UK).

Cryo-scanning Electron Microscopy—Polyhedral and spherical/tubular niosomes, prepared in water, were plunge frozen in liquid nitrogen slush and transferred to a Philips XL20 scanning electron microscope (SEM), and the surface moisture was removed by sublimation (at −40 °C for 10 min). Samples were gold coated at −180 °C and photographed by SEM.

In Vitro Evaluation—*Animal Husbandry*—Male Wistar rats weighting 200 g (Bantin and Kingman Universal Ltd., Aldbrough, Hull, UK), were given diet (Rat and Mouse No. 1, SDS Ltd, Witham, Essex, UK) and drinking water ad libitum. A temperature of 20−22 °C was maintained with a relative humidity of 45 to 65% and a 12:12 h light:dark cycle (lights on at 07.00 h). Animals were acclimatized for at least 5 days before each experiment and were observed daily for clinical signs of illness.

Preparation of Plasma—Rats were killed by the intraperitoneal (ip) injection of pentobarbitone sodium (Sagatal, Rhône Mérieux Ltd., Harlow, Essex, UK). Blood was removed from the abdominal aorta and anticoagulated with lithium heparin, and the plasma was removed after centrifugation and stored at −30 °C.

Preparation of 5% Muscle Homogenate—Rats were sacrificed as already described. Skeletal muscles were removed from the posterior and anterior thighs, weighed, and homogenized with 19 parts of PBS, and aliquots were stored at −30 °C.

Evaluation of Niosomes In Vitro—A 0.1-mL sample of each niosome dispersion was mixed with 0.9 mL of rat plasma or 0.9 mL of 5% muscle homogenate in a glass vial, which was then incubated at 37 °C in a thermostated water bath (Grant Instruments, Cambridge Ltd., Cambridge, UK). Then, 0.1-mL aliquots were collected at 30 min, and 2, 5, and 9 h and mixed with 1.9 mL of PBS before being ultracentrifuged. Radioactivity in 1 mL of supernatant was counted (1275 Minigamma Gamma Counter, LKB Wallac, Turku, Finland), and the count/min in 2 mL was calculated as % LHRH released by comparison with the initial count/min of 0.01 mL of niosome dispersion.

In Vivo Evaluation—Male Wistar rats, 190 to 230 g, were injected intramuscularly (im; 25 GA 5/8 needle; right posterior thigh) with 0.1 mL of [^{125}I]LHRH prepared in pH 7.4 PBS, or spherical/tubular niosomes, polyhedral niosomes, or polyhedral niosomes prepared with a high concentration of NaCl. At 10 min, and 2, 7, 25, 32, and 49 h after injection, animals ($n = 2$) were weighed and killed by ip injection of pentobarbitone sodium, and blood was collected into lithium heparin. The radioactivity remaining at the injection site was determined by removing the injected leg and detaching the thigh muscles. The radioactivity in whole blood (2 mL) and muscle was counted using the gamma counter. The [^{125}I]LHRH in the total blood volume at each time point was calculated, based on the formula of total blood volume being 6 mL/100 g body weight in the mature male rat, and the count of radioactivity in 0.1 mL of [^{125}I]LHRH solution or niosome dispersion.

Results

Cryo-scanning Electron Microscopy—Cryo-scanning electron micrographs confirmed that niosomes formed by varying the amount of $C_{16}G_2$, cholesterol, and Solulan C24 resulted in a variety of vesicle structures (Figure 1). Polyhedral niosomes were formed in the absence of cholesterol whereas conventional spherical vesicles and also tubules were produced in the lipid/surfactant mixtures prepared with an equimolar level of cholesterol, confirming our previous findings.[3,4]

Effects of Preparation Methods on Entrapment Efficacy—Figure 2 shows that only a small amount of LHRH acetate could be entrapped into polyhedral niosomes using passive loading methods (i.e., direct hydration at pH 7.4 and 3.0, and DRV and REV) in comparison with higher levels of entrapment obtained by active loading methods [i.e., $(NH_4)_2SO_4$ gradient and pH gradient]. Calculated on the basis of available LHRH (2 mg), the entrapment levels obtained by passive loading methods were in the range 14−24%. The $(NH_4)_2SO_4$ gradient and pH gradient methods led to entrapments of 44% and 51%, respectively; these figures correspond to ratios of 12.4 and 14.5 nmol of entrapped LHRH/μmol of surfactants, respectively.

In Vitro Stability Study—As shown in Figure 3, polyhedral vesicles release more LHRH in both plasma and muscle homogenate than do spherical/tubular systems. Muscle homogenates are perhaps a better model for im formulations. Both formulations release less LHRH in these homogenates than in plasma.

In Vivo Clearance from Intramuscular Site—All niosomes used in vivo were unsonicated. The mean sizes were in the range of 6 to 9 μm, which was deemed most appropriate for im depot formulation. From Figure 4, it is seen that 99% of [^{125}I]LHRH in PBS was cleared from the site of injection in the first 2 h, whereas 14% and 70% of injected [^{125}I]LHRH prepared in polyhedral and spherical/tubular niosomes, respectively, was still present at the injection site. All the [^{125}I]LHRH in polyhedral niosomes was cleared from the injection site by 25 h, whereas some (8.5%) of the radioactivity in spherical/tubular niosomes could still be detected.

Figure 5 shows the level of [^{125}I]LHRH in the blood over the 49-h period after dosing. Unformulated [^{125}I]LHRH disappears from the injection site into the blood very rapidly, with a t_{max} of 12 min post dosing. Niosome preparations sustain the release of drug into the blood and prolong blood levels. Polyhedral niosomes exhibited a t_{max} of 2 h. Spherical/tubular niosomes provide a better sustained release system, with a t_{max} of 7 h post dosing. These results closely parallel the clearance data.

Co-entrapment of NaCl with [^{125}I]LHRH in polyhedral niosomes, which reduces the permeability of the bilayers,[4] was found not to change either the release pattern of the drug from the injection site (Figure 4), or the level of [^{125}I]-LHRH in the blood (Figure 5).

Discussion

We have previously reported the entrapment of hydrophilic solutes in $C_{16}G_2$ niosomes and described the morphology of these vesicle using fluorescence light microscopy and confocal laser scanning microscopy.[6,7] In this paper,

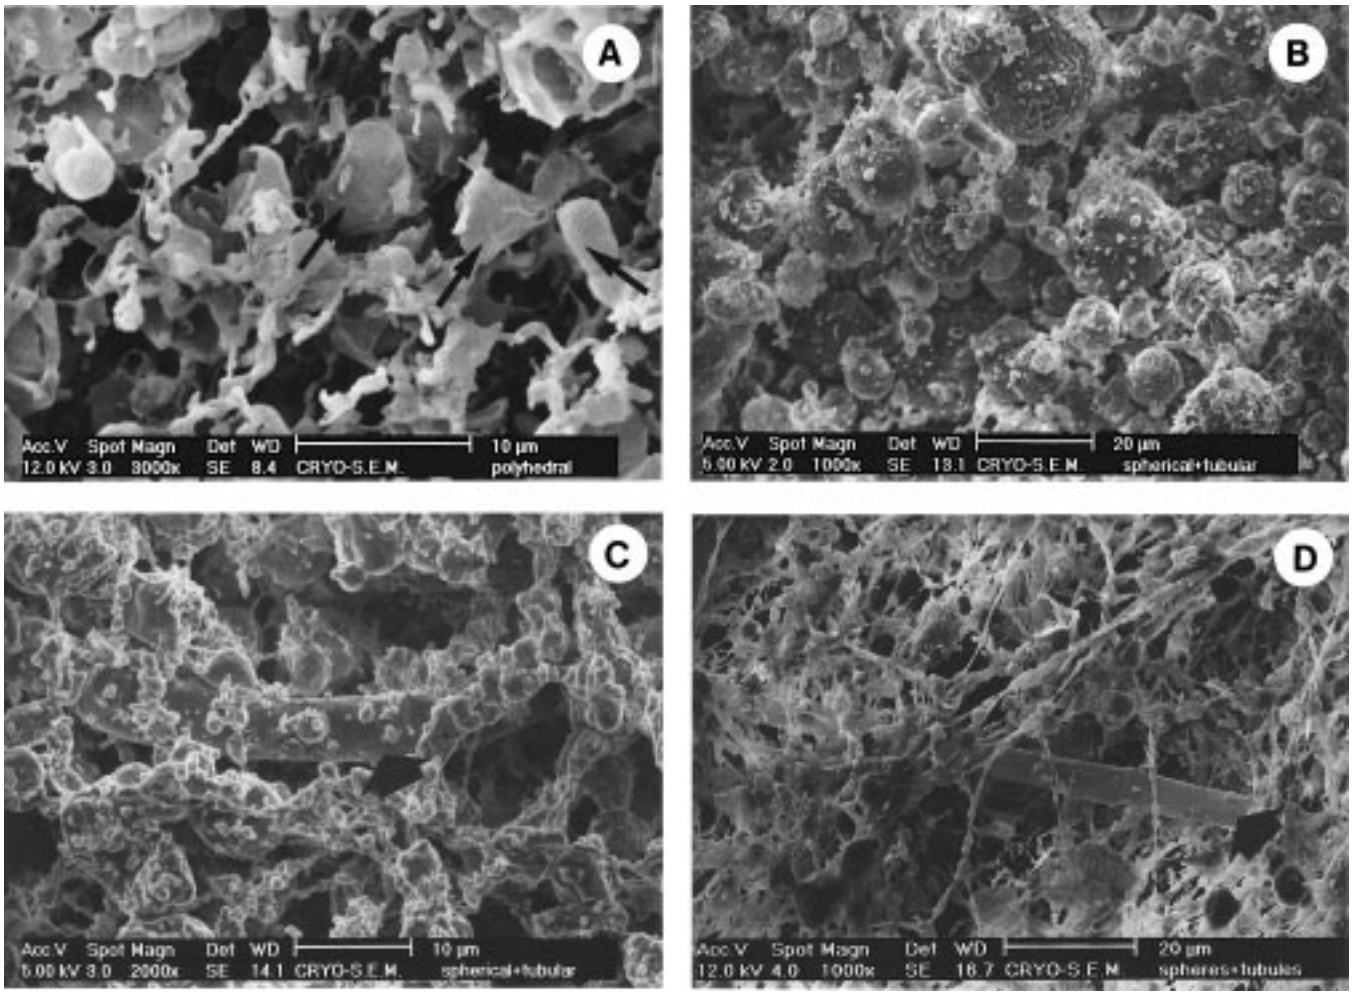

Figure 1—Cryo-scanning electron micrographs of (A) polyhedral niosomes (→) formed by $C_{16}G_2$:Solulan C24 (91:9), (B) spherical niosomes formed by $C_{16}G_2$:cholesterol:Solulan C24 (49:49:2), and (C) and (D) tubular structures (→) identified in the spherical niosome preparations of $C_{16}G_2$:cholesterol:Solulan C24 (49:49:2).

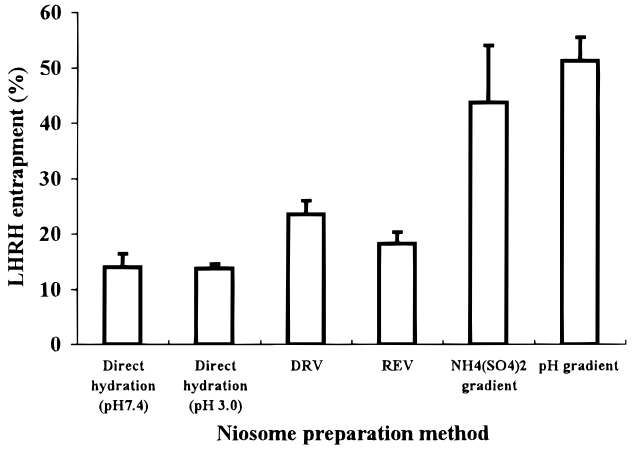

Figure 2—Percentage entrapment of LHRH acetate into polyhedral niosomes by six different preparation methods. Data are expressed as means and SD; $n = 3$, except for direct hydration at pH 3.0 and pH gradient entrapment, where $n = 2$ (DRV = dehydration–rehydration vesicles; REV = reversed-phase evaporation vesicles).

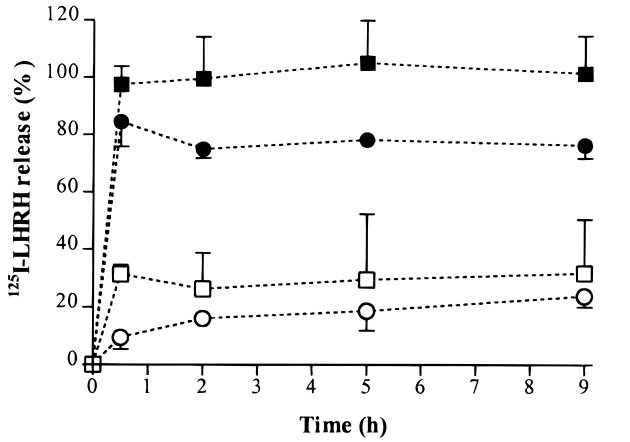

Figure 3—Release profile of [^{125}I]LHRH from polyhedral niosomes over a 9-h period in plasma (■) and in 5% muscle homogenate (□), and from spherical/tubular niosomes in plasma (●) and in 5% muscle homogenate (○). Data are expressed as means and SD; $n = 2$ for each niosome preparation at each time point.

the morphology of the vesicles has been examined using cryo-SEM. Polyhedral niosomes formed from $C_{16}G_2$ and Solulan C24 without cholesterol are asymmetric in nature, and different in their morphology from vesicles formed by these surfactants with 45 mol % cholesterol. The absence of cholesterol causes the membranes of $C_{16}G_2$ to form vesicle membranes with a lower curvature and fluidity.[4,7]

To study the possible use of such systems as sustained-release vehicles, LHRH acetate was selected as a model peptide. The binding of peptide to lipids can be enhanced by modifying the electrical charge or the hydrophobicity of the peptide.[8] However, LHRH is very hydrophilic and becomes a univalent cation at physiological pH. An increase in lipid–peptide interaction via electrostatic binding was

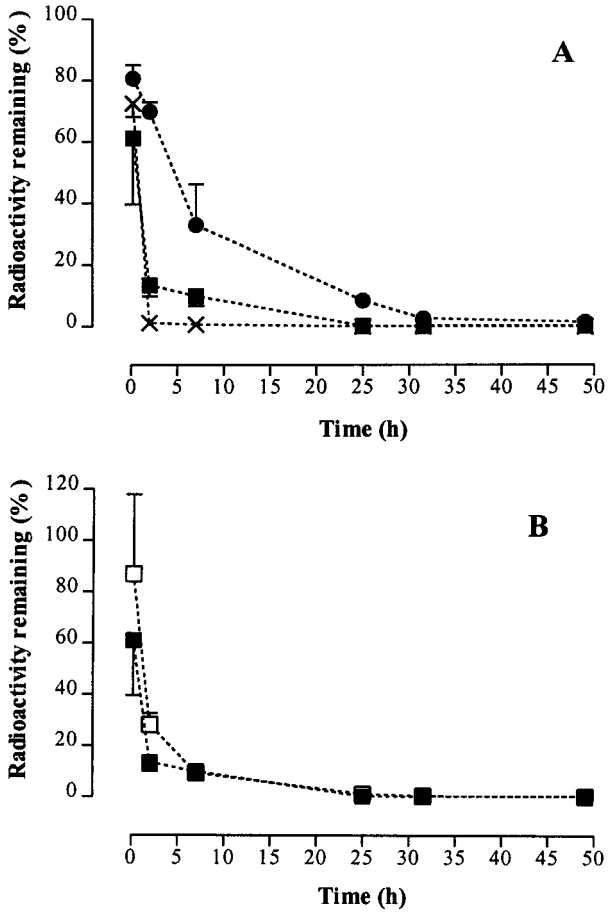

Figure 4—The amount of [^{125}I]LHRH as percent remaining at the injection site. (B) The [^{125}I]LHRH prepared in polyhedral niosomes (■), as presented in Figure 4A, and in polyhedral niosomes with NaCl (□). Data are expressed as means and SD; $n = 2$ for each niosome preparation at each time point.

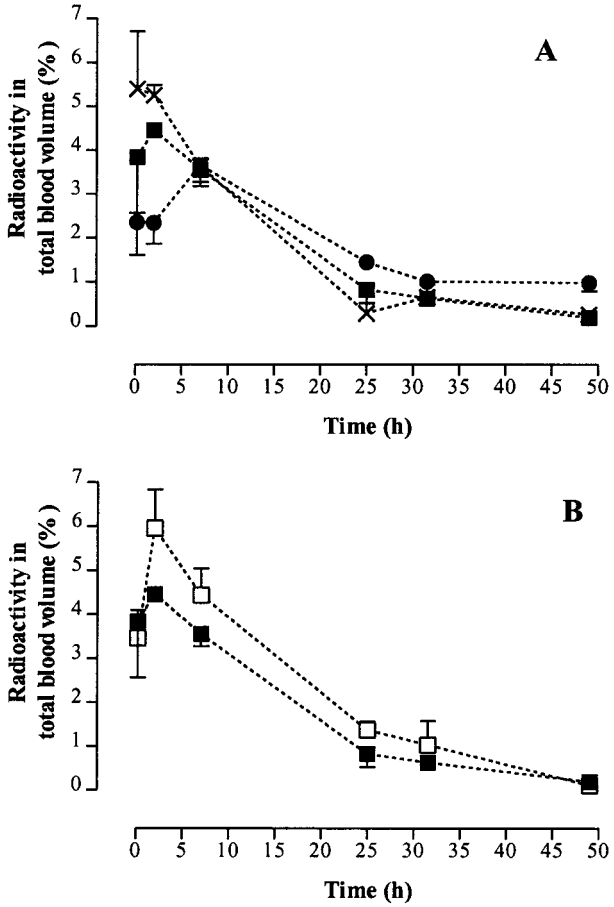

Figure 5—The amount of [^{125}I]LHRH as percent detected in blood after injection. The amount of radioactivity in the total blood volume was estimated and expressed as a percentage of the dose of radioactivity administered. (A) The [^{125}I]LHRH prepared in PBS at pH 7.4 (X), in polyhedral niosomes (■), and in spherical/tubular niosomes (●). (B) The [^{125}I]LHRH prepared in polyhedral niosomes (■), as presented in Figure 5A, and in polyhedral niosomes with NaCl (□). Data are expressed as means and SD; $n = 2$ for each niosome preparation at each time point.

described by Schäfer et al.[9] by the addition of phosphatidic acid, an anionic lipid, into the membranes of phosphatidyl choline vesicles. We obtained a very low entrapment of LHRH by passive loading methods (Figure 2), with the highest entrapment being achieved by the remote loading method (so-called "active" loading), which makes use of either the difference in pH, or in the amount of $(NH_4)_2SO_4$, between the inside and the outside of the vesicle. It is also of interest that LHRH (a decapeptide with a MW of 1182 Da) can be introduced through the vesicle membrane using a pH gradient[10] or an $(NH_4)_2SO_4$ gradient,[11] as has been demonstrated for other small molecules such as doxorubicin (MW of 543.5 Da). In our studies, the highest amount of drug to be entrapped using the pH gradient method was 14.5 nmol of LHRH/μmol of surfactants. This level appears low in comparison with values achieved for other drugs such as doxorubicin.[12] However we used a low concentration of LHRH (1 mM surfactants: 0.028 mM LHRH) and the amount of LHRH encapsulated was around 50% of the available drug.

The stability of parenteral drug delivery systems can be evaluated by measuring drug release during incubation in serum or plasma,[13,14] and muscle homogenate.[15] Both polyhedral and spherical vesicles are more stable in a 5% muscle homogenate than in plasma (Figure 3). Zuidema et al.[16] showed that plasma had a higher potential than muscle components to induce solute leakage from liposomes. Figure 3 also demonstrates that spherical/tubular niosomes released less [^{125}I]LHRH than polyhedral niosomes and these results compare with our earlier findings using CF as a marker.[4]

The mean size of both the polyhedral and the spherical/tubular niosomes were within the range of 6 to 9 μm. Zuidema et al. suggested that small liposomes (<200 nm) can be cleared from the im injection site by the lymphatic system,[16] whereas larger vesicles (4.9 μm) have been found to have a longer retention time at the site of injection.[17] It was thought that polyhedral niosomes, having a higher viscosity than spherical/tubular niosomes,[3] might remain at the site of injection for a longer period than spherical vesicles. However, probably due to differences in membrane permeability, this effect is masked as spherical/tubular vesicles were able to more effectively prolong the blood level of the peptide. These results compare therefore with the earlier in vitro stability studies.

Earlier we reported that the co-entrapment of NaCl with drug reduced the membrane permeability of polyhedral niosomes.[4] However, only a slight improvement in the release profile of LHRH-loaded polyhedral niosomes was observed in vivo (Figure 4B). Although liposomes may remain at the site of injection for <1 week,[18] their ability to retain the solute is an important factor in their use as a sustained-release system. Such an ability is related to the composition of the membranes, their lamellarity,[19] and the presence of cholesterol in the membranes.[14] Polyhedral niosomes formed without cholesterol, although being in the

gel phase, are therefore more leaky than their spherical/tubular counterparts.

LHRH is fairly stable in aqueous solution over a wide range of pH and temperature.[20] The blood levels of [^{125}I]-LHRH detected in this study were low, indicating that the peptide rapidly becomes accessible to protease enzymes on its release from the niosomes.

Conclusions

Niosomes can be used as sustained drug delivery systems that remain at the injection site over a period of around 48 h and slowly release drug into the blood. The shape of the vesicle, which gives a high viscosity to concentrated polyhedral niosome suspensions, is not as important as membrane permeability. Spherical/tubular niosomes that possess more stable membranes than polyhedral niosomes are more effective intramuscular depots.

Solubility and Mass and Nuclear Magnetic Resonance Spectroscopic Studies on Interaction of Cyclosporin A with Dimethyl-α- and -β-Cyclodextrins in Aqueous Solution

KOUZOU MIYAKE, FUMITOSHI HIRAYAMA, AND KANETO UEKAMA*

Contribution from *Faculty of Pharmaceutical Sciences, Kumamoto University, 5-1 Oe-honmachi, Kumamoto 862-0973, Japan.*

Received July 13, 1998. Accepted for publication October 27, 1998.

Abstract □ The interaction of cyclosporin A (CsA) with dimethyl-α- and -β-cyclodextrins (DM-α-CyD and DM-β-CyD) was investigated by the solubility method, electrospray ionization mass spectrometry (ESI-MS) and ^{1}H-nuclear magnetic resonance spectroscopy (^{1}H NMR). The extremely low solubility (1.9×10^{-5} M at 25 °C) of CsA in water was significantly improved by the complexation with DM-CyDs: for example, the solubility increased 87-fold in the presence of 5.0×10^{-2} M DM-β-CyD. The phase solubility diagram of CsA/DM-CyD systems showed an Ap type and the stability constants (1060 M^{-1} and 1050 M^{-1}, respectively) of the 1:1 CsA/DM-α-CyD and CsA/DM-β-CyD complexes were much higher than those of the 1:2 complexes (15 M^{-1} and 21 M^{-1}, respectively). In ESI-MS spectra of the CsA/DM-β-CyD system, a new signal emerged at 1268 which corresponds to the 1:1 adduct of the di-ionized guest molecule with the host molecule. This signal intensity was significantly decreased by the addition of chlorpromazine (CPZ) which has a large stability constant (8800 M^{-1}) of the DM-β-CyD complex, whereas the signal corresponding to the CPZ/DM-β-CyD complex was little affected by the addition of CsA, indicating a competitive inclusion of CPZ and CsA within the host cavity. CsA gave many new peaks in the ^{1}H NMR spectrum when the solvent was changed from chloroform to methanol/water, suggesting conformational diversity of CsA in polar solvents. Inspection of ^{1}H-chemical shift changes and the two-dimensional rotating frame nuclear Overhauser effect (ROESY) spectra of the CsA/DM-CyD system suggested that the side chains of amino acids in CsA molecule take part in the inclusion within DM-CyDs, although there is seemingly no preference of particular amino acid residues. All the data obtained here suggested that CsA forms inclusion complexes with DM-α- and -β-CyDs in an aqueous medium and side chains of CsA are mainly involved in the inclusion.

Introduction

Cyclodextrins (CyDs) are known to form inclusion complexes with various drug molecules in both solution and solid state, and their host/guest interaction has been investigated by using a number of chemical and physical techniques such as spectroscopies, potentiometric titration, kinetics, and the solubility method, etc.[1,2] For example, changes in ultraviolet (UV) and fluorescence spectra of a guest molecule due to the complexation are quantitatively analyzed to obtain the stability constant and stoichiometry of the complex and to gain insight into the inclusion structure in aqueous solution.[3] These physicochemical techniques are applicable on the interaction studies without difficulty when the guest or host is soluble in water and has some chromophores higher than about 210 nm. However, such application is limited when the guest is less soluble or insoluble in water and simultaneously has no chromophores in a molecule, because of difficulty in the preparation of the guest or host solution at suitable concentrations for UV or fluorescence measurements. Cyclosporin A (CsA) employed in this study falls under the category of drugs described above, i.e., the solubility in water being very low (1.9×10^{-5} M at 25 °C) and having no strong chromophore above 210 nm (Figure 1). Recently, mass spectrometry with the use of soft ionization techniques such as electrospray, ionspray, and fast atom bombardment has allowed the study of supramolecular complexes involving CyDs and crown ether,[4] etc., to go forward and has demonstrated capabilities for detecting intact noncovalent bound complexes including peptide/CyD complexes.[5−7] Furthermore, it is possible to use organic solvents such as methanol, acetonitrile, or glycerol as a matrix for solubilization of highly hydrophobic guest molecules.

CsA is an immunosuppressive drug and used in the treatment of autoimmune diseases and prevention of allograft rejection after organ transplantation. However, as has been pointed out, it is a drug exhibiting low oral bioavailability and quite large variability in absorption.[8,9] In a previous paper,[10] we reported that the low oral absorption and large variability of CsA is significantly improved by complexation with CyDs, particularly dimethyl-α- and -β-cyclodextrins (DM-α-CyD and DM-β-CyD, respectively) in rat model. In this continuing study, we investigated the complexation of CsA with DM-α-CyD and DM-β-CyD in water by means of the solubility method and electrospray mass spectrometry, both being useful for the interaction study of guests having low aqueous solubility. Furthermore, ^{1}H-nuclear magnetic resonance (NMR) spectroscopic studies of the CsA/CyD system were carried out in order to gain insight into the inclusion mode of CsA, using a mixed solvent of water/methanol.

Experimental Section

Materials—CsA was donated by Research Center of Shiseido Ltd. (Yokohama, Japan). DM-α-CyD and DM-β-CyD were supplied from Japan Maize Co. (Tokyo, Japan) and contained hexakis(2,6-di-*O*-methyl)- and heptakis(2,6-di-*O*-methyl)cyclodextrins (degrees of substitution of methyl group (DS) = 12 and 14, respectively) as a major component and the over-methylated homologue, 2,6-per-*O*-methyl-3^A-*O*-methyl-α- and -β-CyDs (DS = 13 and 15, respectively) as a minor component.[11] Because the separation of the minor component by recrystallization and column chromatography was significantly difficult, the DM-CyDs were used after recrystallization from methanol/water. The composition of the pure dimethyl derivative and the over-methylated homologue was determined to be 3:1 by fast atom bombardment mass spectrometry. All other chemicals and solvents were of analytical reagent grade, and deionized double-distilled water was used throughout the study.

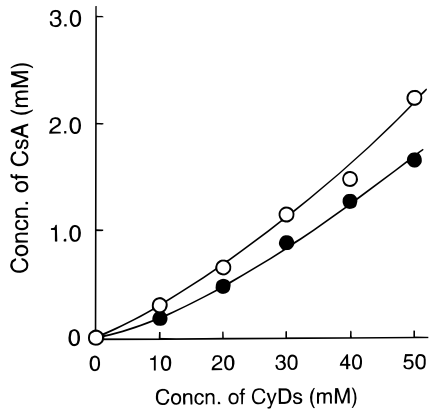

Figure 2—Phase solubility diagrams of CsA/DM-CyD systems in water at 25 °C. (○) DM-α-CyD, (●) DM-β-CyD.

Solubility Measurements—The solubility method was carried out according to the method of Higuchi and Connors.[12] The screw-capped vials containing CsA (5.0 mg) in excess amount in aqueous CyD solutions (5.0 mL) at various concentrations ($1.0-5.0 \times 10^{-2}$ M) were shaken at 25 °C. After equilibrium was attained (about 4 days), the solution was centrifuged at 800*g* force for 5 min, and the supernatant was filtered through a membrane filter (cellulose acetate membrane filter, ADVANTEC DISMIC 3CP045 (TOYO-Roshi), Tokyo, Japan) and analyzed for CsA by high-performance liquid chromatography (HPLC) under the following condition: a Hitachi L-6000 pump and an L-4000 UV detector (Tokyo, Japan) at 214 nm; a YMC ODS AM-312 column (6.0 mm × 150 mm i.d., Kyoto, Japan); a mobile phase of acetonitrile/methanol/water (60:30:10 v/v); a flow rate of 1.0 mL/min and a column temperature of 50 °C.

Mass Spectrometries—Electrospray ionization mass spectrometry (ESI-MS) was carried out on a Hitachi M-1200H LC/MS system (Tokyo, Japan) equipped with an electrospray ionization source. Ionization was achieved by applying 3.0 kV to the spray needle. The orifice potential was maintained at 70 V, and the spectra were recorded over a mass range of 300−2000 units in the positive-ion detection mode. Mass scale calibration was conducted using poly(ethylene glycol) 400, 600, and 1000, and agreement between observed and calculated *m/z* values was within 0.4. CsA or chlorpromazine (CPZ) was dissolved in water/methanol/acetic acid (47:47:6 v/v, pH ≈ 3) in the absence or presence of DM-CyDs. The final concentrations of CsA, CPZ, and DM-CyDs were 1.0×10^{-3} M, 1.0×10^{-3} M, and 2.0×10^{-3} M, respectively. An aliquot (2.0 μL) of the solution was injected into a flow (0.1 mL/min) of water/methanol/acetic acid (47:47:6 v/v) and transferred to the electrospray source.

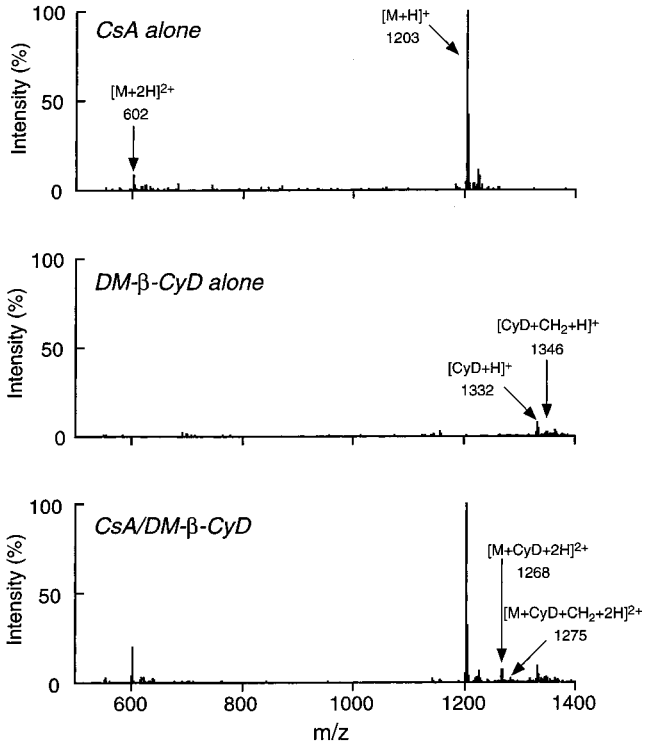

Figure 3—ESI mass spectra of CsA (1 mM) in positive ion mode in the absence and presence of DM-β-CyD (2 mM) in water/methanol/acetic acid (47/47/6 v/v).

^{1}H NMR Spectroscopies—^{1}H NMR spectra were obtained with a JEOL JNM-α 500 instrument (Tokyo, Japan) with a 5 mm inverse broad band probe, operating at 500 MHz and a sweep width of 10000 Hz, at 25 °C. Chemical shifts are given as parts

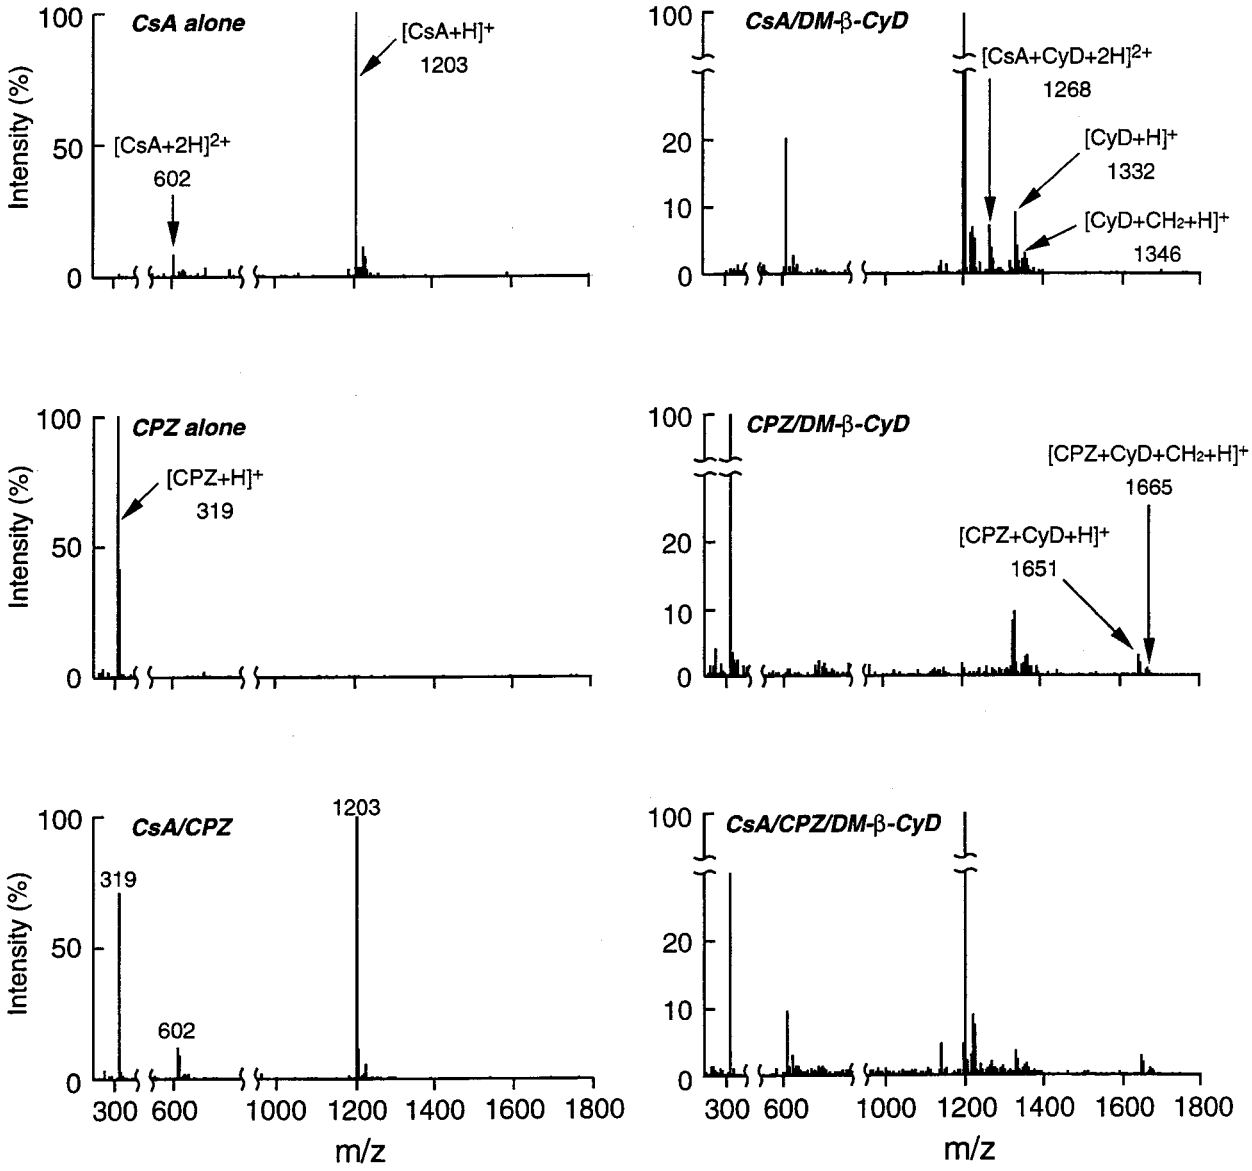

Figure 4—Effect of CPZ (1 mM) on ESI mass spectra of CsA (1 mM) in positive ion mode in the absence and presence of DM-β-CyD (2 mM) in water/methanol/acetic acid (47/47/6 v/v).

per million (ppm) downfield from that of tetramethylsilane, with an accuracy of 0.005 ppm. Phase-sensitive ROESY spectra were measured under the following conditions: sweep width, 5000 Hz; carrier frequency, 2.95 ppm; spin-lock field, 4 kHz; mixing time, 200 ms; 32 scans for each t_1 point with a pulse delay of 1.5 s; data matrix, 2 × 256 × 1K. CsA and DM-CyDs were dissolved at concentrations of 4.0×10^{-3} M and 3.0×10^{-2} M, respectively, in 50% v/v deuterated methanol (CD_3OD)/deuterium oxide (D_2O).

Results and Discussion

The solubility method is useful for investigating inclusion complexation of poorly water-soluble drugs with CyDs in water, because it gives not only the solubilizing ability of host molecules but also the stability constant of complexes by analyzing the solubility curve.[2] Figure 2 shows the phase solubility diagrams of CsA for the DM-α-CyD and DM-β-CyD complexes in water. The extremely low solubility (1.9×10^{-5} M at 25 °C) of CsA was markedly increased by the complexation with DM-CyDs: i.e., the solubility of CsA increased 87-fold in the presence of 5.0×10^{-2} M DM-β-CyD. The phase solubility diagrams showed an Ap type, as defined by Higuchi and Connors,[12] indicating the formation of high order complexes. Therefore, these upward curvatures were analyzed, by the method of Kristiansen and Higuchi using the iteration method,[13] to obtain the stability constants ($K_{1:1}$ and $K_{1:2}$) of 1:1 and 1:2 (guest:host) complexes. The $K_{1:1}$ and $K_{1:2}$ were determined to be 1060 M^{-1} and 15 M^{-1} for the DM-α-CyD complexes and 1050 M^{-1} and 21 M^{-1} for the DM-β-CyD complexes, respectively. The $K_{1:1}$ values were much higher than the $K_{1:2}$ values, suggesting that CsA forms predominantly the 1:1 complex with DM-CyDs in water.

As described in the Introduction section, the extremely low solubility of CsA together with the absence of chromophores above 210 nm in the molecule make it difficult to utilize UV, circular dichroism and fluorescence spectroscopic techniques for the investigation of CyD interaction with CsA in water. On the other hand, mass spectrometry has proved to be useful as one of the promising tools for detecting CyD complexes with peptides such as bradykinin (consisting of 9 amino acids),[5] synthetic Alzheimer amyloid (consisting of 40 amino acids),[6] and insulin (consisting of 51 amino acids),[7] etc. Therefore, the complexation of CsA (consisting of 11 amino acids) with DM-β-CyD was investigated by ESI-MS, using a water/organic solvent. Figure

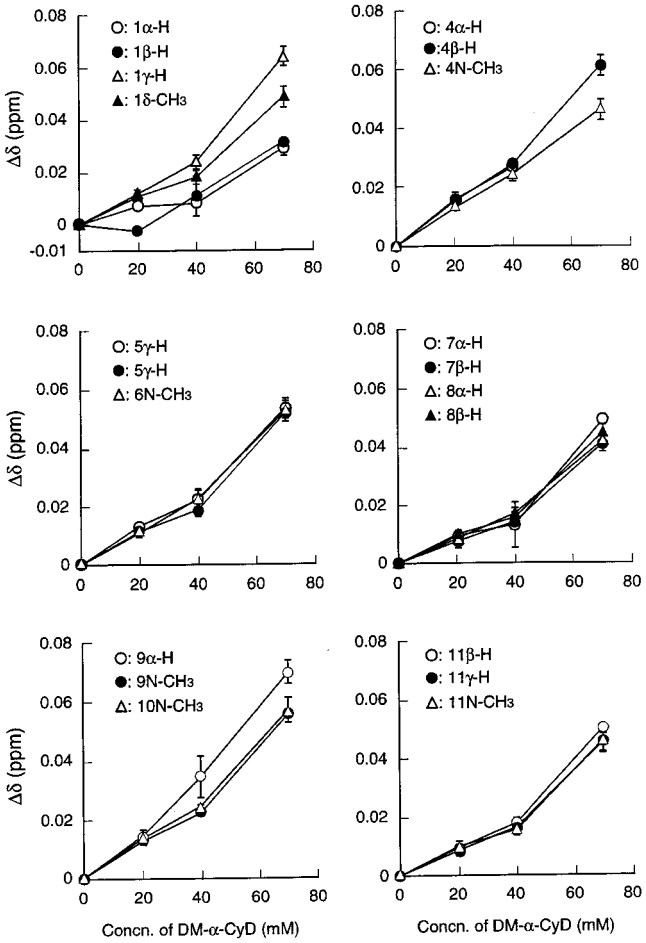

Figure 6—^{1}H NMR chemical shift displacements ($\Delta\delta$) of CsA (4 mM) as a function of DM-α-CyD concentrations in 50% v/v CD_3OD/D_2O. $\Delta\delta = \delta_{\text{in the presence of CyD}} - \delta_{\text{in the absence of CyD}}$.

3 shows ESI mass spectra of CsA alone, DM-β-CyD alone and the CsA/DM-β-CyD mixture in a molar ratio of 1:2 which were dissolved in water/methanol/acetic acid (47:47:6 v/v). CsA gave two signals at 1203 and 602 corresponding to $[M + H]^+$ and $[M + 2H]^{2+}$ ions and DM-β-CyD gave two signals at 1332 and 1346 corresponding to $[CyD + H]^+$ and $[CyD + CH_2 + H]^+$ of the pure DM-β-CyD and the over-methylated derivative, respectively, in a peak ratio of about 3:1. By the addition of DM-β-CyD (Figure 3), a new signal was observed at 1268 which corresponds to the 1:1 adduct of di-ionized CsA with DM-β-CyD, $[M + CyD + 2H]^{2+}$, whereas no signal corresponding to the adducts was observed by the addition of glucose and maltose. The peak of the 1:1 adduct of CsA with the over-methylated homologue was also observed at 1275, although its intensity was significantly weak and fell within a noise range. These results suggest that CsA interacts with DM-β-CyD, presumably involving hydrophobic groups of CsA amino acids in the interaction.

The inclusion of a guest molecule within the CyD cavity is inhibited by the addition of a second guest molecule, the extent of the inhibition being dependent on the stability constant of each complex. This competition is a characteristic feature of host/guest inclusion complexations involving CyDs and crown ethers, etc. Therefore, the competitive inclusion studies were conducted by ESI-MS in order to confirm the complexation of CsA with DM-β-CyD. CPZ was chosen as a competitive guest molecule because of the larger stability constant (8800 M^{-1}) of its DM-β-CyD complex,[14] compared with that (1050 M^{-1}) of the 1:1 CsA/DM-β-CyD complex. The relative magnitude of the constants was assumed not to change in the mixed solvent.[15] Figure 4 shows the effect of CPZ on the ESI mass spectra of CsA/DM-β-CyD complex. The CPZ alone gave a peak at 319 due to $[M + H]^+$, and the mass spectrum of the CsA/CPZ system was simply the superposition of each component, indicating no interaction between CsA and CPZ. The CPZ/DM-β-CyD system gave two new peaks at 1651 and 1665 corresponding to the 1:1 adducts of CPZ/DM-β-CyD, $[CPZ + CyD + H]^+$, and CPZ/the over-methylated homologue, $[CPZ + CyD + CH_2 + H]^+$, respectively, in a peak ratio of about 3:1. In the case of the ternary CsA/CPZ/DM-β-CyD system, the peak intensity of 1268 corresponding to the CsA/DM-β-CyD markedly decreased, whereas the intensity of the 1651 and 1665 peaks corresponding to CPZ/DM-β-CyD complex was almost constant. For example, the peak ratio of the CsA complex to the free drug ($I_{\text{complex}}/I_{\text{drug}}$) decreased from 0.064 (binary CsA/DM-β-CyD system) to 0.027 (ternary CsA/CPZ/DM-β-CyD system), whereas that of the CPZ complex was almost constant (0.039 and 0.040 for the binary and ternary systems, respectively). These results apparently indicate that CsA forms the complex with DM-β-CyD and the equilibrium is competitively inhibited by the addition of CPZ.

To gain insight into the inclusion mode of CsA with DM-CyDs, ^{1}H NMR spectroscopic studies were carried out.

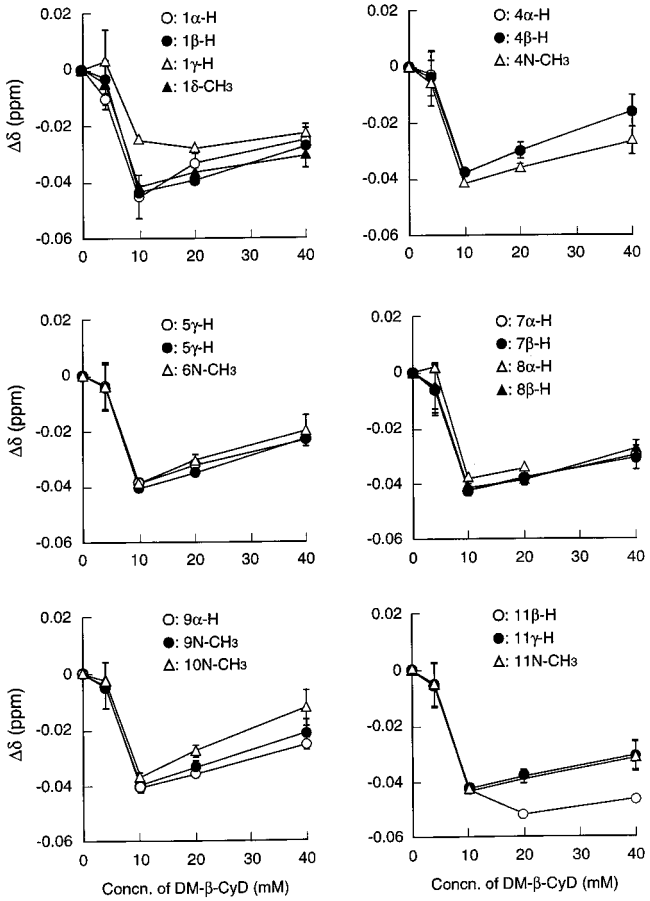

Figure 7—^{1}H NMR chemical shift displacements ($\Delta\delta$) of CsA (4 mM) as a function of DM-β-CyD concentrations in 50% v/v CD_3OD/D_2O. $\Delta\delta = \delta_{\text{in the presence of CyD}} - \delta_{\text{in the absence of CyD}}$.

Figure 5 shows ^{1}H NMR spectra of CsA in chloroform, 50% v/v methanol/chloroform, methanol, 75% v/v methanol/water, and 50% v/v methanol/water. It was difficult to obtain high-resolution spectra of CsA below 50% methanol concentration, because of precipitation of the substrate. The ^{1}H NMR signals of CsA in chloroform were successfully assigned according to the report of Kessler et al.[16] However, many new peaks appeared with severe splitting in methanol/chloroform solution, and this tendency became significant when polarity of solvents increased. For example, by changing the solvent from chloroform to 50% v/v methanol/water, the quintet (4.52 ppm) of the α proton of Ala7 (7α-H, Figure 1) changed to the multiplet (4.41 ppm), and the double-doublet (5.70 ppm) of the α proton of MeLeu9 (9α-H) changed to at least two double-doublets (5.60 and 5.52 ppm). Furthermore, the peak area of 5.60 ppm increased compared with that of 5.52 ppm. These results were in agreement of those reported by Kessler et al.,[16] Ko et al.[17] and Hasumi et al.,[18] suggesting that several conformational isomers of CsA may exist in polar solvents and they exchange slowly on the NMR time scale, whereas in chloroform CsA exists in one conformation. Because of the conformational diversity of CsA in polar solvents, it was difficult to assign unambiguously all ^{1}H-signals of CsA protons, but some of them in 50% v/v methanol/water solution could be assigned as follows: [1α-H (5.30 ppm), 1β-H (4.02 ppm), 1γ-H (2.33 ppm), and 1δ-CH_3 (0.76 ppm) for MeBmt], [4α-H (5.18 ppm), 4β-H (1.64 ppm), and 4N-CH_3 (3.08 ppm) for MeLeu4], [5γ-H (1.01 and 0.81 ppm) for Val5], [6N-CH_3 (3.15 ppm) for MeLeu6], [7α-H (4.41 ppm) and 7β-H (1.30 ppm) for Ala7], [8α-H (4.83 ppm) and 8β-H (1.28 ppm) for D-Ala8], [9α-H (5.60 ppm) and 9N-CH_3 (3.13 ppm) for MeLeu9], [10N-CH_3 (2.71 ppm) for MeLeu10]

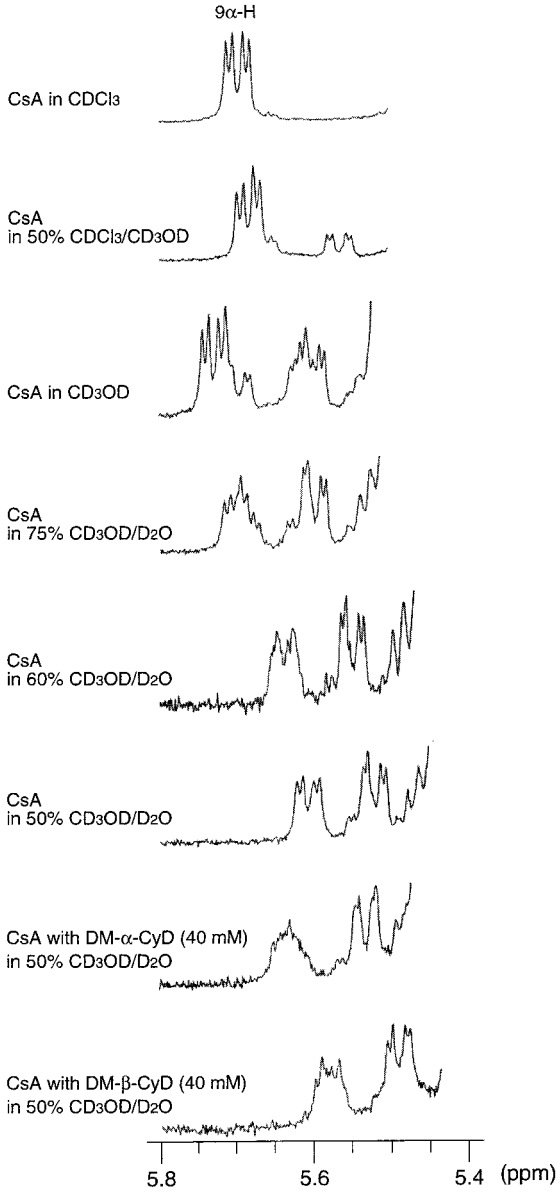

Figure 8—Changes of α proton peaks of MeLeu9 by the addition of DM-CyDs (40 mM) in 50% v/v CD_3OD/D_2O.

and [11β-H (2.11 ppm), 11γ-H (1.24 ppm) and 11N-CH_3 (2.76 ppm) for MeVal11].

Figures 6 and 7 show the effect of DM-α-CyD and DM-β-CyD, respectively, on the chemical shift of the assigned protons of CsA in 50% v/v methanol/water solution. The chemical shift of CsA protons shifted downfield by the addition of DM-α-CyD and magnitude of the change decreased generally in the order of (MeBmt ≈ MeLeu9 ≈ MeLeu10 ≈ MeLeu4) > (MeLeu6 ≈ Val5) > (MeVal11 ≈ Ala7 ≈ Ala8). These results suggest that DM-α-CyD includes preferably the hydrophobic side chains of amino acids such as the butenylthreonine and leucine, although there is seemingly no preference of the inclusion between MeBmt and four leucine residues in CsA molecule. On the other hand, DM-β-CyD system showed the upfield shift of CsA protons at lower concentrations of the host, while the shift was directed gradually toward downfield at higher concentrations, suggesting high order complexation. Similar biphasic change of ^{1}H NMR chemical shift was observed for the interaction of an antiulcer chalcone derivative with β-CyD.[19] The DM-β-CyD-induced shifts were uniform for all protons of CsA, indicating that the host having the larger cavity includes loosely a side chain of CsA without

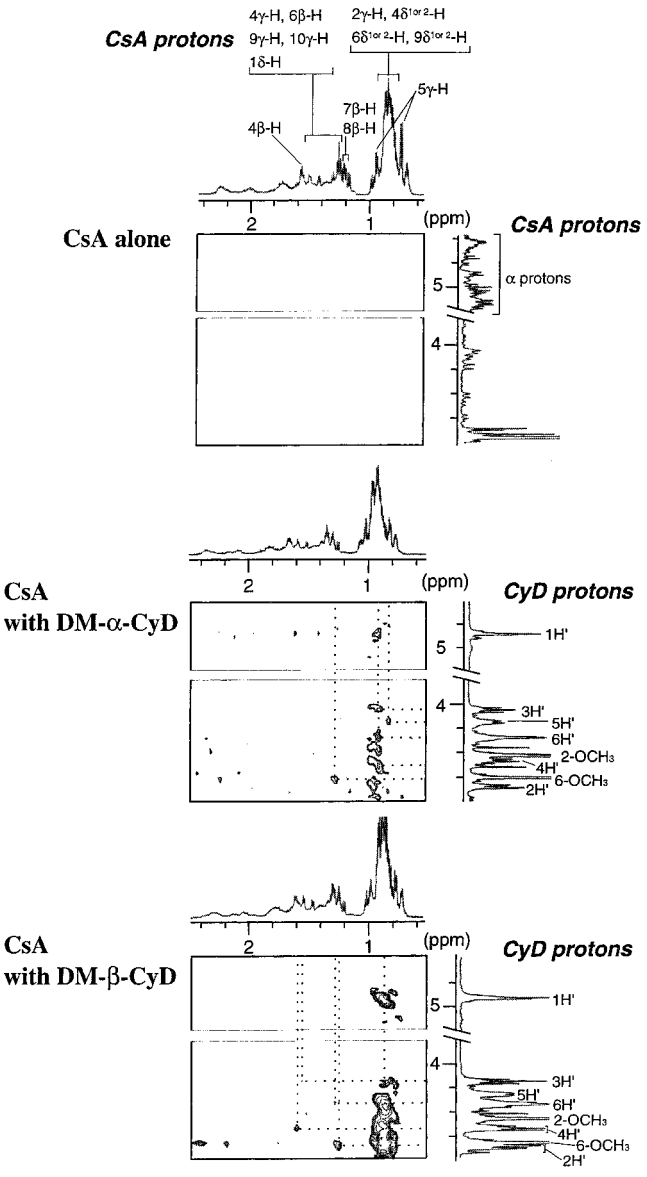

Figure 9—Partial contour plots of ROESY spectra of CsA (4 mM)/DM-CyDs (30 mM) systems in 50% v/v CD_3OD/D_2O.

a preferential inclusion of one particular amino acid. Figure 8 shows the changes of the α proton peaks of MeLeu9 (9α-H) due to the addition of DM-CyDs. As described above, the double-doublet (5.70 ppm) of 9α-H proton changed to at least two double-doublets (5.60 and 5.52 ppm), and the ratio of peak areas ($A_{5.52}/A_{5.60}$) at 5.60 and 5.52 ppm increased from 0 to 0.20, 0.69, 0.93, 0.95, and 1.00 by changing the solvent from chloroform to 50% v/v chloroform/methanol, methanol, and 75%, 60% and 50% v/v methanol/water solutions, respectively. The ratio of the peak area in 50% v/v methanol/water solution was insignificantly altered by the addition of DM-CyDs (0.91 and 1.06 in the presence of 4.0×10^{-2} M DM-α-CyD and 4.0×10^{-2} M DM-β-CyD, respectively). These results suggest that DM-CyDs do not interact so strongly with CsA as to alter the backbone structure of the guest, while they interact rather weakly with the side chains of CsA. The partial inclusion mode was further confirmed by ROESY spectra,[20,21] as described below. Figure 9 shows ROESY spectra of CsA in the absence and presence of DM-CyDs in 50% v/v methanol/water solution. DM-CyDs gave one ^{1}H-signal at 5.1 ppm and other signals between 3−4 ppm, and all signals were assigned according to the report of Chujo et al.[22] The signals of CsA can be generally classified to three groups, i.e., 4−6 ppm for α protons of amino acids, 2.5−3.5 ppm for *N*-methyl protons, and 0−2.4 ppm for protons of alkyl side chains. By the addition of DM-CyDs, new ROESY cross-peaks emerged between CyD protons and CsA alkyl side chain protons, whereas no cross-peaks were observed for *N*-methyl protons and α protons of CsA amino acids. These cross-peaks between DM-CyDs and the alkyl side chains were not observed in the absence of DM-CyDs. Furthermore, not only the inside protons of CyD (H3 and H5) but also the outside protons (H2 and H4) were involved in the cross-peaks. These results suggest that a hydrophobic side chain of CsA is included within the DM-CyD cavity, and other side chains interact with or fold on the outside of CyDs.

In conclusion, the data obtained from the solubility method and mass and NMR spectroscopic studies indicate that CsA interacts with DM-CyDs in aqueous solution, and the side chains of CsA may be involved in the inclusion. Furthermore, there is seemingly no preference of the inclusion of a particular side chain of CsA amino acid, but several complexes with different inclusion structures may exist simultaneously in solution, i.e., the so-called multimodal inclusion occurs in the interaction of CsA with DM-CyDs.

Accepted for publication October 2, 1998.

Abstract □ Prednisolone (5 mg/kg intravenous) was administered to adrenalectomized male and female Sprague-Dawley rats (250–350 g) to assess the effects of gender on disposition and pharmacoimmunodynamics. Plasma concentrations of prednisolone were determined by high-performance liquid chromatography. Incorporation of [^{3}H]thymidine (^{3}H-TDR) was used to determine whole blood T-cell (WBTC) trafficking and deactivation following stimulation with Concanavalin-A. Whole blood T-cell trafficking was determined indirectly by using the glucocorticoid receptor antagonist RU-40555 (250 ng/mL) added to ex vivo cultures of whole blood from animals dosed with prednisolone. Mean (± SD) prednisolone clearance values were 3.22 ± 0.88 and 3.46 ± 0.96 L/h/kg in males and females, respectively. After administration of prednisolone, relative T-cell counts decreased slowly with time to reach a nadir at 3–5 h and returned to baseline levels by 8 h. Fitting data using an indirect response model yielded mean prednisolone 50% inhibitory concentration for inhibition of WBTC trafficking (IC_{50T}) that was lower in males compared with females (0.14 ± 0.16 versus 1.03 ± 0.06 ng/mL; $p < 0.05$). In the absence of RU-40555, an immediate and complete inhibition of ^{3}H-TDR incorporation into WBTC was observed (deactivation) and baseline levels were recovered slowly as prednisolone was cleared from blood. The mean 50% inhibitory concentration for inhibition of WBTC deactivation (IC_{50D}) based on an inhibitory I_{max} model was similar in males and females (0.20 ± 0.24 versus 0.18 ± 0.12 ng/mL). Although male and female rats have similar exposure to prednisolone after 5-mg/kg doses, males are more sensitive to the inhibition of WBTC trafficking, whereas no gender effects on deactivation of WBTC exist.

Introduction

Glucocorticoids have a major role in the treatment of allograft rejection and several allergic, autoimmune, and malignant diseases in humans.[1] They profoundly suppress various nonspecific inflammatory responses and specific immunologic processes.[2] The mechanism by which they exert these actions is yet to be fully understood. However, lymphocytes mediate several glucocorticoid responses. The importance of trafficking of circulating lymphocytes and monocytes in mediating corticosteroid action has been documented.[3] In addition, corticosteroids profoundly inhibit T-cell activation (clonal expansion of antigen specific T-cells), cellular events that occur during an encounter with peptide antigens. Some of the current knowledge of cellular events in T-cell activation is based on in vitro experiments in which T-cells can be stimulated in a controlled manner with lectins, such as concanavalin-A (Con-A), and their proliferation can be measured by the incorporation of [^{3}H]-thymidine (^{3}H-TDR).[4]

Considering heart transplant recipients treated with prednisone and cyclosporine, female recipients have more rejection episodes at 3 and 12 months than do males. Also, early withdrawal of maintenance steroids is less often achievable in women as compared with men (17 versus 65%).[5] These differences may be explained by genetic differences between genders and/or by the interactions of sex hormones with glucocorticoids in the regulation of the immune system. Indeed, estrogens stimulate the production of corticosteroid binding globulin (CBG) in rats.[6] This stimulation may alter the kinetics of prednisolone.[7] The influence of female sex hormones on glucocorticoid receptor binding parameters has also been observed in some responsive organs.[8,9] Lew et al.[10] found a correlation between the logarithm of plasma estradiol-17β and sensitivity of women to methylprednisolone inhibition of basophil trafficking. Moreover, estradiol inhibits rat thymocyte proliferation, T-cell suppressor activity, and mixed lymphocyte reactions.[11−13]

Improved use of glucocorticoids as antiinflammatory or immunosuppressive agents may be achieved by an understanding of the influence of covariates, such as gender, in their pharmacokinetics (PK) and pharmacodynamics (PD). The objectives of this work were to assess the influence of gender on prednisolone pharmacokinetics in conjunction with gender influences on prednisolone effects on whole blood T-cell (WBTC) trafficking and deactivation in rats.

Experimental Section

Animals—Adrenalectomized Sprague-Dawley male and female rats weighing 250−350 g were purchased from Harlan Sprague-Dawley Inc. (Indianapolis, IN) and housed in a 12 h light/12 h dark cycle and constant temperature environment (22 °C). The rats had free access to rat chow (Agway RMH 1000) and normal saline (NaCl, 0.9%) prior to the experiments. A total of 8 rats (4 males and 4 females) were used in the study, which adhered to the principles of Laboratory Animal Care (NIH publication # 85-23, revised 1985). Female rats were taken at proestrus (phase of the ovarian cycle exhibiting high levels of sex hormones). The rat estrus cycle lasts 4−5 days and is identifiable by changes in the vaginal cytology. Each phase exhibits different levels of sex hormones.[14]

A silastic cannula was surgically implanted in the right jugular vein for drug administration and blood sampling 7 days prior to study day. The surgery was done aseptically under ketamine/xylazine anesthesia (50/10 mg/kg). Cannulas were flushed daily and kept patent with 200 U/mL of heparin.

Materials—Prednisolone hemisuccinate and betamethasone were purchased from Sigma (St. Louis, MO). A working solution of prednisolone hemisuccinate at 13.4 mg/mL (equivalent of 10 mg/mL prednisolone) was made in sterile saline to administer a total volume of 500 μL/kg to the animals. RU-40555 was obtained as a gift from Roussel Uclaf (Romainville, France). Tritiated thymidine (^{3}H-TDR; 6.7 Ci/mmol) was purchased from Amersham

(Arlington Heights, IL). Concanavalin-A (Con-A) was obtained from ICN Biomedicals (Cleveland, OH).

Experimental Design—For assessment of incorporation of ^{3}H-TDR into WBTC (relative cell counts) as a function of time at baseline, 0.3 mL of blood were drawn with a heparinized syringe at 0, 3, 6, 9, and 12 h. Each blood sample was replaced with 0.3 mL of sterile normal saline. Because each phase of a 4-day estrus cycle lasts only 24 h, prednisolone was administered 4 days after baseline measurements. This delay allowed measurement of T-cell counts during baseline and prednisolone phases at the same stage of the estrus cycle of female rats. Prednisolone hemisuccinate (equivalent of 5 mg/kg of prednisolone) was administered as an intravenous (iv) bolus through the cannula, and then blood was sampled frequently over 12 h. After prednisolone administration, 0.4 mL of blood was withdrawn at 0.16, 0.33, 0.5, 0.75, 1, 2, 3, and 4 h and 0.2 mL at 0, 5, 6, 8, 9, and 12 h. Each blood sample was replaced with an equivalent volume of sterile normal saline. One hundred microliters of heparinized blood were used for ex vivo whole blood cultures. The remaining blood was centrifuged for 10 min at 5000 x *g*. The plasma was then aliquoted into Eppendorf tubes and stored at −20 °C for assay of prednisolone concentrations.

Assay Methodology—Whole Blood Cultures—The method of Fasanmade and Jusko[15] was used. Blood diluted 15-fold (145 μL) was dispensed into each well of 96-well flat-bottomed polystyrene multiple-well plate. Con-A (20 μL) was added to culture medium to give a final concentration of 10 ng/mL. Supplemented RPMI 1640 was added to give a total volume of 200 μL per well. Cells were incubated at 37 °C under a humidified atmosphere of 7% CO_2 for 96 h before adding ^{3}H-TDR (1 μCi per well). Cells were harvested with an automatic harvester (Skatron Instruments, Sterling, VA) at 20 h after the addition of ^{3}H-TDR. Cellularly incorporated radioactivity was assessed using a Packard Topcount microplate scintillation counter (Downers Grove, IL).

In Vitro Interaction of RU-40555 with Prednisolone in WBTC Deactivation—To determine the competitive inhibition of glucocorticoid receptors in vitro, whole blood from male rats was spiked with prednisolone to obtain final concentrations of 200, 1000, 2000, and 5000 ng/mL and incubated for 2 h at 37 °C prior to adding RU-40555 (250 ng/mL). The optimum concentration of RU-40555 was determined by Fasanmade and Jusko.[16] Whole blood was then diluted and stimulated with Con-A and cultured for an additional 96 h as described in the previous section. RU-40555 produces a complete inhibition of glucocorticoid receptor when the molar ratio RU-40555/glucocorticoids is 10 or greater. There is no difference between genders regarding the molar ratio for optimum inhibition (Dr. Gaillard-Kelly, personal communication, Roussel Uclaf).

High-Performance Liquid Chromatography (HPLC)—Prednisone was measured by the HPLC method of Rose and Jusko[17] as adapted for rats[18,19] using betamethasone as internal standard. The lower and upper limits of quantitation were 10 and 1500 ng/mL. The interday coefficient of variation (CV) for prednisolone was 7.03% at 25 ng/mL, 2.70% at 150 ng/mL, and 2.76% at 600 ng/mL.

Data Analysis—*Pharmacokinetics*—Prednisolone plasma concentrations (C_p) versus time (t) were described by:

$$C_p = Ae^{-\alpha t} + Be^{-\beta t} \quad (1)$$

The intercept coefficients (A and B) and slopes (α and β) were estimated by least-squares fitting using the ADAPT II.4 program (Biomedical Simulation Resource, Los Angeles, CA). The area under the prednisolone concentration−time curve (AUC = $A/\alpha + B/\beta$) and the area under the first-moment curve (AUMC = $A/\alpha^2 + B/\beta^2$) were then calculated. The mean residence time (MRT) was determined as the ratio of AUMC/AUC. Clearance (CL) was obtained as dose/AUC. The volume of distribution at steady-state was determined as $CL \cdot$MRT.

Pharmacodynamics—The model describing the time course of lymphocyte and ex vivo mitogen activation is depicted in Figure 1.

Lymphocyte Trafficking—Incorporation of ^{3}H-TDR into WBTC was used as an indirect measurement of WBTC counts. Because prednisolone inhibits lymphocyte trafficking, the incorporation of ^{3}H-TDR into WBTC varied with time following the pattern of a typical indirect response. Because blood samples from animals dosed with prednisolone contained the drug, complete deactivation of lymphocytes was observed after stimulation with Con-A causing inhibition of ^{3}H-TDR incorporation into WBTC. Thus, to assess the relative number of T-cells in 100 μL of diluted whole blood at each time point, samples of diluted blood from dosed animals were incubated with the glucocorticoid receptor antagonist RU-40555 (250 ng/mL). Complete blockade of prednisolone action then allowed the incorporation of ^{3}H-TDR into lymphocytes present in whole blood samples.

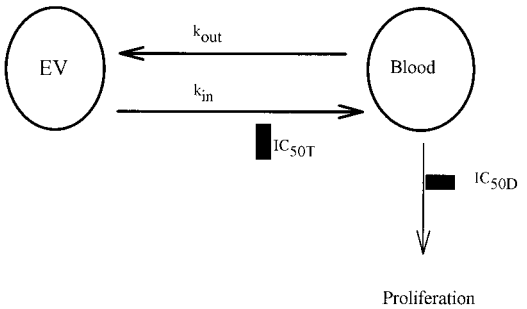

Figure 1—Pharmacodynamic model for the effects of prednisolone on whole blood T-cell trafficking and deactivation. Cells egress from blood to extravascular (EV) tissues with rate constant k_{out}, and the rate constant for return to blood is k_{in}. The IC_{50T} reflects prednisolone inhibition of k_{in} and IC_{50D} reflects the inhibition of mitogen-stimulated activation of whole blood T-cells.

Blood lymphocytes (L) circulate between the central and extravascular compartments. Corticosteroids inhibit the zero-order rate (k_{in}) of return of lymphocytes from the extravascular compartment without affecting their movement out of the central blood compartment (k_{out}). The scheme in Figure 1 and the following equation describe lymphocyte trafficking:[20]

$$\frac{dL}{dt} = k_{in} - k_{out}L \quad (2)$$

in which $L = L_0$ (cpm pre-dose) at $t = 0$. In the presence of prednisolone, the k_{in} is inhibited and the rate of change of lymphocyte counts with time is described by

$$\frac{dL}{dt} = k_{in}\left(1 - \frac{I_{max}C_p}{IC_{50T} + C_p}\right) - k_{out}L \quad (3)$$

where C_p is prednisolone plasma concentration, IC_{50T} is the concentration of prednisolone producing half-maximal inhibition (I_{max}) of k_{in}, and L is the observed cpm in ex vivo cultures treated with RU-40555.

Lymphocyte Deactivation—When whole blood samples drawn at various time points after prednisolone administration were cultured, an immediate and complete inhibition of ^{3}H-TDR incorporation into lymphocytes was observed and baseline levels recovered gradually. This inhibition was due to prednisolone concentrations present in blood samples. The level of ^{3}H-TDR observed was a function of the number of cells present in the blood at a given time (trafficking) and also a function of prednisolone plasma concentrations.

Lymphocyte deactivation by prednisolone is described as follows by the I_{max} model:

$$E = \left(1 - \frac{I_{max}C_p}{IC_{50D} + C_p}\right)L \quad (4)$$

where E is the observed cpm in cells from blood samples not treated with RU-40555 (intrinsic deactivation) and L is the observed cpm in cells treated with RU-40555, C_p is prednisolone plasma concentrations corrected for the dilution of blood, and IC_{50D} is prednisolone concentration producing half-maximal inhibition (I_{max}) of lymphocyte activation.

When both inhibition of cell trafficking and deactivation of lymphocytes occur, eqs 3 and 4 are fitted simultaneously.

To assess the net deactivation of WBTC following prednisolone administration, the area under lymphocyte trafficking (baseline for the deactivation process) and deactivation curves from 0 to 12 h were calculated using the Spline method.[21] These values were used to calculate the area between baseline and effect curves (ABEC) and the area suppression ratio (AUC_{SR}) determined by

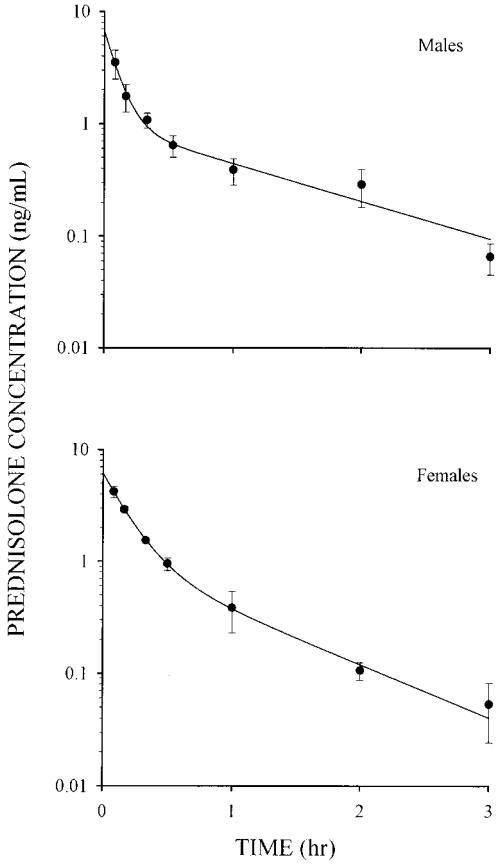

Figure 2—Mean (± SD) plasma concentration versus time profiles of prednisolone for males and females after iv administration of prednisolone 5 mg/kg. Symbols represent experimental data and lines are least-squares regression fittings.

eqs 5 and 6

$$\text{ABEC} = \text{AUC}^{12}_{0\ \text{BL}} - \text{AUC}^{12}_{0\ \text{E}} \quad (5)$$

$$\text{AUC}_{\text{SR}} = \frac{\text{AUC}^{12}_{0\ \text{E}}}{\text{AUC}^{12}_{0\ \text{BL}}} \quad (6)$$

where $AUC_0{}^{12}{}_E$ is the area under the deactivation curve from 0 to 12 h and $AUC_0{}^{12}{}_{BL}$ is the area under the trafficking curve from 0 to 12 h. Larger ABEC and smaller AUC_{SR} (which accounts for differing baselines) indicate greater net suppression.

The pharmacodynamic parameters for lymphocyte trafficking were determined by fitting cpm obtained with RU-40555 to eq 3, whereas pharmacodynamic parameters for lymphocyte deactivation were determined by simultaneously fitting cpm obtained with RU-40555 to eq 3 and cpm obtained without RU-40555 to eq 4. Prednisolone pharmacokinetic parameters were provided via eq 1. The ADAPT II.4 program (Biomedical Simulation Resource, Los Angeles, CA) was used for nonlinear regression fittings.

Statistical Aanalysis—The effects of gender on prednisolone CL, Vss, AUC_{SR}, ABEC, IC_{50T}, and IC_{50D} were assessed by an unpaired Student t-test, with statistical significance set at $p < 0.05$, using INSTAT (GraphPad Software, La Jolla, CA).

Results

Pharmacokinetics—Figure 2 shows mean plasma (± SD) concentrations versus time profiles of prednisolone in male and female rats. The disposition of prednisolone was biexponential, with a rapid initial phase followed by a slower elimination phase. Table 1 lists prednisolone pharmacokinetic parameters in the two groups. Mean (± SD) prednisolone clearance values were 3.22 ± 0.88 and 3.46 ± 0.96 L/hr/kg in males and females, respectively. Mean prednisolone $t_{1/2}$ values were 0.41 ± 0.12 h in males and 0.63 ± 0.40 h in females.

Table 1—Mean (± SD) Pharmacokinetic Parameters for Prednisolone in Male and Female Rats Following a Single iv Dose of 5 mg/kg (n = 4)

	males		females	
parameter	mean	SD	mean	SD
AUC (ng•h/mL)	1616	384	1526	436
MRT (h)	0.38	0.10	0.55	0.30
CL (L/h/kg)	3.22	0.88	3.46	0.96
Vd_{SS} (L/kg)	1.21	0.22	1.96	1.07
$t_{1/2}$ (h)	0.41	0.12	0.63	0.40

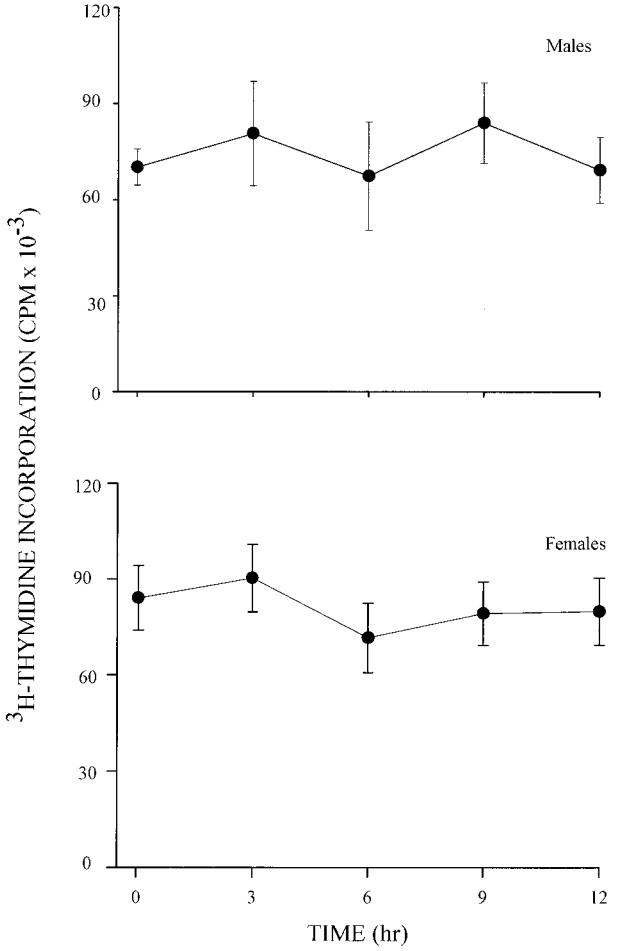

Figure 3—[^{3}H]Thymidine incorporation into whole blood T-cells as a function of time at baseline for male and females. Symbols represent mean (± SD) of data from four animals.

Pharmacodynamics—*Baseline ^{3}H-TDR Incorporation*—Figure 3 illustrates ^{3}H-TDR incorporation into WBTC (relative cell counts) as a function of time at baseline in male and female rats. No statistical differences were observed between time points, suggesting that baseline levels were steady over 12 h.

In Vitro Interaction of RU-40555 with Prednisolone in WBTC Deactivation—Figure 4 shows the influence of RU-40555 on prednisolone inhibition of lymphocyte proliferation in vitro (deactivation). This agent completely antagonized the effects of the steroid at all concentrations investigated. Additionally, RU-40555 did not produce any changes in WBTC from control values.

Lymphocyte Trafficking—Figure 5 depicts mean ± SD relative WBTC counts and T-cell deactivation as a function

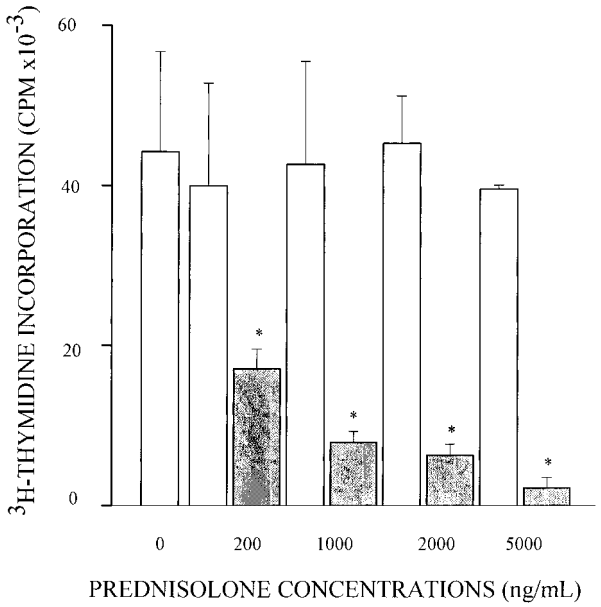

Figure 4—Joint effects of RU-40555 and prednisolone on whole blood T-cell deactivation in vitro. Key: (open bars) prednisolone + RU-40555 (250 mg/mL); (shaded bars) prednisolone alone; (*) $p < 0.05$ comparing single versus dual agents.

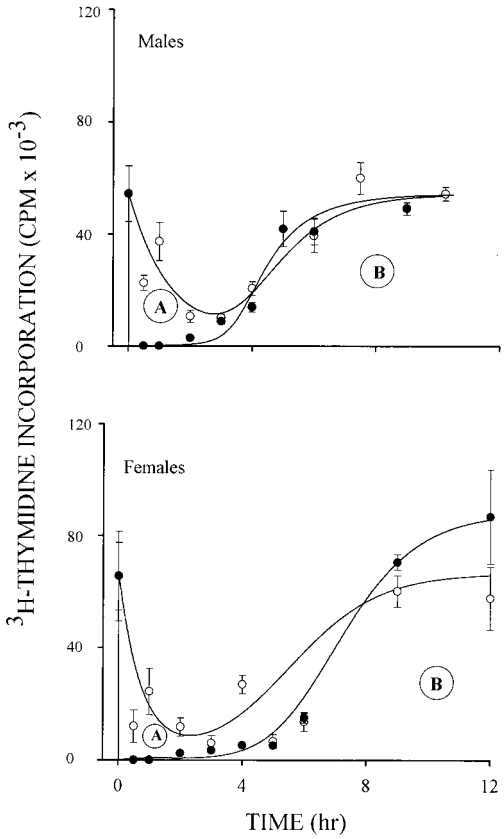

Figure 5—Mean (± SD) [^{3}H]thymidine incorporation into whole blood T-cells as a function of time in male and female rats after administration of prednisolone. Symbols are experimental data and lines represent fittings to the pharmacodynamic model. Key: (○) [^{3}H]thymidine incorporation in the presence of RU-40555 (trafficking); (●) [^{3}H]thymidine incorporation in absence of RU-40555 (deactivation). $AUC_{BL} = A + B$; $AUC_E = B$, and $AUC_{SR} = B/(A + B)$.

of time in male and female rats. After administration of prednisolone, the incorporation of ^{3}H-TDR into WBTC cultured with RU-40555 (relative WBTC counts) decreased slowly with time to reach a nadir at 3−5 h and returned to baseline levels by 8 h. Table 2 lists the pharmacodynamic parameters for trafficking and deactivation. Responses attained zero values and this complete inhibition allowed I_{max} to be set to 1. The mean (± SD) prednisolone IC_{50T} values for inhibition of WBTC trafficking was smaller in males compared with females (0.14 ± 0.16 versus 1.03 ± 0.06 ng/mL; $p < 0.05$). The net effect of prednisolone on lymphocyte trafficking (AUC_{SR}) could not be calculated because of the rebound effect observed in lymphocyte proliferation after the recovery of baseline in several animals (T-cell count rose above baseline levels).

Table 2—Mean (± SD)[a] Pharmacodynamic Parameters for Prednisolone Effects on Whole Blood T-Cell Trafficking and Deactivation in Male and Female Rats Following a Single iv Dose of 5 mg/kg

	trafficking				deactivation			
	males		females		males		females	
parameter	mean	SD	mean	SD	mean	SD	mean	SD
k_{in} (cpm/h) × 10^{-3}	44.0[b]	4.2	119	38	NA[c]	NA	NA	NA
k_{out} (h^{-1})	0.73[b]	0.18	1.35	0.44	NA	NA	NA	NA
IC_{50T} or IC_{50D} (ng/mL)	0.14[b]	0.16	1.03	0.06	0.20	0.24	0.18	0.12
ABEC (cpm·h) × 10^{-3}	NA	NA	NA	NA	130	80	232	208
AUC_{SR}	NA	NA	NA	NA	0.72	0.22	0.72	0.26

[a] All values represent the mean (± SD) of four individual animals. [b] $p < 0.05$ as compared with the respective value in females. [c] NA, Not applicable.

Lymphocyte Deactivation—Following prednisolone administration, an immediate and complete inhibition of ^{3}H-TDR incorporation into lymphocytes cultured without RU-40555 was observed and baseline levels recovered slowly as prednisolone was cleared from blood (Figure 5). This response also showed complete inhibition, allowing I_{max} to be set to 1.0. The mean (± SD) IC_{50D} values for WBTC deactivation were similar in males and females (0.20 ± 0.24 vs 0.18 ± 0.12 ng/mL). A reduced ^{3}H-TDR incorporation into lymphocytes was still observed after prednisolone concentrations declined below the limit of quantitation (3 h post dose). There were no statistically significant differences between males and females with respect to the net deactivation of WBTC as shown by the mean AUC_{SR} values (0.72 ± 0.22 in males and 0.72 ± 0.26 in females).

Discussion

To assess gender as a covariate in the optimization of glucocorticoid immunosuppressive therapy, we investigated WBTC trafficking and deactivation in male and female rats following a single dose of prednisolone. The pharmacokinetic parameters for prednisolone obtained in the present study were in the same range as those reported by Boudinot et al.[18] Although evidence exists supporting the role of sex steroid hormones in the regulation of transcortin (CBG), no statistical differences in prednisolone *CL* and steady-state volume of distribution (Vd_{ss}) between males and females were found (Table 1). These results may be explained by the relatively low dose used in this study (5 mg/kg). The binding of prednisolone to CBG is responsible for its dose-dependent disposition.[19] Unfortunately, we were unable to measure unbound prednisolone in this study.

Glucocorticoids exert some of their antiinflammatory actions by inhibiting the return of WBTC from the extravascular compartment to the blood compartment. In addition to such lymphocytopenia, these drugs deactivate T-cells to render them nonresponsive to peptide antigens. Glucocorticoids affect T-cell trafficking and deactivation via regulation of the secretion of cytokines, such as IL-2, and adhesion molecules.[22] Bloemena et al.[23] demonstrated that

decreased lymphocyte numbers in the peripheral blood are one of the determinant of the proliferative response of WBTC. Because proliferation of peripheral blood lymphocytes was measured in a standardized volume of blood (100 μL) at every time point, it was assumed that ^{3}H-TDR incorporation was determined by the proliferative capacity of individual lymphocytes as well as by the number of lymphocytes present in the peripheral blood. Thus the incorporation of ^{3}H-TDR into whole blood cultures was used to simultaneously determine the effects of prednisolone on WBTC trafficking and their intrinsic activation.

Relative WBTC number was determined by using the glucocorticoid receptor antagonist RU-40555 added to ex vivo cultures of whole blood from dosed animals.[24] This agent antagonizes prednisolone deactivation of WBTC in vitro (Figure 4) in the same concentration range as that obtained with a 5-mg/kg dose (Figure 2). The concentration of RU-40555 utilized did not affect WBTC (Figure 4). Therefore, the incorporation of ^{3}H-TDR into whole blood cultures measured in the presence of RU-40555 could be taken as the relative number of WBTC present at each time point. In normal humans, lymphocyte trafficking between blood and extravascular compartments parallels the circadian variation of endogenous cortisol (the number of lymphocytes shows a clear rhythmicity with high values at night and low values during the day).[25] In this study, we utilized adrenalectomized animals to suppress the effect of the latter because the adrenal gland is the main source of endogenous glucocorticoids. This objective was achieved because the incorporation of ^{3}H-TDR into whole blood cultures at baseline was stable over 12 h (Figure 3). Whole blood lymphocytes decreased after administration of prednisolone. This time profile (Figure 5) was similar to that obtained in humans. The maximum response was delayed with respect to prednisolone concentrations, showing that our method describes well the movement of cells between the blood and extravascular compartments. An innovative PK/PD model that incorporates features of indirect effects of prednisolone on cell trafficking as well as direct inhibition of ex vivo T-cell activation was used.[16] The model described well the experimental data, and pharmacodynamic parameters were obtained with relatively good precision (5−20% CV). Prednisolone had a significantly smaller IC_{50T} in males compared with females. This result show that male rats may be more sensitive than females to inhibition of WBTC trafficking by prednisolone. These observations may be due to gender differences in estrogen levels. Indeed, estrogen receptors are found on lymphoid cells.[26] Estradiol inhibition of polymorphonuclear leukocyte chemotaxis is mediated by estrogen receptors.[27] Also, estradiol down-regulates the expression of P-selectins, molecules involved in the regulation of cell trafficking.[28]

Following prednisolone administration, an immediate and complete inhibition of ^{3}H-TDR incorporation into lymphocytes was observed in whole blood without RU-40555. Baseline values were recovered slowly as prednisolone was cleared from blood. The diminished responsiveness of WBTC to stimulation with Con-A (intrinsic deactivation) appeared to be a direct effect of prednisolone because the degree of inhibition of ^{3}H-TDR incorporation paralleled that of prednisolone concentrations. This result required very small steroid concentrations. Indeed, considerable inhibition remained when the drug fell below the limit of quantitation. The sensitivity of WBTC to prednisolone deactivation was not affected by gender as no statistical differences were observed in the mean IC_{50D} and AUC_{SR} (net suppression) values between males and females. Ferron and Jusko[29] also recently found no gender differences in in vitro WBTC effects of prednisolone in adrenalectomized rats and in humans.

In conclusion, by using a glucocorticoid receptor antagonist, we were able to monitor simultaneously two major components of glucocorticoid immunosuppression (trafficking and deactivation). The use of RU-40555 allowed separation of these phenomena, permitting estimation of IC_{50} values for prednisolone effects on each component. Greater immunosuppression was achieved overall in male rats compared with females following a 5-mg/kg single dose of prednisolone. However, no gender differences were observed in either the exposure to the drug or WBTC deactivation.

Abbreviations

^{3}H-TDR	[^{3}H]thymidine
WBTC	whole blood T-cell
Con-A	concanavalin-A
IC_{50T}	concentration producing 50% inhibition of the zero-order rate constant (k_{in}) for return of blood T-cells from the extravascular compartment to the blood compartment
IC_{50D}	concentration producing 50% inhibition of whole blood T-cell activation
I_{max}	maximum inhibition of the zero-order rate constant (k_{in}) for return of blood T-cells from the extravascular compartment to the blood compartment or maximum inhibition of whole blood T-cell activation.
ABEC	area between baseline and effect curves
AUC_{SR}	ratio of the area between the effect curve and the area at baseline
cpm	counts per minute
k_{in}	zero-order rate for return of lymphocytes from the extravascular compartment to the blood compartment
k_{out}	first-order rate constant for exit of lymphocytes from the blood compartment
CL	Clearance
Vd_{ss}	apparent volume of distribution at steady state
$t_{1/2}$	terminal half-life
MRT	mean residence time
AUC	area under the plasma concentration−time curve
AUMC	area under the first moment curve

Abstract □ β-1-*O*- (NAG) and 2-*O*-glucuronides (2-isomer) of (*S*)-naproxen (NA) were prepared to determine which positional isomer(s) of the acyl glucuronide of NA is responsible for forming covalent adducts with human serum albumin (HSA). Their comparative stability and covalent binding adduct formation with HSA were investigated at pH 7.4 and at 37 °C. NA and its acyl glucuronides were simultaneously determined by HPLC. Three positional isomers were formed successively after incubation of NAG in the buffer only. However, when NAG was incubated with HSA (30 mg/mL), isomers other than the 2-isomer were formed in little or negligible quantities. In HSA solution, NAG ($k_d = 2.08 \pm 0.08$ h^{-1}) was four times less stable than 2-isomer ($k_d = 0.51 \pm 0.02$ h^{-1}). NAG was degraded by hydrolysis ($k_{hyd} = 1.01 \pm 0.10$ h^{-1}) and isomerization ($k_{iso} = 1.07 \pm 0.07$ h^{-1}) to the same extent; however, hydrolysis was predominant for the 2-isomer ($k_d = 0.51 \pm 0.02$ h^{-1}). The incubation of both NAG and 2-isomer with HSA led to the formation of a covalent adduct; however, the adduct formation from the 2-isomer proceeded more slowly than that from NAG. The present results suggest that the covalent binding of NA to HSA via its acyl glucuronides proceeds through both transacylation (direct nucleophilic displacement) and glycation mechanisms; NAG rapidly forms an adduct that may be unstable, and the protein adduct from the 2-*O*-acyl glucuronide is as important for the covalent binding as those from the 1-*O*-acyl glucuronides.

Many acidic drugs with carboxylic acid functions are metabolized to reactive acyl glucuronides, which are susceptible to hydrolysis, isomerization (intramolecular acyl migration), and irreversible (covalent) binding to proteins under physiological conditions.[1,2] These reactions are considered to proceed through transacylations to the hydroxyl ion, to a different OH-group of the glucuronic acid moiety and to a nucleophilic group on the protein molecule, respectively, as suggested in an oxaprozin glucuronide study.[3] Formation of irreversible binding of carboxylic acid-containing drugs, such as nonsteroidal antiinflammatory drugs (NSAIDs), via their acyl glucuronide metabolites, is now well recognized and is a potential cause of hypersensitivity.[2,4,5] The exact mechanism underlying irreversible binding to proteins, however, has not yet been clarified due to the instability of acyl glucuronides. Two possible mechanisms can be considered: transacylation and glycation mechanisms.[6,7] Based on these proposed mechanisms, two different types of adduct can be formed: one is a transacylation adduct, where aglycon binds, via displacement of the glucuronic acid moiety from acyl glucuronide, directly to the protein NH_2, SH, or OH groups to yield an irreversibly bound adduct of aglycon linked to the protein by an amide, thioester, or ester linkage; the other is a rearrangement/glycation adduct, where acyl migration of the glucuronide has occurred, allowing the open chain form of the glucuronic acid moiety to react with an amino group to form an imine (Schiff's base). Subsequent Amadori rearrangement can then yield a more stable ketamine derivative.

The extent of covalent adduct formation via the acyl glucuronides varies from their parent NSAIDs. Benet et al.[6,8] showed that a striking correlation was observed between the extent of irreversible binding to protein and the degradation rate constant of acyl glucuronides. This strongly suggests that covalent adduct formation may reflect the reactivity of the corresponding acyl glucuronide. Although the degradation and covalent binding have been simultaneously investigated for some β-1-*O*-acyl glucuronides of NSAIDs,[9−11] it is not clear which ester(s) contributes to the formation of covalent binding to proteins. If the transacylation mechanism is predominant for the formation of irreversible binding to proteins, β-1-*O*-acyl glucuronide should relate mainly to the formation; if the Schiff's base mechanism is predominant, positional isomer(s) of β-1-*O*-glucuronide should contribute to the formation of covalent binding. In vitro stereoselective stability and binding properties of β-1-*O*-acyl glucuronides of (*S*)- and (*R*)-naproxen (NA) and in vivo stereoselective disposition of naproxen β-1-*O*-acyl glucuronide (NAG), using rats, have been reported by Benet et al.[8,12] However, the individual contributions of both hydrolysis and transacylation to the overall degradation of NAG, and the stability of positional isomers of NAG and their contribution to covalent protein binding, remain unclear.

In this study, we isolated the 2-*O*-acyl positional isomer (2-isomer) of (*S*)-NAG, in which the acyl-containing aglycon migrates from the glycosidic linkage at C-1 to a new ester linkage with a hydroxyl group at C-2 of the glucuronic acid moiety, and investigated its reactivity with human serum albumin (HSA) comparing it with that of (*S*)-NAG to test which possible mechanism is dominant for the formation of covalent binding. Our results show that (1) in the presence of HSA, NAG is subjected to both hydrolysis to NA and isomerization to the 2-isomer to the same extent, while further isomerization to the 3- and 4-*O*-acyl positional isomers is negligible, and (2) the covalent adduct of NA is formed mainly from 1-*O*-acyl- and 2-*O*-acyl glucuronides, not 3-*O*-acyl and 4-*O*-acyl glucuronides; the former may be unstable and act as an intermediate for HSA-catalyzed hydrolysis while the latter may be a stable adduct, which will be important for immunoreactive side-effects.

Experimental Section

Materials—(*S*)-NA (enantiomeric excess > 0.98), phenylmethylsulfonyl fluoride, and fatty acid free-HSA (fraction V) were purchased from Sigma Chemical Co. (St. Louis, MO). The molecular weight of HSA was assumed to be 69000.[13] Tryptophol [2-(3-

indolyl)ethanol] was obtained from Tokyo Kasei Co. (Tokyo, Japan). Other chemicals used were of analytical or HPLC grade.

Preparation of Glucuronides of NA—(*S*)-NAG was extracted from human urine, which was collected following a 600 mg oral administration of (*S*)-NA (Naixan, Tanabe Pharmaceutical Co., Tokyo, Japan). Urine was collected over 24 h into a vessel containing phosphoric acid to stabilize the NAG by lowering the pH to 3−4. The urine was treated as described by Smith et al.,[14] with minor modifications. The extract was then separated by liquid-chromatography with a Cosmosil 75C18-OPN column (Nacalai Tesque Inc., Kyoto, Japan). NAG was eluted from the column with the stepwise gradient of acetonitrile/0.05 M acetic acid, 10:90, 20:80, and 30:70 (v/v). After the fractions containing NAG were evaporated with a rotary evaporator at 30 °C, the remaining aqueous solution was lyophilized. The 2-*O*-acyl positional isomer (2-isomer) of (*S*)-NAG was prepared after 6-h incubation of (*S*)-NAG in 0.1 M phosphate buffer at pH 7.4 and at 37 °C. 2-Isomer extracted from the solution was purified by Sephadex LH-20 using 50% methanol as an eluting solvent. The purity of the glucuronides obtained was determined by analytical HPLC and exhibited homogeneous properties (>98%) at a UV wavelength of 254 nm, with the remaining fraction represented by polar impurities that did not yield NA when treated with 1 M NaOH for 1 h. The structures of the glucuronides were confirmed by ^{1}H NMR and ^{1}H−^{1}H shift correlation NMR. NMR spectra were obtained on a JEOL GX-500 at 500 MHz using deuterated methanol, with tetramethylsilane as an external reference.

Analysis of NA and Its Glucuronides Using HPLC—Analyses of NA and NAGs were performed according to the method described by Bischer et al.[8] using a Shimadzu LC6AD solvent delivery system (Shimadzu Co., Kyoto, Japan), a Shimadzu RF-535 fluorescence monitor, a Shimadzu C−R4A Chromatopac integrator, and a Cosmosil 5C18-AR column (5 μm particle size, 4.6 × 250 mm, Nacalai Tesque Inc., Kyoto, Japan).

Stability Studies—NAG (35−40 μM) was incubated at 37 °C in 0.1 M sodium phosphate buffer (pH 7.4), and 50 μL aliquots were collected at timed intervals for analysis. Similar incubations using (*S*)-NAG (ca 35 and 135 μM) and *S*-2-isomer (ca. 30 μM) were also run in the presence of 30 mg/mL (435 μM) HSA. Aliquots were immediately mixed with 10 μL of 17% phosphoric acid and 50 μL of acetonitrile containing 4 μg/mL of tryptophol as an internal standard. The precipitated protein was removed by centrifugation, and a 3 μL-portion of the supernatant was analyzed by HPLC.

Determination of in Vitro Covalent Binding to HSA—NAG or 2-isomer was incubated at 37 °C for 30 h in 0.1 M phosphate buffer containing 30 mg/mL HSA, as described above. Aliquots (300 μL) of each reaction mixture were taken at different time points to assay the covalently bound drug. The binding yield for irreversible binding of the glucuronides was quantified using the method of Bischer et al.[8]

Data Analysis—The rate constants for hydrolysis and isomerization of the glucuronides were estimated using the model shown in Figure 1. The calculation for the kinetic parameters was performed with a nonlinear least-squares fitting program, WinNonlin (Scientific Consulting, Inc., Apex, NC).

Results

NMR Spectra of NAG and Its 2-*O*-Regioisomer—Identification of the purified acyl glucuronides was achieved using proton NMR analysis. Spectral features of NAG were similar to those reported by Wilson and Nicholson,[16] although confirmation of each proton signal was not performed. The results are summarized in Table 1, in which ^{1}H signals observed for GlcA in deuterated water and NA in deuterated methanol are also included as the reference compounds. A one-proton signal observed at 5.522 ppm as a doublet was easily assigned to H-1′ of the GlcA residue. The large coupling constant (J = 8.2 Hz) suggested that D-GlcA was bound to NA through a β-linkage. Due to lack of protons at the C-6 position, the proton signal (H-5′) attached to C-5 was also clearly observed as a doublet at a lower field (3.730 ppm). Starting from these characteristic signals of H-1′ and H-5′ of GlcA, all the proton signals were easily assigned by using the ^{1}H−^{1}H shift correlation spectra (data not shown).

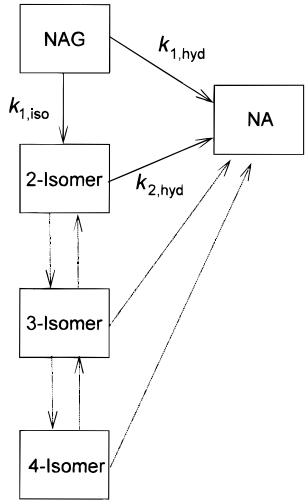

Figure 1—Kinetic model employed for the estimation of rate constants of hydrolysis and isomerization of NAG in HSA solution: $k_{1,hyd}$ and $k_{1,iso}$ are the first-order rate constants of hydrolysis to NA and isomerization to the 2-isomer from NAG, respectively. $k_{2,hyd}$ is the first-order rate constant of hydrolysis to NA from the 2-isomer.

The most abundant compound, 2-isomer, after 6-h incubation of NAG at pH 7.4 and at 37 °C was obtained in an almost pure state (>97% by HPLC). The ^{1}H−^{1}H shift correlation spectra of the 2-isomer is shown in Figure 2, which indicates the presence of a small amount of other isomers. Signals of GlcA moiety were assigned in Figure 2. The H-1′ signal of GlcA was observed at 5.345 ppm as a doublet with a small coupling constant (J = 3.4 Hz), indicating that the isomer was an α-isomer. The H-1′ signal of the corresponding β-isomer was not observed, probably due to overlap with a signal of HOD.[17] However, we were able to assign all of the signals from the ^{1}H−^{1}H shift correlation spectra. The H-2′ signal was observed at 4.652 ppm, which is 1.22 ppm lower than that of NAG. This

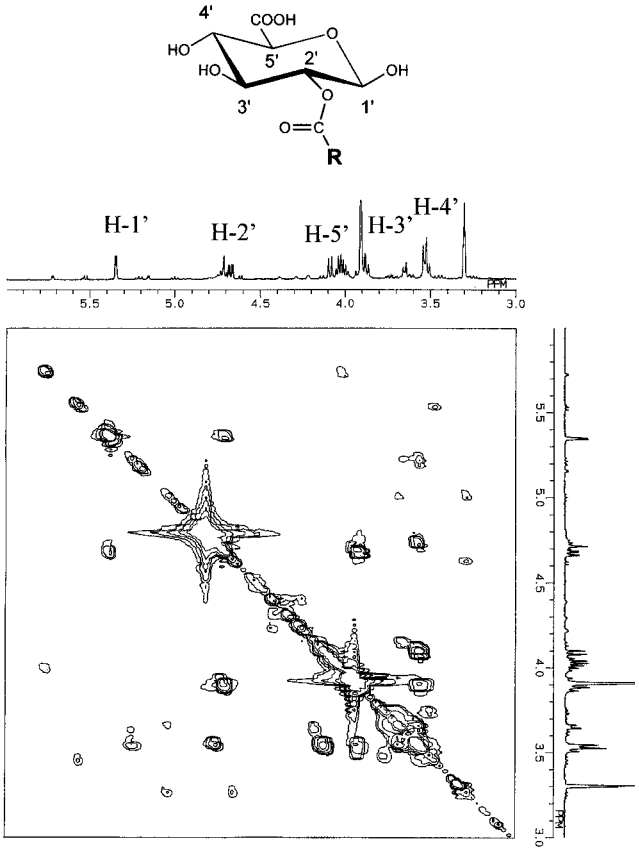

Figure 2—^{1}H–^{1}H shift correlation spectra of the *S*-2-isomer.

shift obviously indicated that the hydroxyl group attached at C-2 of GlcA was substituted with NA.

Degradation of NAG and Its Regioisomer—(*S*)-NAG was incubated at pH 7.4 and at 37 °C in 0.1 M phosphate buffer for 72 h. The HPLC chromatograms of the incubation medium of NAG are shown in Figure 3. The time dependence of the degradation of (*S*)-NAG and the appearance of its isomers and hydrolyzed NA is shown in Figure 4. As has been reported for several other 1-*O*-acyl glucuronides, (*S*)-NAG underwent nonenzymatic isomerization (acyl migration) and hydrolysis at pH 7.4. In HSA-free buffer, (*S*)-NAG was subjected predominantly to acyl migration resulting in a rapid appearance of the 2-*O*-acyl isomer (2-isomer) and then gradual formation of other isomers (at least three peaks detected by HPLC). Hydrolysis of 1-*O*-glucuronide and/or its isomers to NA was slow when compared with isomerization. After 72-h incubation, three regioisomers, including the 2-isomer, equilibrated to almost the same concentration; about half of the initial amount of NAG was hydrolyzed to NA. The apparent degradation rate constant ($k_{1,deg}$) for (*S*)-NAG was 0.343 ± 0.010 h^{-1} in HSA-free buffer.

The time dependence of degradation of the β-1-*O*- and 2-*O*-glucuronides of (*S*)-NA was investigated in the presence of 30 mg/mL of HSA. The results are shown in Figure 5, parts A and B, respectively. For comparison, the logarithmic plots for degradation of the glucuronides of NA in HSA solution are presented in Figure 6 as well as the result obtained in HSA-free buffer. As shown in Figure 6, the incubation of NAG with HSA at pH 7.4 resulted in a more rapid degradation when compared with the corresponding rate constant in HSA-free buffered solution, showing that HSA plays a major role in the degradation of NAG. In the presence of HSA, the contribution of hydrolysis to total degradation of NAG increased when compared with that in HSA-free buffer, as seen by the rapid

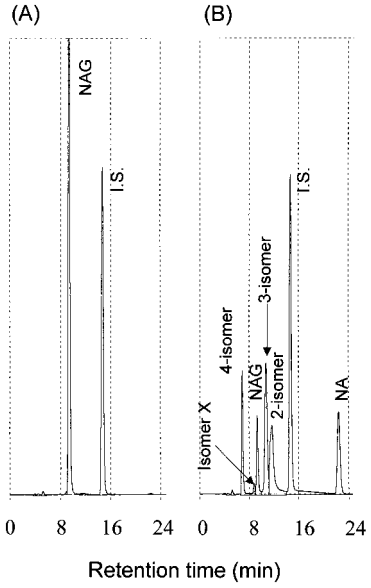

Figure 3—HPLC chromatograms of product mixtures from incubation of NAG after incubation in 0.1 M phosphate buffer (pH 7.4) at 37 °C for 30 s (A) and 6 h (B). Isomer X is an unidentified minor isomer which was hydrolyzed by 1 M NaOH but not β-glucuronidase. I.S. is tryptophol and was used as an internal standard. Retention times of NAG, 2-, 3-, 4-isomers, isomer X, and NA are 9.2, 11.6, 10.8, 7.0, 8.8 and 22.2 min, respectively.

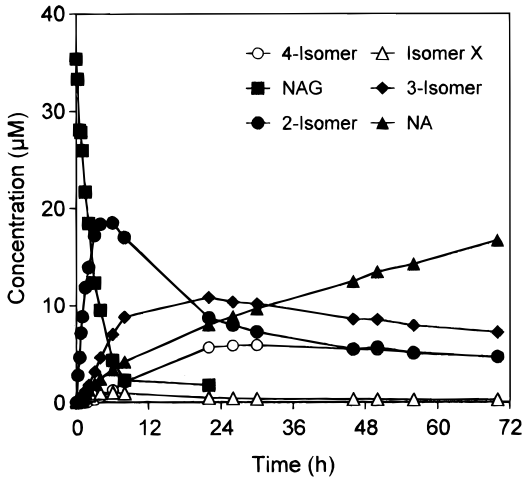

Figure 4—Time courses of rearrangement and hydrolysis of (*S*)-NAG in 0.1 M phosphate buffer (pH 7.4) at 37 °C. Only mean values (n = 3) are shown for the sake of visual clarity. Coefficients of variation for the data points ranged from 1 to 25%. Isomer X is an unidentified minor isomer which was hydrolyzed by 1 M NaOH but not β-glucuronidase.

appearance of NA. NAG was rapidly hydrolyzed to NA and isomerized to the 2-isomer, but no significant further acyl migration was observed in the buffer containing HSA (Figure 5A). This confirmed that further acyl migration of the 2-isomer to form the 3- and 4-isomers was negligible in the presence of HSA. The degradation rate constant ($k_{2,deg}$ = 0.514 ± 0.015 h^{-1}) was extremely slow for 2-isomer when compared with that for its β-1-*O*-acyl conjugates ($k_{1,deg}$ = 2.08 ± 0.08 h^{-1}), as shown in Figure 6. The 2-isomer was almost entirely hydrolyzed before further rearrangement, although only a small amount of the isomers was detected (Figure 5B). A higher initial concentration of (*S*)-NAG (mean 134 μM) resulted in a similar degradation pattern to the lower concentration experiments (data not shown).

The kinetic parameters of degradation reflecting both rearrangement and hydrolysis of each glucuronide were estimated based on the model shown in Figure 1. The

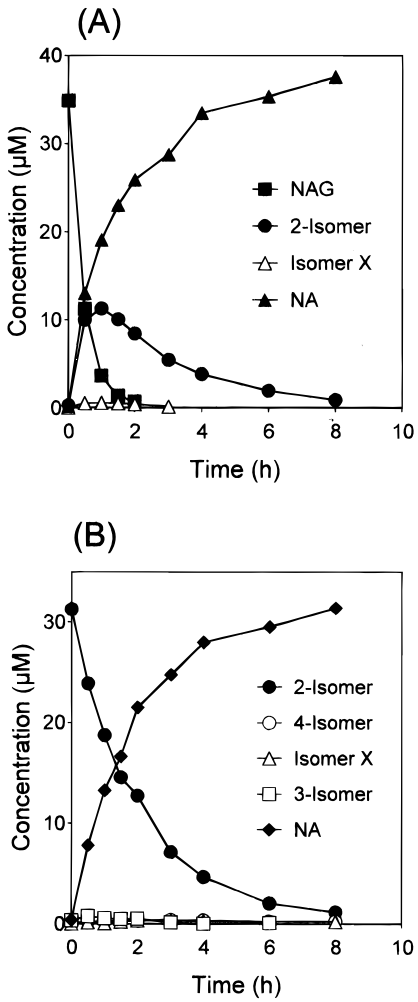

Figure 5—Time courses of rearrangement and hydrolysis of (*S*)-NAG (A) and *S*-2-Isomer (B) in 0.1 M phosphate buffer including 30 mg/mL of HSA (pH 7.4) at 37 °C. Only mean values ($n = 3$) are shown for the sake of visual clarity. Coefficients of variation for the data points ranged from 1 to 13%. Isomer X is an unidentified minor isomer which was hydrolyzed by 1 M NaOH but not β-glucuronidase.

parameters are shown in Table 2. The parameters were almost the same for the lower and higher initial concentrations, showing the linear kinetics in the degradation of β-1-glucuronides and its isomers under the conditions used. The contribution of hydrolysis of (*S*)-NAG to its total elimination was almost identical to the isomerization. The hydrolysis of the purified 2-isomer ($k_{2,hyd} = 0.514 \pm 0.015$ h^{-1}) occurred at approximately the same rate as for the 2-isomer formed in the (*S*)-NAG incubation experiment ($k_{2,hyd} = 0.446 \pm 0.043$ h^{-1}). The isomerization rate constant of (*S*)-NAG in the presence of HSA was also greater than its overall degradation rate constant in HSA-free solution, suggesting that HSA accelerated transacylation of (*S*)-NAG as well as its hydrolysis.

Irreversible Binding to HSA—The time dependence for irreversible binding formation of NA was investigated after incubation of NAG and 2-isomer at pH 7.4 and at 37 °C over 30 h. As shown in Figure 7, NAG rapidly produced a covalent adduct with HSA; the maximum yield was achieved after 1 h of incubation. The isomeric conjugate (2-isomer) also produced an irreversible binding adduct, although the maximum yield was achieved after ca. 8−10 h. The extent of irreversible binding yield from each of the glucuronides tested reached almost the same level, regardless of the differences in their stability. We calculated empirically the apparent first-order formation rate

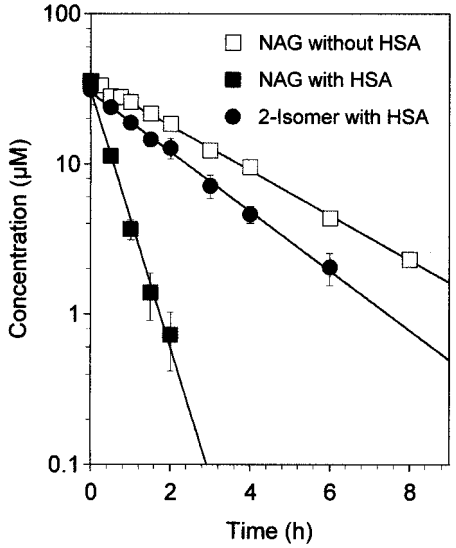

Figure 6—Logarithmic plots for degradation of NAG and 2-isomer without or with HSA. Each point and vertical bar represent the mean ± SD of three independent series. Error bar lines of NAG without HSA are within the outline of the symbol.

Table 2—Kinetic Parameters[a] for Hydrolysis and Isomerization of Glucuronides of NA in HSA Solution

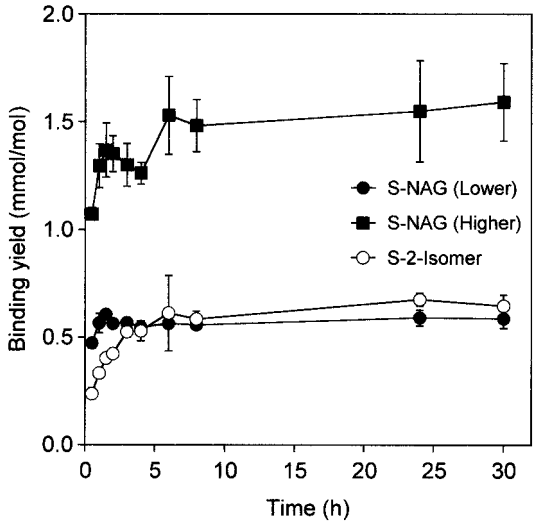

Figure 7—Time courses of irreversible binding of NA to HSA from acylglucuronides of NA in 0.1 M phosphate buffer (pH 7.4) at 37 °C. Each point and vertical bar represent the mean ± SD of three independent series.

constant of covalent binding using the following exponential equation: $BY = A(e^{-k_e t} - e^{-k_f t})$, where BY is the covalent binding yield, k_e and k_f being the apparent elimination and formation rate constants of the covalent adduct, respectively. The apparent formation rate constant ($k_f = 0.684 \pm 0.086$ h^{-1}) for irreversible binding from the

S-2-isomer was considerably smaller than that ($k_f = 3.55 \pm 0.39$ h^{-1}) from β-1-glucuronide, indicating that protein adduct formation from the 2-isomer occurred at a slower rate than that from NAG.

To test whether the extent of irreversible binding depended on the NAG concentration, a higher concentration of NAG was incubated under the same conditions. The increase in initial concentration of NAG to 134 μM from 35 μM for (*S*)-NAG produced a proportional increase in maximum adduct formation. However, interestingly, a secondary increase in adduct formation followed by a plateau level was observed. This phenomenon was not observed in the lower NAG concentration experiment.

Discussion

The stability and irreversible binding to protein of β-1-*O*-acyl glucuronides of many other carboxylic acid drugs have been reported. In this study, we compared the reactivities of a model acyl glucuronide, NAG, and its 2-*O*-positional isomer (2-isomer) in the presence of HSA, to gain an insight into the favored mechanism for irreversible binding. The present study clearly showed the regioselective differences of acyl glucuronides of NA in their stability and the formation of covalent binding to HSA.

To perform the study, we initially isolated a positional isomer (2-*O*-acyl derivative) of (*S*)-NAG and recorded its one-dimensional and two-dimensional proton NMR spectra when compared with (*S*)-NAG. The NMR data of some 1-*O*-acyl glucuronides[17,18] and the positional isomers of 1-*O*-acyl glucuronides[16,19,20] have been reported. In this study, all the proton signals of the positional isomer of NAG were confirmed. The regioisomers of β-1-acyl glucuronide can exist as α- and β-anomers. From a comparison with the NMR spectrum of GlcA, the 2-isomer exists mainly as α-anomer. The NMR spectrum of the mixture of isomers, which was obtained 6 h after incubation of (*S*)-NAG, was also analyzed (data not shown). Although other positional isomers (3- and 4-isomers), unfortunately, could not be obtained in a pure state, signals due to the H-1′ protons of the isomers were isolated from other ring protons of the GlcA residue. Hence, these signals in the anomeric region (around 5 ppm) may be good markers for determining the relative abundance of each isomer.

In the HSA-free buffer solution, at least four isomers of NAG were detected after incubation of NAG (Figure 3). Like diflunisal acyl glucuronide,[11,21] the 2-isomer was formed first followed by formation of other positional isomers. Finally, three abundant isomers reached an almost equivalent concentration. Since the 2-isomer was generally subject to further acyl migration,[11,21] these isomers, which appeared later, were probably 3- and 4-isomers. Acyl migration in the glucuronic acid residue is considered to proceed through an ortho ester-like intermediate.[22] Thus, we conclude that acyl migration occurs through the sequence β-1-glucuronide → 2-isomer, 2-isomer → 3-isomer and 3-isomer → 4-isomer. Therefore, the peaks of the isomers on the HPLC chromatogram are assigned here based on their order of appearance, as reported by Faed.[1] A similar result was reported for flufenamic acid and benoxaprofen.[18] The unidentified small amount of esters is probably their anomeric isomers.

In the buffer including HSA, the 2-isomer as well as NA was predominantly formed after incubation of NAG, and the formed 2-isomer was sequentially hydrolyzed before further rearrangement. Unlike the case in HSA-free buffer, the levels of regioisomers other than 2-isomer were near or below the detection limit. Additionally, the stability experiment of the purified 2-isomer (Figure 5B) in HSA solution showed that the rearrangement from the 2-isomer to the 3-isomer or 4-isomer was hardly observed. Although we cannot account clearly for the observation of no further acyl migration of the 2-isomer to form a 3- or 4-isomer in HSA solution, HSA may retard the formation of the ortho ester-like intermediate between the C-2 and C-3 positions of GlcA, resulting in predominant hydrolysis of the 2-isomer in its degradation pathway. In the case of β-1-acyl glucuronides of diflunisal,[11] tolmetin,[9] and salicylic acid,[26] it has been reported that HSA seems to stabilize the glucuronides.

On the basis of the calculation of the individual rate constants using the model shown in Figure 1, (*S*)-NAG was decomposed by hydrolysis and intramolecular rearrangement almost to the same extent (Table 2). Our preliminary experiment using *R*-NAG showed that *R*-NAG was preferentially isomerized (unpublished data), suggesting that the HSA-mediated hydrolysis was predominant for (*S*)-NAG. In many other acyl glucuronides,[3,23–25] including NAG,[8] the catalytic role of HSA in the degradation (hydrolysis and intramolecular rearrangement) has been reported. Our calculations of the individual rate constants of NAG in HSA solution clarified that both the hydrolysis and acyl transformation rate constants of NAG were greater than the overall degradation rate constant ($k_d = 0.343 \pm 0.010$ h^{-1}) in HSA-free solution, which should reflect acyl transformation and hydrolysis rate constants. This suggests the catalytic role of HSA not only in the hydrolysis of NAG but also in the isomerization of NAG. This may be due to the lowered free energy of ortho ester formation between the hydroxyl group at C-2 of the GlcA residue and the carboxyl group of NA by reversible binding to HSA, although we cannot explain exactly the enhancement effects of HSA on the isomerization of NAG.

We compared the stability and covalent binding formation of the 1-*O*- and 2-*O*-acyl glucuronides of (*S*)-NA. The 2-isomer, which was more stable than NAG, formed a protein adduct more slowly when compared with NAG. NAG, which forms the protein adduct most easily, achieved a maximum binding within 1 h of incubation. Although evidence exists for the two major mechanisms of covalent binding, it has not been clarified as to which of these is principally responsible.[28–32] If a covalent adduct is formed predominantly from the regioisomers of NAG, the formation rate of the adduct should be faster for the 2-isomer than for NAG, since no acyl migration time is required. Consequently, our results suggest that NAG can directly bind to the protein. Interestingly, the protein adduct formation temporarily declined, and a secondary increase in the formation was observed after incubation at a higher concentration of NAG. On the basis of comparison of the time dependence of degradation of NAG with the pattern of adduct formation, the covalent adduct in the earlier stage could be formed by β-1-acyl glucuronide, and the secondary peak of binding formation may arise from the formed 2-isomer. Additionally, in the case of NAG, 3-*O*- and 4-*O*-acyl glucuronides contribute little to the adduct formation under the conditions used. Finally, the covalent binding of NA to HSA seems to proceed via its acyl glucuronides in both the transacylation and glycation mechanisms. In the case of tolmetin, not only the β-1-isomer of tolmetin glucuronide but also other isomers can react with protein to give irreversibly linked products.[9] In this study, β-1-*O*- and 2-*O*-acyl glucuronides of NA clearly contribute the formation of protein adduct of NA. We quantified the regioselective difference in stability and covalent binding of acyl glucuronides of (*S*)-NA, although the stereoselective difference of *R*- and *S*-β-1-*O*-acyl glucuronides of NA in the protein adduct formation have been reported.[8]

Smith et al.[19] have reported that isomeric conjugates of zomepirac glucuronide occur via imine formation between

the free aldehyde of the open-chain GlcA and protein, followed by an Amadori rearrangement to the more stable adduct. The data suggest that although NAG can directly and rapidly form an adduct that is unstable and hydrolyzed almost as quickly as it is formed, intramolecular transacylation may well be a prerequisite for formation of a stable adduct. Presumably, the rapid complex formation of β-1-*O*-acyl glucuronide with HSA may assist in the HSA-mediated hydrolysis of NAG. We speculate that hydrolysis of acyl glucuronides may proceed through an acylated intermediate (acyl-HSA intermediate) such as an ester with a serin residue, thioester with a cysteine residue and/or acylimidazole with a histidine residue in HSA.[33] In the second step, the acyl-HSA intermediate is deacylated by hydrolysis. Thus, this transient adduct may be less important than the persistent one that arises from the 2-*O*-acyl glucuronide.

In conclusion, the present results indicate that covalent adduct formation proceeds via the proposed two kinds of mechanisms, transacylation and imine formation, according to the degree of formation of isomeric forms of the acyl glucuronide of NA.

Accepted for publication September 21, 1998.

Abstract □ PEGylation of proteins is of great interest to the pharmaceutical industry as covalent attachment of poly(ethylene glycol) (PEG) molecules can increase protein sera half-lives and reduce antigenicity. Not surprisingly, PEGylation significantly alters the surface characteristics of a protein, and consequently, its conformational stability during freezing and drying. Freeze concentration-induced phase separation between excipients has been previously shown to cause degradation of the secondary structure in lyophilized hemoglobin. In this report we show how PEGylation of two proteins, hemoglobin- and brain-derived neurotrophic factor (BDNF), influences partitioning and protein secondary structure as determined by FTIR spectroscopy in a system prone to freezing-induced phase separation. PEGylation of hemoglobin reduces the loss of structure induced by lyophilization in a PEG/dextran system that phase separates during freezing, perhaps due to altered partitioning. The partition coefficient for native hemoglobin favors the dextran-rich phase (PEG/dextran partition coefficient = 0.3), while PEGylated hemoglobin favors the PEG phase (partition coefficient = 3.1). In addition, we demonstrate that PEGylation alters hemoglobin's stability during lyophilization in the absence of other excipients. In contrast, because native BDNF already partitions into the PEG-rich phase, PEGylation of BDNF has a less dramatic effect on both partition coefficients and conformational stability during lyophilization. This is the first report on the effects of PEGylation on protein structural stability during lyophilization and points out the need to consider modification of formulations in response to changing protein surface characteristics.

Introduction

The covalent attachment of poly(ethylene glycol) (PEG) to enzymes and proteins,[1] a process known as PEGylation, has received recent increased attention. PEGylation has created enzyme derivatives with improved solubility in organic solutes, making the process of interest to the field of nonaqueous enzymology.[2,3] Attachment to PEG has been used as a method of immobilizing enzymes.[4] Of greater interest to the pharmaceutical biotechnology arena, PEGylated proteins have demonstrated dramatically increased plasma half-lives and very low immunogenicity.[5] It is thought that PEGylation provides a biocompatible "protective coating" to proteins, reducing immune response. It also increases the effective molecular weight of the protein and thus reduces the rate of clearance through the kidney. These are both extremely attractive properties for proteins administered as therapeutic agents since clearance of such drugs from the bloodstream is often too rapid for a therapeutic response. In addition, PEGylated proteins generally remain biologically active. Reports of numerous PEGylated proteins exist in the literature, including superoxide dismutase,[6] horse cytochrome *c*,[7] hemoglobin,[8−10] recombinant human granulocyte-colony stimulating factor,[11] human growth hormone and growth hormone antagonist,[12] and brain-derived neurotrophic factor,[13] just to name a few. With the original patent covering PEGylation[1] expiring, many biotechnology companies are now considering PEGylated versions of protein products.

PEGylation affects a protein's immunogenicity and circulation half-life in part by altering the protein's surface characteristics. Clearly, PEGylation should also significantly alter a protein's partitioning in a PEG/dextran two-phase system. Similarly, we can expect that PEGylation may change the protein's storage stability and behavior in a given formulation. Considering PEG's incompatibility with a number of polymers and salts in aqueous solutions, phase separation of a PEGylated protein from other formulation components may be a potential instability pathway in lyophilization formulations.

Partitioning of proteins in an aqueous two-phase system depends on specific surface features of the protein, along with system conditions such as total composition, pH, ionic strength, etc. Numerous approaches to altering the partitioning behavior of a protein have been considered for improving selectivity of two-phase separation methods. These include immunoaffinity partitioning[14] and metal affinity partitioning,[15,16] to name a few. Metal affinity partitioning involves partially chelating a transition metal ion to a linear polymer such as poly(ethylene glycol) (PEG). Transition metals demonstrate strong affinity for electron-rich amino acid residues such as histidine and cysteine. Thus, the use of PEG-bound metal chelates in PEG/dextran two-phase systems can dramatically increase the partitioning of proteins with accessible surface histidines or cysteines to the PEG phase.

In this paper, we investigate the stability of PEGylated hemoglobin and BDNF lyophilized in PEG/dextran formulations. By altering the partitioning of protein in a PEG/dextran two-phase system through PEGylation, we provide additional information on the mechanisms responsible for protein damage during lyophilization. To our knowledge, this is also the first report on the conformational stability of PEGylated therapeutic proteins during freeze-drying and as such offers an introduction to possible concerns in formulating such products. We also consider a noncovalent attachment of PEG to hemoglobin via chelation using a PEG-copper complex.

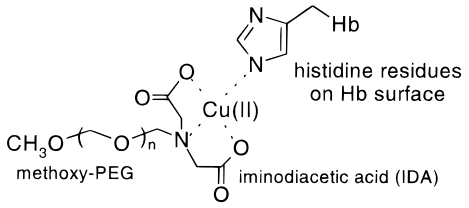

Figure 1—Structural representation of Cu(II)IDA-PEG. Copper partially coordinated with the IDA-modified PEG has a strong affinity for electron-rich surface amino acids. Adapted from Guinn.[16]

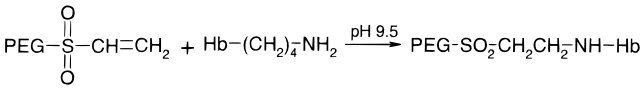
Materials and Methods

Materials—Recombinant human hemoglobin (Hb) was provided by Somatogen, Inc. (Boulder, CO). Poly(ethylene glycol) 3350 (PEG), average molecular weight 3350, was obtained from Sigma Chemical Co. and dextran T500, weight average molecular weight 519000, was obtained from Pharmacia Biotech. Polymers were dissolved in a stock solution at 20% (w/w) and combined to obtain solutions of 4% (w/w) PEG, 4% (w/w) dextran, and 10 mg/mL Hb (or PEG-Hb) with 5 mM potasssium phosphate buffered at pH 7.4 and 150 mM NaCl (or KCl). Cu(II)IDA-PEG 5000, a copper-chelated PEG derivative (average PEG molecular weight = 5000), was synthesized by Martin Guinn (lot no. MRG 5-105).[16] A structural representation of Cu(II)IDA-PEG is shown in Figure 1. For closer comparison to the 5000 molecular weight copper-chelated PEG, hemoglobin was also lyophilized in a solution of PEG 4600 (Aldrich) and dextran T500.

Human brain-derived neurotrophic factor (BDNF) and PEG-BDNF were supplied by AMGEN, Inc. (Thousand Oaks, CA). BDNF is a noncovalent homodimer with an approximate molecular weight of 27.8 kDa.[17] PEG-BDNF contains a PEG with average molecular weight of 20 kDa covalently attached to the N-terminal methionine of each BDNF monomer unit.[18] BDNF was received in 10 mM sodium phosphate/150 mM NaCl (pH 7.0). PEG-BDNF was received in 10 mM histidine/150 mM NaCl (pH 7.5), and transferred by dialysis to 10 mM sodium phosphate/150 mM NaCl (pH 7.0). All BDNF lyophilization solutions were made in this same sodium phosphate/NaCl buffer at a protein concentration of 1 mg/mL. It should be noted that, as defined in this report, mass concentrations of PEGylated proteins represent only the protein portion of the molecule. For example, a 1 mg/mL solution of BDNF and PEG-BDNF contains the same amount of protein.

PEGylation of Hemoglobin—Hb was PEGylated using a PEG–vinyl sulfone (molecular weight 5000)-activated PEG from Shearwater Polymers, Inc. (Huntsville, AL). At high pH (9–9.5), PEG–vinyl sulfone (PEG-VS) will react slowly with lysine groups:[19]



While more selective coupling with sulfhydryl groups occurs at lower pH (7–9), reaction with hemoglobin at lower pH was unsuccessful.

Hemoglobin in 5 mM potassium phosphate/150 mM NaCl was adjusted to pH 9.5 by careful addition of NaOH solution and a 2.4× molar excess of dry PEG-VS was dissolved in the solution. The reaction mixture was allowed to sit at 4 °C overnight. Half of the solution was dialyzed against 5 mM potassium phosphate/150 mM NaCl (pH 7.4) while the other half was dialyzed against 5 mM potassium phosphate/150 mM KCl (pH 7.4). Confirmation of PEGylation and fractionation of PEGylated and non-PEGylated hemoglobin was performed by FPLC size exclusion chromatography on a HiPrep 16/60 column containing Sephacryl S-200 resin (Pharmacia) with an elution buffer of 5 mM phosphate (pH 7.4)/150 mM NaCl at a flow rate of 0.7 mL/min. UV absorbance at 280 nm was used for detection. Hb and PEG-Hb concentrations were measured with a BCA total protein assay (Pierce).

Two-Phase Partitioning—The partitioning coefficient of each protein (concentration in the PEG phase divided by concentration in the dextran phase) was measured in a system of 7% PEG 3350/7% dextran/1 mg/mL protein. This system separates at room temperature. Samples were allowed to come to equilibrium over several hours, and the two phases were physically separated. Protein concentration in each phase was determined by UV absorbance at 280 nm for BDNF and PEG-BDNF and with a BCA total protein assay for Hb and PEG-Hb.

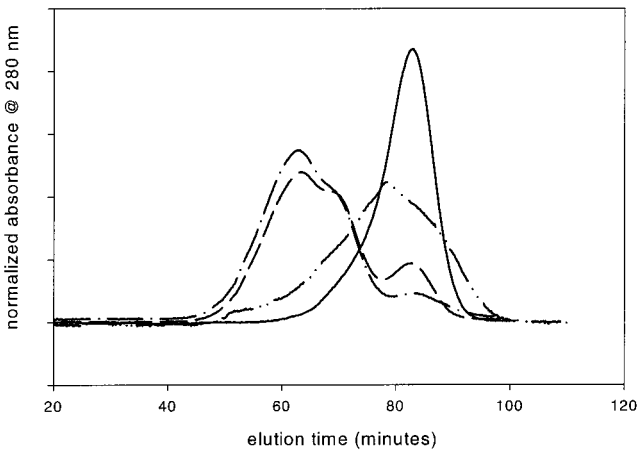


Figure 2—Normalized size exclusion chromatogram demonstrating PEGylation of hemoglobin. Solid trace: Hb; dashed trace: after PEGylation reaction; dash–dot trace: PEG-rich phase of 7% PEG/7% dextran/10 mg/mL PEG-Hb; dash–dot–dot trace: dextran-rich phase of 7% PEG/7% dextran/10 mg/mL PEG-Hb. All curves are normalized to the total area under peaks.

Lyophilization—Lyophilization was conducted in an FTS Systems microprocessor controlled tray dryer (Dura-Stop, Dura-Dry-MP). Samples were freeze-dried by the method previously described.[20] In short, samples for annealing experiments were quench frozen in a dry ice/acetone slurry and placed on the freeze-dryer shelf precooled to −7 °C. Samples were allowed to anneal at −7 °C for different lengths of time prior to drying. At "time zero", the samples were cooled to below −30 °C and held for 120 min. Primary drying proceeded at 60 mT vacuum with the shelf temperature set at −20 °C for 1000 min. Secondary drying consisted of 120 min at 0, 10, and 25 °C, while maintaining vacuum of 60 mT.

Infrared Spectroscopy—Protein secondary structure was monitored using Fourier transform infrared spectroscopy (FTIR). Spectral collection and processing were as previously described.[20,21]

IR Curve Fitting—Curve fitting of the second derivative IR spectra was used to determine the relative secondary structural content of BDNF in solution.[22,23] Normalized second derivative spectra were inverted by multiplying by −1 and then fitted with Gaussian band profiles using the Grams/386 (Galactic Enterprises) fitting routine. Component bands were assigned to secondary structural elements based on wavenumber according to the method of Dong and Caughey.[24]

Scanning Electron Microscopy—Lyophilized cake structures were examined using an ISI–SX-30 scanning electron microscope operating at an acceleration voltage of 30 kV. Dried samples were adhered with a graphite adhesive to SEM stubs and gold sputter coated.

Results and Discussion

Characterization of PEGylated rHb—PEGylation obviously increases the size and molecular weight of a protein; thus, size exclusion chromatography (SEC) can be used to evaluate the PEGylation reaction and offer some information on the extent of PEGylation. Figure 2 shows representative chromatograms of Hb before and after PEGylation. Clearly, PEGylation causes a gross shift to reduced elution times (and hence larger molecular weights), though it is also apparent that the entire Hb population was not PEGylated. Fractionation of PEG-Hb from non-PEGylated Hb was made between peaks at an elution time of approximately 75 min in Figure 2. A minimum of two peaks is identifiable in the PEGylated population, indicating that different degrees of PEGylation exist in the sample. Since PEG molecules (and therefore PEGylated

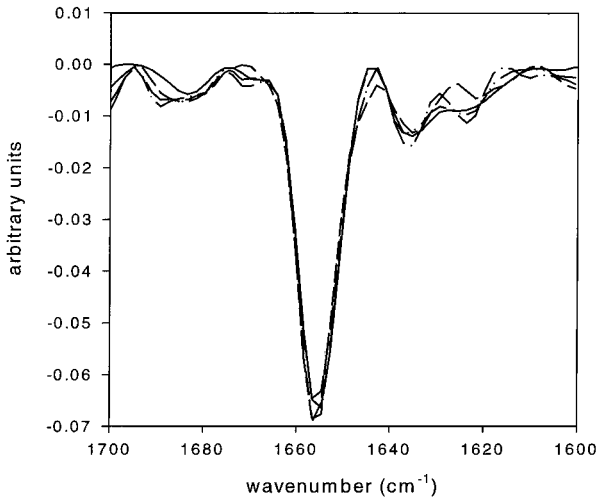

Figure 3—Second derivative IR spectra of hemoglobin controls in solution. Solid trace: Hb in buffer (pH 7.4); dashed trace: Hb in top phase of a 7% Cu(II)IDA-PEG/7% dextran system; dash–dot trace: Hb at PEGylation reaction conditions (pH 9.5); dash–dot–dot trace: PEG-Hb in buffer (pH 7.4).

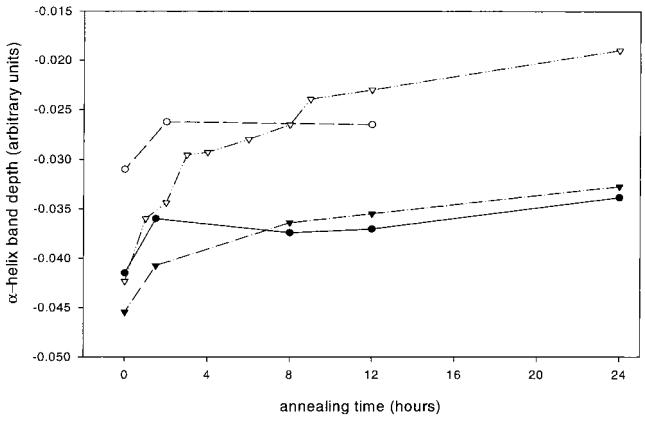

Figure 4—Effect of PEGylation on hemoglobin structure annealed in the PEG/dextran system. Depth of the α-helix band (ca. 1656 cm^{-1}) from second derivative infrared spectra of lyophilized Hb (open symbols) and PEG-Hb (filled symbols) as a function of sample annealing time at −7 °C prior to drying. Circles are for 10 mg/mL protein in 5 mM potassium phosphate/150 mM NaCl (pH 7.4). Triangles also contained 4% PEG 3350/4% dextran T500. Open triangles presented previously.[20,21]

proteins) "act" much larger in gel chromatography (as well as gel electrophoresis) than do proteins used for column calibration, it is difficult to assign quantitative information to the elution peaks corresponding to PEGylated proteins in Figure 2. However, based on the initial PEG-VS:HB stoichiometry and on SEC performed at different reaction times, the three main peaks observed by SEC can be tentatively assigned to un-PEGylated-, mono-PEGylated-, and di-PEGylated-Hb. PEGylation has no effect on the secondary structure of hemoglobin as seen by FTIR spectroscopy (Figure 3). However, partitioning of hemoglobin between the two phases of a system of 7% PEG 3350 and 7% dextran T500 is drastically effected by PEGylation. Hemoglobin partitions preferentially to the dextran phase with a partition coefficient (PEG phase/dextran phase) of about 0.3. PEGylated hemoglobin on the other hand has a partition coefficient of 3.1. In other words, while only about 30% of Hb is in the PEG phase, over 80% of the PEG-Hb sample is in the PEG phase.

Lyophilization of PEG-Hb—The formation of pure ice during freezing results in concentration of solutes. In protein formulations containing excipients, such concentration can cause solute−solute phase separation to become thermodynamically favored, albeit often with slow kinetics.[20,21,25] Annealing frozen solutions at subzero temperatures allows phase separations to proceed toward equilibrium and serves to magnify effects of such separations on protein stability. Annealing experiments that mimic those in the previous report[20] were conducted on PEG-Hb samples. In brief, samples were quench frozen and allowed to anneal for various lengths of time at −7 °C before freeze drying. After freeze-drying, hemoglobin structure in the dried solid was analyzed by IR spectroscopy as a function of annealing time. Figure 4 shows the depth of the α-helix band (ca. 1656 cm^{-1}) from second derivative IR spectra as a function of annealing time. The depth of the α-helix band is the primary indicator of "nativelike" structure in these hemoglobin studies (more negative values correspond to greater retention of nativelike structure; native hemoglobin has a α-helix band depth of ∼ −0.07 as can be seen in Figure 3). The first thing apparent in the data in Figure 4 is that PEG-Hb lyophilized in buffer alone retains more α-helix in the dried state than does Hb. This raises important questions regarding the possibility of covalently attached PEG acting as a stabilizer during freeze-drying. PEG is known to be an excellent protein stabilizer in frozen solutions.[26] However, studies in the literature have demonstrated the failure of PEG as a desiccoprotectant.[27] This is attributed to the tendency of PEG to crystallize during freeze-drying, making it unavailable to hydrogen bond with the protein[27] or form a "single phase glass".[25,28] It is likely, however, that covalent attachment to a protein surface will prevent, or at least greatly decrease, PEG crystallization. Whether one or two PEG molecules per protein would be sufficient to replace hydrogen bonds or form a protective glass is unknown.

Hb and PEG-Hb freeze-dried in 4% PEG/4% dextran also differ significantly in their native structural retention as seen in Figure 4. PEGylation appears to reduce the loss of nativelike structure with annealing. A number of explanations are possible. It may be that the added protection provided by PEGylation is also effective in reducing the damage in the phase-separating system. PEGylation also alters the surface properties of the protein, perhaps making it less active at the liquid−liquid interface created by the PEG/dextran phase separation. Since concentration and denaturation at this interface is a probable mechanism of damage,[20] removal of the protein from the interface by PEGylation could prevent this damage. Finally, if the loss of native structure of Hb with annealing is due to partitioning away from a stabilizer (PEG in this case), then reversing this partitioning would dampen the effect. Although dextran can form protective glasses and potentially replace some hydrogen bonds, its bulky size could make it less effective than PEG as a dessicoprotectant. This explanation seems unlikely, however, since Hb lyophilized in either 8% PEG or 8% dextran shows essentially equivalent levels of structural retention (data not shown).

PEG-Hb was also lyophilized in a 4% PEG/4% dextran solution with NaCl replaced with KCl. The results with PEG-Hb are the same as those seen with Hb: essentially no change in α-helix content occurs with annealing (Figure 5). We have previously shown[20] that switching to KCl prevents the phase separation from occurring. This is thought to be due to kinetic prevention of the PEG/dextran phase separation by the formation of a strong glass. Figure 5 also contains an anomalous result where an abrupt loss in structure occurs after 8 h of annealing. It is thought that this is the result of the thermodynamically unstable yet kinetically hindered phase separation relaxing sporadically. A corresponding radical change in cake structure is also seen in scanning electron microscopy images (not shown). The initiation of this relaxation is unknown. This

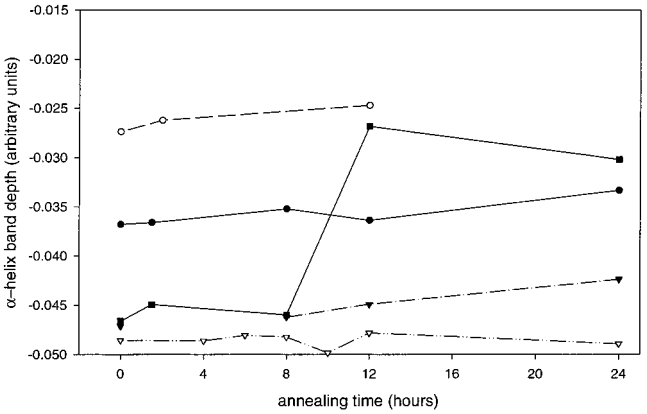

Figure 5—PEG-Hb lyophilized in KCl buffer. Depth of the α-helix band (ca. 1656 cm^{-1}) from second derivative infrared spectra of lyophilized Hb (open symbols) and PEG-Hb (filled symbols). Circles are for 10 mg/mL protein in 5 mM potassium phosphate/150 mM KCl (pH 7.4). Triangles also contain 4% PEG 3350/4% dextran T500. The square data points represent an anomalous example of a "relaxation" of the kinetically hindered phase separation (solutions same a triangles). Annealing is at –7 °C prior to drying. Open triangles presented previously.[20,21]

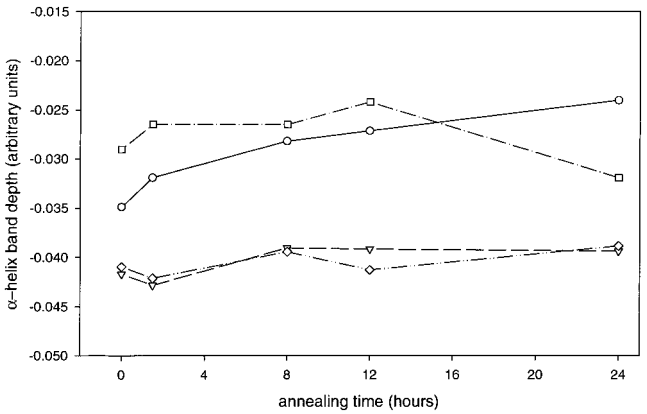

Figure 6—Hb lyophilized in Cu(II)IDA-PEG solutions. Circles, Hb in 3% PEG 4600/3% dextran T500; squares, Hb in 3% Cu(II)IDA-PEG; triangles, Hb in 3% Cu(II)IDA-PEG/3% dextran. All solutions contain 5 mM potassium phosphate/150 mM NaCl (pH 7.4).

is the only observed example of such sporadic behavior in kinetically hindered samples.

Lyophilization of Hb with Cu(II)IDA-PEG—Solutions of 4% Cu(II)IDA-PEG and 4% dextran T500 containing 10 mg/mL Hb form two phases at 0 °C. Thus, polymer concentrations were reduced to 3% Cu(II)IDA-PEG/3% dextran in freeze-drying studies to ensure single-phase solutions prior to freezing. Hb in a solution of 7% Cu(II)-IDA-PEG/7% dextran is entirely (within limits of detection) in the PEG-rich phase. While considerable copper-catalyzed oxidation of hemoglobin occurs in solutions of Cu-(II)IDA-PEG,[16] this is not a concern for the present study. Hb secondary structure is not affected by the presence of even high concentrations of Cu(II)IDA-PEG, as seen in Figure 3.

IR spectroscopy of Hb lyophilized in Cu(II)IDA-PEG-containing samples is summarized in Figure 6. There is not a significant change in α-helix content with annealing time in the system of 3% Cu(II)IDA-PEG/3% dextran. As in the case with PEG-Hb, the use of a metal affinity partitioning agent greatly increases the partitioning of hemoglobin to the PEG phase. The increased partitioning is even greater with the use of the metal-chelating ligand: essentially all of the hemoglobin is moved to the PEG phase at equilibrium. This increase in partitioning is larger than that caused by the covalent attachment of PEG-VS. This

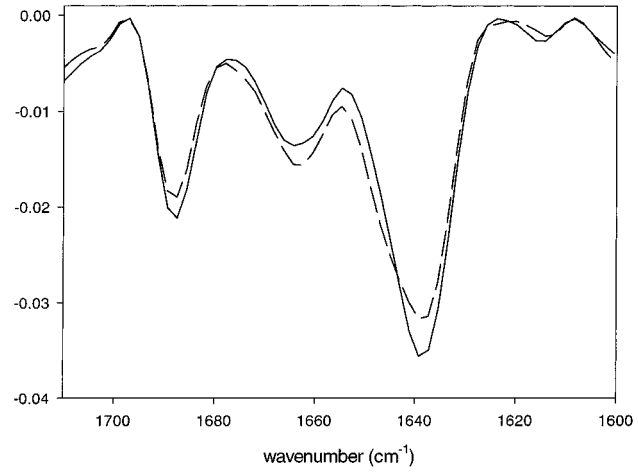

Figure 7—Amide I region of second derivative IR spectra of BDNF (solid trace) and PEG-BDNF (dashed trace) in solution (10 mM sodium phosphate (pH 7.0)/150 mM NaCl). Protein concentrations were >20 mg/mL.

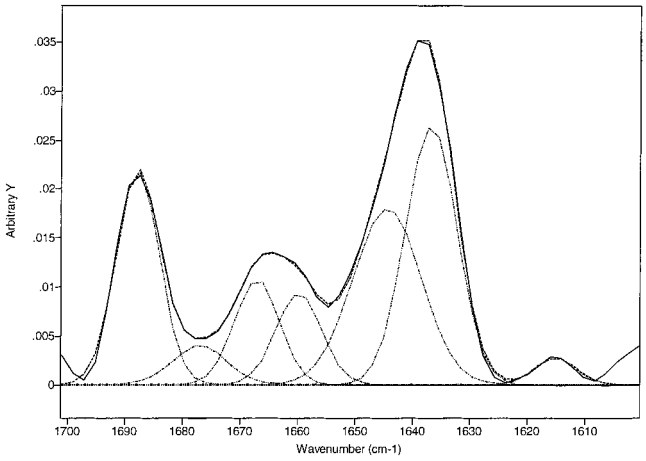

Figure 8—Curve-fitted inverted second derivative spectrum of BDNF in solution. Areas of fitted peaks are summarized in Table 1.

can be understood in terms of relative PEG attachment densities. Hb has 16 sites available for PEG attachment via Cu(II)IDA-PEG.[16] Although it is unlikely for steric reasons that all of the potential sites could ever be filled, there is almost certainly more PEG attached to Hb via Cu-(II)IDA-PEG chelation than by covalent attachment with PEG-VS. By increasing the affinity of the protein for the PEG phase, we are depleting the dextran phase of hemoglobin, but there is likely also a decreased concentration of protein at the liquid–liquid interface, due to the large difference in protein affinity of the two phases.

BDNF Solution Structure—FTIR spectroscopy of BDNF and PEG-BDNF in solution was first performed to gain information on the secondary structural content. Figure 7 shows the amide I region of second derivative IR spectra of BDNF and PEG-BDNF in 10 mM sodium phosphate/ 150 mM NaCl (pH 7.0). Quantitative analysis of BDNF secondary structure was obtained by curve fitting the second derivative spectra as seen in the example in Figure 8 and summarized in Table 1. This quantification is in fair agreement with reported structural assignments for BDNF (47% β-structure, 31% random coil, 22% reverse turns, no α-helix).[29] Table 1 shows that there is a slight increase in bands assignable to random structure and turns, and decreases in β sheet bands for the PEGylated protein, possibly indicating a less ordered structure.

Lyophilization of BDNF and PEG-BDNF—BDNF and PEG-BDNF were freeze-dried in the presence of 4%

Table 1—Band Positions, Relative Intensities, and Secondary Structural Assignment for the Amide I Region of Infrared Spectra of BDNF and PEG-BDNF

frequency (cm^{-1})	assignment	% area	
		BDNF	PEG-BDNF
1688	β-sheet	20.7	17.5
1677	turn	4.4	3.1
1667	turn	10.6	10.7
1660	turn	9.3	10.3
1644	random	26.9	35.1
1637	β-sheet	29.9	23.3

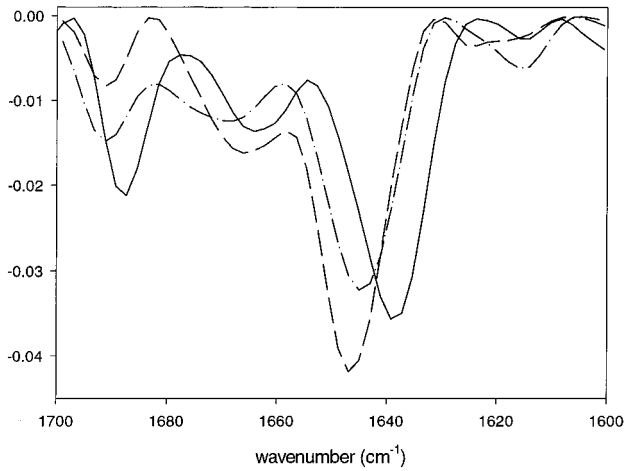

Figure 9—Second derivative IR spectra of BDNF (dashed trace) and PEG-BDNF (dash–dot trace) in the dried state, freeze-dried from buffer alone. The BDNF solution spectrum (solid trace) is shown for reference.

PEG/4% dextran, as well as in solutions containing only PEG or only dextran. Figure 9 shows the IR spectral changes seen with both BDNF and PEG-BDNF freeze-dried from buffer alone. In the dried state spectra, there is a considerable shift to higher wavenumbers for all of the structural bands. Frequency shifts in structural bands upon dehydration have been reported previously for β-sheet proteins.[23,30,31] Yet, it remains unresolved whether such a shift in band frequency reflects gross conformational changes in the protein upon dehydration or is simply due to a change in stretching vibration (and thus IR absorbance) in secondary structures due to the removal of hydrogen-bonded water. Allison et al.[30] report that shifts seen in the β-sheet bands upon lyophilization of chymotrypsinogen return to the frequencies of the solution state spectrum (before freeze drying) when the protein is freeze-dried in the presence of sucrose. This could be due to hydrogen bond replacement by the sugars.[32] In our studies with BDNF, all dried state spectra, regardless of excipient, have demonstrated the same shifting in resolved band frequencies. However, if the band frequencies and structural assignments for the solution spectra are fitted to the dried state spectra of BDNF, the result is a dramatic change in band area from the β-sheet band at 1637 cm^{-1} to the random structure band at 1644 cm^{-1} while maintaining the β-sheet band at 1688 cm^{-1}. This is an unlikely interpretation of the data: it seems unreasonable that one β-sheet vibrational mode would be nearly eliminated but not the other. Thus, for the sake of this study, we will interpret the shifting in band frequencies as a dehydration effect and not necessarily a secondary structural perturbation. In other words, the bands ca. 1645 and 1691 cm^{-1} in the dried solid will be considered to coincide with the 1637 and 1688 cm^{-1} β-sheet solution bands, respectively. The relative intensities of these bands, however, can be considered structural perturbations.

Table 2—Structural Retention of BDNF Freeze Dried in Various Excipient Combinations

excipient(s)	depth of band ca. 1690 cm^{-1} (arbitrary units)	β-sheet ratio[b]

[a] Samples annealed for 8 h at –7 °C prior to drying (see materials and methods). [b] β-Sheet ratio = (depth of band ca. 1690 cm^{-1})/(depth of band ca. 1640 cm^{-1}).

The two β-sheet bands in BDNF presumably correspond to different types of β-sheet configurations. Monitoring the depth of the two β-sheet bands (as an indicator of band intensity) may be useful in resolving structural differences seen in different freeze-drying formulations. Table 2 reports the depth of the β-sheet band ca. 1690 cm^{-1} as well as the ratio of the band depth at 1640 cm^{-1} to that at 1690 cm^{-1} from second derivative IR spectra of BDNF in solution and freeze-dried in a number of formulations. Deviations in band depth from the solution spectrum are considered structural perturbations from the native structure. The formulations in Table 2 are ordered by the band depth at 1640 cm^{-1}. By this ordering, there is a clear segregation between samples containing PEG and those containing only dextran, with the PEG-containing samples retaining more nativelike structure. Unlike the hemoglobin results, little change in BDNF structure is seen with 8 h of annealing at −7 °C for the 4% PEG/4% dextran sample.

PEG-BDNF freeze-drying results are summarized in Table 3. While the order dictated by the β-sheet band at 1640 cm^{-1} is slightly different with PEG-BDNF than with BDNF, the general segregation between PEG and dextran samples remains. By this quantification, structural retention is better for PEG-BDNF lyophilized in buffer alone than in the presence of polymer. There may also be some

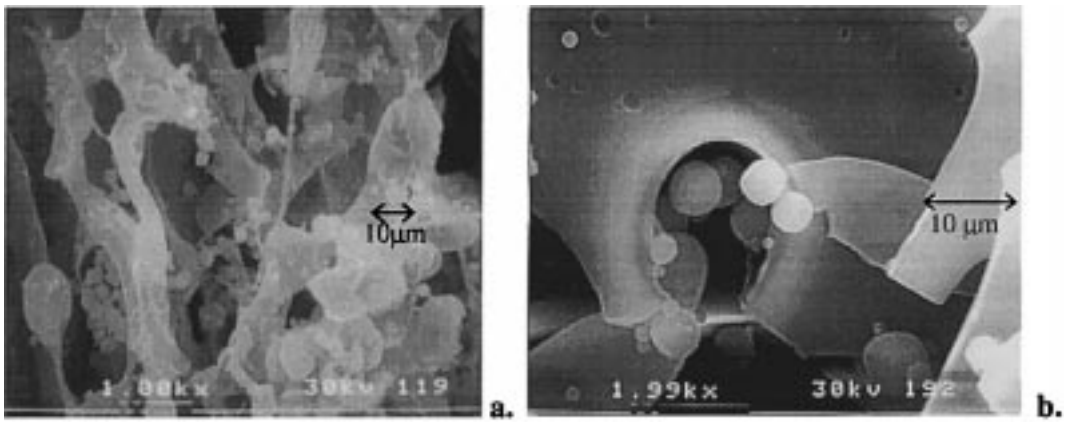

Figure 10—Scanning electron microscopy images showing potential polymer/protein phase separation. (a) BDNF freeze-dried in 8% dextran (1000× magnification) and (b) PEG-BDNF freeze-dried in 8% dextran (2000× magnification).

improvement in retention of secondary structure after annealing for PEGylated BDNF in the PEG/dextran system.

The detrimental effects of phase separation seen in hemoglobin studies (Figure 4) is not as apparent with BDNF or PEG-BDNF over the annealing times examined here, despite the fact that the PEG/dextran phase separation in the dried solid as seen by scanning electron microscopy looks similar (SEM not shown). The equilibrium partitioning of BDNF in a PEG/dextran two-phase system may be partly responsible for this result. While hemoglobin has a partition coefficient (concentration in the PEG phase divided by concentration in the dextran phase) of around 0.3 in a PEG/dextran two-phase system, BDNF's partition coefficient has been measured to be 2.4. This means that about 70% of hemoglobin partitions to the *dextran*-rich phase while about 78% of BDNF is in the *PEG*-rich phase. PEGylating hemoglobin causes the amount of protein in the PEG-rich phase to increase to over 80% while PEGylating BDNF causes the partition coefficient to increase to around 4.2 which means around 86% of the protein is in the PEG-rich phase. Thus, the change in partitioning as a result of PEGylation is considerably less for BDNF compared to hemoglobin. Therefore, unmodified BDNF may already receive the protective effect of a partitioning that favors the PEG-rich phase, namely removal from an interface and/or increased availability of PEG during drying. Alternatively, the differences in behavior between hemoglobin and BDNF may be intrinsic to the structural motifs of the two proteins. During lyophilization, secondary structural damage to hemoglobin is seen primarily as loss of α-helix. BDNF does not contain α-helical structure and therefore may not be sensitive to the same stresses.

Protein/Polymer Phase Separation—SEM images of the freeze-dried cake of BDNF and PEG-BDNF in dextran suggest a possible protein–polymer phase separation during lyophilization (Figure 10). A dispersed phase is present that is not typical of lyophilized dextran. Given BDNF's partitioning behavior in a PEG/dextran system, it may be reasonable to say that BDNF is more "PEG-like", which could lead to incompatibilities with dextran that result in a phase separation. Samples of PEG-BDNF-lyophilized in dextran show a similar separated phase. Phase separation in solutions of dextran and PEG-BDNF has been observed at room temperatures. Closer examination of BDNF structure when freeze-dried in dextran (Figure 11) suggests a structural change with annealing. The broad, flattened bands in the spectra of both BDNF and PEG-BDNF in dextran are typical of denatured proteins, representing a more disperse conformational population. These bands

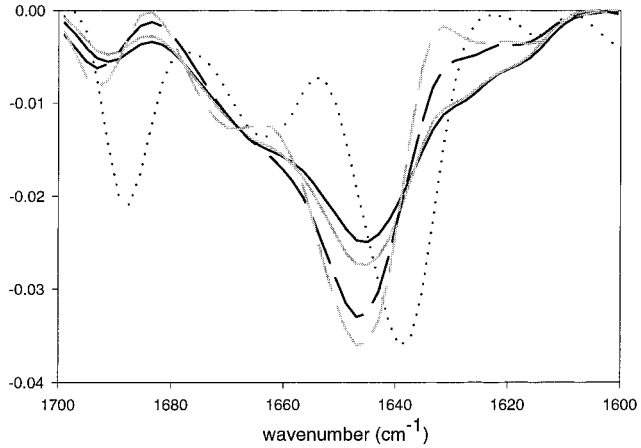

Figure 11—Second derivative IR spectra from BDNF (black lines) and PEG-BDNF (gray lines) lyophilized in 8% dextran. Broken lines were annealed at –7 °C for 8 h prior to drying while solid lines were not annealed. BDNF solution spectrum (dotted trace) is shown for reference.

narrow and deepen with annealing prior to drying, which could indicate added conformational stability. If a BDNF/dextran phase separation is occurring, more of the protein would be contained in a nondextran, high concentration protein phase with annealing. Protein self-association in a phase out of contact with dextran appears to provide BDNF with added stability in the dried state. This effect is greater with PEG-BDNF, emphasizing the greater separation driving force due to greater incompatibility with dextran.

Conclusions

Alteration of hemoglobin partitioning by PEGylation as well as by metal affinity ligands increases the structural integrity of the protein when lyophilized from a PEG/dextran system as well as from buffer alone. In contrast, both BDNF and PEGylated BDNF exhibit similar levels of damage during freeze-drying. This can in part be explained by the relative affinities of the various proteins and protein derivatives for PEG. Although PEG can be a potent stabilizing excipient, hemoglobin partitions away from a PEG-rich phase in PEG/dextran two-phase systems; this behavior is reversed upon PEGylation. On the other hand, unmodified BDNF favors the PEG-rich phase, and PEGylation only increases this tendency.

PEGylation of a protein can be expected to alter the protein's surface characteristics, and thus its interaction with other "surfaces", including interfaces and cosolutes.

Current theories of stabilizing mechanisms during lyophilization[27,28,33] all allude to the importance of compatibilities between the protein and a formulation's glass forming excipients. Addition of PEG to a protein surface changes the interactions between excipients and the protein. In this study, PEGylation actually improves hemoglobin structural retention in the dried state, and reduces BDNF structural loss during annealing in frozen solutions. However, caution is appropriate: therapeutic protein formulations optimized for the nonmodified protein may not generally provide adequate protection when formulating PEGylated derivatives.

Accepted for publication September 30, 1998.

Abstract □ A novel mathematical model for the water transport into and drug release from hydroxypropyl methylcellulose (HPMC) tablets is presented. Fick's second law of diffusion is used to describe the mass transfer processes in the three-component system drug/polymer/water. Numerical solutions of the respective set of partial differential equations are provided, considering axial and radial diffusion within cylindrical tablets. It is shown that the diffusion coefficients strongly depend on the water concentration (parameters quantifying this dependence have been determined). Swelling of the device is considered using moving boundary conditions, whereas dissolution processes are neglected. Experiments proved the applicability of the theory. The practical benefit of the new model is to calculate the required shape and dimensions of HPMC tablets to achieve a desired release profile.

Introduction

Hydroxypropyl methylcellulose (HPMC) is the dominant hydrophilic carrier material used for the preparation of oral controlled drug delivery systems.[1] One of its most important characteristics is the high swellability, which has a significant effect on the release kinetics of a drug. Upon contact with a dissolution medium, water or biological fluid diffuses into the tablet, resulting in polymer chain relaxation with volume expansion. Then, the drug diffuses out of the device.

Numerous studies have been reported in the literature to investigate the drug release kinetics from HPMC tablets.[2−4] The modification of the surface area of HPMC tablets in order to achieve a desirable release rate has been studied by Colombo et al.[5,6] Various techniques have been used to elucidate the physical processes involved in the release of drugs from HPMC tablets. For example, pulsed-field-gradient spin−echo NMR methods have been employed to measure the diffusivities of water and drugs in HPMC gels.[7] Recently, Fyfe and Blazek[8] investigated the hydrogel formation by NMR spectroscopy and NMR imaging techniques.

Yet, up to now there has not been any complete mathematical model that takes into account all the important phenomena occurring during drug release. Various simplifications have been made, e.g., neglect of the swelling process,[9] or assumption of constant diffusion coefficients.[11] Fu et al.[12] derived an analytical solution of Fick's second law, using cylindrical coordinates. The model is applicable to tablets that range from the shape of a flat disk (radius ≫ thickness) to that of a cylindrical rod (radius ≪ thickness), but they did not consider the volume expansion of the system and assumed constant diffusion coefficients.

A model for the prediction of the relative change in drug release rate as a function of formulation composition for HPMC tablets of adinazolam mesylate and alprazolam has been developed by Gao et al.[9] It is based on the equation derived by Higuchi[10] for the diffusional release of soluble drugs from polymeric matrixes, considering concentration dependent diffusivities. The swelling of the system is not taken into account, and the mathematical analysis reduced to one dimension. Cohen and Erneux[13,14] used free boundary problems to model swelling controlled release. Drug release is achieved by countercurrent diffusion through a penetrant solvent with the release rate being determined by the rate of diffusion of the solvent in the polymer.

Korsmeyer et al.[15] developed a model describing the diffusion of a penetrant and a solute in a swellable polymer slab and verified the model experimentally.[16] Concentration dependent diffusivities and dimensional changes in the system have been considered, but these theories[13−16] have been developed for thin films, not for cylindrical tablets.

The purpose of this study was to develop a new, physically realistic mathematical model, taking into account all the important processes including Fickian diffusion of water into and drug out of cylindrical tablets (in axial and radial direction, with concentration dependent diffusivities), as well as swelling. The model does not take into account dissolution processes. Thus, it is not valid for water-insoluble drugs whose release is governed by dissolution rather than by diffusion. To test the applicability of the new model, experiments were conducted with various drugs (chlorpheniramine maleate, diclofenac sodium, and propranolol hydrochloride) in different release media (0.1 M HCl, 0.1 M phosphate buffer (pH 7.4), and deionized water). The practical benefit of the new model is to optimize the shape and dimensions of HPMC tablets to achieve a desired release profile. For instance, the effect of the aspect ratio (radius/height) and size of the system on the release kinetics of a drug has been simulated.

Experimental Section

Materials—The following chemicals were obtained from commercial suppliers and used as received: chlorpheniramine maleate (Sigma Chemical Co., St. Louis, MO), diclofenac sodium (Lederle Arzneimittel GmbH, Wolfratshausen, Germany), propranolol hydrochloride (Sigma Chemical Co., St. Louis, MO), hydroxypropyl methylcellulose (Methocel K15M Premium Grade) (Colorcon, Nordmann Rassmann GmbH & Co., Hamburg, Germany).

Methods—The drug (20 mg) and HPMC were blended with a pestle in a porcelain mortar by geometric dilution. Tablets (200 mg, 13 mm diameter) were prepared by compressing the powder blend manually (Specac Hydraulic Press P/N 25.011, Specac Limited, Kent, UK; compaction force = 5 t, holding time = 15 s).

The USP XXIII rotating paddle method (37 °C, 50 rpm, 900 mL of deionized water, 0.1 M HCl or 0.1 M phosphate buffer (pH 7.4) USP XXIII) was used to study the drug release. The samples (2 mL, replaced with fresh medium) were withdrawn at predeter-

mined time intervals, filtered, and assayed spectrophotometrically (chlorpheniramine maleate, $\lambda = 264$ nm; diclofenac sodium, $\lambda = 276$ nm; propranolol hydrochloride, $\lambda = 290$ nm). All experiments have been conducted in triplicate.

Mathematical Modeling

A new model has been developed to describe water and drug transport in HPMC tablets. The following assumptions have been made: (i) Dissolution processes are neglected. (ii) Swelling is ideal, isotropic, and homogeneous throughout the device (including water-poor regions). The error resulting from this approximation only becomes significant in the case of extreme aspect ratios. The experimental results presented in this study and further results to be presented in a future paper prove the validity of this assumption for pharmaceutically common aspect ratios. (iii) The water concentration at the surface of the tablet is at its equilibrium value. (iv) Perfect sink conditions are maintained. (v) Water imbibing in axial/radial direction leads to a volume increase in axial/radial direction that is proportional to the relative surface area in this direction.

The mass transfer processes are based on Fick's second law of diffusion in cylindrical coordinates:[17]

$$\frac{\partial c_k}{\partial t} = \frac{1}{r}\left\{\frac{\partial}{\partial r}\left(rD_k\frac{\partial c_k}{\partial r}\right) + \frac{\partial}{\partial \theta}\left(\frac{D_k}{r}\frac{\partial c_k}{\partial \theta}\right) + \frac{\partial}{\partial z}\left(rD_k\frac{\partial c_k}{\partial z}\right)\right\} \qquad (1)$$

Here, c_k and D_k are the concentration and diffusion coefficient of the diffusing species ($k = 1$: water; $k = 2$: drug), respectively, and r denotes the radial coordinate, z the axial coordinate, θ the angle perpendicular to both axis, and t represents time. As there is no concentration gradient of any component with respect to θ [Figure 1a], this equation can be transformed into:

$$\frac{\partial c_k}{\partial t} = \frac{\partial}{\partial r}\left(D_k\frac{\partial c_k}{\partial r}\right) + \frac{D_k}{r}\frac{\partial c_k}{\partial r} + \frac{\partial}{\partial z}\left(D_k\frac{\partial c_k}{\partial z}\right) \qquad (2)$$

Two important features of diffusion in swellable polymer systems are considered in this mathematical model: (i) strong concentration dependence of diffusivities and (ii) volume changes due to water imbibition and drug release.

According to the free volume theory, a Fujita-type[18] exponential dependence of the diffusion coefficients for water and drug, D_1 and D_2, can be written as:

$$D_1 = D_{1eq}\exp\left(-\beta_1\left(1 - \frac{c_1}{c_{1eq}}\right)\right) \qquad (3)$$

$$D_2 = D_{2eq}\exp\left(-\beta_2\left(1 - \frac{c_1}{c_{1eq}}\right)\right) \qquad (4)$$

where β_1 and β_2 are dimensionless constants, characterizing this concentration dependence. Also c_{1eq} (762 mg/mL[20]) denotes the water concentration and D_{1eq} and D_{2eq} the respective diffusion coefficients of water and drug in the equilibrium swollen state of the system.

A schematic of the tablet for mathematical analysis is given in Figure 1, parts a and b. The tablet is allowed to swell in both axial and radial direction. The swelling is assumed to be ideal. Hence, the total volume of the tablet at any instant is given by the sum of the volumes of polymer, water, and drug. At $t = 0$ the tablet is dry and thus the water concentration at any position is equal to zero. The drug concentration within the tablet is uniform and equal to its initial concentration, c_{in}. This can be written for water as:

$$t = 0 \qquad c_1 = 0 \qquad 0 \le r \le R_0 \qquad 0 \le z \le Z_0 \qquad (5)$$

and for drug as:

$$t = 0 \qquad c_2 = c_{in} \qquad 0 \le r \le R_0 \qquad 0 \le z \le Z_0 \qquad (6)$$

where R_0 is the initial radius of the tablet, and Z_0 denotes the initial half-thickness of the cylindrical tablet.

At the surface of the tablet, the concentration of water is assumed to be at its equilibrium value, c_{1eq}, for $t > 0$. The respective boundary conditions are written as follows:

$$t > 0 \qquad c_1 = c_{1eq} \qquad 0 \le r \le R_t \qquad z = Z_t \qquad (7)$$

and

$$t > 0 \qquad c_1 = c_{1eq} \qquad 0 \le z \le Z_t \qquad r = R_t \qquad (8)$$

Here, R_t and Z_t represent the time dependent radius and half-height of the tablet. The drug concentration at the surface of the tablet is assumed to be equal to zero (perfect sink condition):

$$t > 0 \qquad c_2 = 0 \qquad 0 \le r \le R_t \qquad z = Z_t \qquad (9)$$

$$t > 0 \qquad c_2 = 0 \qquad 0 \le z \le Z_t \qquad r = R_t \qquad (10)$$

To minimize computation time, the origin of the coordinate system is placed at the center of the tablet (Figure 1a). As can be seen in Figure 1b, there are two symmetry planes for the drug and water concentration profiles. Thus, only the concentration profiles within a quarter of the cylindrical tablet have to be calculated. The mathematical treatment of this phenomenon is given by the following

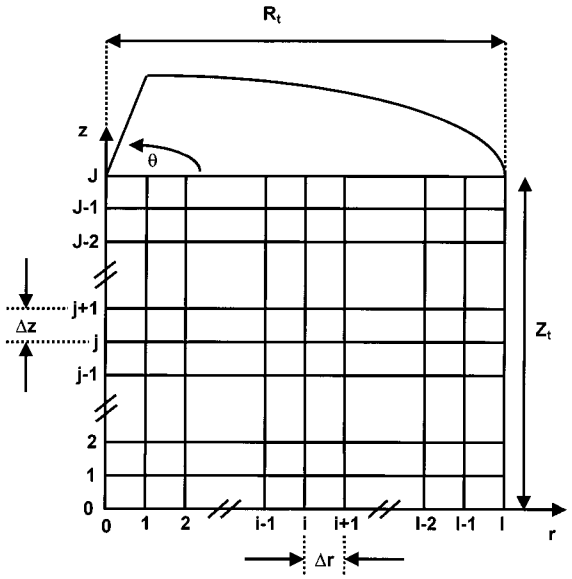

Figure 2—Schematic of the tablet for numerical analysis.

boundary conditions:

$$t > 0 \qquad \frac{\partial c_1}{\partial z} = 0 \qquad 0 \le r \le R_t \qquad z = 0 \qquad (11)$$

$$t > 0 \qquad \frac{\partial c_1}{\partial r} = 0 \qquad 0 \le z \le Z_t \qquad r = 0 \qquad (12)$$

for water, and

$$t > 0 \qquad \frac{\partial c_2}{\partial z} = 0 \qquad 0 \le r \le R_t \qquad z = 0 \qquad (13)$$

$$t > 0 \qquad \frac{\partial c_2}{\partial r} = 0 \qquad 0 \le z \le Z_t \qquad r = 0 \qquad (14)$$

for the drug.

Due to the concentration dependence of the diffusion coefficients, there is no analytical solution of this set of partial differential equations (eqs 2−14). Thus, they were solved numerically, using finite differences.

The principle of this method is illustrated in Figures 2 and 3. The time dependent radius, R_t, and half-height, Z_t, of the cylindrical tablets are divided into I and J space intervals, Δr and Δz, respectively, generating a grid of $(I + 1) \times (J + 1)$ grid points. The time is divided into g time intervals Δt (for most of the simulations we have chosen: $I = J = 50$ and $g = 500000$). Using eqs 2−4 and eqs 7−14, the concentration profiles of water and drug for a new time step ($t = t_0 + \Delta t$) can be calculated, when the concentration profile is known at the previous time step ($t = t_0$). The concentration at a certain inner grid point ($i \times \Delta r$, $j \times \Delta z$) for the new time step ($t = t_0 + \Delta t$) is calculated from the concentrations at the same grid point ($i \times \Delta r$, $j \times \Delta z$) and its four direct neighbors [$(i - 1) \times \Delta r$, $j \times \Delta z$; $i \times \Delta r$, $(j - 1) \times \Delta z$; $i \times \Delta r$, $(j + 1) \times \Delta z$; $(i + 1) \times \Delta r$, $j \times \Delta z$] at the previous time step ($t = t_0$). The concentrations at the outer grid points ($i = 0$ v $i = I$ v $j = 0$ v $j = J$) for the new time step ($t = t_0 + \Delta t$) are calculated using the boundary conditions (eqs 7−14). At time $t = 0$ the concentration profile of the drug and water are given by the initial conditions (eqs 5 and 6). Hence, the concentration profiles at $t = 0 + \Delta t$, $t = 0 + 2\Delta t$, $t = 0 + 3\Delta t$,..., $t = 0 + g\Delta t$ can be calculated sequentially.

In addition, the total amount of water and drug within the system is calculated at each time step (by integrating the respective concentrations with respect to r, z, and θ).

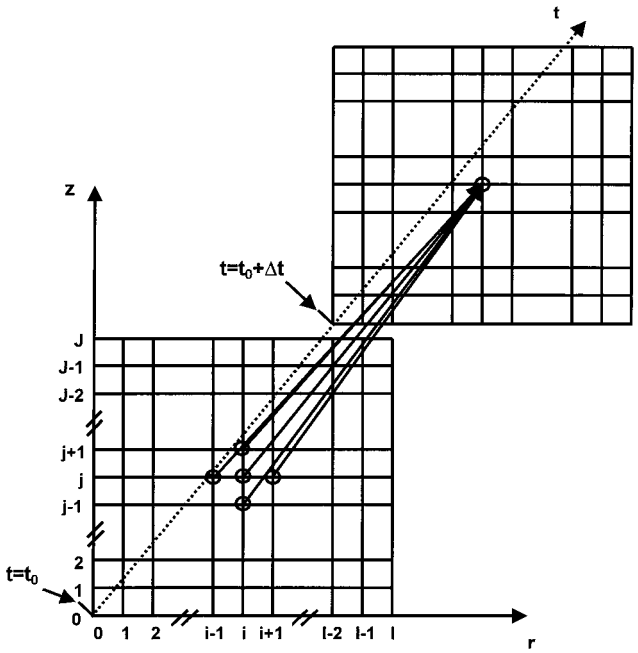

Figure 3—Principle of the numerical analysis: calculation of the concentration profile of a diffusing species at a new time step from the concentration profile at the previous time step.

Then, assuming ideal swelling, the new volume of the system is determined. With this knowledge, the new radius and height of the tablet are calculated. It is assumed that water imbibing in the axial direction leads to a volume increase in the axial direction, whereas water imbibing in the radial direction leads to a volume increase in the radial direction. The increase in volume in each direction is proportional to the surface area in this direction.

There are four unknown parameters in the presented model which have to be determined: β_1, β_2, D_{1eq}, and D_{2eq}. The constants β_1 and D_{1eq} are obtained by fitting eqs 2, 3, 5, 7, 8, 11, and 12 to experimental water uptake data of drug-free tablets ($c_{in} = 0$, thus, values for β_2 and D_{2eq} are not required) (least-squares method, combined with the Nelder−Mead method,[19] two-parameter fit), whereas the values for β_2 and D_{2eq} are subsequently determined by fitting the model (eqs 2−14) to experimental drug release data (two-parameter fit).

Results and Discussion

Water Uptake—Data for water uptake studies in HPMC were reported by Tahara.[20] Figure 4 shows the fit of the new model (to determine β_1 and D_{1eq}) to the experimentally determined relative amount of water taken up by HPMC tablets versus time. There is good agreement between theory and experiment (correlation coefficient = R^2 = 0.994). Thus, diffusion governs the water uptake into HPMC tablets. It was found that the diffusion coefficient of the diffusing species significantly depends on the water content of the system. The explanation for this phenomenon is based on the fact that the mobility of the polymer chains strongly depends on the water content of the tablet. Hence, the free volume available for diffusion is a function of the water concentration, resulting in concentration dependent diffusivities. The constant that characterizes this dependence, β_k, is specific for the diffusing molecules. For water, a value of $\beta_1 = 2.5$ was calculated. In addition, the diffusion coefficient of water within the fully swollen tablet was determined as $D_{1eq} = 5.6 \times 10^{-6}$ cm^2/s.

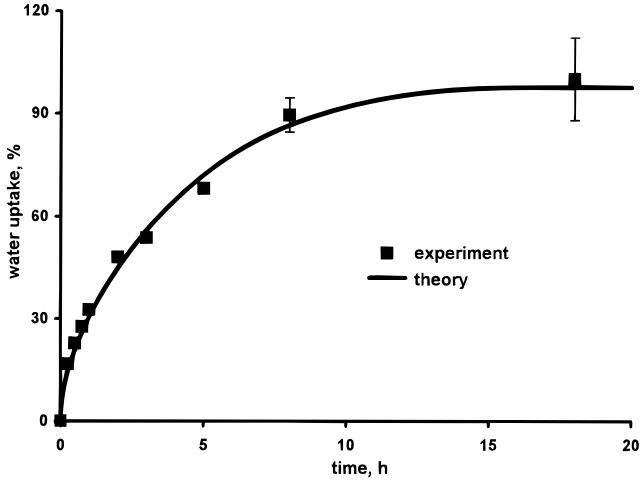

Figure 4—Fit of the model to the experimentally determined water uptake data.[20]

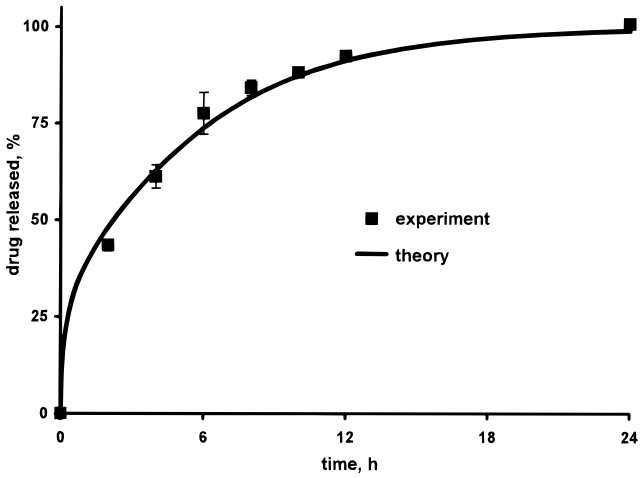

Figure 5—Fit of the model to the experimentally determined amount of propranolol hydrochloride released [release medium: phosphate buffer (pH 7.4)].

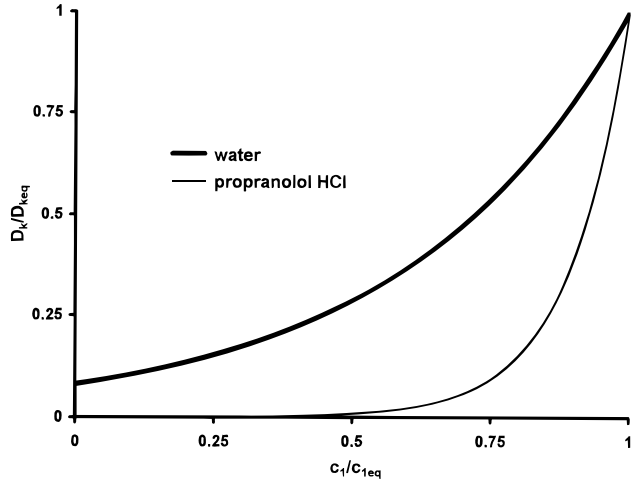

Figure 6—Normalized concentration dependencies (calculated) of the diffusion coefficients of water and propranolol hydrochloride on the water concentration in the system.

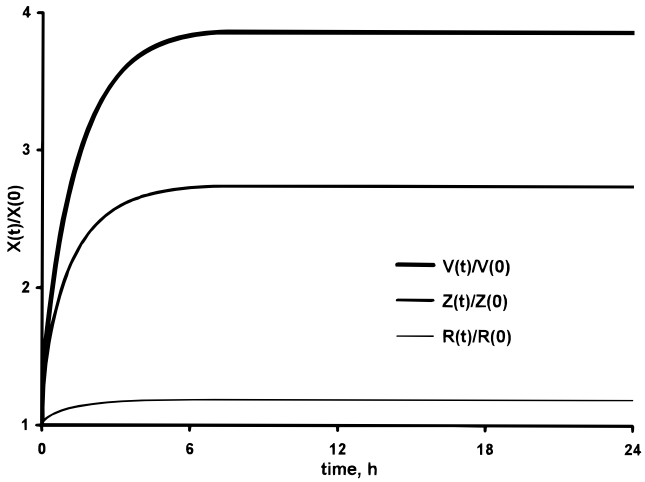

Figure 7—Swelling kinetics (calculated) of the HPMC tablets: increase in volume (*V*), half-height (*Z*), and radius (*R*).

Drug Release—The drug release kinetics of propranolol hydrochloride in 0.1 M phosphate buffer (pH 7.4) are shown in Figure 5 for tablet dimensions of $R_0 = 0.65$ cm, $Z_0 = 0.069$ cm. The new model was fitted to the experimentally determined relative amount of drug released versus time (correlation coefficient = $R^2 = 0.993$). Once more, diffusion governs the transfer kinetics, with concentration dependent diffusion coefficients. The two important parameters characterizing this process, the diffusion coefficient of the drug within the fully swollen tablet, D_{2eq}, and the constant β_2, characterizing the concentration dependence of D_2 on the water content, were determined as $D_{2eq} = 6.3 \times 10^{-7}$ cm^2/s, and $\beta_2 = 9.5$.

As expected from the free volume theory, D_{2eq} is less than D_{1eq}, and β_2 is greater than β_1. According to the theory, the size of the diffusing molecules significantly affects the transfer rate. The jump from one cavity to another for a given cavity size distribution is easier for smaller than for larger molecules. Hence, the diffusion coefficient of water in the fully swollen tablet is higher than the respective diffusion coefficient of propranolol hydrochloride.

Concerning the β-values, the relations are more complex. The dependence of the diffusivity on the water content of the system is a function of the molecular size of the diffusing species. The diffusion rate of small molecules within the polymer system is less affected by the mobility of polymer chains than is the diffusion rate of big molecules (above a certain minimum void size). For small diffusing molecules, much smaller than the average void size, diffusion occurs by localized activated jumps from one preexisting cavity to another; only a few monomer segments are involved. With larger diffusing species, preexisting cavities may be unable to accommodate the diffusing molecules. Therefore, larger numbers of monomer segments must be rearranged to allow the molecules to diffuse.[21] Thus, the relative increase of the diffusion coefficient of water with increasing water content is less steep than the respective increase of the diffusion coefficient of propranolol hydrochloride. These relations are illustrated for water and propranolol hydrochloride diffusivities in Figure 6, normalized to the equilibrium concentration of water and to the respective diffusion coefficients in the fully swollen tablet ($\beta_1 = 2.5$, $\beta_2 = 9.5$).

Swelling Kinetics—Swelling is associated with polymer chain relaxation with volume expansion. The increasing dimension of the system is considered in the new model by moving boundary conditions (eqs 7−14). It is assumed that the total volume of the system is equal to the sum of the volumes of the polymer, water, and drug. The increasing radius, R_t, half-height, Z_t, and volume, V_t, of the tablets can be calculated. Figure 7 shows the respective data of propranolol hydrochloride containing tablets ($R_0 = 0.65$ cm, $Z_0 = 0.069$ cm, release medium: phosphate buffer (pH 7.4), $\beta_1 = 2.5$, $D_{1eq} = 5.6 \times 10^{-6}$ cm^2/s), normalized to the

respective initial values at $t = 0$. It is shown that the swelling of the tablet is much faster than the release of the drug (Figure 5 shows the release profile of the same tablets). The water uptake is complete after approximately 6 h, whereas the drug is released over a period of approximately 24 h. This is due to the higher mobility of the water molecules in the system, resulting in higher diffusion coefficients in the fully swollen tablet. In addition, the β-value of water is much smaller than the β-value of propranolol hydrochloride.

The increase in radius and height is very high at the beginning and then declines with time. Interestingly, the relative increase in height is approximately 9-fold of the relative increase in radius. The reason for this phenomenon is the difference in the surface area of the tablet in both directions. In the axial direction the surface area is much greater than in the radial direction (2.65 cm^2, instead of 0.56 cm^2). Hence, more water can imbibe in the axial direction and cause the tablet to swell in this direction. The increase in volume of the tablet (by a factor equal to 4) is very important for the additional imbibition of water and for the drug release kinetics. As shown above, both processes are governed by diffusion. Increasing dimensions of the tablets lead to increasing diffusion pathways and thus to decreasing diffusion rates. The effect of the increasing diffusion pathways competes with the effect of the increasing diffusivities of the diffusing species, due to the increasing polymer mobility.

Water and Drug Concentration Profiles—With the new model, further insight into the mass transfer mechanisms is achieved. The concentration profiles of both species, water and drug, can be calculated at any instant. Figure 8 shows the water profiles within the tablets ($R_0 =$ 0.65 cm, $Z_0 = 0.069$ cm, release medium: phosphate buffer (pH 7.4), $\beta_1 = 2.5$, $D_{1eq} = 5.6 \times 10^{-6}$ cm^2/s) at 30 min (Figure 8a), and 3 h (Figure 8b). For reasons of clarity, the concentration profiles within only one-quarter of the tablet (as indicated in Figure 1b) are presented. Steep concentration gradients directed to the middle of the tablets are observed for small time periods. They are the driving force for additional water imbibition. The steepness of these curves declines with time; thus, the transfer rate declines with time. This effect overlaps with the two others, described above: the increasing diffusion pathways and the increasing diffusion coefficients. The respective concentration profiles of propranolol hydrochloride are presented in Figure 9 ($R_0 = 0.65$ cm, $Z_0 = 0.069$ cm, release medium: phosphate buffer (pH 7.4), $\beta_1 = 2.5$, $D_{1eq} = 5.6 \times 10^{-6}$ cm^2/s, $\beta_2 = 9.5$, $D_{2eq} = 6.3 \times 10^{-7}$ cm^2/s), at 30 min (Figure 9a), and 3 h (Figure 9b). Again, at the beginning there are steep concentration gradients, which are declining with time. The high driving force at the beginning, in combination with short diffusion pathways, leads to high release rates, as can be shown theoretically as well as experimentally (Figure 5).

Concentration Dependent Diffusivities—As described above, the diffusion coefficients of water and drug strongly depend on the water content of the tablet. Thus, they are functions of both time (t) and position (r, z, θ) within the system. With the new model, the diffusivities can be calculated at any time and position.

Figure 10 shows the diffusion coefficient of propranolol hydrochloride at three different positions as a function of time: (i) at the surface of the tablet, (ii) within the tablet ($r = R_t/2$, $z = Z_t/2$, θ), and (iii) at the center of the tablet. The following parameters have been used: $R_0 = 0.65$ cm, $Z_0 = 0.069$ cm, $\beta_1 = 2.5$, $D_{1eq} = 5.6 \times 10^{-6}$ cm^2/s, $\beta_2 = 9.5$, $D_{2eq} = 6.3 \times 10^{-7}$ cm^2/s (release medium: buffer pH 7.4). For reasons of clarity, the data are normalized to the respective diffusivities in the fully swollen system. The

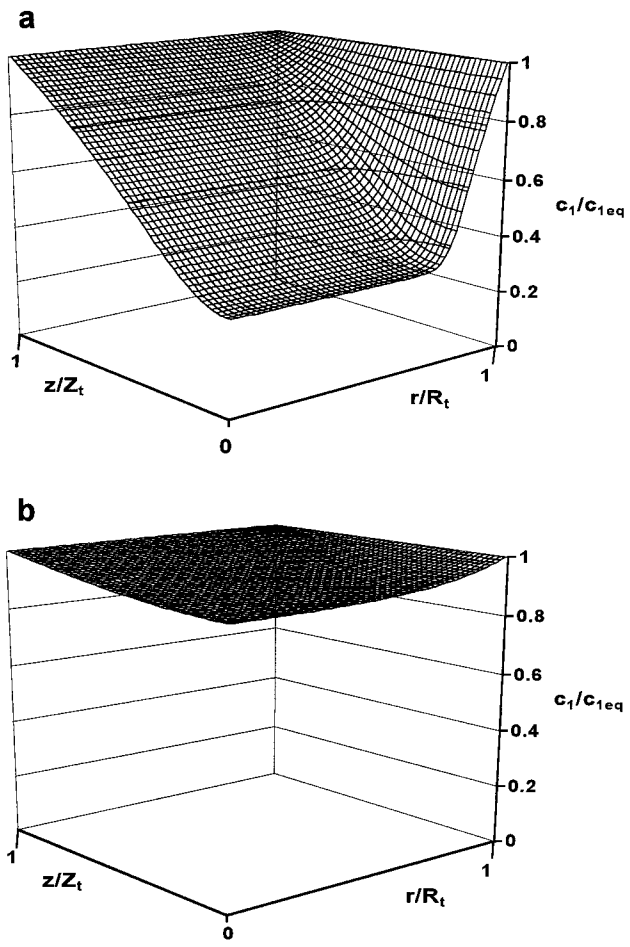

Figure 8—Concentration profile (calculated) of water within the tablets (containing propranolol hydrochloride): (a) $t = 30$ min, (b) $t = 3$ h [release medium: phosphate buffer (pH 7.4)].

diffusion coefficient levels off instantaneously to its equilibrium value at the surface of the tablet upon contact with the release medium. In contrast to this, the diffusivity within the tablet, as well as at the center, shows a sigmoidal behavior. First, it is very low and approximately constant. After a certain time period, it levels off and reaches its equilibrium value. The moment of leveling off is a function of the position (r, z, θ) within the tablet (Figure 10). The knowledge of these data is of great practical importance, when designing a new tablet with, e.g., nonuniform initial drug distribution, to achieve a desired release profile.

Influence of the Aspect Ratio of the Tablet on the Drug Release Kinetics—An easy tool to modify the release kinetics of a drug from a tablet is to vary its shape. The effect of the aspect ratio (radius/height) of the tablet on the drug release rate can be simulated with the new model. Figure 11 clearly shows the release kinetics of propranolol hydrochloride in phosphate buffer (pH 7.4) from three different types of tablet with the same volume (0.18 cm^3): (i) flat cylinders with $R_0/(2Z_0) = 20$, (ii) regular tablets with $R_0/(2Z_0) = 2$, and (iii) almost rod-shaped cylinders with $R_0/(2Z_0) = 0.2$ ($\beta_1 = 2.5$, $D_{1eq} = 5.6 \times 10^{-6}$ cm^2/s, $\beta_2 = 9.5$, $D_{2eq} = 6.3 \times 10^{-7}$ cm^2/s). It is shown that the release rate from the flat tablets is significantly higher than from the other two types: 90% of the drug is released within only 4.5 h, instead of 18.9 and 21.6 h, respectively. The reason for this phenomenon is the difference in the surface area of the tablets: 7.3 cm^2 in the case of flat tablets, 2.3 cm^2 and 1.9 cm^2 for the regular and "rodlike" tablets, respectively. Within a certain range, determined

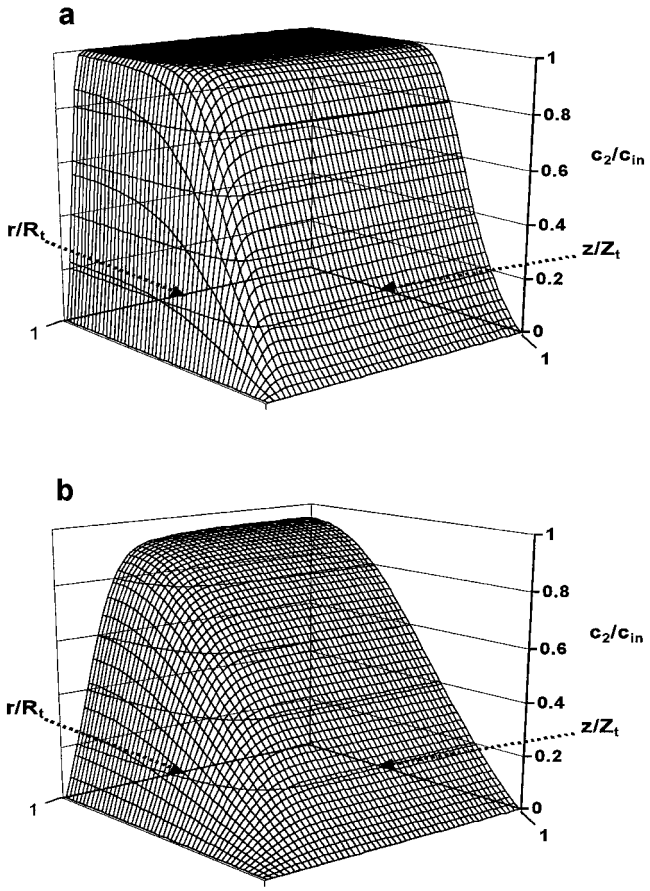

Figure 9—Concentration profile (calculated) of propranolol hydrochloride within the tablets: (a) $t = 30$ min, (b) $t = 3$ h [release medium: phosphate buffer (pH 7.4)].

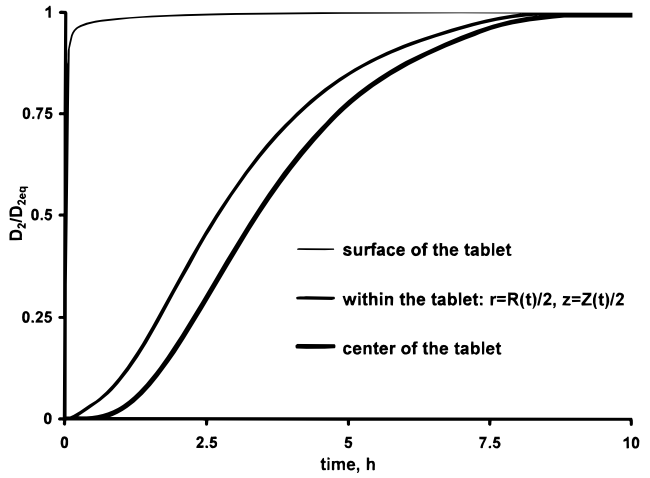

Figure 10—Diffusion coefficient (calculated) of propranolol hydrochloride at different positions within the tablet versus time [release medium: phosphate buffer (pH 7.4)].

by the applicability of the tablets, the variation of the aspect ratio (radius/height) is thus a very easy and effective tool to modify the release rate of the system. With the new model, the optimal shape can be calculated to achieve a desired release profile, without the need of experiments.

Influence of the Tablet Size on the Drug Release Kinetics—Another convenient method to achieve a desired release profile is to vary the size of the tablet. This effect is illustrated in Figure 12. Three types of propranolol hydrochloride tablets (with the same aspect ratio = radius/height = 1.25 and initial drug concentration $c_{in} = 109$ mg/

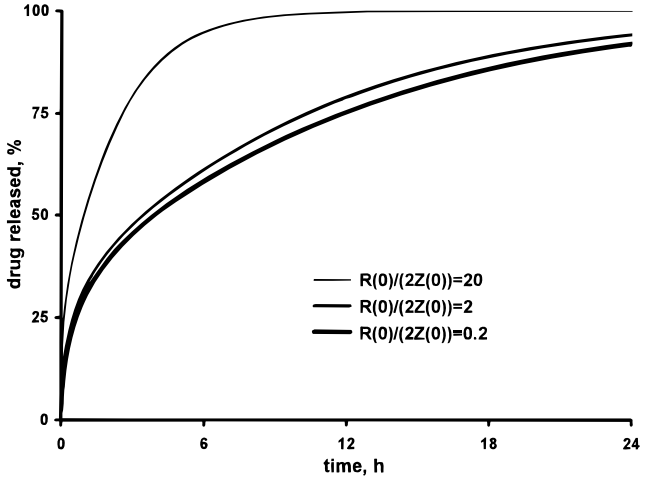

Figure 11—Influence of the aspect ratio (radius/height) of the tablet on the release kinetics (calculated) of propranolol hydrochloride [release medium: phosphate buffer (pH 7.4)].

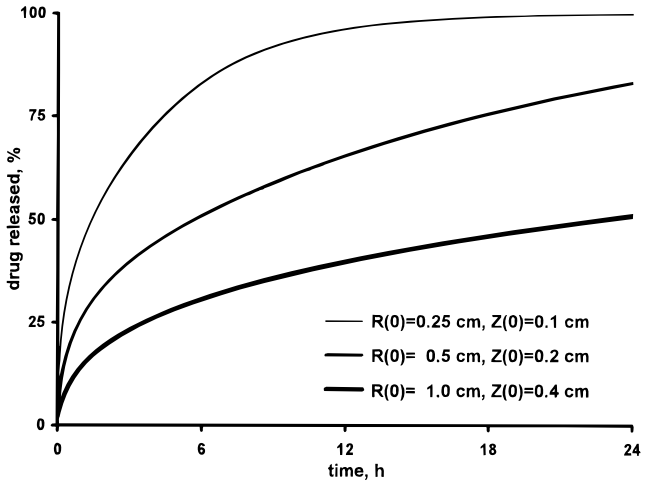

Figure 12—Effect of the size of the tablet on the release kinetics (calculated) of propranolol hydrochloride [release medium: phosphate buffer (pH 7.4)].

mL) have been investigated in phosphate buffer (pH 7.4): (i) small ones, with $R_0 = 0.25$ cm and $Z_0 = 0.1$ cm, (ii) medium-sized ones, with $R_0 = 0.5$ cm and $Z_0 = 0.2$ cm, and (iii) large ones, with $R_0 = 1.0$ cm and $Z_0 = 0.4$ cm ($\beta_1 = 2.5$, $D_{1eq} = 5.6 \times 10^{-6}$ cm^2/s, $\beta_2 = 9.5$, $D_{2eq} = 6.3 \times 10^{-7}$ cm^2/s). As expected, a very strong influence of the size of the tablet on the release rate is observed: Within 24 h, 99.8% of the drug has been released from the small, 83.1% from the medium-sized, and only 50.9% from the large tablets. The explanation for this phenomenon is obvious. Small tablets have a higher relative surface area (referred to the volume) than large tablets. In addition, the diffusion pathways are much longer in large tablets than in small ones. Thus, the relative amount of drug released versus time is much higher for small tablets. To release the same absolute amount of drug, more small tablets have to be administered than large ones. The variation of the size of the tablets is a very effective and easy tool to achieve a desired release rate. The new model can be used to simulate the drug release kinetics for different tablet sizes. Thus, the required dimensions to obtain a certain release profile can be predicted, avoiding time-consuming experiments.

Applicability of the Model—The release mechanism of a controlled drug delivery system can be affected by various parameters, e.g., type of drug and release medium. To prove the applicability of the presented model for

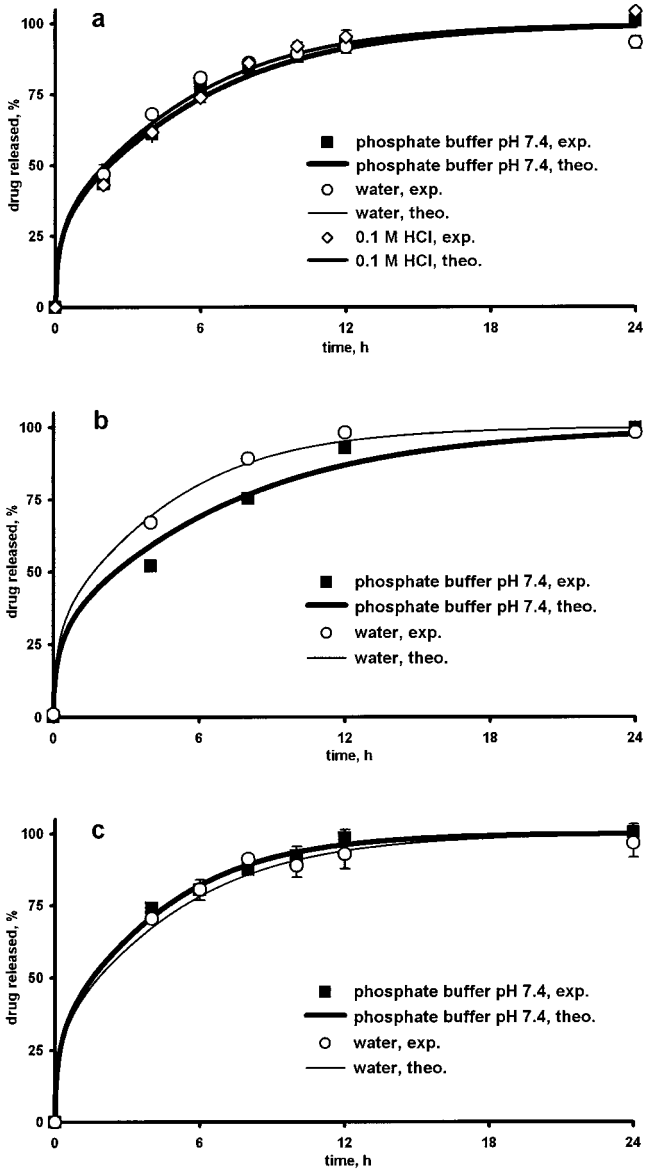

Figure 13—Applicability of the model for different drugs and release media: (a) propranolol hydrochloride, (b) diclofenac sodium, (c) chlorpheniramine maleate.

different drug-release media combinations, experiments have also been conducted with propranolol hydrochloride in 0.1 M HCl and deionized water, diclofenac sodium and chlorpheniramine maleate in deionized water and phosphate buffer (pH 7.4), respectively. Figure 13, parts a–c, show the theoretically ($\beta_1 = 2.5$, $D_{1eq} = 5.6 \times 10^{-6}$ cm^2/s, $R_0 = 0.65$ cm, $Z_0 = 0.069$ cm) and experimentally determined release kinetics. In each case, the experimentally determined data can be explained by the presented Fickian analysis considering concentration dependent diffusivities (correlation coefficient: $R^2 > 0.985$, Table 1). This is of great practical importance for the new model. It is not restricted to a certain drug-release medium combination. In addition, the respective diffusion coefficients in the fully swollen tablets, D_{2eq}, and the constants, characterizing the concentration dependence of the drug diffusivities on the water content of the tablet, β_2, have been determined (Table 1).

Influence of the Type of Release Medium on the Drug Release Kinetics—For propranolol hydrochloride, the calculated β_2-values in different release media (phosphate buffer (pH 7.4), deionized water, and 0.1 M HCl) are very similar: $\beta_2 = 9.5$, 9.4, and 9.4, respectively. This indicates the negligible effect of the type of release medium on the concentration dependence of the diffusivity. In addition, the diffusion coefficient of the drug within the fully swollen tablet varies only between 6.3×10^{-7} cm^2/s and 7.0×10^{-7} cm^2/s. Thus, the resulting release curves (Figure 13a) are very similar. For diclofenac sodium in phosphate buffer (pH 7.4) and deionized water, D_{2eq} was determined as 4.9×10^{-7} cm^2/s and 8.0×10^{-7} cm^2/s, respectively. The calculated β_2-values however, are approximately equal: $\beta_2 = 8.1$ and 8.3. As can be seen in Figure 13b, this results in a slightly different release rate of diclofenac sodium in phosphate buffer (pH 7.4) and deionized water. The explanation for this phenomenon is probably based on the different interactions of the phosphate buffer ions (K^+, Na^+, HPO_4^{2-}, $H_2PO_4^-$) with diclofenac sodium, HPMC, and water. The exact analysis of these interactions is beyond the scope of this study. For chlorpheniramine maleate, the following values have been calculated: D_{2eq}(buffer pH 7.4) $= 8.7 \times 10^{-7}$ cm^2/s, D_{2eq}(water) $= 7.3 \times 10^{-7}$ cm^2/s, β_2(buffer pH 7.4) $= 8.5$, and β_2(water) $= 8.4$. As in the case of propranolol hydrochloride, these values are approximately equal. The resulting release profiles are shown in Figure 13c, illustrating the negligible effect of the type of release medium on the liberation of chlorpheniramine maleate.

Table 1—Parameters Characterizing the Diffusion of Drugs within HPMC Tablets

drug	release medium	$D_{2eq} \times 10^7$ (cm^2/s)	β_2	R^2
propranolol hydrochloride	buffer pH 7.4	6.3	9.5	0.993
	deionized water	7.0	9.4	0.988
	0.1 M HCl	6.9	9.4	0.988
diclofenac	buffer pH 7.4	4.9	8.1	0.986
sodium	deionized water	8.0	8.3	0.997
chlorpheniramine	buffer pH 7.4	8.7	8.5	0.997
maleate	deionized water	7.3	8.4	0.991

Conclusions

The two major benefits of the presented model are: (i) the gain of further insight into the release mechanism of drugs from HPMC tablets and (ii) the ability to calculate the required shape and dimensions of HPMC tablets to achieve desired drug release profiles.

Notation

c	concentration within the tablet
c_{eq}	concentration in the equilibrium swollen state
c_{in}	initial concentration of the drug within the tablet
D	diffusion coefficient
D_{eq}	diffusion coefficient in the fully swollen tablet
g	number of time intervals for numerical analysis
i	integer for numerical analysis
I	number of space intervals along the radial axes for numerical analysis
k	subscript, indicating the diffusing species: $k =$ 1: water, $k = 2$: drug
j	integer for numerical analysis
J	number of space intervals along the axial axes for numerical analysis
r	radial coordinate
Δr	space interval along the radial axes for numerical analysis

R^2	correlation coefficient
R_0	initial radius of the tablet
R_t	radius of the tablet at time t
t	time
Δt	time interval for numerical analysis
V_t	volume of the tablet at time t
z	axial coordinate
Δz	space interval along the axial axes for numerical analysis
Z_0	initial half-height of the tablet
Z_t	half-height of the tablet at time t
β	constant, characterizing the dependence of the diffusion coefficient on the water concentration
θ	angle

Accepted for publication September 8, 1998.

Abstract □ The equilibrium and relative rate of rotamer interconversion around the bond joining the 2,2′-bipyrrolyl and pyrromethene moieties in a synthetic analogue of immunosuppressant prodigiosin are investigated as a function of pHapp in a water/acetonitrile mixture (1/1 by volume). Two chromatographically separable isomeric forms are obtained in acid solutions (pHapp < 4), whereas rapid interconversion occurs above neutrality. Furthermore, pH modulates the conformational preference of the molecule according to nitrogen protonation on the three pyrrole rings system ($pK_a = 7.2$). At high pHapp (neutral form), the same conformer that is observed in pure acetonitrile prevails, whereas the other one is preferred by the protonated form. The nuclear magnetic resonance data indicate that the structures of the two conformers mainly differ in the value of the torsion angle around the aforementioned C–C bond. Kinetic and equilibrium data are quantitatively interpreted with a cyclic mechanism including two protonation ($pK_{a1} = 8.23 \pm 0.03$, $pK_{a2} = 5.4 \pm 0.2$) and two conformational rearrangement steps. A molecular interpretation of the observed behavior includes, for the preferred conformer at low pH, formation of a new hydrogen bond between the exocyclic oxygen and the neighboring pyrrole NH upon protonation of the three pyrrole rings system.

Introduction

Prodigiosins are a class of natural red pigments isolated from *Streptomyces Genus* that are endowed with potent antibacterial and cytotoxic properties.[1] More recently, immunosuppressive properties have been discovered for some members of this class,[2,3] and ascribed to a mechanism of action well distinguished from that exerted by cyclosporin A or other related drugs.[4] In a medicinal chemistry program devoted to the preparation of synthetic analogues of the natural prodigiosins,[5] PNU-156804 (Figure 1) emerged as a lead with very favorable pharmacological properties. These favorable properties prompted a detailed investigation of the solution properties of this analogue and the development of a specific analytical high-performance liquid chromatography (HPLC) method. Anomalous behavior (peak splitting, tailing, etc.) was immediately detected by reversed-phase HPLC under various conditions and attributed to geometrical isomerization in the time scale of chromatography. On the basis of this result, the equilibrium and kinetics of this geometrical transformation in solution were investigated with the aim of both optimizing conditions for chromatography and better understanding the molecular properties of this new class of compounds in water-containing solutions.

PNU-156804 contains the 2,2′-bipyrrolyl−pyrromethene chromophore whose structure is compatible with several

Figure 1—Chemical structure of PNU-156804 and PNU-156737. The numeration system used in the presentation af results is shown for PNU-156804 together with the torsion angle that is involved in rotamer interconversion.

geometrical isomers arising from different equilibrium positions around the bonds connecting the three pyrrole rings. The extensive conjugation of this chromophoric system is apparent from the different mesomeric structures that can be written. As a consequence, rotation barriers lower than expected for ordinary double bonds may arise, and interconversion among geometrical isomers may become detectable at ordinary temperatures. In the present investigation we report data on both the equilibrium composition and the rate of interconversion for the two geometrical isomers that are chromatographically resolved at room temperature under acidic conditions. The compound is not soluble enough in pure water, but a study as a function of pHapp in solutions of water/acetonitrile (1/1) proved feasible. The study was carried out for solutions of various pHapp (glass electrode readings) as it was immediately clear that protonation of the molecule greatly affected the conformational equilibrium and the rate of interconversion. Finally, a structural model of the two conformers is proposed on the basis of two-dimensional nuclear magnetic resonance nuclear Overhauser enhancement spectroscopy (2D-NMR NOESY) data.

Materials and Methods

Materials—PNU-156804 (either as HCl or as CH_3SO_3H salt) and PNU-156737 were prepared as previously described.[5] The structure of both compounds has been verified with NMR and mass spectroscopy (MS) techniques. HPLC grade acetonitrile and methanol were Carlo Erba products. Methylene chloride RPE, trifluoroacetic acid RPE, and all chemicals for buffer preparation were purchased from Carlo Erba. Water was purified with a Milli-Q apparatus (Waters). Deuterated solvents were purchased from Merck.

Spectrophotometric Titrations and Kinetic Measurements—Data were collected on a Perkin-Elmer Lambda 4 instru-

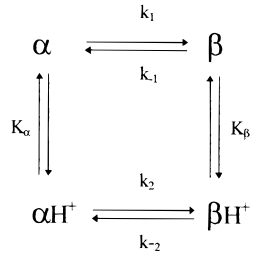

Scheme 1

ment connected to a Perkin-Elmer 7700 computer. The cuvette holder was thermostated at 25 °C with fluid circulation from a water bath (LTD-6, Grant). A fresh solution was prepared for each determination by adding 0.200 mL of a stock solution in acetonitrile (concentration (C) ≈ 0.04 mg/mL) to 2 mL of a titration solvent with pH near the desired value (the final concentration of PNU-156804 was around 0.004 mg/mL). The actual pHapp value (range 2−11) was determined in the cuvette immediately after the spectroscopic measurement (absorbance at 525 nm). The titration solvent was made out of a mixture containing 275 mL of aqueous phosphate 0.02 M, NaCl 0.1 M, and 225 mL of acetonitrile, whose pHapp was adjusted with small additions of 2 N HCl or NaOH to the desired value. The final solvent composition in the cuvette was 1/1 acetonitrile/aqueous phase by volume. Solutions for kinetic measurements were similarly prepared with both titration solvent and stock solution pre-thermostated at 25 °C, and the instrument was set in the time drive mode.

Kinetic Measurements: Stopped Flow—A High Tech SF51 instrument in the light absorption mode was used for fast kinetic measurements. The conformational change was induced by a change of pH and monitored by measuring light absorption at 500 nm at pH values between 3 and 7, and at 430 nm at pH values >7. In detail, the two syringes were filled with either a solution of PNU-156804 in acetonitrile/buffer at about pH 11 (1/1) when jumping from alkaline to neutral/acid region and at about pH 3 when jumping from the acid to the neutral/alkaline region or acetonitrile/buffer at the desired pH (0.02 M phosphate, NaCl 0.1 M). The pHapp of the final solution was determined after mixing equal volumes of the two solutions just mentioned in a test tube, and the final concentration of PNU-156804 in the observation chamber of the stopped flow was similar to that used for the spectrophotometric experiments (C ≅ 0.004 mg/mL).

HPLC Measurements—Chromatograms were collected with a Perkin-Elmer instrument with a LC-410 quaternary pumping system, a 235C diode-array detector, and a Turbochrom data station. Ordinary chromatograms were obtained with a Hipak C8 AB (250 × 4.6 mm, 5 μm) with a mobile phase (flow = 1 mL/min) of methanol/tetrahydrophuran/water (55/25/20 by volume) upon buffering the aqueous phase to the desired pH. Fast resolution was obtained with a C18 cartridge (3 × 3 CR, Perkin-Elmer) with a mixture of water/methanol/methylene chloride/acetonitrile/trifluoroacetic acid (300/400/150/150/1 by volume) as mobile phase at the flow rate of 2 mL/min. This procedure provided sufficient separation of the two isomeric forms in a short analysis time (8 min), which was needed to limit interconversion of the two conformers. Generally, 20 μL of an approximately 0.05 mg/mL solution were injected, and detection was obtained at 500 nm.

NMR Measurements—The ^{1}H NMR data were collected at 28 °C with a Varian Unity 600 instrument operating at 600 MHz. The standard Varian pulse sequences and processing software were used. Mixing times of 2.0 and 0.080 s were used in the 2D experiments NOESY and total correlation spectroscopy (TOCSY), respectively.

Equilibrium and Kinetic Model—Data interpretation was obtained with the following cyclic reaction model (Scheme 1), where α and β indicate the two conformers in neutral form and αH^+ and βH^+ indicate the corresponding protonated forms. No kinetic parameters are indicated for the two protonation steps, which are expected to be much faster than the other two conformational reorientations.

The four equilibrium parameters (two microscopic acidity constants, K_α and K_β, and two equilibrium constants, $K_1 = k_1 / k_{-1}$, $K_2 = k_2 / k_{-2}$) are not independent but are related through the cyclic equilibrium condition as follows:

$$K_\beta = K_\alpha \frac{K_1}{K_2} \tag{1}$$

The macroscopic equilibrium acidity constant, K_a, is consequently given by

$$K_a = K_\alpha \frac{1 + K_1}{1 + K_2} \tag{2}$$

With the assumption that both protonation reactions rapidly equilibrate and that only the two conformational isomerization steps contribute to the observable time dependence of the optical signal, only one reciprocal relaxation time, $k = 1/\tau$, is expected for the kinetic model just described. The derivation of the dependence of k on $[H^+]$ is shortly outlined here according to standard procedures.[6]

The rate equation for conformer α is

$$\frac{d(\alpha + \alpha H^+)}{dt} = -k_1\,\alpha - k_2 \alpha H^+ + k_{-1}\beta + k_{-2}\beta H^+ \tag{3}$$

Upon introducing the mass balance condition:

$$C_o = \alpha + \alpha H^+ + \beta + \beta H^+ \tag{4}$$

and the equilibrium condition for the two protonation steps

$$\alpha H^+ = \alpha [H^+]/K_\alpha \qquad \beta H^+ = \beta [H^+]/K_\beta \tag{5}$$

equation 3 transforms into

$$(1 + [H^+]/K_\alpha)\frac{d\alpha}{dt} = -\alpha\,(k_1 + k_2\,[H^+]/K_\alpha) - \alpha(k_{-1} + k_{-2}[H^+]/K_\beta)(1 + [H^+]/K_\alpha)/(1 + [H^+]/K_\beta) + C_o\,(k_{-1} + k_{-2}\,[H^+]/K_\beta) \tag{6}$$

which rearranges into a standard first-order rate equation:

$$d\alpha/dt = -k\alpha + \text{const} \tag{7}$$

with const = $C_o\,(k_{-1} + k_{-2}\,[H^+]/K_\beta)/(1 + [H^+]/K_\alpha)$ and the first-order rate

$$k = \frac{k_1 + k_2\,[H^+]/K_\alpha}{1 + [H^+]/K_\alpha} + \frac{k_{-1} + k_{-2}\,[H^+]/K_\beta}{1 + [H^+]/K_\beta} \tag{8}$$

At low pH values $k \approx k_2 + k_{-2}$, and the interconversion rate coincides with that of the protonated form; at high pH $k \approx k_1 + k_{-1}$, and the interconversion rate of the neutral form sets the pace.

Data Analysis—Best fit of experimental data to equations was obtained with the nonlinear regression procedure of the MATH menu within program SIGMAPLOT (Jandel). Analysis of first-order kinetics used the equation

$$y = A\,(1 - e^{-kt}) + \text{offset} \tag{9}$$

Spectrophotometric titration curves and pH dependence of HPLC peak areas and of the interconversion rate were analyzed with the following equation:

$$y = \frac{A + B\,10^{(pH - pK_a)}}{1 + 10^{(pH - pK_a)}} \tag{10}$$

where A is the limiting value of the observed property at low pH and B is that at high pH.

Analysis of pH dependence of kinetic data was accomplished with 8 (method 1) or with a combination of eqs 8 and 1 to reduce the number of free parameters (method 2) by means of a nonlinear

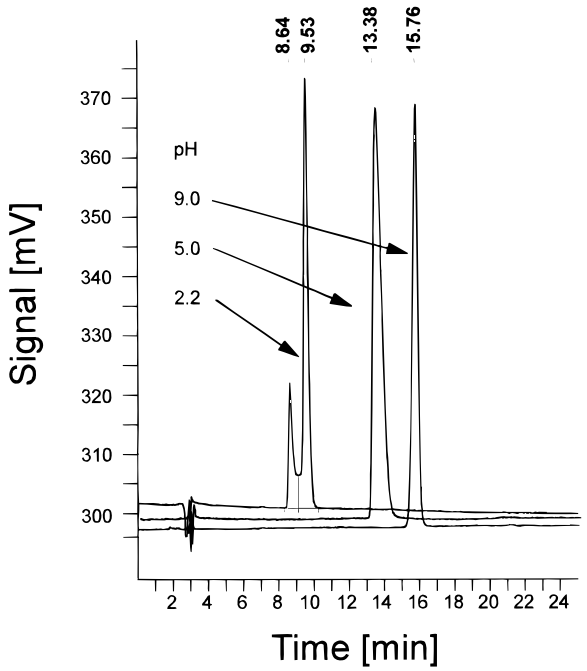

Figure 2—HPLC separation of PNU-156804 rotamers as a function of pH. Three chromatograms obtained with mobile phases buffered at different pH values are superimposed. Two peaks are obtained only with the most acidic mobile phase: the minor peak corresponds to β-rotamer in this case.

weighted least squares procedure (weights = $1/k$) written whithin the program SCIENTIST (Micro-Math).

Results

Spectrophotometric Titration—In the ultraviolet (UV)−visible spectrum of PNU-156804 dissolved in (1/1) water/acetonitrile, the long wavelength absorption band is observed at about 525 nm in acidic solution and, with reduced intensity, at about 460 nm in alkali conditions. This spectroscopic change is the basis for a spectrophotometric titration that leads to $pK_a = 7.20 \pm 0.04$ (average of two determinations: 7.16 and 7.25). This result is attributed to nitrogen protonation in the system of three conjugated pyrrole rings. Data were obtained with solutions equilibrated for at least 30 min at pHapp < 5 and for 10 min above this value, therefore, the pK_a value refers to the equilibrium mixture of two geometric isomers as discussed later.

Equilibrium and Rate of Conformational Change—The HPLC chromatograms of PNU-156804 are greatly affected by the pH of the mobile phase: above neutrality, a sharp peak is obtained that broadens at around pH 5 and splits into two peaks with an acid mobile phase (see Figure 2). Under these latter conditions, the interconversion rate is long in comparison with the chromatographic separation time (the retention times of the two peaks differ by about 1 min) and the relative peak areas approximately correspond to the population of the two conformers in the injected solution, which is a function of the pH and of the composition of this solution. Thus, conformational equilibrium composition of PNU-156804 in solution may be investigated by HPLC.

A pure acetonitrile solution produces a chromatogram similar to that obtained for water containing solutions at high pH (predominance of β-conformer). Preequilibrated solutions at low pH correspond to chromatograms with predominance of α-conformer. The pH dependence of relative peak area (Figure 3) nicely fits a titration curve corresponding to a pK_a of 7.16, which is in very good

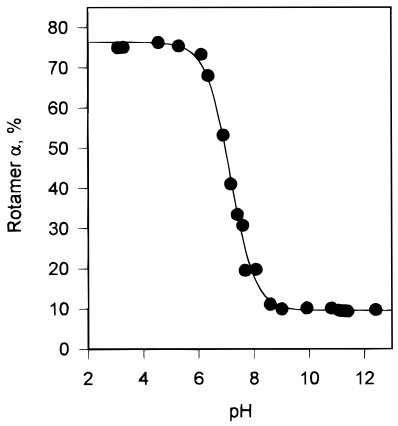

Figure 3—Equilibrium α-rotamer population as determined by HPLC using an acidic mobile phase. The pH dependence is well interpreted with a titration curve corresponding to $pK_a = 7.16$, which is in good agreement with spectroscopic titration data.

agreement with the value obtained from spectrophotometric titration. The limiting value of α-conformer population goes from about 75% at low pH down to 10% at high pH. Actually, high pH data are affected by partial reequilibration during chromatography in the acid mobile phase; thus, the effective limiting population of α-conformer can be much lower than 10%. Perturbation of the equilibrium during chromatographic separation is also likely at low pH, where conformer half-life is about 5 min and thus comparable with the separation time, and may depend on the composition of the mobile phase, which is not the 1/1 water/acetonitrile mixture used in all other experiments. Accordingly, the estimates of equilibrium constants ($K_2 \cong 0.3$ and $K_1 \geq 10$) as obtained with these data should be considered as approximate values.

The UV−visible absorption spectra of the two geometric isomers, as measured with diode array detection in HPLC, are similar but not identical, and the largest difference (about 10% of total absorbance) is observed at around 500 nm. The same spectroscopic change is seen when an acetonitrile solution of PNU-156804 is diluted to acetonitrile/acid buffer (1/1) and the spectrum measured soon after solution preparation is compared with that taken after 30 min. This difference is the basis for kinetic measurements that were made in an ordinary spectrophotometer at pHapp between 2 and 5, and with a stopped-flow apparatus at higher pHapp values by the pH-jump technique. At above pH 7, where the spectrum of the neutral form predominates, the best signal is obtained with detection at 430 nm. For acid solutions, where determination of rates was spectrophotometrically accessible, the two methods gave identical results. Data are analyzed with a first-order kinetic model (eq 4) that leads to determination of the reaction rate k. The dependence of this parameter on pHapp is shown in Figure 4 together with the results of model fitting obtained with eq 8 (method 1, 6 free parameters) and a combination of eq 8 and eq 1 (method 2, 5 free parameters). Values of the two acidity constants (see Table 1) are reasonably well determined and agree in both fitting methods. No error estimate is possible for the rate constants in method 1 because of strong parameter correlation; method 2 provides error estimates for all k values and also suggest a major indetermination for rate constants k_2 and k_{-2}, which are strongly method dependent. Not surprisingly, the estimated values of the equilibrium constants ($K_2 = 0.06$ and $K_1 = 30$, method 2) only qualitatively agree with results of the chromatographic investigation. Most likely as a consequence of the poor evaluation of the kinetic parameters, the estimate $pK_a =$

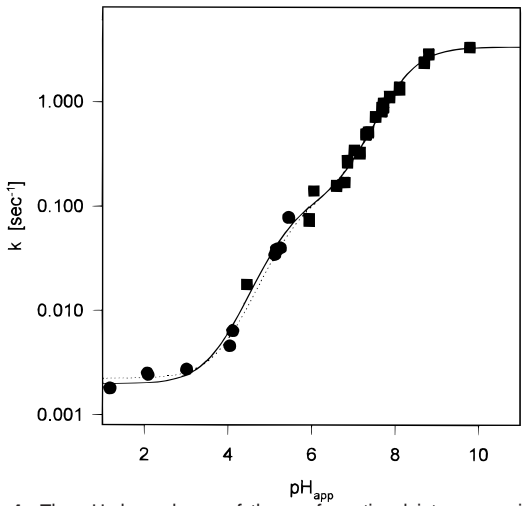

Figure 4—The pH dependence of the conformational interconversion rate constant *k*; the logarithmic scale is used to highlight the two-step behavior. Filled circles are results of spectrophotometric experiments, and squares are stopped-flow data. Fitting by method 1 (all parameters in eq 8 are allowed to vary) produced the solid line, a very similar result (dotted line) is obtained by method 2, where explicit use is made of the cyclic equilibrium condition, thus reducing the number of free parameters. Parameter values are reported in Table 1. The interconversion rate increases about 1000-fold for the unprotonated with respect to the protonated form of PNU-156804.

Table 1—Estimates of Kinetic Parameters from pH Dependence of Interconversion Rate

method[a]	k_1 [s^{-1}]	k_{-1} [s^{-1}]	k_2 [10^{-4} s^{-1}]	k_{-2} [10^{-3} s^{-1}]	pK_α	pK_β
1	3.3	0.1	5	1.5	8.23 ± 0.03	5.4 ± 0.2
2	3.26 ± 0.08	0.11 ± 0.02	1.3 ± 1.1	2.1 ± 1.6	8.23 ± 0.03	(5.5)

[a] Method 1 is nonlinear regression with eq 8 and 6 free parameters; method 2 makes explicit use of the cyclic equilibrium condition to reduce the free parameters to 5. In this latter case, pK_β is derived from the other 5 parameters according to eq 1.

6.7 according to eq 2 is significantly lower than the experimental value (7.2).

NMR Studies—The ^{1}H NMR spectra of PNU-156804, HCl salt, dissolved in $CDCl_3$ or in CD_3CN reveal the presence of only one conformer, which is β according to the notation just presented. Signals of the two conformers are well resolved in solvent mixtures containing H_2O or D_2O at low pH, such as CD_3CN/D_2O (1/1, pH 1.1), where conformer α and β coexist at about 2/1 ratio. This result is at variance with HPLC data (α/β ratio = 3/1). The higher concentration (~ 0.15 mg/mL) used in NMR work is not the cause of the observed discrepancy because no change of the conformer ratio was detected upon dilution of the NMR sample up to 8-fold. Most likely, the NMR data gave a correct measurement of the unperturbed conformer equilibrium in the 1/1 water/acetonitrile mixture, which is not the case of the HPLC data.

Rapid exchange of NH protons with water protons completely excludes (in D_2O) or greatly reduces (in H_2O) the detection of the corresponding signals and NOESY cross-peaks, which are of great structural significance. Fortunately, the $CH_3SO_3^-$ salt of PNU-156804 in $CDCl_3$ solution is found as a mixture of conformers (α/β = 1/2) in the presence of about 30% molar excess CH_3SO_3 H (see ^{1}H NMR spectrum in Figure 5), where a detailed structural identification of the two conformers is possible. Correspondence of conformers in different solvents is based on chemical shifts: CH_2-1′ protons resonate at 2.0−2.1 ppm in the α-conformer and at 2.6−3.0 ppm in the β-conformer and are highly diagnostic to this purpose. Other protons of the molecule display a definite chemical shift pattern: H-1″, OCH_2, H-4b, and the phenyl group (more deshielded in the α-conformer) or H-3c and NH-1c (more deshielded in the β-conformer). The NOESY data point out that the two conformers mainly differ for the C-2b−C-1″ torsion angle value and are thus rotamers; this angle is close to 0° for the β-rotamer and close to 180° for the α-rotamer (see Figure 6). Conformer α coincides with the reported crystal structure of a prodigiosin analogue[7] containing a sulfur atom in place of nitrogen at ring A (Figure 1). In this case, a hydrogen bond between the protonated nitrogen of the pyrromethene group and the exocyclic oxygen is apparently stabilizing the 180° rotamer. This result agrees

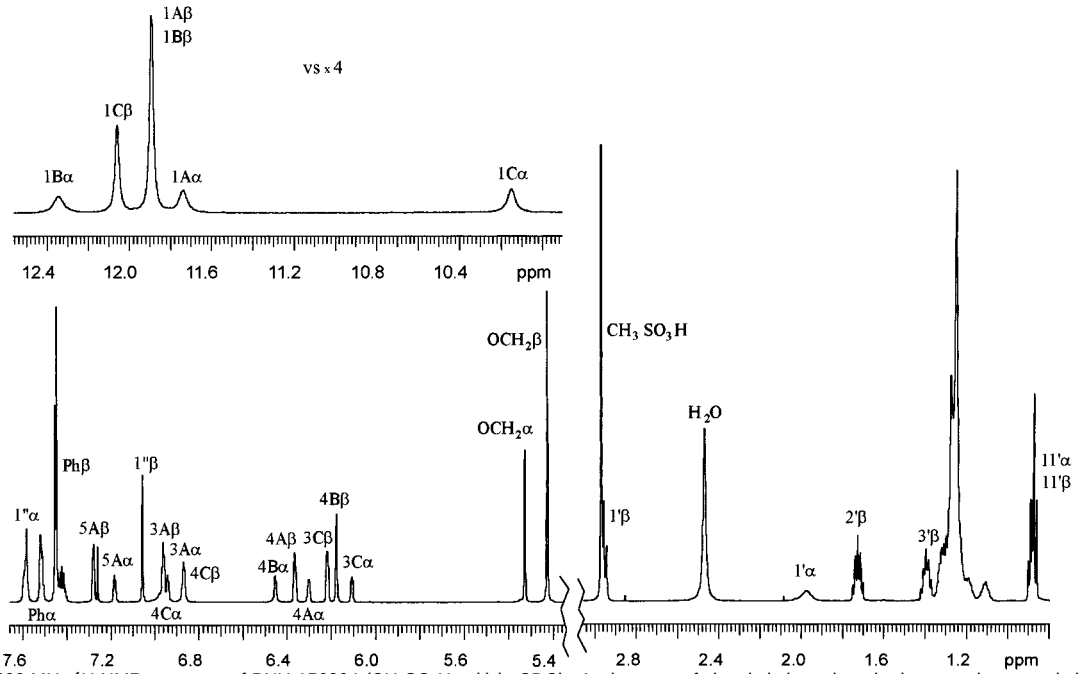

Figure 5—The 600 MHz ^{1}H NMR spectrum of PNU-156804 (CH_3SO_3H salt) in $CDCl_3$. Assignment of signals is based on the homonuclear correlation experiments TOCSY and NOESY. For proton numbering, see at Figure 1. Resonances of each pyrrole ring are recognized in the TOCSY spectrum from the different number of protons in each spin system (4, 2, and 3, respectively) and signal assignment is based on NOE effects with adjacent protons as detected in the NOESY spectrum (e.g., NH-1a/H-5a or CH_2-1′/H-3c).

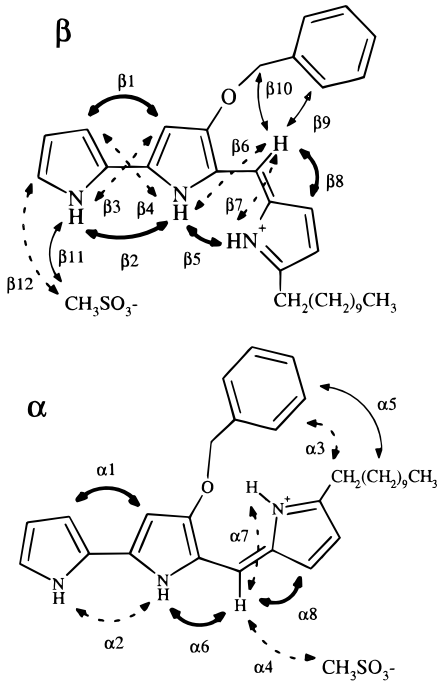

Figure 6—Structure of the α- and *β*-conformers as deduced from NOESY data on PNU-156804 in $CDCl_3$. The significant NOESY cross-peaks are indicated here with double arrows according to the following intensity-related code: heavy lines, strong, thin lines, moderate; and dashed lines, weak. Cross-peak *β*2 is not detected in this spectrum because of NH1a and NH1b signal overlapping. This NOE is detected in the NOESY spectrum of PNU-156804 (HCl salt) dissolved in $CDCl_3$, where only the *β*-conformer is present.

with the predominance of α-conformer at low pH values, as already observed.

Hindered rotation around (C-2a−C-5b) or (C-1″−C-5c) bonds can be excluded as a source of conformational diversity: the same nuclear Overhauser effects (NOEs) are detected for the two conformers in that part of the molecule (cross-peaks corresponding to *β*3 and *β*4 are not detected in the α-conformer because these NOEs are very weak and α is the minor isomer) and suggest a torsion angle close to 0° for both (C-2a−C-5b) and (C-1″−C-5c) bonds. This suggestion is consistent with the X-ray structure of the aforementioned prodigiosin analogue.[7] The most indicative NOEs that distiguish and characterize the two conformers are those labeled α6 (also present in *β* but very weak), α3 and α5 for the α-conformer, and *β*5, *β*9, and *β*10 for the *β*-conformer. The presence of NOEs between the methyl group of the methansulfonate and protons of the molecule (α4, *β*11, and *β*12) is probably due to ion-pairing with formation of hydrogen bonds between the counterion oxygens and NH protons. Chemical shift variation of CH_2-1′ in the two conformers (α, 1.98 ppm; *β*, 2.96 ppm) are simply rationalized in terms of a different C-2b−C-1" torsion angle value: when these protons are oriented toward the phenyl group (conformer α), its shielding cone causes an upfield shift. This interpretation is confimed by the ^{1}H NMR spectrum of PNU-156737 (the natural undecyl-prodigiosin that bears a methoxy group in place of the benzyloxy of PNU-156804, see at Figure 1), which shows no such chemical shift difference between the two conformers (α, 2.77 ppm; *β*, 2.86 ppm) as obtained in $CDCl_3$ solution in the presence of an excess CF_3COOH. Chemical shift changes of NH-1c (α, 10.15 ppm; *β*, 11.89 ppm) and H-1″ (α, 7.59 ppm; *β*, 7.06 ppm) must have a different origin because these are equally well observed for PNU-156737.

Conclusions

The conformational model of Figure 6 satisfactorily explains the results of the present investigation: the two geometrical isomers differ for the polar head structure (the conjugated system is expanded in α and compact in *β*) and for the solvent exposed hydrophobic surface (reduced in the α-conformer by the contact between phenyl and alkyl chain). This result explains the chromatographic separation on a reversed-phase HPLC column. In turn, this result is experimentally feasible only at low pH, where the interconversion rate of the two conformers is comparable or slower than analysis time. In 1/1 water/acetonitrile as solvent, the measured interconversion half-life is about 5 min for the protonated form, but this rate is probably slower in the HPLC mobile phase, which contains less water. Thus, the reasonably good quantitation of the two conformers by HPLC is understandable.

Both the rate of interconversion and the equilibrium distribution of the two conformers are greatly affected by nitrogen protonation. This influence can be attributed to hydrogen bonding between the protonated nitrogen and the exocyclic oxygen, as found in the crystal of a prodigiosin analogue,[7] but a general redistribution of the electron density in the system of three conjugated pyrrole rings after protonation may also play a role. In particular, our data indicate an increase of the rotational energy barrier around C-2b−C-1″ bond in the protonated form and the consequent freezing of the conformational equilibrium. On the basis of a rate-on comparison (k_1 and k_2), if we assume identical preexponential factor, a difference of 25 kJ/mol is estimated, which may be attributed to a strong hydrogen bond.

The different pK_a values of the two conformers, which drive the shift of the equilibrium position from preferred α-form at low pH to almost pure *β*-form at high pH (see eq 1), indicate that the α-conformer is much more easily protonated than the *β*-conformer. This observation is in keeping with the aforementioned extra hydrogen bond in the protonated α-rotamer. However, a clear intepretation of the observed experimental properties must clearly await a detailed theoretical study of the electronic properties of the 2,2′-bipyrrolyl−pyrromethene moiety, which appears well motivated by the important pharmacological effect of this group. In fact, the very limited conformational energy difference in play (few kilocalories, as inferred by the equilibrium constant values) suggests the possibility that equilibrium freezing may occur at the (yet unknown) biological receptor in either the pure α- or the pure *β*-form. In this regard, most intriguing is the analogy with the case of immunophilins, which are enzymes capable of catalyzing cis−trans amide bond isomerization in peptidyl-proline sequences[8] and are the primary target of the well-known immunosuppressant drugs cyclosporin A (cyclophilin) and FK506 (FK binding protein).

Abstract □ The reaction of ascorbate with recombinant hemoglobin (rHb1.1) in the presence of differing partial pressures of oxygen was studied. In the presence of 15 000 ppm (1.5%) residual oxygen, ascorbate/oxygen-mediated reactions resulted in an increased rate of autoxidation, modification of the β-globin, increased oxygen affinity and decreased maximum Hill coefficient. One of the observed modifications to the β-globin was a 72 Da addition to its N-terminus. Detailed characterization indicates the modification was an imidazolidinone type structure. Thorough deoxygenation of the hemoglobin solution to <150 ppm of oxygen prior to addition of ascorbate was required to prevent these modifications. Addition of ascorbate to the deoxy hemoglobin (deoxyHb) at pH 8 induced aggregation, eventually leading to precipitation. No such precipitation was observed at pH 7. Long-term storage of the hemoglobin was carried out by addition of ascorbate to deoxyHb at pH 7. The level of methemoglobin remained at <2% for up to 1 year at 4 °C, with no detectable precipitation of the protein. Modifications similar to those observed by the acute studies were observed over the 1-year period and correlated with disappearance of the added ascorbate.

Introduction

Recombinant human hemoglobin (rHb1.1) is a pseudo-tetramer composed of two β-globins and genetically fused α-globins (di-α-globin). Each of the four subunits contains a heme prosthetic group. The Presbyterian mutation in the β-globin (Asn-108β→Lys) was introduced to decrease the oxygen affinity. Genetic fusion of the two α-globins prevents dissociation of the hemoglobin into αβ-dimers,[1] such that rHb1.1 can be used as an oxygen-carrying therapeutic. The ability to package and store this type of product as a ready-to-use large volume parenteral (LVP) liquid has many potential advantages during situations such as trauma and surgery when use of frozen formulations would not be as practical.

One of the major obstacles to long-term storage of hemoglobin is its propensity to autooxidize. Upon binding oxygen, the reduced form of the heme iron (ferrous, Fe^{2+}) can react with the oxygen to form ferric (Fe^{3+}) iron and superoxide:[2−4]

$$HbFe^{2+} + O_2 \leftrightarrow HbFe^{2+} - O_2 \rightarrow HbFe^{3+} + O_2^-$$

When the iron in heme is oxidized to the ferric form, oxygen can no longer bind to the heme iron and the hemoglobin is nonfunctional. Oxidation of the heme also leads to an approximately 1000-fold increase in the rate of heme loss,[5] which can result in denaturation and precipitation of the globin.[6] The activated oxygen species produced during the autoxidation reaction can damage the hemoglobin causing polymerization,[7,8] oxidation of the amino acid side chains,[9] and hemichrome formation.[10,11] These modifications can lead to changes in the tertiary and quaternary structure, resulting in decreased oxygen equilibrium binding parameters and eventually precipitation of the protein. In contrast, ferrous deoxy hemoglobin (deoxyHb) does not undergo autoxidation and is known to be intrinsically more stable than oxy hemoglobin (oxyHb) against thermal and chemical denaturation and precipitation of the protein.[12−14]

The nonenzymatic reduction of methemoglobin (metHb) has been achieved using reducing agents such as dithionite and ascorbate. In solution under deoxy conditions, dithionite ($S_2O_4^{2-}$) dissociates into $2SO_2^{\bullet-}$,[15] which can quickly react with MetHb, reducing it back to the ferrous form.[16,17] The byproduct of the reaction, bisulfite (HSO_3^-), can generate severe or fatal adverse reactions in humans,[18] making it unsuitable as a component of a LVP formulation. Ascorbate has been known since the 1940s to reduce deoxygenated metHb to the ferrous form[19,20] and can safely be given intravenously.[18] The literature indicates that ascorbate reduces metHb by first ionizing to the anionic form, ascorbate^{2-}, which reacts with the ferric iron to form ferrous hemoglobin and the anionic ascorbate radical, which eventually rearranges to form dehydroascorbate.[21]

To overcome the problems associated with storage of oxyHb solutions, we examined methods to store deoxygenated hemoglobin solutions at 4 °C. Ascorbate was added to reduce residual methemoglobin to the more stable ferrous form. Here we present studies that determined the effects of pH, oxygen tension, and ascorbate levels on rHb1.1 stability.

Materials and Methods

Materials—Recombinant hemoglobin (rHb1.1) was produced at Somatogen as previously described.[1] Ascorbic acid (sodium salt), sodium phosphate (monosodium and disodium salts), sodium chloride, ethylenediaminetetraacetic acid (EDTA, disodium salt), (*N*-[2-hydroxyethyl]piperazine-*N*′-[2-ethanesulfonic acid]) (HEPES), potassium cyanide, and tris(hydroxymethyl)aminomethane (Tris hydrochloride and sodium salt) were all purchased from Sigma Chemical Company (St. Louis, MO). Polysorbate 80 was purchased from either Calbiochem Corporation (San Diego, CA) or ICN Chemicals (Los Angeles, CA). Glass vials and gray butyl

rubber stoppers were purchased from Wheaton Corporation (Charlotte, NC). Stedim-5 bags were purchased from Stedim Corporation (Pleasant Hill, CA), aluminum foil overwraps were purchased from Kegan Corporation (Auburn, IN), and ZPT 100 "Ageless" oxygen scavengers were purchased from Mitubiabi Gas and Chemical Company (Japan).

Methods—*Dynamic Light Scattering*— Dynamic light scattering (DLS) was performed using a Nicomp 370 Submicron Particle Sizer equipped with a 40mW HeNe laser. Data were collected and averaged over 10 min and analyzed using the C370 v.12 software program provided by PSS (Particle Sizing Systems, Santa Barbara, CA).

Equilibrium Oxygen Binding—The parameters P_{50} and n_{max} were determined using a hemox analyzer as previously described[22] at 37 °C and pH 7.40 in 50 mM HEPES (free acid) and 150 mM NaCl.

Methemoglobin Concentration—Percent metHb was measured by determining the fractions of reduced and oxidized hemes using difference spectroscopy as described by Kerwin et al.[43]

Ascorbic Acid Analysis—Ascorbic acid analyses were performed by diluting samples 1:1 into 10 mM homocysteine (sparged with helium) to stabilize the ascorbate. The diluted samples were centrifuged in Centricon-30 microconcentrators (Amicon Inc., Beverly, MA), and the filtrate was analyzed by size exclusion chromatography (SEC) on a TosoHaas G2500W_{XL} (7.6 × 300 mm) column using an isocratic elution with 5 mM KH_2PO_4, pH 3, as the mobile phase. Flow rate was 1 mL/min. Analyte peaks were detected at 255 nm, and their concentration was determined by comparison with standards of known concentration.

Reversed-Phase HPLC (RP-HPLC)—Samples were prepared by precipitation with ice-cold acid/acetone[23] and solubilization of the pellet in 0.1% trifluoroacetic acid (TFA)/20% acetonitrile. The RP-HPLC analyses were performed using a Zorbax C3 analytical column (0.46 × 25 cm) mounted on an HP1090 HPLC system (Hewlett-Packard, Wilmington, DE). The oven temperature was maintained at 40 °C. Solvent A was 0.1% TFA in water and solvent B was 0.1% TFA in acetonitrile. The flow rate was 1 mL/min. The column was equilibrated in 65% solvent A/35% solvent B. Following sample injection, the column was maintained at the starting conditions for 5 min then ramped to 51% solvent A/49% solvent B over a period of 45 min.

Size Exclusion Chromatography—The molecular weight distribution of the hemoglobin was monitored by high-performance SEC (HPSEC) as described by Kerwin et al.[43]

Liquid Chromatography-Mass Spectrometry (LC-MS)—Mass spectrometry was performed using a Finnigan Mat LCQ as the end detector with an HP1090 HPLC on the front end to run reversed-phase separation. Analysis by MS/MS was performed as previously described by Lippincott et al.[24]

Tryptic Mapping—Tryptic mapping was performed as previously described by Lippincott et al.[24]

Sodium Dodecyl Sulfate Polyacrylamide Gel Electrophoresis (SDS-PAGE)—SDS-PAGE was performed based on the method of Laemmli.[25] Aliquots (5 μg) were diluted with 2 volumes of SDS sample buffer (Novex Corp., San Diego, CA) containing 0.1 M dithiothreitol (DTT) and heated at 65 °C for 5 min. Samples were electrophoresed on an 8−16% polyacrylamide gradient Tris-glycine gel for 2.5 h at 120 V. The gel was stained with Coomassie blue and then destained with a solution of 40% methanol, 10% glacial acetic acid, and 50% water. Destained gels were digitized using an IS-1000 digital imaging system (Alpha Innotech Corp., San Leandro, CA).

Pepsin Mapping of Multimeric rHb1.1—The multimeric fraction of rHb1.1 was isolated using SEC as previously described. The globins were precipitated with 20 volumes of cold 0.6% HCl in acetone, solubilized in 0.1% TFA, and separated by C3 RP-HPLC as previously described. Fractions containing β-globin and di-β-globin were collected, lyophilized, then resuspended in 8 M urea. Following resuspension, the samples were heated for 10 min at 60 °C, then diluted with 0.1% TFA to a final urea concentration of 2 M. The final globin concentration was 1 mg/mL. Pepsin (Pierce, Rockford, IL) was added to the sample at an enzyme: substrate ratio of 1:50 (w/w). After 2 h, the peptides were separated by RP-HPLC using a C18 column (Zorbax SB-300, 0.46 × 25 cm) on an HP1090 HPLC. Solvent A was 0.1% TFA(v/v) in water and solvent B was 0.1% TFA (v/v) in acetonitrile. The column was equilibrated in 5% solvent B at 1 mL/min. Following injection, the starting conditions were maintained for 5 min. The gradient was then developed by increasing to 70% solvent B over a period of 70 min. The absorbance was monitored at 215 nm.

Preparation of rHb1.1 Solutions Equilibrated with Headspace Oxygen Concentrations of 15 000 or 150 ppm—For oxygen and ascorbate modification experiments, solutions of rHb1.1 (50 mg/mL in 150 mM sodium chloride, 5 mM sodium phosphate, pH 7.2) were equilibrated with either a gas mixture of 15 000 ppm oxygen in nitrogen or purified nitrogen containing <10 ppm of oxygen. Equilibration was achieved by passing the gas mixture through water for humidification then over the hemoglobin solution, which was mixed using a Rotovap (Brinkman Instruments). The equilibration procedure was typically performed for 4−6 h, and the hemoglobin solution was maintained at ~10 °C in an ice-water bath. Following equilibration, the flask containing the hemoglobin solution was capped and transferred into a glovebag (Aldrich Chemical Company, Milwaukee, WI) along with all necessary equipment and solutions. The bag was sealed and equilibrated with either the gas mixture containing 15 000 ppm of oxygen or the mixture containing <10 ppm of oxygen. The oxygen content in the bag equilibrated with the <10 ppm oxygen mixture measured at 150 ppm of oxygen when monitored with a Mocon HS-750 analyzer (Modern Controls Inc.). Ascorbate (0.5 M in deoxygenated water) was added to aliquots of the hemoglobin solution to give final concentrations of 0.5, 1, 2, and 5 mM. Solutions were filtered through 0.2-μm syringe filters. Aliquots (0.5 mL) were transferred into 2-mL Wheaton glass vials, capped with gray butyl rubber stoppers, and sealed with crimp rings. All solutions were incubated at 4 °C. For pH-induced aggregation studies, hemoglobin solutions were diafiltered into buffer (150 mM sodium chloride, 5 mM sodium phosphate) at pH 7 or pH 8 at 4 °C. Solutions were equilibrated with nitrogen containing <10 ppm oxygen, reduced with 2 mM ascorbate, filtered through a 0.2-μm filter, and aliquoted into 2-mL glass vials as already described. The oxygen tension in the glovebag was maintained at ≪200 ppm oxygen.

Shaking-Induced Aggregation Studies—All manipulations of material were done in a nitrogen flushed glovebag (Aldrich) kept at <300 ppm of oxygen. Tween 80 was added to aliquots of deoxy-rHb1.1 (80 mg/mL in 150 mM sodium chloride, 5 mM sodium phosphate, pH 7.2, and <5 μM EDTA) to approximate final concentrations of 0, 0.025, 0.05, 0.075, and 0.1% (w/v). The solutions were then realiquoted (1.5 mL) into 3.5-mL Wheaton vials and sealed with gray butyl rubber stoppers, and the Tween 80 concentrations were measured as described below. The final Tween 80 concentrations were 0, 0.019, 0.045, 0.071, and 0.095%. All prepared samples were used within 1week of preparation. The deoxyHb aliquots (1.5 mL) were placed on their sides on a Hoeffer rotary shaker and shaken at either 100, 170, or 225 rpm for 1 h at room temperature. The samples were then assayed for protein aggregation by light obscuration.

Measurements of Protein Aggregates by Light Obscuration—Aggregates ≥2 μm were measured using a HIAC/Royco light particle counter equipped with a HIAC HRLD400HC sensor and a model 3000A sampler. Data were corrected for background counts and reported as the average from separate samples.

Measurement of Tween 80 Concentration in Hemoglobin Solutions—Samples were analyzed for Tween 80 in the following fashion: To a 1-mL aliquot of sample in a 15-mL polypropylene Falcon tube was added 1 mL of 6 M guanidine hydrochloride and 4 mL of dichloromethane. The mixture was then vortexed for 1 min to form a thick emulsion. The emulsion was separated by centrifugation at 4000 rpm for 20 min. The lower organic layer was isolated and placed into a clean 15-mL polypropylene Falcon tube. To that organic layer was added 1 mL of a cobalt ammonium thiocyanate test solution (250 g of ammonium thiocyanate, 110 g of cobalt nitrate, and 200 g of sodium chloride in 1 L of purified water). The mixture was then vortexed for 30 s and allowed to separate. The organic layer was then analyzed spectrophotometrically at 320 nm. The concentration of Tween 80 in the original sample, which is proportional to the absorption at 320 nm, was then calculated from a standard curve of know Tween 80 concentrations.

Preparation of deoxyrHb1.1 Solutions for Long-Term Stability Studies in Vials—Recombinant hemoglobin from our manufacturing plant (~50 mg/mL), in 150 mM sodium chloride, 5 mM sodium phosphate (pH 6.8−7.2), ~0.03% polysorbate 80, and <5 μM EDTA, was deoxygenated by stripping the oxyHb solution with nitrogen gas. Following deoxygenation, the hemoglobin was

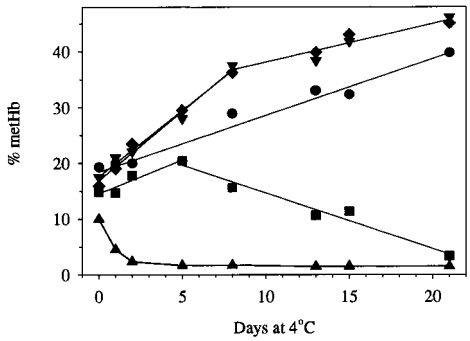

Figure 1—MetHb formation of rHb1.1-containing ascorbate in solution and equilibrated with 15 000 ppm of oxygen in the headspace. Recombinant hemoglobin (rHb1.1) was equilibrated with 15 000 ppm of oxygen and reacted with increasing concentrations of ascorbate. Symbols represent the following ascorbate concentrations in each sample: (circles) 0 mM ascorbate; (octagons) 0.5 mM ascorbate; (diamonds) 1 mM ascorbate; (squares) 2 mM ascorbate; (triangles) 5 mM ascorbate. Data from samples containing 0, 0.5, 1, and 2 mM ascorbate were fit using linear regression to generate rates of metHb formation.

concentrated to 80 mg/mL and ascorbate was added to a final concentration of 2 mM. The solution was then packaged into the glass vials as already described and incubated at 4 °C for up to 1 year.

Preparation of DeoxyrHb1.1 Solutions for Long-Term Stability Studies in Bags—Recombinant hemoglobin from our manufacturing plant (<50 mg/mL), in 150 mM sodium chloride, 5 mM sodium phosphate (pH 6.9−7.1), ~0.03% polysorbate 80, and <5 μM EDTA, was deoxygenated by stripping the oxyHb solution with nitrogen gas. Following deoxygenation, the hemoglobin was concentrated to 80 mg/mL and ascorbate was added to a final concentration of 2 mM. The solution was transferred to a nitrogen-purged glovebox and packaged as 30-mL aliquots in 60-mL flexible Stedim-5 containers then overwrapped with aluminum foil pouches. ZPT 100 "Ageless" oxygen scavengers were placed between the foil overwrap and the flexible containers prior to heat sealing the overwrap containers. The foil pouches were heat sealed and incubated at 4 °C for up to 1 year.

Results

Acute Studies—*Effects of Ascorbate and Oxygen Concentrations on Methemoglobin Formation*—The ability of ascorbate to reduce recombinant methemoglobin (met-rHb) in the presence of differing partial pressures of oxygen in the vial headspace was studied. Equilibration of the rHb solution with a gas mixture containing 15 000 ppm oxygen caused an increase in the rate of met-rHb formation above that observed for recombinant oxyhemoglobin (oxy-rHb) of 1% per day versus 0.7% per day, respectively (see Figure 1, oxy-rHb data not shown). Addition of ascorbate to 0.5 and 1 mM produced a two-stage autoxidation profile with an initial autoxidation rate of 2.4% per day through 8 days of storage, followed by a slower rate of 0.7% per day. Increasing the ascorbate concentration to 2 mM decreased the autoxidation rate to ~1.1% per day for the first 5 days, followed by a reduction in the met-rHb content at a rate of 1% per day for the remainder of the study period (15 days). In contrast, the hemoglobin solution containing 5 mM ascorbate demonstrated no overall increase in the level of met-rHb and showed a complete reduction by approximately 2 days following addition of the ascorbate. Hemoglobin equilibrated with 150 ppm of oxygen in the headspace oxidized at the rate of approximately 0.2% per day (see Figure 2). Addition of ascorbate (0.5−5 mM) decreased the concentration of met-rHb. The rate of reduction was dependent upon the concentration of ascorbate.

Effects of Ascorbate and Oxygen Concentrations on P_{50} and n_{max}—Recombinant hemoglobin typically has a P_{50} of

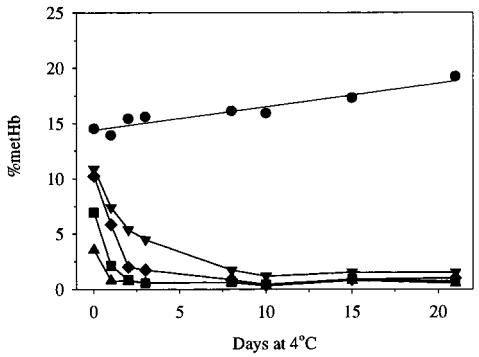

Figure 2—MetHb formation of rHb1.1-containing ascorbate in solution and equilibrated with 150 ppm of oxygen in the headspace. Recombinant hemoglobin (rHb1.1) was equilibrated with 150 ppm of oxygen and reacted with increasing concentrations of ascorbate. Symbols are the same as in Figure 1. The data for the sample containing 0 mM ascorbate were fit by linear regression to generate the rate of metHb formation.

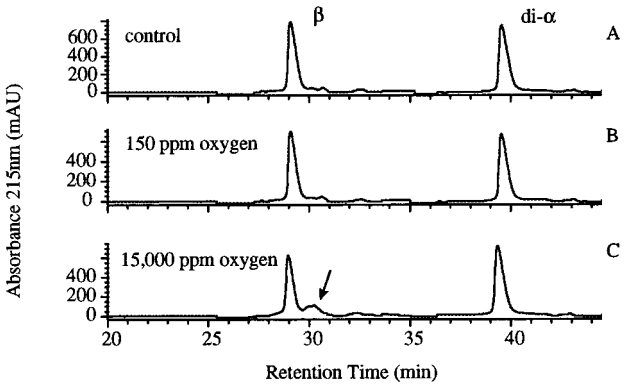

Figure 3—Reversed phase HPLC analysis of hemoglobin after incubation with 5 mM ascorbate at differing partial pressures of oxygen. Samples were the same as in Figure 1 and were analyzed following 15–16 days of storage at 4 °C. The control hemoglobin represents a sample of rHb incubated with 15 000 ppm of oxygen and 0 mM ascorbate. The arrow indicates the difference peak of the β-globin shoulder containing the M+72 addition.

32 mmHg and an n_{max} coefficient of 2.3. By 21 days, the hemoglobin sample equilibrated with 15 000 ppm of oxygen and containing 5 mM ascorbate demonstrated a P_{50} of 37.3 mmHg and an n_{max} coefficient of 1.5. The hemoglobin equilibrated with 150 ppm of oxygen and 5 mM ascorbate demonstrated a P_{50} of 33.8 mmHg and an n_{max} coefficient of 2.11 at 21 days.

Characterization of Ascorbate-Mediated Modification of Hemoglobin—Reversed-phase HPLC was used to evaluate potential ascorbate-mediated modifications of the globins. The sample equilibrated with 15 000 ppm oxygen and containing 5 mM ascorbate showed a decrease in the height of the β-globin peak compared with the control along with the appearance of an increased area on the trailing shoulder of the β-globin peak (Figure 3). In contrast, the chromatographic profile of the sample equilibrated with 150 ppm oxygen and containing 5 mM ascorbate was not significantly different from a control sample with no added ascorbate. The sample equilibrated with 15 000 ppm oxygen and 5 mM ascorbate was further analyzed by LC-MS. The analyses of the shoulders on the β-globin peak revealed the presence of three significant β-globin adducts with mass additions of 16, 42, and 72 Da. With the exception of the 42 Da mass gain on the β-globin, these mass additions were not observed in the hemoglobin solution prior to addition of the ascorbate. Tryptic mapping of the starting hemoglobin revealed a small peak assigned to acetylation of the N-terminus of the β chain with a characteristic 42 Da mass gain. Additionally, using single ion chromatograms, we searched for modifications on

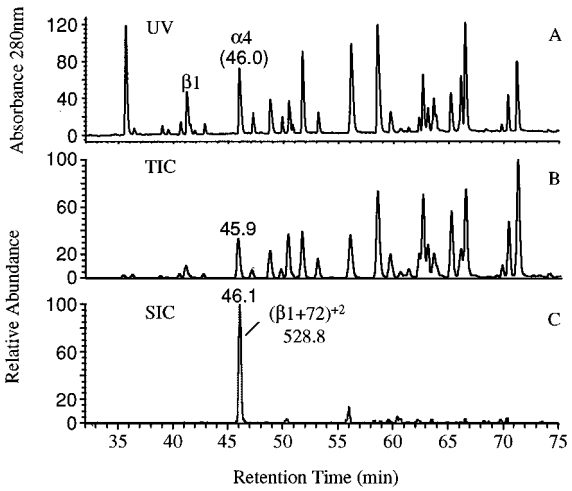

Figure 4—Tryptic map of ascorbate modified rHb1.1. Tryptic peptides of rHb1.1 incubated with 2 mM ascorbate were separated by C18 RP-HPLC and analyzed by mass spectrometry: panel A, UV trace at 280 nm; panel B, total ion chromatogram; panel C, specific ion chromatogram of the double-charged β1+72 ion.

tryptic peptides. Only one significant difference peak was found at 45 min; exhibiting a mass of 1055.4 amu and eluting as a trailing shoulder on the α4 peptide (see Figure 4). The peak was previously identified as the M+72 modification of the N-terminus of the β-globin affected by ascorbate and oxygen.[26] In agreement with the tryptic mapping, V8 mapping of this hemoglobin confirmed the existence of the M+72 at the N-terminus of the β-globin and did not show additional difference peaks.

The fraction containing the M+72 peptide from the tryptic map was isolated and infused into the LCQ mass spectrometer. The double-charged ion (528.8) was fragmented to elucidate the position and structure of the modification. MS/MS fragmenation spectra (see Figure 5) showed an unusual pattern of a neutral loss of 44 Da followed by an additional loss of 18 Da. These mass losses corresponded to mass gains of 28 and 10 Da on the unmodified peptide. The neutral loss of 44 and 18 Da is usually associated with decarboxylation and loss of water, respectively. The observed B ions, starting from B_2, showed gains of 10, 28, or 72 Da, confirming the presence of the modification within the first two residues. The series of Y ions was consistent with unmodified peptide, except the Y_7 and Y_8 ions. The Y_7+10 mapped a mass gain of 10 Da to His2 and the Y_8 ion mapped a mass gain of both 10 and 28 Da to the Met1 position. A mass gain corresponding to Y_7+28 was not found. The N-terminus was shown to be blocked to Edman sequencing.[26] Reduction with cyanoborohydride did not change either the elution position or the mass of the M+72 peptide. The data are consistent with an imidazolidinone structure for the modification.

Effects of pH on the Stability—The propensity of the deoxy-rHb in the presence of 2 mM ascorbate to aggregate and precipitate during 4 °C storage was studied at pH 7 and pH 8 by DLS. Comparison of the day 0 samples at pH 7 and pH 8 indicated that their size profiles are similar with no apparent aggregation (see Figure 6). Aggregates of ~100 and 500 nm were observed in the pH 8 sample after 2 weeks of incubation at 4 °C. Following an additional 2 weeks of storage, the size of the aggregates appeared to increase, and by 6 weeks a precipitate was visible in the bottoms of the vials. The pH 7 samples did not display any indications of aggregation or precipitation for up to 8 weeks of storage.

Effects of Tween 80 on Aggregation—The ability of Tween 80 to prevent protein aggregation of deoxy-rHb1.1 at a liquid surface interface was examined by shaking-induced aggregation. Samples not containing Tween 80 demonstrated an increase in the number of aggregates per milliliter at ≥2 μm with increasing shaking speed, resulting in an ~500-fold increase between 0 and 225 rpm (Figure 7A). Even greater increases were observed for aggregates ≥10 μm (Figure 7B) and ≥25 μm (Figure 7C), resulting in ~2000- and ~4000-fold increases, respectively. Addition of Tween 80 significantly decreased aggregation of the deoxyHb when shaken at speeds up to 170 rpm. At this speed, a slight increase in aggregates was observed compared with the 0 rpm sample, but no difference was seen between any of the Tween 80-containing solutions. Increasing the speed to 225 rpm produced a level of aggregation in the hemoglobin sample containing 0.019% Tween 80 similar to that observed without surfactant. In contrast, at 225 rpm, the samples containing 0.045−0.095% Tween 80 did not demonstrate an increase in aggregate levels above that observed for 170 rpm. Furthermore, these samples produced only an ~10-fold increase in counts for aggregates ≥2 μm (Figure 7A) and ≥10 μm (Figure 7B) and an ~5-fold increase for aggregates ≥25 μm (Figure 7C) compared with those observed prior to shaking.

Long-Term Storage in Vials—*Overall Stability of the Hemoglobin during Long-Term Incubation at 4 °C in Vials*—Based on the observations made during the acute stability studies, four sets of samples of rHb1.1 were prepared under deoxy conditions, defined as 150 ppm oxygen, followed by addition of 2.0 mM ascorbate. Polysorbate 80, 0.03%, was added to preclude aggregation of the protein during storage. The levels of ascorbate dropped steadily during the 12-month storage period from approximately 1.75 to 0.25 mM (see Figure 8, panel A). In accordance with the presence of ascorbate, the concentration of metHb remained at <2% (limit of quantitation) of the total protein during the course of the study (data not shown). Starting samples had a P_{50} value of approximately 32 mmHg and did not change for the first 6 months of storage (see Figure 8, panels B and C). Between 6 and 12 months, the P_{50} dropped slightly to 30 mmHg. The Hill Coefficient measured at n_{max} demonstrated a slight decrease between 0 and 6 months from an initial value of 2.2 to 2.0. A further change was observed at 12 months, with the n_{max} further decreasing to 1.8.

The propensity of the protein to aggregate during the incubation was measured by both SEC and DLS. We did not observe a change in the multimeric hemoglobin level (see Figure 8, panel D) or changes in the overall chromatographic HPSEC profile of the hemoglobin during the first 6 months of storage (data not shown). Between 6 and 9 months an increase in the level of multimer was observed which increased further between 9 and 12 months. Higher order aggregates (>2 μm) were not seen in the samples until 12 months incubation (see Figure 8, panel E). An initial apparent diameter of 6.2 nm was measured by DLS at the beginning of the study, with an apparent increase to 6.8 nm and the appearance of species with apparent diameters of 212, 240, and 306 nm at the end of 12 months. Precipitation was not observed on the vial walls during the study period (data not shown).

Characterization of the Multimeric Species—The multimer observed by SEC analysis was further characterized. Hemoglobin samples following 15 days and 1 year incubation at 4 °C were treated with 0.1 M DTT for 15 min and analyzed by SEC (Table 1). The DTT treatment of the 15-day sample resulted in reduction of 50% of the multimer, whereas only 25% of the multimer was reduced by DTT following a 1-year incubation. Prior to deoxygenation and addition of ascorbate, multimer present in the hemoglobin was completely reducible by DTT treatment (data not

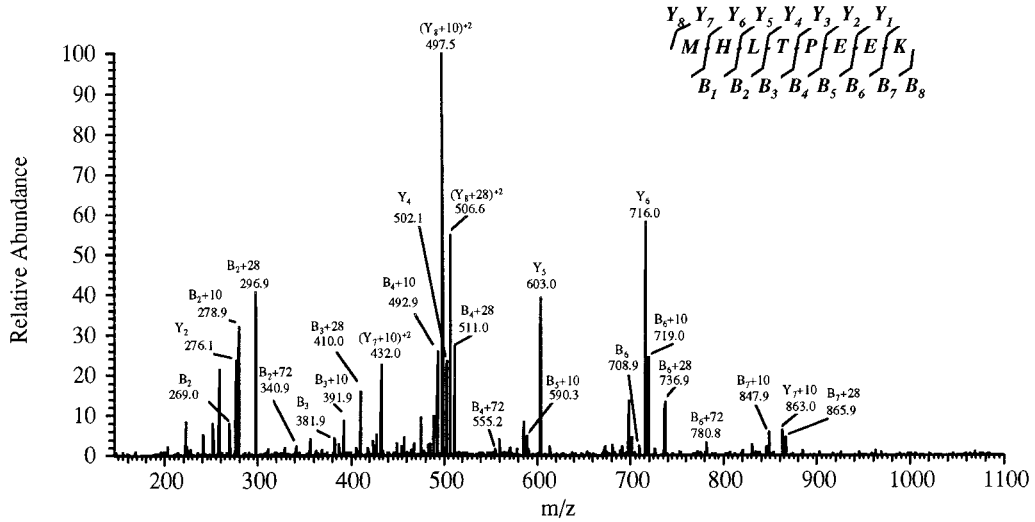

Figure 5—MS/MS fragmentation spectra of the M+72 difference peptide. The double-charged ion *m/z* 528.8 was chosen and fragmented. Due to the limits of the LCQ, the B_1 ion or its adducts were to small to detect. The B and Y ions were annotated according to the legend in the upper right of the figure.

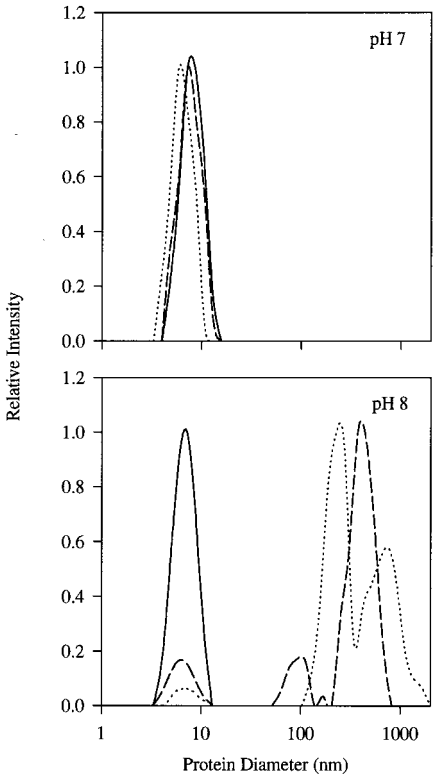

Figure 6—Dynamic light scattering analysis on the effect of pH during 4 °C storage: (solid line) starting material after equilibration at the indicated pH; (dashed line) after 4 °C incubation for 2 weeks; (dotted line) after 4 °C incubation for 4 weeks.

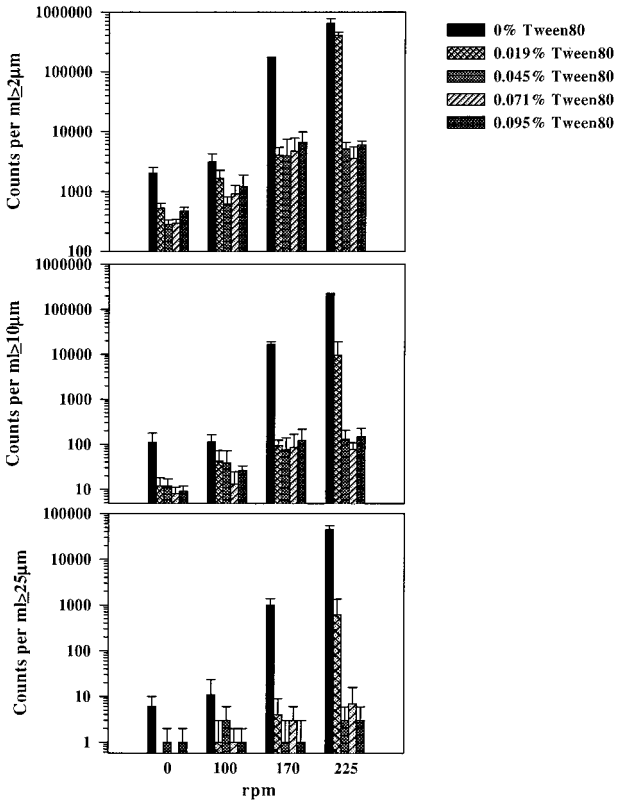

Figure 7—Effect of Tween 80 on protein aggregation of deoxy Optro during shaking in vials. Samples were prepared as described in *Materials and Methods* and shaken at the indicated speeds for 1 h at room temperature. Protein aggregation was measured using the Hiac/Royco particle counter. Triplicate vials were prepared for each Tween 80 concentration and analyzed separately. Values are reported as the average of values from the three vials ± standard deviation.

shown). Following treatment with DTT, the remaining multimer was isolated from the SEC column and analyzed by SDS-PAGE. As shown in Figure 9 (panel A), the isolated monomer peak only contained the β- and di-α-globin bands. A number of bands were present in the isolated non-DTT-reducible multimer peak with molecular weights ranging between 45 and 68 kDa. The origin of the cross-linked hemoglobins observed by SDS-PAGE was further investigated. Addition of ascorbate directly to oxyHb followed by overnight incubation at room temperature produced a cross-linking pattern similar to that observed for the 1-year samples (see Figure 9, panel B, lane 3). Saturation of the hemoglobin with carbon monoxide (lane 5) or deoxygenation (lane 8) prior to ascorbate addition prevented additional formation of the higher molecular weight bands. Addition of hydrogen peroxide to the CO-Hb sample (lane 6) produced a banding pattern similar to that observed with ascorbate and oxyHb. Deoxy-Hb incubated with ascorbate demonstrated a small increase in the intensity of the banding pattern over that seen in deoxyHb alone.

The DTT-reducible multimer was characterized by pepsin mapping. The SEC purified multimer from freshly prepared rHb1.1 was separated by C3 RP-HPLC and the

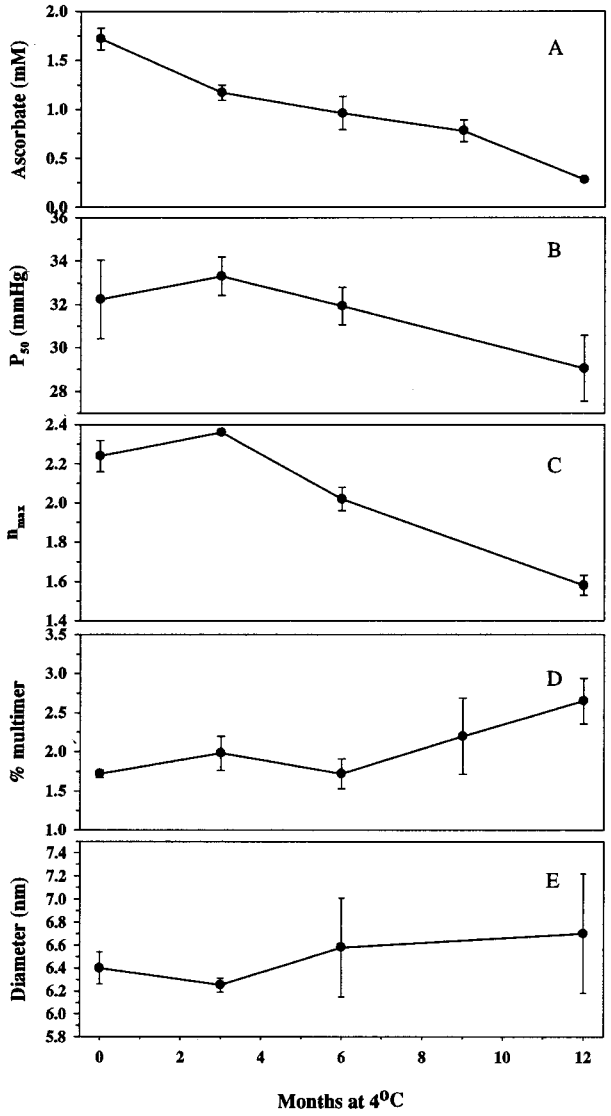

Figure 8—Change in ascorbate, P_{50}, n_{max}, percent multimer, and apparent diameter of samples of rHb during long-term storage in vials. All values are the average from four samples analyzed at the indicated time points. The value for ascorbate at 12 months is from a single sample. Data were analyzed for statistically relevant differences during the storage period using a one-way analysis of variance (ANOVA) and a Newman-Keuls post-hoc analysis. Panel A is the ascorbate concentration ($p < 0.05$ for 0 versus 3, 6, and 9 months; $p < 0.05$ for 3 versus 6 and 9 months; 6 and 9 months were not differerent). Panel B is the parameter P_{50} ($p < 0.05$ for 0, 3, and 6 versus 12 months; all others were not different). Panel C is the Hill coefficient, n_{max} ($p < 0.05$ for all samples versus each other). Panel D is the percent multimeric hemoglobin ($p < 0.05$ for 0, 3, 6, and 9 months versus 12 months). Panel E is the apparent diameter of the hemoglobin during incubation at 4 °C (samples were not statistically different from each other).

Table 1—Size Exclusion Chromatographic Analysis of Multimeric rHb Before and After Treatment with Dithiothreitol[a]

treatment	% multimer (–DTT)	% multimer (+DTT)	% change
15 days incubation at 4 °C	1.47	0.75	–50%
1 year incubation at 4 °C	2.84	2.05	–25%

[a] Analysis were performed on single samples.

β globin and di-β-globin were isolated and cleaved with pepsin. The pepsin-generated peptides were separated by C18 RP-HPLC, and a single difference peak in the di-β-globin map was found (see Figure 10, panel B). The same pepsin digest was incubated at pH 8.0 with 0.1 M DTT and

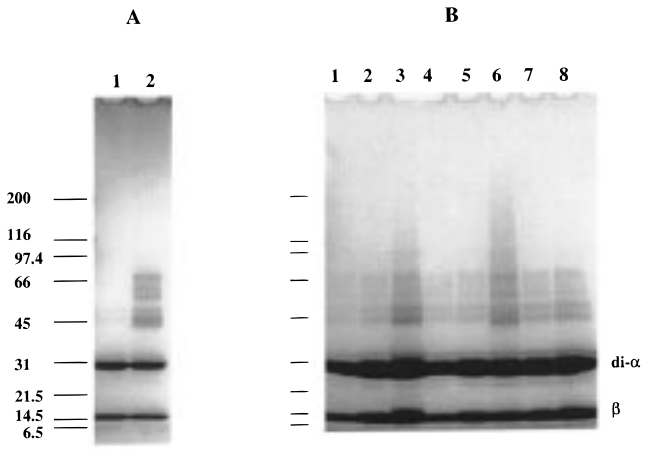

Figure 9—SDS–PAGE analysis of isolated monomer and multimer and reactions of rHb1.1 with ascorbate. Panel A: Hemoglobin (rHb1.1), incubated with 2 mM ascorbate for 1 year at 4 °C under reduced oxygen tension was reduced with DTT, and the nonreducible multimer was separated from the monomer by SEC and isolated: lane 1, isolated monomer; lane 2, isolated multimer. Panel B: Hemoglobin (rHb1.1) at 75 mg/mL, prepared as oxy, carbonmonoxy, or deoxy, was incubated overnight at room temperature with 2 mM ascorbate and then precipitated with acid acetone and resuspended in reducing buffer and analyzed: lane 1, rHb1.1 control; lane 2, oxy-rHb1.1 at room temperature overnight; lane 3, oxy-rHb1.1 + ascorbate; lane 4, CO-rHb1.1 at room temperature overnight; lane 5, CO-rHb1.1 + ascorbate; lane 6, CO-rHb1.1 + 4 mM hydrogen peroxide; lane 7, deoxy-rHb1.1 at room temperature; lane 8, deoxy-rHb1.1 + ascorbate.

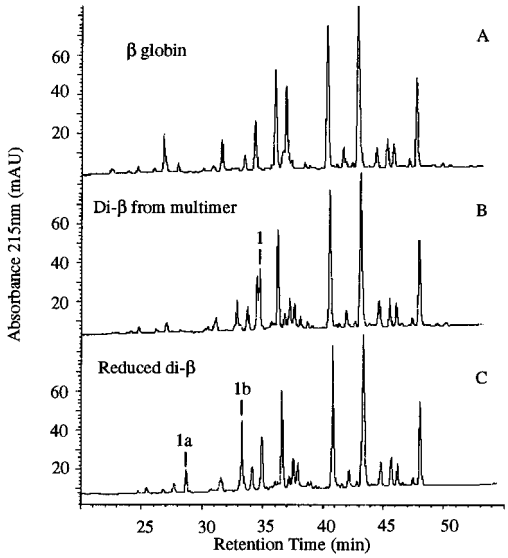

Figure 10—Pepsin maps of DTT-reducible cross-linked β-globin. Multimeric rHb1.1 was isolated by SEC and further separated by C3 RP-HPLC: panel A, pepsin-treated β globin isolated from RP-HPLC; panel B, pepsin-treated cross-linked β-globin from RP-HPLC (arrow denotes the difference peptide); panel C, isolated difference peptide from B after reduction with DTT.

rechromatographed. Two new difference peptides were generated, the first eluting at 28.7 min (1a, Panel C) and the second eluting at 32.6 min (1b, Panel C). Sequencing of the isolated peptides by Edman degradation identified the first peptide as β89−102 and the second as β86−102. Both of these peptides contain cysteine at position 93, suggesting the hemoglobin was cross-linked through Cys93 of the β-globins from separate monomeric hemoglobins.

Characterization of Globin Modification During One Year Incubation at 4 °C in vials—Modification of the hemoglobin primary structure was further examined by RP-HPLC analysis and in-line mass spectrometry (RP/LC-MS) to detect potential storage induced modification of the protein primary structure. Comparison of the control hemoglobin

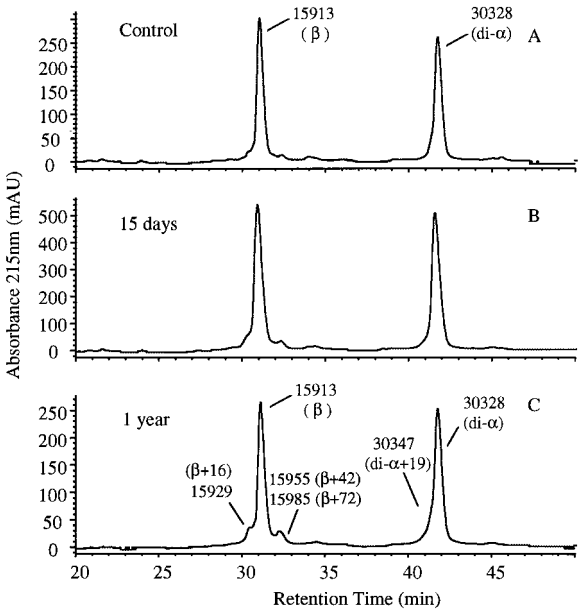

Figure 11—Reversed-phase HPLC analysis of rHb1.1 during 1 year of storage at 4 °C in vials. Samples were prepared and stored as already described. At the indicated period of time, samples were removed and aliquots were stored at –80 °C until analysis. Samples were prepared for analysis by acid/acetone precipitation immediately upon thawing and analyzed by RP-HPLC and RP/LC-MS as described in *Materials and Methods*.

with the samples stored in ascorbate for 1 year shows modification to both shoulders of the β-globin peak and the leading shoulder of the di-α-globin peak (see Figure 11). The main β globin peak showed a characteristic mass of 15 913 Da. The adduct eluting at 28.8 min in front of the main β peak had a mass increase of 16 Da, likely due to oxidation. The quantity of this adduct varied during the study period. Two β-globin adducts were observed in the peak eluting at 30.6 min and included mass additions of 42 and 72 Da. The peak eluting at that position increased from 2.2 to 4% during the study period. Cross-linked β globins were observed with masses of 31 825 and 31 908 Da. Only one modification was observed on the di-α-globin peak occurring on the leading shoulder with a mass increase of 19 Da compared to 30 328 Da observed for the main di-α peak. The main di-α peak is composed of the methylated (30 338 Da) and the unmethylated (30 324 Da) forms of the di-α-globin.[27]

Long-Term Storage in Bags—Studies of deoxy-rHb1.1 were also carried out with deoxyHb stored in oxygen-impermeable containers to prevent ascorbate degradation. Aggregation was not definitively observed with the long-term studies in vials, so polysorbate 80, 0.03%, was again included in the formulations to preclude aggregation of the protein during storage. The initial ascorbate levels present in each of the three lots were not significantly different from those present following 12 months incubation at 4 °C (Table 2). In accordance with the presence of ascorbate, the concentration of met-rHb remained at <2% (limit of quantitation) of the total protein during the course of the study. Changes were also not observed in the P_{50} and n_{max} measurements, with average values of 32 mmHg for the P_{50} and 2.17 for the n_{max} during the incubation period (Table 2). Additionally, we did not observe an increase in the multimer content (Table 2) or changes in the overall chromatographic HPSEC profile of the hemoglobin (data not shown).

Dynamic light scattering was used to ascertain the presence of higher order aggregates not detected by HPSEC. As seen in Figure 12, an initial diameter of 5.9–6.2 nm was measured by DLS at the beginning of the study, with

Table 2—Ascorbate, P_{50}, n_{max}, and Multimer Data for Deoxy-rHb1.1 Stored in Oxygen-Impermeable Bags[a]

lot	months at 4 °C	ascorbate (mM)	P_{50} (mmHg)	n_{max}	multimer (% of total Hb)
1	0	1.65 ± 0.03	32.5 ± 0.5	2.21 ± 0.03	2.7 ± 0.5
	12	1.67 ± 0.01	32.9 ± 0.2	2.21 ± 0.03	1.7 ± 0.1
2	0	1.42 ± 0.02	33.5	2.44	2.1 ± 0.3
	12	1.39 ± 0.01	33.4 ± 0.4	2.15 ± 0.04	2.1 ± 0.5
3	0	1.70 ± 0.02	32.0	2.01	1.3 ± 0.2
	12	1.64 ± 0.01	32.8 ± 0.1	2.22 ± 0.01	1.8 ± 0.4

[a] Three bags were analyzed at each time point, and the average ± standard deviation are reported. Samples without standard deviation are from analysis of a single analysis only.

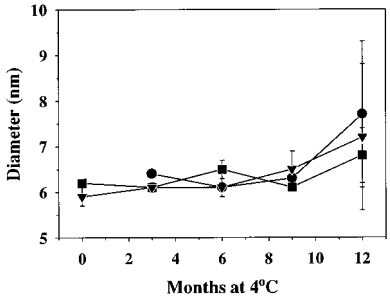

Figure 12—Dynamic light scattering analysis of rHb1.1 during 1 year of storage at 4 °C in bags. At the indicated periods of time, samples were removed and immediately analyzed for aggregates <0.2 μm by DLS as described in *Materials and Methods*. Three bags of each lot were analyzed at each time point, and the average ± standard deviation are reported.

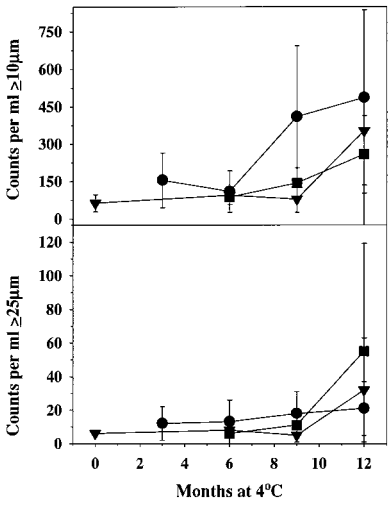

Figure 13—Light obscuration analysis of rHb1.1 during 1 year of storage at 4 °C in bags. At the indicated period of time, samples were removed and immediately analyzed for aggregates ≥10 and ≥25 μm by light obscuration as described in *Materials and Methods*. Three bags of each lot were analyzed at each time point and the average ± standard deviation are reported.

no discernible change through 9 months of storage. At 12 months, the mean diameter of the rHb in each of the lots increased to an average diameter of 7.2 nm, indicating the presence of aggregates. Distinct peaks were not differentiated by the instrument, rather the aggregation was detected as an overall increase in the size of the protein. Aggregates of 10 μm (Figure 13A) and 25 μm (Figure 13B) demonstrated a similar pattern with minimal changes through 9 months and a sharp increase between 9 and 12 months. Increases in the levels of aggregates were not associated with measurable precipitation of the protein because the soluble protein concentration did not decrease significantly during the course of the study (data not shown).

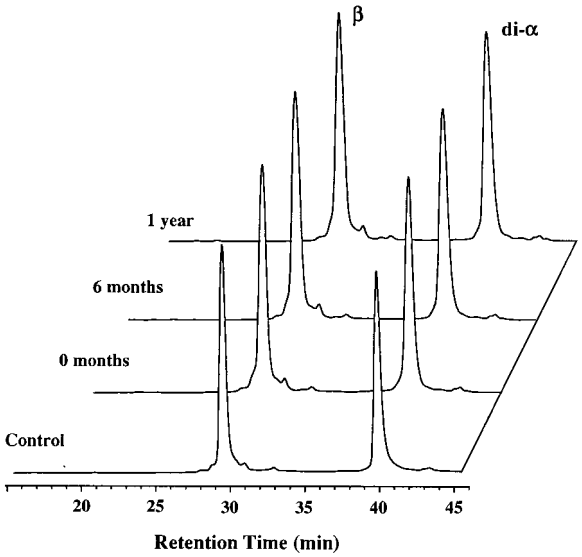

Figure 14—Reversed phase HPLC analysis of rHb1.1 during 1 year of storage at 4 °C in bags. At the indicated period of time, samples were removed and aliquots were stored at –80 °C until analysis. Samples were prepared for analysis by acid/acetone precipitation immediately upon thawing and analyzed by RP-HPLC and RP/LC-MS as described in *Materials and Methods*.

Modification of the hemoglobin primary structure was again examined by RP/LC-MS to detect potential storage-induced degradation of the protein primary structure. Comparison of the control hemoglobin with the hemoglobin formulated in ascorbate (Figure 14, compare panels A and B) shows modification to both the leading and lagging shoulders of the β-globin peak, with a corresponding decrease in the ratio of β- to di-α-globin peak heights from 1.14 to 1.07, respectively. Once the hemoglobin was formulated and put in storage conditions, RP-HPLC profiles did not reveal the presence of new peaks nor decreases in the height ratio of the β-globin-to-di-α-globin peaks. Ascorbate/oxygen-mediated modifications that were previously described were observed in the samples but did not appear to change qualitatively during the study period. We were unable to quantitate these adducts (in the hemoglobin) by RP/LC-MS due to a lack of mass resolution. The RP/LC-MS analysis of the β- and di-α-globin peaks demonstrated a consistent molecular weight for each of the globin chains during storage of 15 913 Da for the β globin and 30 330 for the di-α-globin.

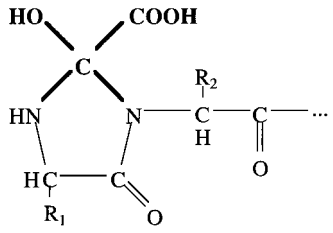
Discussion

The purpose of this study was to investigate the effects of ascorbate, oxygen, and pH on the long-term stability of deoxyHb. Storage of deoxyHb has been investigated by other researchers.[28,29] Kramlova et al.[29] attempted to store stroma-free hemoglobin following bubbling of nitrogen through the solution. After 1 year at 4 °C, the metHb content increased from 5 to 41%. De Venuto[28] stored hemoglobin at 25 °C in sealed glass ampules following three cycles of gas evacuation and flushing with nitrogen. In those studies, the metHb content increased from 6.1 to 52.8% during the 8-week storage period. It is likely that the hemoglobin in those investigations oxidized due to incomplete deoxygenation of the solutions. Keilin[30] demonstrated that the rate of autoxidation increases dramatically if the hemoglobin is only partially deoxygenated. Investigations by Brantley et al.[2] using myoglobin confirmed these observations and demonstrated that under saturating oxygen conditions autoxidation occurs through a unimolecular dissociation of the neutral superoxide radical ($HOO^{\bullet}$) from the heme. At low oxygen concentrations, autoxidation may occur through the unimolecular reaction as well as a bimolecular reaction. The bimolecular reaction is facilitated by the structure of partially deoxygenated Mb, which allows a water molecule to coordinate with His64 and the ferrous iron of the deoxy heme. The water molecule is capable of stabilizing the ferric state of the oxidized heme, thereby facilitating the extraction of an electron from the ferrous iron by an approaching oxygen. When rHb1.1 was equilibrated with 15 000 ppm of oxygen in the headspace and stored at 4 °C, the autoxidation rate increased by approximately 50% over that normally observed for oxy-rHb1.1. Equilibrating the hemoglobin with 150 ppm of oxygen in the headspace of our containers did not completely prevent autoxidation, although it did decrease the rate by approximately 5-fold from that observed with 15 000 ppm of oxygen in the headspace (see Figures 1 and 2). Further reduction of autoxidation was accomplished by inclusion of the reducing agent, ascorbate. The ascorbate likely reacted with excess oxygen present in the solution and reduced any ferric hemoglobin back to the ferrous state.

Reaction of reducing agents such as ascorbate with oxygen can produce superoxide.[31] During our studies, inclusion of 0.5 and 1 mM ascorbate in formulations containing 15 000 ppm of oxygen in the headspace increased the autoxidation rate compared with the rate in solution without ascorbate (see Figure 1). The increased oxidation rate observed for the first 8 days was likely due to production of superoxide by ascorbate and oxygen until all the ascorbate in the solution was consumed. Superoxide quickly disproportionates to hydrogen peroxide, which can react with and oxidize ferrous Hb. In the sample of hemoglobin incubated with 2 mM ascorbate, it is likely that ascorbate consumed the oxygen and reduced the metHb. Both reactions conceivably occurred in competition, resulting in the slower rate of metHb reduction than that seen with 5 mM ascorbate.

The protein modifications observed during the long-term studies in vials (Figures 8–11) were similar to those observed during the acute studies and are likely related to the reaction of ascorbate with oxygen which produces superoxide.[31] Oxygen may have entered the reaction vials during the study period through the permeable butyl rubber stoppers. The protein cross-linking observed by SDS-PAGE (Figure 9) was likely related to formation of hydrogen peroxide from the superoxide anion because the cross-linking pattern in the presence of H_2O_2 was similar to that when the oxyHb was incubated with ascorbate. Additionally, a similar type of cross-linking pattern was observed when HbAo was incubated with hydrogen peroxide (data not shown), suggesting that the cross-linking was not due to a difference in susceptibility of the two hemoglobins to H_2O_2. The cross-linking of the protein would explain the decrease in the P_{50} and n_{max} observed during our long-term studies. A decrease in the oxygen binding parameters of recombinant hemoglobin has been observed after heterogeneous intramolecular cross-linking of the globins.[32]

Chemical modifications of the hemoglobin observed during the acute studies (see Figures 3 and 4) were also present in the material used for long-term stability following addition of ascorbate (see Figures 10 and 14), and increased during storage of the rHb1.1 in vials (see Figure 10). The modifications did not appear to increase when the hemoglobin was stored in an oxygen-impermeable storage system (Figure 14, compare panels B–D). Reduction of metHb by ascorbate produces dehydroascorbate, which could subsequently react with low levels of residual oxygen and produce other potentially highly reactive



R_1 = Met
R_2 = His

Figure 15—Proposed structure of the M+72 addition to the N-terminal tryptic peptide of the β-globin. The section in boldtype represents the proposed +72 addition.

byproducts that could modify the protein.[33−36] A number of new modifications of hemoglobin were detected by C3 RP/LC-MS analysis. The most significant mass gains were 16 and 72 Da. Mass gains of 58 Da (carboxymethylation) and 130 Da (dehydroascorbate addition) could not be definitively assigned by LC-MS (data not shown). Only one difference peak was observed during peptide mapping and was assigned as a 72 Da addition to the N-terminus of the β chain. This result may indicate that other modifications are labile or heterogeneously distributed across β and di-α-globins. Heterogeneous modifications not detectable by tryptic mapping have also been observed.[32] The mass increase of 16 Da is likely due to oxidation of side chains of labile amino acids.[37,38] Amino acid analysis indicated the presence of a low level of labile oxo-histidine in the sample equilibrated with 15 000 ppm of oxygen and incubated with 5 mM ascorbate (data not shown).

Efforts were made to identify the M+72 modification at the N-terminus of the β-globin. The results from the MS/MS fragmentation together with the protein chemistry (blocked to Edman degradation and not reducible by borohydride) suggest that the modification is distributed between the Met1 and His2 residues, which is consistent with an imidazolidinone structure. Imidazolidinone structures have been postulated to form at the N-terminus of the β globin in reactions of human hemoglobin A_0 with aldehydes.[39−42] Our results also indicate that the modification is likely to contain labile carboxy and hydroxy groups, which is consistent with the observed neutral loss of 44Da- and 18 Da-derived fragments. The proposed structure for the modification is presented in Figure 15. The structure indicates a similarity to an oxalate-derived modification. However, incubation of hemoglobin with oxalate did not produce any trace of the M+72 modification (data not shown). Examination of the known ascorbate degradation pathway[34−36] did not indicate the presence of degradation byproducts that could directly derivatize the hemoglobin and result in a mass increase of 72 Da. A number of ascorbate degradation products containing carbonyl groups could initially form a Schiff's base with the N-terminus followed by rearrangement to the imidazolidinone structure and further degradation (i.e., oxidation) to produce the observed mass gain.

Surfactants may stabilize protein structure by binding to hydrophobic surfaces on proteins [44−46] or by competing with proteins for adsorption at liquid−surface interfaces.[47−49] Studies by Kerwin et al.[43] demonstrated that Tween 80 does not bind to the rHb1.1, suggesting that the decreased aggregation observed during the shaking studies (Figure 7) was due to competition of the surfactant with the liquid−surface interfaces. Therefore, because the hemoglobin would be stored for long periods of time while in contact with the ethyl vinyl acetate surface of the bag, Tween 80 was added to the hemoglobin solutions to circumvent possible aggregation during the study period. In contrast to the long-term study in vials in which little aggregation was observed by DLS, a variable degree of aggregation was observed by both DLS and light obscuration when the hemoglobin was stored in the bags. This difference may be due to differential affinities of the surfactant and the hemoglobin for either the glass or ethyl vinyl acetate surfaces. Work by Hlady and co-workers[49,50] has demonstrated that the interaction of proteins with surfaces is dependent on the surface chemistry. It is not likely that the aggregation was due to the initial modification of the hemoglobin following ascorbate addition (Figure 14) because similar observations were made during the long-term studies of deoxy-rHb in vials (Figure 11), which contained a much higher degree of protein modification at the end of the study period. The concentration of Tween 80 used in our formulation may have been too low to successfully prevent interaction of the hemoglobin with the ethylvinyl acetate bag surface, eventually leading to aggregation. It is also possible that the N-terminal methionine and the "glycine linker" between the α subunits, which are not present in HbAo, add to the instability of the protein, making it more prone to aggregation. However, we do not feel that this is the case because comparison of the α-carbons of the X-ray crystallographic structures of deoxy-rHb1.1 and HbAo have a root-mean-square (RMS) deviation of 0.187 with the met1-Cα and an RMS deviation of 0.170 without the met1-Cα (E. Brucker, personal communication).

The data presented here demonstrate a significant advance in our ability to successfully store hemoglobin-based oxygen-carrying therapeutics. To our knowledge this is the first evidence that a deoxygenated hemoglobin can be stored for an extended period of time in the presence of reducing agents without metHb formation or precipitation. Stability against met-rHb formation was increased >50-fold by deoxygenation and reduction of the protein with ascorbate. Storage of the deoxy-rHb in vials resulted in modification to the protein primary structure (Figure 11), decreased P_{50} and n_{max} values (Figure 8), and formation of cross-linked protein (Figure 9). These modifications were all likely related to the influx of oxygen through the vial stopper and were not observed following storage of the hemoglobin in the foil overwrapped containers.

Ionization Constants and Distribution Coefficients of Phenothiazines and Calcium Channel Antagonists Determined by a pH-Metric Method and Correlation with Calculated Partition Coefficients

ULRICH FRANKE, ANGELA MUNK, AND MICHAEL WIESE*

Contribution from *Department of Pharmaceutical Chemistry, University of Halle and Wittenberg, Wolfgang-Langenbeck-Str. 4, D-06120 Halle, Germany*

Received May 13, 1998. Accepted for publication October 13, 1998.

Abstract □ The pH–metric technique was used to determine the ionization constants and distribution coefficients of 10 phenothiazines and five ionizable calcium channel antagonists. Because the studied compounds were poorly water soluble and quite lipophilic with partition coefficients in the range of 3.5 to 5.5, organic cosolvents had to be added for the determination of the ionization constants to avoid precipitation of the free bases. The effect of the cosolvents dioxane and methanol on the extrapolation to pure water was compared. For both cosolvents a very good agreement with accessible published ionization constants was obtained, however the slope of the regression line was much smaller for dioxane, yielding more reliable estimates according to the standard deviation of the extrapolated values. Thus, dioxane might be preferable to methanol as a cosolvent for the determination of ionization constants of sparingly water soluble bases. Also the *n*-octanol/water partition coefficients were determined and compared with published data and values calculated with the ClogP, ACD, and HINT programs. Although the obtained values were approximate in conformity with the published data, the calculated partition coefficients differed from the experimental ones considerably for the majority of the investigated compounds. Furthermore, the ion pair partitioning and the distribution coefficients at physiological pH 7.4 were determined. The pH-dependent distribution profiles showed the strong influence of the ionization constants and of the distribution of the ion pairs on the overall distribution. This result strongly suggests that greater use should be made of measured distribution coefficients in quantitative structure–activity relationship studies. The potentiometric method is a convenient way to determine the distribution properties of drug molecules at pH values relevant for the biological system under investigation.

Introduction

The knowledge of drug membrane interactions is important in the understanding of the biological action of many drugs.[1] Often the pharmacological behavior of drugs is related to their distribution or nonspecific binding in or to membranes.[2,3] *n*-Octanol/water is often used to model the distribution of a drug by measuring the partition coefficient in this system.[4] The partition coefficient, *P*, is most commonly defined for the uncharged form of an ionizable substance; in addition it can be also defined for the charged form of the substance. Often the neutral and charged forms of lipophilic molecules are able to partition into the organic phase in solvent/water mixtures.[5] The pH-dependent distribution profile enables the identification of the number of species present and is a powerful tool for comparing the properties of clusters of similar compounds.[6] Precisely and accurately determined values of the ionization constants, pK_a, and the partition coefficients of the neutral and charged species are necessary to obtain distribution coefficients. The conventional methods for measuring pK_a and/or log *P* values are UV spectroscopy, the shake-flask method,[7] HPLC,[8] and centrifugal partition chromatography,[9] respectively. A major drawback of these methods is that they are very time-consuming. An additional problem for these kinds of determination is often the very low solubility of pharmaceutical compounds. The acid−base titration in aqueous solution is an alternative for ionizable compounds.[10−15] To increase the solubility, a water-miscible cosolvent (methanol, dioxane, dimethyl sulfoxide) is added for the pK_a determination of sparingly water soluble compounds.

For phenothiazines used as neuroleptics, a good correlation between the determined log *P* values and a selected biological action has been reported.[16−20] Also, for calcium channel antagonists, the lipophilicity and interaction with membrane phospholipids seem to play a major role in their pharmacological activity.[2] In our efforts to characterize and better understand drug−membrane interactions and the distribution of membrane-active compounds, we first report in this paper the application of the pH−metric method to the determination of pK_a, log *P*, and log P_{ion} values for 10 structurely related phenothiazines and five calcium channel antagonists in *n*-octanol/water.

The aims of this work were severalfold: to validate the pH−metric method and to advance the exact analysis of pK_a values and the distribution in *n*-octanol/water of neutral and positively charged drugs; to study the influence of the cosolvents dioxane and methanol necessary in cases of poorly soluble compounds on the determined pK_a value; to compare experimental with calculated log *P* values to estimate the reliability of the latter ones; to establish the pH-dependent distribution profile of every sample; and to compare the application of either the log *P* values or apparent distribution coefficient (log *D*) values at physiological pH in quantitative structure−activity relationships (QSAR) studies (i.e., in attempting to predict the pharmaceutical potency or the in vivo absorption).

Experimental Section

Reagents—The pharmaceutical substances used are as follows: promethazine hydrochloride, chlorpromazine hydrochloride, triflupromazine hydrochloride, prochlorperazine dimaleate, trifluoperazine dihydrochloride, perphenazine, fendiline hydrochloride, and 1-octanol (HPLC grade) from Sigma Chemical Company, Germany; verapamil hydrochloride from Aldrich, Germany; methanol (HPLC grade) from Carl Roth GmbH, Karlsruhe, Germany; hydrochloric acid standardized ampules and potassium hydroxide

standardized ampules from Riedel-de-Haen AG, Seelze, Germany; and potassium chloride (pro analysis) and dioxane from VEB Laborchemie, Apolda, GDR. The dioxane was distilled twice before use. The following drugs were generous gifts: levomepromazine hydrochloride from Bayer AG, Leverkusen, Germany; thioridazine hydrochloride and thiethylperazine dimaleate from Sandoz AG, Nürnberg, Germany; gallopamil hydrochloride from Knoll Deutschland GmbH, Ludwigshafen, Germany; amlodipine besylate from Pfizer GmbH, Karlsruhe, Germany; and nicardipine hydrochloride from Ciba-Geigy GmbH, Wehr, Germany. The water used was purified with an Elgastat Maxima, Elga Ltd., Bucks, UK.

Practical Part of pH−Metric Method—The pK_a and the log *P* values were determined by potentiometric titration using a PCA 101 instrument from Sirius Analytical Instruments Ltd., Forrest Row, UK, at 25.0 ± 0.2 °C at an adjusted ionic strength of the aqueous phase of 0.15 M potassium chloride. Details of the method have been previously published elsewhere.[10−15] The pK_a and log *P* measurements were done in separate experiments, and the concentration of the drug titrated was between 0.08 and 0.15 mM. The lower pK_a values of the diprotic phenothiazines were determined in triplicate in pure aqueous 0.15 M KCl. To avoid precipitation of the neutral bases, certain amounts of cosolvents were added in case of the higher pK_a values. The concentration of the dioxane cosolvent varied between 15 and 40 wt % and, for the phenothiazines, 20−50 wt % methanol cosolvent was used additionally. The apparent pK_a values (p$_s K_a$) were measured in at least five different cosolvent/water mixtures. The log *P* determinations were replicated at least three times with different volume ratios of *n*-octanol/water. Because of the high partitioning of all samples into the organic phase, a reasonable volume ratio of 0.005 to 0.05 was applied (0.1 to 1.0 mL octanol in 20 mL total volume). For the dimaleate counterion present in the prochlorperazine and thiethylperazine salts, a pK_a of 5.78 and a log *P* of −0.47 were determined in the pH range between pH 2.5 and 10.5, which is in close agreement with the literature (pK_a = 5.80; log *P* = −0.4).[21]

Theoretical Part of pH−Metric Method—An iterative least squares refinement procedure was used to calculate the final values. Typically, the values of the goodness of fit (GOF) weighting scheme used for all refinements were in the range from 0.6 to 1.4 for pK_a measurements without cosolvent, log *P* titrations, and multi-set refinements. A GOF value of 1 means that on average the observed and calculated curve differ not more than one internal standard deviation of the device. The Yasuda−Shedlovsky procedure extrapolates the real aqueous pK_a from the obtained p$_s K_a$ values by plotting the p$_s K_a$ value and the logarithm of the water concentration against the reciprocal of the dielectric constant, ϵ, for the mixtures according to eq 1:[13]

$$p_s K_a + \log [H_2O] = a + b/\epsilon \quad (1)$$

A negative slope of the regression line is characteristic for basic substances. To investigate the reliability of the electrode calibration factors supplied, comparative titrations in dioxane and methanol cosolvent mixtures were performed.

The partition coefficient, log *P*, of the neutral bases was calculated according to eq 2:

$$\log P = \log(10^{(pK_a - p_o K_a)} - 1) - \log(r) \quad (2)$$

If only the partitioning of the neutral species into *n*-octanol was assumed, the calculated partition coefficients decreased with increasing amounts of *n*-octanol, indicating a significant contribution of the monoprotonated form to partitioning. Therefore, the partitioning of the monoprotonated form was taken into account in the fitting process. For the monoprotic bases, the partition coefficient of the ion, log P_{ion}, was calculated iteratively, correcting the apparent log *P* value obtained in different *n*-octanol/water ratios to a constant value. According to this procedure, only the partitioning of the monoprotonated form accounted for the distribution for the investigated diprotic phenothiazine derivatives. To investigate the influence of the uncertainty in the pK_a determination on the log *P* measurement, the log *P* values were calculated again at ± one standard deviation of the determined pK_a value. Only in this manner, by taking into account the errors of measurements and extrapolations, can a realistic estimate of the reliability of the log *P* results be obtained. Finally, the pH-dependent apparent distribution coefficients, log *D*, were calculated as pH − log *P* − log P_{ion} profile by the analysis software.

Table 1—Comparison of Measured pK_a Values with Published Data

drug	measured pK_a in dioxane[a]	in methanol[b]	in water[c]	published pK_a

Calculation of log *P* Values—For comparative purposes, the partition coefficients in the *n*-octanol/water system were calculated with the programs ClogP,[22] ACD,[23] and HINT.[24] ClogP is based on the two-dimensional fragment method developed by Leo and Hansch[25] using fragment constants derived from differences in partition coefficient of substituted and unsubstituted compounds together with several correction terms that account for neighbor-group effects. The ACD program uses a similar algorithm, where the log *P* contribution values of atoms, fragments, and intramolecular interactions were derived from 3600 experimental log *P* values.[23] The calculated results are given with auxiliary certainty limits. HINT was developed as computational method for three-dimensional structures using hydrophobic atom constants. The lipophilicity contributions of hydrogens are constant and the lipophilicity values of the central atom(s) of a fragment are adjusted in a way that the sum of the atomic constants is equal to the fragment-constant value.[26] This program offers two methods for taking into account neighboring effects, either via bonds (e.g., according to the connectivity pattern) or through space, thus considering additionally the conformation of a molecule. The three-dimensional modeling was done with SYBYL.[27] The starting structures were extracted from the Cambridge Structural Database,[28] where entries for all compounds except gallopamil and nicardipine were found. The structures for these two compounds were built by modification of the X-ray structures of verapamil and amlodipine, respectively. The geometry optimization and the atom charge calculation of the neutral forms was performed with MOPAC 6 as implemented in SYBYL using the AM1 Hamiltonian and the keywords 'precise' and 'gnorm-0.2'. Both HINT log *P* values, with proximity effects via bonds, HINT-2D, and through space, HINT-3D, were calculated for the optimized structures.

Results and Discussion

The pK_a values measured in this study together with available published data are shown in Table 1. A very good agreement between potentiometrically measured and formerly reported pK_a values can be seen. The differences are mostly in the range of 0.1 to 0.2 units. This agreement can be regarded as very satisfactory because the published values have been determined in several laboratories and usually not all details about the conditions of the pK_a determination were given, so ionic strength and temperature might differ from our experimental conditions. The structures of all samples are shown in Figures 1 and 2.

Considering the statistics of the pK_a determinations, it can be concluded that the errors of pK_a values determined

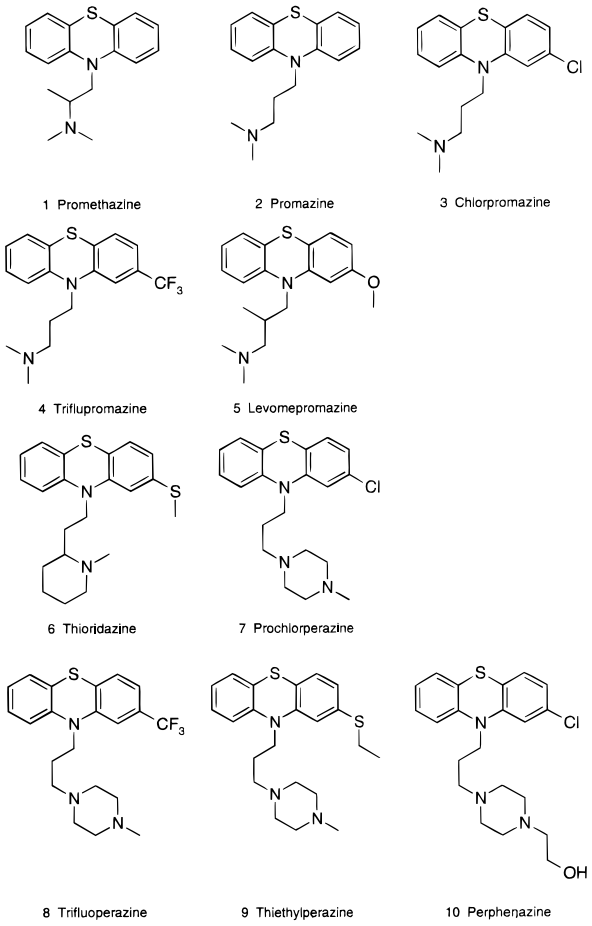

Figure 1—Structures of the phenothiazine derivatives investigated.

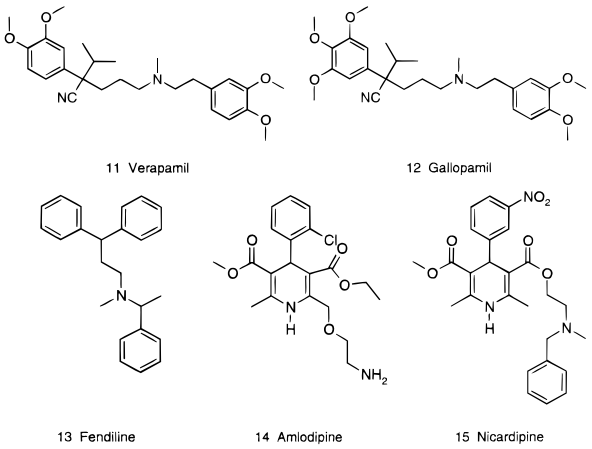

Figure 2—Structures of the calcium channel antagonists investigated.

in purely aqueous 0.15 M KCl seem to be negligible (standard deviations of about ±0.01). The quality of the Yasuda−Shedlovsky extrapolation depended on the number of titrations introduced, the amount and kind of cosolvent, and the quality of the electrode parameter validation at certain cosolvent concentrations. The comparison of the pK_a values obtained from either dioxane or methanol cosolvent mixtures showed generally good agreement, with differences in the range of <0.1 to 0.2 units. For all compounds, except promethazine, gallopamil, and the highest pK_a values of prochlorpromazine and trifluoperazine, the confidence intervals of the pK_a values overlap; therefore, they are statistically identical. The results obtained with dioxane seemed more reliable because lower concentrations were needed to keep the free bases in

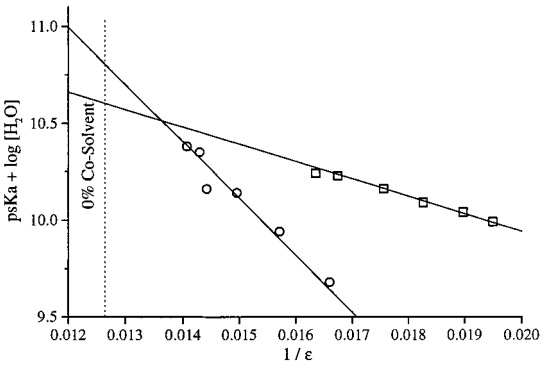

Figure 3—Yasuda–Shedlovsky extrapolation: cosolvent dioxane (□); pK_a of promethazine; extrapolation equation: $p_sK_a + \log [H_2O] = 11{,}745 - 89{,}6/\epsilon$; $pK_a = 8.86 \pm 0.01$ cosolvent methanol (○); pK_a of promethazine; extrapolation equation: $p_sK_a + \log [H_2O] = 14{,}528 - 291{,}9/\epsilon$; $pK_a = 9.07 \pm 0.08$.

Table 2—Comparison of Measured log *P* Values with Published Data

drug	measured log *P*	− limit[a]	+ limit[a]	GOF	published log *P*[b]
promethazine	4.51	4.47	4.55	1.15	4.30,[37] 4.75,[29] 4.81[30]

fendiline	4.89	4.84	4.91	0.93	
amlodipine	3.17	3.06	3.27	1.10	3.15,[40] 3.30[30]
nicardipine	4.65	4.53	4.74	0.60	3.82,[41] 4.96[30]

[a] The ± limits of log *P* based on ± one standard deviation of the corresponding pK_a values. [b] All published values were obtained by shake-flask method.

solution and the slope of this extrapolation line was less steep (Figure 3). In other words, the influence of the dielectric constant to the sum pK_a + log[H_2O] was less pronounced.

This result is also reflected in the lower standard deviations of pK_a values determined in dioxane/water compared with methanol/water mixtures. A comparison by linear regression yielded eq 3:

$$pK_a(\text{methanol}) = 0.14(\pm 0.14) + 0.99(\pm 0.02)\, pK_a(\text{dioxane}) \quad (3)$$

$$n = 15 \qquad SD = 0.15 \qquad r = 0.99 \qquad F = 3104.0$$

Intercept and slope of the regression line do not deviate significantly from their ideal values. Thus, the values obtained in both systems are comparable, confirming that the quality of the electrode parameter validation made by Sirius Analytical Instruments Ltd. is sufficient if the pK_a lies in the investigated pH range (3 to 10).

The log *P* results are shown in Table 2 together with estimated errors for the log *P* values. The given error estimations are based on the uncertainty in the pK_a determination and not on the much lower ones that result from the fitting procedure that assumes a perfect determination of pK_a. The range of the log *P* uncertainty reflected directly the limits of the pK_a determination.

For the investigated compounds, a good agreement with available experimental log *P* values from the literature was

found. Two major exceptions are evident: in this study a log *P* value of 5.32 was determined for thioridazine in comparison with published values of 5.8 and 5.9. The source for this difference is not clear but it should be kept in mind that the determination of such high log *P* values by the shake-flask method is very difficult. This difficulty is also substantiated by the large variation of log *P* values reported in the literature for promethazine, levomepromazine, thiethylperazine, perphenazine, verapamil, and nicardipine (Table 2). For prochlorperazine, the log *P* value determined in this study was considerably higher than that published in ref 18. A comparison of this log *P* with values from other sources show that the values published in this article are much lower than expected and probably in error. This conclusion is also supported by comparison with log *P* values of other closely related phenothiazines, such as trifluoperazine.

As at least one of the reference values is in approximate agreement with the log *P* values determined by potentiometric titration, the applied two-step method for the determination of log *P* values of poorly water soluble compounds can be regarded as reliable.

The measured log *P* values were also compared with the values calculated by the ClogP, ACD, and HINT software (Table 3) to estimate the ability of the programs to predict log *P* values without experimental work.

Mannhold and Dross regarded a calculated partition coefficient as acceptable if the difference between experiment and calculation was lower than ±0.5 log *P* units.[42] In general, this wide range can be accepted in QSAR studies only if a large variance in log *P* among the compounds investigated exists. We used more stringent reliability measurements; first, the estimated error interval of the experimental values, and second, the range of ±0.3 units of the calculated values because this is the generally accepted error in log *P* values determined by the shake-flask method.

Visual comparison of experimental and calculated log *P* values showed that according to either of these criteria, none of the programs was able to calculate log *P* values accurately (Figure 4). The 'best' results were obtained with the ACD software where the standard errors given by the software overlapped with the experimental values in 10 cases. Comparing the calculated with experimental log *P* values, including their estimated error intervals, overlap was observed in only two cases for the ACD, three for the ClogP, one for HINT-2D, and in no case for the HINT-3D software. If the less stringent criterion of ±0.3 log *P*

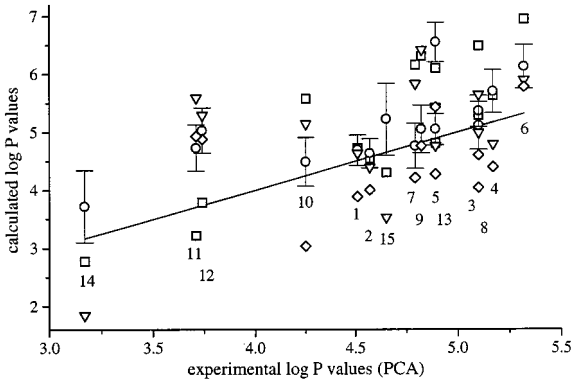

Figure 4—Prediction of measured log *P* values for the tested drugs; reference PCA (straight line), ClogP (□), ACD (○); (with error bars, values printed in Table 3), HINT-2D (▽), HINT-3D (◇).

deviation of the calculated values was applied, the success rate of the software did not increase much: seven coincidences in the case of ACD followed by five for ClogP, four for HINT-2D, and only one for HINT-3D.

For structurally related derivatives, the picture seemed to be less disappointing because all programs except HINT-3D predicted the log *P* values of promazine-type phenothiazines quite well. However, ClogP and HINT-2D highly overestimated the lipophilicity of the piperazine substituent (Table 3). The presence of a piperazine ring did not increase the partition coefficient very much compared with the corresponding promazine derivatives. Instead, the second polar nitrogen appeared to reduce the tendency of drug enrichment in *n*-octanol.[5]

A quantitative comparison of the quality of log *P* predictions was carried out by linear regression. Because we were interested in the calculation ability of the programs, the experimentally determined log *P* value was the dependent variable. This situation corresponds to the condition frequently encountered in a QSAR analysis; that is some log *P* values are known and one wants to calculate the missing ones. It also ensures that the standard deviations of estimation can be compared directly.

For all phenothiazines ($n = 10$) covering a log *P* range of about one log unit, the following results were obtained:

$$\log P_{\mathrm{PCA}} = 3.62 + 0.21 \log P_{\mathrm{ClogP}}$$
$$\mathrm{SD} = 0.30 \quad r = 0.53 \quad F = 3.5$$

$$\log P_{\mathrm{PCA}} = 1.84 + 0.59 \log P_{\mathrm{ACD}}$$
$$\mathrm{SD} = 0.15 \quad r = 0.91 \quad F = 29.1$$

$$\log P_{\mathrm{PCA}} = 4.02 + 0.16 \log P_{\mathrm{HINT.2D}}$$
$$\mathrm{SD} = 0.31 \quad r = 0.34 \quad F = 1.0$$

$$\log P_{\mathrm{PCA}} = 3.19 + 0.39 \log P_{\mathrm{HINT.3D}}$$
$$\mathrm{SD} = 0.21 \quad r = 0.81 \quad F = 14.8$$

As can be seen, only the equations using ACD or HINT-3D as the calculation method are significant at all. In all cases, the slopes are considerably lower than one and the intercepts are much higher than zero. According to these criteria and the statistical parameters, only the ACD program yielded reliable estimates. Inspection of the residuals showed, that in no case was an 'outlier' based on statistical reasoning present, meaning that the low correlations were due to the scatter in the calculated data. The exclusion of thioridazine from the regression, because our log *P* value differed by 0.5 from published data, even worsened the results (data not shown). Only for ACD were the statistics virtually unchanged; however, the intercept dropped to 1.17 and the slope increased slightly to 0.73.

To study the influence of the overestimation of the lipophilicity of the piperazine-containing compounds, the regressions for the two subsets of phenothiazines with alkyl amino or piperazine side chains were derived.

Phenothiazines with alkyl amino side chain ($n = 5$):

$$\log P_{PCA} = 1.79 + 0.61 \log P_{ClogP}$$
$$SD = 0.15 \quad r = 0.91 \quad F = 13.8$$

$$\log P_{PCA} = 1.58 + 0.64 \log P_{ACD}$$
$$SD = 0.09 \quad r = 0.97 \quad F = 45.1$$

$$\log P_{PCA} = -0.39 + 1.11 \log P_{HINT.2D}$$
$$SD = 0.20 \quad r = 0.81 \quad F = 5.7$$

$$\log P_{PCA} = 0.71 + 0.98 \log P_{HINT.3D}$$
$$SD = 0.11 \quad r = 0.94 \quad F = 24.6$$

Phenothiazines with piperazine ring ($n = 4$):

$$\log P_{PCA} = -0.73 + 0.89 \log P_{ClogP}$$
$$SD = 0.07 \quad r = 0.99 \quad F = 87.5$$

$$\log P_{PCA} = -0.83 + 1.15 \log P_{ACD}$$
$$SD = 0.17 \quad r = 0.92 \quad F = 11.6$$

$$\log P_{PCA} = 2.54 + 0.38 \log P_{HINT.2D}$$
$$SD = 0.36 \quad r = 0.57 \quad F = 0.9$$

$$\log P_{PCA} = 3.29 + 0.36 \log P_{HINT.3D}$$
$$SD = 0.30 \quad r = 0.73 \quad F = 2.2$$

It should be mentioned that the variance of log *P* in the subsets is only slightly lower than for all phenothiazines and that therefore the statistical parameters are comparable. The fit of the alkyl amino compounds was improved in all cases. The best results were obtained with the ACD program and especially with HINT-3D. A comparison of the slopes and intercepts of the equations shows that they differ considerably between the subsets. This difference clearly marks that even such small structural changes such as the replacement of an alkyl amino by a piperazine group are not well handled by the log *P* calculation programs. For the perazine-type phenothiazines, the best fit was obtained with ClogP.

The data for the investigated calcium channel antagonists ($n = 5$) comprised structurally diverse compounds and covered a slightly larger log *P* range of 1.7 units. For this subset, the following equations were obtained:

$$\log P_{PCA} = 1.99 + 0.51 \log P_{ClogP}$$
$$SD = 0.35 \quad r = 0.91 \quad F = 14.2$$

$$\log P_{PCA} = 0.81 + 0.64 \log P_{ACD}$$
$$SD = 0.35 \quad r = 0.91 \quad F = 14.0$$

$$\log P_{PCA} = 3.25 + 0.18 \log P_{HINT.2D}$$
$$SD = 0.75 \quad r = 0.41 \quad F = 0.6$$

$$\log P_{PCA} = 3.76 + 0.09 \log P_{HINT.3D}$$
$$SD = 0.77 \quad r = 0.37 \quad F = 0.5$$

As expected for a more diverse data set, the correlation decreased and the standard deviation increased. But again, no outliers were present so the regressions were not unduly influenced. As with the phenothiazines, high intercepts and low slopes were observed, pointing to a general overestimation of lipophilicity by the programs. Combining all investigated drugs ($n = 15$) yielded the following equations:

$$\log P_{PCA} = 2.40 + 0.43 \log P_{ClogP}$$
$$SD = 0.33 \quad r = 0.85 \quad F = 34.7$$

$$\log P_{PCA} = 1.33 + 0.64 \log P_{ACD}$$
$$SD = 0.45 \quad r = 0.71 \quad F = 13.2$$

$$\log P_{PCA} = 3.14 + 0.29 \log P_{HINT.2D}$$
$$SD = 0.54 \quad r = 0.52 \quad F = 5.1$$

$$\log P_{PCA} = 3.85 + 0.19 \log P_{HINT.3D}$$
$$SD = 0.53 \quad r = 0.55 \quad F = 5.5$$

Although the whole data set had a larger variance in log *P* (about 2.2 log units), the relationship between experimental and calculated log *P* values did not improve. It can be concluded that none of the programs used can calculate log *P* values for the investigated compounds with satisfying accuracy at all.

The ACD program performed best for phenothiazines, but did not yield satisfactory results for the other drugs investigated, and was followed next by the ClogP program. Phenothiazines with a piperazine or a piperidine ring in the side chain deviated the most; their lipophilicity was greatly overestimated by the programs. The HINT methodology, especially when taking into account the three-dimensional structure gave the least correlation between measured and calculated log *P* values for the studied derivatives. This result is mainly due to large errors for two calcium channel antagonists of the dihydropyridine type whose lipophilicity was greatly underestimated. HINT was also the only program that incorrectly assigned a chloro-substituent, which is a larger lipophilicity contribution in comparison with a trifluoromethyl group, at the same position in case of the phenothiazines (nos. 2 & 6 versus 3 & 7) and also overestimated the contribution of a 3,4,5-trimethoxyphenyl group compared with its 3,4-dimethoxyphenyl counterpart for the pair gallopamil and verapamil. These results emphasize the need for a further improvement in the accuracy of prediction of log *P* by calculation.

Additionally we focused our attention on the partition coefficients of the ions, log P_{ion}, and on the distribution coefficients at pH 7.4, log *D*, a quantity relevant for the distribution behavior of drugs under physiological conditions. Depending on the quality and quantity of the hydrophobic parts of a compound, a charged drug molecule can enter the organic phase. For example the ionized form of phenothiazines participated in hydrophobic interaction when its charge was suitably neutralized by appropriate anions.[5] Most of drugs analyzed were monoprotic bases that could be present as the neutral and ionic species in the organic phase. For phenothiazines with two basic nitrogens that were doubly protonated at low pH, only the neutral and the monoprotonated components were observed in the organic phase. Table 4 summarizes the partition and distribution coefficients together with published data.

A big advantage of the pH−metric method is that the distribution profile over the entire pH range can be obtained from the titration curves.[44] The calculated log *D* at pH 7.4 for promethazine, chlorpromazine, thioridazine, trifluoperazine, thiethylperazine, and perphenazine based on the measured log *P* and log P_{ion} corresponded excellently to values obtained earlier by the shake-flask method. On average, the distribution coefficients, log *D*, of bases containing two basic nitrogens were higher than those with only one basic nitrogen. This result was the opposite order in relation to the log *P* values. One reason for this discrepancy could be identified clearly; that is, because one

Table 4—Comparison of pH-dependent Distribution in *n*-Octanol/Water

drug	log *P*	log P_{ion}	log *D* pH 7.4	log D_{lit} pH 7.4
promethazine	4.51	1.38 ± 0.03	2.95	2.79,[37] 2.88[17]

chlorpromazine	5.10	1.52 ± 0.02	3.26	3.26,[16] 3.39[38]
triflupromazine	5.17	1.87 ± 0.03	3.52	3.39,[16] 3.70[37]
levomepromazine	4.89	1.76 ± 0.03	3.17	2.62[37]
thioridazine	5.32	2.08 ± 0.02	3.45	3.51[37]
prochlorperazine	4.79	1.47 ± 0.08	3.83	
trifluoperazine	5.10	2.26 ± 0.02	4.23	4.36[37]
thiethylperazine	4.82	1.92 ± 0.03	4.04	3.82[37]
perphenazine	4.25	1.50 ± 0.06	3.56	3.65[37]
verapamil	3.74	1.10 ± 0.09	2.37	1.83[43]
gallopamil	3.71	1.29 ± 0.06	2.45	
fendiline	4.89	2.14 ± 0.12	3.19	
amlodipine	3.17	1.06 ± 0.03	1.41	1.11[40]
nicardipine	4.65	1.39 ± 0.10	4.33	

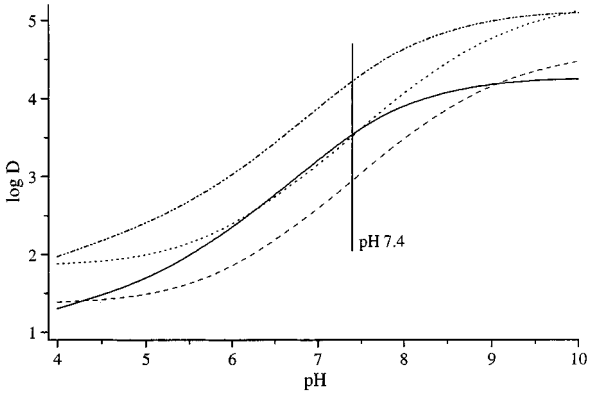

Figure 5—The pH-dependent distribution profile of four phenothiazines; promethazine (dashed line), triflupromazine (dotted line), trifluoperazine (dash/dotted line), and perphenazine (solid line).

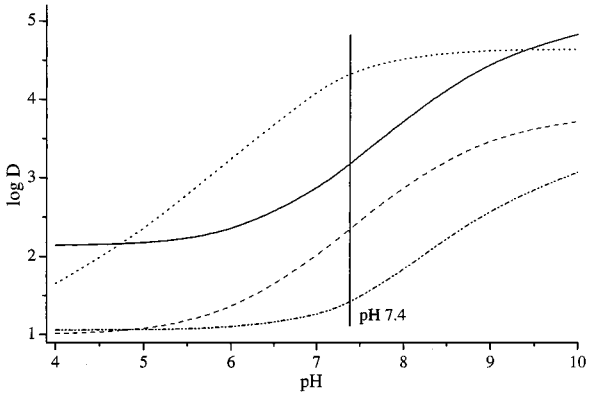

Figure 6—The pH-dependent distribution profile of four calcium channel antagonists; verapamil (dashed line), fendiline (solid line), amlodipine (dash/dotted line), nicardipine (dotted line).

pK_a value of the amino group of the piperazine ring is close to the physiological pH, the degree of protonation is relatively low compared with the monobasic drugs. The changes in lipophilicity of several drugs inspected that occurred during small changes in pH around 7.4 (Figures 5 and 6) were remarkable.

The pH-dependent distribution profiles of trifluoperazine and perphenazine shifted significantly to the curves of triflupromazine and promethazine (Figure 5). The order of the drugs (high to low values of log *P*) changed from triflupromazine = trifluoperazine > promethazine = perphenazine to trifluoperazine > perphenazine = triflupromazine > promethazine (high to low values of log *D* at pH 7.4). The phenothiazines containing a piperazine ring were more lipophilic at pH 7.4 than those with a dimethyl amino group. This result is in agreement with the pharmacological potency of the phenothiazine drugs because a replacement of the dimethyl amino group by a piperazine ring led to an increase of the neuroleptic power.

In Figure 6 the quite different pH-dependent distribution profiles of the structurally heterogeneous calcium channel antagonists verapamil, fendiline, amlodipine, and nicardipine are shown as a further example. The order of log *D* values at pH 7.4 (high to low values) was nicardipine > fendiline > verapamil > amlodipine. Fendiline and nicardipine had nearly the same log *P* values, but differed in their pK_a values. Therefore, the partitioning of nicardipine shifted to higher log *D* values over the whole pH range. As a consequence, the partitioning behavior became even more different at pH 7.4. This result illustrates that the choice of either of the partition or distribution coefficient can have a significant influence on the results of QSAR studies. The distribution coefficient should become more valuable than log *P* for many applications.

Conclusion

The pH−metric method is advantageous for the determination of pK_a values of ionizable compounds. The quality of the Yasuda−Shedlovsky extrapolation depends on the number of titrations performed and the concentrations and kind of cosolvent used. The pK_a values calculated from either dioxane or methanol cosolvent mixtures were in very good agreement in general, but the extrapolated pK_a was much less influenced by the cosolvent concentration in the case of dioxane. The log *P* measurements provided reliable and accurate partition coefficients of the neutral species and also of the corresponding ion. The pH-dependent partition profile can be obtained over the whole pH range investigated and should provide a better descriptor than log *P* for relationships between structure and distribution at physiological pH because it includes the contribution of the charged species to overall distribution. Although the studied data set is small, it can be concluded that the accuracy of log *P* calculation methods is not satisfactory for general use in QSAR analysis, because satisfying correlations were obtained only for selected subsets. None of the investigated programs showed a general superior performance. Therefore, calculation methods for log *P* without any experimental verification should be used with care.

A drawback of the popular *n*-octanol/water model system for the determination of the lipophilicity of drugs is, that it does not take into account specific ionic and hydrophobic interactions that can occur at an ordered interface like a membrane. Therefore, further studies to characterize and compare the distribution behavior in water/phospholipid systems are currently under way.

Abstract □ Liposomes have been used widely to improve the therapeutic activity of pharmaceutical agents. The traditional approach for such applications has been to formulate the pharmaceutical agent in liposomes prior to administration in vivo. In this report we demonstrate that liposomes exhibiting a transmembrane pH gradient injected intravenously (iv) can actively encapsulate doxorubicin in the circulation after iv administration of free drug. Small (110 nm) liposomes composed of phosphatidylcholine (PC)/cholesterol (Chol, 55:45 mol:mol) exhibiting a pH gradient (inside acidic) were administered iv 1 h prior to free doxorubicin, and plasma drug levels as well as toxicity and efficacy were evaluated. Predosing with egg PC/Chol pH gradient liposomes increased the plasma concentration of doxorubicin as much as 200-fold compared to free drug alone as well as to predosing with dipalmitoyl PC/Chol pH gradient liposomes or EPC/Chol liposomes without a pH gradient. The ability of the liposomes to alter the pharmacokinetics of doxorubicin was dependent on the presence of a transmembrane pH gradient and correlated with the extent of doxorubicin uptake into the liposomes at 37 °C in pH 7.5 buffer, indicating that doxorubicin was being actively accumulated in the circulating liposomes. This in vivo drug loading was achieved over a range of doxorubicin doses (5 mg/kg–40 mg/kg) and was dependent on the dose of EPC/Chol liposomes administered prior to free doxorubicin injection. The altered pharmacokinetic properties of doxorubicin associated with in vivo doxorubicin encapsulation were accompanied by a decrease in drug toxicity and maintained antitumor potency. These results suggest that pretreatment with empty liposomes exhibiting a pH gradient may provide a versatile and straightforward method for enhancing the pharmacological properties of many drugs that can accumulate into such vesicle systems at physiological temperatures.

Introduction

The developmental process for conventional liposomal anticancer drug formulations most typically includes studies where variations in the physical properties of the lipid carriers (size, lipid composition, and drug-to-lipid ratio) are evaluated in order to select the characteristics that provide optimized therapeutic and toxicity behavior. In addition, pharmaceutical criteria such as trapping efficiency, drug retention, and stability must be satisfied in order for these drug delivery systems to be considered clinically viable. The evolution of liposomal systems that could actively accumulate many lipophilic amine drugs in response to transmembrane ion gradients provided an avenue whereby these demands could be met (see refs 1−3 for review). The use of K^+, H^+, and $(NH_4)_2SO_4$ gradients resulted in liposomal anticancer drug formulations that could be loaded with trapping efficiencies approaching 100% at high drug-to-lipid ratios and for a wide variety of lipid compositions.[1−5] The most extensively studied drugs in this regard are the anthracycline anticancer agents doxorubicin and daunorubicin, both of which have obtained market approval in liposomal formulations.

Although transmembrane ion gradient liposomes have addressed many of the problems facing delivery vehicle-based drug formulations, maintaining the necessary physical and chemical stability properties for pharmaceutically relevant time periods (12−24 months) has still presented significant challenges. Retention of chemically intact drug inside the liposomes after the encapsulation procedure has remained the most problematic characteristic for liposomal formulations of doxorubicin and daunorubicin. This has resulted in formulations that either have a relatively limited shelf life,[6] utilize the transmembrane pH gradient to load the drug just prior to use at the hospital pharmacy[7] or have required extensive development of formulations with physical−chemical properties that will maintain the drug inside the liposomes for time periods beyond 1 year.[8] Clearly, any subsequent liposomal formulations of other drugs that use this encapsulation strategy will require significant characterization and development in this area prior to widespread clinical use.

Given that liposomes display low inherent toxicity and can remain intact in the blood stream over days post iv administration,[9−11] it may be postulated that vesicles with appropriate transmembrane ion gradients could accumulate drugs (those known to respond to these gradients in vitro) while circulating in the plasma compartment. If this could be accomplished, then one may predict that the in vivo loaded liposomes would engender pharmacological properties similar to those observed for drug encapsulated into liposomes prior to injection. This approach could significantly improve the versatility of liposome encapsulation applications, since a single formulation of empty ion gradient liposomes could be readily implemented in a variety of therapeutic applications once their inherent toxicity properties were established in initial Phase I clinical trials. In addition, information on the ability of empty ion gradient liposome to accumulate of drugs in vivo may be very useful in identifying potential interactions between systemic liposomal drug formulations and coadministered pharmaceutical agents.

For in vivo drug encapsulation to be pharmacologically effective, the liposomes would need to (1) retain their transmembrane ion gradient for extended times, (2) be constructed of lipid compositions that will allow membrane permeation and uptake of the drug at physiological tem-

peratures, (3) be present in the plasma at sufficient concentrations to completely sequester the subsequently administered drug without depleting the transmembrane ion gradient, and (4) rapidly accumulate drug in the plasma before distribution into tissues occurs upon iv drug injection. Data from previous studies suggest that small (approximately 100 nm diameter) egg phosphatidylcholine (EPC[1])/cholesterol (Chol) liposomes exhibiting a pH gradient (inside acidic, see references) may be well suited for such applications. Investigations have demonstrated that these liposomes can efficiently accumulate doxorubicin at physiological temperatures in vitro and, at appropriate doses, are retained for extended periods of time in the circulation.[2,9,12]

In the studies described here, we have evaluated the ability of EPC/Chol liposomes circulating in the plasma compartment to encapsulate doxorubicin administered iv in free form. The selection of doxorubicin for this investigation was based on its well characterized response to liposomes exhibiting a pH gradient as well as the extensive data available on the pharmacological properties of an EPC/Chol liposomal doxorubicin formulation in which the drug is encapsulated prior to in vivo administration.[2,9,12–14] These investigations demonstrate that empty pH gradient liposomes circulating in the central blood compartment can efficiently encapsulate subsequently injected free doxorubicin in a manner that provides improved in vivo activity comparable to that obtained for formulations where the drug is entrapped inside the liposomes prior to administration. The implications of this phenomenon with respect to its utility in favorably altering the pharmacology of drugs as well as potential drug–drug interactions that could arise from a wide range of therapeutic agents is discussed.

Materials and Methods

Materials—Egg PC and DPPC were purchased from Avanti Polar Lipids (Alabaster, AL) while cholesterol and all salts were obtained from Sigma Chemicals (St. Louis, MO). Adriamycin RDF was was obtained from Adria Laboratories (Mississauga, Ontario). Female DBA/2J mice were purchased from Jackson Laboratories (Bar Harbor, MA). Tritiated cholesteryl hexadecyl ether, a nonexchangeable, nonmetabolizable lipid used as a tracer for the liposomes, and ^{14}C-methylamine were purchased from NEN-Dupont (Mississauga, Ontario).

Production of Liposomes—Egg PC/Chol and DPPC/Chol liposomes were produced by lipid thin film hydration/extrusion methods described in detail previously.[15] Briefly, lipid mixtures consisting of EPC and cholesterol (55:45, mol %) were dissolved in $CHCl_3$ and subsequently concentrated to a homogeneous lipid film under a stream of nitrogen gas. The lipid film was placed under high vacuum for at least 4 h prior to hydration at room temperature (EPC/Chol) or 45 °C (DPPC/Chol) with 300 mM citrate buffer pH 4.0 to achieve a final lipid concentration of 100 mg/mL. The sample was frozen and thawed five times[16] before extruding 10 times through two stacked 100 nm pore size polycarbonate filters (Poretics) employing an extrusion device (Lipex Biomembranes, Inc., Vancouver, Canada). The resulting liposomes were sized by QELS using a Nicomp 270 submicron particle sizer operating at 632.8 nm. The liposomes exhibited a mean size distribution of approximately 110 nm. Transmembrane pH gradients were generated in the liposomal preparations prior to administration to mice by dialyzing the liposomes against 1000 volumes of 20 mM Hepes, 150 mM NaCl buffer overnight.

Plasma Clearance Studies—Female DBA/2J mice (18–22 g) were given a single bolus lateral tail vein injection of the indicated doses of liposomes. One hour later, free doxorubicin was injected via the tail vein at the indicated doses. At various times after free doxorubicin administration, mice (4 per group) were terminated by CO_2 asphyxiation. Blood was immediately removed by cardiac puncture and collected into an EDTA-coated microtainer tube. The sample was centrifuged at 500*g* in a clinical benchtop centrifuge for 10 min. Plasma was removed and placed into an eppendorf tube prior to analysis of lipid and/or doxorubicin.

Quantitation of Liposomal Lipid and Doxorubicin—Liposomal lipid was quantified by employing the nonexchangeable and nonmetabolizable lipid marker, ^{3}H-cholesteryl hexadecyl ether.[9] Upon animal termination plasma was assayed for lipid content. The samples (200 μL) were added directly to Pico-fluor 40, and radioactivity was determined by liquid scintillation counting.

Doxorubicin was quantified by a modified Bligh and Dyer based extraction assay as previously outlined.[9] Fifty μL of plasma was diluted to 0.8 mL with distilled H_2O. One hundred μL of 10% sodium dodecyl sulfate (SDS) and 100 μL H_2SO_4 (10 mM) were then added. Subsequently, doxorubicin was extracted into an organic phase following addition of 2 mL of chloroform/isopropyl alcohol (1:1, v/v). The mixture was vortexed vigorously and frozen at −20 °C overnight. After thawing and further vortexing, the samples were centrifuged at 1500*g* for 10 min at room temperature, and the organic phase was collected. The fluorescence of this phase was determined employing a Perkin-Elmer LS 50 B Luminescence Spectrometer with an excitation wavelength of 500 nm and emission wavelength of 550 nm. A standard doxorubicin curve was prepared in blank plasma employing an identical extraction procedure. Drug levels were estimated on the basis of doxorubicin fluorescent equivalents.

Sepharose CL4B gel filtration column separations were performed in order to confirm that doxorubicin, present in plasma containing pH gradient liposomes, was encapsulated inside these vesicles. This allowed for differentiation between free doxorubicin, doxorubicin associated with liposomes and doxorubicin associated with plasma proteins. A 1.5 cm × 18.5 cm Sepharose CL4B column was packed using 20 mM Hepes, 150 mM NaCl buffer, pH 7.5. The elution pattern of protein (plasma from untreated mice), free doxorubicin in plasma, doxorubicin encapsulated in EPC/Chol (55:45, mol/mol) liposomes, and liposomes containing doxorubicin was characterized by loading 200 μL of sample onto the column and collecting 0.6 mL fractions using a Gilson Micro Fractionator fraction collector. Protein content was determined using the Sigma Bicinchonic Acid Protein Assay. A protein standard curve was prepared from a stock bovine serum albumin solution. Two mL of protein determination reagent (4% copper(II) sulfate pentahydrate solution: bicinchoninic acid solution; 1:50, v/v) was added to both the standard curve samples and column fraction samples. Samples were incubated at 37 °C for 30 min, and absorbance was measured at 562 nm using a Beckman DU-64 spectrophotometer. Protein levels were determined by regression analysis of the standard curve. Lipid and doxorubicin were quantitated as described above. The gel filtration column was standardized for elution profiles of plasma (protein determination) and 100 nm liposomes as well as doxorubicin in buffer and plasma.

Once these elution patterns had been characterized, CD-1 mice (3/group) were given a 500 mg/kg bolus lateral tail vein injection of EPC/Chol (55:45, mol/mol) liposomes with or without a pH gradient. One hour later, free doxorubicin was injected via the tail vein at 20 mg/kg. One hour after free doxorubicin administration, the mice were terminated by CO_2 asphyxiation. Blood was removed and processed as previously above. Plasma samples from each group were pooled and run down the CL4B column. Fractions were collected and analyzed for lipid and doxorubicin as described above.

Determination of Transmembrane pH Gradient in Liposomes Recovered from Mouse Plasma—At various times after iv injection of pH gradient-bearing liposomes to DBA/2J mice, ^{14}C-methylamine was added to the collected plasma to achieve 0.1 μCi/mL. After 10 min incubations at room temperature, 150 μL samples were applied to 1 mL Sephadex G-50 spin columns[2] followed by 50 μL of Hepes/NaCl pH 7.5 buffer. The liposome-containing eluant fraction was collected, and aliquots from this fraction as well as the precolumn plasma samples were quantified for radioactivity by liquid scintillation counting. The transmembrane pH gradient was then determined by correlating the intravesicular and extravesicular methylamine concentration to transmembrane proton concentration gradients as described previously.[17]

Toxicity and Efficacy Studies—The toxicity of doxorubicin administered to mice injected 1 h previously with empty liposomes was assessed in dose range-finding studies using female DBA/2J mice. Mice were administered increasing doses of doxorubicin until either the weight loss nadir was greater than 20% or any mice died. Mice were monitored twice daily over 14 days for survival and signs of stress (ruffed coat, lethargy, impaired gait, etc.). The

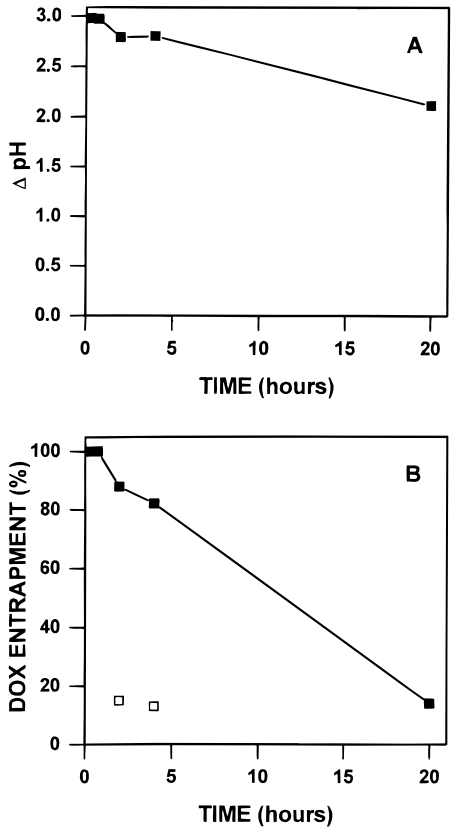

Figure 1—100 nm EPC/CHOL liposomes were administered IV to mice at a dose of 100 mg lipid/kg, and at the indicated times the liposomes recovered in the plasma were tested for residual pH gradient (panel A) and DOX trapping efficiency (panel B). Liposomes were administered exhibiting an internal pH of 3.0 (closed squares) or 7.5 (no pH gradient, open squares).

maximum tolerated dose of doxorubicin was defined as that where no deaths were observed and the body weight loss nadir was ≤15%. The L1210 ascites lymphocytic leukemia was utilized to determine the antitumor activity for the various treatment groups. In this model, 1×10^5 L1210 cells (maintained by serial passage in DBA/2J mice) were injected intraperitoneally in female DBA/2J mice (10/group) and iv doxorubicin treatment was initiated 24 h later (1 h after empty liposome iv injection, where indicated). Mice were then monitored twice daily for survival and weight loss/gain. The extent of antitumor activity was revealed as an increase in the survival time of treated mice relative to untreated mice (saline injections only). Comparisons were based on the percent increase in life span (%ILS) which was calculated as [(median survival time of treated mice ÷ median survival time of control mice) − 1] × 100. Statistical significance of differences between different groups was determined employing a two-tailed Wilcoxon ranking test.

Results

Initial experiments were designed to evaluate the ability of EPC/Chol liposomes to retain their transmembrane pH gradient in the blood compartment after iv injection and subsequently accumulate doxorubicin. These features are minimum criteria that must be met for the liposomes to be capable of altering the pharmacology of doxorubicin through in vivo drug encapsulation. Liposomes exhibiting a 3.5 unit pH gradient (pH 4.0 inside/7.5 outside) were injected iv at a dose of 100 mg total lipid/kg. At various times blood was harvested and the pH gradient of liposomes in the plasma was determined using ^{14}C-methylamine as described in Materials and Methods. As shown in Figure 1A, the EPC/Chol liposomes exhibited a pH gradient between 2.75 and 3.0 units over 4 h post administration. This pH gradient decreased to 2.0 units by 20 h.

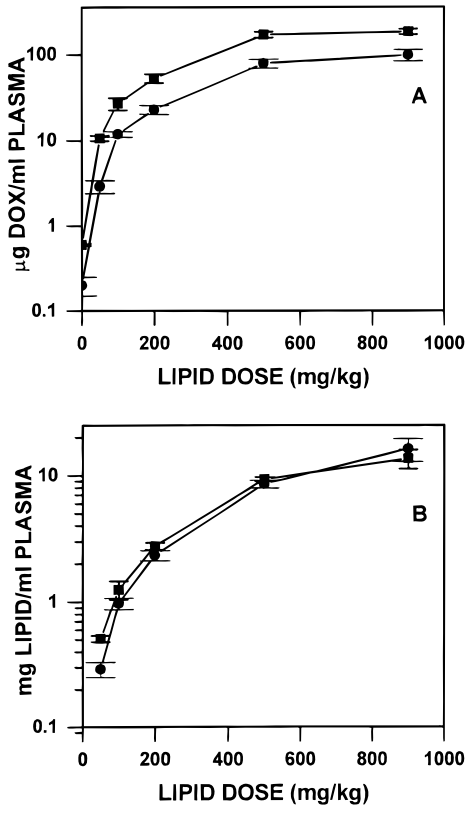

Figure 2—DOX (panel A) and lipid (panel B) concentrations in the plasma at 1 h (■) and 4 h (●) after administration of DOX at 20 mg/kg to mice pretreated with EPC/Chol pH gradient liposomes.

As a control, EPC/Chol liposomes exhibiting no pH gradient (pH 7.5 inside and outside) administered at 100 mg/kg yielded pH gradient measurements of approximately 0.5 units (data not shown). The basis of this small, nonspecific pH gradient appeared to reflect methylamine binding to either protein or lipoprotein components that coeluted with the liposomes during the gel filtration plasma processing step. Quantification of the liposomal lipid remaining in the plasma for pH gradient bearing liposomes at the dose of 100 mg/kg indicated that greater than 72%and 13% of the administered dose of liposomes remained in the circulation at 4 h and 20 h, respectively. Comparable lipid levels were observed for EPC/Chol liposomes in the absence of a pH gradient (data not shown).

Free doxorubicin was added to an aliquot of the liposome-containing plasma samples, and doxorubicin uptake into the vesicles was determined using the same gel filtration procedure as described for methylamine analysis. Liposomes obtained over the first hour after iv injection were able to encapsulate the doxorubicin with trapping efficiencies approaching 100% (Figure 1B). At the 2 h, 4 h, and 20 h timepoints, the efficiency of doxorubicin entrapment fell to 88%, 82%, and 14%, respectively. In contrast, EPC/Chol liposomes without a pH gradient provided doxorubicin entrapment levels that were approximately 10-fold lower than obtained for pH gradient bearing liposomal systems.

The data presented above suggest that optimal in vivo encapsulation of doxorubicin into EPC/Chol vesicles will be obtained when the doxorubicin is injected within 1 h of pH gradient-bearing liposome administration. Using this dosing schedule, the influence of liposome and doxorubicin dose was investigated in order to establish conditions that lead to optimized in vivo drug encapsulation and pharmacokinetic properties. In the first set of experiments, the dose of small (110 nm) EPC/Chol liposomes bearing a 3.5 unit pH gradient was varied from 50 mg/kg to 900 mg/kg. At 1

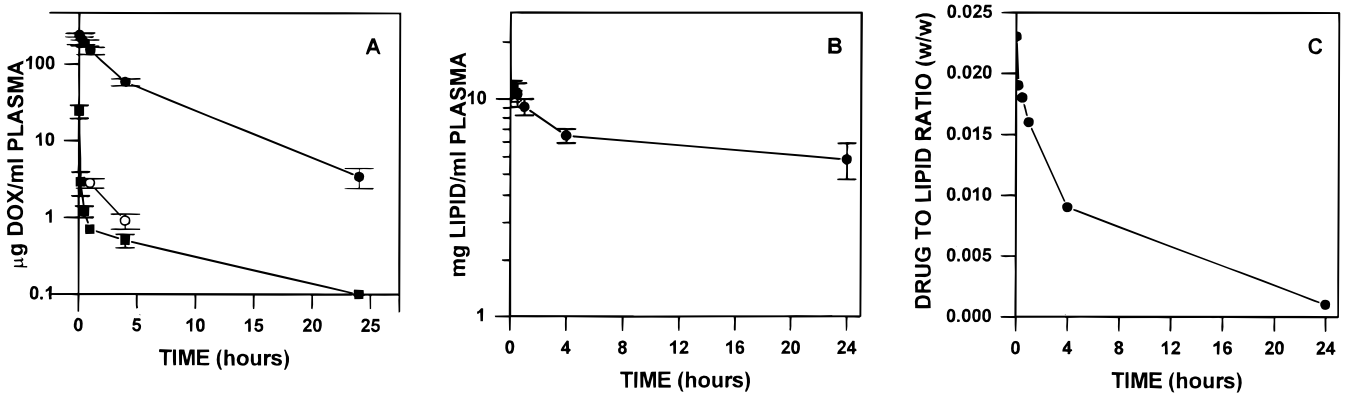

Figure 3—DOX (panel A) and liposomal lipid (panel B) plasma concentrations and circulating drug-to-lipid ratio (panel C) after administration of DOX in free form to mice in the absence (■) and presence (●) of a 500 mg/kg pretreatment dose of 100 nm EPC/CHOL liposomes.

h after iv liposome administration, doxorubicin was injected iv at a dose of 20 mg/kg. At a liposome dose of 50 mg/kg, the concentration of doxorubicin in the plasma was 17.6- and 14.5-fold higher than that observed for free doxorubicin injected in the absence of liposomes at 1 h and 4 h after drug administration, respectively (Figure 2A). Increases in the liposome dose led to increases in the concentration of circulating liposomes as well as the concentration of doxorubicin in plasma. Whereas the concentration of liposomes in the circulation increased proportional to the liposome dose between 50 and 1000 mg/kg for both 1 h and 4 h time points (Figure 2B), the concentration of doxorubicin in the plasma reached plateau levels at a liposome of 500 mg/kg (Figure 2A). At this dose of EPC/Chol pH gradient bearing liposomes, the circulating drug-to-lipid ratios (wt/wt) at 1 h and 4 h after 20 mg/kg doxorubicin injection were 0.02 and 0.01, respectively. Increasing the liposome dose further from 500 mg/kg to 1000 mg/kg resulted in a small increase in circulating doxorubicin concentrations from 170.9 +13.5 μg/mL to 184.8 ± 13.2 μg/mL.

A more detailed pharmacokinetic study was undertaken in order to characterize the effect of in vivo liposome encapsulation on the plasma elimination properties of doxorubicin. Mice were administered pH gradient-bearing EPC/Chol liposomes at a dose of 500 mg/kg 1 h prior to iv injection of 20 mg/kg doxorubicin. Mice were then sacrificed at various times postdrug injection, and their plasma was analyzed for doxorubicin and liposomal lipid as described in Materials and Methods. A comparison was made with doxorubicin injected iv at 20 mg/kg in the absence of any liposome pretreatment. As shown in Figure 3A, doxorubicin in the absence of liposomes is eliminated very rapidly from the circulation after iv injection, with a minimum of two distinct elimination phases. Within 2 min postinjection, >94% of the drug administered has been removed from the plasma and the level of drug eliminated increases to >99.7% within 30 min. In contrast, doxorubicin administered to mice pretreated with 500 mg/kg EPC/Chol pH gradient bearing liposomes is eliminated much more slowly, where <36% and <42% of the drug is removed from the plasma at 2 and 30 min after drug injection, respectively. The increases in doxorubicin concentration observed for mice pretreated with pH gradient liposomes compared to no pretreatment were 9.9-, 157.6-, 115.2-, and 35.0-fold at 2 min, 30 min, 4 h, and 24 h after doxorubicin administration, respectively. The corresponding 0−24 h trapezoidal area under the curve (AUC) values calculated using all time points were 5.5 μgh/mL for doxorubicin alone and 408.8 μgh/mL for doxorubicin in mice pretreated with 500 mg/kg EPC/Chol liposomes which reflected a 74.3-fold increase in total doxorubicin exposure in the plasma. Pretreatment with empty EPC/Chol liposomes prepared without a pH gradient (pH 7.5 inside and outside) at 500 mg/mL resulted in circulating doxorubicin levels that were comparable to those observed with free doxorubicin alone (Figure 3A). In addition, pretreatment with pH gradient-bearing liposomes composed of DPPC/Chol (55:45 mol %) provided circulating doxorubicin concentrations that were <10% of those obtained with EPC/Chol liposomes at 1 h and 4 h after drug administration (data not shown).

Although the plasma doxorubicin concentration in mice pretreated with EPC/Chol liposomes decreased from 237.4 ± 12.3 μg/mL at 2 min postinjection to 3.4 ± 1.5 μg/mL at 24 h (70-fold reduction), the circulating liposomal lipid levels over this time period decreased by only 2-fold from 10.4 ± 0.7 mg/mL to 5.3 ± 1.0 mg/mL (Figure 3B). As a result, the circulating drug-to-lipid ratio for this treatment group decreased from an initial (2 min) value of 0.023:1 (wt/wt) to a value of 0.0006:1 at 24 h (Figure 3C). This drug release (as defined by changes in the drug-to-lipid ratio) followed first-order kinetics and led to a reduction of the circulating drug-to-lipid ratio by 63% within 4 h and 97.4% within 24 h. These results suggest that the circulating liposomes initially accumulate the doxorubicin after it is injected iv and then slowly release the drug subsequently while remaining in the central blood compartment.

The fact that increased doxorubicin concentrations in plasma were obtained only when EPC/Chol liposomes exhibiting a pH gradient (inside acidic) were utilized as a pretreatment before free doxorubicin administration strongly suggested that doxorubicin was being actively sequestered inside the liposomes in response to the pH gradient. This was confirmed by chromatographing plasma from mice treated with EPC/Chol liposomes either with or without a pH gradient (500 mg/kg) and 20 mg/kg free doxorubicin on a Sepharose CL4B column (Figure 4). This resulted in the separation of liposomes (and entrapped doxorubicin) from plasma proteins and free drug. The column was first calibrated for elution profiles of empty liposomes, plasma protein content, and doxorubicin incubated in plasma. Liposomes were readily separated from plasma proteins and free doxorubicin, and it was observed that >90% of doxorubicin in plasma was recovered in the included volume of the column (Figure 4). When plasma obtained 1 h after doxorubicin injection to EPC/Chol liposome (with pH gradient) pretreated mice was applied to this column, >95% of the liposomal lipid and doxorubicin detected was recovered in the liposome fraction. Due to the very low doxorubicin concentrations in plasma after pretreatment with empty EPC/Chol liposomes without a pH gradient, doxorubicin could not be detected in any of the elution fractions (data not shown). It should be noted, however, that lipid concentrations for this treatment group were

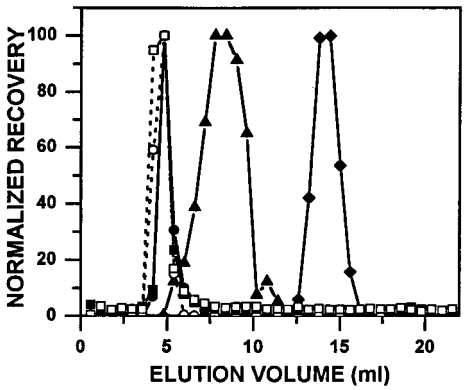

Figure 4—Sepharose CL4B elution profiles for liposomes and doxorubicin incubated in plasma (solid lines) or plasma from mice administered 500 mg/kg pH gradient-bearing EPC/Chol liposomes followed 1 h later by 20 mg/kg free doxorubicin (dashed lines). Elution fractions were analyzed for protein (▲), doxorubicin (◆), liposomal lipid for pre-encapsulated EPC/Chol doxorubicin (●), and doxorubicin pre-encapsulated in EPC/Chol pH gradient liposomes (■) to calibrate the elution positions of the various components. Doxorubicin (○) and liposomal lipid (□) were analyzed from mouse plasma following iv administration of 100 nm EPC/CHOL liposomes containing a pH gradient and free doxorubicin.

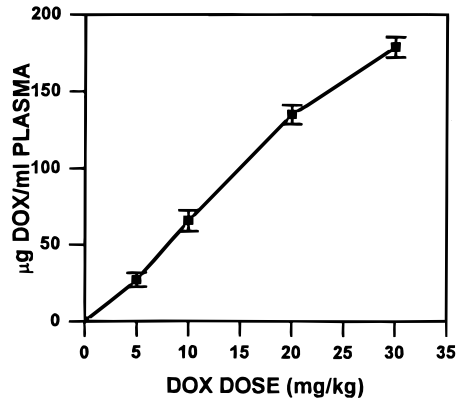

Figure 5—Pretreatment with 100 nm empty pH gradient EPC/CHOL liposomes was administered iv at 500 mg lipid/kg, and plasma DOX concentrations were determined at 4 h after free DOX administration iv at the indicated doses.

identical to those for pH gradient bearing liposomes and all of the liposomal lipid was recovered in the liposome elution volume.

In addition to altering the dose of pH gradient-bearing liposomes, the dose of doxorubicin administered after the liposome pretreatment was manipulated in order to determine the drug–dose dependence of the liposome induced pharmacokinetic changes. As shown in Figure 5, increasing the doxorubicin dose from 5 mg/kg to 30 mg/kg increased the plasma concentration of drug 4 h post iv injection from 27.1 ± 4.6 μg/mL to 178.8 ± 6.6 μg/mL. This increase was proportional to the doxorubicin dose where the percent administered doxorubicin recovered in the plasma at 4 h remained relatively constant (range of 29% to 35%) over a 6-fold range of drug dose. These results indicate that the doxorubicin pharmacokinetic alterations induced by pH gradient-bearing EPC/Chol liposomes are dose independent with respect to doxorubicin over the range studied here.

The biological activity evaluation of the in vivo drug encapsulation strategy described above was performed in order to correlate the changes in doxorubicin pharmacokinetics induced by pH gradient liposome pretreatment with toxicity and efficacy properties. These characteristics were also compared to treatment with free drug alone as well as doxorubicin administered in traditional liposomal formulations where the drug is encapsulated prior to use.

Table 1—Effect of In Vivo Liposomal Capture on Doxorubicin Toxicity[a]

group	DOX dose (mg/kg)	weight loss nadir (%)	toxicity-related mortality
free DOX	20	16	0/6
	25	26	2/6
	30	NA	6/6
preloaded	20	2	0/6
liposomal DOX	30	15	0/6
	40	NA	6/6
in vivo capture	20	5	0/6
liposomal DOX	30	16	0/6
	40	NA	6/6

[a] Preloaded liposomal DOX was prepared by entrapping DOX into 100 nm EPC/Chol liposomes exhibiting a 3.5 unit transmembrane pH gradient (inside acidic). In vivo capture DOX was performed by pretreating DBA-2J mice iv with empty pH gradient bearing EPC/Chol liposomes 1 h before iv injection of free DOX. NA: not applicable since animals died and nadirs cannot be accurately determined.

Table 2—Therapeutic Efficacy of Doxorubicin in Free Form, Preloaded Liposome Encapsulated Form and in Vivo Liposomal Capture Form against L1210 Murine Ascitic Leukemia Model[a]

group	dose (mg/kg) lipid	dose (mg/kg) DOX	median survival time (days)	60-day survival	%ILS
saline control	–	–	11.0	0/6	–
liposomes alone	500	0	10.5	0/6	–5
free DOX	0	10	18.5	1/12	68
	0	20	29.0	1/12	164
preloaded	50	10	19.5	0/6	77
liposomal DOX	100	20	31.0	1/6	182
in vivo capture	500	10	19.0	0/6	73
liposomal DOX	500	20	28.5	1/6	159

[a] Preloaded liposomal DOX was prepared by entrapping DOX into 100 nm EPC/Chol liposomes exhibiting a 3.5 unit transmembrane pH gradient (inside acidic). In vivo capture DOX was performed by pretreating tumor-bearing mice iv with empty pH gradient bearing EPC/Chol liposomes 1 h before iv injection of free DOX.

The results shown in Table 1 demonstrate that free doxorubicin administered iv to mice in the absence of a liposomes pretreatment exhibits signs of drug toxicity at doses of 20 mg/kg and higher. The occurrence of weight loss nadirs in excess of 20% as well as toxicity-related mortality at 25 mg/kg and above indicated a maximum tolerated dose of 20 mg/kg for this treatment group. In comparison, administration of free doxorubicin to mice pretreated with 500 mg/kg EPC/Chol pH gradient liposomes provided minimal weight loss at 20 mg drug/kg and a weight loss nadir of 16% with no mortality over 14 days was observed at 30 mg/kg (Table 1). However, increasing the doxorubicin dose to 40 mg/kg in pretreated mice resulted in 100% mortality. The dose response for doxorubicin toxicity (manifested by weight loss and mortality) observed in the group pretreated with empty pH gradient-bearing liposomes was very comparable to that obtained for doxorubicin entrapped inside 100 nm EPC/Chol liposomes using the pH gradient entrapment procedure just prior to in vivo administration (Table 1).

The antitumor activity of doxorubicin in mice pretreated with pH gradient-bearing EPC/Chol liposomes was evaluated in the murine L1210 ascites tumor model and compared with free doxorubicin alone as well as conventional liposomal doxorubicin encapsulated in pH gradient liposomes prior to injection. The results shown in Table 2 demonstrate that empty liposomes administered iv at a dose of 500 mg lipid/kg did not provide any antitumor activity compared to the saline treated control group. Free doxorubicin administered iv at 10 mg/kg and 20 mg/kg in

the absence of liposome pretreatment increased the median survival time to 18.5 days and 29.0 days, respectively. These survival times reflected increase in life span (ILS) values of 68% and 164% respectively, and one long-term survivor was observed in each treatment group. Administration of doxorubicin as either the EPC/Chol liposomal formulation (prepared prior to use) or as free drug in mice pretreated with EPC/Chol pH gradient-bearing liposomes provided equivalent antitumor activity as free doxorubicin alone. Median survival times for the conventional EPC/Chol liposomal doxorubicin formulation reflected ILS values of 77% and 182% at drug doses of 10 mg/kg and 20 mg/kg while the group receiving pretreatment with empty EPC/Chol pH gradient-bearing liposomes exhibited ILS values of 73% and 159% at 10 mg/kg and 20 mg/kg, respectively (Table 2). One long-term survivor was observed at the 20 mg/kg drug dose for both groups using liposomes. In all treatment groups, the 20 mg/kg drug dose levels were statistically more therapeutically active than 10 mg/kg ($p < 0.05$); however, no statistical significance could be established between groups treated with different formulations for a given doxorubicin dose.

Discussion

The use of liposomal carriers to improve the therapeutic activity of a variety of pharmacological agents in clinical settings has well established this technology as a viable and important approach in the design of pharmaceutical formulations. Early examples of the benefits of liposome encapsulation came primarily from their ability to decrease drug exposure to healthy, susceptible tissues which led to reductions in target organ toxicities.[2,12,18–21] Subsequently, it became apparent that liposomes also exhibit preferential accumulation into disease sites such as tumors and areas of infection/inflammation, thus providing increased selectivity for disease tissue and improved therapeutic index.[22–24] Various combinations of these properties have been utilized in clinically approved liposomal formulations for drugs such as doxorubicin, daunorubicin, and amphotericin B. For all of these liposomal formulations, a key feature that was important in obtaining regulatory approval was the reduced toxicity compared to their free (nonencapsulated) drug counterparts. This buffering of toxicity allows increased doses to be employed without compromising antitumor potency, thus improving the drug's therapeutic index. For the drugs cited above, many of the toxicities to healthy tissues have been associated with early stage drug distribution phases. Consequently, it is believed that the dramatic reduction of free drug exposed to susceptible tissues after administration of the liposomal formulations is largely responsible for the toxicity buffering effects.

The results presented here not only demonstrate that pH gradient bearing EPC/cholesterol liposomes are capable of encapsulating doxorubicin while circulating in the central blood compartment, but that this entrapment process is very efficient in sequestering free doxorubicin before the drug distributes into tissue compartments throughout the body. This is revealed by the fact that at a liposome pretreatment dose of 500 mg/kg, the amount of doxorubicin in the plasma reflects approximately 50% of the administered drug dose. This is comparable to the results observed previously for EPC/cholesterol liposome formulations with pre-encapsulated doxorubicin where approximately 50% of the entrapped drug is released from the liposomes over the first hour after iv injection.[2] It should be noted, however, that the lipid dose required to achieve this effect is 50-fold higher when pretreatment with empty pH gradient EPC/cholesterol liposomes is employed. Nonetheless, it is striking that the accumulation of doxorubicin into liposomes exhibiting a pH gradient can preempt the early phase distribution of free doxorubicin since >98% of free drug is eliminated from the plasma within 5 min of iv administration in the absence of any liposome pretreatment.

In vivo liposome entrapment of doxorubicin was shown here to be dependent on the presence of a transmembrane pH gradient (inside acidic) as well as low phase transition temperature phospholipid compositions. This indicates that the increased plasma doxorubicin concentrations observed in the presence of liposome pretreatment reflect drug that has been actively sequestered inside the liposomes in response to a pH gradient rather than simple passive partitioning of doxorubicin into the bilayer. Such conclusions are based on the fact that high doses of empty EPC/cholesterol liposomes exhibiting no pH gradient (pH 7.5 inside and outside) did not result in elevated plasma doxorubicin concentrations. In addition, the fact that minimal pharmacokinetic alterations were obtained with DPPC/cholesterol liposomes bearing a pH gradient suggests that doxorubicin uptake into such vesicles is relatively slow at 37 °C,[4] and free doxorubicin may be expected to distribute into tissue compartments prior to accumulation into the liposomes under these conditions. It should be pointed out that although the in vivo drug uptake phenomenon described here was accomplished using a pH gradient, alternate transmembrane ion gradients resulting in membrane potentials sufficient to drive drug accumulation could also provide similar effects.[1,4,5] Indeed, the presence of a transmembrane pH gradient in itself generates a membrane potential that would be expected to facilitate doxorubicin uptake.

Pretreatment with empty EPC/cholesterol liposomes that exhibit a pH gradient provides similar buffering of toxicity effects as EPC/cholesterol liposomes in which doxorubicin has been encapsulated prior to administration. This observation suggests that in vivo entrapment may represent a viable alternative to delivering doxorubicin in preencapsulated form. This approach would have clear advantages regarding problems related to chemical stability and liposome retention integrity that are experienced with traditional liposome entrapped formulations. Further, given that several other cancer chemotherapeutic agents such as other anthracyclines and vinca alkaloids[6,7,25–26] as well as drugs from a wide range of therapeutic classes can be efficiently loaded into liposomes displaying a pH gradient,[27] pretreatment with empty liposomes to improve therapeutic activity could be readily applied and evaluated in a variety of pharmaceutical applications. The pH gradient bearing liposomes may also be capable of favorably altering the pharmacokinetic and toxicity properties of combinations of drugs that can be sequestered into liposomes in response to a pH gradient. This is an important feature for many anticancer treatment regimens where combinations including anthracyclines and vinca alkaloids are often utilized. As such, these studies reveal the therapeutic potential of a novel application of pH gradient bearing liposomes.

A more direct and current application of the results obtained here concerns the potential for preloaded liposomes that exhibit transmembrane ion gradients (such as those employed for clinically used formulations of liposomal doxorubicin, daunorubicin, and vincristine) to sequester additional coadministered drugs in the circulation. This could have significant implications, either adverse or beneficial, on the pharmacology of the sequestered agents. Further, in vivo accumulation of additional agents into preloaded liposomes could affect the retention of the primary encapsulated drug (e.g. doxorubicin, daunorubicin, or vincristine) if the transmembrane ion gradient is altered.

This suggests that increased attention should be given to the pharmacology of relevant coadministered drugs when these types of liposome formulations are administered systemically.

Demonstration of the Terms Enantiotropy and Monotropy in Polymorphism Research Exemplified by Flurbiprofen

JAN-OLAV HENCK* AND MARIA KUHNERT-BRANDSTATTER

Contribution from *Institut für Pharmakognosie der Universität Innsbruck, Josef-Moeller-Haus, Innrain 52, A-6020 Innsbruck, Austria.*

Received May 5, 1998. Accepted for publication October 8, 1998.

Abstract □ The thermodynamic terms enantiotropy and monotropy are demonstrated by means of solid-state analytical results of polymorphous flurbiprofen (FBP). Vibrational spectra, differential scanning calorimetry (DSC), and thermomicroscopy investigations as well as X-ray powder patterns for three modifications of FBP are described. The melting points are mod. I 113–114 °C (enthalpy of fusion 27.9 ± 0.2 kJ mol^{-1}) for modification I (mod. I), 92 °C for mod. II, and 87 °C for mod. III. The true densities of mod. I (1.279 ± 0.001 g cm^{-3}) and mod. II (1.231 ± 0.002 g cm^{-3}) were measured at 25 °C. Modification I (commercial product) is the thermodynamically stable crystal form from absolute zero to its melting point. Modification II was crystallized on a gram scale from a warm saturated solution of FBP in *n*-heptane and rapid cooling of the solution to –18 °C. Modification I is monotropically related to mod. II and mod. III, due to application of the density rule and the entropy-of-fusion rule. The thermodynamic relationships between the three modifications are demonstrated by a semischematic energy/temperature diagram. Theoretical vapor pressure/temperature diagrams and energy/temperature diagrams are compared and briefly discussed.

Introduction

Compared with mineralogy and metallography, pharmacy was relatively slow to deal with the terms enantiotropy and monotropy, which are very important in crystal polymorphism research. Even today, some authors working in this area seem to have great trouble with these terms, as has been shown by recent publications in respected journals on chloramphenicol palmitate[1] and flurbiprofen.[2] Two pharmaceutically relevant modifications, mod. I (A) and mod. II (B), are of particular interest in the case of chloramphenicol palmitate. The lower melting form II is pharmacologically active and is used in suspensions, whereas form I is inactive as an antibiotic.[3] The reason for the loss of activity of suspensions of the drug substance is that mod. II is thermodynamically unstable under ambient conditions and, due to its better solubility, this crystal form slowly recrystallizes into mod. I in suspensions.

From the many papers about the polymorphism of chloramphenicol palmitate only the one published by Burger[4] will be mentioned here because it also contains a critical review of earlier contributions. Due to the differences in solubility (thermodynamically unstable modifications exhibit better solubility than the thermodynamically stable one at a given temperature) and the differences in the enthalpy of fusion (unstable modifications show a lower enthalpy of fusion than the stable one in a monotropically related system) it is obvious, that mod. II is thermodynamically unstable in relation to mod. I from absolute zero up to its melting point (mp); that is, mod. I and mod. II are monotropically related. This fact was denied by the cited authors[1] and they postulated enantiotropy in this case because they succeeded in obtaining mod. II by quenching and recrystallizing the melt of mod. I. This mistake obviously happened because these authors[1] are unaware of the fact that the terms enantiotropy and monotropy are related to the direct transition between two crystalline phases; that is, that solid−solid transitions occur and intervening melting processes are excluded. The term "enantiotropy" was chosen by Lehmann[5] because it refers to a reversible process in the solid state, whereas the converse "monotropy" implies that the transition can occur in one direction only. Furthermore, it seems that the authors[1] are not familiar with the fact that for more than 100 years, one of the most common methods to obtain polymorphic modifications is crystallization of supercooled melts. Of course, nature has used this method thousands of years ago to create polymorphic modifications of minerals and chemical elements. It is a matter of fact that the method of crystallizing mod. II out of the melt of mod. I using differential scanning calorimetry (DSC) has been successfully tested on numerous drugs.[6] Because the authors of the second paper[2] just mentioned were not quite sure whether the two modifications of flurbiprofen described by them are enantiotropic or monotropic ("probable enantiotropic transition of form II into form I"), we decided to check the polymorphism and found a third modification as well. With this new result it is possible to explain most of the apparent discrepancies.

It is a general question in pharmacy whether polymorphic modifications can transform reversibly (enantiotropy) or irreversibly (monotropy) at atmospheric pressure, because polymorphic crystal forms of a specific chemical compound have different physical properties caused by different arrangements of the molecules in the crystal lattice. These different characteristics often lead to considerable differences in grinding and compression behavior as well as in hygroscopicity, solubility, and bioavailability, etc. All these properties are of great importance for the production of pharmaceutical formulations. Using a thermodynamically unstable modification in the production of tablets, creams, suspensions, solutions, etc. is sometimes the reason why unwanted changes take place in such formulations after a time of storage, caused by transition into the room temperature, thermodynamically stable modification. In the worst case, as shown by the case of chloramphenicol palmitate, this transition may lead to a complete loss of activity of the drug substance. On the other hand it is possible, to apply thermodynamically unstable modifications intentionally, to take advantage of very special properties. There are thermodynamically unstable modifications known, which turned out to have a consider-

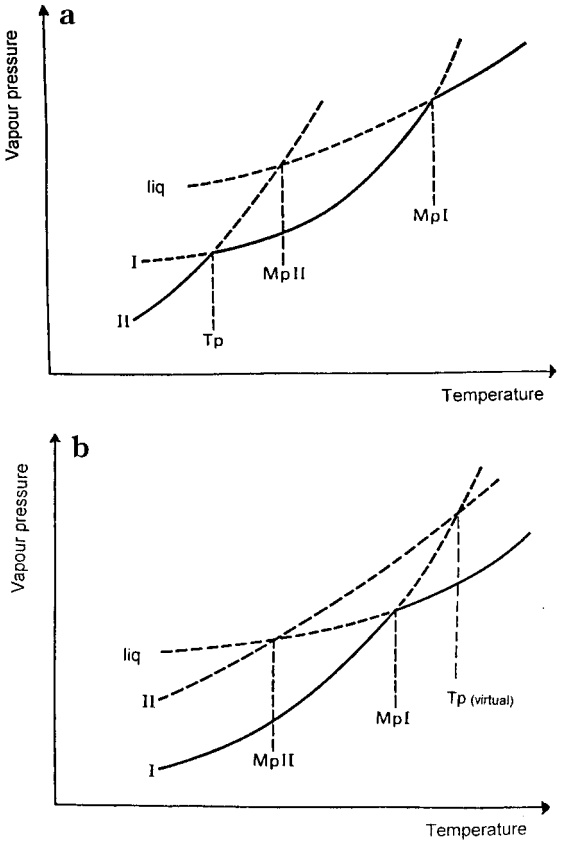

Figure 1—(a) Vapor pressure/temperature diagram: enantiotropy (*Mp*, melting point; *Tp*, thermodynamic transition point). (b) Vapor pressure/temperature diagram: monotropy (*Mp*, melting point; *Tp (virtual)*, thermodynamic transition point).

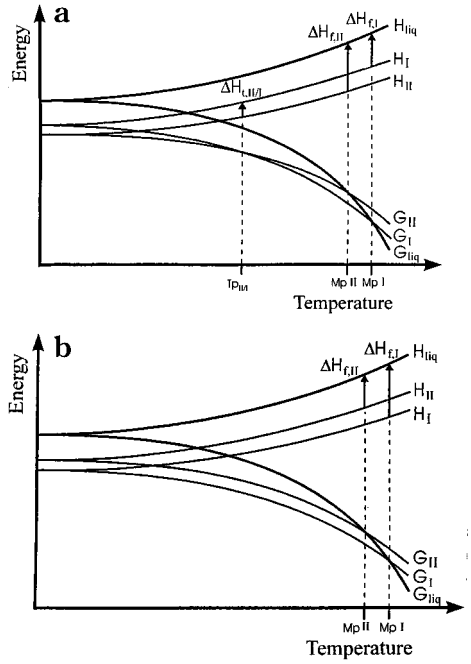

Figure 2—(a) Energy/temperature diagram: enantiotropy (*G*, free energy; *H*, enthalpy; ΔH_f, enthalpy of fusion; *liq*, melt; *Mp*, melting point; *Tp*, thermodynamic transition point; ΔH_t, enthalpy of transition). (b) Energy/temperature diagram: monotropy (*G*, free energy; *H*, enthalpy; ΔH_f, enthalpy of fusion; *liq*, melt; *Mp*, melting point).

able kinetic stability and show a very low transition tendency, if kept dry. Such modifications are called metastable and they may be enantiotropic or monotropic. One example is piracetam, where mod. II and mod. III appeared to show equivalent thermodynamic stability. Only after stirring a suspension of both forms in dioxane did the enantiotropic transition of the metastable and thermodynamically unstable mod. II into mod. III take place.[7]

Because of the increasing spread of generics, more drugs are appearing that exhibit different crystal forms. Often, their stability relationships need to be explained. One example should be mentioned here: 17 different samples of piroxicam supplied by eight pharmaceutical companies were investigated for polymorphism at the Instituto National de Medicamentos (Buenos Aires, Argentina). It was shown that some of the samples contained the pure β form (mod. I), some the 2 °C lower melting pure α form (mod. II), and some contained mainly the α or β form contaminated with the other polymorph.[8] The two forms are monotropically related.

The difference between enantiotropy and monotropy was defined by Ostwald[9] more than 100 years ago using a vapor pressure/temperature diagram, which was brought close to students for decades in standard textbooks of physical chemistry. The difference between enantiotropy and monotropy is defined by the position of the vapor pressure curves. In the case of enantiotropy, the vapor pressure curves intersect below the melting points, whereas in the case of monotropy, the intersection is above the melting points. The intersection point of two vapor pressure curves is the thermodynamic transition point (tp). Therefore the difference between enantiotropically and monotropically related modifications is based on the relative position of the melting points and tp. In an enantiotropic system, the two modifications of interest are in equilibrium at tp and the transition can take place in either direction depending on the temperature (Figure 1a). On the other hand, the tp is virtually in a monotropic system; therefore, the transition can only occur in one direction from the unstable to the stable form. (Figure 1b). The crystal form that shows the lowest vapor pressure at any temperature is the most thermodynamically stable one. The condition for validity of this rule is constant pressure (atmospheric pressure).

The semischematic energy/temperature diagram[10,11] (*E*/*T* diagram), which is based on the Gibbs function, offers more information than the vapor pressure/temperature diagram. For a detailed discussion on the construction and interpretation of *E*/*T* diagrams in general, refer to the literature.[10,11] To draw the *E*/*T* diagram, the isobars of the Gibbs free energy *G* and of the enthalpy *H* of (at least) two modifications, I and II, as well as of the melt *liq* are related to each other. At a given temperature, the thermodynamically stable modification has the lowest Gibbs free energy. Figure 2a represents a given enantiotropically related system of two modifications. Modification II shows the lowest Gibbs free energy until the tp is reached and is therefore thermodynamically stable from absolute zero up to tp. Beyond tp, the Gibbs free energy of mod. II is larger than for mod. I; therefore, this mod. II is thermodynamically unstable from tp up to its mp. At tp, mod. I and mod. II have equal Gibbs free energy and equal thermodynamic stability. The two modifications are enantiotropically related. ΔH_t represents the enthalpy of transition for the transformation II/I and ΔH_f the enthalpy of fusion for mod. II and mod. I, respectively.

Figure 2b describes the relations in a monotropic system. Modification II shows a larger Gibbs free energy than mod. I and is therefore thermodynamically unstable compared with mod. I from absolute zero up to its mp. There is no tp in this temperature region, but a transition in the solid state of mod. II into mod. I is possible; however, never the reverse transition.

Table 1—Flurbiprofen: Important Physicochemical Parameters of the Modifications

parameter	mod. I	mod. II	mod. III
preparation	crystallization from given solvent at 20 °C	crystallization from *n*-heptane, rapid cooling to –18 °C	crystal film
Mp [°C] DSC–onset	114.5	91[a]	—[e]
thermomicroscopy	113–114	92	87
enthalpy of fusion [kJ mol^{-1}]	27.9 ± 0.2[c]	—[e]	25[b]
enthalpy of transition [kJ mol^{-1}] to mod. I		—[e]	–2.9 ± 0.4
entropy of fusion [J mol^{-1} K^{-1}]	72.0[d]	—[e]	69.4[d]
measured density [g cm^{-3}]	1.279 ± 0.001[c]	1.231 ± 0.002[c]	—[e]

[a] Incongruent melting. [b] Calculated by heat-of-fusion rule:[10] $\Delta H_{f,III} = \Delta H_{f,I} + \Delta H_{t,III\rightarrow I}$. [c] ±95% CI. [d] Calculated by entropy-of-fusion rule:[11] $\Delta S_f = \Delta H_f/T_m$. [e] Not determined.

The heat physicists and mineralogists of the turn of this century were well aware of the fact that enantiotropic transition of the modification that is thermodynamically stable below tp into the higher temperature stable one is an endothermic process. On the other hand, the crystal form that is thermodynamically stable above tp shows an exothermic transition if cooled well below tp. Also it was very well-known that a monotropic transition is an exothermic process.[12] This knowledge, in connection with results using the DSC method, was laid down in modern literature as the **heat-of-transition rule**.[10]

Experimental Section

Materials and Solvents—The studies of flurbiprofen (FBP) INN [2-(2-fluorobiphenyl-4-yl) propionic acid; $C_{15}H_{13}FO_2$, M_r, 244.3] were carried out using the commercial product (mod. I) provided by Profarmaco Nobel (Italy). Modification II was obtained by rapid cooling of a warm saturated solution of FBP in *n*-heptane (analytical grade) to −18 °C. Modification III was obtained by quenching a melt film of flurbiprofen to 20 °C on a metal block. Afterward, heating the liquid amorphous material to 30 °C leads to crystallization of mod. III.

Thermoanalytical Methods—*Polarized thermomicroscopy*[13,14] was performed using a Kofler hot stage microscope (Thermovar, Reichert, Vienna, Austria). To prepare a crystal film, ca. 2 mg of FBP were heated between a microscope slide and a cover glass using a Kofler hot bench (Reichert, Vienna, Austria). The molten film was quenched to 20 °C using a metal block. To determine the melting points of mod. II and mod. III the hot stage was preheated to 85 °C. A crystal film preparation containing the two modifications was watched immediately after being placed onto the hot stage. The heating rate was 2 or 5 K min^{-1}. The *solubility test for stability relationships*[15] is made by carefully loosing the cover slip over a crystal film containing the three modifications and touching a drop of solvent to its edge so that the solvent flows in under the cover slip. The solvent must not be so good that the entire film is dissolved away. In the case of FBP, ethanol (70%) was used.

Differential scanning calorimetry (DSC) was carried out with a DSC-7 and Pyris software for Windows NT (Perkin-Elmer, Norwalk, CT) using perforated aluminum sample-pans (25 μL). Sample masses for quantitative analysis were 1−3 (±0.0005) mg (Ultramicroscales UM3, Mettler, CH-Greifensee, Switzerland). Nitrogen 99.990% (20 mL min^{-1}) was used as the purge gas. Calibration of the temperature axis was carried out with benzophenone (mp, 48.0 °C) and caffeine (mp, 236.2 °C). Enthalpy calibration of the DSC signal was performed with indium 99.999% (Perkin-Elmer, Norwalk, CT). The normal heating rate was 2 or 5 K min^{-1}.

Spectroscopic Methods—*Fourier transform infrared (FTIR) spectra* were recorded with a Bruker IFS 25 FTIR spectrometer (Bruker Analytische Meβtechnik GmbH, Karlsruhe, Germany) connected to a Bruker FTIR microscope (15 × Cassegrain-objective and visible polarization). Samples were scanned as potassium bromide pellets at an instrument resolution of 2 cm^{-1} (50 interferograms, internal mode). For recording microscope spectra,[16] small samples were rolled on a round zinc selenide window (13 mm diameter x 1 mm thickness) or a crystal film was made between two zinc selenide windows. The spectral resolution is 4 cm^{-1} (focus diameter 50 μm, 100 interferograms).

FT-Raman spectra were recorded with a Bruker RFS 100 FT-Raman spectrometer (Bruker Analytische Meβtechnik GmbH, Karlsruhe, Germany) equipped with a diode pumped 100 Nd:YAG Laser (1064 nm) as excitation source and a liquid nitrogen-cooled high-sensitivity detector (64 scans at 4 cm^{-1} instrument resolution).

X-ray powder diffraction patterns were obtained on a Siemens D-5000 X-ray diffractometer equipped with Θ/Θ-Goniometer (Siemens AG, Karlsruhe, Germany) using monochromatic Cu Kα radiation (tube voltage 40 kV, tube current 40 mA) from 2 to 40° 2Θ at a rate of 0.005° 2Θ s^{-1}. The diffractometer was fitted with a Göbel mirror and a scintillation counter. The single-crystal data for mod. I (data from Flippen and Gilardi[17]) were used to calculate the idealized X-ray powder pattern for a Cu Kα radiation with the program *PowderCell for Windows* (Kraus, W.; Nolze, G. PowderCell for Windows (V 1.0), *Program for manipulation of crystal structures and calculation of X-ray powder patterns*; Federal Institute for Materials Research and Testing: Berlin, Germany, 1997).

Density Measurements—The determination of the powder volumes were carried out with an air comparison pycnometer (Ultrapycnometer 1000, Quantachrome Corp., Syosset, NY) provided with a small sample cell at 25 °C. The samples (2−3 ± 0.0005 g) were purged with helium for 15 min. Calibration was carried out with a steel sphere.

Results

Thermomicroscopy—A melt film of FBP quenched on a metal cooling block (20 °C) and afterward heated (heating rate: 5 K min^{-1}) on the polarizing hot stage microscope leads to gray quadrangles and hexagons of mod. III (ca. 30 °C) and varicolored columnar aggregates and spherulites of mod. II (ca. 45 °C) and mod. I (ca. 45 °C). According to its morphology, mod. III differs considerably compared with the other crystal forms, whereas mod. I and mod. II are very similar. Continued heating leads to the transition of mod. III into mod. II and to the transition of mod. III into mod. I at about 50 to 60 °C at first, followed by the transition of mod. II into mod. I at about 75 °C. Transfer of a crystal film preparation that contains the three modifications to a preheated hot stage microscope allows the detection of the melting points (Table 1). After cooling the crystal film, the spherulites of mod. I show concentric shrinkage cracks, which are absent in mod. II. Modification II from *n*-heptane, consisting of fine needles, melts incongruently with separation of coarse prisms of mod. I.

The result of the *solubility test for stability relationships*[15] showed that the thermodynamically most unstable form (mod. III) dissolves immediately followed by mod. II after a few seconds. Because of the differences in solubility, crystals of the modification thermodynamically stable at room temperature (mod. I) grow in this solution.

Differential Scanning Calorimetry—Melting the commercial product in an aluminum pan using a hot bench and afterward quenching on a cooling block leads to a liquid amorphous phase, analogous to the melt film used for thermomicroscopy. Heating such a cooled melt in the DSC at a start temperature of 25 °C (heating rate: 2 K min^{-1})

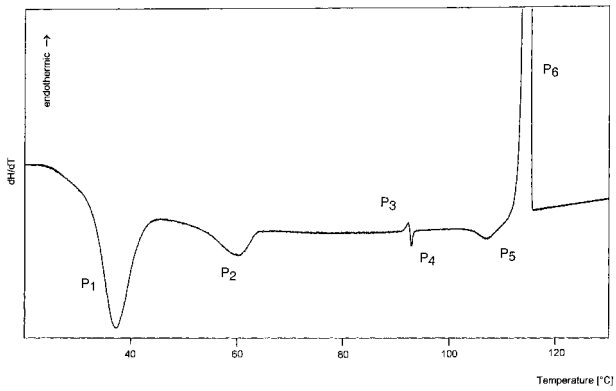

Figure 3—DSC curve of the quenched melt of flurbiprofen starting at 25 °C (heating rate: 2 K min^{-1}).

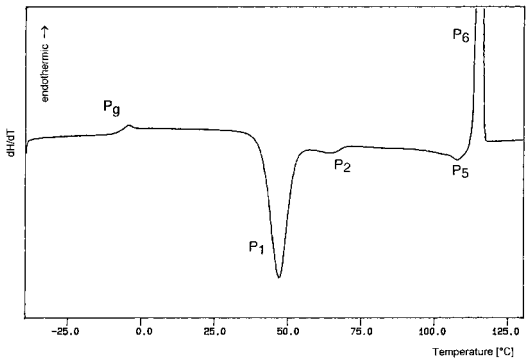

Figure 4—DSC curve of the quenched melt of flurbiprofen starting at −40 °C (heating rate: 5 K min^{-1}).

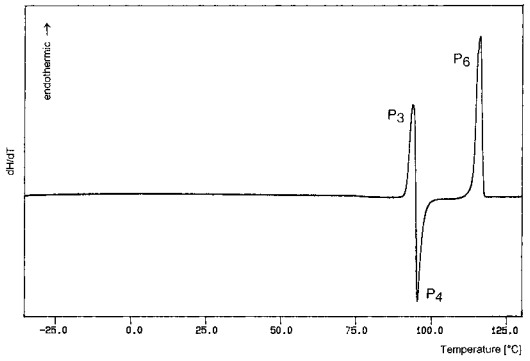

Figure 5—DSC curve of flurbiprofen starting with crystals of mod. II from *n*-heptane (heating rate: 5 K min^{-1}).

leads to crystallization of mod. III between 35 and 40 °C (P_1). The second exothermic peak (P_2) with a maximum at 60 °C represents the transition of mod. III to mod. I. In very few cases, small amounts of mod. II may also sometimes appear; these melt incongruently as indicated by P_3 and P_4. P_5 represents crystallization of remaining melt and P_6 marks the melting of mod. I (Figure 3). Cooling the melt to −40 °C leads to a solid amorphous phase. The DSC trace (Figure 4) of such a glass shows an endothermic peak (P_g), representing the glass transition at −8.5 °C, followed by an exothermic crystallization peak (P_1) and the transition peak (P_2). The DSC trace of pure mod. II (Figure 5) shows the incongruent melting (P_3), followed by the solidification of the melt to form mod. I (P_4) and the melting of mod. I (P_6).

DSC experiments where heating rates of up to 80 K min^{-1} were applied also show the incongruent melting of mod. II. Therefore it was not possible to measure the enthalpy of fusion for this crystal form. Also, attempts to determine the enthalpy of transition for the exothermic

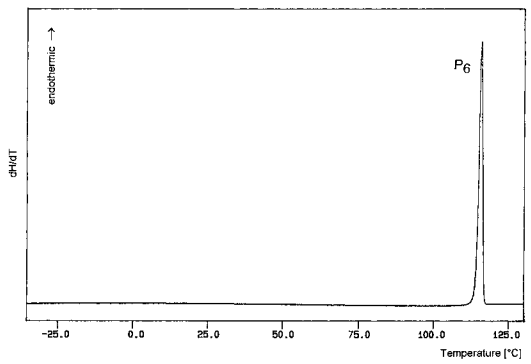

Figure 6—DSC curve of flurbiprofen starting with crystals of mod. I (commercial product, heating rate: 5 K min^{-1}).

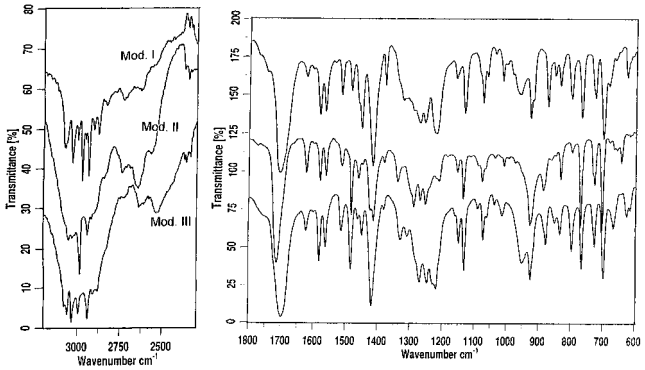

Figure 7—IR spectra of mod. I, mod. II, and mod. III of flurbiprofen recorded by FTIR microscopy.

transition of mod. II into I using a heating rate of 1 K min^{-1} were not successful. Thus, these two values are not given in Table 1. But the negative enthalpy of transition for mod. III into mod. I could be measured using preparations that contained this crystal form purely. The thermogram of mod. I shows one endothermic peak representing the melting of this crystal form (Figure 6).

FTIR Spectroscopy—The FTIR spectra of mod. I and mod. II were recorded using both the crystal powder (by means of KBr pellets) and using a crystal film on a zinc selenide window containing two kinds of spherulites representing the two crystal forms by FTIR microspectroscopy. Due to the two different methods of sampling, the spectra are identical except for small differences in the intensity of several absorption bands.[16] The spectrum of mod. III was only obtained by FTIR microscopy using a crystal film on zinc selenide. Because all three modifications show numerous shifts of significant absorption bands, they can easily be distinguished by their FTIR spectra (Figure 7). Good diagnostic value can be particularly attributed to the band representing the C═O (acid) functional group. The C═O stretching vibration appears to be located for mod. III at 1699 cm^{-1}, for mod. II at 1715 cm^{-1}, and for mod. I at 1705 cm^{-1}.

Raman Spectroscopy—FT-Raman spectra of mod. I and mod. II were also recorded. They show substantial differences in the region around 3000 cm^{-1} and between 300 and 50 cm^{-1} (Figure 8). Modification III could only be obtained as a crystal film, therefore a Raman spectrum of this crystal form could not be recorded.

X-ray Diffractometry—All three modifications were analyzed by X-ray powder diffractometry (Figure 9). A special method was used to prepare mod. III. The crystallization conditions were modified in such a way that in a melt film only this crystal form was created. The cover slip was removed from this preparation and the crystal film

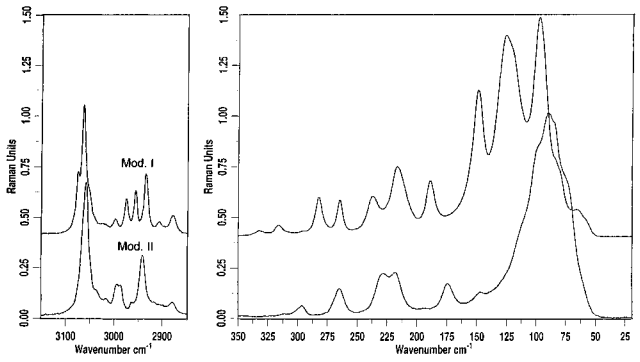

Figure 8—Raman spectra of mod. I and mod. II of flurbiprofen.

surface was used instead of the crystalline powder. The powder pattern calculated from the single-crystal structure data[17] is in very good agreement with the experimental pattern obtained for mod. I (Figure 9).

Density—The density is a very important parameter for determining which one of two modifications is the thermodynamically stable one at absolute zero. Therefore, the true densities of FBP mod. I (commercial product) and mod. II were determined. The result is that mod. I has the higher density than mod. II (Table 1). Because mod. III cannot be produced in macroscopic amounts, this value is missing in Table 1. According to the **density rule**[10] the modification with the lower density is thermodynamically unstable at absolute zero compared with the crystal form with the higher density. Therefore, mod. II is thermodynamically unstable from zero Kelvin up to its melting point compared with mod. I. More detailed remarks will be given in the Discussion.

Discussion

The measured and calculated physicochemical parameters for the three modifications of FBP are summarized in Table 1. The enthalpy of fusion could only be measured directly for mod. I. The enthalpy of fusion for mod. III was calculated by applying the heat-of-transition rule[10] using the enthalpy of transition for mod. III into mod. I measured by DSC. The enthalpy of fusion of mod. I is higher than that of mod. III. Therefore, it follows by means of the heat-of-fusion rule,[10] that these two crystal forms are monotropically related. The same is true for the entropy of fusion.[11] As already described, it was not possible to measure the enthalpy of fusion for mod. II because of its incongruent melting. The proof for the monotropic relation between mod. I and mod. II arises from the comparison of the density of these two crystal forms. Modification I shows higher density than mod. II and thus, according to the density rule,[10] monotropism is realized in this case. The *E*/*T* diagram[10,11] of FBP illustrates the thermodynamic relationships of the three modifications (Figure 10). Because the relevant physical parameters (Table 1) indicate monotropy between mod. III and mod. I (heat-of-transition rule[10]), as well as between mod. II and mod. I (density rule[10]), the diagram is in principle similar to the one given in Figure 2b. Modification I is the most stable crystal form of FBP. The result of the *solubility test for stability relationships* proves that mod. III is the most thermodynamically unstable crystal form at 20 °C and that mod. II is more stable than mod. III at ambient conditions because of its lower solubility. The thermoanalytical behavior of mod. III allows the assumption that monotropy is realized in relation to mod. II with high probability. In the case of FBP, this question is not of practical relevance. The FTIR spectra of the three modifications show significant differences. Compared with the IR spectra published by Lacoulonche et al.,[2] it is clear that our mod. I corresponds to their form I and our mod. II to their form II "recrystallized in heptane".[2] Comparison of the X-ray powder patterns of the different crystal forms clearly indicates that their form II[2] obtained by crystallization from the melt corresponds to our mod. III. This fact is also confirmed by the morphological description[2] of the crystals.

The results of our study on the polymorphism of FBP clearly show that three crystal forms can be obtained by crystallization from solution and the melt. Lacoulonche et al.[2] did not realize that they had obtained three modifications instead of two. Therefore, the physical properties of the modifications could not be assigned in a correct way and, hence, this led to the wrong conclusion on the thermodynamic relationships of this polymorphic system.

Modification III of FBP is only of analytical interest because this modification is not only thermodynamically unstable at 20 °C but also kinetically unstable. This crystal form can only be obtained in microscopic amounts. It transforms into mod. I at ambient conditions within a few minutes. Modification II is also thermodynamically un-

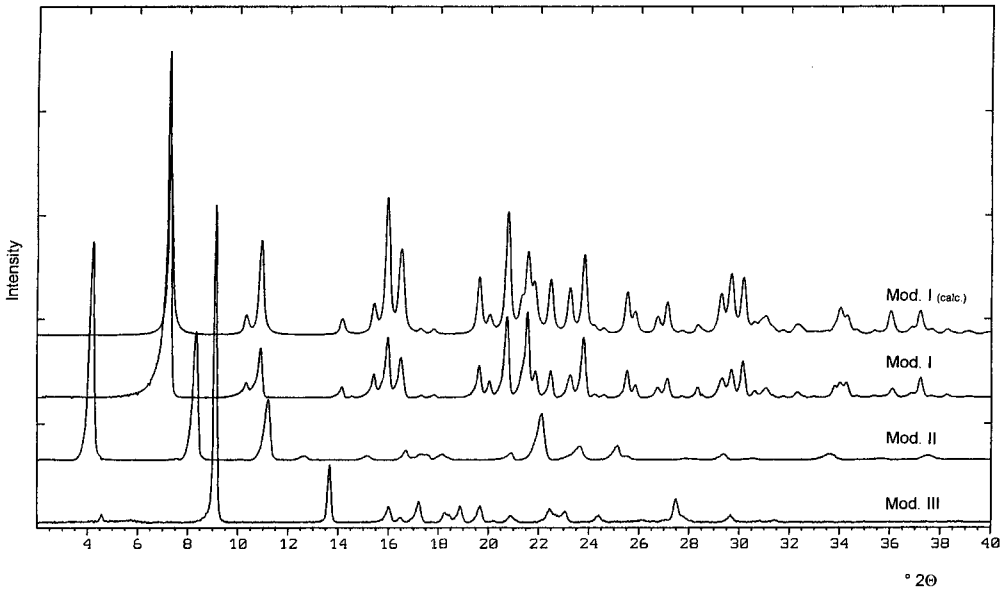

Figure 9—X-ray powder diffraction patterns of mod. I (also calculated from single-crystal data), mod. II, and mod. III of flurbiprofen.

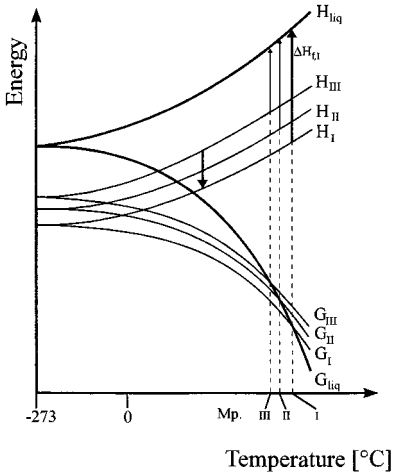

Figure 10—Energy/temperature diagram of the crystalline modifications of flurbiprofen and its melt: *G*, free energy; *H*, enthalpy; ΔH_t, enthalpy of fusion; *liq*, melt; *Mp*, melting point; measured enthalpy effects are drawn bold.

stable at 20 °C, but is durable for more than 6 months if kept under dry conditions. Also, grinding of mod. II with a mortar and pestle has not caused a transition into mod. I. Therefore this crystal form may have some practical implications. As has been shown on other polymorphic drug substances (e.g., paracetamol[18]), this marked kinetic stability could be suitable to perform direct compression experiments using this crystal form.

As a chiral substance, the modifications of FBP are in principle able to crystallize as conglomerates, racemic compounds, or solid solutions. Unfortunately, we did not have one pure enantiomer to investigate the phase diagram of this binary system and to answer this question on the nature of the three modifications.

Estimation of Aqueous Solubility for Some Guanine Derivatives Using Partition Coefficient and Melting Temperature

ALBIN KRISTL

Contribution from *Faculty of Pharmacy, University of Ljubljana, Aškerčeva 7, 1000 Ljubljana, Slovenia*

Received April 28, 1998. Accepted for publication September 8, 1998

Abstract □ Aqueous solubilities for some guanine derivatives were estimated by semiempirical equations developed by Yalkowsky and Valvani[1] using the data for partition coefficient and melting temperature. It was shown that in the case of guanine derivatives examined in this study, the solubility values could not be estimated adequately by these equations.

Introduction

There exist several different methods of aqueous solubility estimation for organic compounds:[1] methods based directly on group contributions to measured aqueous activity coefficients; techniques based on experimental physicochemical properties such as partition coefficient, chromatographic retention, boiling point, and molecular volume; methods based on properties that cannot be experimentally determined but can be calculated from molecular structure (molecular surface area, molecular connectivity, and parachor); and techniques based on combinations of two or more parameters that can be experimentally measured, calculated, or generated empirically (solubility parameter, linear solvation energy relationship and others).

The first who recognized the relationship between aqueous solubility and *n*-octanol water partition coefficient (P) were Hansch et al.[2] One of the most well-known and popular equations for predicting the solubility of liquid and solid organic solutes using the *n*-octanol water partition coefficient was derived by Yalkowsky and Valvani:[1,3]

$$\log S_w \approx -1.00\log P - 1.11\frac{\Delta S_f(\mathrm{mp} - 25)}{1364} + 0.54 \quad (1)$$

where S_w is aqueous solubility in mol/L, mp is the solute melting point temperature in °C, and ΔS_f is the entropy of fusion. The parameter P is given as the concentration ratio in octanol and aqueous phases (C_o/C_w).

For rigid molecules, where ΔS_f was taken as 56.7 J/molK, one obtains

$$\log S_w \approx -1.05\log P - 0.012\mathrm{mp} + 0.87 \quad (2)$$

These semiempirical equations showed excellent correlation between the values for aqueous solubility and P for many nonelectrolytes, weak electrolytes, and even for acidic and basic substances.[1,3,4] They were used by many different researchers for aqueous solubility estimation of various substances, and good correlation between experimentally determined and calculated solubility values was shown.[5,6]

In this work we wanted to evaluate eqs 1 and 2 for predicting the aqueous solubility for some antivirus guanine derivatives, acyclovir (ACV) and deoxyacyclovir (DCV), and their acetyl derivatives.

Materials and Methods

The substances examined in this study, ACV (9-(2-hydroxyethoxymethyl)guanine) and DCV (2-amino-9-(2-hydroxyethoxymethyl)-9-*H*-purine) with their *O*-acetyl (OAcACV and OAcDCV), *N*-acetyl (NAcACV and NAcDCV), and *N*,*O*-diacetyl (diAcACV and diAcDCV) congeners were synthesized at the National Institute of Chemistry, Ljubljana, Slovenia.[7]

The melting temperatures (mp), entropies of fusion (ΔS_f) and corresponding activity coefficients (γ) as well as the values for aqueous solubility (S_w), partition coefficients, and different octanol/water solubility ratios at 22 ± 0.1 °C were determined previously[8] and are given in Table 1. Additionally, the thermal analysis measurements for all tested substances showed no enthalpy changes that would correspond to desolvation, except for ACV, which existed in hydrated form but after drying (T = 150 °C, air atmosphere), a stable anhydrous form was obtained.[9]

Experimentally determined values for partition coefficients[8] were used in eqs 1 and 2. The values for partition coefficients of tested guanine derivatives calculated by Rekker's fragmental approach differed significantly from those obtained by the experiment.[10]

Results and Discussion

Calculated values for aqueous solubility of tested substances, using eqs 1 and 2 are presented in Table 1. Equation 2, where the entropy value for the rigid molecules (56.5 J/mol K) is used, gives completely different results from the measured values, although tested substances are rigid and mostly do not have more than five nonhydrogen atoms in a flexible chain (the molecules with more than five units in the side chain are assumed to be partially flexible molecules).[1,3] These results were expected because all the experimentally determined values of ΔS_f for tested substances (Table 1) differ a lot from 56.5 J/mol K (except for ACV for which the ΔS_f value is close to 56.5 J/mol K).

Comparing the logarithmic values for aqueous solubility calculated by eq 1 (where the experimentally determined values for ΔS_f were used) with the measured ones reveals a rather large disagreement. The log P values determined for the same compound are acceptable if they do not differ by >0.2 log units[11] or even 0.3 log units,[12] which represent about two times higher/lower values in the nonlogarithmic scale. Using these estimations, one can say that calculated (by eq 1) and experimentally determined log S_w values are in good accordance for diAcACV and diAcDCV, are rather good for OAcACV and OAcDCV, and differ by large amounts in the case of the other tested substances.

Equations 1 and 2 were derived on the basis of the following rationales:[13]

(1) The solubility of nonpolar and semipolar solutes in octanol is approximately equal to the ideal solubility, γ_o = 1. Because $P = \gamma_w/\gamma_o$, it follows that log $\gamma_w \approx$ log P.

(2) The ideal solubility can be estimated from mp and ΔS_f of the solute.

(3) The ΔS_f of the solute is constant for rigid molecules.

log S_w[c]	−0.54	−0.37	−0.91	−0.69	−0.26	0.09	−0.11	0.36
log S_w[d]	−2.14	−1.92	−2.70	−2.14	−1.08	−0.86	−0.97	−0.73
log P[d]	−1.57	−1.30	−1.07	−0.85	−1.08	−1.33	−0.61	−1.05
log S_o/S_w[d]	−1.82	−2.10	−2.15	−1.66	−1.96	−2.40	−1.40	−1.90
log S_{ow}/S_{wo}[d]	−1.60	−1.45	−1.16	−0.96	−1.26	−1.54	−0.72	−1.12

[a] Activity coefficients (γ) were calculated by the equation $\gamma = (f_2/f_2°)/S_2V_1$, where f_2 and $f_2°$ are the fugacities of the pure solid solute and of its subcooled liquid at the temperature of the solution, respectively, S_2 is the molar solubility of the solute and V_1 is the molar volume of the solvent.[8] [b] Calculated by eq 1 at T = 22 °C. [c] Calculated by eq 2 at T = 22 °C. [d] The logarithms of aqueous solubilities (log S_w), partition coefficients (log P), octanol/water solubility ratios (log S_o/S_w) and mutually saturated octanol/water solubility ratios (log S_{ow}/S_{wo}) for examined substances are also given (T = 22 ± 0.1 °C).[8]

(4) The ratio S_o/S_w is equivalent to P, that is, S_w is equal to S_o divided by P. These statements were additionally supported by recently published papers[14,15] where the authors confirmed the negligible effect of octanol/water mutual saturation on the partition coefficient. They stated that the octanol/water solubility ratio, S_o/S_w, can be used as the estimate for the partition coefficient and that there is negligible effect of octanol/water mutual saturation on the partition coefficient, although the average absolute estimation errors (when correlating log P with log(S_o/S_w) for 82 solutes) were >0.4 log units (which means >2.5-fold higher/lower values in the nonlogarithmic scale).[14] Additionally, the solubility of different organic compounds in octanol (using 124 solutes) was estimated by five methods (i.e.; ideal solubility, regular solution approach, UNIFAC approach, PS_w method, and OCTASOL), and the most reliable results were obtained by PS_w method (log S_o = log P + log S_w), where the average error of estimates is 0.29 log units (2-fold higher/lower value than the experimental one in nonlogarithmic scale).[15]

Regarding the observed discrepancies in calculated and experimentally determined values for aqueous solubilities of tested guanine derivatives one can assume that some of the aforementioned rationales could be invalid for predicting the aqueous solubility of these substances; although they represent semipolar solutes.[16] The values for γ_o of tested substances (Table 1) differ significantly from 1 in all cases, indicating that the solubility of these substances in *n*-octanol is not ideal. Despite these differences, the observed and calculated log S_w values (by the eq 1) are reasonably close in four out of the eight cases. This nonideal solubility in *n*-octanol also indicates that the activity coefficients of tested substances in water (γ_w) cannot be equal to P, expressed in mole fractions.

Additionally it was shown that in the case of tested guanine derivatives, ΔS_f of the solute is not constant for rigid molecules and cannot be taken as ΔS_f = 56.7 J/mol K.

We also found large differences in the solubility values determined in neat and mutually saturated solvents and consequently in the solubility ratios (Table 1), showing that mutual saturation plays an important role in partitioning and solubility not only of many highly lipophilic and hydrophilic solutes but also of semipolar substances such as the tested guanine derivatives.[8] It can be deduced that the values for partition coefficients (P) are not equivalent to the neat octanol/water solubility ratios (S_o/S_w) but more to the mutual saturated octanol/water solubility ratios (S_{ow}/S_{wo}; Table 1). These findings were also confirmed with the partition experiments performed with some higher alkanols (i.e., heptanol and nonanol).[17]

One can thus conclude that eqs 1 and 2 in the case of tested guanine derivatives do not give reasonable estimation of aqueous solubility.

Abstract □ We advance the concept that tautomerism is crucial for the understanding of the chemical behavior of tetracycline. Indeed, considering four deprotonations, there are 64 different possible tautomers to be considered for tetracycline. Our results indicate that tetracycline is a very adaptive molecule, capable of easily modifying itself through tautomerism in response to various chemical environments. Indeed, its situation in solution can be more accurately pictured as an equilibrium among a diversity of tautomeric species–an equilibrium that can be easily displaced depending on the various possible chemical perturbations, such as varying the pH or the dielectric constant of the solvent. Moreover, we also show that tetracycline could undergo four deprotonations and predict for it a fourth pK_a of 13 and refer to our experimental determination of this parameter, which yielded the value of 12. We conclude that tautomerism is essential to the comprehension of the chemical behavior of tetracycline as determined by the semiempirical method AM1 as well as by the self-consistent reaction field method, which estimates the effects of the solvent on the tautomers. All tautomers in their different conformations have been fully optimized for each of the possible degrees of protonation of this molecule. Thus, the relative stabilities of the different tautomeric species have been computed.

1. Introduction

Tetracycline (TC, Figure 1) and its derivatives are widely used antibiotics.[1] The chemical−structural properties of tetracycline have been extensively studied.[2] TC has different acid groups in its chemical structure and the possibility to adopt different conformations. The different proton-donating groups of this molecule offer several possibilities of metal ions substitution. The complexation with metal ions increases the stability of the various TC derivatives.[3] In some cases, metal ion complexation reduces the availability of TC in the blood plasma[4] or eliminates its biological activity.[5] It is known that TC forms complexes in different positions with calcium and magnesium ions that are available in the blood plasma.[6,7] Undoubtedly TC is a complex molecule and, despite all effort, its mechanism of action is still not well understood.

The three acid dissociation constants normally observed in potentiometric experiments and the appropriate assignment of the various acid groups of TC to the respective dissociation constants are important to understand the chemical behavior in blood plasma and the biological

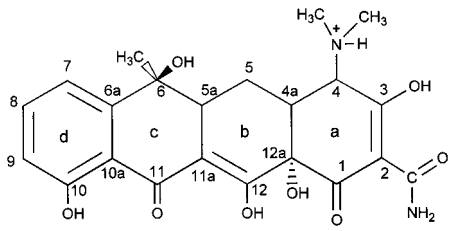

Figure 1—Chemical structure of TC.

activity of TC. The protonation scheme of TC has been the subject of controversy and intense study.[8−11] In 1956, Stephens et al.[8] proposed that pK_1 (= 3.30) is due to the protonation of the oxygen bonded to the C(3), pK_2 (= 7.68) is due to the protonation of the dimethylamino group, and pK_3 (= 9.69) is due to the protonation of the oxygen atoms bonded to the C(10) and C(12). Later, Leeson et al.[9] comparing the pK_as of different TC derivatives, suggested that pK_2 should be assigned to the protonation of the oxygen atoms bonded to the C(10) and C(12) and pK_3 to the protonation of the dimethylamino group. The effect of dielectric constant on the pK_a values of TC has been investigated by Garrett[12] studying TC in dimethylformamide−water mixtures. The observed decrease in pK_a values of uncharged acids with increasing dielectric constants supports the reversal in assignment of the 2nd and 3rd pK_as of TC. Rigler et al.,[10] using ^{1}H NMR, proposed a different protonation scheme. The chemical shifts of protons of the 4-dimethylamino group and the nonlabile protons of the phenolic group have been monitored as a function of pH. They assumed that the chemical shifts change depends exclusively on the respective protonation sites. Based on this assumption, they suggested that pK_2 and pK_3 have contributions from the dimethylamino and phenolic C(10) groups, respectively. The work of Asleson and Frank[11] using ^{13}C NMR supports the suggestion of Rigler et al.[10] and proposed that the protonation of the oxygen in C(12) is preferential with respect to the phenolic group C(10). They used the chemical shift of C(8) (see Figure 1) as a measure of protonation of the phenolic group C(10) and assumed that pK_1 is due to the tricarbonyl system of ring "a".

Another important aspect is the different conformations that this molecule can have depending on the medium. Mitcher et al.[13] have used circular dichroism (CD) to show that the conformation of TC in acid solution is different from the conformation it displays in neutral or basic solutions. Stezowski[14] showed that the hydrate crystals of TC are composed of zwitterionic structures. On the other hand, the anhydrous crystals of TC obtained by Stezowski and Jogun[15] have a different conformation. Stezowski et al.[16] studied the oxytetracycline in an ethanol/water solvent and showed evidence of the coexistence of zwitterionic and un-ionized forms of the free base in solution. They suggested that two conformations of TC are in equilibrium.

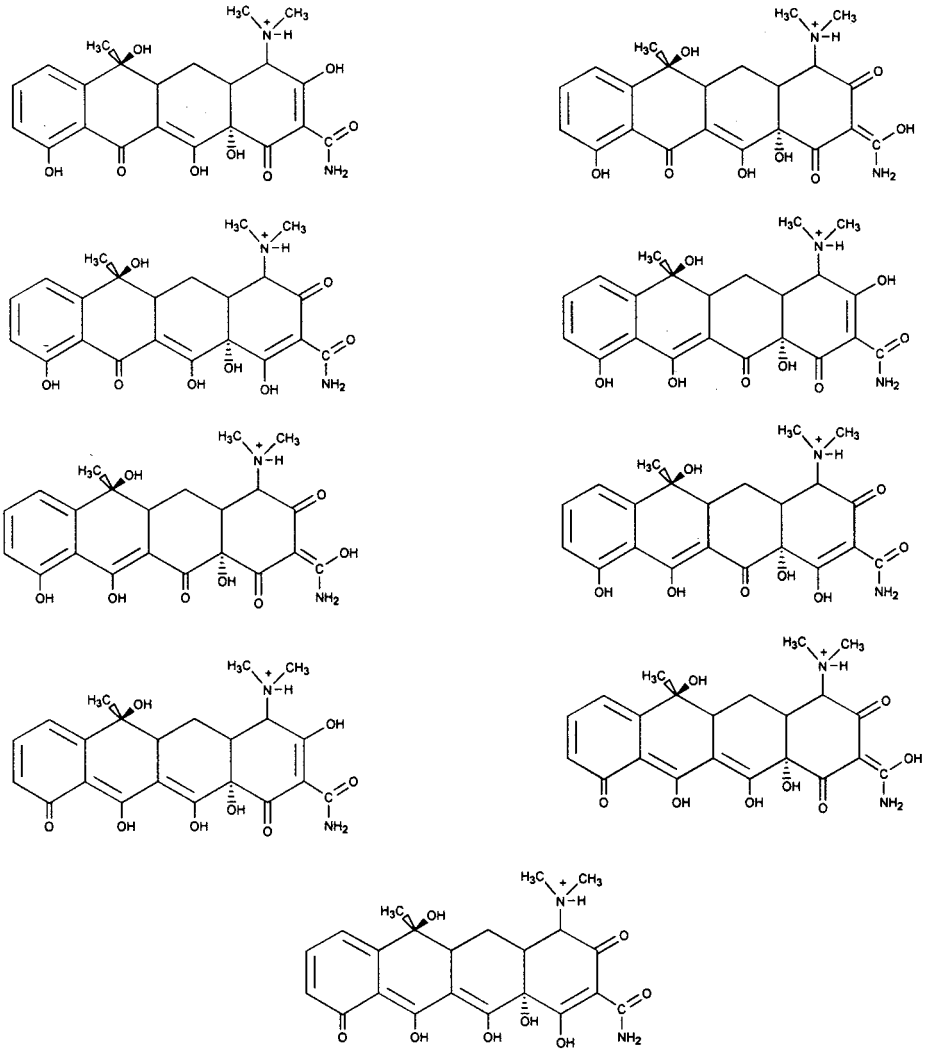

Figure 2—Possible tautomers of the completely protonated TC.

Metal ion coordination by TC has also received appreciable attention by researchers[6] due to the fact that some of the biological effects of TC and its derivatives arise from their interactions with metal ions.[17,18] TC has various possibilities for metal ion increasing the complexity of this system. Although some metallic complexes of TC in solid state have been isolated, most of them are studied in solutions. Complexes with Cr^{3+}, Nb^{2+}, Mn^{2+}, Fe^{2+}, Fe^{3+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, Hg^{2+}, Pb^{2+}, Al^{3+}, VO^{2+}, and VO_2^{2+} have been studied[6,7,19–22] and, according to different reports, the metal ions are either bonded to the O(1) or O(3) and to the oxygen of the amide group, or bonded to the acidic groups of the rings b, c, and d. Recently, anhydrotetracycline, a decomposition product of TC, has also received attention because of its importance to the understanding of the side effects and the mechanism of action of this drug.[23]

Despite all studies reported concerning the chemical and structural properties of TC, there are still several aspects that remain not well understood. Figure 1 shows the tautomer normally used to describe the structure of TC. However, this molecule has several other possibilities of tautomerism (see Figure 2). It is evident that different tautomeric species are present in the medium contributing to the macroscopic chemical behavior of TC. The relative ratio of different tautomers depends on the difference of free energy between two tautomeric species.

To our knowledge, the tautomerism of TC and its consequences for the understanding of chemical properties has not received attention, although it is of clear interest. In this paper we advance the concept that different tautomers of TC may be involved in its protonation scheme, in its metal ion complexation, in its chemical behavior in blood plasma, in its biological activity, etc. Moreover, we also show theoretical and experimental evidences that TC can undergo four deprotonations.

Recently, quantum mechanical semiempirical methods have been applied successfully to perform a conformational analysis of anhydrotetracycline[24] and to investigate its near ultraviolet (UV) and visible (VIS) electronic spectra.[25]

In the present work we have studied all possible tautomers of TC in different conformations and degrees of deprotonation using the semiempirical method AM1. The solvent effects have been included using the self-consistent reaction field (SCRF) method. Potentiometric and spectrophotometric experiments are also being presented showing evidences that TC undergoes a 4th deprotonation.

2. Computational Aspects

The semiempirical AM1 method (Austin Model 1)[26] implemented in the program MOPAC 6.0[27] was used to study the tautomerism of TC in its different degrees of deprotonation. The geometries were fully optimized and vibrational analysis was performed. All frequencies were positive, ensuring that true minima in the potential energy surface had been found. Finally, the solvent effect was

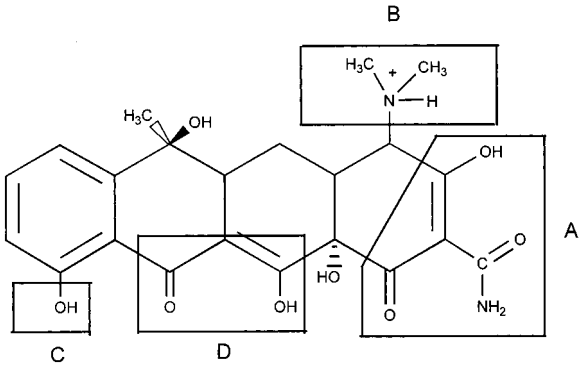

Figure 3—Possible sites of protonation of TC.

determined by the SCRF method, proposed by Tapia et al.,[28] merged with semiempirical methods of Zerner and co-workers.[29]

In this SCRF method, the solute lies inside a spherical cavity within a continuous dielectric medium representing the solvent. To determine the SCRF radius of the spherical cavity, rc, in which the tautomers are inserted, we used the method of Aguilar and Valle.[32] We chose this method because it is less arbitrary than most used to find the cavity radius. Indeed, it not only generates a single value per molecular structure but it is also based on a well-defined procedure for the adaptation of the molecular solute cavity size in a solvent that takes into account the charge distribution of the molecule.

The AM1/SCRF method is a reasonably good one to study this highly versatile and adaptive character of TC. This can be verified by examining the studies by Zerner et al.[29–31] on the tautomeric equilibria of the 5-nitroimidazole and 4-nitroimidazole, on the tautomeric equilibria of five-membered rings with two heteroatoms, and on 2-, 3-, and 4-substituted pyridines in aqueous solution.

3. Results and Discussion

3.1. Conformations and Protonation Sites of TC—The acid/base properties of TC are difficult to analyze because of its several protonation sites. Its deprotonation scheme has been subject of discussion and controversy.[8–11] Figure 3 shows the totally protonated TC and its four sites of protonation: $A^0B^+C^0D°$. According to this notation (and hereafter), A, B, C and D are protonation sites of TC. The superscripts −1 and 0 represent the ionic charge of the respective site. Therefore, superscripts + and − mean that this site has either received or lost one proton.

We have analyzed the two conformations that have been reported from X-ray experiments, the extended and folded conformations, by optimizing the zwitterionic form of TC, $A^{-1}B^+C^0D^0$ structure. The conformation we have obtained is similar to the one observed by Stezowski[14] when he analyzed hydrated crystals of TC; that is, the extended conformation. The difference between the experimental and calculated bond distances is <0.02 Å, which is in agreement with the expected accuracy of the calculated bond distances calculated by the AM1 method.[27] The dihedral angles are compared with the experimental data in Table 1. The differences for some dihedral angles can be explained if one takes into account that TC has been calculated in the gas phase without intermolecular interactions and the experimental geometry has been obtained from crystals.

The folded conformation of oxytetracycline has been observed in anhydrous crystals[14] in its nonionic form, $A^0B^0C^0D^0$ structure (according to the notation adopted in the present work). Because oxytetracycline and tetracycline are very similar,[14] the oxytetracycline is a suitable reference to compare with the calculated values of TC. The bond distances are <0.02 Å different from the available experimental data. The dihedral angles shown in Table 2 are in reasonable agreement with the experimental data.

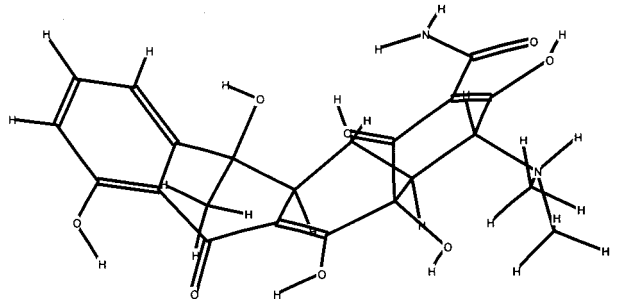
[a] Calculated geometry. [b] Crystallographic data of oxytetracycline.

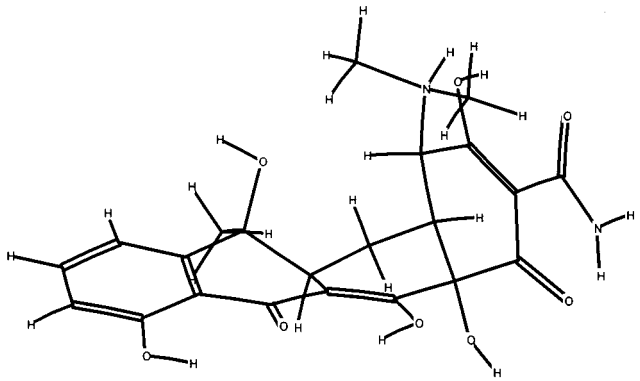
The two conformations shown in Figure 4 have been used to generate all the tautomers studied in their different degrees of protonation.

3.2. Tautomerism and the Chemical Behavior of TC in Solution—It is important to analyze all possible tautomers of this molecule in their different degrees of protonation and conformation to understand the role of tautomerism in the chemical behavior of TC. We have optimized the structures of all 64 tautomers and calculated their heats of formation (ΔH_f^o). The use of heat of formation instead of the more correct Gibbs free energy is because it is difficult to evaluate the entropy factor for molecules in solution. Tests with totally protonated species in the gas phase showed that the entropy contribution to the relative stability is of about 0.1 kcal mol^{-1} and therefore much lower than the relative accuracy of AM1. This result has also been pointed out by Santos et al.[24] in their study of anhydrotetracycline, in which they used a thermodynamic cycle to justify the use of the entropy calculated in the gas phase as an estimate of the entropy contribution to the Gibbs free energy of species in solution.

There are different tautomers in equilibrium in each degree of protonation of TC. They have similar stabilities



extended conformation



folded conformation

Figure 4—Two conformations of TC obtained from AM1 calculations.

and, therefore, they are present in considerable amount in the medium. The average error of the calculated heat of formation using AM1 is about 7 kcal mol^{-1} compared with experimental values.[26] This error should be much smaller when the relative stability of species is analyzed. Previous works showed that the relative stability of species calculated by the AM1 method is correctly predicted even for challenging systems.[29–31] However, the error bars of the calculated differences of enthalpies of different species are still too large to allow estimation of equilibrium constants.

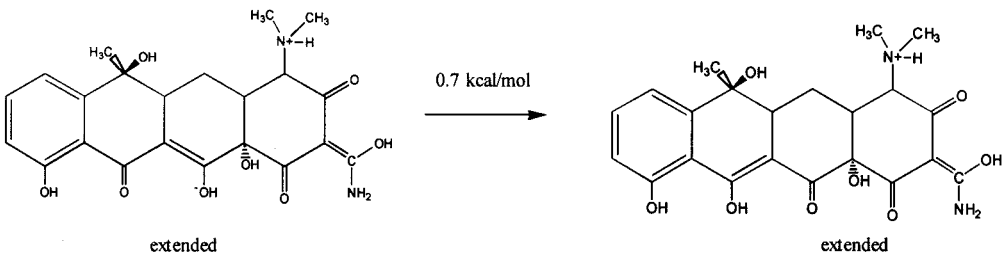
It is important to observe that the interaction of those species with the solvent has been described by the SCRF method, which does not include specific interactions with the solvent. In the gas phase, the favored species are different, due to the lack of interaction with the solvent i.e. (with the dielectric constant of the medium). Therefore, one species that is favored in aqueous solution may not be favored in ethanol solution, due to the difference in the dielectric constant. These two species can have different conformations and different protonated sites. Stezowski,[16] for example, has shown that two species (zwitterionic and nonionized) are in equilibrium in ethanol/water mixtures. One could also argue that specific interactions (which are not taken into account in our model) of the tautomers with the solvent may also alter with a change of the medium. Thus, these specific interactions would modify the relative stabilities of different species. The chemical behavior of TC can therefore change depending on the conditions of the medium (solvent, ionic force, concentration, etc.) because different tautomers have different chemical properties.

Conformations, protonation sites and metal ion complexation sites of TC and its derivatives have been extensively studied in different solvents.[6–11,13–16,19–22] However, the difficulties and disagreements among researchers with respect to the interpretation of their experimental results and the assignment of metal ion complexation sites of TC, as a whole, constitute circumstancial evidence of the influence of the tautomers.

Now, we turn to the discussion of the tautomers in each one of the degrees of protonation of TC.

3.3. Degrees of Protonation of TC—*Totally Protonated Species*—The extended conformation is favored with respect to the folded one by about 2.8 kcal mol^{-1}. However, the most stable tautomer is the one with the proton of the site A on the amide group instead of the oxygen bonded to the C(3). It is important to notice that Stezowski[33] has already observed this type of tautomerism in solid state for a tetracycline derivative. Crystals of α-6-deoxyoxytetracycline have the amide oxygen of the site A protonated. The second most stable tautomer is 0.7 kcal mol^{-1} less stable than the first one. It is extended and has one proton on the oxygen bonded to the C(11) instead of the oxygen of the C(12). Figure 5 shows these two tautomers. Other tautomers lie at least 2.8 kcal mol^{-1} higher in energy than the most stable tautomer.

1st Deprotonation—Species resulting from the 1st deprotonation can be either in a neutral or zwitterionic form, in which case a positive charge is located on the amine group of the C(4) and a negative one on the site A (Figure 3). It has been experimentally shown that, in aqueous solution, TC attains the zwitterionic form. However, in the gas phase (or in a nonpolar solvent), it is expected that the neutral form of TC is favored. In solution, the separation of charge is stabilized by the polarization of the solvent around the TC. This stabilization depends on the value of the dielectric constant of the medium, this being the basic idea of the SCRF method used. However, the SCRF method has not been able to sufficiently stabilize the zwitterionic tautomers in order to invert its relative stability with respect to the neutral species. The results show that, despite the major stabilization of the zwitterionic species (because they have the largest dipole moments) with respect to the neutral ones, they are still not favored. It is important to observe that the SCRF method does not consider the specific interactions such as those arising from intermolecular hydrogen bonding and dipole–dipole interactions. These facts are important and should be kept in mind, because, the neutral species of TC are present in hydrophobic media like those found in biological systems.[16] Figure 6 shows the 10 most stable species. Folded conformation is favored, but the species still have the proton on the amide group.



extended extended

Figure 5—Most stable completely protonated species according to AM1/SCRF calculations. The indicated value is $\Delta(\Delta H_f; r_c = 5.5$ Å).

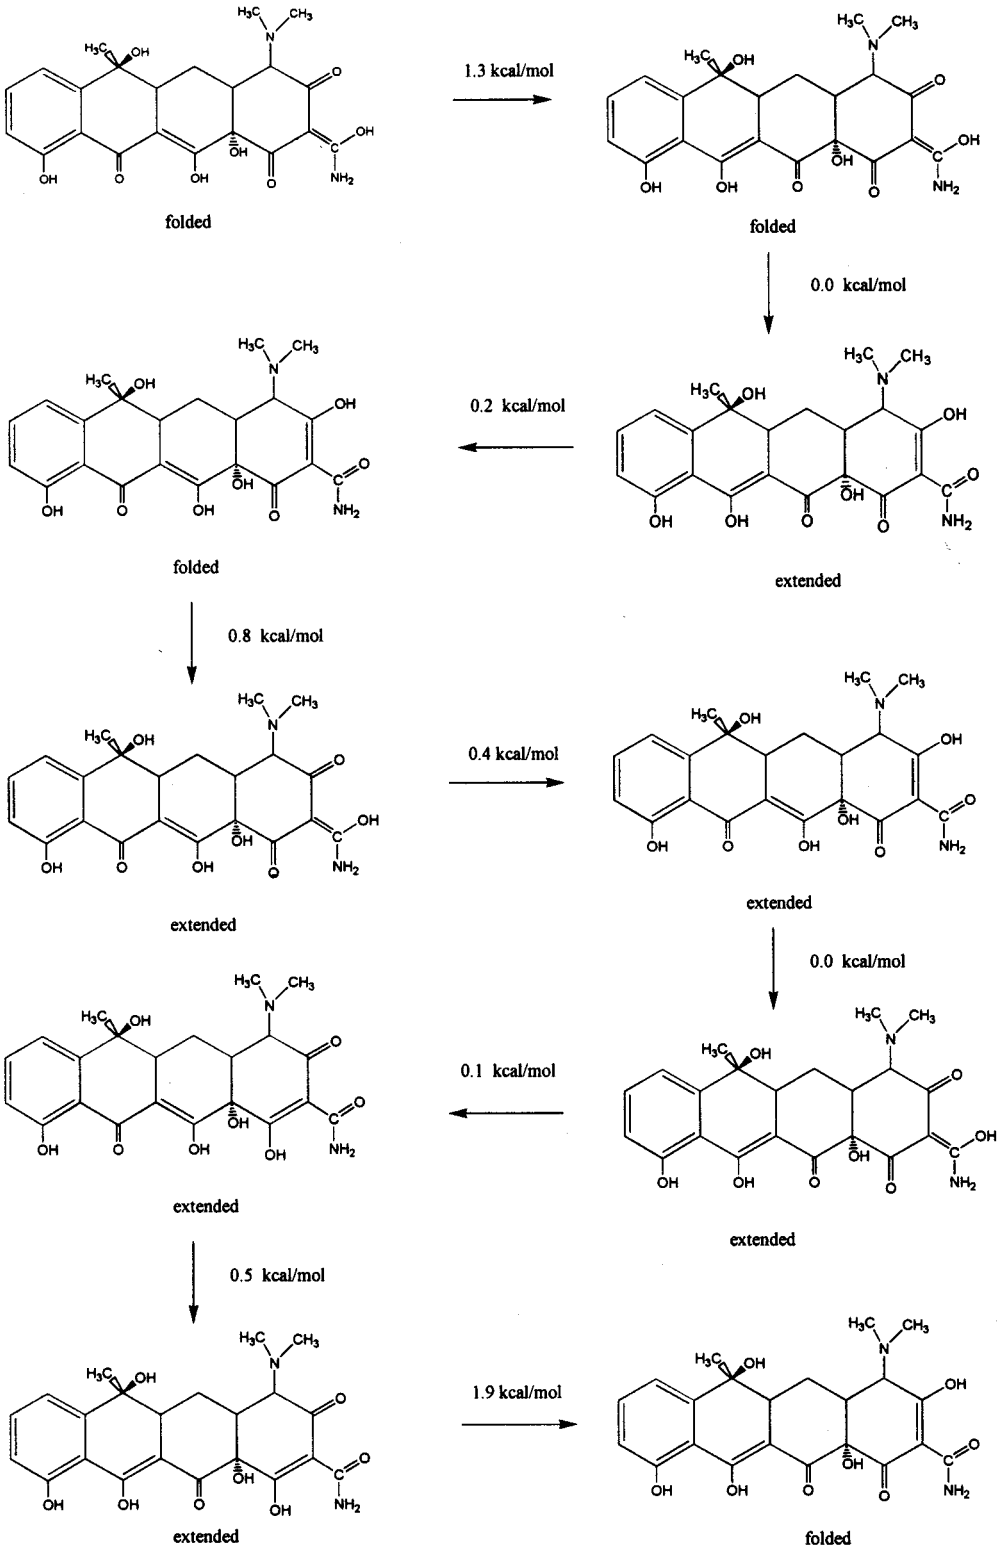


Figure 6—Most stable tautomers that arise from the 1st deprotonation according to AM1/SCRF calculations. The indicated values are $\Delta(\Delta H_f;\ r_c = 5.5$ Å).

2nd Deprotonation—It is accepted that the 2nd deprotonation lead to the formation of species of the form $A^{-1}B^0C^0D^0$ (i.e., species that have lost protons from sites A and B). Our results are in good agreement with these assumptions because the most stable tautomers present sites A and B deprotonated. The different tautomers arise from different conformations and from the exchange of protons between the oxygen bonded to C(11) and C(12). Figure 7 shows the most stable species.

3rd Deprotonation—The 3rd deprotonation occurs in the C and D sites. In fact, it is not possible to distinguish between these two sites. The most stable species have a proton bonded to one of the oxygens of either C(10), C(11), or C(12). Figure 8 shows the three most stable species. The most stable conformation is a folded one.

4th Deprotonation of TC—Even though only three acidic protons have been observed in potentiometric experiments with TC,[8–11] the analysis of its structure shows the pos-

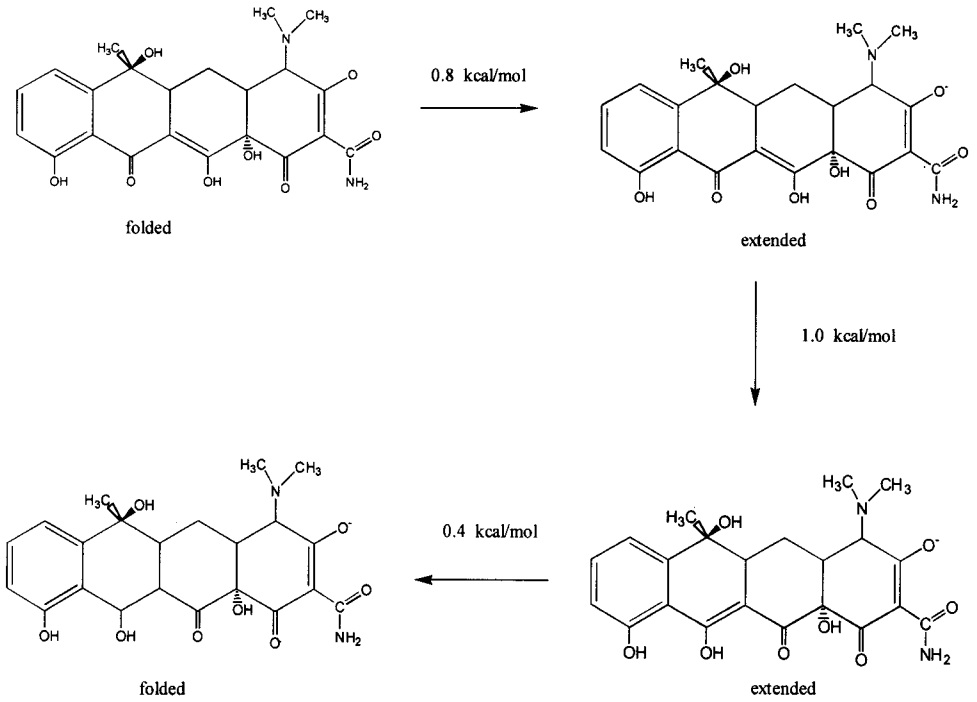

Figure 7—Most stable tautomers that arise from the 2nd deprotonation according to AM1/SCRF calculations. The indicated values are $\Delta(\Delta H_f;\ r_c = 5.5\ \text{Å})$.

sibility of a 4th deprotonation. Therefore, we have also analyzed the completely deprotonated species, aiming to contribute to the understanding of this so far unresolved problem. Our results indicate that the completely deprotonated species is a folded one and the extended conformation lies 4.4 kcal mol^{-1} higher in energy than the extended one.

Tetracycline methiodide possesses the equivalent of the TC acidic site B blocked by a methyl group. Therefore, Rigler et al.[10] had already suggested that the existence of three pK_as of tetracycline methiodide, the third equaling 10.67, should be construed as an evidence that TC itself should have a fourth acid group, which to date has seemingly not been accessible to potentiometric experiments.

One could suggest using the calculated heat of formations of the species to fit the known pK_a and to use this to estimate, by extrapolation, the rth dissociation constant of TC. This procedure is reasonable because a direct absolute calculation of pK_as would require computation of the proton solvation energy, which is very difficult to be evaluated theoretically with high accuracy.[34] Furthermore, the AM1 calculated values of Gibbs free energy[27] are in error of only about 7 kcal mol^{-1}, which is an additional argument in favor of the fit.

$$\Delta = A - B \ln K_n \qquad (1)$$

where

Table 3—Estimate of pK_4 According to Equations 1 and 2

n	Δ (kcal/mol)	-ln(K)[a]	pK_a[a]
4	–104.0	7.6 (8.2)	3.3 (3.6)
3	–87.1	17.5 (15.8)	7.6 (6.9)
2	–70.9	22.1 (23.2)	9.6 (10.1)
1	–54.0	(30.9)	(13.4)

[a] Estimated values in parentheses.

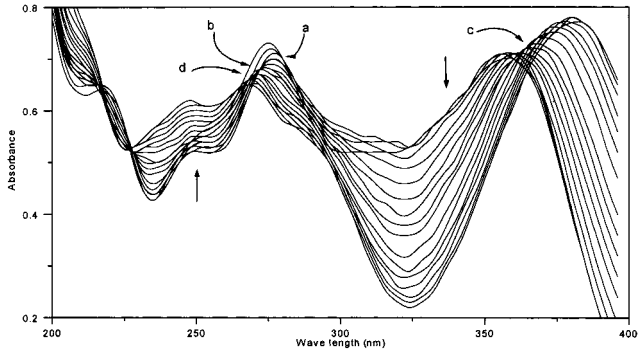

Figure 9—Spectra of a 0.5 mmol L-1 aqueous TC solution in the pH (–log(H^+)) range from 3.6 to 11.5 (as indicated by the arrows). Small letters correspond to isosbestic points. See text for details.

$$\Delta = \Delta H_{H_{n-1}L} - \Delta H_{H_nL} \qquad (2)$$

with n = 1, 2, 3, and 4 and H4L being the completely protonated TC. The values of A and B can be determined with the three experimental acid dissociation constants (3.3, 7.68, and 9.69) by least-squares fit. Accordingly, the estimated values of A and B are −121.8 and 2.19 kcal mol^{-1}, respectively, with correlation factor (**R**) of 0.98. Table 3 shows the experimental and estimated values of the pK_as using eq 1, together with the estimation of the pK_4 of about 13. Although these results are not conclusive, they are evidence that the discussions concerning a 4th deprotonation are meaningful.

If the possibility of a 4th deprotonation is accepted, then the value of pK_3 should be smaller. The determination of the dissociation constants from the experimental data neglecting the 4th deprotonation probably led to an overestimation of the pK_3 to compensate the lack of the 4th deprotonation.

3.4. Spectrochemical Evidence of the 4th deprotonation of TC—At the biological pH (about 7.4), the 4th deprotonation does not interfere in acid/base equilibria and can be neglected. However, in multiligand/multimetal systems, like blood plasma, considering the 4th dissociation constant of TC (hereafter the totally protonated tetracycline species is represented as H_4L^+) may have important consequences for the understanding of its chemical behavior. Therefore, we have carried out simultaneous potentiometric and spectrophotometric experiments (see *Appendix* for details of the experiments), searching for experimental evidences of the 4th deprotonation.

A series of spectra of a 0.5 mmol·L^{-1} TC aqueous solution in the pH range 3.5−11.5 is shown in Figure 9. Close inspection of these spectra reveal the existence of several isosbestic points, which prevail in limited pH ranges. Considering only the data >250 nm, four isosbestic points can be noticed. Below pH 5, a first one "a" can be seen at 280 nm and it can be related to the H_4L^+/H_3L equilibrium. In the pH interval from 5.5 to 7.5, two isosbestic points are seen at 272 "b" and 360 "c" nm, respectively, and they can be related to the H_3L/H_2L^- equilibrium. A fourth isosbestic point can be seen at 260 nm "d", limited to the pH range 9−10.5. This point can be related to the H_2L^-/HL^{2-} equilibrium. Its disappearance above pH 10.5 is clear evidence of a 4th deprotonation. Another piece of evidence is obtained when the absorbance at 380 nm is plotted against pH, as shown in Figure 10, together with a species distribution diagram. The absorbance at this wavelength increases up to pH 10 while the first three deprotonations occur, and absorbance starts to decrease when the 4th deprotonation starts to take place. A rapid acidification restored the spectrum of H_4L^+, ruling out the hypothesis of ligand degradation associated with the spectral modifications observed in high pH values. As mentioned before, the low concentration of L^{3-} in the pH range studied could explain the absence of the fourth dissociation constant in the literature.

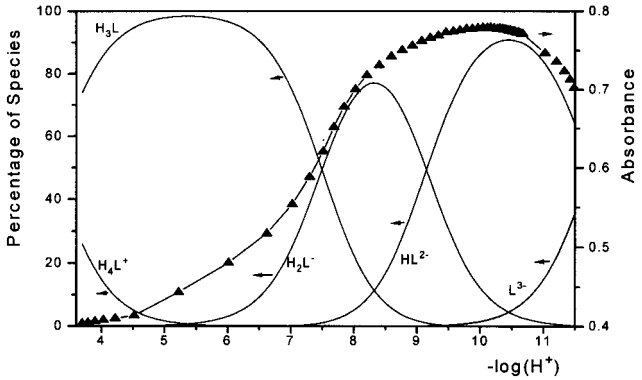

Figure 10—Distribution of TC species and the absorbance of TC in aqueous solution measured at 380 nm as functions of –log(H^+).

Table 4—Deprotonation Constants of Tetracycline at 25 °C (I = 0.1 mol/L, $NaClO_4$)

	measurements	
pK_n	potentiometric	spectrophotometric
1	3.24	3.36
2	7.49	7.33
3	9.15	8.97
4	11.75	11.81

Table 4 shows the estimated dissociation constants for TC obtained from potentiometric and spectrophotometric measurements. The different measurements have led to estimates of the dissociation constants that are in a good agreement with each other. With regard to the potentiometric data, we have observed that if the 4th deprotonation is neglected, pK_3 is estimated to be 10.7, one logarithmic unit larger than the value reported in the literature, which is 9.7. In addition, the statistical parameters C^2 and S, calculated by SUPERQUAD, decrease from 81.5 to 5.6 and from 12.24 to 0.86, respectively, when the 4th deprotonation is taken into account.

3.5. Importance of Tautomers in the Analysis of the Experimental Data—The tautomers of TC seem to have an important and so far unsuspected role in the actual behavior of TC, which explains a certain level of confusion present in the various interpretations of experimental results that appear in the scientific papers dealing with TC.

For example, the protonation scheme of TC and its derivatives has been a subject of discussions and disagreements between researchers about the interpretation of experimental results. Stezowski et al.[16] studied the behavior of free TC in ethanol/water solution using circular dichroism. According to them, two species are in equilibrium and are represented by (i) a zwitterionic species with extended conformation, which predominates in aqueous solution, and (ii) a neutral one with folded conformation,

which predominates in ethanol. It is important to note that our results are in agreement with this observation. Depending on the ethanol/water proportion, not only the conformation can be changed but also the tautomeric form of TC. However, our results do not support that the 1st deprotonation is due to site A. According to our results, the heat of solution of the zwitterionic species has to be >30 kcal mol^{-1} to invert the relative stability of the neutral form. This value is much larger than the expected error bar of the calculations performed in the present work. On the other hand, the solvent effects calculated by the SCRF method do not take into account the specific interactions (hydrogen bonding, dipole−dipole, etc.), and this could perhaps explain the discrepancies between calculated and the current interpretation of experimental results concerning the 1st deprotonation. The dimeric form of TC also has to be taken into account because it has been shown by Bogardus and Blackwood[35] that such species are also formed as a result of intermolecular hydrogen bonding of phenolic diketone system.

Stephens et al.[8] have eliminated some protonation sites of TC through reactions of etherification. The product dimethiloxytetracycline has the methoxy groups of the C(12) and C(1) and/or C(3) blocked for protonation. By means of potentiometric and UV spectra they determined two pK_as (7.5 and 9.4) and they concluded that the $pK_2 = 7.5$ should be assigned to site B. Therefore, the $pK_1 = 3.3$ of TC could not be assigned to site B because the electronegative inductive effect of the methoxy group could not increase the pK_1 from 3.3 to 7.5. It is necessary to consider that in the case of dimethiloxytetracycline, the $pK_2 = 7.5$ is related to a deprotonation of a positively charged species (because the site A is blocked by a methoxy) to a neutral one. In the case of TC, the situation is different. Supposing that $pK_a = 7.68$ is the deprotonation of site B, it would be related to a deprotonation of a neutral species to a negatively charged one. Thus, the two models are not so similar as to warrant straightforward conclusions.

Leeson et al.[9] have also compared values of three molecules derived from TC, however, these molecules have different total charges. Furthermore, different TC derivatives have different tautomers and conformations. Consequently, the chemical properties of the molecule can be completely changed. So, comparison between different molecules derived from TC, all probably also presenting a large degree of tautomerism, must be done with caution.

Rigler et al.[10] attributed the chemical shift of the dimethylamonium group exclusively to the protonation state of site B and the chemical shifts of the protons bonded to the phenolic ring to the protonation state of this group. They concluded that pK_2 and pK_3 should have contributions from sites B and C or D. According to Martin,[2] their supposition is not valid and the conclusions consequently not reasonable. For example, Martin mentioned the fact that after addition of 1 equivalent of base to the TC, the site A is 19% protonated, and after addition of 2 equivalents, 33% of site A remains protonated. It is known that chemical shifts are modified by the tautomeric forms and that has to be taken into account in the analysis by ^1H NMR. Deprotonation of site B modifies the electronic environment of the atoms around this site. However, if this deprotonation is followed by a change in the tautomeric form of site A, the chemical shifts of the protons of this site will also be changed. Eventually, unsuspected tautomerism can lead to wrong interpretations of the experimental data.

Asleeson and Frank,[11] from their ^{13}C NMR experiments, also concluded that the pK_2 and pK_3 have contributions from the B and C or D sites. They assumed that the 1st deprotonation is due exclusively to site A. Our results show that the site A proton is bonded to the oxygen of the amide group. After the 1st deprotonation, which our results indicate should occur on site B, the charge distribution on site A could, in turn, be completely modified because of changes in tautomeric forms that would change the ^1H and ^{13}C chemical shifts on site A.

Metal ions complexation by TC is also a field where there are disagreements among researchers. TC has several ways to complex metal ions. Depending on the solvents and conditions, different tautomeric species predominate in the medium and specific sites become more suitable for complexation of metal ions. This differentiation could explain the ability of TC to complex metal ions in different positions (see, for example, the Ca^{2+} and Mg^{2+} in the works of Caswell and Hutchison[7] and Lambs et al.[6]).

4. Conclusions—TC and its derivatives are a group of broad spectrum antibiotics that have been extensively studied in the last years. Their acid/base properties and chemical behavior in different mediums are extremely important to understand their mechanism of action and side-effects. However, tautomerism in these molecules has not received attention commensurate with its importance to the complete understanding of their chemical behavior in different mediums. We have explored all possibilities of tautomerism of TC by semiempirical calculations. We have shown that in solution, TC is in reality an equilibrium of different tautomers. This equilibrium can be displaced by varying the pH and the dielectric constant (solvent) of the system. We have also presented theoretical and experimental evidence that the discussion concerning the 4th deprotonation of TC is coherent. A theoretical estimation of the pK_4 of about 13 is in a good agreement with the potentiometric and spectrophotometric determinations of the pK_4 of about 12.

We conclude that TCycline seems to be a sort of a chameleon and highly adaptive molecule capable of modifying itself (its chemical bonds and of folding or extending itself) in a great diversity of manners in response to the environment in which it is immersed. And we extend this conclusion to the various TC derivatives with direct consequences to the understanding of their mechanisms of action.

6. Appendix

Potentiometric Measurements—Potentiometric titrations of 3 mmol L^{-1} aqueous solutions of TC HCl (Merck) were carried out with an automatic Methohm 670 apparatus coupled to a Metrohm Dosimat 665 autoburet. Experiments were carried out under nitrogen atmosphere and the temperature was kept constant at 25 °C. The ionic strength was maintained at 0.1 mol/L with sodium perchlorate. The electrode system was calibrated for $[H^+]$ before the measurements, by titration of $HClO_4$ with standardized NaOH, and vice versa, at an ionic strength of 0.10 mol L^{-1} with $NaClO_4$ solution. The symbol pH therefore represents $-\log[H^+]$ in this paper. TC stock solutions were prepared just before use to avoid ligand degradation caused by oxygen and light. The acidity constants were calculated from the potentiometric titration data with the SUPERQUAD[36] computer program, based on pH values ranging from 2.0 to 11.5.

Spectrophotometric Measurements—A typical spectrophotometric titration involved 25.0 mL of a 0.5 mmol L^{-1} TC HCl solution being titrated with 0.08 mol L^{-1} NaOH. This solution, while being potentiometrically titrated, was continuously circulated with a peristaltic pump through a 0.1-cm continuos flow quartz cuvette installed in a model 8451A Diode Array Hewlett-Packard spectro-

photometer. This setup allowed simultaneous measurements of the volume of titrant (NaOH) added, of the hydrogen ion concentration, and of the absorbance of the solution. This titration was performed with increments of volume and time intervals, both pre-fixed (known as monotonic titration), to obtain an absorbance spectrum and the hydrogen ion concentration after each addition of the titrating solution. Results are shown in Figure 9. The data were treated with the program SQUAD[37] to calculate both pK_as and molar absorptivities of each one of the species.

Accepted for publication July 31, 1998.

Abstract □ Thalidomide, a glutamic acid derivative, has recently been shown to inhibit in vitro angiogenesis, the process of formation of new blood vessels. This Phase II study examined the pharmacokinetics of thalidomide in patients with clinically progressive hormone-refractory prostate cancer. Patients (aged 55 to 80 years) were randomized to two different arms, low dose versus high dose. Patients in the low-dose group were given 200 mg of thalidomide and patients in the high-dose group received 200 mg of thalidomide, with subsequent dose escalations to 1200 mg. Serial serum or blood samples were obtained for pharmacokinetic assessment after administration of a single oral dose or multiple daily dosing of thalidomide and were assayed by reversed-phase HPLC. Pharmacokinetic parameters for both the single and multiple dosing were calculated with ADAPT II. A one-compartment model best fit the data. After single dosing, the oral clearance and apparent volume of distribution for the low-dose regimen ($n = 13$) were 7.41 ± 2.05 L/h and 66.93 ± 34.27 L, respectively, whereas for the high-dose regimen ($n = 11$), these values were 7.21 ± 2.89 L/h and 165.81 ± 84.18 L, respectively. The elimination half-lives for the low and high dose were 6.52 ± 3.81 and 18.25 ± 14.08 h, respectively. After the multiple dosing of thalidomide, the oral clearance and apparent volume of distribution for the low-dose group ($n = 10$) were 6.35 ± 1.64 L/h and 64.63 ± 23.20 L, respectively, whereas for the high-dose group ($n = 11$), these values were 7.73 ± 2.27 L/h and 167.85 ± 82.08 L, respectively. The elimination half-lives for the low and high dose were 7.08 ± 1.87 and 16.19 ± 9.57 h, respectively. For both the single and multiple dosing of thalidomide, the apparent volume of distribution and half-life were significantly higher for the high-dose group than those for the low-dose group. The higher apparent volume of distribution may be attributable to several factors, such as change in absorption, protein binding, etc. A dose-proportional increase in thalidomide steady-state concentrations was seen after multiple daily dosing of thalidomide.

Introduction

Prostate carcinoma is currently the most common cancer in American men. The initial therapy for metastatic prostate cancer is androgen deprivation; that is, medical or surgical castration with or without an androgen receptor antagonist. Once metastatic prostate cancer progresses in the face of hormonal therapy, it is classified as being hormone refractory. Therapeutic options for hormone-refractory prostate cancer are extremely limited, and cytotoxic chemotherapy has not been successful in prolongation of survival.

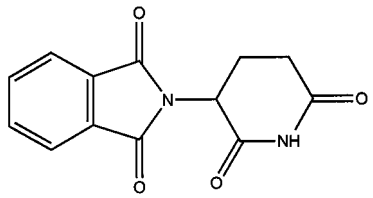

Figure 1—Structure of thalidomide.

Thalidomide (*N*-phthalidoglutarimide; $C_{13}H_9O_4N_2$; Figure 1) was initially introduced in 1954 as a sedative but was withdrawn from the market in the early 1960s because of its teratogenic effects. During the following years, this drug was found to be extremely effective in lepromatous leprosy and is currently being evaluated as an experimental drug in the treatment of a variety of diseases with an autoimmune character, including human immunodeficiency virus (HIV) infection and graft versus host disease.[1,2,3,8] Folkman and colleagues recently reported that thalidomide inhibited angiogenesis in the rabbit cornea micropocket assay.[4] Bauer et al. went on to show that a metabolite of thalidomide was responsible for the antiangiogenic properties.[5] Based on those data, four phase II clinical trials using thalidomide were initiated in solid tumors (Kaposi's sarcoma, glioblastoma, breast cancer, and prostate cancer). Herein, we characterize the pharmacokinetics of thalidomide from an open-labeled, phase II, randomized study (comparison of two dosing regimens) in an elderly population of men with hormone-refractory prostate cancer.

Patients and Methods

Patient Eligibility—Patients with clinically progressive hormone-refractory prostate cancer documented for at least 1 month and who had not undergone a radical prostatectomy or received radiation therapy, with a life expectancy of >3 months and an Eastern Cooperative Oncology Group performance status of 0 to 2, were eligible. Refractory disease was demonstrated after the withdrawal of the antiandrogen (i.e., flutamide). Patients were required to have a granulocyte count of >1000/mm^3, a platelet count of >75 000 mm^3, a measured creatinine clearance of >40 mL/min, and a total bilirubin of ≤1 mg/dL. At least 4 weeks must have elapsed from receipt of any form of anticancer therapy, and patients must have recovered from all toxicities related to the prior therapy.

Drug Administration—All eligible patients were randomized to two different arms, low dose or high dose. Patients on the low-dose arm were given 200 mg of oral thalidomide in the morning as the first dose and, thereafter, 200 mg of thalidomide orally every evening starting on day 2. Treatment was continued provided that there was no dose-limiting toxicity or progression of the disease. Patients on the high-dose arm were given 800 mg of oral thalidomide in the morning on day 1 and, thereafter, thalidomide was

10.1021/js980172i Not subject to U.S. copyright. *Published on Web 11/26/1998*

administered orally every evening starting at 200 mg/day on day 2 and increasing by 200 mg/day every 2 weeks to a maximum dose of 1200 mg/day. Dose increases were continued only if no side effects were noted. Treatment was continued provided there was no dose-limiting toxicity or disease progression. Patients took thalidomide at approximately the same time daily.

Pharmacokinetic Sampling—Blood samples were obtained from all patients for pharmacokinetic assessment. Samples (7 mL) were drawn in heparinized tubes immediately prior to the dose on day 1 (pre-level) and then at 0.5, 1, 1.5, 2, 3, 4, 5, and 7 h on day 1 and at 24, 27, and 31 h on day 2. Samples were also obtained in the morning at each clinic visit throughout the study. The instability of thalidomide requires that the plasma be harvested within 1 h of obtaining the blood samples.[6,7] After centrifuging the blood samples, the plasma was drawn off and stored at −70 °C until analysis. Plasma levels of thalidomide were determined using high-performance liquid chromatography (HPLC) with ultraviolet (UV) detection.

Analytical Method—A Hewlett-Packard 1090 Series II Liquid Chromatograph equipped with a photodiode-array detector was used for the chromatographic analysis of total thalidomide. A Waters Nova-Pak C-18 (3.9 × 300 mm) column was used, and a gradient mobile phase of water, acetonitrile, and a 0.5 M NaH_2PO_4 buffer (pH 3.0) was run at a flow rate of 1 mL/min. Thalidomide and phenacetin, the internal standard were isolated from the plasma by solid-phase extraction and detected at UV wavelengths of 220 and 248 nm, respectively, with a run time of 16 min. Ten percent H_2SO_4 was added to the plasma to prevent the nonenzymatic degradation of thalidomide (rate constant for degradation of thalidomide is ~0.175/h[8]). Standard curves were found to be linear in the range of 25 to 10 000 ng/mL, with the coefficient of determination (r^2) ≥0.995. The intraassay as well as inter-assay precision and accuracy errors were <10%.[6]

Pharmacokinetic Analysis—Plasma samples were obtained for pharmacokinetic assessment after administration of a single oral dose or multiple daily dosing of thalidomide. Pharmacokinetic parameters for both the single and multiple dosing of thalidomide were calculated by weighted nonlinear least-squares analysis fitting a one-compartment and two-compartment open linear model computed by ADAPT II (Biomedical Simulations Resource, University of Southern California, Los Angeles, CA). Model selection was determined based on Akaike's Information Criterion (AIC) and visual examination of the difference between the measured and fitted concentration. Pharmacokinetic parameters determined from single-dose studies were used as priors for determination of multiple-dosing parameters. In the present pharmacokinetic analysis, outlier points (points ≥2 standard deviations outside the fitted line) were not disregarded and all the data points were included in the fitting of the data. The r^2 values reported are the actual values and not the skewed values.

Statistical Analysis—The two-tailed Wilcoxon rank sum test was used for comparison of pharmacokinetic parameters.

Results

Pharmacokinetics—Data were obtained from 24 patients for the single dosing of thalidomide, out of which 13 patients received the low dose (200 mg) and 11 received the high dose (800 mg). Weighting with least-squares fitting as the estimator provided the best fit for 23 patients, whereas maximum likelihood gave the best fit in one patient. In addition, a one-compartment model fit the data best. Figure 2A shows a concentration versus time profile (mean ± SD) for patients on the low dose (200 mg), who received a single dose of oral thalidomide and Figure 2B shows a concentration versus time profile (mean ± SD) for patients on the high dose (800 mg), who received a single dose of oral thalidomide. Pharmacokinetic parameters obtained after the single dose are listed by dose level in Table 1. The t_{max} of thalidomide ranged between 2.01 and 7.09 h, with a median value of 3.32 h for the low-dose regimen (200 mg of thalidomide on day 1). For the high dose (800 mg of thalidomide on day 1), the t_{max} ranged from 1.35 to 7.12 h, with a median value of 4.40 h. Median C_{max} values of 1.97 μg/mL (range of 1.15 to 3.79) and 4.42 μg/mL (range of 2.41 to 8.41) were reported for the initial low-dose (200 mg) and the initial high-dose (800 mg) groups, respectively. The oral clearance and apparent volume of distribution for the low-dose regimen were 7.41 ± 2.05 L/h and 66.93 ± 34.27 L, respectively, whereas for the high-dose regimen, these values were 7.21± 2.89 L/h and 165.81 ± 84.18 L, respectively. The elimination half-lives for the low and high dose were 6.52 ± 3.81 and 18.25 ± 14.08 h, respectively (p = 0.0037). In general, an increase in the half-life of thalidomide was seen for the high-dose group. Also, there was a significant difference in the apparent volume of distribution between the low and the high-dose groups (p = 0.0039), with the high-dose group having a higher apparent volume of distribution.

Data were obtained from 21 patients for the multiple dosing of thalidomide. Ten patients received the low dose and 11 were randomized to the high-dose arm. In the low-dose arm, one patient was removed from the study because of unresolved grade 2 neuropathy. In the high-dose arm, 10 patients either had dose held for a period of time or

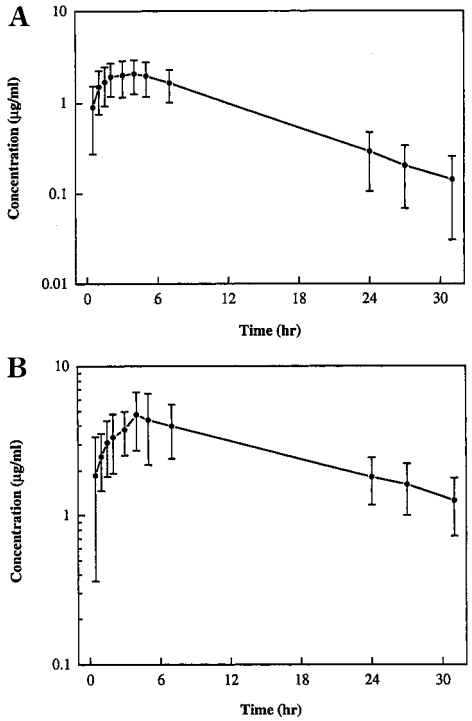

Figure 2—Plasma concentration versus time curves. (A) Plasma concentration versus time curve (mean ± SD) for patients in the low-dose group after a single oral dose of 200 mg of thalidomide. (B) Plasma concentration versus time curve (mean ± SD) for patients in the high-dose group after a single oral dose of 800 mg of thalidomide.

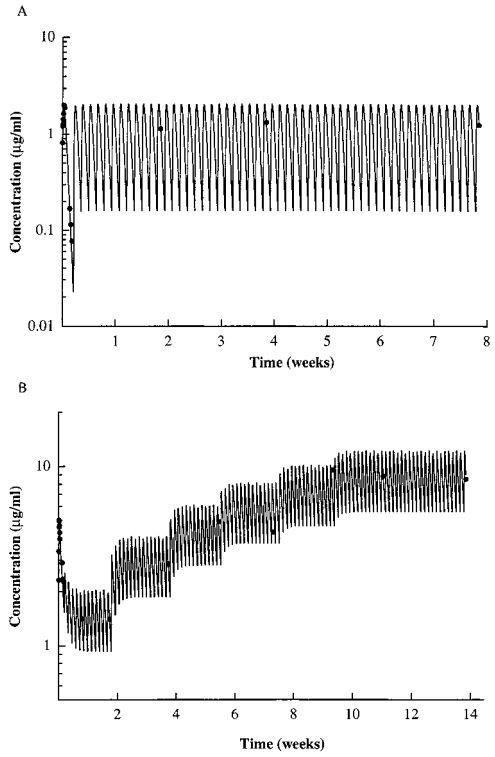

Figure 3—Plasma concentration versus time curves. (A) plasma concentration versus time curve for a patient in the low-dose group during daily oral dosing of 200 mg of thalidomide. (B) Plasma concentration versus time curve for a patient in the high-dose group during daily oral dosing of thalidomide with dose escalations after every 2 weeks.

received no dose escalations because of complications. The first patient had drug held for 24 days because of a pulmonary embolism, after which the dose was reduced to 200 mg of thalidomide followed by escalation every 2 weeks up to 1200 mg. The second patient had drug held for 7 days because of neutropenia and subsequently there was no dose escalation above 200 mg of thalidomide. The third patient had his dose held at 800 mg for 4 weeks because of shortness of breath, after which the dose was escalated to 1000 mg and subsequently to 1200 mg of thalidomide. The fourth patient had no dose escalation beyond 200 mg because of sedation, and the fifth patient had dose held at 400 mg for 5 weeks and subsequently there was no dose escalation beyond 600 mg. The sixth and seventh patients received no dose escalation beyond 800 mg of thalidomide, and thalidomide was discontinued after a dose of 200 mg for the eighth and ninth patients. The tenth patient had drug discontinued after a dose of 400 mg of thalidomide.

Figure 3A shows a representative concentration versus time profile for a patient on the low-dose arm (200 mg per day) who received multiple daily doses of oral thalidomide, and Figure 3B shows a representative concentration versus time profile for a patient on the high-dose arm (200 mg per day increasing by 200 mg every 2 weeks to a maximum of 1200 mg per day) who received multiple daily doses of oral thalidomide. Patients on the low-dose arm of the study were maintained on thalidomide for a mean of 67 days (median = 62 days), ranging from 55 to 123 days. Pharmacokinetic parameters and the average maximum concentrations at steady state ($C_{max\ ss}$) after the multiple dosing are listed by dose level in Tables 2and 3, respectively. The oral clearance and apparent volume of distribution for the low-dose regimen were 6.35 ± 1.64 L/h and 64.63 ± 23.20 L, respectively, whereas for the high-dose regimen, these values were 7.73 ± 2.27 L/h and 167.85 ± 82.08 L, respectively ($p = 0.31$ and 0.0028). The elimination half-lives for the low- and high dose groups were 7.08 ± 1.87 and 16.19 ± 9.57 h, respectively ($p = 0.013$). Similar to the single-dosing results, the apparent volume of distribution and half-life were significantly higher for the high-dose group than those for the low-dose group.

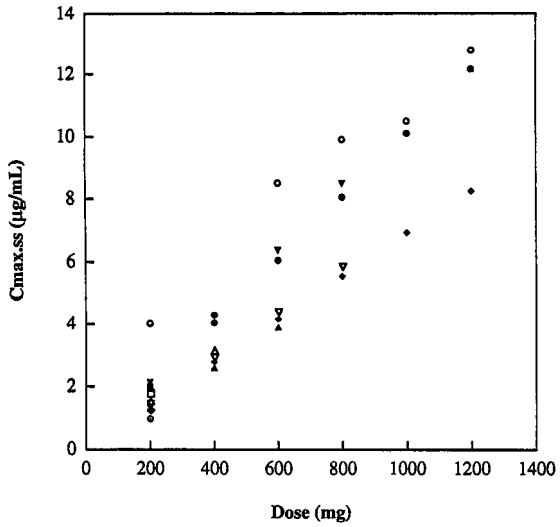

Figure 4—Maximum steady-state thalidomide concentrations as a function of dose after multiple daily dosing of oral thalidomide.

Figure 4 presents the model-predicted maximum steady-state concentrations of thalidomide as a function of dose. A dose-proportional increase in steady-state concentration of thalidomide was seen. Overall, the one-compartment linear model with first-order absorption fit the data well, as evidenced by the plot of observed versus fitted concentration for both single and multiple daily oral dosing of thalidomide (Figure 5A and B).

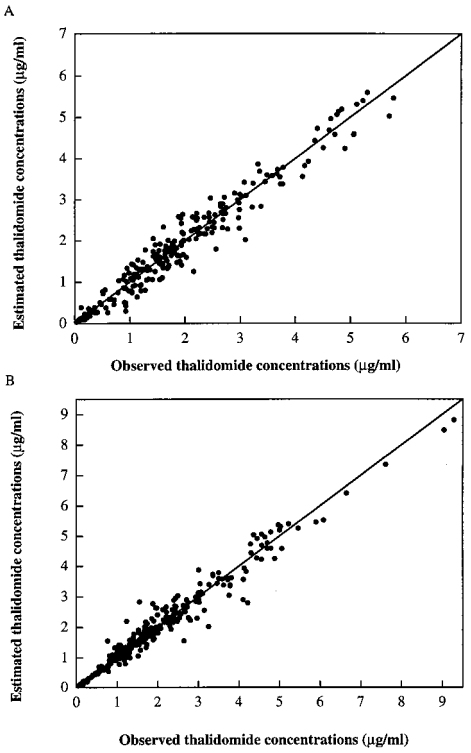

Figure 5—Estimated versus observed thalidomide concentrations. (A) Thalidomide concentrations estimated by a one-compartment model plotted against the observed thalidomide concentrations after a single oral dose. (B) Thalidomide concentrations estimated by a one-compartment model plotted against the observed thalidomide concentrations after multiple daily dosing.

Discussion

Thalidomide has been shown to inhibit tumor angiogenesis, the process of new blood vessel formation within a malignancy. Despite extensive clinical work with this compound for some 40 years, there are generally few data on the pharmacokinetics of thalidomide. Chen et al.[28] reported the pharmacokinetics of thalidomide after oral dosing in healthy male volunteers. The disposition of thalidomide in these patients was characterized by an elimination half-life of approximately 9 h, a clearance of 10 L/h, and an apparent volume of distribution of nearly 121 L. Piscitelli et al.[22] reported the pharmacokinetics of thalidomide in HIV-infected patients after a single oral dose. Thalidomide pharmacokinetics in these patients was characterized by slow absorption, with a mean t_{max} of 3.4 h, an elimination half-life of approximately 6 h, an oral clearance of approximately 8.5 L/h, and an apparent volume of distribution of approximately 85 L. For both the studies, the dose was no more than 300 mg. Our study reported nearly identical values for the low-dose arm (200 mg), but the apparent volume of distribution and the half-life were significantly different for the high-dose arm (800 mg test dose and then dose escalations every 2 weeks).

A one-compartment first-order oral absorption model provided the best fit for the data after single and multiple oral dosing of thalidomide in patients with hormone-refractory prostate cancer. In general, the model fit the data well, as evidenced by the plot of observed versus fitted concentrations. The oral clearance was comparable for the low- and the high-dose groups, but the apparent volume of distribution and half-life were significantly higher for the high-dose group. The higher volume of distribution may be attributable to several factors, such as change in absorption, protein binding, etc. Many drugs have been shown to have extended half-lives due to low aqueous solubility. The pH 7 solubility of thalidomide is 50 μg/mL.

Pharmacokinetic evaluation was reliable for 24 patients for the single dosing and 21 patients for the multiple dosing of thalidomide, (patients ranged in age from 55 to 80 years). No significant age dependency was observed in plasma clearance and elimination half-life. No dose-related changes in oral clearance were seen.

The pharmacokinetics of thalidomide have not been clearly characterized in men. Our study described the pharmacokinetic profile of thalidomide, after single as well as multiple oral dosing in an elderly population of men with cancer. Low- and high-dose groups were studied and pharmacokinetic parameters were determined for both. Patients in this study were diagnosed with hormone-refractory prostate cancer, but did not have active opportunistic infections or concomitant diseases. Additional studies are necessary to determine if age affects the clearance of thalidomide and whether the formation of the active metabolite of thalidomide that inhibits angiogenesis is altered by changes in clearance.

PLGA Microspheres Containing Plasmid DNA: Preservation of Supercoiled DNA via Cryopreparation and Carbohydrate Stabilization

SHUICHI ANDO, DAVID PUTNAM, DANIEL W. PACK, AND ROBERT LANGER*

Contribution from *Massachusetts Institute of Technology, E25-342, 45 Carleton Street, Cambridge, Massachusetts 02139.*

Received April 17, 1998. Accepted for publication October 12, 1998.

Abstract □ Biodegradable microspheres containing plasmid DNA have potential uses as mediators of transfection in cells, particularly phagocytic cells such as macrophages. However, the hydrophilic nature and the structural instability of supercoiled DNA preclude its facile encapsulation in polymer matrixes such as poly(*d*,*l*-lactic-*co*-glycolic acid) (PLGA) by traditional methods. We initially studied the microencapsulation of plasmid DNA using the established water-in-oil-in-water double-emulsion solvent-evaporation method and found that (1) the encapsulation efficiency was low (about 20%), (2) the microencapsulation procedure nicked (degraded) the supercoiled DNA, and (3) lyophilization of the microsphere also nicked the DNA. We have therefore designed a new microsphere preparation method (called cryopreparation) to specifically address these concerns. Using the cryopreparation method, the aqueous phase of the primary emulsion containing the plasmid DNA is frozen and then subjected to homogenization. Because there is no shear stress inside a solid, we hypothesized that freezing the aqueous phase of the primary emulsion would help to preserve the supercoiled plasmid DNA during formation of the secondary emulsion. We also hypothesized that the formation of crystals from buffers within the primary emulsion was a causative factor for nicking during freezing or lyophilization, and that disruption of the crystal formation by the addition of saccharides into the primary emulsion would improve the supercoiled-DNA content of the spheres. Our results support the two hypotheses. Not only was the supercoiled-DNA content increased from 39% to over 85%, but the encapsulation efficiency was also elevated from 23% to over 85%.

Introduction

The importance of DNA therapeutics, in particular in gene therapy, has led to increased research and development in this area.[1−5] The use of such therapeutics can be problematic, however, because during delivery the DNA is subject to degradation. To maximize the power of these agents, it would be desirable to develop a mode of delivery in which the DNA-based therapeutic is protected from degradation. It is known that nano- or micro-encapsulation techniques can be used to protect sensitive bioactive agents, such as DNA, from degradation.[6−10]

Biodegradable microspheres, such as those based on PLGA, have the potential to act as mediators of DNA transfection targeted to phagocytic cells such as macrophages, and to protect against biological degradation by nucleases. Uptake of biodegradable microspheres by macrophages has been extensively studied,[11] and more recently Ciftci et al.[12] reported a method to introduce DNA into mammalian cells using a polymer-based gene-delivery system. Spheres in the range of 1−10 μm are too large to enter cells via endocytosis, and therefore "target" phagocytic cells such as macrophages by size exclusion. Because macrophages are antigen-presenting cells for the immune system, microencapsulated plasmid DNA is particularly useful for the rapidly developing field of DNA-based vaccines.[13]

One of the most common techniques for preparation of biodegradable polymer microspheres encapsulating hydrophilic molecules is the double-emulsion solvent-evaporation method. Using this technique, the molecule to be encapsulated is placed in aqueous solution while the polymer is dissolved in an organic phase commonly consisting of methylene chloride or ethyl acetate. The two phases (volume organic/volume aqueous = 3−20) are emulsified, typically by sonication or homogenization. This primary emulsion is then added to a second aqueous phase (20- to 100-fold larger volume) and again mixed by homogenization to form the (water-in-oil)-in-water double emulsion. Upon evaporation of the partially water-miscible solvent, the polymer-containing droplets harden to form microspheres which can then be isolated by filtration or centrifugation. Lyophilization removes water from the interior aqueous phase resulting in a dry suspension of the encapsulated material within the polymer matrix.

Our initial experiments using the standard double-emulsion microsphere formulation process demonstrated the tendency of plasmid DNA to be converted from its supercoiled state to a nicked or linear state. The preservation of the supercoiled DNA is important because it is known that supercoiled DNA retains the highest level of bioactivity.[14−16] Furthermore, the encapsulation efficiency of DNA into the hydrophobic matrix of PLGA was low, on the order of 20%. On the basis of these observations, we formulated hypotheses for the mechanisms of DNA degradation during the microsphere formulation process and then adopted a design approach to develop an encapsulation process that maximized both the supercoiled-DNA content in the microsphere and its overall encapsulation efficiency. Our hypotheses were as follows: (1) shear stress-induced plasmid DNA degradation occurred during homogenization and (2) buffer salt crystal formation induced plasmid DNA degradation during freezing or drying.

The first hypothesis led to the design and development of a new microencapsulation process for plasmid DNA called cryopreparation. Cryopreparation describes a process in which the temperature of the DNA-containing primary emulsion is lowered below the freezing point of the aqueous inner phase resulting in a solid particulate suspension prior to homogenization to form the secondary emulsion. Because the shear stress within a solid equals zero, the plasmid DNA frozen in the inner phase is exposed to minimum shear stress during homogenization, and the supercoiled state of the plasmid DNA should be preserved. Cryopreparation should also enhance the overall encapsulation efficiency by preventing diffusion of the plasmid DNA out of the microsphere during homogenization. Cryopreparation differs from other microsphere preparation methods that

use temperature as a variable parameter in that cryopreparation involves selective freezing of the aqueous inner emulsion whereas other procedures freeze or gel the entire microsphere.[17,18] The second hypothesis led to the inclusion of saccharides in the primary emulsion to disrupt the formation of DNA-nicking crystals during homogenization and lyophilization.

Experimental Section

Materials—Plasmid DNA (pCMV-β-gal) was purified from *E. coli* (DH5α) using Plasmid Mega Kit column isolation (QIAGEN, CA), followed by ethanol precipitation. Poly(*d,l*-lactic-*co*-glycolic acid) (PLGA), with a comonomer ratio of 50:50 and an inherent viscosity $\eta = 0.4$ (Resomer RG503, MW 34 000) was purchased from Boehringer Ingelheim (Germany). The emulsifier, poly(vinyl alcohol) (PVA) (88 mol % hydrolyzed, MW 25 000), was purchased from Polysciences, Inc. (Warrington, PA). All other chemicals used were of the highest grade commercially available.

Cryopreparation—DNA-containing microspheres were prepared following the established water-in-oil-in-water double-emulsion solvent-evaporation method[19] except for specific steps noted below. The two phases, consisting of 250 μL of DNA solution (250 μg of DNA) and 7 mL of methylene chloride containing 200 mg of PLGA, were emulsified by sonication for 10 s (ultrasonic probe, Sonic & Materials Inc.) at room temperature. The primary emulsion temperature was then lowered below the freezing point of the aqueous inner phase by liquid nitrogen immersion, and 50 mL of a 5% PVA solution (4−7 °C) was added and homogenized at 5000−9000 rpm for 14 s (Silverson L4R homogenizer). After homogenization, the resulting emulsion was diluted in 100 mL of 1% PVA, and the system was stirred magnetically for 3 h to allow for evaporation of the organic solvent. Microspheres were finally collected by centrifugation and washed 3 times with water to remove excess PVA. Note that all PVA solutions were adjusted to the osmotic pressure of the inner aqueous phase using agents such as saccharides. The microspheres were resuspended in approximately 1 mL of water, frozen in liquid nitrogen, and lyophilized at room temperature for 24 h on a Labconco Freeze-Dryer 8.

Achieving DNA Stability against Lyophilization Using Excipients—The effect of lyophilization on DNA was studied by directly lyophilizing DNA samples (20 μg/mL). Aliquots (1 mL each) of the DNA solutions, with or without excipients, were frozen in 20-mL disposable scintillation vials by liquid nitrogen immersion and immediately lyophilized at room temperature for 15 h.

Optimized Microsphere Preparation—The two phases, consisting of 250 μL of DNA in water (750 μg of DNA) containing 1 mM EDTA and 300 mM lactose (pH 7.0) and 7 mL of methylene chloride containing 200 mg of PLGA, were emulsified by sonication as described above. After the primary emulsion was cryoprepared, 50 mL of 5% PVA solution containing 300 mM lactose was added to the solution and homogenized at 7000 rpm for 14 s. The resulting double emulsion was then diluted in 100 mL of 1% PVA solution with 300 mM lactose, and the system was stirred magnetically for 3 h to allow the evaporation of the organic solvent. Microspheres were finally collected by centrifugation, washed three times with distilled water, and then lyophilized at room temperature to obtain a powder.

Analysis of DNA Structure—The DNA structure was analyzed by agarose gel electrophoresis (1% agarose containing ethidium bromide, 110 V, 90 min) and compared to untreated stock DNA for semiquantitative determination of supercoiled-DNA content using a Bio Rad Gel Doc 1000 (Software, Molecular Analyst 2.1).

As shown in Figure 1, each DNA band was integrated as a volume. Supercoiled-DNA (SC DNA) content was defined as the volume integrated from the supercoiled DNA band over the total volume integrated from all bands. In other words, SC DNA content equals (SC DNA volume − background volume)/{SC DNA volume + linear DNA volume + nicked DNA volume − (3 × background volume)}. SC DNA content remaining after preparation was calculated as follows: SC DNA remaining (initial %) = 100 × (SC DNA content of sample DNA)/(SC DNA content of initial DNA).

Quantitation of DNA Content in Microsphere—The microsphere DNA content was determined using fluorescent reagent PicoGreen (Molecular Probes, Eugene, OR) which preferentially binds to double stranded DNA and to a lesser extent to single stranded DNA. Fluorescence (λ_{ex} = 480 nm, λ_{em} = 520 nm) of extracted DNA was compared to a standard curve, using plasmid DNA, which was linear from 1 to 50 ng/mL. The encapsulation efficiency was determined as the amount of DNA recovered from the microspheres relative to the initial amount of DNA used (encapsulation efficiency = 100 × (DNA recovered)/(initial DNA)).

Particle Size of Microsphere—Particle size distribution of microspheres was analyzed by a Coulter MultisizerII (Coulter Electronics Inc., Hialeah, FL), and the mean volume diameter distribution was determined.

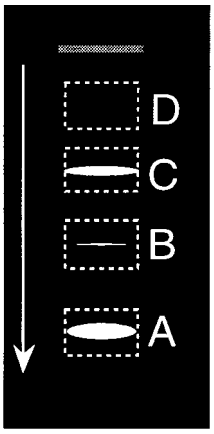

Figure 1—Schematic representation of agarose gel electrophoresis of DNA: (A) supercoiled DNA, (B) linear DNA, (C) nicked DNA, and (D) background.

Table 1—Effect of Homogenization Rate, Cryopreparation, and Addition of EDTA on Remaining Supercoiled DNA (SC DNA) ($N = 3$)

DNA solution	SC DNA remaining (initial% ± SD) at homogenization rate		
	5000 rpm	7000 rpm	9000 rpm
water without cryopreparation	36.9 ± 1.9	26.1 ± 3.6	20.1 ± 3.4
water with cryopreparation	54.4 ± 1.1	46.2 ± 0.7	37.3 ± 4.7

EDTAa with cryopreparation	92.2 ± 1.3	75.5 ± 2.1	64.7 ± 3.5

[a] 1 mM EDTA, pH 7.5.

Results and Discussion

Stability of DNA Structure against Shear Stress—In the cryopreparation method, the aqueous phase of the primary emulsion is frozen. Since the shear stress inside a solid equals zero, we hypothesized that cryopreparation would help to preserve the supercoiled DNA during homogenization. To test this hypothesis, the structure of the DNA after homogenization (and before lyophilization) was checked by agarose gel electrophoresis. Table 1 indicates that the supercoiled-DNA content decreases with an increase in homogenization rate, and that using the cryopreparation method preserves the supercoiled-DNA content. These results support our hypothesis that freezing the inner DNA solution protects the DNA from degradation by shear stress, and suggests that cryopreparation is a useful method to prevent supercoiled DNA from degrading during microsphere preparation. When ethylenediaminetetraacetic acid (EDTA) was added to the DNA solution, the supercoiled-DNA content of the resulting microspheres was significantly higher than in the absence of EDTA. EDTA is a chelator of divalent metal cations and inhibits the activity of DNase by this mechanism.[16] Therefore, it was possible that the DNA stability in the presence of EDTA was actually due to DNase inhibition. To examine the possibility of calcium-dependent DNase-mediated degradation, we also included a calcium ionophore (*N,N,N′,N′*-

Table 2—Effect of Excipients on Retaining Supercoiled DNA (SC DNA)[a]

DNA solution	SC DNA remaining (initial% ± SD)
water	46.2 ± 0.7
1 mM EDTA solution, pH 7.5	75.5 ± 2.1
1 mM calcium ionophore II	36.1 ± 0.8
10 mM Tris buffer, pH 7.5	40.5 ± 2.5
phosphate-buffered saline, pH 7.5	36.1 ± 3.5
300 mM lactose solution, pH 7.5	39.6 ± 2.7
1 mM EDTA/10 mM Tris buffer, pH 7.5	62.1 ± 2.7
1 mM EDTA/phosphate-buffered saline, pH 7.5	68.2 ± 5.2
300 mM lactose/1 mM EDTA solution, pH 7.5	94.5 ± 1.0
300 mM lactose/1 mM EDTA/10 mM Tris buffer, pH 7.5	86.2 ± 3.6

[a] Samples were prepared by cryopreparation; homogenization rate = 7000 rpm, 14 s (n = 3).

tetracyclohexyldiglycolic diamide: calcium ionophore II, log K_{Ca} = 10.1, μ = 0.1, 20 °C)[20] instead of EDTA (log K_{Ca} = 11.0, μ = 0.1, 20 °C).[21] As shown in Table 2, it is apparent that the calcium ionophore II did not act as a DNA stabilizer. Therefore, it is likely that the mechanism of DNA stabilization during cryopreparation is not a result of calcium-dependent DNase inhibition. However, DNase activity dependent on other divalent ions such as manganese and magnesium,[22] could not be eliminated. In addition, Table 2 indicates that DNA degradation during cryopreparation was not inhibited by the addition of PBS (1 mM K_2HPO_4, 10 mM Na_2HPO_4, 137 mM NaCl, 2.7 mM KCl, pH 7.0), Tris, or lactose to the DNA solution. In the case of addition of PBS or Tris to the DNA solution containing unbuffered EDTA, the supercoiled-DNA content was slightly lower than that in unbuffered EDTA solution, but we found that by adding lactose to the DNA/EDTA solution, the supercoiled-DNA content was increased from 75% to 95%. The exact mechanism of DNA stabilization is unknown. However, it is apparent that the presence of both lactose and EDTA in the DNA solution is important for the stabilization of supercoiled DNA against degradation during cryopreparation.

Regarding the analysis of the DNA structure by agarose gel electrophoresis, it is well-known that the intercalation efficiency of ethidium bromide to DNA is not the same among supercoiled, nicked, and linear DNA. In fact, the intercalation efficiency of ethidium bromide to supercoiled DNA is the lowest.[23] Thus we consider that the estimation of SC DNA ratio in our method is lower than the true value, and that this analytical method is a semiquantitative determination of the supercoiled-DNA content.

Predictably, the microsphere diameters are dependent on the homogenization rate.[24] The volume-mean diameters of microspheres formulated by cryopreparation were 10.2 (±2.4) μm at 5000 rpm, 4.6 (±0.3) μm at 7000 rpm, and 3.6 (±0.2) μm at 9000 rpm (N = 3). For optimum phagocytosis by macrophages, spheres with a size of approximately 5 μm or less are desired.[11] However, increasing the homogenization rate leads to increased DNA degradation. Therefore, homogenization at 7000 rpm was optimal for the cryopreparation method.

Stability of DNA Structure during Lyophilization—DNA samples were directly lyophilized to study the effect of lyophilization on DNA stability. Table 3 indicates that the DNA stability in 300 mM lactose and in 1 mM EDTA was the same as that of DNA in water. On the other hand, when Tris buffer or PBS was used in the DNA solution, DNA degradation was increased. Salts such as sodium phosphate are known to form crystals upon freezing,[25] and we speculated that DNA nicking was caused by the salt crystallization. (In the presence of 1 mM EDTA, however, the salt concentration might not be high enough to degrade DNA by its crystallization.) Saccharides are known cryoprotectants for proteins during lyophilization,[26,27] and we reasoned they may protect DNA in a similar fashion. Therefore, the effect of saccharides on DNA stability upon lyophilization from TE buffer was examined. Figure 2 indicates that the DNA degradation was decreased with an increase in the amount of saccharide. Other disaccharides such as maltose, trehalose, and cellobiose showed DNA stabilization similar to the effect of lactose (data not shown). The addition of saccharides in the inner aqueous phase of the primary emulsion improved the supercoiled-DNA content of the microspheres, as well (vide supra). Note that the concentrations of glucose are 100, 200, and 600 mM while those of sucrose and lactose are 50, 100, and 300 mM. This indicates that DNA stability depends on the total mass of saccharide and not the molar concentration of sugar.

Table 3—Effect of Lyophilization on Retaining Supercoiled DNA (SC DNA)[a]

DNA solution	SC DNA remaining (initial% ± SD)
water	97.9 ± 1.0
1 mM EDTA solution, pH 7.5	95.2 ± 0.6
10 mM Tris buffer, pH 7.5	70.1 ± 2.5
phosphate-buffered saline, pH 7.5	42.5 ± 3.8
300 mM lactose solution, pH 7.5	95.8 ± 0.4
1 mM EDTA/10 mM Tris buffer, pH 7.5	73.0 ± 0.8
1 mM EDTA/phosphate-buffered saline, pH 7.5	47.4 ± 2.6
300 mM lactose/1 mM EDTA solution, pH 7.5	95.6 ± 0.6

[a] DNA samples were directly lyophilized without the presence of plga or undergoing microsphere preparations.

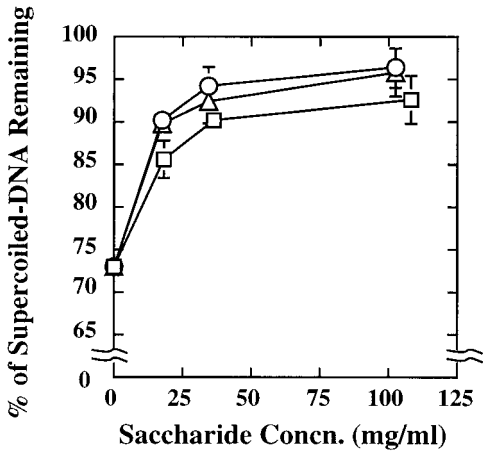

Figure 2—Effect of saccharides on DNA stability during lyophilization (DNA in TE buffer with increasing saccharide concentration). ○: Glucose, □: lactose, and △: sucrose.

Acidic pH is also known to damage DNA by depurination.[28] Freezing of sodium phosphate buffer, initially at pH 7.0, may result in pH as low as 4.0,[29] and this process could potentially contribute to the observed plasmid degradation. However, DNA which was incubated for up to 60 min at room temperature in PBS (Figure 3) or TE (10 mM Tris/1 mM EDTA; data not shown) showed no degradation at either pH 7.4 or pH 4.0. Thus, we believe any pH changes in the solution upon freezing have negligible effect on the DNA stability during microsphere preparation.

Characteristics of Microspheres Optimized for High Supercoiled-DNA Content—We have found that both (1) the addition of lactose and EDTA to the DNA solution and (2) the cryopreparation procedure were important to stabilize DNA against degradation during homogenization and lyophilization. We manufactured mi-

Table 4—Effect of Excipients on Retaining Supercoiled DNA (SC DNA) under Microsphere Procedure Such as Homogenization and Lyophilization[a]

	SC DNA remaining (initial% ± SD)	
	before lyophilization	after lyophilization
water	42.3 ± 0.7	39.0 ± 4.2
1 mM EDTA solution, pH 7.5	78.2 ± 1.7	68.3 ± 3.6
phosphate-buffered saline, pH 7.5	49.1 ± 4.8	19.8 ± 0.4
300 mM lactose solution, pH 7.5	41.7 ± 2.4	20.8 ± 1.3
300 mM lactose/1 mM EDTA solution, pH 7.5	95.1 ± 0.7	88.6 ± 1.9

[a] Samples were prepared by cryopreparation, and the homogenization rate was 7000 rpm for 14 s ($n = 3$).

crospheres according to optimized conditions for the microsphere preparation described above to determine these combined effects. The characteristics of the microsphere such as particle size distribution, DNA conformation, and DNA encapsulation efficiency were determined.

Using the optimized conditions for microsphere preparation, the mean volume diameter of the microspheres was 4.8 μm, the remaining supercoiled DNA was 88% (Figure 4 and Table 4), and the DNA encapsulation efficiency was 89%. In comparison, using the standard double-emulsion preparation method (5000 rpm homogenization rate), the resulting microspheres had a mean volume diameter of 4.5 μm, a remaining supercoiled-DNA content of 39%, and a DNA encapsulation efficiency of 23%. It is apparent that cryopreparation prevents degradation of DNA and increases the encapsulation of DNA. These results suggest that the increase in DNA encapsulation efficiency is caused by preventing its diffusion out of the inner aqueous phase by freezing the primary emulsion. Furthermore, addition of DNA-nicking inhibitors to the DNA solution is important to prevent DNA degradation during this microsphere manufacturing process. Ninety-five percent of supercoiled DNA was retained before lyophilization, and 88% of supercoiled DNA was retained after lyophilization as shown in Figure 4. In addition, Table 4 compares the supercoiled-DNA content in microspheres using water, EDTA, PBS, or lactose in the DNA solution. The results also show the reproducibility of the DNA stability data as compared to the isolated homogenization and lyophilization experiments (Tables 2 and 3).

In conclusion, a method for the microencapsulation of plasmid DNA is presented. The method, cryopreparation, maximizes both the retention of supercoiled DNA and the overall DNA encapsulation efficiency. Cryopreparation is characterized by the freezing of the aqueous phase of the primary emulsion. DNA-nicking inhibitors such as lactose and EDTA significantly improve the supercoiled-DNA content in the final sphere preparation.

Abstract □ The pharmacokinetics and the pharmacological effects of the deleted form of hepatocyte growth factor (dHGF) after intravenous (iv), subcutaneous (sc), or intramuscular (im) administration (0.25 and 2.5 mg/kg) were studied in rats. After single iv administration (2.5 mg/kg), dHGF in serum rapidly decreased (α- and β-phase half-life: 3.2 and 26.5 min, respectively). Two to four hours after single sc or im administration (2.5 mg/kg), the serum level of dHGF reached a maximum and then gradually declined (half-life: 2.7 h). The serum levels were not changed by repetitive iv administration, but were dramatically decreased by repetitive sc or im administration. Liver weight and serum levels of total protein, albumin, and HDL-cholesterol were significantly increased by iv administration of dHGF (twice daily for 4 days at 0.25 mg/kg). Sc or im administration of dHGF did not increase these parameters at the same dose, but did significantly at 2.5 mg/kg. These observations suggest that iv administration is the most effective in exerting the pharmacological effects of dHGF among three administration routes. dHGF after iv administration was distributed mainly and rapidly into liver (53.6% of the injected dHGF within 5 min) and was sustained at a higher level in the liver than in plasma. In infusion (0.5 mg/kg/3 h), dHGF level in plasma and liver reached a steady-state 15 and 60 min after starting the infusion, respectively. The steady-state level of dHGF was 7- to 9-fold higher in liver than in plasma, and the higher level in liver was sustained beyond the steady-state.

Human hepatocyte growth factor (HGF) was purified and characterized as a mitogen for adult rat hepatocytes.[1,2] Two different complementary DNAs (cDNAs) encoding human HGF were cloned from human liver[3] and placenta[4] cDNA libraries. A major variant of HGF, the deleted form of HGF (dHGF), has been purified from conditioned medium of human fibroblasts.[5] dHGF cDNA, which lacks 15 nucleotides encoding a five-amino acid residue in the first kringle domain of HGF, has been isolated from human fibroblast cDNA library.[6] Like HGF, dHGF is a heparin-binding basic protein with an apparent molecular mass (M_r) of 76−80 kD and is a heterodimer composed of a large α-chain with a M_r of 52−56 kD and a small β-chain with a M_r of 30−34 kD.[6] dHGF is more mitogenic than HGF for adult rat hepatocytes[6−8] and epithelial cells.[7] HGF and dHGF are distinguishable in their target cell specificity in growth stimulation and in their tertiary structure.[7] Serum HGF or dHGF levels in patients with liver diseases are higher than those in healthy subjects.[9,10] These observations suggest that dHGF acts on hepatocytes and plays an important role in liver regeneration.

To determine the most suitable administration route of dHGF, we investigated pharmacokinetics of dHGF after intravenous (iv), subcutaneous (sc), or intramuscular (im) administration and compared the effects of dHGF on hepatic protein synthesis, hepatic cholesterol metabolism, and liver weight among three routes of administration. dHGF exerted the most potent accelerating effect on liver functions and on increase of liver weight after iv administration. We also examined distribution of dHGF into the liver after iv administration. Exogenous dHGF was distributed mainly and rapidly into the liver and was sustained at higher concentrations in the liver than in plasma.

Experimental Section

Animals—Male Wistar rats were obtained from Charles River Japan (Kanagawa, Japan). The animals were housed for at least 1 week before the study at 23 ± 2 °C under a 12 h light−dark cycle. Water and laboratory chow were provided ad libitum. All animals used were 7 weeks old and weighed between 185 and 245 g.

Reagents—dHGF was purified from the conditioned medium of Namalwa cells transfected with an expression plasmid comprising human dHGF cDNA.[7] The purified dHGF was diluted with sterile phosphate-buffered saline (PBS) containing 0.01% Tween 80. All other reagents were of analytical grade and were commercially available.

Preparation of Anti-dHGF IgG—Female Japanese White rabbits weighing about 2 kg received sc injections of dHGF (100 μg/rabbit) with complete Freund's adjuvant six times at intervals of 2 weeks, and blood was collected from the animals 1 week after the last injection. Anti-dHGF serum was subjected to protein A column (Nippon Bio-Rad Laboratories, Tokyo, Japan) chromatography, and the purified anti-dHGF IgG was stored at −20 °C. The concentration of anti-dHGF IgG was determined by the method of Lowry,[11] using bovine IgG as a standard protein.

Preparation of Anti-dHGF IgG-Peroxidase Conjugate—The anti-dHGF IgG was further purified by affinity chromatography on an Affigel 10 column (Nippon Bio-Rad Laboratories) coupled with dHGF. The purified anti-dHGF specific antibody (IgG) was conjugated to horseradish peroxidase using a ImmunoPure Maleimid Activated Horseradish Peroxidase kit (Pierce, Rockford, IL). The anti-dHGF IgG-peroxidase conjugate was supplemented with the same volume of glycerol and stored at −20 °C.

Collection of Serum Samples for Pharmacokinetic Study—In single administration, dHGF (0.25 or 2.5 mg/kg) was administered to rats through the tail vein (iv injection), dorsimesal subcutis (sc injection), or hind limb (im injection) of animals. In repetitive administration, dHGF (0.25 and 2.5 mg /kg/injection) was administered twice daily for 4 days to rats by iv, sc, or im injection as described above. Under ether anesthesia, blood was collected in a polypropylene tube through a glass capillary tube inserted into the orbital vein of the animals from 5 min to 24 h after iv injection and from 30 min to 24 h after sc or im injection. The blood samples were allowed to clot at room temperature and were centrifuged at 1300*g* for 10 min to separate serum. Each serum sample was transferred into a polypropylene microtube and was stored at −80 °C until used for dHGF assay.

Analysis of Liver Functions—dHGF (0.25 or 2.5 mg/kg) or vehicle was given to rats twice daily for 4 days by iv, sc, or im

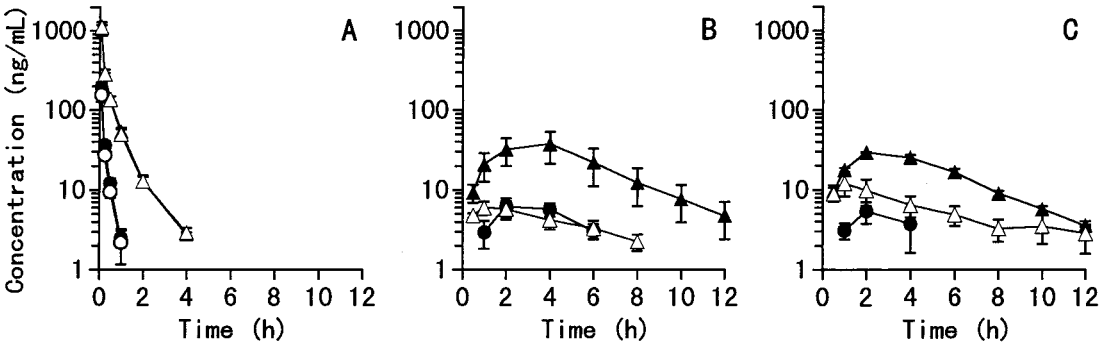

Figure 1—The concentration–time profiles of dHGF in serum after single and repetitive (A) iv, (B) sc and (C) im administrations of 0.25 and 2.5 mg/kg dHGF to rats. Key: single administration of 0.25 (●) and 2.5 (▲) mg/kg; repetitive administration of 0.25 (○) and 2.5 (△) mg/kg. Each point and bar represents the mean ± SD ($n = 3$). The concentrations of dHGF in serum after repetitive sc and im administrations of dHGF at a dose of 0.25 mg/kg were undetectable level (<1.25 ng/mL) in the greater part of the sampling time points.

injection. Under ether anesthesia 12 h after the last administration, blood was sampled from the inferior vena cava of the animals using a vacuum tube (Terumo, Tokyo, Japan). The blood sample was treated to separate serum as described above. The liver of each animal was excised for weighing at the same time. Serum samples were stored at −80 °C until used for assay. The concentrations of total protein, albumin, and HDL-cholesterol in serum were determined with a type 7150 automatic analyzer (Hitachi, Tokyo, Japan), using commercially available test reagents (Daiichi Pure Chemicals, Tokyo, Japan).

Collection of Plasma and Liver Samples for Distribution Study—The experiment on distribution of dHGF after iv bolus administration was carried out as follows. dHGF (0.5 mg/kg) was administered to rats through the tail vein. Under ether anesthesia, blood was collected from the inferior vena cava of the animals from 2 to 120 min after the administration using a vacuum tube containing EDTA. The liver was removed after perfusion with saline at the same time. The collected blood samples were centrifuged at 1300*g* for 10 min, and the obtained plasma samples were stored at −80 °C until used for dHGF assay. The removed liver was homogenized in 20 mM Tris-HCl (pH 7.5) containing 2 M NaCl, 0.1% Tween 80, 1 mM phenylmethylsulfonyl fluoride, and 1 mM EDTA with 4-fold volume of liver weight. The homogenate was centrifuged at 19000*g* for 30 min at 4 °C, and the resultant supernatant (liver extract) was collected and stored at −80 °C until used for dHGF assay. In addition, dHGF was administered to other rats at the same dose, and plasma and liver samples were collected up to 6 h after the administration as described above.

The experiment on distribution of dHGF after iv infusion was performed as follows. Under ether anesthesia, the right jugular vein was cannulated with polyethylene tubing (SP31, Natume, Tokyo, Japan). After recovery from anesthesia, iv infusion of dHGF solution through the tubing was performed at a flow rate of 2.1 μL/min (0.5 mg dHGF/kg/3 h) using a microsyringe pump (EP-60, Eicom, Kyoto, Japan). Under pentobarbital anesthesia, blood was collected and the liver was taken out from 15 min to 3 h after starting the infusion and from 15 min to 3 h after terminating the infusion, and these samples were treated and stored as described above.

Enzyme-Linked Immunosorbent Assay for dHGF—dHGF concentrations in serum, plasma, and liver extract were measured by a two-step sandwich enzyme-linked immunosorbent assay (ELISA) using rabbit anti-dHGF polyclonal antibody, which has no cross-reactivity to rat HGF.

ELISA for dHGF in serum or in plasma was performed as follows. Anti-dHGF IgG was diluted with 0.1 M $NaHCO_3$ to give a final concentration of 10 μg/mL. The diluted IgG solution (100 μL) was added to each well in 96-well immunoplates (MaxiSorp, InterMed, Roskilde, Denmark). The plates were allowed to stand at room temperature overnight. Subsequently, nonspecific binding sites of each well in the plates were blocked with 200 μL of Block Ace (Snow Brand Milk Products Co., Ltd., Tokyo, Japan) diluted 2-fold with water at room temperature for 1 h. After washing each well three times with PBS containing 0.1% Tween 20 (PBS-Tween), 50 μL of the first reaction buffer (50% Block Ace, 0.2 M NaCl, 0.1% Tween 20, 0.2% 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate, 20 mM benzamidine hydrochloride, 10 mM EDTA in 0.2 M Tris-HCl, pH 7.3) was added to each well.

Table 1—Pharmacokinetic Parameters of dHGF after iv, sc, and im Administrations in Rats[a]

pharmacokinetic parameter	route of admin	single admin 0.25 mg/kg	single admin 2.5 mg/kg	repetitive admin 0.25 mg/kg	repetitive admin 2.5 mg/kg
AUC_{last}, ng·h/mL	iv	37.9 ± 3.4	302.5 ± 20.7	29.6 ± 3.4	309.9 ± 42.2
	sc	26.7 ± 6.2	230.9 ± 100.8	*b*	32.8 ± 7.0
	im	14.9 ± 4.7	177.8 ± 8.6	*b*	66.9 ± 20.4
F, %	sc	70.6	76.3	*b*	10.6
	im	39.3	58.8	*b*	21.6

[a] Each value is the mean ± SD of three animals. [b] Not calculated.

Then 50 μL of each serum (or plasma) sample or each dHGF standard prepared in normal rat serum (or plasma) was added to each well in the plates, and the plates were allowed to stand at 4 °C overnight. After washing each well three times with PBS-Tween, 100 μL of anti-dHGF IgG-peroxidase conjugate diluted 100-fold with the second reaction buffer (10% Block Ace, 0.15 M NaCl, 0.1% Tween 20 and 4% rat serum in 0.1 M phosphate buffer, pH 7.0) was added to each well, and the plates were incubated at 37 °C for 2 h. After washing each well six times with PBS-Tween, 100 μL of substrate solution (0.4 mg/mL of *o*-phenylenediamine dihydrochloride and 0.006% H_2O_2 in 0.1 M citrate−phosphate buffer, pH 4.5) was added to each well in the plates, and the plates were incubated at 37 °C for 30 min. The enzymatic reaction was terminated by addition of 50 μL of 6 N H_2SO_4. Absorbance at 492 nm was read using a microplate reader (MTP-32, Korona, Ibaragi, Japan).

To determine dHGF in liver extract, the ELISA system was modified slightly as follows. Here, 50 μL of liver extract in place of serum (or plasma) or 50 μL of dHGF standard prepared in liver extract derived from normal rats was added to each well containing 50 μL of the first reaction buffer. The plates were incubated at room temperature for 2 h. After washing the plates, 100 μL of anti-dHGF IgG-peroxidase conjugate diluted 200-fold with the second reaction buffer was added to each well in the plates, and the plates were incubated at room temperature for 2 h. After washing, bound peroxidase was assayed as described above.

Pharmacokinetic Analysis—The half-life in iv administration of dHGF (2.5 mg/kg) was calculated by fitting a biexponential equation using a nonlinear least-squares program of WinNonlin (Scientific Consulting Inc., Apex, NC). The terminal elimination half-lives in sc and im administrations (2.5 mg/kg), and the area under the concentration versus time curve up to the last measured time point (AUC_{last}) was calculated by using noncompartmental analysis program of WinNonlin. The bioavailability (*F*) was calculated by comparison of the AUC_{last} after sc or im administration with that after iv administration.

Statistical Analysis—The pharmacological data were analyzed by analysis of variance followed by Fisher's LSD test. Significance was established at $p < 0.05$ or $p < 0.01$. The values are expressed as the mean ± SD, unless otherwise noted.

Table 2—Effect of dHGF on Liver Weight and Serum Levels of Proteins and Cholesterol in Normal Rats[a]

route of admin	dose (mg/kg/injection)	liver weight (g/100 g body weight)	total protein (g/100 mL)	albumin (g/100 mL)	HDL-cholesterol (mg/100 mL)
iv	control	3.34 ± 0.04	5.6 ± 0.1	2.7 ± 0.0	38.8 ± 2.2
	0.25	3.71 ± 0.13[b]	6.4 ± 0.1[c]	3.1 ± 0.0[c]	72.0 ± 4.0[c]
	2.5	4.30 ± 0.17[c]	7.0 ± 0.1[c]	3.3 ± 0.1[c]	99.9 ± 6.9[c]
sc	control	3.44 ± 0.10	5.4 ± 0.0	2.6 ± 0.0	37.5 ± 2.0
	0.25	3.28 ± 0.09	5.6 ± 0.1	2.8 ± 0.1	44.6 ± 1.5
	2.5	4.33 ± 0.14[c]	6.9 ± 0.1[c]	3.4 ± 0.1[c]	99.4 ± 7.8[c]
im	control	3.34 ± 0.10	5.6 ± 0.1	2.7 ± 0.1	37.4 ± 1.0
	0.25	3.34 ± 0.06	5.7 ± 0.1	2.8 ± 0.0	39.8 ± 3.9
	2.5	4.08 ± 0.09[c]	6.8 ± 0.1[c]	3.3 ± 0.0[c]	83.1 ± 4.0[c]

[a] Measurements were made after eight administrations (twice daily for 4 days) of dHGF. Each value represents the mean ± SEM of five animals. [b] $p < 0.05$ vs control (solvent) of the same route. [c] $p < 0.01$ vs control (solvent) of the same route.

Results

Pharmacokinetics of dHGF—The concentrations of dHGF in serum decreased rapidly within 15 min and reached an undetectable level (<1.25 ng/mL) 2 to 8 h after a single iv administration of dHGF (0.25 and 2.5 mg/kg) to rats (Figure 1A). The profiles of dHGF level in serum after repetitive iv administration (twice daily for 4 days) of dHGF at the same doses were similar to the dHGF-elimination curves after single iv administration (Figure 1A). dHGF in serum after single and repetitive iv administrations (2.5 mg/kg) decreased biexponentially with a half-life of 3.2 min in the α-phase and with a half-life of 25.7 to 26.5 min in the β-phase. Single and repetitive iv administrations of dHGF at a dose of 2.5 mg/kg were about 10-fold larger in AUC_{last} value than those at a dose of 0.25 mg/kg (Table 1).

The concentration−time profiles of dHGF in serum after single sc and im administrations of dHGF (0.25 and 2.5 mg/kg) were similar (Figure 1, parts B and C). In both single administrations (2.5 mg/kg), the concentrations of dHGF in serum reached a maximum after protracted absorption, which continued at least for 2 to 4 h after the injections and then decreased with a half-life of 2.7 h. The maximum level of dHGF in serum after sc or im administration was lower than after iv administration. On the other hand, the concentrations of dHGF beyond 1 or 2 h after administration were sustained at higher levels for sc and im administrations than for iv administration (Figure 1, parts A−C). The bioavailabilities of dHGF after single sc and im administrations were 70.6−76.3% and 39.3−58.8%, respectively (Table 1).

The concentrations of dHGF in serum after repetitive sc and im administrations (twice daily for 4 days) at a dose of 0.25 mg/kg were undetectable level (<1.25 ng/mL) in the greater part of the sampling time points. The serum levels and the AUC_{last} values of dHGF in sc and im administrations of dHGF (2.5 mg/kg) were dramatically decreased by repeating their administrations (Figure 1, parts B and C, Table 1). The AUC_{last} values of dHGF in repetitive sc and im administrations at a dose of 2.5 mg/kg were decreased to 14.2 and 37.6% of those in single sc and im administrations at the same dose, respectively, and were almost comparable to those in single and repetitive iv administrations at a dose of 0.25 mg/kg.

Effect of Administration Routes of dHGF on Liver Weight and Functions—Rats were treated by repetitive iv, sc or im administration of dHGF (twice daily for 4 days at 0.25 and 2.5 mg/kg). Serum levels of total protein, albumin, HDL-cholesterol, and liver weight after the administration are shown in Table 2. These parameters were significantly increased by repetitive iv administration of dHGF at a dose of 0.25 mg/kg, but not by repetitive sc or im administration at the same dose. However, repetitive sc or im administration significantly increased these parameters at a dose of 2.5 mg/kg.

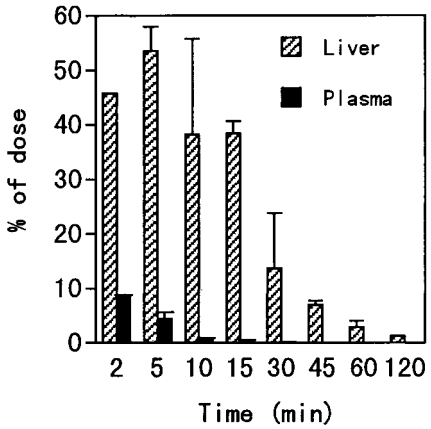

Figure 2—Distribution of dHGF in liver and plasma after iv bolus administration (0.5 mg/kg) to rats. Each value represents the mean ± SD (n = 2–3).

Distribution of dHGF into Liver—After iv bolus injection of dHGF (0.5 mg/kg) to rats, 53.6 ± 4.4% of the injected dHGF was distributed into liver within 5 min, and 1.2 ± 0.1% of the injected dHGF remained in liver up to 120 min (Figure 2). dHGF distributed in plasma 2 min after iv injection was only 8.8% of the injected dHGF (Figure 2). The concentration−time profiles of dHGF in plasma and liver up to 6 h after iv bolus injection (0.5 mg/kg) are shown in Figure 3A. The concentrations of dHGF decreased more slowly and were sustained at higher level in the liver than in plasma. The ratios of the dHGF level in liver to that in plasma after iv injection ranged from 4 to 166.

When dHGF was infused to rats at a rate of 0.5 mg/kg/3 h, the dHGF level in plasma reached a steady-state 15 min after starting the infusion and declined rapidly after terminating the infusion (Figure 3B). The steady-state level of dHGF in plasma ranged from 53.7 ± 10.0 to 76.0 ± 22.1 ng/mL. The dHGF level in the liver reached a steady-state 60 min after starting the infusion and declined more slowly than did that in plasma after terminating the infusion (Figure 3B). The steady-state level of dHGF in the liver was 7- to 9-fold higher than that in plasma and ranged from 486 ± 59 to 551 ± 51 ng/g liver.

Discussion

The concentrations of dHGF in serum after single iv administration of dHGF (2.5 mg/kg) decreased rapidly with an initial half-life ($t_{1/2}\alpha$) of 3.2 min. The initial half-life data reported here are consistent with the result on native dHGF purified from human embryonic fibroblasts[12] and with those on recombinant human HGF.[13−16]

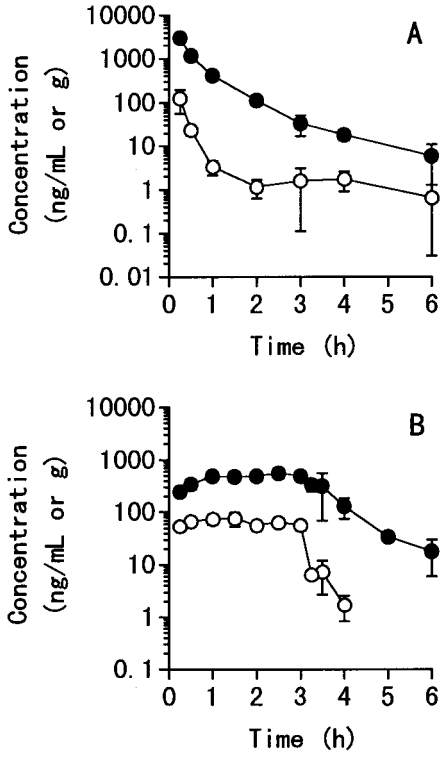

Figure 3—The concentration–time profiles of dHGF in plasma (○) and liver (●) after (A) iv bolus administration (0.5 mg/kg) and (B) iv infusion (0.5 mg/kg/3 h) to rats. Each point and bar represents the mean ± SD (n = 2–3).

The concentrations of dHGF in serum beyond 1 or 2 h after single sc and im administrations were sustained at a higher level than those in serum after single and repetitive iv administrations (Figure 1, parts A−C), indicating that dHGF was slowly released from injection sites into the systemic circulation. The concentration−time profiles of dHGF in serum after single sc and im administrations in rats were similar to those of other recombinant proteins such as human erythropoietin (EPO)[17] and human granulocyte colony-stimulating factor (G-CSF).[18] The values of terminal elimination half-life after single sc or im administration were larger than that after iv administration. The prolongation of half-life suggested that the absorption rate may be smaller than the elimination rate (i.e., "flip-flop") as found in G-CSF.[18]

dHGF has been found to ameliorate disorders of liver functions such as hepatic protein synthesis and cholesterol metabolism in various liver-injured rat models[19] and exert preventive effects against various liver injuries.[20] The prolongation of half-life in sc or im administration may be effective in enhancing the pharmacological effects of dHGF as found in EPO and G-CSF.[17,21]

We therefore compared the pharmacological effects of dHGF among iv, sc, and im administration. Serum levels of total protein, albumin, HDL-cholesterol, and liver weight were significantly increased by repetitive iv administration (twice daily for 4 days) of dHGF (0.25 mg/kg), but not by repetitive sc or im administration. However, repetitive sc or im administration of dHGF at 2.5 mg/kg significantly increased these parameters, indicating that repetitive sc or im administration was less effective in exerting the pharmacological effects of dHGF than repetitive iv administration. Although there was no difference in serum level and AUC_{last} value of dHGF between single and repetitive iv administrations (Figure 1A, Table 1), the serum level and the AUC_{last} values after sc or im administration of dHGF were dramatically decreased by repeating its administration (Figure 1, parts B and C, Table 1). Accordingly, the reduced pharmacological effects of dHGF in repetitive sc or im administration seemed to be due to the drastic decrease in serum level and AUC_{last} value of dHGF caused by repeating its administration. These findings suggested that a release of dHGF from injection sites into the systemic circulation declined. One of the mechanisms by which such a phenomenon occurs in repetitive sc or im administration may be due to altered absorption kinetics (related to dermal vascular changes, or other local and/or systemic processes). Such a phenomenon is also observed when recombinant human interlukin-3 (rhIL-3) has been administered by repetitive sc administration once daily for 4 days.[22] However, the decrease of AUC_{last} values of dHGF after repetitive sc administration was much greater than that of rhIL-3. The distinction between rhIL-3 and dHGF may be due to differences in the number of times of repetitive administration and/or in their physicochemical properties.

We next examined distribution of dHGF into liver after iv administration. A large amount of dHGF (53.6% of the injected dHGF) was distributed rapidly (5 min after iv injection) into liver. The high distribution of dHGF into liver may be due to its binding to extracellular matrix components such as heparan sulfate, because dHGF has a high affinity for heparin.[6] It has also been shown that HGF has a high affinity for heparin[2,23,24] and binds to heparin-like substances on the cell surface [25,26] and the extracellular matrix[27] in liver.

dHGF exerts maximal mitogenic activity for adult rat hepatocytes in a dose range of 10 to 500 ng/mL in vitro,[7] suggesting that a hepatic dHGF concentration of 10 ng/g of liver would be sufficient to exert a physiological function. The iv bolus injection of dHGF (0.5 mg/kg) sustained the effective hepatic level for more than 4 h (18.1 ± 4.9 ng/g) (Figure 3A). In addition, when dHGF (0.5 mg/kg/3 h) was administered by infusion, the effective level of dHGF in liver was sustained beyond the steady-state (for more than 6 h) (Figure 3B), suggesting that infusion would be more effective than iv bolus injection in enhancing the pharmacological effects of dHGF.

In conclusion, we demonstrated that dHGF in serum decreased more rapidly after iv injection than after sc and im injections, but that iv administration exerts the most potent pharmacological effect of dHGF among three administration routes. Further, we found that dHGF is distributed mainly and rapidly into liver and is sustained at a higher level in liver than in plasma.

Abstract □ The preparation and characterization of microparticles produced from a new class of functionalized, biodegradable, comblike graft copolymers is presented. The copolymers are polyester–polyamino acid hybrids, composed of a poly(L-lactic acid–*co*-L-lysine) (PLAL) backbone, and poly(L-lysine), poly(D,L-alanine) or poly(L-aspartic acid) side chains extending from the lysine residues of PLAL. The microparticles have been characterized with regard to their surface properties, morphology, and size. Thus, electron spectroscopy for chemical analysis data and results of Zeta potential measurements suggest that the polyamino acid side chains tend to concentrate at the surface of the particles. Also, analyses by environmental scanning electron microscopy and confocal scanning laser microscopy indicate that particles carrying poly(lysine) chains have an unusual porous structure, most probably due to the combined effects of the amphiphilic, polyelectrolyte, and chemical nature of the composing copolymer, as well as of the particular preparation technique employed. The capabilities of the microparticles to serve as carriers in controlled drug release and delivery devices were demonstrated by encapsulation and release of rhodamine B, a low molecular weight drug model.

1. Introduction

The use of synthetic degradable polymers in drug delivery systems has dramatically expanded in the past decade. Several "old" drugs have gained renewed interest by improving their pharmacokinetic profile upon incorporation in polymer-based controlled-release systems.[1] Also, such systems, in the form of microcapsules, microparticles, and nanoparticles were found to be useful carriers for many low molecular weight compounds, peptides, and proteins, whose efficacy as drugs is highly dependent on the mode of their delivery to the body.[2−7]

One of the most advanced strategies in biopharmaceutics for the delivery of drugs and vaccines relies on the use of polymeric nano- and microparticles as carriers, mainly those composed of poly(lactic acid) (PLA) or poly(lactic acid−*co*-glycolic acid) (PLGA).[8] These degradable polyesters are nontoxic, well tolerated by living tissues, and degrade hydrolytically at controllable rates to yield naturally occurring metabolites. The procedure for incorporation of bioactive agents in these polymers is generally rather simple and reproducible. However, cases have been reported in which the conformational stability of incorporated proteins was impaired.[9,10]

The successful utilization of polymeric particles as drug carriers is highly dependent on their distribution in the body. Because of the surface characteristics of the particles, this distribution may not always be favorable. Thus, it has been extensively demonstrated that nanoparticles with a hydrophobic surface (e.g., PLA and PLGA) are rapidly taken up by the cells of the reticuloendothelial system (RES).[11−13] On the other hand, particles with a more hydrophilic surface can avoid this uptake to a greater extent, thus achieving a prolonged lifetime in the circulation and a better chance to efficiently deliver the therapeutic agent.[11−13] Toward this goal, such hydrophilic characteristics have been provided by modifying the surface of the otherwise hydrophobic particles with a hydrophilic polymer, either by chemical attachment or physical adsorption.[11−21]

These examples of modification of the preexisting PLGA copolymer represent an interesting approach for several applications. To advance this approach even further, it could be highly beneficial to prepare particles from an amphiphilic polymer that also possesses functional sites where chemical modifications can be carried out, and to utilize them for tailoring specific surface characteristics such as charge, hydrophilicity or targeting capabilities. For this purpose, we have prepared nanoparticles (data not presented) and microparticles from a new family of functional, degradable graft copolymers (PLAL-Lys, PLAL-Asp, and PLAL-Ala)[22,23] and from the linear copolymer PLAL.[24] The incorporation of poly(amino acid) side chains and PLA backbone in a hybrid copolymeric structure provides a unique opportunity to combine the attractive properties of these two classes of important biomedical polymers. PLAL-Lys and PLAL-Asp possess a large number of amino and carboxylic acid functional groups, respectively, and these may be utilized for further chemical modification (e.g., direct attachment of targeting moieties or drugs). At neutral pH, the poly(amino acid) side chains are positively charged (PLAL-Lys), negatively charged (PLAL-Asp), or neutral (PLAL-Ala). Here, we present the preparation of these microparticles and their characterization with regard to their surface properties (functionalization and charge), morphology, and size. In addition, incorporation in these particles of rhodamine B as a drug model and its release are also presented, and the data are considered for assessing the potential use of these particles as drug carriers. The use of PLAL-Lys microparticles as dry powder aerosols for pulmonary drug delivery has been investigated.[25,26]

2. Experimental Section

Materials—Poly(vinyl alcohol) (PVA; 88% hydrolyzed, MW 25 000) was obtained from Polysciences (Warrington, PA), rhodamine B base from Sigma (St. Louis, MO), and rhodamine B

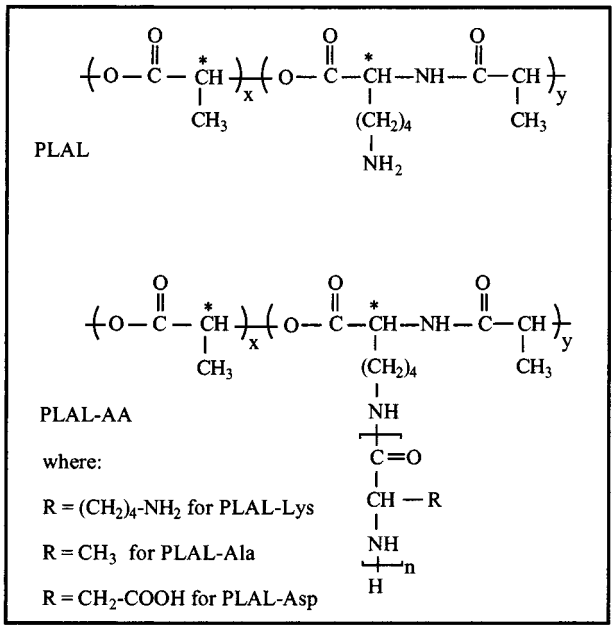

Scheme 1

isothiocyanate from Research Organics (Cleveland, OH). Phosphate buffered saline solution (PBS, 1 mM in KH_2PO_4, 10 mM in Na_2HPO_4, 137 mM in NaCl, 3 mM in KCl) was prepared with a pH of 7.4 unless otherwise noted.

Methods—*Synthesis of Copolymers*—PLAL was synthesized as described previously by Barrera et al.,[24] and PLAL-Lys, PLAL-Asp, and PLAL-Ala were synthesized as described by Hrkach et al.[22,23] The chemical structures of these copolymers are presented in Scheme 1. PLAL is a linear copolymer with approximately 2 mol % lysine randomly situated in a PLA backbone. The ϵ-amino groups of these lysine units are utilized as initiating sites for building poly(amino acid) chains from the PLAL backbone, thus leading to a comblike graft copolymer structure for PLAL-Lys, PLAL-Asp, and PLAL-Ala with total amino acid content of 15−20 mol %.

Preparation of Microparticles—Microparticles were prepared by the single emulsion/solvent evaporation method. One hundred milligrams of polymer were dissolved in 1 mL of dimethyl sulfoxide (DMSO) and subsequently mixed with 3 mL of methylene chloride. This solution was emulsified in 100 mL of PVA solution (5% w/v) for 60 s, using a homogenizer at 7500 rpm. The resulting emulsion was stirred continuously for 3 h in an open beaker to remove the organic solvents. The precipitated microparticles were centrifuged at 1000x *g* for 10 min, washed three times with distilled water, lyophilized, and stored under desiccation at room temperature.

For the preparation of particles incorporating rhodamine B, the same procedure was followed but 10 mg of rhodamine B were dissolved in CH_2Cl_2 before mixing with the polymer solution in DMSO.

Surface Modification—To investigate the structure of the PLAL-Lys and PLAL microparticles and their potential for attachment of targeting moieties or drugs, rhodamine B moieties were chemically attached to the lysine ϵ-amino groups on the surface of the microparticles. Two milligrams of microparticles were suspended in 1.5 mL of PBS and 0.5 mg of rhodamine B isothiocyanate (RITC) was added to the suspension. After stirring for 3 h, the suspension was centrifuged and washed three times with methanol to remove unreacted RITC. Microparticles were then suspended in water and analyzed by confocal microscopy (Biorad, MRC 600).

Characterization of Microparticles—*A. Size Distribution*—After lyophilization, a small amount of particles was resuspended in aqueous solution (Isoton solution) and the size distribution was measured using a Coulter Counter (Coulter Multisizer II, Coulter Electronics Ltd.). The average diameter was calculated as a mean value of the volume distribution.

B. Surface Charge—To evaluate the presence of electrostatic charges on the surface of the particles, the Zeta potential was determined by laser doppler anemometry (Zetasizer 3, Malvern Instruments, Malvern, UK) after suspending the particles in PBS at pH 7. The measurements were taken at 20 °C for 20 s, with an applied voltage of 150 V.

Table 1—Mean Diameters of Plain and Rhodamine-Loaded Particles

	plain particles	rhodamine-loaded particles	
constitutive polymer	average diameter (μm)	average diameter (μm)	dye loading (%w/w)
PLAL	4.9	6.1	2.2
PLAL-Lys	7.4	6.7	2.2
PLAL-Ala	6.2	8.5	18.7
PLAL-Asp	6.0	5.5	14.2

C. Surface Chemical Composition—For the chemical characterization of the particle surface, electron spectroscopy for chemical analysis (ESCA, also known as X-ray photoelectron spectroscopy, XPS, Model 5100, Perkin Elmer, with a magnesium anode as X-ray source at 15 kV and 300 W) was used. Aqueous suspensions of particles were mounted on metal stubs, and then the water was evaporated under vacuum over phosphorus pentoxide for at least 12 h. The angle between the sample surface and the analyzer was set to 45°. An elemental survey spectrum (0−1000 eV) was acquired for each sample.

D. Morphology—The morphology and structure of the microparticles were characterized using environmental scanning electron microscopy (ESEM, ElectroScan), and confocal scanning laser microscopy (MRC 600, BioRad Company, with rhodamine filter). For ESEM, samples were mounted with double-sided adhesive tape on metal stubs coated with gold−palladium to a thickness of 200−400 Å, and analyzed at 3−10 kV. For confocal microscopy, samples were first labeled with rhodamine isothiocyanate and suspended in water.

E. Incorporation and Release of Rhodamine B—To assess the incorporation efficiency and release characteristics of low molecular weight agents, rhodamine B base was used as a drug model. The incorporation efficiency was evaluated by measuring the fluorescence intensity (excitation: 554 nm; emission: 574 nm) of the solution obtained after complete degradation of 10 mg of particles in 0.1 M NaOH at 37 °C and by relating the results obtained to the fluorescence of a standard solution of rhodamine B in the same solvent. For these measurements a spectrofluorimeter (Photon Technology International) was used.

For the release studies, a known amount of dried microparticles were suspended in 5 mL of PBS in a plastic tube and incubated at 37 °C under continuous shaking. One milliliter of the supernatant from each tube was collected periodically after centrifugation and replaced each time with fresh PBS to mimic infinite sink conditions. The fluorescence intensity of the samples was measured as indicated for determination of loading and compared with a standard solution of rhodamine B base in the same solvent.

3. Results and Discussion

3.1. Particle Size Distribution—The size distribution of particles made of PLAL-Lys, PLAL-Asp, PLAL-Ala, or PLAL are presented in Figure 1. The PLAL microparticles show the narrowest size distribution and lowest mean diameter, whereas microparticles prepared from the graft copolymers exhibit a broader size distribution and a slightly larger average diameter. Nevertheless, it can be concluded that the commonly used single emulsion/solvent evaporation technique can be utilized effectively for the preparation of microparticles with relatively low average size ($<10\ \mu$m) from the new class of PLAL-amino acid graft copolymers. Table 1 summarizes the mean diameters of these particles, as well as of those in which rhodamine B base was incorporated. We note that, although different loading levels were achieved with various particles, incorporation of dye molecules had only a minimal effect on the average size of the particles.

3.2. Surface Chemical Composition—The presence of amino acid residues at the surface of the particles was confirmed by ESCA (Figure 2). The small nitrogen peak

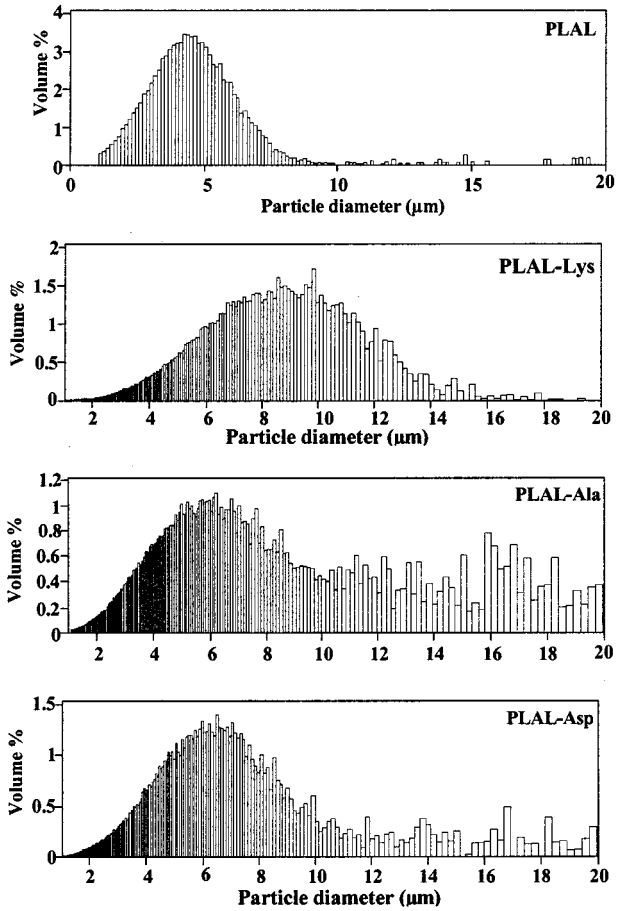

Figure 1—Size disributions of microparticles made of PLAL, PLAL-Lys, PLAL-Ala, and PLAL-Asp.

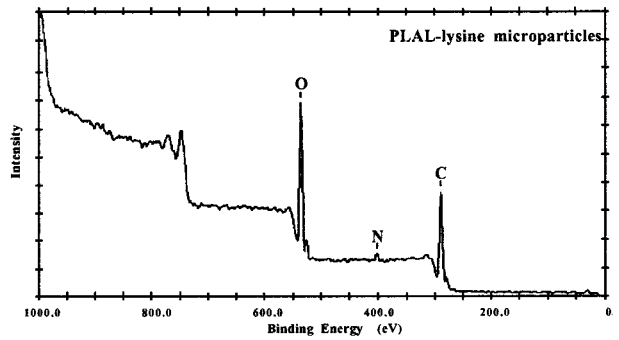

Figure 2—ESCA survey spectrum of PLAL-Lys microparticles.

at approximately 400 eV proves the presence of lysine residues at the outer layer of the particles, because these residues are the only nitrogen-containing ones in the copolymer. This result is in agreement with the hypothesis that the preparation procedure employed promotes orientation of the amino acid chains of the copolymer toward the outer layer of the particles. The relatively small size of the nitrogen peak in the ESCA spectrum is most likely due to the presence of PVA molecules in the outermost layer of the particles. As already stated, PVA was used as a surfactant to stabilize the microparticle structure during preparation. Thus, quantitative analysis of the nitrogen content, based on the ESCA spectrum, was not attempted.

ESCA spectra, similar to that of PLAL-Lys, were also obtained for PLAL-Asp and PLAL-Ala microparticles. However, for PLAL particles, the nitrogen peak was negligible due to the very low nitrogen content of their constitutive polymer (spectra not shown).

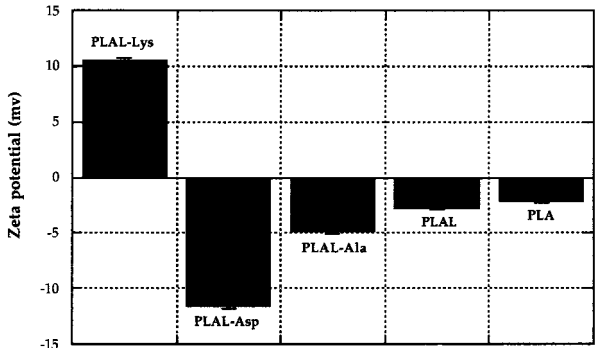

Figure 3—Zeta potential of microparticles made of PLAL, PLAL-Lys, PLAL-Ala, PLAL-Asp, and PLA.

3.3. Zeta Potential—Figure 3 shows the Zeta potentials of the microparticles in PBS at pH 7. The graph emphasizes the difference in surface charge among the microparticles studied. Thus, PLAL-Lys microparticles carry a positive charge, as expected from the presence of protonated ϵ-amino groups of the lysine residues at the particle surface. PLAL-Asp, PLAL-Ala and PLAL, on the other hand show negative charges. The large negative value for PLAL-Asp is attributed to the β- carboxylate groups of the aspartic acid residues. The apparently unexpected small negative charges exhibited by PLAL and PLAL-Ala particles are probably due to the terminal carboxylate groups of the backbone of their constitutive polymers. This view is supported by the fact that a similar, small negative charge is also exhibited by PLA particles. These results provide additional evidence for the presence of amino acid side chains on the surface of the particles, resulting from the extension of the hydrophilic portion of the comblike graft copolymer into the outer aqueous phase during preparation. More important, they demonstrate the versatility of this new class of materials. The ability to change the charge characteristics (type and strength) of the microparticles can be utilized to tailor their use for various drug delivery systems.

3.4. Particle Morphology and Surface Modification—ESEM and confocal microscopy were utilized to study the structure and morphology of the particles. As seen in Figure 4, ESEM reveals that PLAL particles show a smooth surface and a spherical structure, similar to what is observed with PLA or PLGA particles (data not shown). Apparently, the low amount of lysine (about 2 mol %) present in the PLAL chain does not significantly affect the particle morphology. On the other hand, PLAL-Ala and PLAL-Asp particles have a slightly corrugated surface. Most likely, the extension of the hydrophilic amino acids chains into the aqueous phase during particle preparation promotes the formation of the rougher surface exhibited by these particles, compared with that of PLAL, PLA, or PLGA particles prepared by the same technique. In strong contrast to the microparticles just mentioned, PLAL-Lys particles have an unusual shape and also a porous, spongelike structure. It is likely that the large amount of lysine in the copolymer structure, in the form of grafted poly(lysine) side chains, imparts specific characteristics to the polymer and to the resulting particles. The fact that only microparticles made of PLAL-Lys exhibit this structure is highly relevant. From these results it is possible to conclude that the porous structure does not stem solely from the presence of an amphiphilic or amino acid-based polymer in general, but specifically from the presence of lysine chains (and perhaps other poly-cationic chains).

The results of confocal microscopy analysis of PLAL-Lys and PLAL particles are shown in Figure 5. Covalent attachment of the fluorescent marker to the particles was

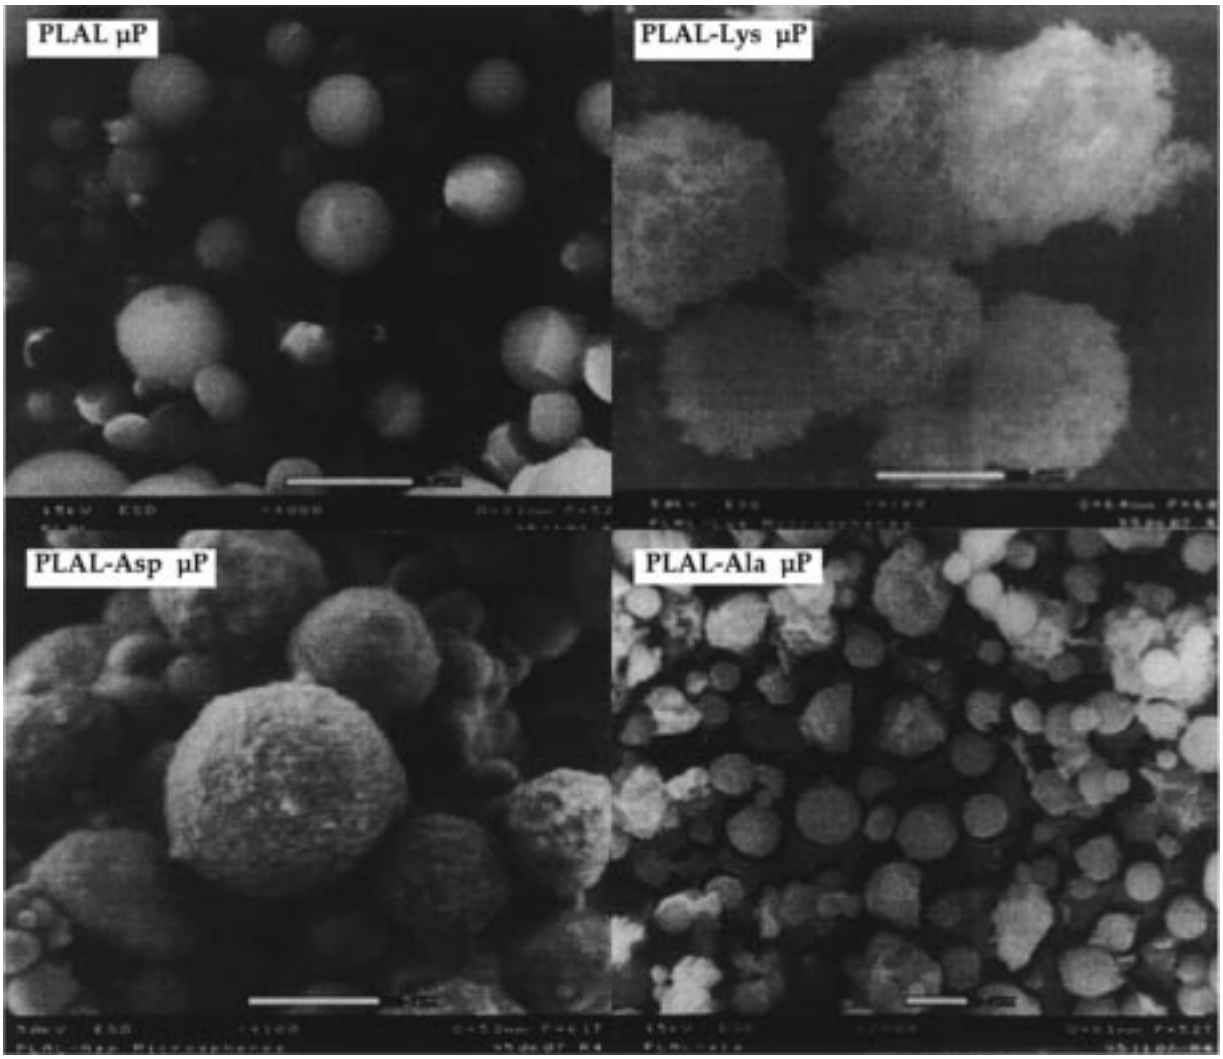

Figure 4—ESEM pictures of microparticles made of PLAL (magnification, ×4000), PLAL-Lys (x4100), PLAL-Ala (x2000), and PLAL-Asp (x4100). All scale bars = 5 μm.

accomplished through the reaction of rhodamine isothiocyanate with the lysine ϵ-amino groups on the surface of the particles. Under the same experimental conditions, PLA particles yield no fluorescent response (a completely dark field) confirming covalent attachment of rhodamine moieties at the surface amine groups of PLAL-Lys and PLAL and ruling out nonspecific adsorption of the dye to the particle surface. The successful coupling of rhodamine proves the availability of the surface amino groups for further chemical modification. This characteristic imparts great versatility to this new class of functional particles, and may be utilized to improve cellular targeting and uptake of peptides/proteins, anticancer drugs, and other therapeutic agents that require or could benefit from site-specific delivery.

The capacity of these particles for binding functional molecules onto their surface is very high indeed. For example, for PLAL-Asp particles with an aspartic acid content of 20 mol % and assuming that all the β-COOH groups of Asp residues are present at the surface, a capacity of 2.7 mmol-COOH/g is calculated. And if each carboxyl group would bind one molecule of dye of opposite charge and of molecular weight 440 (similar to that of rhodamine B base) a loading capacity of about 55% (w/w) dye could be accommodated. A similar calculation, when performed for PLAL-Lys particles contaning 20 mol % Lys residues, yields 2.4 mmol-NH_2/g and 50% (w/w) labeling capacity.

The structural characteristics of the PLAL-Lys particles have highly valuable implications in the area of pulmonary drug delivery as well. The flight characteristics of dry powders are crucial for the efficient delivery of therapeutic agents to the lungs, for either local or systemic therapy. In vitro aerosolization experiments carried out in our laboratory show that 57 ± 1.9% of the PLAL-Lys particles are in the respirable fraction, whereas only 9.3 ± 0.6% of the nonporous PLA or PLGA particles of the same size are respirable. Furthermore, in vivo studies in rats show that the pulmonary delivery of testosterone with PLAL-Lys particles results in prolonged release compared with nonporous particles.[25]

3.5. Incorporation Efficiency and Release Characteristics—In Table 1, data relating the average size of microparticles and their efficiency in incorporating rhodamine B are presented. We note that all the microparticles have essentially similar size distribution and mean diameter. However, their efficiency for loading this low molecular weight drug model seems to be significantly dependent on the chemical nature of the constitutive polymer and its interaction with the drug model molecule. Thus, the basic dye rhodamine B is efficiently incorporated (14.2%) in microparticles made of the acidic, negatively charged PLAL-Asp, but only very little dye (2.2%) is accommodated by particles made of the basic, positively charged PLAL-Lys. The highest incorporation efficiency (18.7%) was

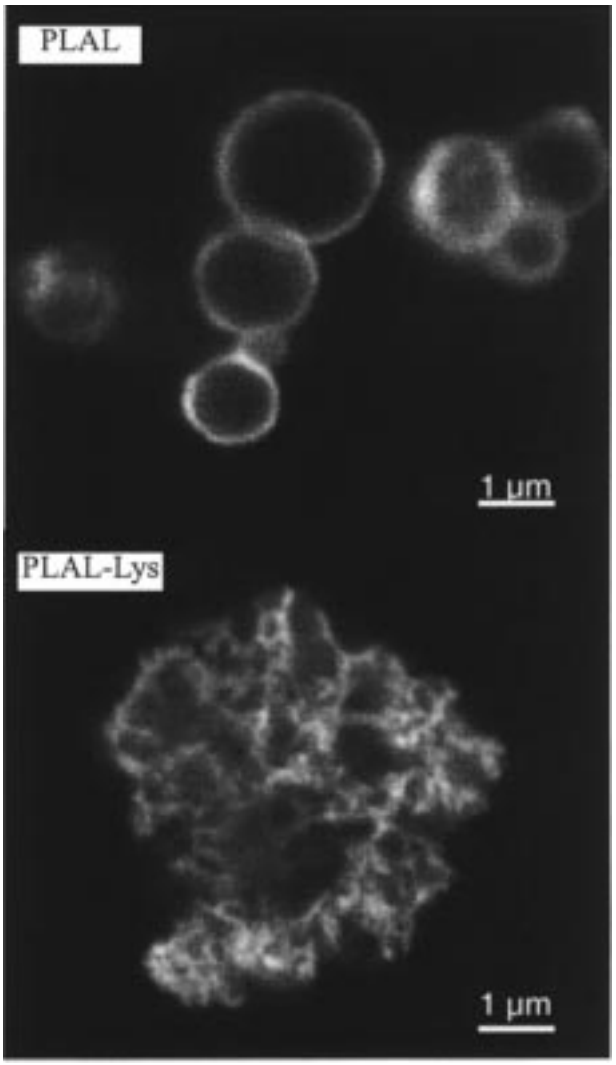

Figure 5—Confocal microscopy pictures of PLAL-Lys and PLAL microparticles, after labeling with rhodamine B isothiocyanate.

reached with the essentially neutral PLAL-Ala, whereas the similarly neutral PLAL particles exhibit very low efficiency (2.2%), similar to PLAL-Lys particles. These results indicate that, in addition to electrostatic interactions, dye incorporation efficiency is also to be related to other factors, such as hydrophobicity/hydrophilicity balance and dye partition characteristics.

The release profiles of rhodamine B from PLAL− and PLAL−poly (amino acid) microparticles over a period of 8 weeks are shown in Figure 6. All of the PLAL−poly(amino acid) microparticles exhibited a basically similar release behavior; namely, an initial burst in the first 2−3 days when some 35% of the incorporated dye is liberated, followed by a continuous much slower process, which was monitored only until day 56. Up to this point, only 45−50% of the dye is released and, obviously, the process continues further on. The release profile of rhodamine B from PLAL microparticles follows, in principle, the same time course as already described for the PLAL−poly(amino acid) microparticles. Yet it differs in the quantitative aspects of it: thus, only 6% dye is released during the initial burst of 1 day and only 25% of the dye is released by day 56, during the subsequent low rate process.

From these results it can be concluded that the very presence of poly(amino acid) side chains into a branched copolymer with PLA backbone may affect the drug loading capacity of these particles (see Table 1) yet may have a

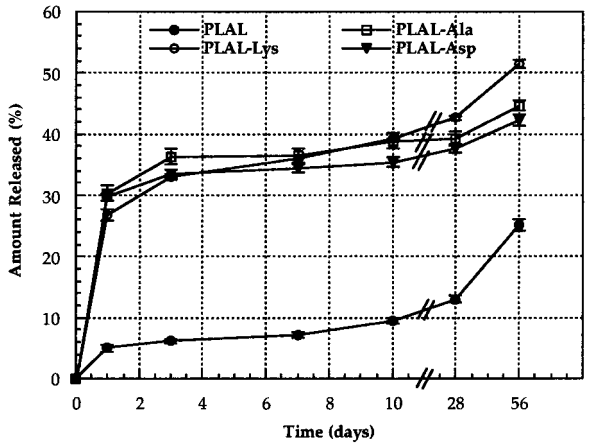

Figure 6—Release profile of rhodamine B from PLAL, PLAL-Lys, PLAL-Ala, and PLAL-Asp microparticles.

significant influence on the release of drugs from microparticles composed of these polymers. However, the specific properties of the various poly(amino acids) considered did not significantly affect the release process because the pertinent profiles for PLAL-Lys, PLAL-Ala, and PLAL-Asp microparticles are all similar. Obviously, depending on specific drug−polymer interactions, the release characteristics may be different when drug molecules of various structure, hydrophobicity, and charge are used.

Further studies focusing on the release of various drugs from these microparticles will be carried out to gain a better understanding of the role of the amino acid chains on the structure and properties of the microparticles and on the mechanism of drug release from them.

4. Conclusions

Microparticles made of PLAL, PLAL-Lys, PLAL-Ala, or PLAL-Asp were prepared and investigated. Due to their specific structure, this new class of copolymers imparts interesting surface (charge, external functional groups) and morphological (porosity) characteristics to the microparticles. The chemical attachment of molecular markers on the surface of PLAL and PLAL-Lys microparticles has also been accomplished. This attachment capability demonstrates the potential use of these particles for attaching various functional moieties, including targeting elements required for site specific controlled drug delivery.

Accepted for publication October 7, 1998.

Abstract □ Previously, we found that monocarboxylic acids undergo carrier-mediated transport in primary cultures of oral mucosal epithelial cells.[1] In this study, we investigated whether carrier-mediated absorption of a monocarboxylic acid from the oral mucosa occurs in vivo. Salicylic acid was administered to hamster cheek pouch. At predetermined intervals, the concentration of salicylic acid in the fluid remaining in the cheek pouch lumen and the blood salicylic acid concentration were determined. The absorption of salicylic acid was saturable at high salicylic acid concentrations. Sodium azide, a metabolic inhibitor, and carbonylcyanide *p*-trifluoromethoxyphenylhydrazone (FCCP), a protonophore, significantly inhibited the absorption of salicylic acid but not the absorption of salicylamide from the oral mucosa. Various monocarboxylic acids inhibited the absorption of salicylic acid, whereas dicarboxylic acids had no such effect. Transfer of [^{14}C]salicylic acid from the cheek pouch mucosa to the systemic circulation was observed, and the blood [^{14}C]salicylic acid concentration in the case of coadministration with propionic acid was significantly lower than that in the case of no propionic acid coadministration. These results show that monocarboxylic acids undergo carrier-mediated absorption from the hamster cheek pouch mucosa.

Introduction

The oral mucosal route is advantageous for drug delivery into the systemic circulation because exposure of the administered drug to gastrointestinal juices and its hepatic first-pass elimination are prevented.[2] In general, the absorption of drugs from the oral mucosa can be explained in terms of the pH−partition hypothesis, which is well illustrated by passive diffusion mechanisms.[3] The hypothesis proposes that the rate of drug absorption depends on the percentage of drug molecules ionized and the lipid solubility of nonionized drug molecules. However, in vivo studies have revealed that some drugs undergo carrier-mediated absorption from the oral mucosa.[4,5] In previous studies, we demonstrated that a carrier-mediated transport system for monocarboxylic acids exists in rabbit oral mucosal epithelial cells in primary culture.[1] However, no data are currently available indicating that carrier-mediated monocarboxylic acid absorption occurs in vivo. In the present study, we investigated whether carrier-mediated drug absorption from hamster cheek pouch mucosa occurs in vivo.

Experimental Section

Materials—[^{14}C]Salicylic acid (55 Ci/mol) was obtained from American Radiolabeled Chemicals (St. Louis, MO). MCDB 153, an epidermal growth factor, and trypsin type III were obtained from Sigma Chemicals (St. Louis, MO). Fetal calf serum (FCS) was purchased from Biotech International Ltd. (Australia). Dispase II was obtained from Boehringer Mannheim (Germany). Tissue culture plates were purchased from Costar (Cambridge, MA). 2-Morpholinoethanesulfonic acid, monohydrate (MES) and *N*-[2-hydroxyethyl]piperazine-*N*′-[2-ethanesulfonic acid] (HEPES) were purchased from Dojin (Kumamoto, Japan). All other chemicals were of the highest available purity and analytical grade, and were purchased from Wako Pure Chemical Industries (Osaka, Japan)

Cell Culture—Oral mucosal epithelial cells were isolated from hamster cheek pouch mucosa and cultured by a previously described method[1] with slight modifications. Briefly, golden hamsters (body weight range, 180−220 g) were sacrificed by the administration of sodium pentobarbital, and their buccae were excised, washed with phosphate-buffered saline (PBS) containing antibiotics (penicillin G, 200 U/mL; streptomycin, 200 μg/mL; and gentamicin, 40 μg/mL), and then cut with a razor into small pieces (each about 3 × 6 mm in size). The tissue pieces were then incubated at 4 °C in Dispase II solution (2.4 U/mL) containing the antibiotics. After a 36-h incubation, the epithelial cell sheets were separated using forceps and centrifuged for 5 min at 200 x *g*. The cell pellets were suspended in a low Ca^{2+} medium, MCDB 153, supplemented with FCS (10%), insulin (5 μg/mL), transferrin (10 μg/mL), phosphorylethanolamine (14.1 μg/mL), penicillin G (100 U/mL), streptomycin (100 μg/mL), gentamicin (20 μg/mL), and epidermal growth factor (10 ng/mL). The resultant suspension was plated onto the wells in a collagen-coated 12-well tissue culture plates. After 24 h of cultivation at 37 °C in a 95% air:5% CO_2 humidified atmosphere, the cells were washed twice with PBS and fresh culture medium was added to each well. After 4 or 5 days of cultivation, drug uptake experiments were performed. The cell type was identified and the purity of the cell preparation was determined by indirect immunofluorescence staining of keratin.[6] More than 95% of the cells were positively stained for keratin (data not shown).

Uptake Experiments—The hamster oral mucosal epithelial cells (HOEpi) were washed twice with Hanks' balanced salt solution (HBSS; 136.7 mM NaCl, 0.385 mM Na_2HPO_4, 0.441 mM KH_2PO_4, 0.952 mM $CaCl_2$, 5.36 mM KCl, 0.812 mM $MgSO_4$, 25 mM D-glucose, and 10 mM MES for adjustment of pH to 5.0) before a test solution containing [^{14}C]salicylic acid was added. [^{14}C]-Salicylic acid (0.25 μCi/mL; 4.5 μM) was used as a marker for monocarboxylic acid carrier-mediated transport. The pH of the test solution was 5.0 except in pH-dependent uptake experiments. In pH-dependent experiments, the pH range of the incubation buffer was 5.0−7.5. The buffer solutions were prepared by adding MES (pH 5.0−6.5) or HEPES (pH 7.0−7.5) to HBSS. After 30 s, the test solution was aspirated and the cells were washed four times with ice-cold HBSS. For quantitation of [^{14}C]salicylic acid uptake, the cells were suspended in 0.5 N NaOH (300 μL) and the suspension was incubated at 37 °C for 12 h at which point 1.0 N HCl (150 μL) was added. The remaining radioactivity was quantified using a liquid scintillation counter (Aloka, LSC-5100). Cellular protein was quantified using a protein assay kit (Bio-Rad, CA), with bovine serum albumin as the standard. Details of the conditions for each experiment are given in the figure legends or table footnotes.

Data Analysis—The kinetic parameters of saturable uptake by HOEpi were determined using a nonlinear least squares

Published on Web 12/01/1998

regression analysis program, MULTI.[7] The uptake rate (J) was fitted to the following equation, which consists of both saturable and nonsaturable linear terms:

$$J = J_{max} \times C/(Kt + C) + k \times C \quad (1)$$

where J_{max} is the maximum uptake rate for a carrier-mediated process, C is the salicylic acid concentration, K_t is the half-saturation concentration (Michaelis constant), and k is a first-order rate constant.

In Vivo Absorption Experiments—The in vivo absorption experiments were performed using a slightly modified version of a method described previously.[3] Briefly, male golden hamsters (body weight range, 120−150 g) were anesthetized with urethane (1.5 g/kg, ip) and fastened onto a platform tilted at an angle of 55°. The cheek pouch was cleaned by multiple saline rinses. A vinyl tube (o.d., 1.2 mm; i.d., 0.8 mm; Natsume, Japan) was inserted into the cheek pouch to a depth of 50 mm. One milliliter of the drug solution (20 μM) dissolved in buffer was administered into the cheek pouch. In pH-dependent absorption experiments, the buffer pH ranged from 3.0 to 7.0. Buffer solutions of pH 6.0 were prepared by adding MES to HBSS, whereas for the pH 7.0 buffer solution, HEPES was added to HBSS. Citric acid−Na_2HPO_4 buffer was used for the pH 3.0−5.0 experiments. For other experiments also, citric acid−Na_2HPO_4 buffer (pH 5.0) was used. At predetermined time points after the drug administration, the fluid in the cheek pouch lumen was collected. The amount of the drug present in the fluid was determined by fluorescence (salicylic acid: Ex. 300 nm, Em. 430 nm) or UV (salicylamide: 235 nm) detectors. The reduction in concentration of the drug in the cheek pouch was used as a measure of the apparent absorption.

Plasma Concentration of Salicylic Acid—Under anesthesia, [^{14}C]salicylic acid solution (2.0 μCi/mL; 36 μM) was administered into the cheek pouch lumen. At predetermined time points after the administration, blood samples were collected from the ophthalmic vessels using a glass capillary coated with heparin (DURAN ringcaps, Germany). Each blood sample was placed in a scintillation vial to which 0.2 mL of perchloric acid solution was added. After vigorous shaking, 0.3 mL of hydrogen peroxide solution was added. After 30 min of incubation at 70 °C, scintillation cocktail (Clear-sol II, Nacalai Tesque, Japan) was added. Radioactivity was quantified using a liquid scintillation counter.

Statistical Analysis—All results were expressed as mean ± standard deviation (SD). One-way analysis of variance (ANOVA) was used for single and multiple comparisons. Values of p of 0.05 or less were considered to indicate statistical significance.

Results

Salicylic Acid Uptake by HOEpi—We reported previously on monocarboxylic acid transport across oral mucosal epithelial cells using cultured epithelial cells from rabbit oral mucosa.[1] The hamster is most widely used for studies of drug absorption from the oral mucosa. In the present study, we first determined whether a carrier-mediated monocarboxylic acid transport system exists in cultured hamster oral epithelial cells.

Concentration and Temperature Dependence of Salicylic Acid Uptake—The effect of incubation temperature on the rate of uptake of [^{14}C]salicylic acid by HOEpi was studied. The rate of uptake was much lower at 4 °C than at 37 °C, as shown in Figure 1. Figure 1 also shows the relationship between the initial rate of uptake of [^{14}C]-salicylic acid and its concentration in the incubation medium. The results indicate that the uptake of salicylic acid consists of two processes, a saturable process evident at low concentrations and an apparently nonsaturable process evident at high concentrations. The uptake processes were analyzed using eq 1. The kinetic parameters calculated for salicylic acid uptake were a J_{max} of 140 ± 16 nmol/30 s/mg protein, a K_t of 0.14 ± 0.03 mM, and a k of 33 ± 3 μL/30 s/mg protein.

Energy and Proton-Gradient Dependence of Salicylic Acid Uptake—The effect of a metabolic inhibitor on the uptake of [^{14}C]salicylic acid was studied to determine whether this uptake requires metabolic energy (Table 1). Sodium azide (10 mM), a metabolic inhibitor, inhibited the uptake of [^{14}C]salicylic acid by HOEpi. Carbonylcyanide *p*-trifluoromethoxyphenylhydrazone (FCCP; 50 μM), a protonophore, also significantly inhibited the uptake. These findings suggest that [^{14}C]salicylic acid uptake by HOEpi is energy- and proton-gradient-dependent.

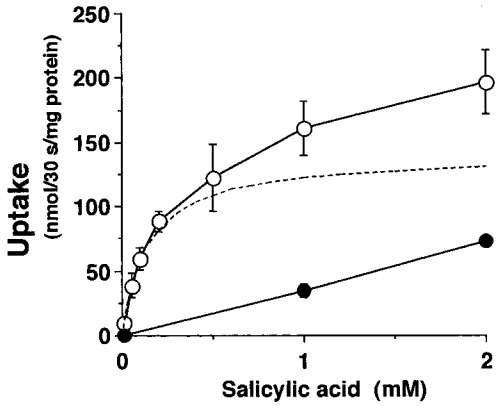

Figure 1—Concentration and temperature dependence of [^{14}C]salicylic acid uptake by HOEpi. The rate of uptake of [^{14}C]salicylic acid by HOEpi was measured at (○) 37 °C and (●) 4 °C. The dotted line represents the saturable component of the uptake of salicylic acid calculated from the kinetic parameters determined as described in the text. The vertical bar through each point represents the SD for four experiments.

Table 1—Effects of a Metabolic Inhibitor, a Protonophore, and Various Carboxylic Acids on [^{14}C]Salicylic Acid Uptake by HOEpi

variable type	compound	relative uptake (% of control)
metabolic inhibitor	sodium azide[a]	33.3 ± 8.7[b]
protonophore	FCCP[a]	15.9 ± 10.1[b]
monocarboxylic acid	*n*-butyric acid	8.0 ± 1.4[b]
	propionic acid	9.9 ± 3.0[b]
	valproic acid	12.2 ± 6.9[b]
	acetic acid	17.0 ± 8.2[b]
	lactic acid	46.6 ± 17.6[b]
	pyruvic acid	50.6 ± 4.6[b]
dicarboxylic acid	glutaric acid	95.4 ± 17.9
	fumaric acid	107.6 ± 37.5
	maleic acid	99.4 ± 24.0

[a] HOEpi were pretreated with sodium azide (10 mM) or FCCP (50 μM) for 15 min; all carboxylic acids were tested at 10 mM. [b] Significantly different from the control value ($p < 0.05$).

pH-Dependent Uptake—Figure 2 illustrates the effect of incubation buffer pH in the range of 5.0 to 7.5 on [^{14}C]-salicylic acid uptake by HOEpi. The rate of [^{14}C]salicylic acid uptake increased with decreasing pH from neutral to acidic. At pH 7.5, little salicylic acid uptake was observed. In the presence of 10 mM unlabeled salicylic acid, the uptake of [^{14}C]salicylic acid was significantly reduced and almost completely suppressed. The inhibitory effect of unlabeled salicylic acid increased with decreasing pH from neutral to acidic, suggesting that the passive diffusion route is a minor route and carrier-mediated transport is the major mechanism involved in the uptake of salicylic acid. Previous studies in our laboratory have shown the existence of pH-dependent, monocarboxylic acid transport in the rabbit oral mucosal epithelial cells.[1] In the present study, we also showed that FCCP inhibited the uptake of salicylic acid by HOEpi (Table 1). Our data suggest that carrier-mediated salicylic acid uptake by HOEpi is proton-gradient-dependent, implying that an acidic pH is suitable for the evaluation of monocarboxylic acid transport in HOEpi.

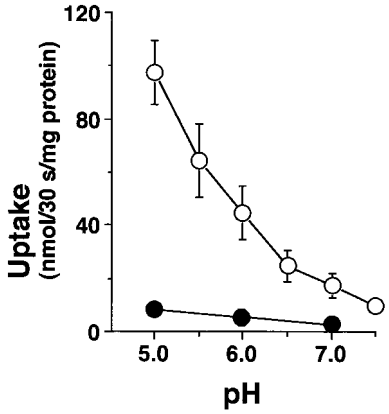

Figure 2—pH Dependence of [^{14}C]salicylic acid uptake by HOEpi. Uptake of [^{14}C]salicylic acid by HOEpi was measured at 37 °C in the (○) absence and (●) presence of 10 mM unlabeled salicylic acid. The vertical bar through each point represents the SD for four experiments.

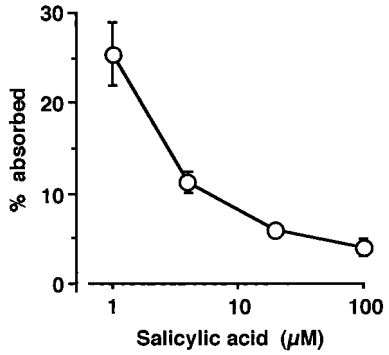

Figure 3—Concentration dependence of salicylic acid absorption. Salicylic acid (1–100 μM) was administered into a hamster cheek pouch. After 15 min, the fluid in the cheek pouch was collected and the amount of salicylic acid present in the fluid was measured. The reduction in concentration of the salicylic acid in the lumen of the cheek pouch was used as a measure of the apparent absorption. The vertical bar through each point represents the SD for four experiments.

Therefore, a pH 5.0 buffer was used for subsequent experiments.

Specificity of the Carrier—To investigate the properties of the carrier involved in [^{14}C]salicylic acid uptake by HOEpi, we studied the effects of various mono- and dicarboxylic acids on this uptake (Table 1). Each monocarboxylic acid significantly inhibited the uptake of [^{14}C]-salicylic acid, whereas none of the dicarboxylic acids had any significant effect. These results imply that the carrier that mediates monocarboxylic acid uptake by HOEpi is a nonspecific monocarboxylic acid carrier.

Salicylic Acid Absorption from the Oral Mucosa In Vivo—We determined whether a monocarboxylic acid transport system exists in hamster cheek pouch mucosa in vivo.

Concentration Dependence of Salicylic Acid Absorption—The effect of luminal concentration of salicylic acid in the hamster cheek pouch on its absorption from the cheek pouch was examined in the concentration range of 1.0 to 100 μM. The percentages of the apparent absorption at 15 min and pH 5.0 are shown in Figure 3. At high concentrations of salicylic acid, the apparent absorption was saturated.

Energy and Proton-Gradient Dependence of Salicylic Acid Absorption—The effects of a metabolic inhibitor and a protonophore on the absorption of salicylic acid were studied (Figure 4). Both sodium azide (10 mM) and FCCP (50 μM) significantly inhibited the apparent absorption of salicylic acid from the oral mucosa. However, neither

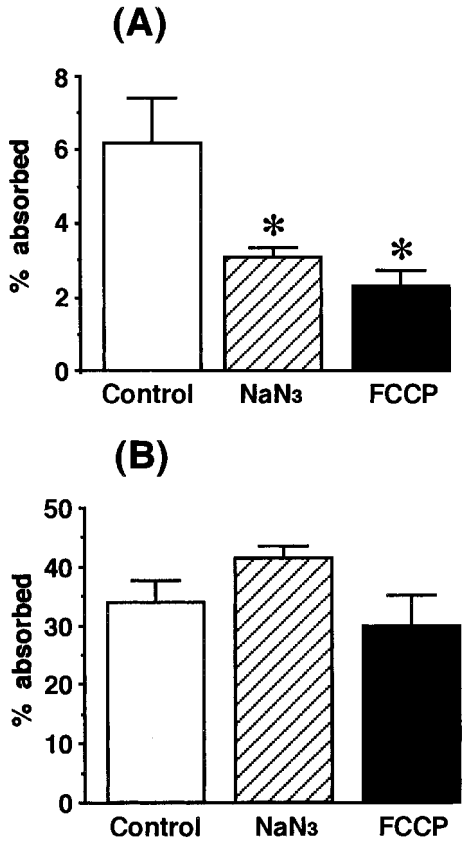

Figure 4—Effects of metabolic inhibitor and protonophore on (A) salicylic acid and (B) salicylamide absorption. A metabolic inhibitor (sodium azide, NaN_3, 10 mM) or a protonophore (FCCP, 50 μM) was administered into the hamster cheek pouch. After 15 min, salicylic acid (20 μM) or salicylamide (20 μM) was added. Then, 15 min later, the fluid in the cheek pouch was collected and the amount of salicylic acid or salicylamide present in the fluid was measured. The disappearance of salicylic acid and salicylamide from the lumen of the oral cavity was defined as the apparent absorption. The vertical bar through each point represents the SD for 3–5 experiments. The asterisk (*) indicates significantly different from the control ($p < 0.05$).

sodium azide nor FCCP affected the apparent absorption of salicylamide. These findings suggest that salicylic acid absorption from hamster oral mucosa is carrier-mediated and depends on the proton gradient and energy.

pH-Dependent Uptake—Figure 5 illustrates the effect of buffer pH in the range of 3.0 to 7.0 on salicylic acid absorption from hamster oral mucosa. The apparent absorption of salicylic acid increased with decreasing pH from neutral to acidic. In the present study, we also showed that FCCP inhibited the absorption of salicylic acid from hamster oral mucosa (Figure 4). These data suggest that salicylic acid absorption is proton-gradient-dependent, implying that an acidic pH is suitable for the evaluation of a monocarboxylic acid transport system in hamster oral mucosa. However, at very low values of pH (e.g., 3.0 or 4.0), most of the salicylic acid in solution exists in the nonionized form. An increase in the fraction of nonionized salicylic acid resulted in an increase in the passive diffusion of salicylic acid across the oral mucosa. Therefore, pH 5.0 buffer was used for subsequent absorption experiments.

Specificity of the Carrier—To investigate the properties of the carrier involved in salicylic acid absorption from hamster oral mucosa, we studied the effects of various mono- and dicarboxylic acids on this absorption (Table 2). Each monocarboxylic acid tested significantly inhibited the apparent absorption of salicylic acid, whereas none of the dicarboxylic acids had any significant effect. These results

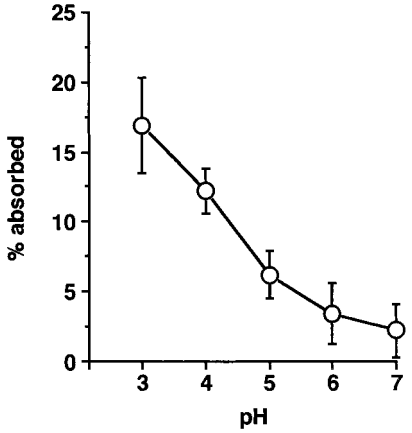

Figure 5—The pH dependence of salicylic acid absorption. Salicylic acid dissolved in various pH buffers (pH 3.0–7.0) was administered into the hamster cheek pouch. After 15 min, the fluid in the cheek pouch was collected and the amount of salicylic acid present in the fluid was measured. The disappearance of salicylic acid from the lumen of the oral cavity was defined as the apparent absorption. The vertical bar through each point represents the SD for four experiments.

Table 2—Effects of Various Carboxylic Acids on Salicylic Acid Absorption from Hamster Cheek Pouch Mucosa[a]

variable type	compound	relative absorption (% of control)
monocarboxylic acid	*n*-butyric acid	22.0 ± 15.3[b]
	propionic acid	7.3 ± 2.6[b]
	valproic acid	45.6 ± 1.5[b]
	acetic acid	14.4 ± 7.6[b]
dicarboxylic acid	glutaric acid	102.5 ± 17.8
	fumaric acid	78.0 ± 27.1
	maleic acid	93.2 ± 8.5

[a] All carboxylic acids were tested at 10 mM. [b] Significantly different from the control value ($p < 0.05$).

suggest that the carrier that mediates monocarboxylic acid absorption is a nonspecific monocarboxylic acid carrier.

Blood Concentration—We further examined whether the [^{14}C]salicylic acid that disappeared from the oral mucosal lumen was transferred to the systemic circulation. The blood concentration−time profiles of [^{14}C]salicylic acid following intracheek pouch administration in the presence and absence of propionic acid (10 mM) are shown in Figure 6. Transfer of [^{14}C]salicylic acid to the systemic circulation was detected. The blood concentration versus time curves demonstrate that propionic acid significantly inhibited the absorption of salicylic acid from the oral mucosa.

Discussion

In previous studies, we demonstrated that carrier-mediated monocarboxylic acid transport systems exist in rabbit oral mucosal epithelial cells in primary culture.[1] However, carrier-mediated absorption of monocarboxylic acids from the oral mucosa in vivo had not been previously described. In the present study, we demonstrated the existence of a carrier-mediated transport system for monocarboxylic acids in the oral mucosa in vivo.

Salicylic acid uptake by HOEpi is characterized as follows: (a) reduction of the incubation temperature from 37 to 4 °C markedly inhibited the uptake; (b) salicylic acid uptake was saturable at high concentrations; (c) a metabolic inhibitor and a protonophore significantly inhibited the uptake, indicating that this uptake process is energy- and proton-gradient-dependent; and (d) monocarboxylic acids significantly inhibited the uptake of salicylic acid.

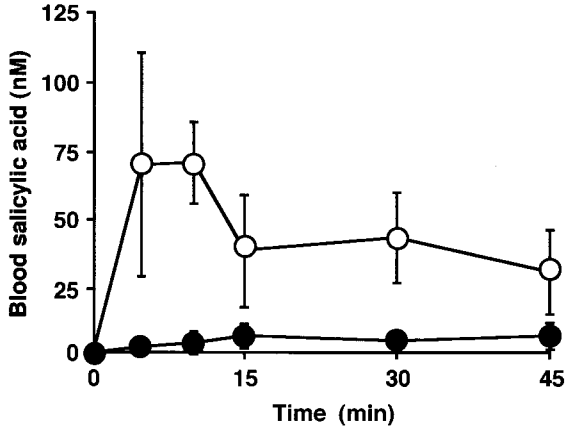

Figure 6—Blood concentration of [^{14}C]salicylic acid after intracheek pouch administration of [^{14}C]salicylic acid (●) with or (○) without 10 mM propionic acid. [^{14}C]Salicylic acid (2.0 μCi/mL; 36 μM) was administered into the hamster cheek pouch. Blood was collected from the ophthalmic vessels. The vertical bar through each point represents the SD for four experiments.

These characteristics of monocarboxylic acid uptake by HOEpi are similar to those observed in rabbit oral mucosal epithelial cells. These data demonstrate the existence of a carrier-mediated monocarboxylic acid transport system in HOEpi.

We also demonstrated carrier-mediated salicylic acid absorption from hamster cheek pouch mucosa. The apparent absorption of salicylic acid from the hamster cheek pouch mucosa in vivo is characterized as follows: (a) the apparent absorption of salicylic acid was saturable at a high initial concentration; (b) a metabolic inhibitor and a protonophore significantly inhibited salicylic acid apparent absorption, indicating that this apparent absorption is energy- and proton-gradient-dependent; and (c) monocarboxylic acids significantly inhibited the salicylic acid apparent absorption. These observations of monocarboxylic acid absorption in vivo are similar to those in vitro and strongly suggest the occurrence of carrier-mediated monocarboxylic acid transport in hamsters in vivo.

Moreover, the present study confirms the transfer of [^{14}C]-salicylic acid from the oral mucosa to the systemic circulation (Figure 6). These data demonstrate that salicylic acid that disappeared from the oral luminal cavity did not remain in the mucosal tissue but was transferred to the blood. Coadministration of propionic acid significantly reduced the blood concentration of [^{14}C]salicylic acid. Passive absorption of salicylic acid was not inhibited by coadministered propionic acid. Therefore, the coexistence of propionic acid with the absorbed salicylic acid indicates passive absorption. Figure 6 also shows that the rate of passive absorption of [^{14}C]salicylic acid from the oral luminal cavity is much lower than that of carrier-mediated absorption of [^{14}C]salicylic acid.

The surface of hamster cheek pouch mucosa is keratinized.[8] Therefore, no carrier-mediated transport occurs across this keratinized part because keratinized cell layers consist of differentiated dead cells. However, our data indicate that carrier-mediated absorption occurs in the hamster cheek pouch mucosa. This result may explain why the keratinized layer is not the main barrier to salicylic acid transport. Salicylic acid may be transported via a carrier-mediated system in the living epithelial cell layers that are located under the keratinized cell layers.

Figures 2 and 5 show pH-dependent uptake or absorption of salicylic acid. At neutral pH, little uptake was observed. However, the uptake of salicylic acid increases with a decrease of pH. Salicylic acid is an acidic compound; therefore, a decrease in pH increases the fraction of

nonionized salicylic acid. According to the pH−partition hypothesis, this increase in the fraction of nonionized form increases the passive absorption of salicylic acid across the oral mucosa. These data (Figures 2 and 5) alone are insufficient to conclude that the uptake of salicylic acid is proton-gradient-dependent. However, it is evident from Table 1 and Figure 4 that FCCP, a protonophore, inhibited the uptake of salicylic acid. These results strongly suggest that salicylic acid uptake is proton-gradient-dependent.

In in vitro experiments (Figure 1), the K_t of salicylic acid was 0.14 ± 0.03 mM. However, in in vivo experiments (Figure 3), the absorption of salicylic acid was saturated at 0.1 mM or less. We have no clear explanation as to why the saturation behavior is different between in vitro and in vivo conditions. There are some differences between in vivo and in vitro states. In vitro, salicylic acid transport was studied in terms of its uptake by cultured epithelial cell monolayers. This means that only the transport of salicylic acid from the apical side to intercellular spaces was evaluated. On the other hand, in vivo, the apparent absorption as determined by its disappearance from the hamster cheek pouch, by the oral mucosa which consists of multilayer epithelial cells was evaluated. The difference in results may be due to differences between cultured cells and cells in vivo, uptake and transport, and monolayer and multilayer.

Figure 4 shows that both sodium azide (10 mM) and FCCP (50 μM) significantly inhibit the apparent absorption of salicylic acid from the oral mucosa. However, neither sodium azide nor FCCP affected the apparent absorption of salicylamide. These findings suggest that salicylic acid absorption from hamster oral mucosa is carrier-mediated and depends on the proton gradient and energy. However, the absorption of salicylamide (the control) is six times higher than that of salicylic acid. The difference in the apparent absorption values between salicylamide and salicylic acid could be due to the differences in their lipophilicities. The apparent octanol−buffer (pH 5.0) distribution coefficient of salicylic acid at 37 °C is 0.45 ± 0.02, and that of salicylamide is 14.56 ± 0.09 (these results were obtained in our laboratory, although details of the experimental conditions are not shown). Salicylamide is 32 times more lipophilic than salicylic acid at pH 5.0, which may account for its higher apparent absorption.

The rate of absorption of a drug from the hamster cheek pouch mucosa is related to the lipophilicity of the drug.[3] A lipophilic index based on the results of reversed-phase HPLC has been used extensively as a measure of the lipophilicity of drugs.[9] Kurosaki et al. reported[3] that the lipophilic index of salicylic acid is the same as that of phenacetin. However, the absorption rate of salicylic acid from the hamster cheek pouch mucosa is about three times higher than that of phenacetin (48.6 ± 4.1 and 16.0 ± 0.6%, respectively, after 1 h). Kurosaki et al. did not discuss this finding in their report.[3] This higher percentage absorption of salicylic acid than that of phenacetin may be accounted for by carrier-mediated absorption of salicylic acid from the hamster cheek pouch mucosa.

Our present results suggest that drugs that have a monocarboxylic acid residue could potentially be delivered into the systemic circulation from the oral mucosa via carriers. This carrier-mediated oral mucosal absorption route may serve as a new approach for drug absorption from the oral mucosa.

Accepted for publication September 2, 1998.

Abstract □ Pharmacokinetics of cationized goat colchicine-specific polyclonal immunoglobulin G (IgG) and antigen binding fragment (Fab) (cIgG and cFab, respectively) were studied in male adult Sprague–Dawley rats and compared with those of the native proteins (nIgG and nFab). All proteins were radioiodinated by the Iodogen method, and kinetics were investigated following trichloroacetic acid (TCA) precipitation or immunoprecipitation. Deiodination and catabolism were more pronounced with the cationized than the native proteins, especially for cFab. Both cIgG and cFab in plasma decreased more rapidly than nIgG and nFab. The elimination half-lives were 52.9 and 81.8 h for cIgG and nIgG, respectively. In addition, there was a 74-fold increase in the volume of distribution and a 114-fold increase in the systemic clearance of cIgG compared with nIgG. For cFab, the volume of distribution and systemic clearance were increased 6.4- and 3.5-fold, respectively. Organ uptake of cIgG and cFab was markedly increased compared with that of nIgG and nFab, especially in kidney, liver, spleen, and lung. Renal clearance of cIgG and cFab was also increased 30- and 10-fold compared with that of nIgG and nFab, respectively. The present data suggest that cationization of colchicine-specific IgG and Fab fragments increased the organ distribution and greatly altered their pharmacokinetics. Nevertheless, the smaller molecular size of Fab versus IgG did not enhance the distribution and clearance of cFab. These data pave the way for evaluating the biological efficacy of these more tissue-organ-interactive antibodies.

Introduction

Antibodies offer considerable potential for disease diagnosis and for treatments, such as the neutralization of bacteria, viruses, oncogenic proteins,[1] and toxins.[2] However, the diagnostic and pharmaceutical potential of antibodies is limited because these high molecular weight proteins [immunoglobulin G (IgG), 150 kDa] do not cross either capillary or cellular barriers.[3,4] Even trunctated forms of antibodies, such as antigen binding fragments (Fab, 50 kDa) or even sFv fragments (27 kDa), are too large to easily penetrate physiological membranes. Therefore, it is important to develop strategies for improving the delivery of antibodies to the site of action.

One of the recent developments in targeted delivery of proteins is their cationization,[5,6] in which the surface carboxyl groups of the protein are conjugated with primary amino groups resulting in an increase in the protein isoelectric point (pI). The positive charges of the cationized proteins so formed bind to negative charges on cellular surfaces and thus trigger absorptive-mediated endocytosis of the cationized proteins.[7] This interaction between cell membrane and cationized proteins can be evaluated by pharmacokinetic studies.

The first studies[5,8] concerning the pharmacokinetics of cationized IgG (cIgG) reported an enhanced organ uptake. However, the experimental protocols had a short sampling period and took little account of the influence of the different antibody size between cIgG and cationized Fab (cFab) fragments. In the present study, we report the plasma pharmacokinetics of cationized goat polyclonal colchicine-specific antibodies (IgG and Fab) and their organ distribution in the rat. In addition, their renal clearance and fecal elimination were also measured. This pilot study was conducted prior to assessing the potency of cationized colchicine-specific IgG and Fab for redistributing intracellular colchicine, a compound toxic to tubulin that either inhibits microtubule-dependent processes or disrupts the cytoskeleton.[9]

Materials and Methods

Materials—Goat IgG and Fab fragments of colchicine-specific polyclonal antibody were prepared as previously described.[10] IgG and Fab fragments were purified by gel chromatography to 97% and 92% for IgG and Fab fragments, respectively. Colchicine and thiocolchicine were obtained from Roussel Uclaf (Paris, France) and [^{3}H]colchicine (Ring C,^{3}H-methoxy, 66 Ci/mmol) was from New England Nuclear (Paris, France). Hexamethylenediamine (HMD), *N*-ethyl-*N*′-(3 (dimethylamino) propyl)carbodiimide (EDC), glycine, and others reagents for protein cationization were obtained from Sigma (St Quentin Fallavier, France). Affinity purified rabbit anti-goat IgG (H and L) antiserum (Rockland, PA) and protein A-agarose specific to rabbit polyclonal antibodies (Santa Cruz Biotechnology, Inc.) were purchased from Tebu (Paris, France).

Cationization of Colchicine Specific IgG and Fab—Native colchicine-specific IgG and Fab were cationized according to the method of Pardridge[11] with a small modification: 10 mg of both native IgG and Fab were slowly added to 4 mL of 2 M hexamethylenediamine (HMD, pH 6.2). To this mixture, 50 mg of fresh EDC was added, and the pH was adjusted to 6.2 with 6 M hydrochloric acid. The mixture was stirred for 3 h at room temperature, and the solution was kept on ice to avoid heating. The reaction was quenched by addition of 2 M glycine following by incubation for 60 min at room temperature. The mixture was then dialyzed overnight at 4 °C against 0.01 M Na_2HPO_4/0.15 M NaCl (PBS, pH 7.4). The precipitate was removed by centrifugation (1000 g, 10 min) and the solution was concentrated with polyethylene (6000 Da) at 4 °C. The solution was stored at −20 °C.

Characterization of Cationized IgG and Fab—The pI of cationized and native IgG and Fab were determined by isoelectric focusing (IEF).[6] Protein samples (30 μ) were dialyzed with 0.05% glycine overnight at 4 °C to eliminate excess ions and analyzed by isoelectric focusing (IEF) according to the manufacturer's instructions (Sigma, St Quentin Fallavier, France). After isoelectrophoresis, the gel was stained with Coomassie blue. The cationized antibodies were also subjected to sodium dodecyl

sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) analysis in 8% or 12% acrylamide, using the Laemmli buffer system, to determine the molecular weight of the cationized and native antibodies.[12]

The affinity constant was determined by competitive radioimmunoassay (RIA) according to the method of Müller.[13] Specificity of the native and cationized antibodies was measured by the cross-reactivity of a colchicine analogue, thiocolchicine, using the RIA as previously described by Scherrmann et al.[2]

Radiolabeling of IgG and Fab—Antibodies were labeled using the Iodogen method.[14] One hundred micrograms of protein were incubated with 0.5 mCi of [^{125}I]Na (Amersham, Les Ulis, France) in Eppendorf tubes coated with 10 μg of Iodogen for 5 min at room temperature. Free iodine was removed by chromatography on a PD-10 Sephadex G-25 column (Pharmacia, Les Ulis, France). Specific activity ranged from 2 to 3 μCi/μg for native IgG (nIgG), 1−2 μCi/μg for cIgG, 1−2 μCi/μg for native Fab (nFab), and 0.6−1.5 μCi/μg for cFab. The radiochemical purity of cIgG, nIgG, cFab, and nFab was analyzed just after iodination and 24, 48, and 72 h and once a week up to 3 weeks after the iodination by SDS−PAGE autoradiography and immunoprecipitation (for procedure see: Comparison of Plasma Antibody Levels following TCA Precipitation and Immunoprecipitation). Finally, the percentage of antibody precipitable radioactivity was determined by trichloroacetic acid (TCA) precipitation.

Intravenous Administration of Cationized and Native IgG and Fab Fragments—Male Sprague−Dawley rats (250−300 g, Iffa Credo, Lyon, France) were given free access to food and water. Each rat was weighed and anesthetized with pentobarbital sodium (60 mg/mL, 60 mg/kg, ip). Body temperature was monitored using a rectal probe (Elba Thermometer model ET 3, Copenhagen, Denmark). During the experiment, each rat was housed in a metabolic cage for collection of urine and feces at the interval of 8 or 16 h. The femoral vein was cannulated with PE−10 tubing (Biotrol, Paris, France). Rats received a single bolus dose of 0.7 mg/kg of unlabeled antibody and 15 μCi of ^{125}I-labeled antibody dissolved in 0.9% NaCl via the cannulated femoral vein. Blood samples were collected in heparinized tubes from the tail at various times (0, 2, 15, 30, and 60 min, 2, 4, 8, and 24 h, and daily for 18 days for nIgG; 0, 1, 10, 20, and 30 min, and 1, 2, 4, 6, 8, 24, 30, 48, 54, 72, 96, and 120 h for cIgG; and 0, 1, 10, 20, and 30 min, and 1, 2, 4, 6, 8, 24, 28, 32, 48, 56, and 72 h for cFab and nFab). Aliquots of plasma were counted for total and TCA-precipitable radioactivity in a gamma counter (Minaxi gamma 5000, Packard Instruments, Rungis, France). Other aliquots were stored at −20 °C for SDS−PAGE followed by autoradiography. Urine and feces were collected throughout the experimental period for measurement of total excreted radioactivity. Free ^{125}I in urine was determined by precipitation with TCA.

Comparison of Plasma Antibody Levels following TCA Precipitation and Immunoprecipitation—To check whether the TCA-precipitable radioactivity corresponded to the intact native or cationized proteins, an immunoprecipitation methodology was applied in a satellite group of rats ($n = 3$). Blood samples (1 mL) were taken 0 and 5 min, and 2, 8, 24, and 48 h for cIgG and at nIgG; and 0 and 5 min, and 2, 4, 8, 24, and 48 h for cFab and nFab after intravenous administration, respectively. Two aliquots of plasma samples were counted for total and TCA-precipitable radioactivity in the gamma counter. Immunoprecipitation was performed as follows: to 200 μL of each plasma sample (or 10 μL of pure radiolabeled native or cationized IgG and Fab diluted in 200 μL rat plasma for the radiochemical purity determination), 100 μL of incubation buffer was added and the solution was incubated at 37 °C for 3 h, then at 4 °C for 1 h. The incubation buffer consisted of PBS (10 mM sodium phosphate, pH 7.4, with 0.14 M NaCl) and 30 μg/mL of rabbit polyclonal anti-goat IgG. Protein A-agarose (40 μL) was added to each tube. After overnight incubation at 4 °C, the immunoprecipitate was collected by centrifugation at 5000 rpm for 7 min at 4 °C, and the supernatant was aspirated and discarded carefully. The immunoprecipitate was washed with PBS (300 μL) and centrifuged as before. This step was repeated three times. After final washing, the immunoprecipitate fractions were counted for radioactivity. The nonspecific precipitation evaluated using normal rabbit plasma was <1%.

Distribution of Cationized and Native Antibodies in Organs—Distribution of antibodies in organs was studied at different times: 6, 72, 120, and 192 h for cIgG; 6, 72, 432, and 456 h for nIgG; and 2 h for both cFab and nFab. Kidneys, liver, spleen, heart, lung, brain, thyroid, and a portion of small intestine were removed, rapidly washed with saline, and blotted dry. Fragments of organs were weighed and solubilized in Soluene 50 according to Pardridge et al.[15] at 60 °C for 60 min and counted for radioactivity in gamma scintillation liquid. Distribution of antibodies in the organ was expressed as ng/g of tissue. Blood samples were taken just before rats were killed, and radioactivity was measured. As radioactivity remaining in the blood at the time of death was very different for native and cationized antibodies, total radioactivity in the organs was corrected according to levels found in the blood.[16]

SDS−PAGE and Autoradiography—Plasma (0.1 mL) containing native or cationized ^{125}I-labeled antibodies was analyzed by SDS−PAGE.[12] Radiolabeled antibodies and metabolites were autoradiographed using X-ray film (Amersham) and intensifying screens for several weeks. The migration zone of native ^{125}I-labeled antibodies or fragments was compared with protein markers of known molecular weights (Rainbow, Amersham, France); they are, myosin (205 kDa), β-galactosidase (116.5 kDa), bovine serum albumin (80 kDa), ovalbumin (49.5 kDa), and soybean trypsin inhibitor (27.5 kDa).

Detection of Rat Anti-goat Immune Response to the Cationized and Native IgG and Fab—An immunoradiometric assay (IRMA) was performed to detect anti-goat cIgG, nIgG, cFab, and nFab in rat plasma 1, 2, and 3 weeks after administration of a single dose (700 μg/kg) of each antibody. Microtitration plates (Falcon microtest III U50, Polylabo, Strasbourg, France) were coated with 200 μL of 100 mM sodium carbonate pH 9.6 containing 20 μg/mL of affinity-purified goat nIgG, nFab, cIgG, and cFab, respectively, by overnight incubation at 4 °C. The plates were washed three times with PBS containing 0.2% Tween-20 (PBS-Tween). Overcoating was achieved by a 1-h incubation at room temperature with 200 μL/well PBS containing 3% BSA to reduce nonspecific serum protein binding. Plates were then washed three times with PBS-Tween. Then, 100 μL of rat plasma samples, 100 μL of normal rat plasma containing 1 μg of rabbit anti-goat IgG (positive control), or 100 μL of normal rat plasma (nonspecific binding) were added to the sensitized plates and incubated for 2 h at room temperature. All assays were performed in triplicate. The plates were washed and incubated 1 h at room temperature with 100 μL of appropriate optimally diluted conjugate ([^{125}I]cIgG, [^{125}I]nIgG, [^{125}I]cFab, or [^{125}I]nFab, 70 000 cpm, respectively). Plates were washed three times with PBS-Tween and dried. Each well was cut out and placed in a 5-mL plastic tube. All tubes were capped and counted in a gamma counter. The radioactivity in each tube was expressed as % binding; that is, $(B - NS)/(T - NS) \times 100\%$, where B = bound, T = total radioactivity and N = the nonspecific binding of the tracer.

Pharmacokinetic and Statistical Analysis—Plasma cIgG, nIgG, cFab, and nFab TCA-precipitable concentrations were analyzed by model-independent techniques using the SIPHAR program (SIMED, Creteil, France). The terminal disposition rate constant (λ_d) was determined by linear regression analysis and the corresponding half-life ($t_{1/2}\lambda_d$) was calculated as $0.693/\lambda$. The area under the curve (AUC) of plasma ^{125}I-cationized or native IgG and Fab concentration versus time curve from zero to infinity was determined by linear trapezoidal estimation from zero to the last measured time with extrapolation to infinity by adding the value of the last measured plasma concentration divided by the terminal rate constant. Total body clearance (CL) and volume of distribution (Vd) were calculated using standard equations.[17]

Renal clearance was calculated by dividing the amount of protein in urine by the plasma AUC at the same time interval. Mean values for pharmacokinetic parameters were compared using one-way analysis of variance (ANOVA) followed by the Student-Newman-Keuls Multiple Comparisons Test (GraphPad software V 2.04 a). Significance was set at $p < 0.05$.

Results

Characteristics of Antibodies after Cationization and ^{125}I Radiolabeling—As measured by IEF, the pI of nIgG and nFab ranged from 5.85 to 9.0 and 8.65 to 9.3, respectively. The pI of cIgG and cFab were both raised and ranged from 8.65 to 10.3 and 9.5 to 11, respectively.

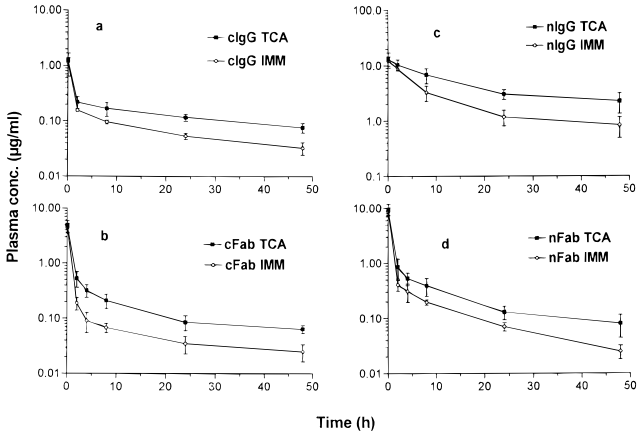

Figure 1—Time courses of plasma ^{125}I-labeled antibody concentrations precipitated by TCA and immunoprecipitation (IMM) in a satellite rat group. Graphs a, b, c, and d represent different antibodies. Data are mean ± SD (n = 3).

However, the process of cationization did not significantly change the affinity and specificity of IgG and Fab fragments. The affinity constants of cIgG and nIgG were 1.2 ± 0.13× 10^9 and 1.58 ± 0.2 × 10^9 M^{-1} (p > 0.05) respectively, and 1.08 ± 0.21 × 10^9 and 0.64 ± 0.18 × 10^9 M^{-1} (p > 0.05) for cFab and nFab, respectively. The cross-reactivity to thiocolchicine did not differ significantly between cationized and native forms. The percentages were 8.6 ± 1.13 and 8.9 ± 0.58% (p > 0.05) for cIgG and nIgG, respectively, and 25 ± 5.9 and 37 ± 8.67% (p > 0.05) for cFab and nFab, respectively. Furthermore, after cationization of IgG and Fab, high molecular weight aggregates were not detected by SDS−PAGE, and no alteration of the migration bands of the native and cationized antibodies were observed by autoradiography after iodination. Most (90−94%) of the total radioactivity of cationized and native antibodies was recovered by immunoprecipitation just after iodination or even 3 weeks later. The percentage of TCA-precipitable radioactivity of the native and cationized antibodies changed from 96−98% following iodination to 85 ± 5% at two weeks later. As a consequence, all pharmacokinetic studies were performed within 24 h after the radiolabeling of the native and cationized antibodies. Finally, we found that the cationized molecules bound nonspecifically to silicon and plastic tubing (nonspecific binding was 1.9 and 2.1%, respectively), we thus used glass tubing to avoid nonspecific binding (<1%).

Detection of Rat Anti-goat Immune Response to Cationized and Native IgG and Fab—The binding capacity of each antibody-treated (cIgG, cFab, nIgG, and nFab) rat plasma sample to its corresponding antigen accounted for <0.3% (but 46.12 ± 1.3% for the positive control) of the total radioactivity during the 3 weeks following the protein administration. This result indicates that no anti-goat immune response occurred during the experimental time period of the pharmacokinetic study after a single iv dose (700 µg/kg,) of the antibodies, not even for cationized IgG and Fab.

Comparison of Pharmacokinetics Following TCA Precipitation and Immunoprecipitation—Figure 1 shows the plasma concentration of cationized and native antibodies detected by TCA precipitation and immunoprecipitation in the satellite group of rats. Except at the earlier time of 5 min, the plasma concentration of each antibody detected by immunoprecipitation was lower than that detected by TCA precipitation, but plasma decline was parallel during terminal decay with both analytical methods. The ratios between immunoprecipitated and the TCA-precipitable AUC_{0-48h} were 0.53, 0.56, 0.41, and 0.39 for nIgG, cIgG, nFab, and cFab, respectively.

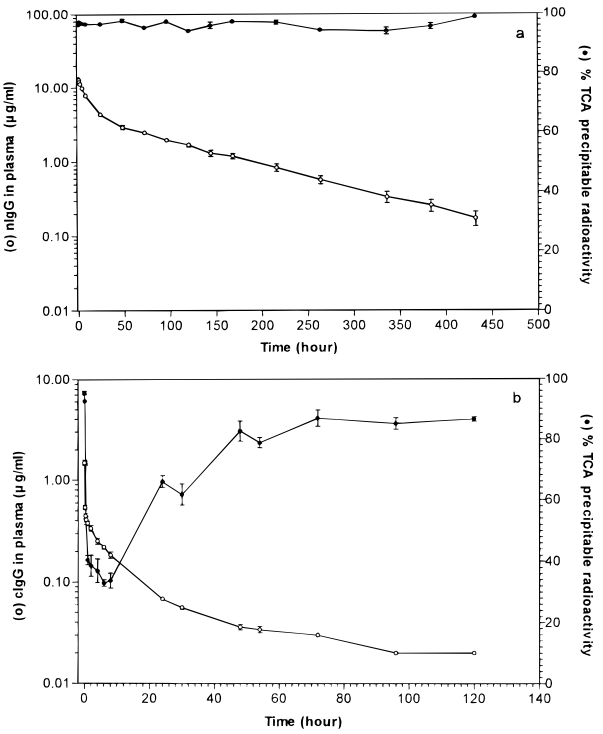

Figure 2—Plasma concentration of ^{125}I-nIgG and ^{125}I-cIgG. Plasma data were corrected for TCA precipitation. (a) The plasma concentration of ^{125}I-nIgG versus time and the percentage of TCA-precipitable plasma radioactivity for nIgG. (b) The plasma concentration of ^{125}I-cIgG versus time and the percentage of TCA-precipitable plasma radioactivity for cIgG. Data are mean ± SD (n = 5).

Pharmacokinetics of cIgG, nIgG, cFab, and nFab in Rat—Plasma TCA-precipitable cIgG and nIgG concentrations are shown in Figure 2. Plasma cIgG declined with a rapid distribution followed by a relatively slow elimination with a terminal half-life of 52.9 h. However, plasma nIgG declined slowly with a terminal half-life of 81.8 h. The $AUC_{0-\infty}$ of cIgG was 116-fold lower than for nIgG. In agreement with the reduction in AUC, the Vd and the total clearance of cIgG were 74 and 114 times higher compared with those of nIgG (Table 1).

Figure 3 shows the decline of TCA-precipitable cFab and nFab in plasma. Plasma cFab decreased more rapidly than plasma nFab in the early phase of decline. The terminal half-life of cFab (27.85 ± 6.75 h) was longer than that of nFab (18.23 ± 2.46 h; p > 0.5). However, the AUC of cFab was 4-fold lower than that of nFab. Systemic clearance of cFab (162.14 ± 32.2 mL/h/kg) was 3.5-fold higher than for nFab (46.85 ± 39.33 mL/h/kg), and Vd of cFab was increased nearly 6.4-fold compared to nFab (Table 1).

The percentage of plasma TCA-precipitable radioactivity for nIgG was >96% at all times (Figure 2a), whereas that of cIgG was about 95% at the beginning, then slowly decreased to 30% at 6 h after the iv injection, then gradually increased up to a plateau of about 88% at the end of the pharmacokinetic analysis (Figure 2b). The plasma TCA-precipitable percentage of cFab and nFab also changed with time, as shown in Figures 3a and 3b. It decreased to 12 and 45% for cFab and nFab, respectively, 6 h after iv injection, and then increased again to 63 and 81%, respectively, at the end of the pharmacokinetic experiment. Autoradiography of plasma samples showed a time-dependent decrease in the intensity of the protein bands of both cationized and native antibodies, and lower molecular weight products (29−35 kDa) were observed with cIgG and nIgG.

Table 1—Pharmacokinetic Parameters of Native and Cationized IgG and Fab[a]

parameter	cIgG	nIgG	cFab	nFab	p^b cIgG–nIgG	p^b cFab–nFab	p^b cIgG–cFab
$t_{1/2}\lambda_d$ (h)	52.92 ± 5.2	81.84 ± 12.3	27.85 ± 6.75	18.23 ± 2.46	>0.05	>0.05	>0.05
AUC (μg/mL h)	5.3 ± 0.17	620.29 ± 92.92	4.52 ± 0.88	18.05 ± 1.64	<0.001	<0.001	>0.05
CL_t (mL/h/kg)	131.6 ± 4.4	1.15 ± 0.16	162.14 ± 32.2	46.85 ± 39.33	<0.001	<0.05	>0.05
CL_r (mL/h/kg)	2.4 ± 0.9	0.08 ± 0.05	16.58 ± 1.58	1.62 ± 0.14	<0.001	<0.001	<0.001
Vd (mL/kg)	10042 ± 864	135.9 ± 5.13	6666 ± 2196	1048 ± 211	<0.05	<0.05	>0.05

[a] In all experiments, the dose was 0.7 mg kg^{-1}; data are mean ± SD (n = 5); $t_{1/2}\lambda_d$, elimination half-life; AUC, area under the plasma concentration–time curve; CL_t, total body clearance; CL_r, renal clearance; *Vd*, volume of distribution. [b] Values are given for comparison of cIgG versus nIgG, cFab versus nFab, and cIgG versus cFab.

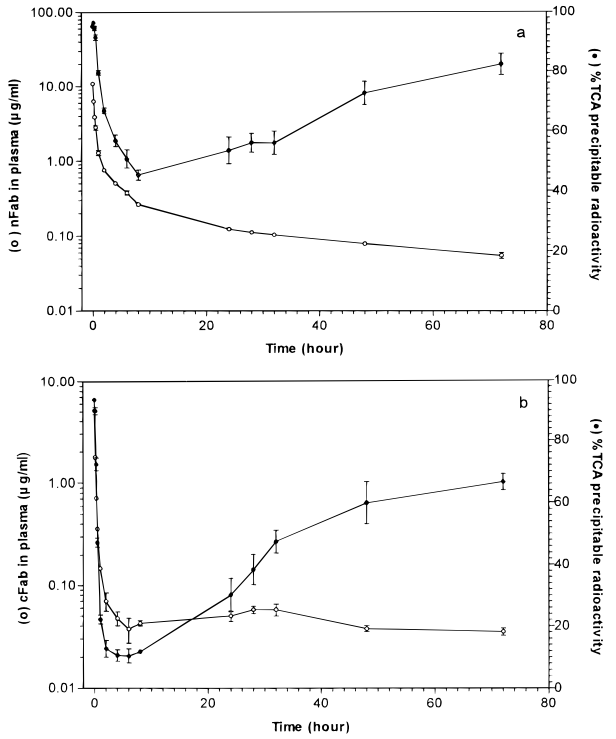

Figure 3—Plasma concentration of ^{125}I-nFab and ^{125}I-cFab. Plasma data were corrected for TCA precipitation. (a) The plasma concentration of ^{125}I-nFab versus time and the percentage of TCA-precipitable plasma radioactivity for nFab. (b) The plasma concentration of ^{125}I-cFab versus time and the percentage of TCA-precipitable plasma radioactivity for cFab. Data are mean ± SD (n = 5).

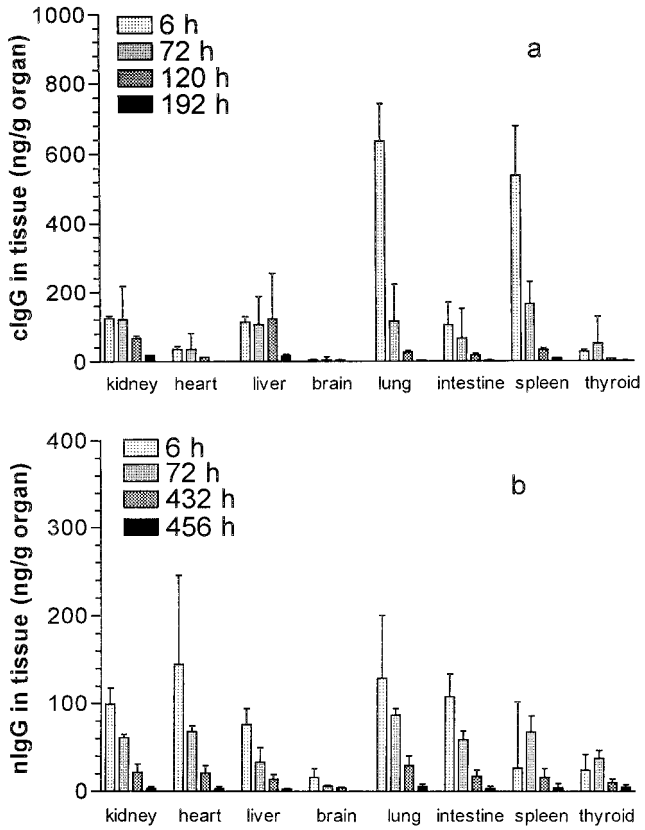

Figure 4—Biodistribution of ^{125}I-cIgG and ^{125}I-nIgG in several organs at different times after intravenous administration: (a) ^{125}I-cIgG; (b) ^{125}I-nIgG. Data are mean ± SD (n = 5).

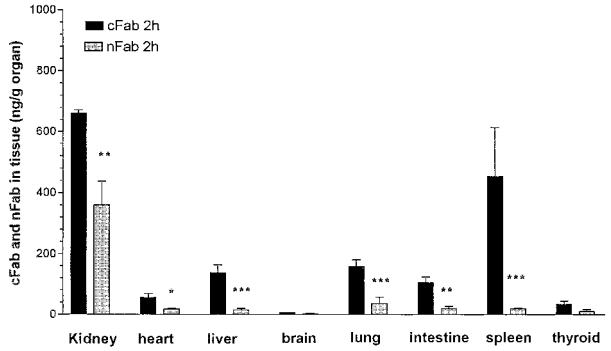

Figure 5—Biodistribution of ^{125}I-cFab and ^{125}I-nFab in several organs 2 h after iv administration. Data are mean ± SD (n = 5). Key: (*) $p < 0.05$; (**) $p < 0.01$; (***) $p < 0.001$.

Renal clearance of cIgG (2.4 ± 0.9 mL/h/kg) was only 1.8 ± 0.55% of total body clearance and 30-fold that of nIgG, which was 0.08 ± 0.05 mL/h/kg, representing 6.95 ± 4.0% of total body clearance. Renal elimination of cFab was the greatest (16.58 ± 1.58 mL/h/kg), which was 10-fold and 6.9-fold higher, respectively, than those values for nFab and cIgG (Table 1). The percentage ratios of renal clearance to the total body clearance of cFab, nFab, and cIgG were 10.2 ± 1.2, 3.46 ± 0.12, and 1.8 ± 0.8%, respectively.

The percentage of total radioactivity recovered in feces for cIgG (over 120 h), nIgG (over 456 h), cFab and nFab (both over 72 h) were 6.03 ± 0.83, 6.73 ± 0.95, 3.8 ± 0.6, and 12.08 ± 0.3%, respectively.

Organ Distribution of cIgG, nIgG, cFab and nFab in Rats—Figures 4 and 5 show the organ uptake of cIgG, nIgG, cFab, and nFab at different times following administration of antibodies. For both cationized antibodies, the organ distribution was much greater than for native antibodies. Nevertheless, this higher uptake of cationized antibodies varied between organs. Six hours after iv administration, uptake of cIgG was higher in lung and spleen (5- and 20-fold that of nIgG, respectively), whereas the uptake by kidney and liver was not so high and remained constant up to 120 h. Tissue uptake of cIgG by kidney, liver, and spleen was greatly superior to that of nIgG at all time points, whereas in lung, cIgG was

significantly increased only at 6 h ($p < 0.01$). There were no significant differences between heart, brain, intestine, or thyroid ($p > 0.05$). Tissue uptake of cIgG measured in lung, spleen, kidney, and liver at 6 h represented 0.43, 0.37, 0.08, and 0.08% of injected dose per gram of tissue, respectively. Compared with cIgG, cFab was more rapidly and extensively distributed to the organs. At 2 h, the uptake of cFab by kidney, spleen, lung, liver, intestine, and heart was greater than that of nFab, which accounted for 0.49, 0.32, 0.12, 0.10, 0.08, and 0.04% of injected dose per gram of tissue, respectively.

Discussion

One of the main problems to be solved to optimize in vivo use of antibodies is their delivery to the site of action, which can be located more deeply than the antibody distribution space. To overcome the physiological barriers limiting their diffusion, cationization based on absorptive-mediated transcytosis,[7] glycosylation,[18,19] hydrophobization,[20] and microinjection or cellular transfection[21] has been proposed for delivery of antibodies to target sites. Successful intracellular immunization of cationized anti-human immunodeficiency virus REV monoclonal antibody in human peripheral blood lymphocytes[11] and enhanced delivery of cationized immunoglobulin G across the blood-brain barrier[6] have already been described using cationized antibodies. These data encouraged us to apply the cationization concept to colchicine-specific IgG and Fab in the hope that they would be able to bind colchicine intracellularly and improve the level of detoxification already described by Chappey et al. with native colchicine-specific Fab.[9]

Following cationization, colchicine-specific IgG and Fab were resolvable into monomeric heavy and light chains with no detection of high molecular weight aggregates using SDS−PAGE. IEF confirmed that the pI of cIgG and cFab was increased to values ranging from 8.65 to 10.3 and 9.5 to 11, respectively. Moreover, there was no measurable alteration of the affinity and specificity of cIgG and cFab compared with those of nIgG and nFab. Surprisingly, we found higher cross reactivity of thiocolchicine with Fab than with either IgG. However, the cationization process cannot explain these differences because both native and cationized Fab had a similar cross reactivity. The cationized proteins were radiolabeled with ^{125}I, and the radiochemical purity and stability were similar to those of the native forms.

Radiolabeling by oxidative methods, such as the Iodogen method, could have two main drawbacks: first, the denaturation of the labeled protein and, second, the release of free iodine or smaller protein fragments labeled with iodine ^{125}I under the influence of catabolism. These drawbacks have been documented by Bauer et al.[22] who compared the pharmacokinetics of recombinant proteins with molecular weights ranging from 23 kDa to 80 kDa, which were either radiolabeled by iodine ^{125}I or quantified by specific immunoassay. This study revealed that the pharmacokinetics of proteins below about 60 kDa were different when assayed by radioactivity or immunoassay, but those proteins with a molecular weight of at least 80 kDa showed only minimal differences. A similar perturbation in the pharmacokinetics of epidermal growth factor, with a molecular weight of about 6 kDa, was attributed to molecular change in the protein configuration after radioiodination.[23] These findings had important implications for our study for at least two reasons: first, the molecular weight of Fab, about 50 kDa, is within the range of iodination side effects described by Bauer,[22] whereas IgG molecules are far above the side effects range, and, second, cationization could also have an influence on protein stability following radioiodination. For these reasons, cationized and native antibodies iodinated by the Iodogen method were measured in rat plasma by both TCA precipitation and immunoprecipitation in a satellite group of rats. More than 90% of the total radioactivity was detected by both TCA precipitation and immunoprecipitation for the four radiolabeled antibodies both before administration in the rat and in the early time in plasma (i.e., 5 min after antibody administration). These results indicate that both methods are almost equally efficient for the precipitation of radioactivity and that both radioiodinated cationized proteins can be kinetically investigated as well as radioiodinated native IgG and Fab. Nevertheless, the increased level of free ^{125}I following TCA precipitation in the distribution phase of the cIgG, cFab, and nFab kinetics suggests that the native and cationized antibodies were metabolized or deiodinated for these three compounds but not for the nIgG. The TCA-precipitable radioactivity markedly decreased and reached its lowest level at about 6−8 h after antibody administration and then increased versus time. This deiodination process could be caused by the sequestration of the native and cationized antibodies in the liver, lung, and spleen, which we have demonstrated to be the major organs of uptake (see Results section). This effect was more pronounced with the cationized than the native protein and more especially with cFab. Furthermore, urinary elimination of free iodine was maximal at 6 to 8 h after iv injection. Most of the urinary radioactivity observed with cIgG and cFab was free ^{125}I, which accounted for 98 ± 1 and 70 ± 1.7% of total radioactivity, respectively. A similar percentage of 98% of free iodine in the urinary excretion of cationized albumin has been reported by Bergmann et al.[24] However, although thyroid has a high affinity for free ^{125}I, we did not observe significant differences in iodine uptake by the thyroid for cIgG or cFab compared with nIgG and nFab. These data confirm the previous observation of Bauer[22] that high molecular weight radioiodinated proteins, such as IgG, are more stable than smaller proteins, such as Fab fragments. In addition, we also found that cationized IgG and Fab are more sensitive to deiodination than native antibodies, especially during the distribution phase. Though the TCA precipitation technique demonstrated the deiodination of the proteins, the immunoprecipitation technique showed a 2-fold decrease in the protein concentration that was similar for both cationized and native forms. This decrease could suggest that proteins were catabolized, which was not observed following SDS−PAGE autoradiography except with cIgG and nIgG for which a lower molecular weight band was observed. Nevertheless, the kinetic decline was parallel with the two techniques. These data demonstrate the analytical complexity of the analysis of radioiodinated proteins.

Another factor that could affect antibody pharmacokinetics is the immunogenicity of the native or cationized goat IgG and Fab in rats. The existence of a rat anti-goat immune response could modify antibody pharmacokinetics during the experiment. To check for such an immune response, an IRMA was used because it has been reported to be a reliable method for detection of trace amounts of protein as low as 0.013 μg/mL.[25] No rat anti-goat antibody immune response was detected following single-dose administration of either native or cationized IgG and Fab. This result can be explained by the fact that we administrated a single and relatively low dose of native and cationized antibodies. Data from the literature are variable. For example, Muckerheide et al.[26] reported that cationized bovine serum albumin (cBSA) exhibited a unique pattern of enhanced immunogenicity, and Apple et al.[27] showed that this enhanced immunogenicity was due to the increased uptake of cationized protein by antigen-present-

ing cells. In that study, the cationized antigens were administrated at high dose (100 μg/mouse) and emulsified in incomplete Freund's adjuvant. Pardridge et al.[28] reported that the repetitive administration of cationized rat albumin to rats (1 mg/kg/day for 8 weeks, sc) resulted in the development of a relatively low antibody response directed against the cationized rat albumin protein. In another study, Pardridge et al.[29] did not find any formation of antibodies directed against mouse IgG in mice treated with either native or cationized mouse IgG (7.5 mg/kg/day for 4 weeks, iv).

Taking into consideration all this methodological information, we have assessed whether the cationization process could offer significant advantages in terms of distribution and clearance between IgG or Fab. Because of the size difference between native IgG (150 kDa) and Fab (50 kDa), the volume of distribution and total clearance of native Fab are known to be higher than those of IgG because of their greater intercompartmental diffusion and glomerular filtration. Our pharmacokinetic parameters for both native molecules reflect these differences and are similar to those of previous studies,[30−32] with the exception that the terminal half-life and volume of distribution of nFab are slightly more elevated than the values most often reported. This effect could result from the persistence of a non-Fab specific radioactivity that is precipitable by TCA. In addition, our cationized antibody data clearly indicate that both cIgG and cFab were rapidly cleared from the plasma. The kinetic differences between the cationized and native forms reflect both phenomena: a marked increase in the volume of distribution, which was more pronounced for cIgG versus nIgG (ratio = 74) than for cFab versus nFab (ratio = 6.4), and in the total body clearance, which was also more pronounced for cIgG versus nIgG (ratio= 114) than for cFab versus nFab (ratio = 3.5). This higher reactivity of cIgG resulted in a volume of distribution and total body clearance that were similar to those of cFab despite its greater molecular size. The pharmacokinetic parameters of cationized and native IgG are consistent with those previously reported,[29,33,34] whereas no data were available for cFab. Based on comparison of the primary pharmacokinetic parameters, there are no marked pharmacokinetic differences between cIgG and cFab, except for the higher renal clearance of cFab (Table 1).

Even if increased transport to the extracellular fluid is in part responsible for the higher distribution and clearance of cIgG and cFab, it cannot be the only mechanism. The extracellular fluid volume in rat is approximately 240 mL/kg,[30] so the *Vd* values of cIgG and cFab are, respectively, 41- and 28-fold greater than the extracellular fluid volume, suggesting extensive tissue interactions and possible endocytosis. Thus, the rapid removal of cIgG and cFab from the plasma could be attributed to several mechanisms, such as increased escape to the extracellular space, binding to cells and basement membrane, intracellular uptake, and degradation or elimination in urine and feces. All these mechanisms are compatible with the observed increase in volume of distribution and total body clearance of cationized IgG and Fab.

The binding of cationized proteins to cells and basement membrane has already been demonstrated.[18,29] However, we have also observed enhanced intracellular uptake of colchicine-specific cIgG and cFab compared with nIgG and nFab by isolated parenchymal and nonparenchymal cells of the rat liver[35]and also in HL60 cells and human peripheral lymphocytes (results not given). Our data confirm the greater organ interaction of cIgG and cFab, although the distribution pattern was not exactly the same for cIgG and cFab. cIgG was predominantly taken up by lung and spleen, whereas kidney and spleen were more interactive with cFab; and, with both cationized compounds, liver uptake was also enhanced, whereas no or only moderate enhancement was observed in brain, thyroid, and intestine. This organ distribution profile is in agreement with previous studies,[7,29] except that we found a greater cIgG uptake in lung and spleen. These observations suggest that the transcapillary or transcellular passage of cationic proteins is an organ- and protein-specific process. The morphology of the vascular endothelium, which varies from organ to organ and from one location to another within the vasculature of the same organ,[33] could explain the differences in uptake of cationized proteins by different organs. Uptake of both cFab and cIgG was higher than that of the native forms in liver, which is to be expected because liver is an important interactive organ for cationic macromolecules.[36] Receptors for positively charged proteins have been identified on Kupffer cells as well as on endothelial cells.[24,37] In contrast to other organs in which the capillaries present a substantial barrier between vascular and interstitial spaces, the discontinuous endothelial capillaries of the liver favor the electrostatic interaction of cationic proteins with the negative charges of the liver cell surfaces.[36] A substance with a net cationic charge can reach a 4-fold higher intracellular concentration due to the inside negative membrane potential of the hepatocyte (−30 to 40 mV).[38] This effect might be the main explanation for the higher liver uptake of cIgG and cFab than of nIgG and nFab. In contrast, the poor enhancement of brain uptake of both cationized antibodies could be explained by the special anatomical features of the endothelial cells in brain capillaries. The tight junctions linking the endothelial cells of the cerebral vessels form a continuous endothelium that does not seem as favorable as fenestrated or discontinuous endothelium for the uptake of cationized antibodies.

In addition to these distribution properties, several clearance mechanisms can be observed with both cationized antibodies. First, renal clearance was enhanced for cationized proteins compared with native forms. The glomerular capillary wall functions as a barrier based on discrimination of molecular size and electric charge.[39] Normally, this wall restricts almost completely the passage of compounds with molecular weight >50 kDa[40] such as IgG. In contrast, the 50 kDa Fab is filtered and partially reabsorbed at the level of the proximal tubule,[41] and then undergoes extensive catabolism into peptides that recirculate in the blood. Little information is available concerning the influence of electric charge. Filtration of negatively charged dextran sulfate (64 kDa) is greatly restricted, whereas the positively charged diethylaminoethyldextran (DEAED, molecular weight 64 kDa) shows enhanced ability to cross the glomerular wall compared with neutral dextrans of similar size.[40] We found increased kidney distribution and renal clearance for both cIgG and cFab, in which renal clearance of cFab accounted for 10% of total body clearance.

Clearance could also be dependent on the degradation process affecting the protein itself and on iodine release. These last effects have been discussed by comparing the TCA and immunoprecipitation data.

In conclusion, this study demonstrates that cationization of both colchicine-specific polyclonal IgG and Fab fragments increased their organ distribution in vivo and markedly altered their plasma pharmacokinetics compared with the native compounds. These pharmacokinetic properties give new insights into the increased detoxification capability of these cationized antibodies. Colchicine has been reported to be ubiquitously distributed, with high accumulation in spleen, kidney, lung, liver, and heart.[42] Because cIgG and cFab also distribute within these tissues, cationized specific

IgG and Fab could be more effective at reversing colchicine toxicity because of their more extensive distribution to the intracellular colchicine action site within the tissues.

Accepted for publication September 8, 1998.

Abstract □ Artificial neural networks applied to in vitro–in vivo correlations (ANN–IVIVC) have the potential to be a reliable predictive tool that overcomes some of the difficulties associated with classical regression methods, principally, that of providing an a priori specification of the regression equation structure. A number of unique ANN configurations are presented, that have been evaluated for their ability to determine an IVIVC from different formulations of the same product. Configuration variables included a combination of architectural structures, learning algorithms, and input–output association structures. The initial training set consisted of two formulations and included the dissolution from each of the six cells in the dissolution bath as inputs, with associated outputs consisting of 1512 pharmacokinetic time points from nine patients enrolled in a crossover study. A third formulation IVIVC data set was used for predictive validation. Using these data, a total of 29 ANN configurations were evaluated. The ANN structures included the traditional feed forward, recurrent, jump connections, and general regression neural networks, with input–output association types consisting of the direct mapping of the dissolution profiles to the pharmacokinetic observations, mapping the individual dissolution points to the individual observations, and using a "memorative" input–output association. The ANNs were evaluated on the basis of their predictive performance, which was excellent for some of these ANN models. This work provides a basic foundation for ANN–IVIVC modeling and is the basis for continued modeling with other desirable inputs, such as formulation variables and subject demographics.

Introduction

It is often desirable to determine a good correlation between the in vitro dissolution data and the in vivo pharmacokinetics. This modeled relationship can then be used in product development or in establishing dissolution specifications. Many of the previous examples of defining an in vitro−in vivo correlation (IVIVC) in drug studies follow simple linear models, relating a parameter or a time point descriptive of the dissolution to a parameter or a time point descriptive of the pharmacokinetic absorption.[1−3] However, often a model is unsuccessful in completely describing the IVIVC and sometimes no relationship can be determined. The number of possible variables, the model being unable to account for some physiological rate determining process, and the possible amount of variability intrinsic to the parameters of these modeled relationships are some examples of these difficulties.[4−6]

It is an aim of the IVIVR Cooperative Working Group to extend the development of IVIVC using newer modeling tools, such as those in the field of artificial intelligence. The self-organizational properties of these methods and their ability to incorporate a large number of possible variables and relationships without a predefined model structure encourage the evaluation of artificial neural networks (ANN) in determining an IVIVC.

The term ANN refers to a group of algorithms used for pattern recognition and data modeling. As its name implies, ANN systems are loosely based on neural physiology, using the concept of a highly interconnected system of parallel processing units. It is not the intent of this paper to intensively cover ANN methodology; a review of the development of ANN can be found elsewhere,[7] as well as a complete description of the theory involved and tested in this research.[8−10]

The application of neural network concepts is relatively new to the field of pharmacokinetics and pharmacodynamics. An introduction to ANN as applied to the field of pharmacokinetics was given by Erb, who described the common back-propagation learning algorithm[11] and demonstrated its ability to be used as a bayesian classifier using simulated data.[12] The application of real pharmacokinetic data for the task of learning interspecies scaling, using different input−output data formats and neural network configurations, has been described by Hussain et al.[13] They also described the problem of the lack of a structured set of rules or guidelines in determining network configuration variables, such as the number of hidden nodes, the necessary number of training iterations, and the proper data format. Application of an ANN to predict drug behavior based on patient demographics and patient factors, and a comparison to a more traditional approach has also been described.[14] The implementation of ANNs in pharmacodynamics to predict the central nervous system activity due to the drug alfentanil has been examined.[15] ANNs have also been successfully implemented in problems very similar to IVIVC, such as product development[16] and quantitative structure−pharmacokinetic relationships,[17] again using a common back-propagation approach to ANN learning.

It is our eventual aim to develop a methodical approach to ANN−IVIVC, and the intent of this paper and current research is to show the feasibility of ANN−IVIVC by presenting the results from some common ANN configurations and data formats, using a relatively small set of IVIVC data for training and prediction. The results from a newer ANN, which does not use the back-propagation iterative learning paradigm, are also presented. It is not the intent of this paper to rigorously compare this method

with other available IVIVC methods, suggest this approach as appropriate for different situations, nor suggest that this method is a simpler means for correlating in vitro–in vivo data. Such comparisons and analyses, which are ongoing within our group, require numerous types of data and experimental design.

Methods

Description of Terms—There is a great deal of diversity in terminology within the ANN literature, and it is necessary to define some important terms that will be used throughout this paper. These defintions are not intended to be a glossary of terms in the area of artificial intelligence programming, but rather a necessary beginning in establishing a common foundation. Beginning with the format of data, each correlation between a set of input variable(s) and a set of output variable(s) is defined as an *input–output association* and all of the input–output associations collectively form a *pattern file.* ANNs learn using a pattern file known as a *training pattern file,* in which the individual input–output associations from this file are presented either randomly or in a defined order. A *validation pattern file,* which does not use data involved in training, is applied to the trained ANN to test the predictive capabilities of the trained ANN. *Memorization* of an ANN is a common problem referring to when an ANN has become over-trained and is mimicking the training pattern file. This is a situation where the ANN does not have the ability to predict well using inputs other than those found in the training pattern file. To avoid memorization and to establish a criteria to stop training, a *test pattern file* is constructed using associations from the training pattern file and applied periodically to the ANN during training. The input–output associations from the test pattern file are not used in the training, but as a measure of memorization and as a criteria to terminate training. The basic functional element of a neural network is defined as a *node,* which possesses a certain type of *transfer function.* The connections between nodes carry a weighting term, which is the element of an ANN that is continually adjusted during training. Nodes are arranged in layers: *input layer, hidden layer(s),* and *output layer.* It is necessary to define these terms prior to describing any methodology or discussing the results to prevent any confusion due to a lack of formalized vocabulary in artificial intelligence research.

Trial Data and Software—The data set reported in this study included in vitro inputs (% dissolved) and in vivo outputs (plasma concentrations). Inputs in the training pattern files consisted of the dissolution values from two extended-release formulations with seven dissolution time points each, at which six tablets were tested per formulation. Each formulation was administered to nine individuals in a crossover trial. Corresponding ANN outputs consisted of the drug plasma concentrations, sampled at 15 time points following oral tablet administration. A third extended release formulation, with the same experimental setup and part of the same crossover study, was used as a validation set. Success of the ANNs was based on the prediction of the validation profile.

The complete data set, consisting of the three separate formulations and correlated kinetics, was chosen because the pharmacokinetics for this drug was known to follow a "flip–flop" first-order absorption model, where the absorption of this drug was relatively slow compared with its elimination. This situation, as a trial for ANN–IVIVC, gave reasonable assurance that the dissolution kinetics could be considered a variable influential throughout the pharmacokinetic profile.

All ANN training and application were performed using Ward Systems' software package, NeuroShell 2.[18]

Choice of Neural Network Configurations—Part of the aim of these studies and the focus of this paper was to determine the best network configuration for this relatively small set of in vitro–in vivo data using a systematic approach. This determination was performed by initially selecting a set of common network architectures. Network configuration variables that are the focus here included the type of input–output association, network architecture, and for some architectures, the number of hidden layers.

Network Architectures—These trials involved four basic types of ANN architectures contained within the NeuroShell 2 software: traditional feed forward neural networks, recurrent neural networks, jump connection neural networks, and generalized regression neural networks. Diagrams of these network structures, with the nodes represented collectively as functional blocks, are shown in Figure 1. Including the type of network architecture and the number of hidden layers, we have tested a total of eight types of network architectures. A summary of each ANN architecture is given below and shown in Table 1.

Two of these ANN architectures are the common three and four layer feed forward neural networks (FFNN3 and FFNN4 shown in Figures 1a and 1b, respectively), which have one and two hidden layers, respectively. To give the network functional flexibility, a linear function ($f_1(x) = x$) was used for the nodes in the input

Table 1—Summary of the Eight Types of ANN Architectures Tested

type	architecture	data presentation	test set	node configuration (input-hidden-output)
FFNN3	feed forward 3 layers	random	≈10% randomly selected	linear–logistic–logistic
FFNN4	feed forward 4 layers	random	≈10% randomly selected	linear–logistic–logistic–logistic
RNNi	recurrent input–input	rotational	individual subject with single formulation with all 6 dissolution sets	linear–logistic–logistic
RNNh	recurrent hidden–input	rotational	individual subject with single formulation with all 6 dissolution sets	linear–logistic–logistic
RNNo	recurrent output–input	rotational	individual subject with single formulation with all 6 dissolution sets	linear–logistic–logistic
JCNN3	jump connections 3 layers	random	≈10% randomly selected	linear–logistic–logistic
JCNN4	jump connections 4 layers	random	≈10% randomly selected	linear–logistic–logistic–logistic
GRNN	general regression neural network	N/A	≈10% randomly selected to determine smoothing	N/A

Table 2—Pattern Files Constructed from the Different Input–Output Association Types[a]

#	association type	association input(s)	association output(s)	pattern structure	#associations/ formulation
1	functional	(7) dissolution set$_j$ (t_{DISS1}:t_{DISS7})	(15) PK$_i$ (t_{PK1}:t_{PK15})	subject$_{1-9}$ (dissolution set$_{1-6}$)	54
2	time series	(8) t_{PK}, dissolution set$_j$ (t_{DISS1}:t_{DISS7})	(1) PK$_i$ (t_{PK})	subject$_{1-9}$ (dissolution set$_{1-6}$($t_{PK\ 1-15}$))	810
3	time series	(2) $t_{DISS|PK}$, dissolution set$_j$ (t_{DISS})	(1) PK$_i$ (t_{PK}) only those outputs where $t_{PK} = t_{DISS}$	subject$_{1-9}$ (dissolution set$_{1-6}$($t_{DISS|PK\ 1-7}$))	378
4	time series memorative association	(1–8) t_{PK}, dissolution set$_j$ (if $t_{DISS} < t_{PK}$)	(1) PK$_i$ (t_{PK})	subject$_{1-9}$ (dissolution set$_{1-6}$($t_{PK\ 1-15}$))	810

[a] PK = Pharmacokinetic observations (in vivo); DISS = % dissolved (in vitro); i = subject number; j = tablet number; t_{PK} = pharmacokinetic time point; t_{DISS} = dissolution time point.

layer and a logistic function ($f_2(x)$, $f_3(x)$, $f_4(x) = 1/(1 + \exp(-x))$) was used for each node in the hidden and output layers.

The recurrent networks defined as RNNi, RNNh, and RNNo (Figures 1c, 1d, and 1e, respectively) had recurrent connections to the input, hidden, and output layers, respectively. Recurrent architectures do not have the input to output feed forward design; their recurrent design allows for a "long-term memory". This type of structure has the ability to learn sequences of input−output associations. Therefore, the setup of input−output data sequence presented in training and prediction becomes very important to these networks and their order must be considered, such as when the data is presented as a time series. The transfer function of each node in the hidden and output layers was set as a logistic function, whereas the input layer nodes were set to a linear function. The fourth layer can be called the network's "long-term memory", and has no node functionality. It contains the contents of the connected layer as it was in the previous training. These types of networks have been shown to work well with time series data that depend on history.[19]

The following two network architectures are a type of ANN known as jump connections. In this type of back-propagation network, every layer is connected in a feed forward manner. Three and four layer jump connection ANN architectures, designated JCNN3 and JCNN4 (Figures 1f and 1g), respectively, were used because they may be possible alternatives to the traditional feed forward structures, and were given the same node functions as FFNN3 and FFNN4.

Unlike the other ANNs, a general regression neural network (GRNN) is not an ANN that uses the back-propagation learning paradigm. The GRNN is an ANN system that involves a statistical technique known as kernel regression and requires the data to only be iterated once through the network during training.[10] Training of the GRNN was done using two options available in the NeuroShell 2 software. Patterns were compared based on their differences in distance using the vanilla or Euclidean distance metric, and smoothing was performed by using a genetic algorithm that selectively breeds a solution to the problem using a fitness function as a measure of survival. The mean squared error of the outputs in the test pattern file is used as the fitness function in the software. The NeuroShell 2 software manual contains descriptions of this terminology and these options with suggestions for their implementation.[18]

In all but the GRNN, training was performed by the software using a back-propagation scheme. Back-propagation is the most widely used learning algorithm employed in training neural networks. In its simplest form, it should be very familiar to those involved in data fitting and regression because it is an iterative gradient descent procedure that minimizes the error.[20]

Network Training Criteria—In all nonrecurrent networks, 10% of the training pattern file was randomly selected and placed aside as a test pattern file during training. Recurrent neural networks, however, rely on previous history, which required the data to be presented as a time series across input−output associations. This presentation also included the application of any test or validation pattern file. For this reason, the test pattern file applied to any recurrent architecture consisted of the associations from the ninth subject/second formulation, kept in time sequence.

The test pattern file was not included in the training, but was used as a periodic measure of the network's ability to successfully predict while being trained. The test pattern file was applied to the network after every 200 input−output associations (training events), using the NET-PERFECT feature in the NeuroShell 2 software. The prediction of the outputs in the test pattern file was used as a stop criterion. In each case, the network was directed to stop training after 20000 training events following a minimum error, and the weights corresponding to that minimum were saved as the trained ANN.

Associations and Pattern Files—Four different types of pattern files constructed from the same data were selected for evaluation. The pattern files, named ASSOCIATION 1 through 4, were unique because of different formatting of the input−output association. Each training pattern file had corresponding validation and test pattern files constructed with the same type of input−output association. A diagram of each type of input−output association is shown in Figure 2, indicating the structure of the relationship as well as using subscripts to show how the data are formatted across associations to create a pattern file. General descriptions of the input−output associations are given next, and a summary of the constructed pattern files is shown in Table 2.

ASSOCIATION 1—Initially the data were presented as the functional relationship shown in Figure 2a, with an input−output association that used all of the pharmacokinetic concentration values from an individual as an output set associated with an input set that consisted of the dissolution profile from an individual tablet. The pattern file then contained each pharmacokinetic observation set associated with each of the six tablet dissolution profiles. The dissolution mean was not used in this type of pattern file, or in either of the other three pattern files.

ASSOCIATION 2—Like ASSOCIATION 1, the input−output associations in this pattern file included the complete kinetic set of dissolution values for each tested tablet, but each was associated with a single respective pharmacokinetic output. Collectively, the input−output association lines of the pattern file formed a pharmacokinetic time sequence. The pharmacokinetic time point

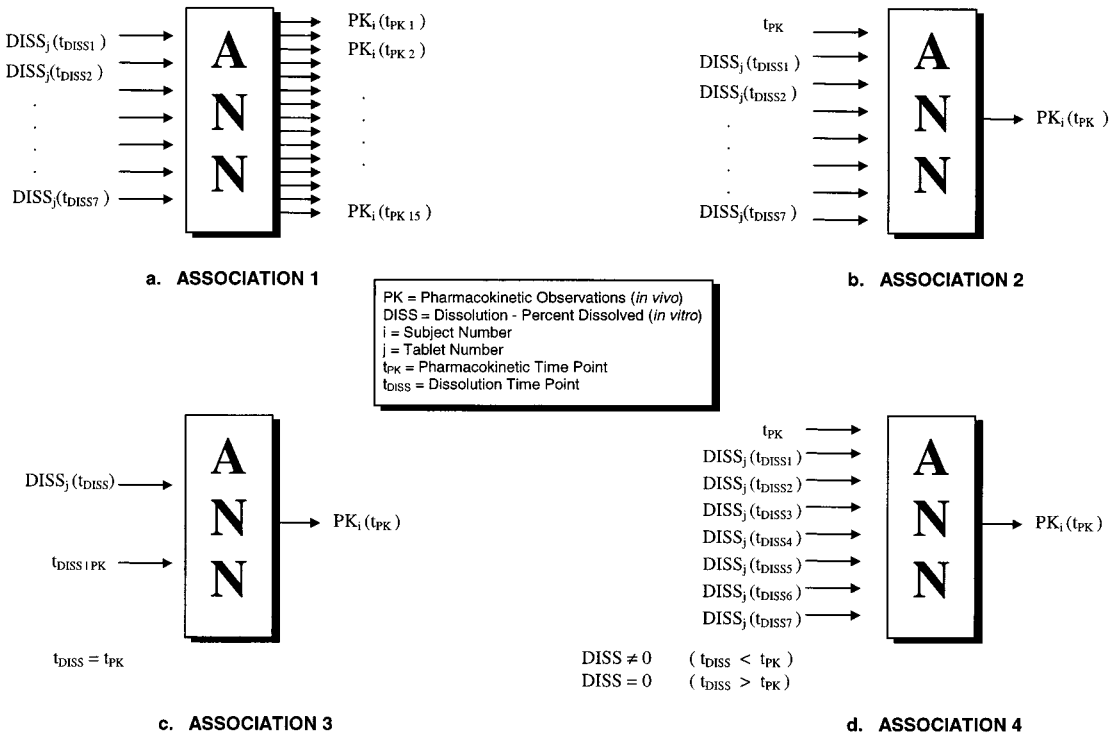

Figure 2—Diagrams of the input–output associations used in pattern files ASSOCIATION 1 through 4. The subscripts i and j are used to show the number of associations across association types.

was also included as an input. A diagram of this relationship is shown in Figure 2b.

ASSOCIATION 3—The input−output associations of this pattern file, shown in Figure 2c, consisted of each in vitro value as an input associated with each in vivo output. Pharmacokinetic observations with no directly associated dissolution observations were not used in the training. The time of the observation was also added as an input.

ASSOCIATION 4—This pattern file, shown in Figure 2d, attempted to unite some of the more desirable features of the previous pattern files that included presenting the entire dissolution profile per tested tablet as inputs (ASSOCIATIONS 1 and 2), presenting the data as a time sequence (ASSOCIATIONS 1, 2, and 3), and utilizing all of the in vitro data (ASSOCIATIONS 1, 2, and 4). Pattern file ASSOCIATION 4 was a sequential time series and included previous dissolution values as inputs. This type of pattern file can be termed a *memorative association* and was a type of time progressive synthesis neural network configuration described by Veng-Pedersen.[15] The output consisted of the pharmacokinetic concentration value, whereas the inputs were the pharmacokinetic time point and all the dissolution values that preceded that point in time. Dissolution values that occurred after that pharmacokinetic time point were set to zero in the pattern file and were interpreted as null inputs by the software.

Results and Discussion

A total of 29 network configurations, which included the eight different types of ANN architectures and four types of input−output associations, were tested. The three recurrent architectures were not used with ASSOCIATION 1, because this type of relationship did not have a sequential format across associations.

Each network was trained as described in the methodology, and the weights of each of the 29 trained ANNs were saved. Inputs from the training and validation pattern files were applied to the trained networks and these respective ANN outputs were compared to the actual observations. Shown in Table 3 are the results for both the training and validation pattern files for each ANN configuration, consisting of the correlation coefficient (R^2), mean prediction error (MPE), and mean absolute error (MAE). These values are defined as

$$R^2 = \frac{\sum(y - \hat{y})^2}{\sum(y - \bar{y})^2}$$

$$\text{MPE} = \frac{1}{N}\sum(\hat{y} - y)$$

$$\text{MAE} = \frac{1}{N}\sum|y - \hat{y}|$$

where y = actual observation, $\hat{y}$ = ANN prediction, $\bar{y}$ = average observation, and N = number of observations. Also shown is the ratio of R^2 between the predictions and training pattern files, as an indicator of possible network memorization.

Results from these trials, as summarized in Table 3, reflect the success of each ANN configuration with this particular set of IVIVC data. These results are measured by the precision and bias of the outputs from the training and validation pattern files. The ANNs attempted to determine a mean concentration curve based on the information contained in the dissolution kinetics, and in some configurations, attempted to account for the variability in the pharmacokinetics due to variability in the dissolution kinetics.

More than half of these ANN configurations could be considered successful in predicting the pharmacokinetic data from the dissolution kinetics. The better network architectures for this IVIVC data set seem to be the feed forward and the generalized regression architectures, based on their ability to give good model predictions with all four pattern files. The more successful pattern files included formatting the data as a functional relationship (ASSOCIATION 1) and as a memorative pattern file (ASSOCIATION 4). An example of a model prediction from one of these network configurations is shown in Figure 3 and Figure 4. In this example, the ASSOCIATION 4

pattern file was used to train the GRNN. Following training, the dissolution values from the training pattern files were used as inputs to predict the pharmacokinetic data. Comparisons of the actual observations with these ANN outputs are shown in Figure 3. The dissolution values from the validation pattern file were then presented to this trained ANN, interpolating the pharmacokinetic predictions shown in a comparison with the actual pharmacokinetic observations in Figure 4. These figures are representative of those network configurations that did relatively well, with a MPE close to zero for both training and validation sets, an R^2 of >0.85 for the training set, and an R^2 of >0.77 for the validation set (R^2 ratio >0.9).

The common and relatively simple FFNN architectures (Figures 1a and 1b) worked well with this data set based on the predictions of the validation pattern file outputs, especially when the data were presented as a functional relationship (ASSOCIATION 1). For some IVIVC data, however, these types of architectures may not work as well as time series predictors. Some IVIVC tend to be nonlinear, requiring the ANN to incorporate past history. The feed forward structure cannot incorporate history, but this may be accounted for if the data is arranged as a memorative association (ASSOCIATION 4), which also proved successful with this IVIVC data. An interesting example of network performance as a function of configuration variables is seen in comparing the ASSOCIATION 2–FFNN3 trial with the ASSOCIATION 2–FFNN4 trial,

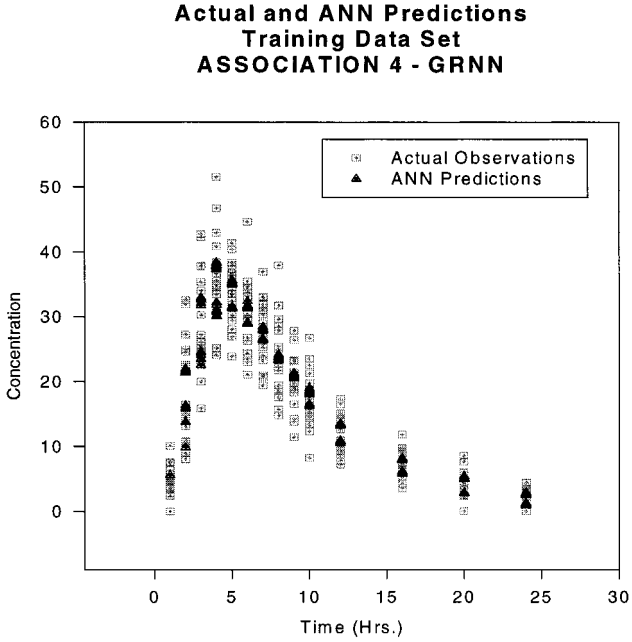

Figure 3—Actual pharmacokinetic observations from the training data set are compared with ANN pharmacokinetic predictions using in vitro inputs from the training data set. The GRNN was trained with the training pattern file ASSOCIATION 4.

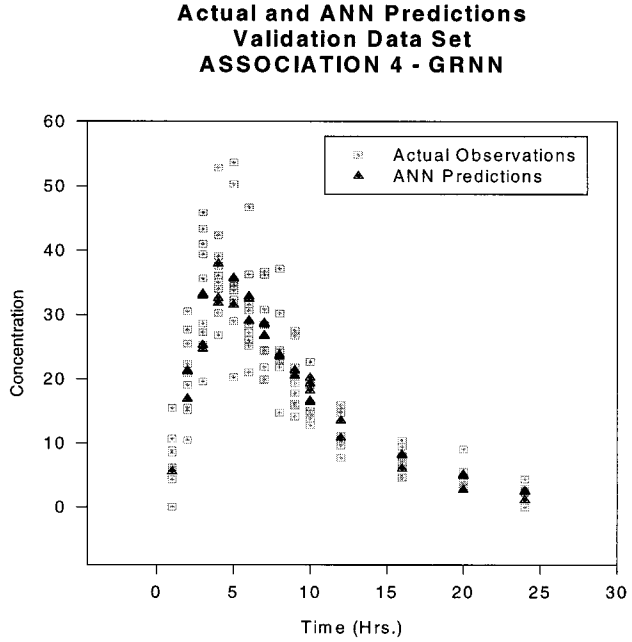

Figure 4—Actual pharmacokinetic observations from the validation data set are compared with ANN pharmacokinetic predictions using in vitro inputs from the validation data set. The GRNN was trained with the training pattern file ASSOCIATION 4.

where the additional hidden layer improved prediction dramatically. Practical ANN experience has shown that a majority of problems can be solved with a three-layered design, and that a four-layered ANN may be prone to fall into a local minima.[21] However, with this IVIVC data set formatted as the ASSOCIATION 2 pattern file, a four-layered feed forward structure predicted well, whereas the three-layered ANN failed to converge on a solution.

The JCNN architectures (Figures 1f and 1g), which are structurally very similar to the FFNN architectures, also compared well. The lack of any significant improvement in describing these data, however, suggests that the additional jump connections were not necessary.

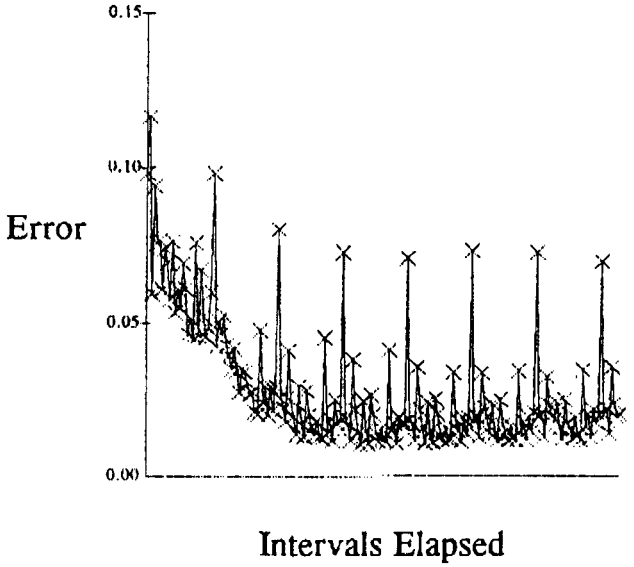

Figure 5—Error between actual observations and ANN predictions of the test pattern file during training of the recurrent network RNNo with ASSOCIATION 3 training pattern file. Each point (x) represents the error when the test pattern file is tested during network learning. The test pattern file was applied once after every 200 input–output associations of the training pattern file.

A thorough description of the theoretical development and implementation of the GRNN is too involved for this discussion, but can be referenced in the work by Specht.[10] This network structure requires only a single iteration to provide estimates of continuous variables and has a distinct advantage in that it can converge to a linear or nonlinear regression surface, even with relatively little data. This property as well as its success in these trials with all of the different types of pattern files encourage its use in this type of research.

A problem in implementing the recurrent network structures, as reflected in the results presented here, was the determination of a stopping criteria. As with all back-propagation network training performed in these trials, the test pattern file was applied periodically throughout training and was a measure used to indicate the completion of training before the onset of memorization. Because of the importance in keeping a sequential structure with recurrent networks, rather than the test set randomly constructed from the training data, the ninth subject receiving the second formulation was used as the selected test pattern file. This procedure proved to be a good measure that prevented memorization, but biased the trained network in the favor of this test set. A typical plot of the error as a function of the training intervals for a recurrent network is shown in Figure 5. Once a minimum is found, network training oscillates across subjects until training is stopped, the time of which is based on the number of iterations following a minimum in the test set. A trained network based on a minimum corresponding to the test pattern file is saved, biasing the results to the data used as the test set. So, although the recurrent ANN structures produced fair results, these results were biased to the selected test pattern file. Better results may be expected if a better "average" or unbiased test pattern can be found, the intersubject variability can be better described using additional inputs, or another method to protect against network memorization can be found.

In most ANN structures, the number of inputs and outputs dictate the number of input and output nodes, respectively. Hence, more inputs and outputs lead to a more complicated network structure. Although relatively successful here, the ASSOCIATION 1 pattern file had a total of 15 outputs, which must be considered in the evaluation of these types of input−output associations for ANN−IVIVC. When the level of complexity of the structure increases, the likelihood of obtaining a good solution decreases. As this research progresses, it is expected that the number of independent variables, or inputs, will be increased, adding to the complexity of the models and making input−output associations, like that found in ASSOCIATION 1, undesirable. The memorative type of input−output association used to construct the ASSOCIATION 4 pattern files worked well with all eight ANN architectures. This type of pattern file had the advantage of being a generalized format with a single output, which also allows the network to incorporate relationships from the previous inputs. A disadvantage of this pattern file is its inability to use information from dissolution values with a time of dissolution greater than the corresponding time of the pharmacokinetic observation. This pattern file may not predict well in data sets where the dissolution lags behind the pharmacokinetics.

The number of network configurations can be immense when considering some of the variables examined here, such as network architecture, data formats, and number of hidden layers, and considering some of the other possible network configuration variables not addressed; for examples, number of hidden nodes, additional network structures, learning algorithms, and the different types of node transfer functions. The number of hidden nodes in these trials were set to the software defaults, which were allowed to be conservatively large, because the periodic application of the test pattern file helps to prevent memorization. Some of the more common network architectures were examined in this study, but there were many more that may prove to be as good or better in ANN−IVIVC. Other possible structures that may prove to be applicable are the newer multilayer networks that include a lag in the data between the dependent and independent variables.[9] The node transfer functions were limited to the linear and logistic transfer functions in this study, but many other different types of functions, such as a limit, competitive, hyperbolic tangent, sine, or Gaussian may be used.

Conclusion

We have evaluated a number of possible network configurations, many of which successfully predicted a mean in vivo plasma concentration profile using dissolution kinetics. This work has demonstrated the feasibility of ANN−IVIVC by showing a number of potential ANN configurations that can be considered successful with this data set, but has illustrated a need for a methodical approach in applying ANN to problems. Additional input variables, including subject demographics, dissolution method variables, and formulation variables, are currently being introduced to attempt to account for the nonrandom error associated in the relationship. The ANN−IVIVC has the potential to establish complex relationships and may also possess the ability to interpolate pharmacokinetic parameters and profiles given formulation specifications. Also, algorithms and software currently exist to reverse map from the plasma concentration curve to the dissolution profile, possibly forecasting a range of dissolution profiles that will provide bioequivalent formulations.

Received October 23, 1998. Accepted for publication November 2, 1998.

Abstract □ The purpose of this study was to test the utility of infrared (IR) spectroscopy to determine protein secondary structure in biodegradable microspheres. Encapsulation of proteins within biodegradable polymers, [e.g. poly(lactic-*co*-glycolic acid) (PLGA)] for controlled drug release has recently been the subject of intense research effort. The ability to assess protein integrity after microsphere production is necessary to successfully produce microspheres that release native proteins. We used IR spectroscopy, a noninvasive method—as opposed to conventional organic solvent extraction or in vitro release at elevated temperature—to assess the secondary structure of recombinant human growth hormone (rhGH) within dry and rehydrated microspheres. PLGA microspheres containing rhGH with different excipients were prepared by a conventional double-emulsion method. The protein IR spectra indicated that the encapsulation process could perturb the structure of rhGH and that excipients could inhibit this damage to varying degrees. A strong positive correlation was found between intensity of the dominant α-helical band in the spectra of rhGH in rehydrated microspheres and the percent monomer released from microspheres during incubation in buffer. We also studied microspheres prepared with zinc-precipitated rhGH. The addition of Zn^{2+} during microsphere processing partially inhibited protein unfolding and fostered complete refolding of rhGH upon rehydration. In conclusion, IR spectroscopy can serve as a valuable tool to assess protein structure within both dried and rehydrated microspheres.

Introduction

Over the past several years, there have been numerous reports of encapsulation of proteins within biodegradable microspheres (for a recent review, see ref 1), which are used for sustained release of therapeutic proteins. For these systems to be successful clinically it is essential that the encapsulated protein be released in a native, functional state. In addition, the structure of the protein in the dried microsphere product could greatly affect the storage stability of the encapsulated protein. However, the integrity of the encapsulated protein is difficult to assess. Organic solvents used in the fabrication process may be required to remove the protein from the microspheres for characterization, and this extraction process may itself cause degradation of the protein. Alternatively, the microspheres may be incubated in aqueous buffers at elevated temperatures (e.g., 37 °C) to facilitate erosion of the polymer matrix and release of the protein into the buffer. During this incubation period, the protein may undergo both physical and chemical degradation. Thus, protein degradation caused by the method of removing the protein from

the microspheres could prevent the accurate determination of protein integrity within microspheres.

Such assessment is necessary to ensure production of microspheres that release native proteins. For example, with a valid method, excipients may be screened for their ability to stabilize the protein during encapsulation and drying, and during rehydration under physiological conditions. The most valuable method is one that allows the encapsulated protein to be studied directly in the microspheres, without the need for extraction or dissolution steps. Infrared (IR) spectroscopy is one promising method because it can be used to study directly the secondary structure of proteins in any state, including dried solids, precipitates and, potentially, intact microspheres.[2−5] In this study, we investigated the utility of this method to determine the structure of recombinant human growth hormone (rhGH) in polylactic-*co*-glycolic acid (PLGA) microspheres. The secondary structure of rhGH in both dry and rehydrated, intact microspheres was compared with that for the native, aqueous soluble protein. Several different formulations of rhGH were screened for their ability to maintain the protein in its native state during a double-emulsion encapsulation process.[6] The degree of nativelike structure was compared with recoveries of native protein with the traditional in vitro release and organic solvent extraction methods.[7−9] Finally, the structure of rhGH was assessed in microspheres prepared by an alternative strategy, which employed protein that was precipitated with Zn^{2+} and spray-freeze-dried prior to encapsulation in PLGA.[7]

Experimental Section

Microsphere Preparation—Two different encapsulation processes were used to produce PLGA microspheres containing rhGH. PLGA polymer (RG502, RG752, and RG756) was purchased from Boehringer Ingelheim, and rhGH was supplied by Genentech Production Recovery Operations. The first encapsulation method was the conventional water-in-oil-in-water double emulsion process, which was performed as described previously.[6] To compare the results of secondary structural analysis obtained with IR spectroscopy to results obtained with dissolution and extraction procedures, microspheres prepared with rhGH containing various different excipients (e.g., mannitol, trehalose, carboxymethylcellulose, and dextran) were studied.[6] These different formulations had already been shown to provide a range of protein stabilities, as assessed by extraction of the native protein from the microspheres.[6] The same samples of these formulations were used here to determine if there would be a corresponding range in the degree of native secondary structure retention in the encapsulated rhGH.

With the second encapsulation method, rhGH was initially precipitated with Zn^{2+} and then spray-freeze-dried.[7] The protein powder was homogenized in methylene chloride containing PLGA and sprayed into liquid nitrogen and solid ethanol, as discussed previously.[7] For both methods, the final microspheres were stored as a dry powders at 2−8 °C prior to analysis.

Analysis of rhGH Release and Extraction from Microspheres Produced by the Double-Emulsion Procedure—To quantify the in vitro release of rhGH from PLGA, the microspheres were incubated in isotonic HEPES buffer, pH 7.4, at 37 °C for 1 h, using a previously described method.[8,9] The protein was extracted from a parallel set of microspheres by dissolution in methylene chloride, as previously described.[7] Protein released or extracted was analyzed by native size exclusion chromatography (SEC) to determine the amount of native monomeric rhGH.[8]

Analysis of Infrared Spectra—The IR spectra were obtained with a Nicolet Magna 550 spectrometer equipped with a DTGS KBr detector. For dry powder and microspheres samples, 0.5−1 mg of sample was mixed with 300 mg of KBr and annealed into disks. This process has previously been shown not to alter the IR spectra of dried proteins.[4] The aqueous protein or rehydrated microspheres samples were placed in a variable path length sample cell containing CaF_2 windows, which were separated by ca. 6 μm.

For each spectrum, 64 or 256 scans for dry or liquid sample, respectively, were collected in a single beam mode with a 4 cm^{-1} resolution. A reference spectrum was recorded under identical scan conditions with protein-free PLGA (placebo) or buffer, as needed. The protein spectra were obtained by subtraction of the reference spectra according to the criteria described in the *Results* section. Signals for liquid and gaseous water were digitally subtracted, as previously described.[10] Final spectra are presented as second derivatives in the conformationally sensitive amide I region. Seven-point smoothing using Omnic software (Nicloet) was performed to remove white noise. To compare spectra, the second-derivative spectra were imported into GRAMS/386 (Galactic) and the area of amide I region was normalized as described previously.[2,11] Finally, the relative degree of retention of native secondary structure was determined by calculating the depth of the dominant α-helix band, relative to that for native, aqueous rhGH.

To examine protein structure in rehydrated microspheres, the samples were incubated in H_2O for 4 h prior to the measurement. For microspheres rehydrated in D_2O, 2 mg of dry microspheres were incubated with 60 μL of D_2O for at least 20 h at room temperature. Prior to measurement, the supernatant was replaced with the same volume of D_2O. This treatment was used to ensure consistent deuterium−hydrogen exchange for each sample.

Results and Discussion

The Structure of rhGH in Dry PLGA Microspheres—For storage of the final product, protein encapsulated in microspheres must be stable in the dried state. There are no published studies defining the critical criteria for storage stability of proteins encapsulated in dried microspheres. However, it is well established for freeze-dried protein formulations that retention of native protein structure is one important factor for storage stability.[3] It seems reasonable to suggest that this factor may also be the case for long-term storage stability of encapsulated proteins. Thus, a noninvasive method, such as IR spectroscopy, to assess the effect of processing and/or formulations on protein structure within dry microspheres is essential to the ultimate development of products with sufficient shelf life.

To obtain a high quality IR spectrum of protein in microspheres, it is necessary to subtract out the contribution of PLGA from the amide I region, which is used for assessment of protein secondary structure. As shown in Figure 1A, the PLGA used in the current study had only minimal absorbance in the amide I region (1600−1700 cm^{-1}). There is a large absorbance of PLGA centered around 1750 cm^{-1}, but only a slight shoulder from this band extends into the region of 1680−1720 cm^{-1}. To ensure that this small contribution from PLGA was not affecting the final protein spectra, we digitally subtracted the absorbance of PLGA microspheres without protein from the spectrum of the microspheres containing rhGH (Figure 1). A successful subtraction was indicated by the presence of a flat region at about 1730−1710 cm^{-1}. We found this criterion provided reproducible results and consistent final protein spectra, even when different investigators performed the spectral subtractions.

Figure 2 shows examples of the resulting spectra of rhGH with different formulations in dry microspheres and the spectrum of native aqueous rhGH. The native protein is primarily α-helical in structure, and hence, its spectrum is dominated by a helix band at 1656 cm^{-1}. In the spectra of the dried microsphere samples, this band is greatly reduced in intensity, indicating a loss of native helix structure. This loss is compensated by an increase in β-sheet, as evidenced by the increase absorbance at ca. 1685 cm^{-1}. The greatest reduction in helix was seen for the microspheres prepared without excipient or with mannitol. There was a slight improvement in recovery of helix content with trehalose. However, in all cases (Figure 2), the helix content of rhGH in dried microspheres was less than that

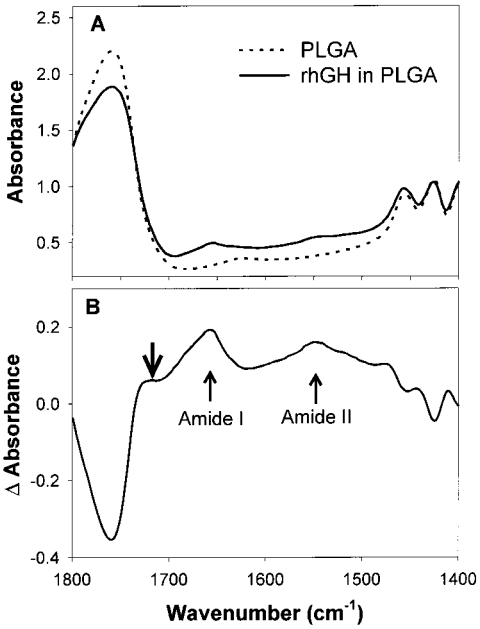

Figure 1—(A) Infrared spectra of dried rhGH in PLGA microspheres and PLGA microspheres alone. (B) The resulting spectrum of rhGH after the PLGA background was properly subtracted. The bold arrow indicates the criterion for the subtraction where a flat region should appear in the region between 1710 and 1730 cm^{-1}.

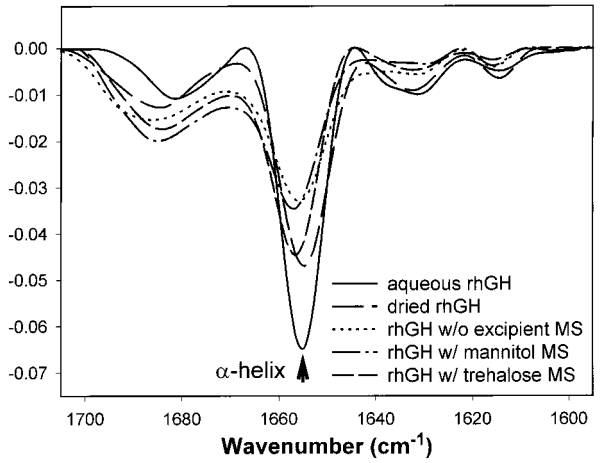

Figure 2—The second-derivative amide I spectra of dried rhGH powder and rhGH with different excipients within microspheres (MS). For comparison, the spectrum of aqueous, native rhGH in solution (measured at concentration of 20 mg/mL) is also shown. The major band at 1656 cm^{-1} is the α-helix, which is the main secondary structure of rhGH. The mannitol and trehalose formulations contained 1:1 and 0.25:1 mass ratios of excipient:rhGH, respectively, and 100 mM potassium phophate buffer, as described previously.[6]

for the protein in a lyophilized powder (prepared without excipient). This result indicates that in addition to the denaturation caused by the initial freeze-drying step, the protein structure could further be perturbed by the subsequent emulsion and encapsulation steps. Further research is needed to assess the relative effectiveness of excipients at inhibiting protein denaturation during the initial lyophilization and subsequent processing steps. This work will be necessary to obtain a final microsphere preparation with the optimal retention of native protein structure. With IR spectroscopy it should be straightforward to monitor the structure at each step.

The Structure of rhGH Microspheres rehydrated in H_2O—Although the structure of proteins in dried microspheres may be important for storage stability of the product, protein structure in rehydrated microspheres is

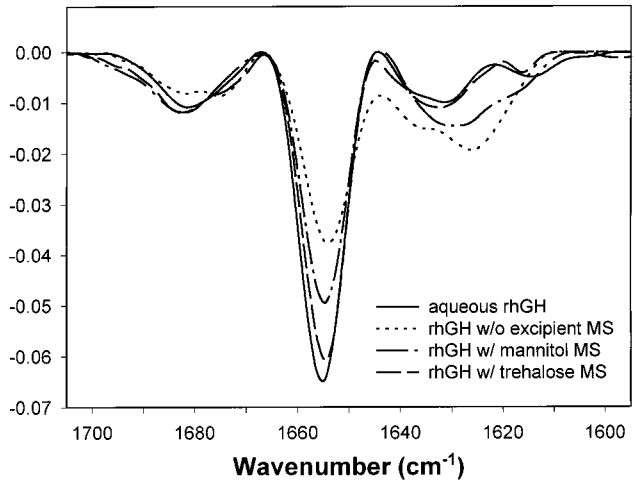

Figure 3—The second-derivative amide I spectra of H_2O-rehydrated rhGH microspheres (MS) and aqueous rhGH. The mannitol and trehalose formulations contained 1:1 and 0.25:1 mass ratios of excipient:rhGH, respectively, and 100 mM potassium phophate buffer, as described previously.[6]

most relevant to the performance of the product under physiological conditions. The structure of a dried protein is not necessarily predictive of that obtained after rehydration.[2–5,11] For example, with lyophilized protein formulations it has been found that unfolded protein molecules in the dried state may fully refold during rehydration.[2–5,11] Conversely, with some systems, it has been observed that not only is the native structure not recovered upon rehydration, but a substantial fraction of the protein population may form non-native aggregates.[2–5,11] These aggregates often have a large fraction of intermolecular beta sheet strucuture, which can be detected by specific bands in the amide I region of the IR spectrum.[2] The behavior of a given sample during rehydration depends on, at least, (1) the physicochemical properties of the protein itself, (2) the initial and final pH, (3) the effects of excipients on protein structure during the drying process and rehydration, and (4) the macroscopic properties of the dried material that dictate rates of rehydration and dissolution of protein molecules.[2–5,11] Clearly, it is not possible to predict how all of these parameters would affect the behavior of protein molecules during rehydration of microsphere formulations. Thus, direct examination of protein structure in the rehydrated microspheres is essential.

With rehydrated samples, we found that the PLGA used in the study had minimal absorbance in the amide I region. As is the case with all aqueous protein samples, the absorbance in this region was dominated by H_2O itself. We found that the well-established methods[10] for quantitatively subtracting this contribution from spectra of protein solutions also was appropriate for spectra of rhGH in rehydrated microspheres. The criterion for a successful subtraction was a flat baseline in the region 1800–2300 cm^{-1}, which has a strong absorbance from water but no signal from protein. This approach worked well for microspheres with a protein content >1% w/w (data not shown).

Figure 3 presents some examples of the second-derivative IR spectra in the amide I region of the rehydrated rhGH microspheres with different formulations. For the trehalose formulation, the α-helix band was almost identical to that for the native protein, indicating that the protein in the microspheres had refolded during rehydration (Figures 2 and 3). In contrast, the apparent extent of recovery of native α-helix was much less for the microspheres containing no excipients or for the mannitol formulation. Furthermore, the spectra for these samples had prominent absorbances in the 1620–1630 cm^{-1} region,

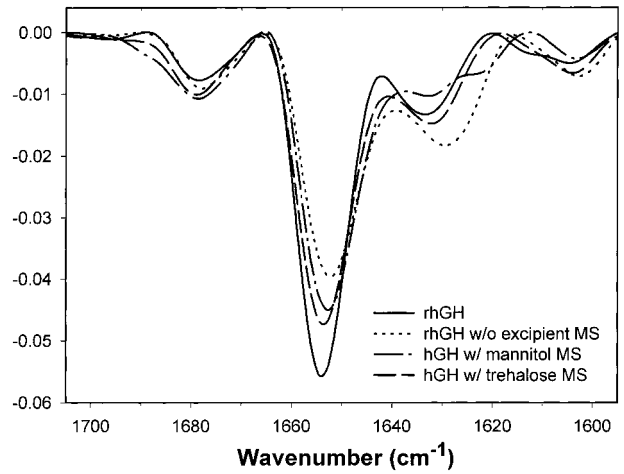

Figure 4—The second-derivative amide I spectra of D_2O-rehydrated rhGH microspheres (MS) and native rhGH in solution in D_2O. The mannitol and trehalose formulations contained 1:1 and 0.25:1 mass ratios of excipient:rhGH, respectively, and 100 mM potassium phophate buffer, as described previously.[6]

which are most likely due to the presence of intermolecular β-sheet.[2] This result indicates that a substantial fraction of the rhGH in these microsphere preparations formed aggregates during rehydration. These three examples clearly document that the behavior of proteins during rehydration of microspheres cannot necessarily be predicted from the structure of the protein in dried microspheres, as is the case for lyophilized protein formulations.

The Structure of rhGH Microspheres Rehydrated in D_2O and Its Correlation with Percent Monomer Released or Extracted from the Same Microspheres—When the protein content of microspheres was <1% wt/wt, we were not able to successfully subtract the contributions of water and PLGA from the spectrum of rhGH in microspheres (data not shown), which was, at least in part, because the concentration of protein relative to the total solution was relatively low. We have found that, even for protein solutions, the contributions of water to the amide I region cannot be subtracted quantitatively if the protein concentration is less than about 5 mg/mL (unpublished observation).

Because D_2O does not absorb strongly in the amide I region, we tested this solvent system for analyzing rehydrated microspheres. Contributions from solvent and PLGA were digitally subtracted from the spectrum for the protein in D_2O-rehydrated microspheres such that the region from 2100 to 2300 cm^{-1} was flat (data not shown).

As shown in Figure 4, the intensity of the α-helical band was again dependent on the formulation used, and we found the results were comparable overall and showed similar trends to those of H_2O-rehydrated microspheres (Figure 3). The most nativelike spectrum was seen for the trehalose formulation. The spectra for the sample prepared without excipients and that for the mannitol formulation had less intense α-helix bands and the presence of bands attributable to β-sheet at ca. 1630 and 1623 cm^{-1}, respectively.

Even microspheres with relatively low protein content could be studied in D_2O. Thus, we rehydrated all of the different formulations of rhGH in PLGA microspheres, which have previously been described,[6] in this solvent. Then, the depths of the α-helical band from the second-derivative spectra, relative to that for the native protein, were measured and used as indicators of degree of retention of native structure within the rehydrated microspheres. For each microsphere formulation, this parameter was plotted against the respective percentage of rhGH monomer recovered from either the 1-h in vitro release

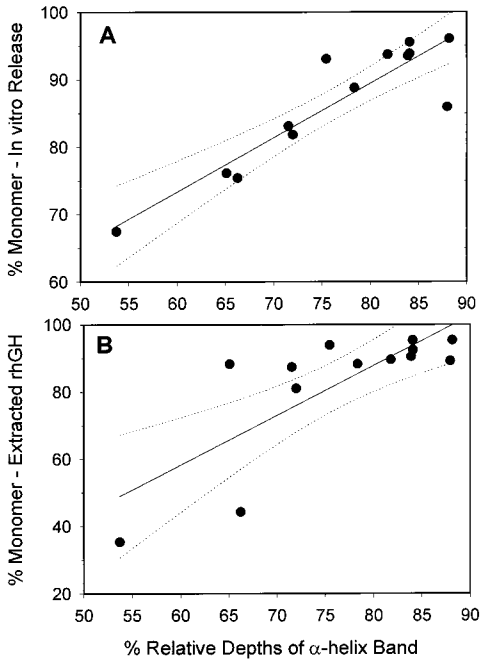

Figure 5—The linear regression analyses of the relative depth of α-helix band versus percent of recovery of rhGH monomers from either (A) 1-h in vitro release or (B) organic solvent extraction. The relations are $y = 25.1 + 0.8x$, $r^2 = 0.818$ and $y = -30.5 + 1.48x$, $r^2 = 0.618$ for A and B, respectively. The dotted lines indicate the 95% confidence intervals.

protocol or the organic solvent extraction of the microspheres (see *Methods*). As can be seen in Figure 5A, there is a strong positive correlation between the relative intensity of the α-helical band and the percent monomer obtained by the in vitro release protocol. The results of this analysis demonstrate that IR spectroscopy can not only be a valuable tool to assess the protein structure within microspheres but also may be useful to predict the integrity of protein initially released from microspheres.

Interestingly, there was a much weaker positive correlation between the relative intensity of the α-helix band and the percent of native rhGH monomer extracted from microspheres (Figure 5B). This result might reflect the fact that the organic solvent extraction of protein from microspheres could by itself furthur perturb protein structure.

The Structure of Zinc-Complexed rhGH within PLGA Microspheres—Recently, rhGH precipitated by Zn^{2+} and spray-freeze-dried has been used for the preparing PLGA encapsulated microspheres.[3] Figure 6 shows the spectra of dry rhGH prepared either from a zinc-free protein solution or from a zinc-induced precipitate (Zn-rhGH) and the spectra for dried microspheres prepared with either preparation. Both freeze-dried powders had similar spectra and almost identical loss in intensity of the α-helix band. Thus, the perturbation of rhGH secondary structure during freeze-drying was essentially the same for both preparations; zinc did not increase resistance to freeze-drying. For Zn-rhGH within microspheres, the reduction of α-helix was slightly greater than that for the freeze-dried powder, but was much less than that for microspheres prepared with non-zinc-treated rhGH. These results suggest that during the encapsulation in PLGA, the protein secondary structure could be further perturbed but that this damage is much less if the protein is initially freeze-dried as a Zn-hGH complex. More importantly, as shown in Figure 7, the Zn-rhGH within the microspheres completely refolded upon rehydration in H_2O. The spectrum for the rehydrated protein is essentially identical to that for the native, aqueous protein. Water was used in this rehydration experiment because the protein content

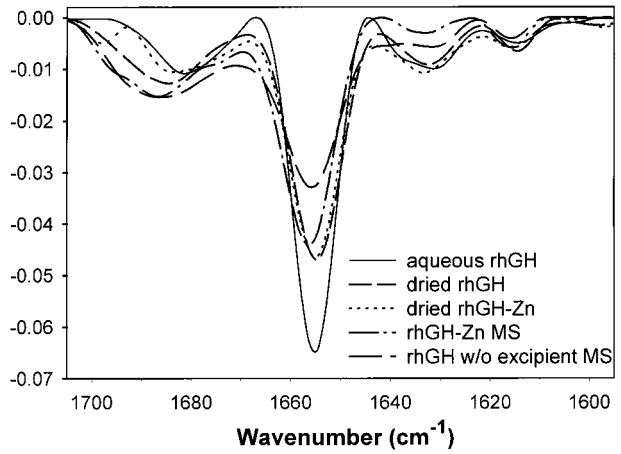

Figure 6—The second-derivative amide I spectra of dried rhGH, rhGH–Zn complex and their microspheres (MS). The spectrum of native, aqueous rhGH is also included for reference.

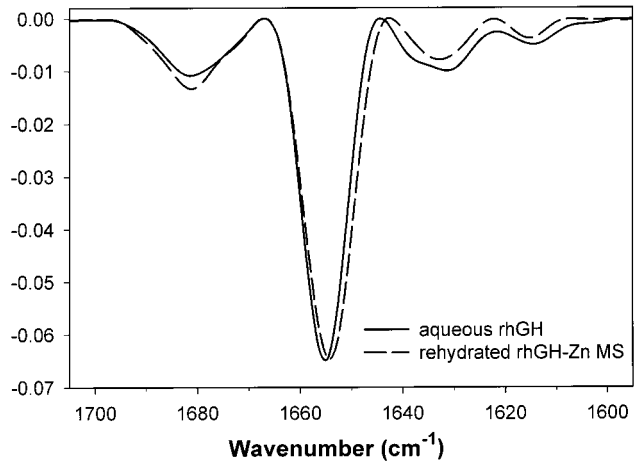

Figure 7—The second-derivative amide I spectra of H_2O-rehydrated rhGH–Zn microspheres and native, aqueous rhGH.

in these microspheres was 15% wt/wt. The refolding of the Zn-rhGH is in contrast to the aggregation of non-zinc-complexed protein during rehydration of microspheres prepared without excipients (Figures 3 and 7).

Conclusions

Noninvasive assessment of protein secondary structure in dried and rehydrated microspheres can be accomplished rapidly (e.g., <10 min is needed to acquire a high quality spectrum) with IR spectroscopy. The structure of the protein in dried microspheres may be predictive of storage stability of the protein, as is the case for lyophilized protein formulations.[3] However, more research on storage stability of proteins in dried microspheres is needed to test this suggestion. The secondary structure of protein in rehydrated microspheres is most relevant to the potential release of native, functional proteins under physiological conditions. With rhGH, the degree of retention of native secondary structure correlated directly with the percent of native monomer released during incubation in buffer. In addition, the relative effects of the method of microsphere preparation and excipients on the structure of rhGH were clearly discernible with IR spectroscopic determination of protein secondary structure. These results document that the method has utility for designing processing conditions and formulations that provide optimal retention of native protein structure in the microspheres. Finally, IR spectroscopic assessment of protein structure in microspheres could prove valuable for routine quality assurance testing of commercial lots.

Abstract □ In this work we describe the structural investigation of the model protein recombinant human growth hormone (rhGH) under conditions relevant to polymeric sustained-delivery depots, including the dried protein entrapped in a film of poly(DL-lactic-*co*-glycolic)acid. At each step of the procedure, dehydration of rhGH by lyophilization, suspension in methylene chloride, and drying from that suspension, the structure of rhGH was probed noninvasively using Fourier transform infrared (FTIR) spectroscopy. We found that the structure of rhGH was significantly changed by the dehydration process as indicated by a marked drop in the α-helix content and increase in the β-sheet content. Subsequent suspension of this powder in methylene chloride, drying from that suspension, and drying from a methylene chloride/PLGA solution introduced only minor additional structural changes when using appropriate conditions. This result is likely due to the limited molecular mobility of proteins in nonprotein-dissolving organic solvents. Finally, when rhGH was co-lyophilized with the lyoprotectant trehalose, which preserves the secondary structure, the rhGH entrapped in the PLGA matrix also had a nativelike secondary structure.

Introduction

Recent advances in biotechnology have facilitated the development of numerous biopharmaceuticals (peptides and proteins). The dozens of biopharmaceuticals already approved by the Federal Drug Administration (FDA),[1] in addition to hundreds of others in clinical trials,[2] will substantially aid in the prevention and management of disease.[1,3] However, drug delivery has been a major stumbling block. Because proteins are rapidly degraded in the gastrointestinal tract,[4] the oral route is impractical. Even when delivered by direct injection (e.g., insulin),[5] frequent administrations are often required. A promising approach is the sustained delivery of proteins from polymer matrixes,[6−8] which offers advantages such as targeting specific tissues and increasing patient compliance (and comfort). Poly(lactic-*co*-glycolic)acid (PLGA) is a good candidate for a protein encapsulation matrix.[9] PLGA, an FDA-approved material, has been intensively studied for its biocompatibility, toxicology, and degradation kinetics.[10−13] For this investigation we chose the model protein recombinant human growth hormone (rhGH) under a variety of conditions relevant to its encapsulation in PLGA as the model polymer.

Protein encapsulation in polymers is challenging because proteins are susceptible to deleterious chemical and structural modifications,[8,14−17] which may be induced by typical encapsulation procedures (e.g., the double-emulsion-solvent-evaporation-technique).[8,16] During such encapsulation procedures, protein structural perturbations may occur due to exposure to organic solvents,[18,19] mechanical stress,[20] creation of hydrophobic interfaces,[21] and dehydration.[22−25] Structural alterations caused by these factors may reverse upon release of protein from the polymeric device into the aqueous environment of body fluids. For example, lyophilization-induced structural changes are frequently reversible for small proteins.[25]

Even so, structural alteration is often the first step toward formation of irreversible aggregates when dehydrated proteins are exposed to moist environments in vitro, simulating the slow rehydration process occurring in a sustained-delivery device in vivo.[26−29] Dehydration-induced structural changes in rhGH are known to promote the formation of insoluble aggregates under accelerated storage conditions.[30] Aggregates may have lower activity (decreasing the efficiency of the expensive pharmaceutical protein) and increased immunogenicity, and thus must be avoided.[13] The simplest procedure to avoid such detrimental reactions would be to avoid any protein structural changes when processing. For rhGH, the addition of sugar excipients, such as trehalose, efficiently prevented storage-induced solid-state aggregation and conserved the protein structure upon lyophilization.[30]

It may be difficult to avoid such structural alterations when following the most common protocol of protein encapsulation in hydrophobic polymers, the double-emulsion-solvent-evaporation technique (also called the water-in-oil-in-water or w/o/w, technique).[16] In this approach, an aqueous protein solution is added to an organic solvent (typically methylene chloride) to form the first emulsion after probe sonication. Next, a second emulsion is formed by adding the first one to an aqueous solution containing an emulsifier followed by homogenization. Finally, microspheres are obtained after polymer hardening by solvent evaporation and dehydration of the particles, typically by lyophilization. A major difficulty is the exposure of the protein to denaturing conditions in aqueous solution. Under such conditions, proteins are relatively unstable and easy to denature, for example by organic solvents.[19] Structural investigations on the consequences of encapsulating the model proteins bovine serum albumin and lysozyme in PLGA microspheres by the w/o/w technique demonstrated substantial structural changes of both proteins.[31] Some of these changes could be prevented by adding the excipient trehalose to the aqueous protein solutions, but the proteins still were very much structurally perturbed in the micro-

spheres, as probed by Fourier transform infrared (FTIR) spectroscopy.[31]

Recently, Johnson et al.[13] reported the successful stabilization of a Zn-protein complex in PLGA for rhGH using a novel cryogenic, nonaqueous methodology (no emulsification). The encapsulated protein was delivered from PLGA with unaltered properties compared with rhGH before the procedure, although the protein structure in the polymer was not reported.[13] Herein, we employ a different (more general) nonaqueous approach, taking advantage of the increased rigidity of dehydrated proteins in organic solvents[19] and employing a sugar excipient to stabilize the protein structure. We have specifically focused on the protein secondary structure under various conditions related to processing in PLGA.

Recent developments of FTIR spectroscopy make this technique the method of choice to noninvasively probe the protein structure under all relevant conditions. Encapsulation in polymers involves steps during which the protein is in different physical states. All these conditions can be analyzed using FTIR spectroscopy; several recent works have utilized this technique to characterize the secondary structure of proteins in the amorphous solid state,[22,24,25,29] in powder suspension in organic solvents,[32,33] and also encapsulated in PLGA.[31] Utilizing FTIR spectroscopy as a noninvasive spectroscopic method, we demonstrate that rhGH can be encapsulated in PLGA with a nativelike secondary structure.

Materials and Methods

Protein—Recombinant human growth hormone (rhGH) was produced at Genentech, Inc. (South San Francisco, CA). The protein bulk containing 2 mg/mL of rhGH, 88 mM mannitol, and 5 mM sodium phosphate (pH 7.8) was buffer-exchanged into a 100 mM ammonium bicarbonate solution and lyophilized to obtain excipient-free protein.[34]

Chemicals—Trehalose and poly(DL-lactic-*co*-glycolic)acid (50:50; MW 40 000−75 000; lot no. 56H1176) were obtained from Sigma Chemical Company (St. Louis, MO) and used as supplied. All other chemicals were of analytical grade and from various suppliers.

Preparation of Lyophilized Excipient/rhGH Samples—Lyophilized excipient-free rhGH was reconstituted with deionized water to form a stock solution containing 2 mg/mL of protein, and trehalose was added at the required protein-to-trehalose ratio of 1:250 (mol:mol). Samples were lyophilized in a Labconco Freezone 6 unit at a chamber pressure of <100 μmHg and a shelf temperature of −42 °C for 48 h. The lyophilized material was used immediately or was sealed in glass vials and stored at 2−8 °C until use.

FTIR Spectroscopy—FTIR studies were conducted with a Nicolet Magna-IR System 560 optical bench as described previously.[19,25,30] A total of 256 scans at 2 cm^{-1} resolution using Happ-Ganzel apodization were averaged to obtain each spectrum. For all experiments involving aqueous solutions, a Spectra Tech liquid cell equipped with CaF_2 windows and 15-μm thick spacers was used. For all experiments involving suspensions in organic solvents, the same liquid cell was used with a 50-μm spacer. Samples of rhGH were dried in poly(lactic-*co*-glycolic)acid by casting (vide infra) and measured as thin films on a CaF_2 window.

Lyophilized protein powders were measured as KBr pellets (1 mg of protein per 200 mg of KBr).[19,25,33,35] It is important to note that the influence of the KBr pellet method on the vibrational spectrum of rhGH has been tested before.[35] In the current study, we have been careful to employ a KBr pellet method that has been shown previously not to induce any artifactual structural changes (i.e., same result as obtained with an IR microscope). It has also been reported that the KBr pellet method does not introduce spectral changes for various other proteins as well.[22] In addition, for recombinant human deoxyribonuclease, the sole protein reported to exhibit structural alterations due to IR sample preparation in KBr,[36] a recent study revealed that under judiciously mild conditions there were no structural changes that could be attributed to pressing the protein in a KBr pellet.[37]

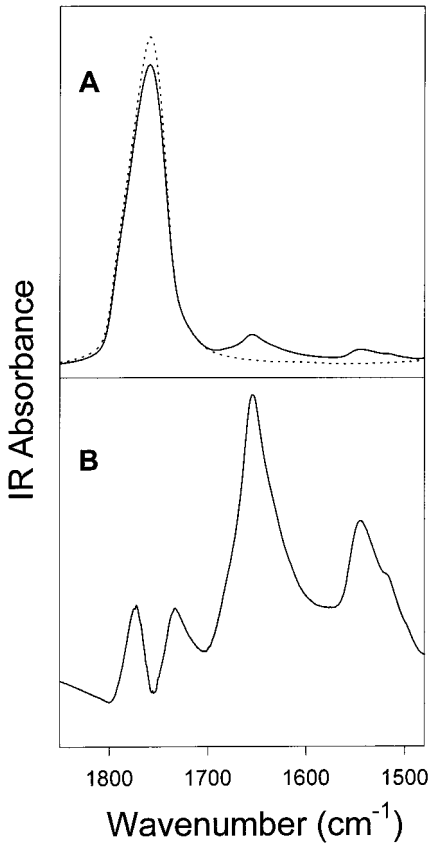

Figure 1—FTIR spectra of (A) rhGH encapsulated in PLGA (solid line) and of pure PLGA (dotted line) and (B) the rhGH spectrum after subtraction of the polymer background.

Each protein sample was measured at least four times. When necessary, spectra were corrected for the solvent background in an interactive manner using the Nicolet OMNIC 3.1 software[19,25,33] to obtain the protein vibrational spectra. We previously confirmed that this procedure is reliable for water background subtraction when using 15-μm thick spacers.[19]

RhGH was suspended in methylene chloride (25 mg protein/mL) using (1) a homogenizer (Virtishear Tempest 500W with an 18-mm shaft generator) for 2 min at the minimum speed setting of 1, (2) a probe sonicator (Branson Sonifier model 450) at 50 W at 50% duty cycle for 2 min, or (3) a sonication bath (Branson Sonication Bath model 2210) for 2 min. After suspension, the IR cell was immediately filled with the protein suspensions and the IR spectra were recorded. Encapsulation of lyophilized and co-lyophilized rhGH samples in poly(lactic-*co*-glycolic) acid (50:50) was carried out by suspending 10 mg of protein in a solution of 98 mg of PLGA in 1 mL of methylene chloride as already described. After suspension, samples were spread as thin films on a CaF_2 window and dried over a flow of dry N_2.

Spectra recorded for rhGH entrapped in PLGA were corrected for the polymer contribution. Although the polymer band with a maximum at ca. 1760 cm^{-1} is well separated from the amide I area (1700−1600 cm^{-1}), we were careful in excluding any artifactual influences of the subtraction procedure on the amide I spectrum. It can be seen from Figure 1A that the spectrum of PLGA was not identical in the absence and presence of the protein and could not be totally eliminated by the subtraction procedure. Thus, in principle, false subtraction could have led to the creation of some artifactual bands at ca. 1680−1700 cm^{-1}, where tailing of the peak into the amide I occurred. However, we were able to exclude such artifacts. To do so, the PLGA background was subtracted from lyophilized and co-lyophilized rhGH samples entrapped in PLGA employing different subtraction factors (e.g., 2.4133, 2.4737, and 2.5744 for the lyophilized protein and 0.9106, 0.9736, and 1.0456 for the co-lyophilizate), and no subtraction at all. For each of the spectra obtained, we calculated the secondary

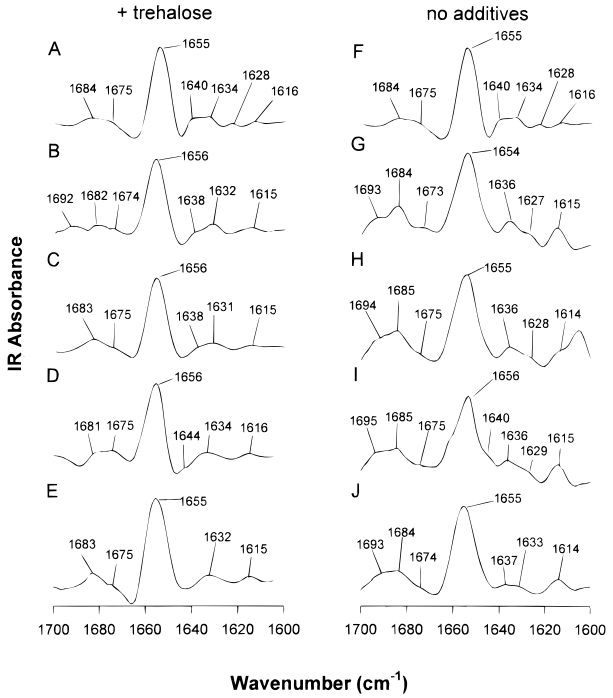

Figure 2—Second-derivative FTIR spectra of rhGH in the amide I region under various conditions. (A, F) rhGH in aqueous solution at pH 7.8; (B–E) rhGH co-lyophilized with trehalose at a 1:250 molar ratio from an aqueous solution at pH 7.8 under different conditions; [(B) co-lyophilized powder, (C) suspension in methylene chloride by homogenization, (D) dried powder after suspension in methylene chloride, and (E) entrapped in PLGA]; (G–J) rhGH powder lyophilized from pH 7.8 without additives under different conditions [(G) lyophilized powder, (H) suspension of the powder in methylene chloride by homogenization, (I) dried from suspension in methylene chloride, and (J) entrapped in PLGA].

structure by Gaussian curve-fitting. For the case of the lyophilized protein, the α-helix content determined was 39%, 35%, 37%, and 41% for four situations tested. For the case of the co-lyophilized protein, the α-helix content determined was 48%, 45%, 48%, and 46% for the four situations tested. The values were the same within the error of the method, excluding a significant influence of the PLGA background subtraction procedure on the amide I protein spectrum.

In addition, second-derivative spectra of rhGH entrapped in PLGA (Figure 2) were analyzed for any new components that could have been the result of the subtraction procedure. This analysis demonstrated no new components in these samples (Figures 2E and 2J) when compared with the spectrum of the lyophilized protein (Figures 2B and 2G). This result also excludes creation of artificial bands by the subtraction procedure.

FTIR Data Analysis—*Second Derivatization*—All spectra were analyzed by second derivatization in the amide I region for their component composition.[19,25,33,38,39] Second-derivative spectra were smoothed with an 11-point smoothing function (10.6 cm^{-1}).[19,25]

Fourier Self-Deconvolution (FSD)—FSD was applied to the unsmoothed spectra to enable quantification of the secondary structure in the amide I region by Gaussian curve-fitting[19,33,40,41] using the program OMNIC 3.1. The parameters chosen, a value of 24 for the full-width at half-maximum (fwhm) and $k = 2.4$ for the enhancement factor, are in the range of those published.[19,33,39,41–43] Note that FSD alters the band shapes but preserves the integrated band intensities when over-deconvolution is avoided.[38,42] The values chosen for FSD in our analyses were checked for the risk of such over-deconvolution (which could result in distorted band areas)[40,41] by the strategy outlined by Griebenow and Klibanov.[19]

Gaussian Curve-Fitting—The frequencies of the band centers found in the second-derivative spectra in the amide I region were used as starting parameters for the Gaussian curve-fitting (performed using the program GRAMS 386 from Galactic Industries, Inc.). The secondary structure contents were calculated from the areas of the individual assigned bands and their fraction of the total area in the amide I region.[19,33,39] Gaussian curve-fitting was performed in the amide I region after band-narrowing of the protein vibrational spectra by FSD.[39,41,43] In all cases, a linear baseline was fitted. The secondary structure content is reported as the averaged standard deviation of at least four measurements. To compare the structure of rhGH under different conditions, we performed a *t* test to determine within the confidence level of 95% whether the α-helix and β-sheet content were statistically significantly different. The null hypothesis used was that for both samples the values were the same within the error.

Band Assignments—The band assignment in the amide I region followed those in the literature[19,24,30,33,41] and is summarized for some typical samples in Table 1. For the aqueous solution, the main band at 1655 cm^{-1} was assigned to α-helices and a band at 1631 cm^{-1} to β-sheets. All other bands were assigned to other structural elements (β-turns, random coil, extended chains). The solution secondary structure content determined by Gaussian curve-fitting in the amide I region using these assignments was very similar to that determined previously [30,35] and to the X-ray crystal structure (60% α-helix).[44] The relatively high α-helix content of rhGH is advantageous when studying the influence of the encapsulation procedure on the structure of the protein under various conditions. For lyophilized or suspended proteins, the α-helix content is the most reliable criterion to describe their structural integrity when utilizing FTIR spectroscopy.[19,25,30]

[a] Data are the average and standard deviation of four to five independent determinations. [b] Second derivative. [c] Gaussian curve-fitting was performed on Fourier self-deconvolved amide I spectra. [d] Other structures include random coil, extended chains, and turns. [e] rhGH co-lyophilized with 1:250 protein: trehalose (mol:mol) prior to encapsulation. [f] The rhGH:trehalose co-lyophilizate was homogenized in methylene chloride containing PLGA and the suspension was subsequently dried to entrap the protein.

Results and Discussion

Previously, we reported the use of FTIR spectroscopy as a tool to investigate the structural alteration of rhGH upon dehydration[35] and to develop strategies for solid-state stabilization.[30] Herein, we have further extended the use of FTIR spectroscopy to probe rhGH structure under a variety of conditions relevant to the encapsulation of the protein in sustained-release formulations.

The structural consequences of the different steps of a nonaqueous encapsulation procedure were probed. Lyophilization of rhGH in the absence of excipients induces significant structural changes, in particular a decrease in the α-helix and an increase in the β-sheet content.[30,35] Our FTIR spectroscopic data obtained for rhGH in aqueous solution at pH 7.8 (Figure 3A) and for the powder lyophilized from that pH value (Figure 3B) are in agreement

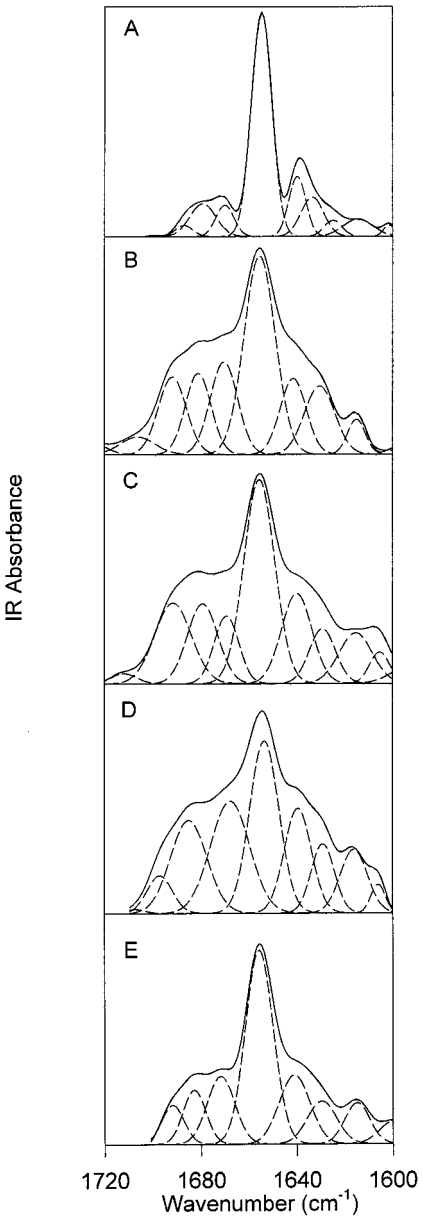

Figure 3—Fourier self-deconvolved FTIR spectra and Gaussian curve-fitting of rhGH without additives in the amide I spectral region under various conditions: (A) aqueous solution at pH 7.8, (B) lyophilized powder from that solution, (C) suspension of the powder in methylene chloride by homogenization, (D) dried from this suspension in methylene chloride, and (E) entrapped in PLGA. The solid lines represent the superimposed FSD and the curve-fit, and the dashed curves represent the individual Gaussian bands.

with these findings: the spectrum of rhGH in the amide I spectral region (1700−1600 cm^{-1}) showed pronounced changes. In particular, a broadening of the spectrum was observed for the lyophilized powder when compared with the aqueous spectrum. Such spectral changes are indicative of structural changes caused by the lyophilization process.[19,22,24,25,33,45] Quantitative analysis of the spectra by Gaussian curve-fitting (Table 2) revealed a statistically significant 20% decrease in the α-helix and 11% increase of the β-sheet content upon lyophilization, which is in agreement with results of previous investigations.[30,35]

When the excipient-free protein was suspended in methylene chloride using a homogenizer, the FTIR spectrum of this suspension (Figure 3C) was similar to the one of the lyophilized protein (Figure 3B). Quantitative analysis also revealed that there were no significant additional structural changes in the α-helix content and only a minor (but statistically significant) increase in the β-sheet content to 22% upon suspension of the protein in the organic solvent (Table 2).

Table 2—Secondary Structure of Excipient-Free rhGH under Various Conditions

sample	secondary structure content (%)[a] α-helix	β-sheet	other[b]
aqueous solution	57 ± 3	7 ± 3	36 ± 1
lyophilized powder	37 ± 4	18 ± 1	45 ± 3
powder suspension by probe sonication			
suspended in methylene chloride	23 ± 2	36 ± 2	41 ± 2

[a] The secondary structure of rhGH was calculated by Gaussian curve-fitting of the Fourier self-deconvolved amide I spectra. [b] Other structures include random coil, extended chains, and turns.

These data are in agreement with the hypothesis that dehydrated proteins have lower molecular mobility than in the aqueous state, which precludes them from being denatured by the organic solvent.[19,33] In contrast, another FTIR spectroscopic study found that suspension of the protein subtilisin in ethanol, hexane, and pyridine led to some structural rearrangements.[32] In that report, the exact details of the suspension conditions were not presented. Thus, to determine whether the suspension conditions used could affect the protein structure, we also suspended rhGH using probe sonication in methylene chloride. In this case, we found a significant additional reduction in the α-helix content to 23% and increase of the β-sheet content to 36% (Table 2). This additional structural instability may be related to the increased localized heating effect of suspensions achieved by probe sonication versus homogenization, which would promote increased molecular mobility.[46] Therefore, the means by which the suspension is obtained is important. FTIR spectroscopy may be useful as a tool to optimize the processing conditions with respect to structural preservation of pharmaceutical proteins.

We examined the effect of removing the organic solvent, which would be the next step in the preparation of an implantable or injectable depot. The spectra for rhGH suspended in methylene chloride with the homogenizer and of the dried powder obtained from that suspension (Figures 2C and 2D) were qualitatively quite similar. Quantitative analysis of the two spectra showed that some minor additional structural changes occurred upon drying of the suspension. There was a slight but statistically significant decrease in the α-helix content from 35% to 29% observed during this process, whereas the β-sheet content remained unchanged (Table 2).

A similar result was obtained when rhGH, suspended by probe sonication in methylene chloride, was dried from that solvent. The spectra were qualitatively very similar (data not shown) and the quantitative data (Table 2) were also similar. Thus, we conclude that removal of the organic solvent resulted in only minor additional structural alterations.

We also tested whether the presence of the polymer PLGA would have any influence on the structure of rhGH when following the same processing protocol. The protein was suspended in methylene chloride containing the polymer (98 mg/mL) using the homogenizer.[47] This suspension was directly applied to a FTIR window and a thin film produced by solvent evaporation under a stream of dry nitrogen gas. The structure of rhGH dried in the PLGA

film was essentially the same as in the lyophilized powder. The α-helix content was the same, but a small decrease in the β-sheet content was observed (Table 2). Thus, the structure of excipient-free rhGH dried in the presence of PLGA was not native. However, it was the freeze-drying process beforehand and not exposure to the organic solvent and/or PLGA that caused the structural perturbations.

Thus, to preserve the structure of rhGH in PLGA, the lyophilized formulation must first be optimized. It is well established from FTIR spectroscopic studies that lyophilization-induced structural changes can be prevented by addition of a co-lyophilized sugar or polyol.[22,24,25] For rhGH, several sugars proficient in stabilization against dehydration-induced structural changes (and also solid-state aggregation) have been identified; for example, trehalose.[30] Trehalose is an efficient lyoprotectant,[48] and has been shown to ameliorate the dehydration-induced structural alteration of various unrelated proteins, such as lysozyme[49,50] and bovine serum albumin.[51]

rhGH was co-lyophilized with trehalose at an excipient-to-protein ratio of 250:1 (mol:mol). At this ratio, the secondary structure of rhGH was largely preserved upon lyophilization. The second-derivative spectrum of the co-lyophilizate (Figure 2B) was very similar to that of the aqueous solution (Figure 2A). The main component was the band assigned to α-helices with a maximum at 1655 cm^{-1}. No significant changes in the frequencies or amplitudes of any component were noted in the second-derivative spectra. The quantitative analysis of the FTIR spectrum of the co-lyophilizate (Figure 4B) confirmed that the secondary structure was largely preserved by the lyoprotectant. The α-helix content for the sample was 52%, only slightly lower than in aqueous solution (57%, Table 3). An increase of 7% for the β-sheet was observed in the co-lyophilizate compared with the 11% increase for the excipient-free protein.

As the subsequent step, the rhGH:trehalose co-lyophilizate was suspended in methylene chloride using three different methods: probe sonication, homogenization, and a sonication bath. Probe sonication resulted in a statistically significant decrease in the α-helix content from 52% to 44%, indicating some pronounced structural changes by the method (Table 3). When we dried rhGH from this suspension, no further structural changes were noted (Table 3). These observations are in agreement with data for excipient-free protein as already discussed. Probe sonication in both cases caused some additional structural perturbation upon suspension in the organic solvent, and caution should be exercised when using this method.

A higher degree of structural preservation was achieved upon homogenization (Figures 2C and 4C) or suspension using the sonication bath (Table 3). The spectral changes upon suspension were very small in both cases. For example, the second-derivative spectrum of the rhGH:trehalose co-lyophilizate suspended by homogenization in methylene chloride (Figure 2C) was quite similar to that of the co-lyophilizate before suspension (Figure 2B). Quantitative analysis of the spectra by Gaussian curve-fitting did not indicate any statistically significant structural alterations upon suspension: the α-helix and β-sheet contents were, within the 95% confidence interval, the same as for the co-lyophilizate before suspension (Table 3).

The secondary structure was also determined for the protein in the co-lyophilizate dried from the organic solvent. Second-derivative spectra did not indicate any structural changes upon organic solvent removal. For the case of rhGH suspended by homogenization, the spectrum of the suspended protein and of the dried protein after suspension were very similar (Figures 2C and 2D). Furthermore, the second-derivative spectrum of the co-lyophilized protein

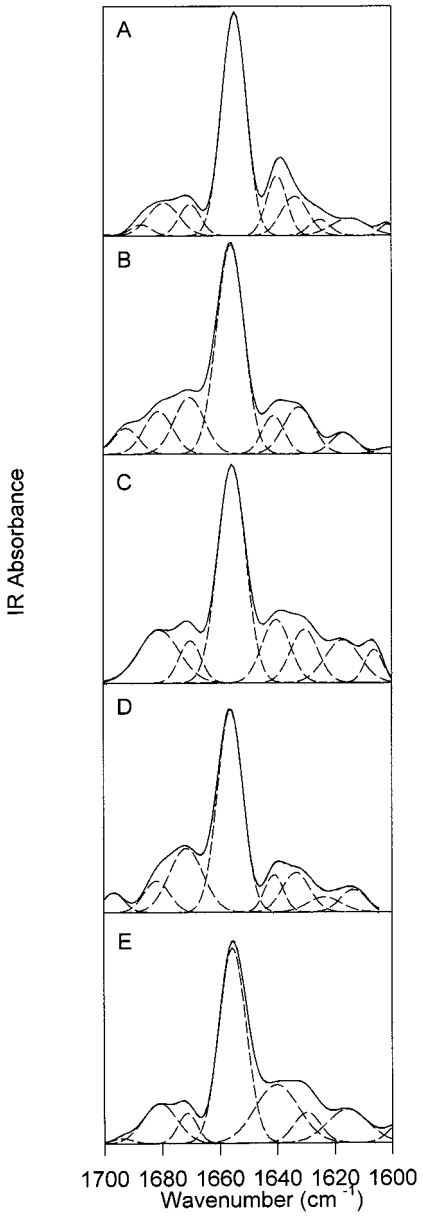

Figure 4—Fourier self-deconvolved FTIR spectra and Gaussian curve-fitting of rhGH in the amide I spectral region under various conditions: (A) aqueous solution at pH 7.8; (B) rhGH co-lyophilized with trehalose at pH 7.8; (C) suspension of the co-lyophilizate in methylene chloride by homogenization; (D) dried from this suspension in methylene chloride; and (E) entrapped in PLGA. The solid lines represent the superimposed FSD and the curve-fit, and the dashed curves represent the individual Gaussian bands.

dried after suspension in methylene chloride was comparable to that in aqueous solution.

Quantitative analysis of the spectra by Gaussian curve-fitting was in agreement with the qualitative observations (Figure 4D, Table 3). For the sample suspended by homogenization, the α-helix content (50%) and β-sheet content (13%) were the same, within the 95% confidence interval, as for the dried protein after suspension (48% and 14%, respectively). A slight but statistically significant decreases in α-helix (from 49% to 45%) and β-sheet content (from 16% to 13%) were noted for the sample suspended with the sonication bath upon drying (Table 3).

The trehalose-containing protein was then suspended in a solution of methylene chloride containing PLGA using the homogenizer and sonication bath because these methods were mild with respect to maintaining protein structure. The suspension was cast on a FTIR window and

Table 3—Secondary Structure of rhGH Co-Lyophilized with Trehalose under Various Conditions

sample	secondary structure content (%)[a]		
	α-helix	β-sheet	other[b]
aqueous solution[c]	57 ± 3	7 ± 3	36 ± 1
powder co-lyophilized with trehalose[d]	52 ± 3	14 ± 2	34 ± 1

dried from methylene chloride/PLGA	51 ± 2	8 ± 3	41 ± 2

[a] The secondary structure of rhGH was calculated by Gaussian curve-fitting of the Fourier self-deconvolved amide I spectra. [b] Other structures include random coil, extended chains, and turns. [c] The aqueous solution did not contain trehalose. [d] The co-lyophilized powder was obtained using a protein-to-trehalose ratio of 1:250 (mol:mol).

evaporated under a stream of dry N_2 gas. The second-derivative spectra qualitatively revealed that the structure of rhGH was very similar to that in aqueous solution and to that of the co-lyophilizate. For example, for the sample obtained by homogenization, only minor differences were evident when comparing the spectrum of the aqueous solution (Figure 2A) and of the entrapped protein (Figure 2E). Quantitative data obtained by Gaussian curve-fitting were in agreement with this qualitative analysis. The spectra of rhGH co-lyophilized with trehalose dried in PLGA from a suspension that was homogenized (Figure 4E) or prepared using the sonication bath (data not shown) were similar to that of the aqueous solution (Figure 4A) and the co-lyophilizate (Figure 4B). Some minor differences were noted in both cases for bands representing unordered secondary structure (ca. 1640 cm^{-1}) and β-sheet structure (ca. 1631 cm^{-1}). Some changes in the area of these components indicate a minor structural rearrangement occurring under the different conditions.

For the protein co-lyophilized with trehalose and entrapped in PLGA, quantitative analysis of the spectra (Table 3) demonstrated that the processing conditions produced only very minor structural changes. The α-helix content of rhGH entrapped in PLGA by homogenization was 48% and thus only slightly lower than for the co-lyophilizate before encapsulation (52%). In addition, only small differences were found for the β-sheet content (11% and 14%, respectively). The same result was evident when employing the sonication bath. The α-helix content for rhGH entrapped in PLGA was 51%, the same (within the 95% confidence interval) as for the co-lyophilized powder (52%), and the β-sheet content was only slightly decreased (14% and 8%, respectively).

The data clearly demonstrate that a nonaqueous strategy can be employed to entrap rhGH in PLGA with a nativelike secondary structure. The key was to lyophilize the protein under conditions ensuring structural integrity and then employ processing conditions that are not detrimental to the structure. This finding is intriguing in light of the common wisdom that organic solvents, such as the one in our study, are known to denature proteins.[8] It should be noted that in the present study, following the lyophilization step, all processes were nonaqueous. A likely explanation is the proposed decreased molecular mobility of proteins in anhydrous organic milieu compared with the aqueous state.

Such increased rigidity of proteins in organic solvents was originally proposed as an explanation for kinetic observations when employing suspended dehydrated enzymes as catalysts in nonaqueous organic solvents. For instance, increased rigidity has been attributed to differences in the enzymatic activity in hydrophobic and hydrophilic organic solvents.[52−54] In addition, it has been hypothesized that the plunge in enzymatic activity when comparing aqueous and nonaqueous systems can in part be attributed to increased rigidity of enzymes in organic solvents.[54,55] Also, the phenomenon of so-called 'molecular imprinting' can only be explained when assuming an increased rigidity of enzymes in organic solvents.[56−58] Furthermore, proteins show an increased stability toward thermal denaturation in organic solvents.[59,60] A few spectroscopic investigations have directly addressed the issue of protein rigidity in organic solvents. Nuclear magnetic resonance experiments on the tyrosyl ring motion in α-lytic protease,[61] electron spin resonance spectroscopic studies,[62,63] time-resolved fluorescence anisotropy measurements,[64] and recently FTIR spectroscopic experiments[19] support the view that proteins have restricted mobility in organic solvents when compared with aqueous systems. Theoretical works support this picture,[65,66] and it has also been pointed out that water serves as a molecular lubricant and promotes extremely fast conformational fluctuations.[67]

In summary, this report illustrates that FTIR spectroscopy can be used as a tool to probe protein structure under various conditions relevant to encapsulation in PLGA. This approach should be generally applicable to the structural stabilization of proteins during encapsulation in other polymeric depots.

Pressure Susceptibility of Polymer Tablets as a Critical Property: A Modified Heckel Equation

MARTIN KUENTZ AND HANS LEUENBERGER*

Contribution from *School of Pharmacy, University of Basel, Switzerland.*

Received September 14, 1998. Accepted for publication November 24, 1998.

Abstract □ The pressure susceptibility (χ_p), which is defined as the decrease of porosity (ϵ) under pressure was investigated. Of special interest are compacts obtained at very low pressures, because of the transition between the state of a powder and the state of a tablet. This range was found to be critical in respect to a diverging pressure susceptibility. Above a critical porosity (ϵ_c) or below the corresponding relative density (ρ_c), no pressure susceptibility can be defined, because of no rigid structure exists. To take this into account, a simple function was proposed for the pressure susceptibility: $\chi_p \propto 1/(\epsilon_c - \epsilon)$. This proposal leads to a new porosity vs pressure relationship. The new model was compared to the Heckel equation that involves a constant pressure susceptibility. Various polymers were tested from "out of die" measurements, and the new relationship was found superior to the Heckel equation. As a conclusion, the pressure susceptibility exhibits a curvature that can be called critical at low relative densities. Consequently, a better understanding evolves as to why the Heckel equation is not valid at low pressures. The new model has proven to be adequate for polymer tablets but, so far it is not clear whether other substances exhibit the same performance. Especially tableting materials exhibiting brittle fracture will be of interest considering their importance in compaction technology.

Introduction

Porosity−Pressure Relationship—A tablet can be considered as a special type of dispersion. The solid fraction and the air in pores constitute two phases of the system. This heterogeneous character of such a particulate material leads to a very complex mechanical behavior. In case of low packing fractions, rheological properties can be found. Thus, individual particles are movable to some extent, enabling many possible configurations. This aspect of a disordered structure holds for an analogy to liquids, and even an entropy S_t can be attributed to a particle packing.[1] Yet, the individuality of particles gets lost in tablets compacted at higher pressures. Consequently, also the entropy of the diverse particle configurations vanishes. Such very dense compacts can approach a continuum of the solid fraction, and therefore mechanics of practically homogeneous solids will evolve.

As a result, the character of the system undergoes dramatic changes as a function of the relative density. Particle rearrangements, occurrence of plastic flow, and possible brittle fracture contribute to a vast complexity. Hence, there is a number of different mathematical models, which are mostly empirical or contain at least some *heuristic* elements.

The most widespread models used in the field of pharmaceutical technology are the Kawakita equation,[2] the approach according to Cooper and Eaton,[3] and the Heckel equation.[4,5] The latter model is of special interest for the present study:

$$\ln\left(\frac{1}{1-\rho}\right) = K\sigma + A \qquad (1)$$

where ρ equals the relative density and σ is the compression pressure, whereas K and A are constants. It is known that tablets compressed at higher pressures fulfill the relationship properly.[6] In a plot of $\ln(1/(1-\rho))$ versus applied pressure, K is determined from the slope, and A from the intercept. The general limitations of Heckel plots have been analyzed rigorously by Rue and Rees.[7]

Recent Developments—The lacking adequacy of the classical compression equations stimulated efforts for current investigations. Yu and Hall[8] analyzed very porous particle packings, using a double-logarithmic form of the Heckel plot. The fit of the new model was better than the original Heckel equation. Yet, the empirical nature of this approach lacking any theoretical background can be considered as a drawback. The same also can be remarked for the *heuristic* equation proposed by Lordi et al.[9]

An interesting modification of the original Heckel equation was attained by Carstensen et al.[10] They assumed the final compact of a pharmaceutical powder to always possess some residual porosity. Accordingly, the void volume decreases exponentially toward a value different from zero. The resulting model seemed capable to also describe experimental data in the nonlinear part of the Heckel plot and can potentially be extended to more than a one-component system.

Confined compression of particle agglomerates is mainly focused by an approach of Adams et al.[11] The bed in the die was modeled as a series of parallel columns, where only processes of friction were allowed. Thus, any system where elastic energy also is stored is not covered by this theory. However, the assumptions lead to a result that took approximately the same form as the Kawakita equation and therefore enabled a physical interpretation of its parameters.

Coming finally to a microscopic theory, Duncan−Hewitt[12] attempted a model of the compression process, where compact properties were predicted by the characteristics of single crystals. The behavior of brittle particles was found to be substantially different from the one of more ductile crystals, and so two distinct models evolved. However, the main problem of any microscopic theory can be understood in the change of relevant binding points. The tablet is heterogeneous, built up by particles whose binding points are distributed randomly to some extent. Consequently, disorder has to be taken into account by any theoretical approach.

The aspect of disorder is most interesting in that some very different physical problems can be treated similarly

from a theoretical point of view.[13] Modern physics of phase transitions and critical phenomena[14] provides interesting new concepts that can potentially be applied to many scientific fields. Yet, an analogy between relevant physical problems may not always be obvious at first, but similarities can be revealed by studying the *response functions* of a system. The present paper introduces such a function in the context of powder compaction.

Theoretical Section

Pressure Susceptibility—For particle systems, a pressure susceptibility can be defined as a function of the porosity and compression pressure as stated below:

$$\chi_p \equiv -\frac{1}{\epsilon}\frac{d\epsilon}{d\sigma} \tag{2}$$

The porosity can equally be expressed by the relative density:

$$\rho = 1 - \epsilon, \quad \text{or in differential form:} \quad d\rho = -d\epsilon \tag{3}$$

Hence, eq 2 reads:

$$\frac{d\rho}{d\sigma} = \chi_p(1-\rho) \tag{4}$$

In case of a constant χ_p, eq 4 just holds for the differential form of the Heckel equation where χ_p equals K. Thus, a constant pressure susceptibility is the base of the theoretical concept of Heckel. Physically, this can be motivated by thinking of uniformly shrinking pores in a solid continuum. However, at low relative densities and pressures, the compacts are essentially particle agglomerates rather than homogeneously dispersed holes in a solid matrix. Consequently, a very different physical behavior can be expected.

Critical Behavior of the Pressure Susceptibility—Especially in the initial stage of the compression process, particle rearrangements dominate in many cases. In addition, fine particle systems can exhibit very porous structures by arching and formation of very loose agglomerates. Such structures are highly unstable and can collapse if only a minimal force is applied. Thus, the susceptibility to an external pressure can theoretically take any high value. Yet, it needs to be highlighted that in the case of a total lack of mechanical rigidity between the punches, the possibility to define pressure susceptibility is not available. Accordingly, a threshold value of the porosity ϵ_c or corresponding relative density ρ_c can be introduced, where a rigidity starts to evolve. The property χ_p exists therefore only for porosities lower than ϵ_c or relative densities higher than ρ_c. Hence, from these characteristics of the pressure susceptibility, the range in vicinity of the threshold can be called *critical*.

In line with these considerations, the Heckel model, where χ_p equals a constant K, needs to be replaced by an alternative approach, taking better account of the characteristics of pressure susceptibility. A related conjecture is an equation describing a hyperbola:

$$\chi_p = \frac{C}{\epsilon_c - \epsilon} = \frac{C}{\rho - \rho_c} \tag{5}$$

Where, C holds for a constant. Considering eq 5, it is interesting to notice that very different physical systems exhibit similar critical behavior. For example, the van der Waals theory expresses the compressibility (χ_T) of a gas as being proportional to $(T - T_c)^{-1}$, where T is the temperature and T_c is the critical temperature. Another example is the Curie–Weiss law that states the same for the magnetic susceptibility (χ_m). Here the critical temperature (T_c) is known in textbooks as the Curie temperature. However, the latter cases both hold for thermal phase transitions, whereas for tablets the relative density holds for an *order parameter*,[14] describing a geometric phase transition. Yet, it should be mentioned that such simple functions for χ_T or χ_m are based on a so-called *mean field approach*.[14] This theoretical view implies a simple mean potential, approximating the molecular interaction. In the context of compaction, the mean field can correspond to a mean pressure. A mean field approximation usually provides a rather good model and is valid in a broad range.

It should further be mentioned that percolation theory[15–18] assumes a power law for modeling a critical property. Unfortunately, such a power law has an unknown range of validity in the critical range. Keeping in mind the goal to find a new relationship between pressure and relative density, we used eq 5 for the present model.

A Modified Heckel Equation—Combination of eqs 2 and 5 results in the differential equation given below:

$$-\frac{1}{\epsilon}\frac{d\epsilon}{d\sigma} = C\frac{1}{\epsilon_c - \epsilon} \tag{6}$$

after separation of variables, it reads:

$$-\frac{\epsilon_c - \epsilon}{\epsilon}d\epsilon = Cd\sigma \tag{7}$$

Integration can be performed starting from the critical porosity ϵ_c at a negligible resting pressure $\sigma_0 \cong 0$:

$$\int_{\epsilon_c}^{\epsilon}\frac{\epsilon - \epsilon_c}{\epsilon}d\epsilon = C\int_0^{\sigma}d\sigma \tag{8}$$

$$[\epsilon - \epsilon_c \ln(\epsilon)]_{\epsilon_c}^{\epsilon} = C\sigma \tag{9}$$

$$\epsilon - \epsilon_c \ln(\epsilon) - [\epsilon_c - \epsilon_c \ln(\epsilon_c)] = C\sigma \tag{10}$$

$$\epsilon - \epsilon_c + \epsilon_c[\ln(\epsilon_c) - \ln(\epsilon)] = \epsilon - \epsilon_c + \epsilon_c \ln\left(\frac{\epsilon_c}{\epsilon}\right) = C\sigma \tag{11}$$

$$\sigma = \frac{1}{C}\left[\epsilon - \epsilon_c - \epsilon_c \ln\left(\frac{\epsilon}{\epsilon_c}\right)\right] \tag{12}$$

Hence, replacing porosity ϵ with the relative density ρ, a modified Heckel equation results:

$$\sigma = \frac{1}{C}\left[\rho_c - \rho - (1-\rho_c)\ln\left(\frac{1-\rho}{1-\rho_c}\right)\right] \tag{13}$$

Materials and Methods

Tablets (round, flat, 11 mm diameter, 400 ± 1 mg weight) were manufactured with a Zwick 1478 Universal Testing Instrument (Zwick GmbH, Ulm, Germany). Different pharmaceutical polymers were chosen as model substances, because of their ability to form tablets in the interesting critical range at comparatively low relative densities (Table 1). True density was determined with an Beckman Air Comparison Pycnometer Model 930 and the particle size assayed using a Malvern Mastersizer X.

For each powder system, five tablets were compressed at different pressure levels ranging from 1.05 MPa up to 105.23 MPa at a relative humidity of 45% ± 10%. The compression speed was 10 mm/min and tablets' geometry was assessed 48 h after manufacture ("out of die" determination).

All data of different substances were used for statistical evaluation, except for Klucel, where only values to a pressure of

36.8 MPa were evaluated. The program used for all calculations was SYSTAT for Windows Version 7.0 (SPSS Inc.).

Results and Discussion

The pressure susceptibility was calculated from experimental data according to eq 4 using finite differences for the differential quotient and plotted against ρ (see Figures1–4A). The graphs show that very high compressibility

decreases sharply with increasing relative densities. Thus, the assumption of Heckel to use a constant pressure susceptibility is only acceptable as a first approximation for comparatively dense compacts. Still, further changes of the property χ_p will take place, until a minimum is achieved at about zero porosity. Note that for the slight changes in this range, the experimental accuracy is a limiting factor. This is reflected by the scatter of the values for PEG 8000 (see Figure 4A).

Very porous tablets produce considerable porosity changes under strain. Such high compressibility can only be explained by particle displacement, i.e., particle rearrangements in the initial stages of compression. As long as a large extraparticulate void volume exists, a reduction of porosity can be achieved by a small pressure. The consequence is a high value of χ_p that was also observed in the experimental results (Figure 1–4A). Theoretically, the curve close to ρ_c can even extend to infinity but directly at the threshold and below the function χ_p vanishes. As a conclusion, the assumption of a hyperbola for χ_p eq 5 appears very suitable, whereas the approximation of a constant value for χ_p is clearly not correct for low-density tablets.

Focusing on the relationship between pressure and relative density,we compared the new model eq 13 and the Heckel eq 1, on the basis of "out of die" measurements (Table 2). A nonlinear fit was conducted with all substances using the new model equation (See Figure 1–4B). It shows that eq 13 is in good agreement with experimental results.

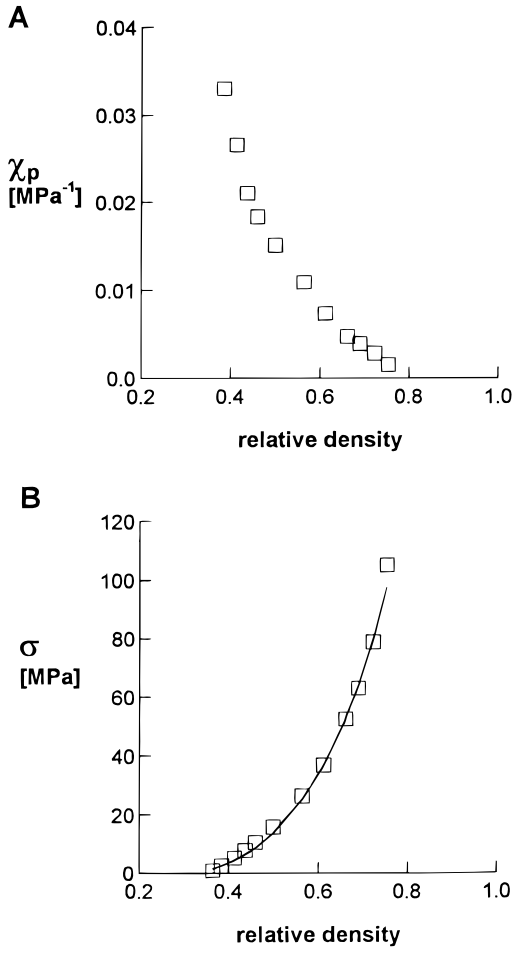

Figure 3—Kollidon CL: (A) Pressure susceptibility χ_p (MPa^{-1}) vs relative density (□). (B) Compression pressure σ (MPa) as a function of the relative density (□). The solid line represents the model according to eq 13.

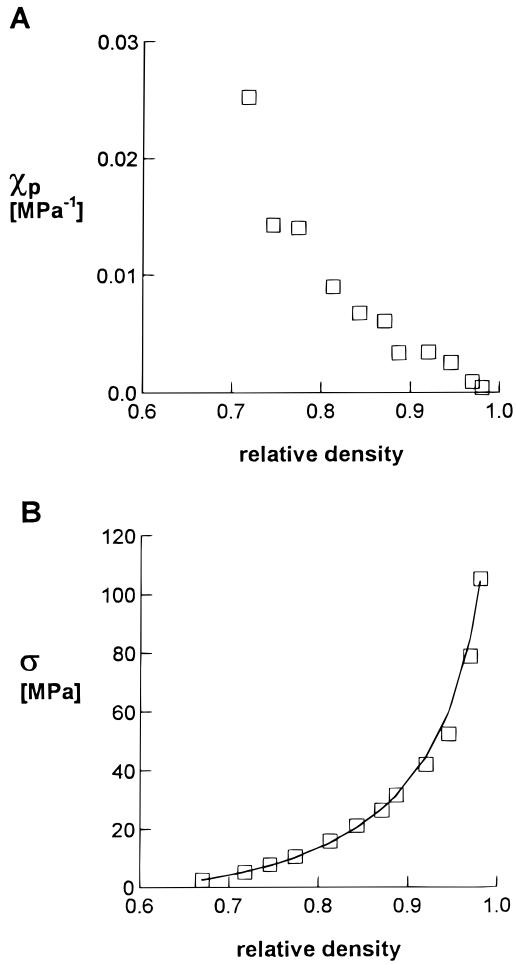

Figure 4—PEG 8000: (A) Pressure susceptibility χ_p (MPa^{-1}) vs relative density (□). (B) Compression pressure σ (MPa) as a function of the relative density (□). The solid line represents the model according to eq 13.

In addition, the comparison with the Heckel equation (Table 2) clearly showed a better goodness of fit of the new model. Yet, in some cases such as for Pharmacoat 606 (Figure 2) and Kollidon CL (Figure 3), the highest pressure did not properly match the new model.

It should be noticed that the number of parameters is the same for the Heckel equation and the new model. This low number of parameters, i.e., the simplicity of a model, is an important aspect. Yet, the complexity of the compression process is awesome, involving several physical phenomena of changing significance in different stages.[19,20] Thus, the proposal of a *power series* might be most adequate to describe the change of pressure susceptibility close to the threshold ρ_c. On the other hand, new parameters would be introduced and the problem of an a priori limited range of validity is still present. Therefore, a simple approximation on the average, as proposed by eq 5, is justified.

Comparing the constants C and K (Table 2), values for the new parameter C were all smaller than those of K by a factor of roughly between 2 and 4. Qualitatively it can be said that both parameters incorporate an experimental minimal susceptibility (χ_{pmin}) close to zero porosity. This parameter is independent of the tablet's pore structure because it is a characteristic of the solid continuum. The constant C is proportional to χ_{pmin} but further involves the threshold value ρ_c, which becomes apparent evaluating eq 5 at unity density. Thus, C depends on the initial structure of the particle packing.

Considering the parameter ρ_c, this value was defined in the theoretical section as a rigidity threshold. Thus, this critical value holds for the packing fraction, producing a negligible mechanical resistance between the punches. In a strictly geometric interpretation, this threshold ρ_c demonstrates the transition between dispersed solid in air and voids in a solid matrix. The coherent contact within the powder column will be already present only when the powder is poured in the die. Yet, it can be argued that contact between particles might not be enough for establishing a relevant rigidity.[21] Some initial particle rearrangements might require only minimal forces that can be

neglected. Thus, the rigidity threshold ρ_c can be higher than the relative density needed for coherent contact.

The values for ρ_c (Table 2) according to eq 13 ranged for all substances close to the interval of the relative bulk density and tapped density (Table 1). It is interesting to notice that the different types of microcrystalline cellulose and poly(vinylpyrrolidone) displayed a trend for lower thresholds. This tendency seemed especially pronounced for Avicel PH102, Kollidon K17, and K90F, where values for ρ_c were even lower than the relative bulk density. The poly(ethylene)glycol)s showed reversed tendency, where critical rigidity was achieved close to the relative tapped density or slightly above as produced by PEG 10000 and PEG 20000. In line with these considerations, it can be concluded that the microstructure, being specific for a given substance, plays an important role for ρ_c.

The Heckel constant K in eq 1 can be used to characterize substances.[22] The question can therefore be asked if a similar information can also be acquired from the new parameters ρ_c and C. In line with the considerations so far, ρ_c appears to be a parameter being strongly affected by the microstructure of the powder system. Of further special interest is that particle systems can behave differently under compression or tension. The behavior under compression gives information on rigidity, whereas a behavior under tension is related to compact strength. Thus, the compressibility of a particle assembly can therefore be considered as a characteristic on its own apart from the binding capabilities. Yet again the situation is different for the dense compacts. If the applied pressure is high enough, plastic flow occurs at a compressive yield pressure (σ_Y). Accordingly, the value for χ_{pmin} can be expected to depend on σ_Y. This aspect can further be stressed by defining a compression modulus (G):

$$G \equiv \frac{1}{\chi_p} \tag{14}$$

The property G expresses the pressure needed to reduce porosity of a tablet. A maximal value (G_{max}) will therefore be limited by a compressive yield strength. Alternatively, it can be stated that the maximal compression modulus equals the maximal hardness (P_{max}) of the material if exclusive plastic flow occurs.

The inverse of the constant K can also be regarded as a compression modulus G. Its determination only from the linear part of the Heckel plot, results again in an estimate of compressibility at high pressures and therefore approximates G_{max}. Note that the constant K was assessed instead over the entire range of the relative density.

However, Heckel already conjectured that the inverse of the Heckel slope was proportional to the yield point of the particles with a proportionality factor equal to three.[5] This observation agrees with our considerations that maximal compressibility is limited by a compressive yield pressure. Furthermore, it should be mentioned that the yield point of a plastic material is known to equal one-third of the indentation hardness.[23] This again supports the view that for plastic substances, the inverse Heckel slope can also be regarded as a measure of maximal hardness. From these considerations it can be qualitatively concluded that G_{max} is a specific property of a substance and can potentially be used for characterization of a tableting material. Yet, it needs to be stressed that experimentally the zero porosity state can hardly be achieved even at highest pressures.[24] Therefore, arguments on G_{max} should be understood qualitatively first.

It is interesting to normalize the compression modulus G by its maximum G_{max}. This quotient only depends on the structure of the tablet. Using eq 5, one obtains:

$$\frac{G}{G_{max}} = \frac{\chi_p^{-1}}{\chi_{pmin}^{-1}} = \frac{(\rho - \rho_c)C}{(1 - \rho_c)C} = \frac{1}{1 - \rho_c}(\rho - \rho_c) \tag{15}$$

This result is consistent with the model of Leuenberger and Leu[25] based on the percolation theory. The eq 15 was previously pointed out to be consistent with a so-called *effective medium approximation*,[26–28] where a disordered medium is replaced on the average by a hypothetical homogeneous one.

Conclusions

It was shown that the pressure susceptibility exhibits very high values at comparatively low relative densities. The property χ_p was expected to be divergent in this range having a singularity at a critical relative density ρ_c. As a consequence, the Heckel equation, assuming a constant value for χ_p, is inadequate in this critical range. The proposal of a simple hyperbola function leads in the integrated form to a modified Heckel equation. This model has shown to be superior in describing different polymer tablets from "out of die" measurements. The understanding of the pressure susceptibility as a critical property links the process of compression to the theory of phase transitions. Thus, the present concept provides not only a new equation for the relationship between pressure and relative density, but contributes also to further insights in the complex nature of the compaction process.

Additional studies are needed for a complete evaluation of the proposed model equation. So far in this study, porosity was determined after manufacture and storage. Additional "in die" measurements would be of interest because no elastic recovery or other postcompressional changes are allowed under these conditions. Plus, brittle substances should be tested. This is especially of interest, regarding the importance of tableting material undergoing fragmentation during compaction.

Glossary

ϵ, ϵ_c	Porosity and critical porosity. The latter value is defined as the threshold porosity of a vanishing rigidity between the punches
ρ, ρ_c	Relative density and critical relative density. The threshold density corresponds to $1 - \epsilon_c$
σ	Applied pressure (MPa)
K, A	Constants of the Heckel equation, where K (MPa^{-1}) equals the slope, and A the intercept of the plot $\ln(1/(1 - \rho))$ with respect to σ
χ_p	Pressure susceptibility or compressibility, defined as $\chi_p \equiv -(1/\epsilon)(d\epsilon/d\sigma) = [1/(1 - \rho)](d\rho/d\sigma)(MPa^{-1})$
χ_{pmin}	Minimal value of the pressure susceptibility (MPa^{-1}) at zero porosity
C	Proportionality constant (MPa^{-1}) that links the porosity with the pressure susceptibility $\chi_p = C/(\epsilon_c - \epsilon) = C/(\rho - \rho_c)$. Hence, C can also be related to with the minimal pressure susceptibility at zero porosity: $C = \chi_{pmin}\epsilon_c = \chi_{pmin}(1 - \rho_c)$.
χ_T	Isothermal compressibility of a gas defined by a relation to the volume V (m^3), pressure P (Pa) and gas density ρ_g (kg m^{-3}): $\chi_T \equiv -(1/V)(dV/dP) = (1/\rho_g)/(d\rho_g/dP)$
χ_m	Magnetic susceptibility, defined over the relationship: $\chi_m \equiv (dM/dH)$, where M (A m^{-1}) is the magnetization and H (A m^{-1}) the magnetic field.

T, T_c Temperature and critical temperature. The threshold temperature can hold, for example, for the singularity at the end of the vapor vs pressure curve, or in case of magnetic systems, it marks the transition of ferromagnetism and paramagnetic behavior.

G Compression modulus (MPa) is by definition the reciprocal of χ_p.

G_{max} Maximal compression modulus (MPa) defined over the reciprocal of χ_{pmin}.

σ_N Compressive yield pressure (MPa).

P_{max} Maximal value of the deformation hardness (MPa).

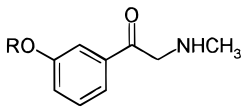
Abstract □ The purpose of this study was to evaluate the permeability characteristics of a previously reported in vitro corneal model that utilizes SIRC rabbbit corneal cells and to investigate the permeability of three novel esters of phenylephrone chemical delivery systems (CDS) under different pH conditions using this in vitro model. The SIRC rabbit corneal cell line was grown on transwell polycarbonate membranes, and the barrier properties were assessed by measuring transepithelial electrical resistance (TEER) using a voltohmmeter. The permeabilities of esters of phenylephrone CDS across the SIRC cell layers were measured over a pH range 4.0–7.4. The esters tested include phenylacetyl (**1**), isovaleryl (**2**), and pivalyl (**3**). The SIRC rabbit corneal cell line, when grown on permeable filters, formed tight monolayers of high electrical resistance with TEER values increasing from 71.6 ± 20.8 Ω·cm^2 at day 3 in culture to 2233.42 ± 15.2 Ω·cm^2 at day 8 in culture and remained constant through day 14 in culture. The transepithelial permeability coefficients (P_{app}) at pH 7.4 ranged from 0.58×10^{-6} cm/s for the hydrophilic marker, mannitol, to 43.5×10^{-6} cm/s for the most lipophilic molecule, testosterone. The P_{app} at pH 7.4 for phenylephrine was 4.21×10^{-6} cm/s. The P_{app} values and the lag times of the three esters of phenylephrone were pH dependent. The P_{app} for **1**, **2**, and **3** at pH 7.4 were 14.76×10^{-6}, 13.19×10^{-6}, and 12.86×10^{-6} cm/s, respectively and the permeabilities decreased at conditions below pH 7.4. The lag times at pH 7.4 were 0.10, 0.17, and 0.12 h for **1**, **2**, and **3**, respectively, and the values increased at lower pH conditions. The TEER values of SIRC cell line observed at day 8 to day 14 in the present investigation are similar to the resistance value reported for rabbit cornea (2 kΩ·cm^2). All the esters showed significantly ($p < 0.05$) higher permeabilities than phenylephrine at pH 7.4. The rate and extent of transport of the drugs across the cell layers were influenced by the fraction of ionized and un-ionized species and the intrinsic partition coefficient of the drug. The results indicate that the permeability of ophthalmic drugs through ocular membranes may be predicted by measuring the permeability through the new in vitro cell culture model.

Introduction

Phenylephrine hydrochloride (HCl) is an α-adrenergic agonist and is commonly used in routine ophthalmic practice as a mydriatic and vasoconstrictor agent. Several cases of adverse systemic reactions after topical ocular application of phenylephrine HCl have been reported and include severe hypertension, subarachnoid hemorrhage, ventricular arrhythmia, and possible myocardial infarction.[1−6] Therefore, it would be most desirable to design a drug that could be delivered to the eye compartments with the least possible systemic absorption and/or no systemic side effects. Previous reports have shown that, after topical application to the eye, esters of adrenalone but not adrenalone itself can be converted via a reduction−hydrolysis sequence to deliver adrenaline (epinephrine) only at the iris−ciliary body, the site of action.[7,8] This suggested that lipophilic ketones can be reduced in the iris−ciliary body. Accordingly, phenylephrone chemical delivery systems (CDS) (Figure 1) were designed to release the active species phenylephrine, by a "reductive−hydrolytic activation" mechanism, selectively to iris−ciliary body, thus avoiding the various systemic side effects. We recently reported the physicochemical properties of the novel compounds as a part of preformulation study.[9]



Phenylephrone CDS

1: R = -$COCH_2C_6H_5$ (phenylacetyl)
2: R = -$COCH_2CH(CH_3)_2$ (isovaleryl)
3: R = -$COC(CH_3)_3$ (pivalyl)

Figure 1—Structures of phenylephrone CDS.

Investigation of the absorption properties of a new drug moiety is also an important part in the preformulation process. The rate and extent of intraocular absorption and therapeutic effectiveness of topically applied drugs are dependent on the transport characteristics of ocular membranes, especially the cornea.[10−12] Characterization of the ocular penetration of drugs has been performed using hard-to-obtain ocular membranes from many animals. The establishment of a predictive method for the drug permeation using a cell culture model would be useful. In vitro cell culture models are of potential utility for some screening studies in which large quantities of corneas are needed. The SIRC rabbit cell line has been used by many researchers as a cellular model in studies of corneal physiology, immunology, and toxicology.[13−17] Hutak et al. recently developed an in vitro model for corneal permeability and reported that a single inoculation of SIRC rabbit corneal cells resulted in the formation of multiple epithelioid cell layers, with the number of layers increasing with culture time.[18] The objectives of the present study are to (a) evaluate the permeability characteristics of the SIRC rabbit corneal cell line system for potential use as an in vitro model for assessing drug permeability and (b) characterize the transport characteristics of three novel esters of the phenylephrone CDS using this model at varying pH conditions.

Materials and Methods

The SIRC cell line was obtained from American Type Culture Collection (ATCC no. CCL60; Rockville, MD). Earle's balanced salt solution (EBSS) without sodium bicarbonate, bovine calf serum,

lactalbumin hydrolysate, yeast extract, trypsin, and gentamycin sulfate were obtained from Gibco BRL, Grand Island, NY. All other chemicals were of tissue culture grade. Plastic filter units, cell culture flasks (75 cm^2), and transwell inserts were obtained from Fisher Scientific, Houston, TX. D-[1-^{14}C]mannitol (mol wt 182.2) with a specific activity of 50.0 mCi/mmol and a radiochemical purity of 98% was purchased from Sigma Chemical Co., St. Louis, MO. [4-^{14}C]testosterone, having a specific activity of 57.0 mCi/mmol and a radiochemical purity of 98.2%, was purchased from Nycomed Amersham, Arlington Heights, IL.

Cell Culture—SIRC cells were cultured as previously described by Hutak et al.[18] The cells were maintained at 37° C in EBSS containing 10% bovine calf serum, 1760 mg/L lactalbumin hydrolysate, 570 mg/L yeast extract, 860 mg/L sodium bicarbonate, and 50 mg/L gentamycin sulfate in an atmosphere of 5% CO_2 and 95% relative humidity. The cells grown in 75 cm^2 flasks were passaged every seventh day of culture at a split ratio of 1:2. The cells were rinsed with 0.1% EDTA (pH 7.4), suspended using trypsin–EDTA in EBSS (37° C, 5 min), and transferred to two new flasks containing fresh growth medium.

In the present investigations, 0.5 mL of growth medium was placed in each well of the microwell plates, and the tissue culture inserts were placed in the wells. The cells, grown for 7 days in culture, were suspended in 50 mL of growth medium. A 0.15 mL aliquot of culture medium was placed into each filter insert, followed by the addition of 0.1 mL cell suspension. The total volume of media and cell suspension was predetermined by the filter capacity specifications. The volume of cell suspension added to the inserts was determined by the relative surface area of the microwell insert to the culture flask. The cell layers were given fresh growth medium on every seventh day of growth. One milliliter of fresh growth medium was placed into a new well. Following removal of the old medium, the insert was placed into this new well, and 0.1 mL of fresh medium was added to each insert.

Electrical Resistance Measurements—The permeability of the cell monolayers was determined by electrical resistance measurements using a voltohmeter. The culture media (0.6 mL and 0.1 mL to the apical and basolateral chamber, respectively) were added prior to electrical measurements. Transepithelial electrical resistance (TEER) values, obtained in the absence of cells (caused by the electrical system and the collagen-coated polycarbonate membrane), were considered as background. For each experiment, total electrical resistance values were corrected for background, which ranged from 20 to 40 Ω·cm^2, to obtain the TEER values of the cell monolayers.

Transport Studies—SIRC cell monolayers grown on collagen-coated polycarbonate filters (Transwell) for 8–10 days were used for transport experiments. On the day of the transport experiment, the culture media (0.6 mL and 0.1 mL to the apical and basolateral chamber, respectively) was replaced with EBSS containing 25 mM glucose. The pH of the transport medium was adjusted with HCl or NaOH. After equilibration at 37 °C for 30 min, TEER values were obtained prior to transport study. The integrity of each batch of cells was further tested by measuring the flux of radiolabeled mannitol (0.01 mM) in representative cell monolayers ($n = 3$). The transport of the novel mydriatic agents (phenylephrone CDS) across SIRC cell monolayers at pH 4.0, 5.0, 6.0, and 7.4 was determined in triplicate. In apical (donor compartment) to basolateral (receiver compartment) transport studies, each well in the 24 well clusters received 0.6 mL of transport medium that had previously been equilibrated at 37 °C. Transport medium (0.1 mL) containing the drug [phenylephrine, 0.1 mM; phenylephrone CDS, 0.1 mM; testosterone, 0.01 mM] was applied to the apical side. Samples (100 μL) were removed from the basolateral side at various times up to 180 min and replaced with the same volume of fresh transport medium. Aliquots of 20 μL were taken from the apical side at the beginning and end of each experiment.

Assay Method—The esters of phenylephrone (phenylacetyl **1**, isovaleryl **2**, and pivalyl **3**) were analyzed by HPLC (Isco pump, Model 2350; Model 484, waters) using an electrochemical detector. The detection potential was 1.15 V. A μBondapak C18 column with a similar 6 cm guard column and a mobile phase (pH 3.6) consisting of acetonitrile:acetate buffer:triethylamine (25:75:0.05) with a flow rate of 1 mL/min were used for the resolution of the compounds. Calibration curves were obtained by plotting the peak area as a function of drug concentration. The radioactive materials were analyzed by using a Beckman LS-3801 liquid scintillation counter.

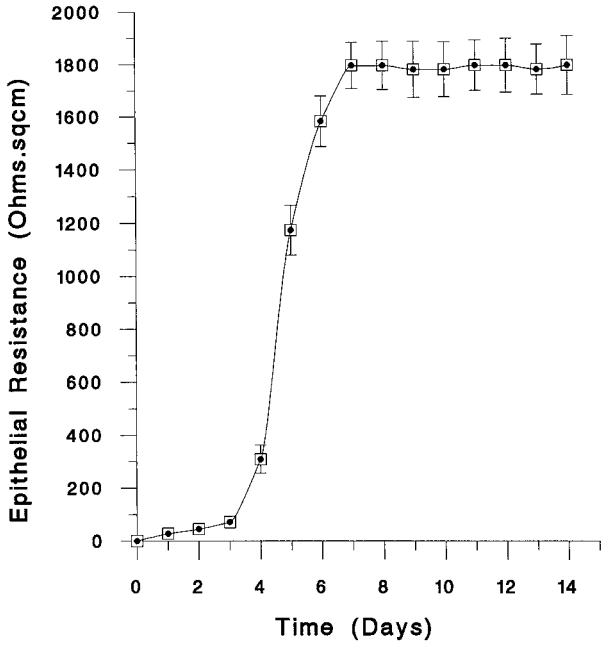

Figure 2—Transepithelial electrical resistance across SIRC cells grown on a polycarbonate membrane. Each value represents average (±SEM) of six experiments.

Data Analysis—Apparent permeability coefficients (P_{app}) of the three esters of phenylephrone and D-[1-^{14}C]mannitol and [4-^{14}C]testosterone were calculated using the following equation:

$$P_{app} = (1/AC_0)\,(dM/dt)$$

where dM/dt is the flux across the cell layers (μg/hr), A is the surface area of the membrane (0.33 cm^2), and C_0 is the initial drug concentration (μg/mL) in the donor compartment at $t = 0$. Flux per unit surface area ($1/A \times dM/dt$) was determined from the slope of linear portion of the cumulative amount permeated per unit surface area vs time plot. The lag time was also determined from this plot by extrapolating the linear portion to the abscissa. The results of experiments performed in triplicate are presented as mean ± SD. Statistical differences between the novel compounds in the amount permeated at each time point, and the means were determined by one-way analysis of variance (ANOVA). The criterion for statistical significance was $p < 0.05$.

Results and Discussion

Transepithelial Electrical Resistance Measurements—Measurement of electrical resistance across the cellular layers is a convenient and relatively sensitive measure of the integrity and permeability of the layer. These measurements reflect predominantly the resistance across the tight junctions and not the cell membranes.[19–23] The transcellular electrical resistance of the SIRC rabbit corneal cell layers increased with time up to the eighth day of culture with a resistance of 2233.42 ± 15.2 Ω·cm^2 and remained constant through the 14th day of culture (Figure 2). The electrical resistances shown by the SIRC cell line are slightly higher than the transepithelial resistances across the corneal membranes (2 kiloohms·cm^2).[24] However, methods used to derive resistance values from cell monolayers and excised tissue are different, and therefore comparisons should be considered with caution. The resistance values shown by the cell layers used in the flux experiments are slightly lower due to effects of media changes during washing. The TEER values were constant

Table 1—The Flux and P_{app} Values of D-[1-^{14}C]Mannitol and [4-^{14}C]Testosterone across SIRC Cell Layers at Different pH Conditions[a,b]

	pH 4.0	pH 5.0	pH 6.0	pH 7.4
		Mannitol		
flux (ng/cm^2 hr)	4.03 ± 0.08	3.87 ± 0.11	3.86 ± 0.21	3.80 ± 0.22
$P_{app} \times 10^6$ (cm/s)	0.62 ± 0.02	0.59 ± 0.01	0.59 ± 0.02	0.58 ± 0.02
		Testosterone		
flux (ng/cm^2 hr)	462.8 ± 12.6	459.3 ± 16.8	451.9 ± 14.7	456.5 ± 18.1
$P_{app} \times 10^6$ (cm/s)	44.1 ± 1.2	43.8 ± 1.6	43.1 ± 1.4	43.5 ± 1.8

[a] Values are means ± SEM of at least three experiments. [b] The values were obtained from the permeation studies performed up to 120 min at pH 4.0 and 5.0 and up to 150 min at pH 6.0 and 7.4.

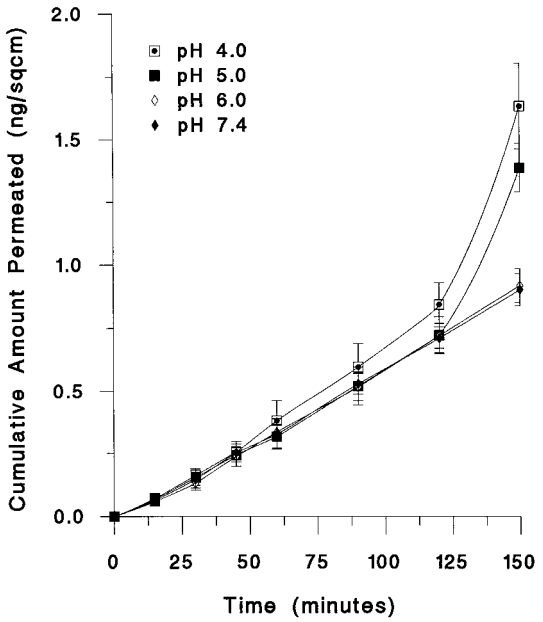

Figure 3—Apical to basolateral transport of mannitol across SIRC cell layers at different pH conditions. Each value represents average (±SEM) of at least three experiments.

throughout the transport studies at pH 6.0 and 7.4, but the values decreased when exposed to pH 4.0 and 5.0 after a period of 120 min.

Transport Studies—The permeability of the hydrophilic marker, D-[1-^{14}C]mannitol, was determined to further characterize the SIRC cell monolayers regarding its integrity as a molecular barrier. Mannitol, a molecule which is transported predominantly via the paracellular pathway, showed low permeabilities (0.58×10^{-6} cm/s) (Table 1) across the SIRC cell layers confirming that the cells formed tight junctions when grown on polycarbonate membranes. The permeability of mannitol across the SIRC cells was less when compared to the permeability across isolated corneal membranes.[25] Figure 3 shows the cumulative amount of mannitol permeated over time at different pH conditions. At pH 4.0, the mannitol permeability at 120 min was 0.62×10^{-6} cm/s and later increased to 2.1×10^{-6} cm/s. Similarly, the P_{app} values at pH 5.0 increased from 0.59×10^{-6} cm/s to 2.02×10^{-6} cm/s after 120 min. These differences in the permeabilities of the paracellular marker over time (and decrease in the resistance values) might be due to the damage caused to the surface layers of the SIRC cells when exposed to low pH conditions.

The gradual and reproducible development of resistance across the SIRC cells, when grown in culture medium, allowed study of the permeability characteristics of a group of novel mydriatic agents, esters of phenylephrone, and the lipophilic marker, testosterone. The highly lipophilic molecule, testosterone, is transported via the transcellular pathway. Testosterone exhibited a high permeability (43.5×10^{-6} cm/s) in the SIRC model at pH 7.4 (Table 1). Figure 4 illustrates the apical to basolateral transport of the phenylephrone esters, mannitol, phenylephrine, and testosterone across SIRC cell layers at pH 7.4.

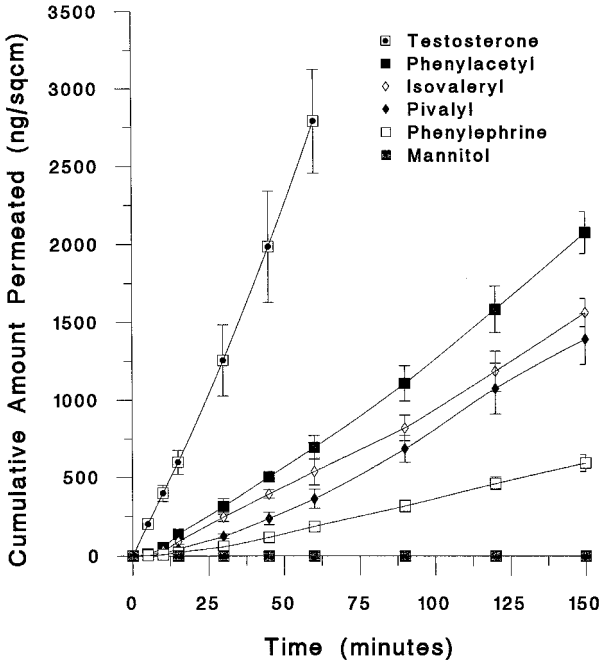

Figure 4—Apical to basolateral transport of testosterone, phenylephrone CDS, phenylephrine, and mannitol across SIRC cell layers at pH 7.4. Each value represents average (±SEM) of at least three experiments.

Table 2—The Flux, P_{app}, and Lag Time Values of Phenylephrone Esters across SIRC Cell Layers at Different pH Conditions[a,b]

	flux (μg/cm^2 h)	$P_{app} \times 10^6$ (cm/s)	lag time (h)
		Phenylephrine	
pH 4.0	0.33 ± 0.04	3.20 ± 0.08	0.51 ± 0.05
pH 5.0	0.35 ± 0.03	3.42 ± 0.10	0.49 ± 0.03

pH 6.0	1.19 ± 0.01	11.65 ± 0.11	0.17 ± 0.02
pH 7.4	1.31 ± 0.04	12.86 ± 0.38	0.12 ± 0.02

[a] Values are means ± SEM of at least three experiments. [b] The values were obtained from the permeation studies performed up to 120 min at pH 4.0 and 5.0 and up to 150 min at pH 6.0 and 7.4.

The physicochemical properties of the diffusing solute and the physiologic function of the cell layer involved are the important factors affecting the transport rate. The phenylephrone esters had molecular weights 285.7−305.6, pK_a's 7.19−7.21, and log P values ranging from 1.92 to 2.35.[9] As shown in Table 2, the permeabilities of all the esters were significantly higher than that of mannitol ($p < 0.05$), indicating that the compounds might be permeat-

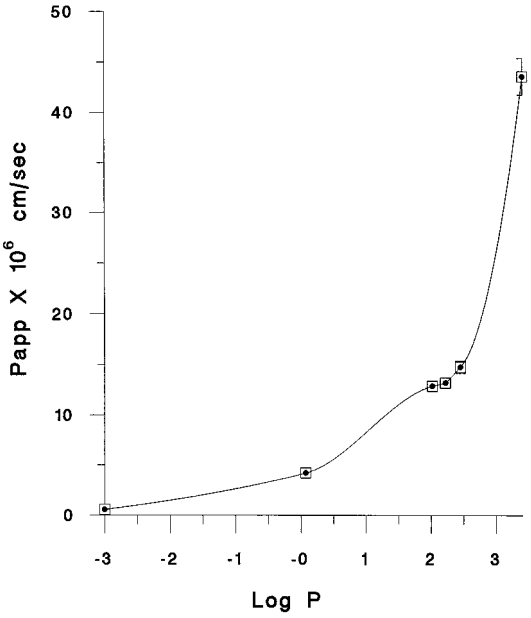

Figure 5—Relationship between apparent permeability coefficients of the various drugs and their respective log octanol–water partition coefficients at pH 7.4. From left to right, the compounds are mannitol, phenylephrine, pivalyl, isovaleryl, phenylacetyl esters of phenylephrone and testosterone. Each value represents average (±SEM) of at least three experiments.

ing via the transcellular pathway. Hamalainen et al. reported that molecules having a molecular weight less than 500 permeate through paracellular route.[26] Since all the compounds under investigation have low molecular weight, the paracellular route can also be considered as a pathway for permeation.

The permeabilities of the phenylpehrone CDS ranged from 12.86×10^{-6} cm/s to 14.76×10^{-6} cm/s at pH 7.4 and were found to be 3-fold higher compared to phenylephrine (4.21×10^{-6}). The rank order of permeation of the esters at any given pH was in accordance with their lipophilicities (**1** > **2** > **3**).[27] Phenylacetyl ester (**1**), which is the most lipophilic, exhibited a higher permeability compared to isovaleryl (**2**) and pivalyl (**3**) esters. Figure 5 illustrates the relationship between log octanol/water partition coefficients and transport rates of the compounds.

Permeability of all the three compounds was markedly dependent on the pH of the transport medium and also on the resistance of SIRC cell layers. The change in pH will affect the degree of ionization of the drug molecule if the drug has pK_a-value in that specific region. At pH 6.0 and pH 7.4, the esters showed significant differences in their permeation at all time points after 15 min ($p < 0.05$) but at pH 4.0 and pH 5.0 the differences in the amount permeated were found significant ($p < 0.05$) at time points after 45 min. At pH 6.0 and 7.4, the P_{app} value of phenylacetyl ester was significantly different from isovaleryl and pivalyl but at pH 4.0 and 5.0, only phenylacetyl and pivalyl esters showed significant difference in their P_{app} values. At higher pH conditions, the compounds under investigation predominantly exist in un-ionized form, causing an increase in diffusion through transcellular pathway resulting in higher permeabilities. The results showed decrease in permeabilities and increase in lag times of the compounds at lower pH conditions. One possible reason for the lag times might be due to the hydrolysis of the esters during the transport studies which are undetectable in the initial time points. Compound **2** showed higher lag time compared to **1** and **3** because of its higher rate of hydrolysis.[9] It is also possible that the lag times may be due to the hydrogen bonding between the compounds and the structures within the intercellular space that could impede molecular movement.[28]

The epithelia are negatively charged and are selective to positively charged solutes at physiological pH or pH above the isoelectric point (pI). Below the pI the reverse was observed.[29,30] Compounds used in this study are positively charged at low pH conditions and are excluded from absorption through aqueous paracellular pathway. This could be another possible explanation for the high lag times and low permeabilities of the phenylephrone esters at low pH conditions.

Conclusions

This paper reports the transport characteristics of the novel mydriatic agents and also the use of SIRC rabbit corneal cell line as an in vitro cell culture model for assessing corneal transport of drug molecules. The SIRC cell layers when grown on polycarbonate membranes exhibited high TEER and a low permeability to the hydrophilic marker, mannitol. This barrier property functionally characterizes these cell lines as "tight" ion transporting cell layers. Testosterone (a lipophilic molecule with a log *P* of 3.31), however, showed a high permeability across the SIRC cells. The results of this investigation suggest that the SIRC cell line, when grown on polycarbonate membranes, is a valid in vitro cell culture model for the study of corneal absorption and transepithelial transport of drugs. Studies on the permeability characteristics of novel mydriatic agents across the SIRC cell layers have shown that the esters of phenylephrone had higher transport rates compared to phenylephrine. The rate and extent of the transport of these compounds are influenced by the fraction of ionized and un-ionized species (which in turn depends on the pK_a of the drug and the pH of the solution) and the intrinsic partition coefficient of the drug. Studies are in progress to test the pharmacological activity and to assess the in vivo distribution and metabolism of the novel compounds in rabbits eyes.

Abstract □ The purpose of these studies was to determine the distribution of a lipophilic antimalarial agent, halofantrine hydrochloride (Hf), in fasted plasma from hypo-, normo-, and hyperlipidemic patients that displayed differences in lipoprotein concentration and lipid transfer protein I (LTP I) activity. To assess the influence of modified lipoprotein concentrations and LTP I activity on the plasma distribution of Hf, Hf at a concentration of 1000 ng/mL was incubated in either hypo-, normo-, or hyperlipidemic human plasma for 1 h at 37 °C. Following incubation, the plasma samples were separated into their lipoprotein and lipoprotein-deficient plasma (LPDP) fractions by density gradient ultracentrifugation and assayed for Hf by high-pressure liquid chromatography. The activity of LTP I in the dyslipidemic plasma samples was determined in terms of its ability to transfer cholesteryl ester from low-density lipoproteins (LDL) to high-density lipoproteins (HDL). Total plasma and lipoprotein cholesterol (esterified and unesterified), triglyceride, and protein levels in the dyslipidemic plasma samples were determined by enzymatic assays. When Hf was incubated in normolipidemic plasma for 1 h at 37 °C, the majority of drug was found in the LPDP fraction. When Hf was incubated in human plasma of varying total lipid, lipoprotein lipid, and protein concentrations and LTP I activity, the following relationships were observed. As the triglyceride-rich lipoprotein (TRL) lipid and protein concentration increased from hypolipidemia through to hyperlipidemia, the proportion of Hf associated with TRL increased ($r > 0.90$). As the HDL lipid and protein concentration increased, the proportion of Hf associated with HDL decreased ($r > 0.70$). As the total and lipoprotein lipid levels increased, the LTP I activity of the plasma also proportionally increased ($r > 0.85$). Furthermore, with the increase in LTP I activity, the proportion of Hf associated with the TRL fraction increased ($r > 0.70$) and the proportion of Hf associated with the HDL fraction decreased ($r > 0.80$). In addition, a positive correlation between the proportion of apolar lipid and Hf recovered within each lipoprotein fraction was observed within hypo- ($r > 0.80$), normo- ($r = 0.70$), and hyperlipidemic ($r > 0.90$) plasmas. These findings suggest that changes in the HDL and TRL lipid and protein concentrations, LTP I activity, and the proportion of apolar lipid within each lipoprotein fraction may influence the plasma lipoprotein distribution of Hf in dyslipidemia.

Introduction

Lipoproteins are macromolecules of lipid and protein that transport lipids through the vascular and extravascular bodily fluids.[1] Great diversity in the composition and physical properties of lipoproteins are possible, particularly in disease states. However, it is becoming apparent that lipoproteins have a wider biological significance than simply in lipid transport. It has been demonstrated that the interaction of several compounds, including amphotericin B (AmpB)[2,3] and cyclosporine (CSA),[4] with plasma lipoproteins modifies the pharmacokinetics, tissue distribution, and pharmacologic activity of these compounds. In addition, recent studies have suggested that not only the relative levels of individual lipoproteins but also their lipid composition define the distribution of a number of hydrophobic compounds among plasma lipoproteins.[5−7]

Halofantrine (Hf), an effective agent in the treatment of malaria, has been shown to bind to lipoproteins upon incubation in human blood[8] and plasma.[9] Cenni et al.[8] have suggested that Hf interacts and binds mostly to low-density lipoproteins (LDL) and high-density lipoproteins (HDL) upon incubation in human blood from noninfected and malaria subjects. However two drawbacks of this work were that the Hf distribution experiments were not done at a physiologic temperature, but rather at 20 °C, and that the total Hf recovery from plasma was as low as 40%. Humberstone et al.[10] have demonstrated that the lipoprotein distribution of Hf within fasted and fed beagle plasma samples may be influenced by the relative pre- and postprandial lipoprotein profiles. Furthermore, McIntosh et al.[9] have recently concluded that these differences are regulated by the respective masses of core apolar lipoprotein lipid.

Recent studies have suggested that the binding of Hf to lipoproteins may also alter its pharmacokinetics and pharmacological effect. Humberstone et al.[10] have observed, following intravenous Hf administration to fasted and fed beagles, that a decrease in Hf clearance and a decrease in Hf volume of distribution was correlated with an increased binding of Hf to plasma lipoproteins in the post-prandial state compared with the fasted state. In addition, they demonstrated that the concentration that is inhibitory in 50% of test subjects (IC_{50}) of Hf within an in vitro culture of *Plasmodium falciparum* was significantly decreased when incubated in the presence of 10% post-prandial serum.[11] Taken together, these studies suggest that the effect of human dylipidemias (aberrant plasma lipoprotein and lipid concentrations) on the plasma distribution of Hf merit further investigation.

Most patients infected with malaria may exhibit disturbances in their lipid metabolism resulting in modified lipoprotein−lipid composition,[8] so we conducted studies to

determine whether the human plasma distribution of Hf was influenced by changes in lipoprotein concentration and composition. Our working hypothesis was that the association of Hf with different lipoprotein classes would be influenced by the relative abundance of these lipid−protein complexes and apolar lipid content. In addition, because Hf is lipophilic, we believed that lipid transfer protein I (LTP I), an endogenous glycoprotein responsible for the transfer of lipids between lipoproteins,[12] may influence Hf lipoprotein distribution in a similar manner as it regulates the transfer of AmpB[13] and CSA[14] between HDL and LDL.

Materials and Methods

Chemicals and Plasma—Halofantrine was provided by Smith-Kline Beecham Pharmaceuticals (King of Prussia, PA). Sodium bromide was purchased from Sigma Chemical Company (St. Louis, MO). Liquid chromatography grade acetonitrile and *tert*-butyl methyl ether (TBME) were obtained from Fisher Canada (Montreal, Quebec). Electrophoresis grade sodium dodecyl sulfate (SDS) was obtained from Eastman Kodak (Rochester, NY). Fasted human plasma samples from hypolipidemic, normolipidemic, and a hyperlipidemic subjects were obtained from the Vancouver Red Cross (Vancouver, British Columbia). Ten microliters of 0.4 M ethylenediaminetetraacetic acid, pH 7.1 (EDTA; Sigma Chemical Company) was added to 1.0 mL of whole blood. In this study, a hypolipidemic plasma sample was defined as having a total plasma cholesterol of <130 mg/dL and total plasma triglyceride of <100 mg/dL, a normolipidemic plasma sample was defined as having a total plasma cholesterol of 130−200 mg/dL and total plasma triglyceride of 100−200 mg/dL, and a hyperlipidemic plasma sample was defined as having a total plasma cholesterol of >350 mg/dL and total plasma triglyceride of >280 mg/dL.[1] For all Hf plasma distribution studies, Hf was dissolved in 100% methanol. The addition of methanol alone did not modify lipoprotein−lipid composition or plasma LTP I activity (data not shown).

Lipoprotein Separation—The plasma was separated into its HDL, LDL, triglyceride-rich lipoproteins (TRL), which consists of VLDL and chylomicrons, and lipoprotein deficient plasma (LPDP) fractions by ultracentrifugation.[15,16] Briefly, human plasma (3.0 mL) samples were placed in centrifuge tubes and their solvent densities were adjusted to 1.006 g/mL by sodium bromide. Following centrifugation (L8−80M; Beckman Canada) at 50 000 rpm for 18 h at 4 °C, the TRL-containing and TRL-deficient plasma fractions were recovered. The TRL-deficient plasma fraction was readjusted to a density of 1.063 g/mL and respun at 50 000 rpm for 18 h at 4 °C to separate the LDL-rich and TRL/LDL-deficient plasma fractions. This fraction was readjusted to a density of 1.21 g/mL and respun at 50 000 rpm for 18 h at 4 °C to separate the HDL-rich and lipoprotein-deficient plasma (LPDP) fractions.

Isolation and Purification of Lipid Transfer Protein (LTP I)—LTP I was purified from human lipoprotein-deficient plasma as has been previously described.[12] Briefly, citrated human plasma was made lipoprotein deficient by the dextran−$MnCl_2$ procedure of Burstein and co-workers.[17] LTP I was then partially purified by sequential chromatography on phenyl-Sepharose and carboxy methyl cellulose gel (CM-52, Whatman Inc., Chifton, NJ). Partially purified LTP I (1.05 mg protein/mL), enriched 800-fold relative to lipoprotein-deficient plasma, was stored at 4 °C in 0.01% disodium EDTA, pH 7.4. The CM-cellulose fraction of LTP I was used in all experiments.

Radiolabeling of Plasma Lipoproteins—Human LDL was labeled by the lipid dispersion technique as previously described.[12] Briefly, human plasma was incubated with a lipid dispersion containing egg phosphatidylcholine (PC), triglyceride (5 mol %), and [^{3}H]cholesteryl ester (CE) (12 mol %) at 37 °C for 20−24 h in the presence of LTP I and diethyl (*p*-nitrophenyl) phosphate. Then the LDL fractions were isolated from the total lipoprotein precipitate by centrifugation as previously described. LDL had a specific activity of 3.423×10^6 cpm/mL (1352 cpm/μg of total cholesterol).

Lipid Transfer Assays—To assess the LTP I activity within the different human plasma samples used in this study, the following protocol was used. Lipid (CE) transfer was performed within the lipoprotein-deficient plasma samples as has been previously described.[14,18] Typically, 10 μg (total cholesterol) of radiolabeled donor (^{3}H−CE LDL) and unlabeled acceptor (HDL) are incubated ± LTP I source (which are the different delipidated human plasma samples used in this study), pH 7.4, for 90 min at 37 °C. Lipid transfer between donor and acceptor lipoprotein is then quantitated by scintillation counting. The fraction of lipid and drug transferred (kt) was calculated as described by Pattnaik and Zilversmit:[19]

$$k_t = -\ln(1 - A_t/D_0) \quad (1)$$

where D_0 and A_t are the amounts of radioactivity in the donor at time 0 and in the acceptor at time t, respectively. The constant k is the fraction of label transferred per unit time (t). Acceptor radioactivity in the absence of LTP (usually < 2−3%) is subtracted before calculating k_t values. Calculations assume steady-state conditions, where all lipid transfer is an exchange process. To minimize calculation errors due to mass transfer, all values were determined from assays in which the extent of radiolabel transfer was small (≤15%).

Quantification of Halofantrine—Plasma lipoprotein and lipoprotein-deficient samples containing Hf (1-mL aliquot) were mixed with 2 mL of acetonitrile and 8 mL of TBME; the mixture was vortexed for 30 s after the addition of acetonitrile and TBME and centrifuged (2000x g for 2 min). The supernatant was transferred to another tube, dried under nitrogen at 30 °C, and reconstituted with 0.5 mL of acetonitrile. The reconstituted extractant was analyzed against an external standard calibration curve for Hf by a high-pressure liquid chromatography (HPLC) procedure developed by Humberstone and co-workers.[20] The internal standard used to account for variation between samples is 2,4-dichloro-6-trifluoromethyl-9-{1-(2-(dibutylamino)ethyl)}-phenanthrenemethanol.[20] The HPLC system consisted of a Beckman model 110A pump, a Shimadzu SIL-9A autoinjector, and a Shimadzu SPD-6A variable wavelength detector. The detector was set at a wavelength of 257 nm, with absorbance sensitivity of 0.05 absorbency units, full scale. Results were recorded on a Shimadzu C−R3A chromatopac integrator. For chromatographic separation, a ultrasphere ODS column (4.6 mm × 25 cm) packed with trimethylsilyl particles (particles of 5 μm in diameter) was used at ambient temperatures. The mobile phase consisted of 75:25 (v/v) acetonitrile:water with 0.2% (w/v) SDS and 0.2% (V/v) glacial acetic acid at a flow rate of 1.5 mL min^{-1}. This assay had a limit of quantitation for Hf of 39 ng/mL and external calibration curves in total plasma, lipoprotein, and lipoprotein-deficient fractions that were linear in a concentration range of 39−5000 ng/mL of Hf (r > 0.90), with an intraday coefficient of variation of 5−8%.

Determination of Plasma Lipoprotein Triglyceride, Cholesterol, and Protein Concentrations—Total plasma triglycerides (TG), cholesterol, and protein concentrations were determined by enzymatic assays purchased from Sigma Diagnostics (St. Louis Mo.) as previously described.[17] The external calibration curve for plasma and lipoprotein triglyceride was linear in a concentration range 10−300 mg/dL (r > 0.95), for cholesterol was linear in a concentration range 10−450 mg/dL (r > 0.96), and for protein was linear in a concentration range of 5−2000 mg/dL (r > 0.90). Free cholesterol was determined using an enzymatic assay purchased from Boehringer Mannheim and was linear in a concentration range 1−100 mg/dL (r > 0.90). Cholesteryl ester concentration was determined by calculating the difference between total and free cholesterol.

Halofantrine (Hf) Distribution Studies in Specific Human Plasma Samples of Varying Lipoprotein Concentration and Composition and LTP I Activity—To gain an understanding on how lipoprotein lipid and protein concentration and LTP I influences the plasma distribution of Hf, Hf (1000 ng/mL) was incubated in 3 mL of plasma samples (total amount of Hf in plasma was 3000 ng) from three different patients (hypo-, normo-, and hyperlipidemic) of varying total and lipoprotein cholesterol, triglyceride, and protein concentrations (Table 1) and composition (Table 2) for 60 min at 37 °C. A Hf concentration of 1000 ng/mL was chosen as a value broadly representative of serum concentrations expected in a clinical enviroment.[21] Following incubation, the plasma was cooled to 4 °C to prevent any drug redistribution (data not shown) and separated into its lipoprotein and lipoprotein-deficient fractions by density gradient ultracentrifugation, and each fraction was quantified for Hf by HPLC.[20] To ensure that the distribution of Hf found in each of these fractions was a result of its association with each lipoprotein or lipoprotein-deficient

[a] Data are expressed as mean ± standard deviation ($n = 4$ replicates for hypolipidemic and $n = 6$ replicates for normolipidemic and hyperlipidemic); (*) $p < 0.05$ versus hypolipidemic; (**) $p < 0.05$ versus normolipidemic; TC, total cholesterol (esterified + unesterified); TG, total triglycerides; TP, total protein; wt/wt, weight/weight; plasma type, hypolipidemic (total cholesterol <130 mg/dL and triglyceride < 100 mg/dL); normolipidemic (total cholesterol 130–200 mg/dL and triglyceride 100–200 mg/dL); hyperlipidemic (total cholesterol > 350 mg/dL and triglyceride > 280 mg/dL).

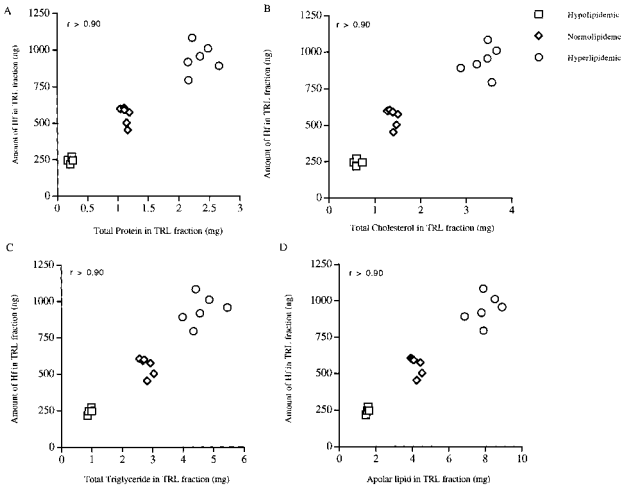

Figure 1—Distribution of Hf at 1000 ng/mL incubated for 60 min at 37 °C in hypolipidemic, normolipidemic, or hyperlipidemic plasma samples: (A) triglyceride-rich lipoprotein (TRL) protein; (B) TRL cholesterol, (C) TRL TG; and (D) TRL apolar lipid (cholesteryl ester and triglyceride) content versus the amount of Hf within the TRL fraction.

fraction and not a result of the density of the drug, the density profile of Hf reconstituted in 100% methanol and incubated in lipoprotein-deficient plasma was determined by ultracentrifugation. The majority of Hf (>85%) was found in the density range >1.21 g/mL (data not shown), suggesting that the Hf distribution within the ultracentrifuge tubes following incubation in human plasma is not a function of drug density.

In addition, to provide further evidence that LTP I may facilitate the movement of Hf between lipoprotein fractions, the lipoprotein distribution of Hf within normolipidemic human plasma (containing 1.0 μg protein/mL of LTP I), which has been supplemented with exogenous LTP I (0.67 μg protein/mL), was determined.

Data and Statistical Analysis—Correlation coefficients between the amount of Hf recovered within the TRL, HDL, and LDL plasma fractions and the amount of cholesterol, triglyceride, and protein within these fractions (Figures 1–3), proportion of apolar lipid within each lipoprotein fraction (Figure 4), and LTP I activity (Figure 5) were determined using Pearson's test. Differences in the human plasma distribution of Hf following incubation in human plasmas of varying lipid and protein concentrations were determined by a two-way analysis of variance (PCANOVA; Human Systems Dynamics). Critical differences were assessed by Neuman–Keuls posthoc tests. Differences were considered significant if p was <0.05. All data are expressed as mean ± standard deviation.

Results and Discussion

Total and Lipoprotein Lipid and Protein Levels in Plasma from Human Subjects—The differences in total and lipoprotein plasma cholesterol (esterified + unesterified), triglyceride, and protein concentrations and composition between hypolipidemic, normolipidemic, and hyperlipidemic human subjects chosen for this study are reported in Tables 1 and 2.

Distribution of Halofantrine (Hf) Following Incubation in Plasma from Human Subjects with Varying Lipid Concentrations—Table 3 reports the plasma distribution of Hf at 1000 ng/mL within plasma obtained from hypolipidemic, normolipidemic, and hyperlipidemic human subjects following incubation for 60 min at 37 °C. A significantly greater percentage of Hf was recovered within the TRL fraction following incubation in hyperlipidemic and normolipidemic patient plasma for 60 min at 37 °C than following incubation in hypolipidemic patient plasma. At the same time, a significantly lower percentage of Hf was recovered within the HDL fraction following incubation in hyperlipidemic and normolipidemic patient plasma samples than following the incubation in hypolipidemic patient plasma samples. In addition, a significantly higher percentage of Hf was recovered within the TRL fraction and significantly lower percentage of Hf was recovered in the HDL and LPDP fractions following incubation in hyperlipidemic compared with normolipidemic patient plasma samples.

Table 3—Distribution of Halofantrine Hydrochloride (Hf·HCl) at 1000 ng/mL within Fasted Plasma from Three Individual Patients Following Incubation for 60 min at 37 °C (following incubation plasma samples were assayed by high-pressure liquid chromatography for drug in each of the lipoprotein and lipoprotein-deficient plasma fractions)[a]

[a] Data are expressed as mean ± standard; (*) $p < 0.05$ vs hypolipidemic patients; (**) p, 0.05 versus normolipidemic patients. [b] Percent of initial Hf·HCL concentration. [b] Percent of initial drug incubated; LPDP, lipoprotein-deficient plasma; HDL, high-density lipoprotein; LDL, low-density lipoprotein; TRL, triglyceride-rich lipoproteins, which includes very-low-density lipoproteins and chylomirons; LTP I, lipid transfer protein I; k, fraction of labeled lipid transferred; t, time; plasma type, hypolipidemic (total cholesterol < 130 mg/dL and triglyceride < 100 mg/dL); normolipidemic (total cholesterol 130–200 mg/dL and triglyceride 100–200 mg/dL); hyperlipidemic (total cholesterol > 350 mg/dL and triglyceride > 280 mg/dL).

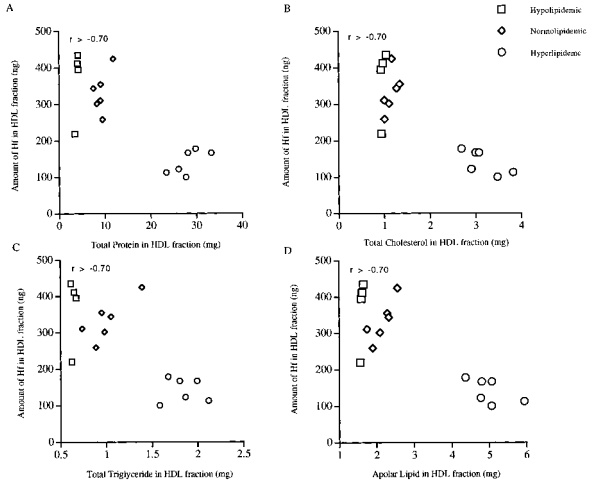

Figure 2—Distribution of Hf at 1000 ng/mL incubated for 60 min at 37 °C in hypolipidemic, normolipidemic, or hyperlipidemic plasma samples: (A) high-density lipoprotein (HDL) protein; (B) HDL cholesterol; (C) HDL TG; and (D) HDL apolar lipid (cholesteryl ester and triglyceride) content versus the amount of Hf within the HDL fraction.

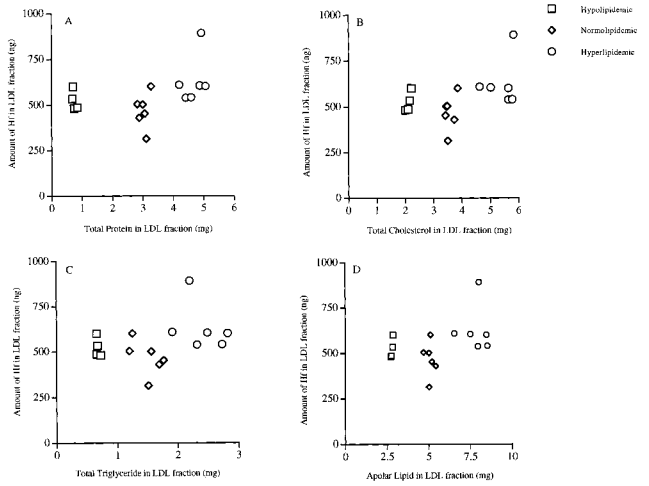

Figure 3—Distribution of Hf at 1000 ng/mL incubated for 60 min at 37 °C in hypolipidemic, normolipidemic, or hyperlipidemic plasma samples: (A) low-density lipoprotein (LDL) protein; (B) LDL cholesterol; (C) LDL TG; and (D) LDL apolar lipid (cholesteryl ester and triglyceride) content versus the amount of Hf within the LDL fraction.

When correlations between the amount of Hf recovered within the TRL, LDL, and HDL plasma fractions and the amount of cholesterol, triglyceride, and protein were calculated for all three patient plasma subgroups, the following relationships were observed. As TRL cholesterol, triglyceride, protein, and apolar lipid (cholesteryl esters and triglycerides) levels increased, the amount of Hf recovered in this fraction proportionally increased (Figure 1; $r > 0.70$). However, as HDL cholesterol, triglyceride, protein, and apolar lipid levels increased, the amount of Hf recovered in this fraction proportionally decreased (Figure 2; $r > 0.70$). Although no correlation between LDL lipid and protein levels and the amount of Hf recovered in this fraction was observed (Figure 3), a positive correlation between the proportion of apolar lipid and percentage of Hf recovered within each lipoprotein fraction was observed within all three plasma groups (Figure 4; $r > 0.70$).

We have further observed that although HDL cholesterol, triglyceride, and protein concentrations increased 3-fold, 3-fold, and 7-fold, respectively, from hypolipidemia through to hyperlipidemia (Table 1), the percent (Table 3)

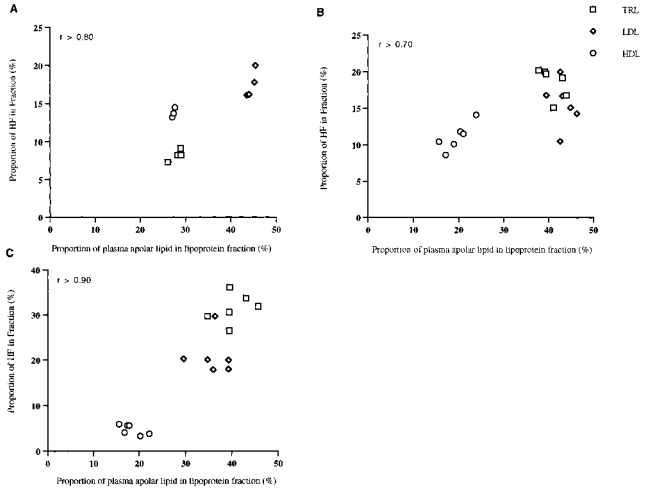

Figure 4—(A) Correlation between the percentage of Hf recovered in triglyceride-rich (TRL), low-density (LDL), and high-density lipoprotein (HDL) fractions in hypolipidemic human plasma and the proportional distribution of apolar lipids (cholesteryl esters and triglycerides) within the individual lipoprotein fractions. (B) Correlation between the percentage of Hf recovered in TRL, LDL, and HDL fractions in normolipidemic human plasma and the proportional distribution of apolar lipids (cholesteryl esters and triglycerides) within the individual lipoprotein fractions. (C) Correlation between the percentage of Hf recovered in TRL, LDL, and HDL fractions in hyperlipidemic human plasma and the proportional distribution of apolar lipids (cholesteryl esters and triglycerides) within the individual lipoprotein fractions.

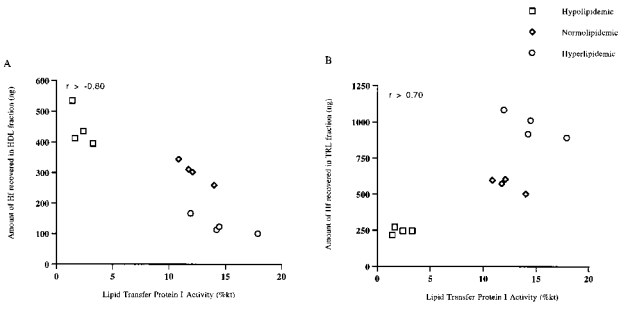

Figure 5—Lipid transfer protein I activity in hypolipidemic, normolipidemic, or hyperlipidemic plasma samples versus the amount of Hf within the (A) high-density lipoprotein (HDL) and (B) triglyceride-rich lipoprotein (TRL) fractions.

Table 4—Influence of LTP I on the Distribution of Halofantrine Hydrochloride (Hf·HCl) at 1000 ng/mL within Normolipidemic Human Plasma Following Incubation for 60 min at 37 °C (following incubation, plasma samples were assayed by high-pressure liquid chromatography for drug in each of the lipoprotein and lipoprotein-deficient plasma fractions)[a]

drug compound	TRL plasma fraction, %[b]	LDL plasma fraction, %	HDL plasma fraction, %	LPDP fraction, %	percent recovery
Hf·HCL	19.9 ± 2.7	20.8 ± 2.5	17.1 ± 1.1	42.1 ± 2.7	83.2 ± 4.2
Hf·HCL + LTP I	44.9 ± 2.7*	12.7 ± 2.0*	7.9 ± 1.2*	34.6 ± 1.9*	98.3 ± 8.9*

[a] Data are expressed as mean ± standard deviation ($n = 6$); (*) $p < 0.05$ vs Hf·HCl; 33 μL CM-LTP I (containing 0.67 μg of LTP I) added to 1 mL of plasma. [b] Percent of initial Hf·HCL concentration. [c] Percent of initial drug incubated; LPDP, lipoprotein-deficient plasma; HDL, high-density lipoprotein; LDL, low-density lipoprotein; TRL, triglyceride-rich lipoproteins, which includes very low-density lipoproteins and chylomicrons; LTP I, lipid transfer protein I; normolipidemic human plasma had a total cholesterol of 161 mg/dL and endogenous LTP I concentration of 1.05 μg protein/mL.

and amount (Figure 2) of Hf recovered within the HDL fraction significantly decreased. However, in these same plasmas, TRL cholesterol, triglyceride, and protein concentrations increased 5.5-fold, 5-fold, and 10-fold, respectively, from hypolipidemia through to hyperlipidemia (Table 1). This resulted in a significant and proportional increase in the percent (Table 3) and amount (Figure 1) of Hf recovered within the TRL fraction. These findings suggest that Hf lipoprotein distribution may be regulated by mass plasma lipoprotein triglyceride concentrations and the number of TRL particles present within plasma. Thus, Hf moved from one lipoprotein class to another and its movement could be influenced by different disease states, such as malaria, and adjunct therapies, such as Intralipid infusion,[3] where lipoprotein composition and plasma concentrations are altered. Furthermore, not only are triglyceride mass and particle number important factors in determining Hf lipoprotein distribution, but to which lipoprotein subfraction changes in composition ocurr may also be important in determining to which component the drug binds. It further appears that TRL may be more effective at binding Hf than either HDL or LDL as you increase lipoprotein lipid-load and particle number.

Influence of Lipid Transfer Protein I (LTP I) on the Plasma Distribution of Halofantrine (Hf)—The LTP I activity within the plasma of these patients were determined by measuring the transfer rate of [^{3}H]CE from LDL to HDL. As the total plasma and lipoprotein lipid concentrations increased from hypolipidemia through to hyerlipidemia, LTP I activity increased from 2.2 ± 0.8% k_t to 14.6 ± 2.5% k_t (Table 3). Furthermore, as LTP I-mediated transfer of CE increased, the amount of Hf recovered in the HDL fraction decreased (Figure 5A), whereas the amount of Hf recovered in the TRL fraction increased (Figure 5B). In addition, a significantly lower percentage of Hf was recovered in the LDL, HDL, and LPDP fractions and a significantly greater percentage of Hf was recovered in the TRL fraction compared with controls when fasted normolipidemic plasma containing 1 μg protein/mL of LTP I was supplemented with 0.67 μg protein/mL of exogenous LTP I (Table 4).

Taken together, these studies demonstrate that as LTP I activity increases, the proportion of Hf associated with the TRL fraction increases ($r > 0.70$) and the proportion of Hf associated with HDL decreases ($r > 0.80$). Because LTP I is the protein that catalyzes the transfer exchange of apolar lipids CE from CE-rich lipoproteins (HDL and LDL) for TG from TG-rich lipoproteins (i.e., VLDL and chylomicrons), our findings suggest that Hf plasma distribution may be related to its lipoprotein apolar lipid content. This suggestion is further supported by the observation within hypo- ($r > 0.80$), normo- ($r = 0.70$), and hyperlipidemic ($r > 0.90$) plasma samples that a proportionally greater percentage of Hf was recovered in those lipoprotein fractions that contained a larger proportion of apolar lipid (Figure 4). These findings are in agreement with our previous studies in pre- and postprandial plasma samples from beagles and humans,[9] where it was concluded that the mechanism of Hf association with plasma lipoprotein was primarily by way of solubilization in the apolar lipid core.

Summary

In conclusion we have determined that Hf associates with lipoproteins upon entrance into the plasma component of the bloodstream and that the distribution of Hf among lipoproteins is defined by the relative levels of individual lipoproteins and the proportion of apolar lipid content within each lipoprotein fraction, and is influenced by LTP I. Furthermore, the amount of Hf recovered in the TRL and HDL fractions correlates to lipoprotein lipid and protein mass and LTP−I activity. The alterations in plasma lipoprotein concentrations, including decreases in HDL-cholesterol and elevations in TRL-triglyceride concentrations,[8] often exhibited by patients with malaria, raises the possibility of altered efficacy and/or toxicity of drugs, such as Hf, which associate with lipoproteins. Recently, Humberstone et al.[11] demonstrated that the IC_{50} of Hf was significantly increased when incubated in the presence of 10% post-prandial serum (which contains elevated TRL triglyceride serum concentrations) compared with normolipidemic serum in a continuous in vitro culture of *Plasmodium falciparum*. In addition, there is an apparent linkage between excessively high plasma Hf concentrations and cardiac toxicity in patients with or without a preexisting cardiopathy.[22] As higher plasma concentrations of Hf are typically observed after post-prandial administration, distribution of Hf into post-prandial lipoproteins (particularly TRL) may contribute to the cardiac side effects of Hf observed in these patients. Future studies are warranted to investigate the pharmacological implications of the predominant association of Hf with TRL when total plasma TG concentrations are elevated.

Abstract □ This work investigates the relationships between the wet mass consistency/viscosity of samples prepared in a mixer-granulator and physical properties of the dry granules produced from the wet mass; namely, size distribution, bulk density (Hausner ratio), friability, and flow avalanching behavior. The correlation between the consistency of the wet mass and the downstream dry granule properties confirms that consistency is the key parameter to control in wet granulation by mechanical agitation. Variations in the formulation affect the dimensionless power relationship of the mixer-granulator considered; that is, the equivalence between wet mass consistency and mixer net power consumption, which is actually the parameter used to monitor the wet granulation process. The same variations in formulation also affect the relationships between wet mass consistency and dry granule properties.

Introduction

Over recent years, a strategy based on the use of dimensionless numbers has been designed to allow a better control and scale-up of wet granulation processes in pharmaceutical mixer-granulators.[1−4] The granulation end point is classically detected by monitoring the power consumption of the mixer-granulator. In this new approach, a dimensionless power relationship is determined that summarizes the overall effect of various process parameters linked to the wet mass and to the mixer-granulator itself. Hence, knowing the wet mass characteristics wanted and the conditions in which the mixer is to be operated, the dimensionless power relationship is employed to give the corresponding target power consumption value that will signal the end point of the granulation.

However, several assumptions are made in this approach. In particular, the wet mass has to be considered as a continuous phase, which is described solely by the composition of its dry formulation, its wet bulk density, and viscosity. The viscosity of the wet mass is assessed using a mixer torque rheometer, an instrument that has been specifically developed to quantify the rheological consistency of the pharmaceutical wet masses.[4,5] It has been demonstrated that wet mass consistency was linearly proportional to wet mass viscosity,[5] while offering the advantage of being easier to measure. Intrinsically, it is also assumed in the methodology that if the wet mass quality can be reproduced, through the control of the wet mass consistency, then the quality of the dry granules produced downstream from the wet mass will also be controlled. This assumption presupposes that there exists a link between the wet mass consistency and the dry granule characteristics.

The objective of this work was to verify this assumption by proving the existence of a relationship between the wet mass consistency and several dry granule properties judged important with regards to tableting. The effect of formulation on the dimensionless power relationship of a given mixer-granulator will also be investigated.

Experimental Section

The wet mass samples were produced in a pharmaceutical, high-shear mixer-granulator (Aeromatic Fielder PMA 100 L, Eastleigh, Hampshire, UK) using five different hydrophilic formulations, coded as 'R', 'L', 'P', 'C', and 'D' and defined in Table 1. Lactose 450 mesh (DMV International, Veghel, The Netherlands), starch (National Starch and Chemical GmbH, Neustadt, Germany), pregelatinized starch (PGS, National Starch and Chemical GmbH, Neustadt, Germany), and dibasic calcium phosphate dihydrate (DCPD, Calipharm, UK) were generously supplied by Zeneca Pharmaceuticals. Lactose 200 mesh was a gift from DMV International, Veghel, The Netherlands. Poly(vinylpyrrolidone) (PVP K25) was supplied by BASF, Ludwigshafen, Germany.

Wet massing runs were carried out at different impeller speeds, whereas water was sprayed at a constant rate. The spray nozzle and the water flow rate were chosen to ensure a quick distribution of the water among the mix. Samples were withdrawn at regular intervals to give a range of increasing consistency values and were immediately analyzed for their bulk density and consistency.

The consistency was determined using a mixer torque rheometer (Caleva MTR, Sturminster-Newton, Dorset, UK) as previously described by Rowe and Parker,[4] run at a shaft speed of 50 rpm. A baseline was recorded for 20 s, then 35 g of wet sample was introduced and mixed for 30 s, and then data were recorded for 30 s. The wet mass consistency of the sample was calculated as the mean torque value recorded with the sample in the mixer less the mean torque value of the baseline recording. All reported values were the average of two determinations.

To obtain dry granules for further analysis, the wet mass samples were subsequently processed, by first passing through a 1000 μm screen, then tray-drying in an oven at 40 °C for 24 h, and finally screening once again through a 850 μm sieve. The undersized fractions were analyzed for size distribution (by sieve analysis); apparent bulk density (aerated and tapped to derive their Hausner ratio); flow (using an Aero-Flow, Amherst Process Instruments, Hadley, MA), based on an avalanching principle;[6] and friability index (using a modified test procedure in a Roche tablet friability test apparatus). The densities were determined in a tapping apparatus similar to that described in the European Pharmacopoeia (second edition, V.5.5.4.). The Aero-Flow measures the time intervals between avalanches generated within a granule sample placed in the slow rotating drum of the apparatus. The assay was made with the 1−600-μm fractions of the samples. The quantity used varied according to the density of the formulation, with 25 g for the lactose-based and 40 g for the DCPD-based formulations. Compilation of the frequency and irregularity of

these time intervals was then used to describe the flow behavior of the sample. In the friability test, 10 g of sample was used regardless of formulation, and the Roche tablet friabilator was run 5 min at 90 rpm with a sample and five small glass balls. The glass balls had a mean diameter of 16 mm and a density of 2.34 g/cm^3. They were preferred to lighter materials (plastic and wooden balls) to maximize the differences in results obtained from various granule samples. The friability index was taken as $100 - x$%, where x is the percentage of the original sample fraction 250–600 μm retained by a 250 μm sieve after testing. Similar methods are encountered in the literature with various drum speeds, sample sizes, and sieve fractions, and presence or absence of inert balls.[7–9] Mechanically stronger granules produce a lower friability index.

Results and Discussion

The dimensionless power relationship of the mixer-granulator gives the relationship between the power consumption of the mixer and the wet mass consistency. The following expression will be used:[2]

$$\log_{10} \mathrm{Np} = a + b^{*}\log_{10} (\Psi\mathrm{Re}^{*}\mathrm{Fr}^{*}\text{fill ratio}) \qquad (1)$$

where Np is the Power number

$$\mathrm{Np} = \frac{\Delta P}{\rho N^3 R^5} \qquad (2)$$

ΨRe is the pseudo Reynolds number

$$\Psi\mathrm{Re} = \frac{\rho N R^2}{\mu} \qquad (3)$$

Fr is the Froude number

$$\mathrm{Fr} = \frac{R N^2}{g} \qquad (4)$$

and fill ratio indicates the fraction of bowl working capacity occupied by the wet mass, and can be represented, for example, by[2]

$$\frac{\rho R_\mathrm{B}^3}{m} \qquad (5)$$

The dimensionless numbers 2 to 5 are defined with the following notations:

ΔP = the net power consumption of the mixer-granulator (W)

(total power consumption less power required to stir the dry mix)

m = the amount of wet mass (kg)

ρ = the wet mass bulk density (kg·m^{-3})

μ = the wet mass consistency (Nm)

N = the impeller rotational speed (s^{-1})

R = the impeller radius (m)

R_B = the bowl radius (m)

g = the gravitational constant (9.81 ms^{-2})

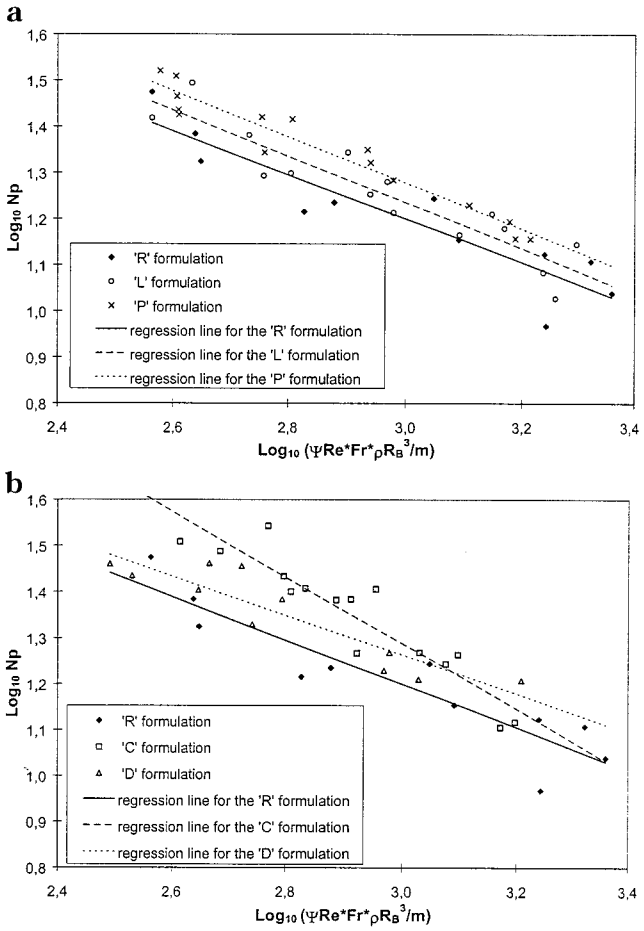

Figure 1—Scale-up relationships obtained for the five formulations tested in the Fielder PMA 100 L mixer-granulator.

Data from the experimental granulation runs were used to determine the dimensionless power relationship of the Fielder PMA 100 L mixer-granulator and to investigate the effect of formulation on this relationship. The results are graphically presented in Figures 1a and b. The statistical analysis on the regression lines was compiled using a statistical software package (SPSS 6 for Windows, SPSS UK Ltd, Chertsey, Surrey, UK) and the results are summarized in Table 2.

No statistical difference can be seen between the regression lines of the three lactose formulations. This result indicates that the dimensionless power relationship is little affected by the change of binder, from PGS to PVP, or by the change of filler particle size from lactose 450 mesh to lactose 200 mesh.

The slope and intercept of the regression line for the 'C' formulation, DCPD based, are distinct from these of the corresponding lactose 'R' formulation. Note, however, that as the confidence limits are determined at ± 1 standard deviation, the observations made are only at 68% confidence. At 95% confidence (i.e., $p = 0.05$), with the confi-

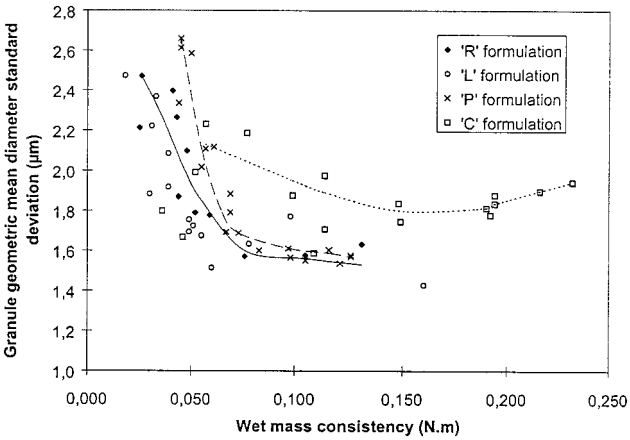

Figure 4—Relationship between the wet mass consistency and the dry granule size distribution standard deviation.

dence limits at ±1.96 standard deviation, the comparisons between slope and intercepts of the 'C' and 'R' regression lines are inconclusive.

When half the DCPD in the 'C' formulation is replaced by lactose 450 mesh ('D' formulation), the effect of this variation of filler on the slope and intercept of the regression line is again not significant. Interestingly the 'D' formulation does not behave intermediate to the 'C' and 'R' formulations but, on the contrary, would tend to present a curve similar to these of the lactose formulations.

To verify the quality of the model, or in other words the accuracy of the target net power consumption deduced from the dimensionless power relationship of the bowl, the case of the 'P' formulation was further studied. Figure 2 represents the percentage of error made in the estimation of ΔP with regards to the real value of ΔP measured experimentally, when the dimensionless power relationships specific to this formulation and the 'R' formulation are respectively used. Figure 2 shows that the dimensionless power relationship specific to the 'P' formulation permits a good prediction of the net power consumption, usually within 5% of error. On the other hand if the relationship established for the 'R' formulation is used, then the predicted power consumption value is systematically underestimated by around 10−20%. For scale-up purposes (i.e., when considering other geometrically similar bowls in the same series of mixer-granulators), it is therefore important to determine the dimensionless power relationship specific to the formulation considered to determine workable power consumption predictions.

In the remainder of this work, the dry granules obtained from the granulation runs on the different formulations were compared to study the link between the consistency of the mass prior to drying and the quality of the downstream granules, and to investigate once again the effect of varying the formulation.

Figures 3 to 6 illustrate the relationships found between the wet mass consistency and different dry granule properties; they are, geometric mean diameter by weight and its standard deviation, Hausner ratio, and friability index. With these tests no significant differences are seen between the three lactose formulations investigated, despite the change in binder composition (PVP or PGS) or in filler particle size (volume median diameter of lactose 450 and 200 mesh were respectively found to be 26 and 44 μm by laser diffraction, Malvern Instruments, Malvern, Worcestershire, UK). Only the granule size distribution of the 'P' formulation is slightly wider than that of the other two lactose formulations, at low levels of granulation (i.e., low wet mass consistency values).

The DCPD-based formulation, 'C', shows a distinct trend for granule size distribution and friability. Higher wet mass consistency values are required to obtain dry granules of a given size compared with the lactose formulation. The 'C' formulation is also more friable than its lactose counterparts, probably due to the absence of a 'secondary binder' effect. DCPD is indeed insoluble in water, the solvent used for granulation, whereas lactose is partially soluble and contributes therefore to the strength of the final dry bridges. The 'D' formulation, made up in equal parts of lactose 450 mesh and DCPD, was only analyzed for

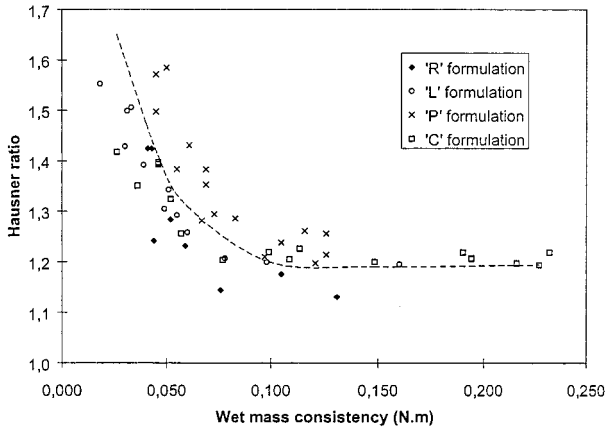

Figure 5—Relationship between the wet mass consistency and the dry granule Hausner ratio.

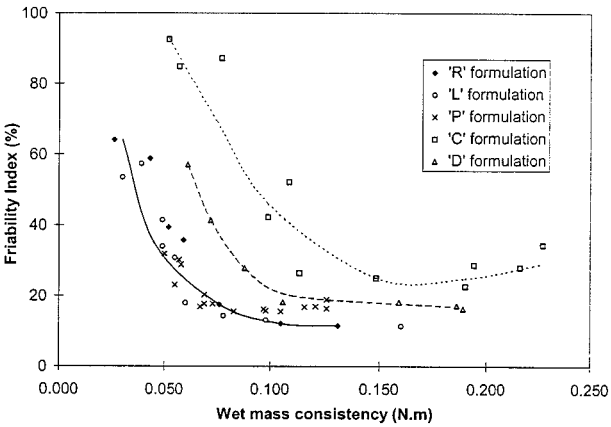

Figure 6—Relationship between wet mass consistency and the dry granule friability index.

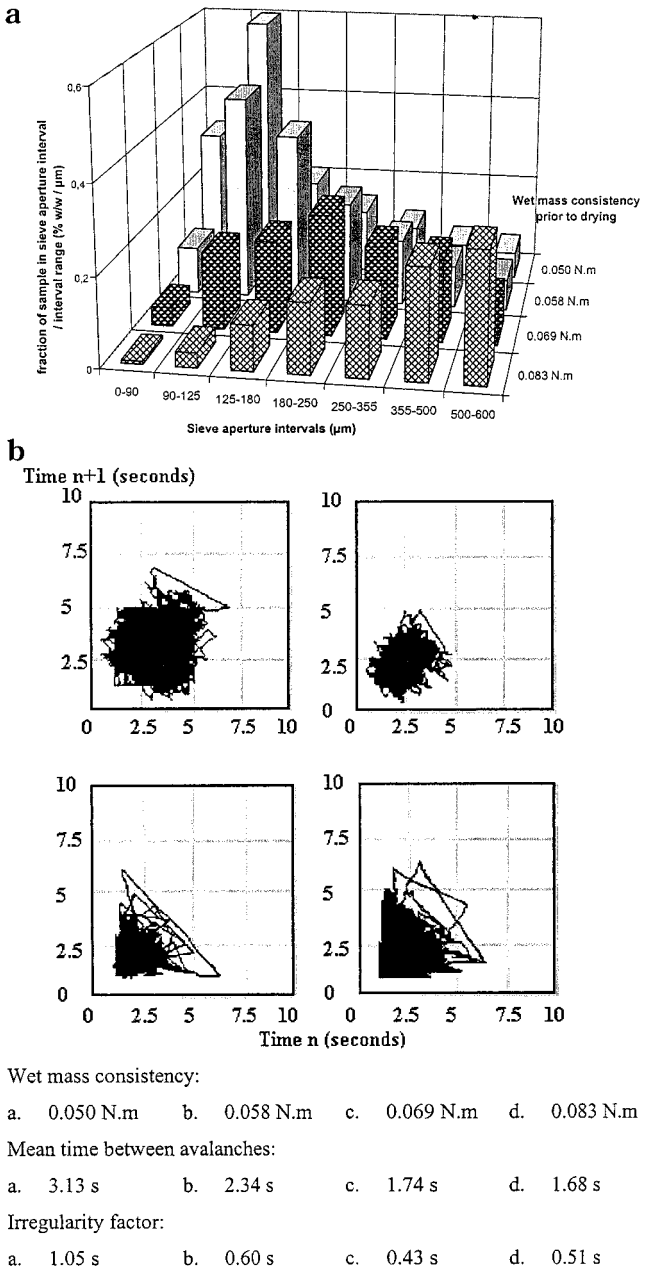
friability. It behaved somewhat intermediate to the 'R' and 'C' formulations, except at high wet mass consistency values, where the level of moisture is such that the lactose contribution to the granule strength was almost comparable to a pure lactose formulation. The differences found between the lactose- and DCPD-based formulations are unlikely to be due to the variation in initial particle size (volume median diameter of 14 μm for DCPD), as there was already no difference in the wet mass consistency/dry granule properties relationships between the 'R' and 'L' formulations.

Overall, it is observed that the dry granule properties considered vary almost linearly with the consistency of the original wet mass, up to approximately 0.08 Nm for the lactose-based formulations, and 0.12 Nm for the 'C' formulation. Above these respective values, further addition of binder liquid (water) does not significantly affect the granule growth and densification (granule geometric mean diameter, standard deviation, and Hausner ratio all roughly level off). Additionally, the mechanical strength of the dry granules stops improving at exactly the same levels of wet mass consistency.

The flow avalanching behavior of the granules was analyzed using the Aero-Flow. As an example, the patterns obtained for different samples prepared from one granulation run with the 'P' formulation are shown in Figure 7a. These graphical representations are compiled by plotting the time between avalanches number n and $n+1$ ('time n+1') against the time between avalanches number $n-1$ and n ('time n'), for $1 < n < n_t - 1$, where n_t is the total number of avalanches recorded during the analysis. Such plots are characterized by their centroid, representing the



Wet mass consistency:

a. 0.050 N.m b. 0.058 N.m c. 0.069 N.m d. 0.083 N.m

Mean time between avalanches:

a. 3.13 s b. 2.34 s c. 1.74 s d. 1.68 s

Irregularity factor:

a. 1.05 s b. 0.60 s c. 0.43 s d. 0.51 s

Figure 7—Example of granule size distribution and corresponding flow patterns observed on four granule samples of increasing wet mass consistency (taken for the same granulation run at 180 rpm with the 'P' formulation).

mean time between avalanches, and the scatter around the centroid (irregularity factor). Free-flowing materials will give a dense pattern (small irregularity factor), close to the origin of the axes (frequent avalanches). The link between the granule size distribution of each of these samples and their flow avalanching behavior is shown in Figure 7b. Flow improves with increasingly bigger granule size, but as the fines almost disappear, the flow of the corresponding sample reverses back to less regular.

It is therefore concluded that a single parameter, the wet mass consistency, can be used to describe a wet mass and the dry granules that will ultimately be generated from it. In this case study of five formulations, it is clearly unnecessary to carry on wet massing beyond the 0.08 Nm consistency value for the lactose-based formulations or 0.12 Nm for the 'C' formulation, as further addition will only lengthen the drying process but not significantly modify the dry granule properties. Hence, the optimal dry granules

should be probed among the batches with consistencies in the 0.02−0.08 and 0.02−0.12 Nm ranges, respectively.

In conclusion, this work has shown that the wet mass consistency, as determined by mixer torque rheometry, is an essential parameter in the development of pharmaceutical wet granulation processes. It links the 'wet' and 'dry' stages of the operation, in terms of downstream production of dry granules of reproducible, optimized properties. This finding also reinforces the strategy of the scaleup methodology presented in the *Introduction* of this paper; that is, the transfer of a wet granulation process to a different manufacturing scale should require the reproduction of the same wet mass consistency and bulk density. In addition, this work suggests that some changes in the formulation can lead to the modification of the dimensionless power relationship. This suggestion was particularly evident when the filler was changed from a soluble to an insoluble hydrophilic material. Although for the limited range examined particle size and binder composition appeared not to be critical factors, in practice, the prediction of the target endpoint power consumption will only be reasonable if the dimensionless power relationship specific to the formulation studied is employed. The individual behavior of the materials is not able to be summed up to predict the wet massing behavior of a mixture of these materials, as demonstrated for the case of the 'D' formulation.

Abstract □ We report thermal and crystallographic evidence for a previously unknown mannitol hydrate that is formed in the process of freeze-drying. The mannitol hydrate was produced by freeze-drying pure mannitol solutions (1–4% w/v) using the following cycle: (1) equilibration at –5 °C for 1 h; (2) freezing at –40 °C; (3) primary drying at –10 °C for 15 h; and (4) secondary drying at 10 °C for 2 h and then 25 °C for 5 h. This crystal form was also observed upon freeze-drying in the presence of sorbitol (1% w/v). The mannitol hydrate showed a distinct X-ray powder diffraction pattern, low melting point, and steplike desolvation behavior that is characteristic of crystalline hydrates. The mannitol hydrate was found to be metastable, converting to anhydrous polymorphs of mannitol upon heating and exposure to moisture. The amount of the mannitol hydrate varied significantly from vial to vial, even within the same batch. The formation of mannitol hydrate has several potential consequences: (1) reduced drying rate; (2) redistribution of the residual hydrate water during accelerated storage to the amorphous drug; and (3) vial-to-vial variation of the moisture level.

Introduction

The crystalline[1−11] and amorphous[12] forms of D-mannitol, a commonly used pharmaceutical excipient, have been extensively studied. The crystallization and polymorphic behaviors of mannitol have also been investigated in frozen aqueous solutions,[13−17] with an aim to understand and control the freeze-drying process. Unlike many excipients (e.g., sorbitol and disaccharides), mannitol has a strong tendency to crystallize from a frozen aqueous solution, both during cooling and reheating. The vial breakage phenomenon[13,14] is a striking illustration of this tendency. Mannitol has been observed to continue to crystallize after freeze-drying, especially as a result of heat and moisture,[18,19] which indicates that the freeze-drying process can produce a partially amorphous and partially crystalline material. The crystallization of mannitol during freeze-drying can lead to different anhydrous polymorphs (α, β, and δ) and their mixtures as a result of different formulation and processing conditions,[15] which leaves room for polymorphic transformations during storage. To the best of our knowledge, hydrated crystal forms of mannitol have not been reported.[20]

The formation of a crystalline hydrate by an excipient during freeze-drying may have several practical consequences. The difficulty of removing bound water from a crystal lattice can significantly limit the drying rate. Certain hydrates lose water without significantly altering the initial lattice structures ("isomorphic dehydration")[21] and lead to materials that are highly hygroscopic and undergo structural relaxation during storage. The residual water that is not removed by freeze-drying may be a potential threat to product stability if it is released during storage, especially under "accelerated" conditions.

We present here thermal and crystallographic evidence for a mannitol hydrate that is formed during freeze-drying and discuss the practical implications in terms of process design and product stability.

Experimental Section

Freeze-Drying—A laboratory freeze-drier (FTS Systems Inc.) was used. The following conditions produced the "mannitol hydrate" as characterized below: (1) equilibration at −5 °C for 1 h; (2) freezing at −40 °C; (3) primary drying at −10 °C for 15 h; and (4) secondary drying at 10 °C for 2 h and then 25 °C for 5 h. The cooling rate not controlled during freezing, and it took approximately 3 h to reach −40 °C. The chamber pressure was set to 100 μm of Hg throughout the drying process. Mannitol solutions were prepared at several concentrations (1, 2, and 4 w/v %) by dissolving mannitol (99+%, ACS reagent, Sigma; USP quality) in deionized water. The freeze-drying vials (tubing type manufactured by Wheaton) were 5 mL with 18.4 mm i.d. The fill volume was 2.0 mL/vial. The samples were stored at −20 °C before analysis.

XRD—A Siemens D5000 X-ray diffractometer was used, which was equipped with a Cu Kα source(λ = 1.54056 Å) operating at a tube load of 50 kV and 40 mA. The divergence slit size was 0.6 mm, the receiving slit 1 mm, and the detector slit 0.1 mm. Data were collected by a Kevex solid-state (SiLi) detector. The freeze-dried cake was broken, spread over the sample holder, and gently pressed before analysis. Each sample was scanned between 4 and 35° (2θ) with a step size of 0.03° and a maximum scan rate of 2 s/step.

DSC—Differential scanning calorimetry (DSC) was conducted in sealed Al pans at 10 °C/min using a Seiko DSC 210 under 50 mL/min nitrogen purge. Samples (5−10 mg) were either loosely packed into sample pans or first pressed into pellets using a stainless steel pellet-maker of local design. Sample preparation was carried out in a dry glovebag maintained at <5% RH.

TG/DTA—Simultaneous thermal gravimetric analysis (TGA) and differential temperature analysis (DTA) were conducted at 10 °C/min in open Al pans using a Seiko TG/DTA 220 under 150 mL/min nitrogen purge. Three to five milligrams were used for each analysis.

Results and Discussions

Figure 1 (curve 1) shows the XRD pattern of a freeze-dried mannitol sample from a 4% w/v solution. In addition to peaks that belong to the δ (major) and β (minor) polymorphs of mannitol,[22] additional peaks (marked by asterisks and listed in Table 1) were observed that could not be attributed to any known mannitol polymorphs. Heating this sample to 70 °C for 30 min eliminated the additional peaks (Figure 1, curve 2), with the remaining peaks attributable to the δ and β mannitol. These observations indicate the existence of a metastable crystal form of mannitol that was produced during freeze-drying and

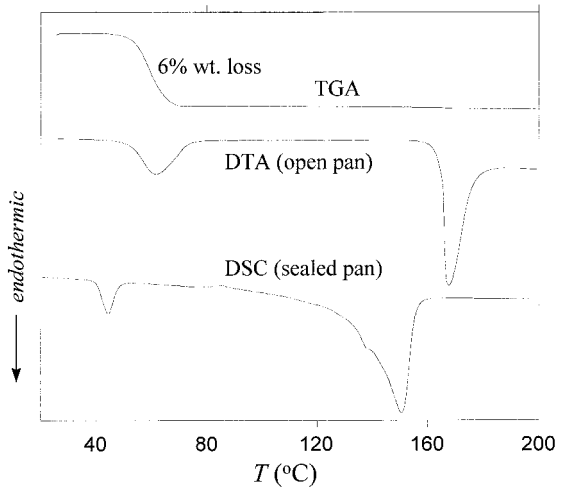

Figure 2—TGA (top), DTA (middle), and DSC (bottom) data of a freeze-dried mannitol sample. The TGA and DTA data were recorded simultaneously in an open sample pan, which show the melt/desolvation behavior of a crystalline hydrate. The DSC data was recorded in a hermetically sealed sample pan, which shows the homogeneous melting of the hydrate.

capable of converting to anhydrous mannitol polymorphs upon heating.

Figure 2 shows the thermal characteristics of the same sample described above. TGA (top curve) showed a steplike weight loss near 50 °C. The simultaneously conducted DTA (middle curve) showed a well-defined endotherm coinciding with the weight loss, which was followed by the melting of the anhydrous mannitol (mp 169 °C). DSC conducted in hermetically sealed pan (bottom curve) showed a sharp endotherm slightly below the desolvation onset.

The thermal data indicate that the crystal form transformation during heating (Figure 1) was accompanied by the loss of solvent (water). The steplike TGA loss and the well-defined DTA endotherm suggest the removal of structural water from a crystalline hydrate, rather than loosely bound ("free") water. This interpretation is supported by the sealed-pan DSC data. The use of sealed sample pans prevented the simultaneous evaporation of water during melting, making it possible to observe a sharp, homogeneous melting of the crystalline hydrate. The broad endothermic event following the sharp hydrate melting in the DSC trace can be attributed to the temperature-depressed melting of anhydrous mannitol crystals in the presence of water. We conclude therefore that a mannitol hydrate was formed in the process of freeze-drying and survived what appeared a "typical" drying cycle. This crystal form was metastable, converting to anhydrous polymorph(s) of mannitol upon heating.

Conditions of Formation—Using the same drying cycle, we have observed the mannitol hydrate under different formulation conditions: mannitol concentrations ranging from 1 to 4% w/v, with or without sorbitol (1% w/v), and in a drug formulation.[23] The same X-ray pattern assigned to the mannitol hydrate (Table 1) has also been observed by Cavatur and Suryanarayanan using in situ powder X-ray diffractometry.[24]

Anhydrous mannitol crystals are nonhygroscopic at room temperature, gaining less than 1% moisture at 90% RH.[25] This indicates that hydrate formation from anhydrous crystals is unlikely upon moisture exposure at the room temperature. The DSC data of Martini et al.[16] indicate that upon cooling a 10% w/v mannitol solution, ice forms (with substantial supercooling) before mannitol crystallizes. These observations, along with the previous failure to crystallize the mannitol hydrate at the room temperature or above,[20] suggest that the formation of the mannitol hydrate is likely a low-temperature phenomenon, relevant in particular to freeze-drying.

We have observed significant vial-to-vial variations in the amount and stability of the mannitol hydrate, even within the same batch. The relative intensity of the hydrate pattern ranged from comparable to that shown in curve 1 (Figure 1) to barely detectable or rapidly diminishing during measurement; the TGA losses ranged from 1 to 6%, and the onset of TGA loss ranged from 40 to 60 °C. The mannitol hydrate produced in certain vials could withstand mild heat (40 °C), humidity (60% RH) and compression (in DSC sample preparation), while in others it was easily destroyed, even by gentle compression. Although the drying cycle used in this study seemed a reasonable one, more aggressive secondary drying (same temperature but longer drying time) did eliminate traces of the mannitol hydrate and resulted in anhydrous mannitol crystals.

Several factors may contribute to the vial-to-vial variation in the amount and stability of the mannitol hydrate. First, the hydrate is formed in a low-temperature, concentrated solution, conditions that are not favorable for producing well-developed crystals in a reasonable processing time. Second, the ice crystallization temperature can vary as a result of the cooling rate[16] and thus the vial location in a drier. Other more subtle factors can also affect the onset of ice crystallization (e.g., defects on the vial surface). Such variability can influence the degree of freeze concentration and the ice structure and, in turn, the subsequent crystallization of mannitol. Finally, the hydrate formation is in competition with the crystallization of the anhydrous polymorphs (α, β, or δ), directly or through subsequent solid−solid conversion. Depending on the rate of anhydrous crystallization, the hydrate amount will vary. We suspect that these effects acting in concert contributed to the vial-to-vial variation and the previous failure to detect the mannitol hydrate.

Practical Implications—The formation of the mannitol hydrate during freeze-drying has several practical implications. First, the rate of water removal may be reduced due to strongly bound water that resides in the crystal lattice. In certain hydrates, such as the mannitol hydrate, the structural water cannot be fully removed without destroying the crystal lattice, a process that may require more aggressive or atypical drying conditions (e.g., longer drying time and higher temperature). Depending on the detailed mechanism of formation, it may be necessary, for example, to anneal the frozen solution to promote crystallization of the anhydrous form, thereby reducing or eliminating the mannitol hydrate.

Second, the residual hydrate water that is not fully removed by freeze-drying may pose a long-term threat to product stability, as the hydrate water can be released and redistributed, especially in "accelerated" storage, to the often amorphous drug and thus increases the potential for chemical and physical changes. Herman et al. have shown that methylprednisolone sodium succinate (MPSS) stored at accelerated conditions and formulated with mannitol is chemically less stable than materials formulated with lactose.[26] The difference in chemical stability was attributed to mannitol crystallization and the redistribution of water within the freeze-dried cake which promoted the hydrolysis of MPSS. Roos and Karel have shown that as amorphous lactose crystallizes and releases water, the glass transition temperature of the remaining amorphous material is depressed and the crystallization process accelerated.[27] It is conceivable, therefore, that the release of hydrate water during accelerated storage may also complicate the interpretation of stability data and cause a premature termination of an otherwise promising formulation.

Finally, our observations indicate that certain vial-to-vial variation in the water level may be associated with the formation of the mannitol hydrate.

Conclusions

We have reported thermal and crystallographic evidence for the formation of a previously unknown mannitol hydrate in the freeze-drying process. The mannitol hydrate can survive a "typical" drying cycle, but can be converted to anhydrous polymorph(s) of mannitol on gentle heating and more aggressive secondary drying. Potential consequences of the mannitol hydration formation include reduced drying rate, moisture release during accelerated storage, and vial-to-vial variation in the water level.

Stability and Surface Activity of Lactate Dehydrogenase in Spray-Dried Trehalose

MICHAEL ADLER AND GEOFFREY LEE*

Contribution from *Department of Pharmaceutical Technology, Friedrich-Alexander-University, Erlangen, Germany.*

Received August 5, 1998. Accepted for publication November 25, 1998.

Abstract □ The stability of the model protein lactate dehydrogenase (LDH) during spray-drying and also on subsequent dry storage was examined. Trehalose was used as a carrier. The spray-drying temperatures T_{inlet} and T_{outlet} have a measurable effect on LDH inactivation. Low T_{inlet} produced the least process inactivation, but gave a high residual moisture content making the protein's storage stability poor. High T_{inlet} reduced residual moisture and improved storage stability, but at the cost of high process inactivation. As already found for other systems, addition of a surfactant (in this case polysorbate 80) could ameliorate process inactivation of LDH at T_{inlet} = 150 °C. Surfactant had, however, a deleterious effect on storage stability of LDH, the vital factor being the molar ratio of surfactant/protein in the dried product. By using electron spectroscopy it was shown that LDH has a 10 times higher surface concentration in the dried trehalose particles than expected for a homogeneous distribution. Surface tension measurements at the water/air interface proved that LDH is surface active, although the Gibbs equation appeared to be inapplicable. Calculations of spray-droplet formation time and drying time indicate than the extent of diffusion-driven LDH adsorption to the liquid/air interface is sufficient to account for the measured amount of LDH inactivation during spray-drying. The presence of 0.1% polysorbate 80 to the spray solution prevents LDH from appearing at the surface of the dried particles. As a negative control, the phosphatide Lipoid E 80 does not prevent the appearance of LDH in the surface according to electron spectroscopy and does not therefore prevent LDH inactivation during spray-drying at T_{inlet} = 150 °C.

Introduction

It is just 6 years since Broadhead et al.[1] concluded in their review article that the full potential of spray-drying of pharmaceutical proteins had yet to be exploited. Since then, a number of papers and patents have addressed the question of spray-drying to produce protein formulations suitable for pulmonary delivery. In most cases, spray-drying of an aqueous solution of the bulk protein led to substantial protein aggregation or inactivation.[2] The addition of stabilizing adjuvants as carriers, typically carbohydrates or amino acids, reduces the extent of protein inactivation during spray-drying. Sucrose (0.25 M), for example, reduced the formation of methemoglobin on spray-drying hemoglobin at an inlet air-temperature of 100 °C from 50% to <4%.[3] Trehalose, arginine, and sucrose completely ameliorated the activity loss of spray-dried β-galactosidase.[4] Both trehalose and sucrose have, however, been reported to be difficult to spray-dry, at least in the placebo state. The latter is extremely hygroscopic[5] whereas the former has been reported to form fused, sticky aggregates at an inlet air-temperature of 90 °C, unsuitable as a protein carrier.[6]

This paper presents part of our work investigating the relationship between process stability, storage stability, and surface activity of proteins in spray-dried powders. The question of process stability of proteins during spray-drying has already been addressed in the papers cited above. The problem of subsequent storage stability of the proteins has, however, received less attention. Broadhead et al.[4] reported that trehalose as a carrier produced the best storage stability of β-galactosidase at ambient temperatures. We wished to reconcile this report with the above-cited difficulty in producing dry spray-dried trehalose particles.[6] For pulmonary application, where the maximum powder-dose is severely limited,[7] the spray-drying of pure proteins appears attractive. Recombinant human growth hormone could, for example, be successfully spray-dried at an inlet air-temperature of 90 °C without a carrier, although only with addition of polysorbate 20 and/or $ZnCl_2$ to the spray solution.[8] The storage stability of such spray-dried proteins having no carrier has, however, yet to be addressed and will certainly be protein-specific. The use of a glass-forming carrier will surely be necessary for many proteins.

We selected lactate dehydrogenase (LDH) as a model protein. It is known to be sensitive to thermal treatment and has the distinct advantage that its enzyme *activity* can be measured directly and not just its degree of aggregation. To reconcile the conflicting reports in the literature regarding its suitability,[4,6] we used trehalose as a carrier. Its high glass transition temperature in the dried state renders trehalose an efficient stabilizer of proteins on storage,[9] even when containing relatively high residual moisture contents. We examined the influence of spray-drying temperatures on both the process and storage stability of LDH in spray-dried trehalose. The results are discussed in terms of the residual water contents and glass transition temperatures of the spray-dried powders. As has been already reported for other proteins,[8] surfactant could reduce loss of LDH activity occurring during the process of spray-drying. We show, however, that polysorbate 80 has an unexpectedly deleterious effect on storage stability of LDH. Surface tension measurements show that LDH is strongly surface-active. A particular feature of this work is the use of electron spectroscopy to assay the surface layer of the spray-dried LDH/trehalose particles. Using this method we find the first unequivocal evidence of protein exclusion from an interface on spray-drying with surfactant. The addition of lecithin did not induce protein exclusion from the interface and did not therefore prevent loss of LDH activity during spray-drying.

Materials and Methods

Materials—Porcine lactate dehydrogenase (LDH) of molecular weight approximately 144 kDa was obtained from Boehringer Mannheim (Mannheim, Germany). This suspension in 3 M $(NH_4)_2$-

SO_4 was dialyzed immediately before use at 4 °C against 0.1 M phosphate buffer of pH 7 using a regenerated cellulose membrane (MW cutoff 12000−14000). The LDH activity of the dialysate was determined by the assay described later. Trehalose dihydrate was used as received from Sigma Chemicals (Munich, Germany). Polysorbate 80 of MW approximately 1300 and HLB value 15 was obtained from ICI (Sandhofen, Germany). Lipoid E 80 is an egg yolk lecithin obtained from Lipoid (Ludwigshafen, Germany) and was used without further refinement. Miglyol 812 came from Pharma Zentrale (Herdeke, Germany), and Span 85 from ICI. Water was double distilled from an all-glass apparatus.

Spray-Drying—Trehalose dihydrate was dissolved either in water or the diluted, dialyzed LDH solution in pH 7 phosphate buffer. Polysorbate 80 was added as appropriate. Fifty milliliters of the resulting trehalose or trehalose/LDH solution (with or without polysorbate 80) was spray-dried on a Büchi model 190 laboratory spray-dryer operated in the cocurrent mode. The liquid feed rate was 4 mL/min (0.24×10^{-3} m^3/h) through a pneumatic nozzle (0.7 mm diameter) driven at 6 bar air pressure. Cooling water was circulated through a jacket around the nozzle. The atomizing-air flow rate was 0.7 m^3/h, and the aspirator vacuum was 38 mbar. It was possible to control only the inlet air-temperature (T_{inlet}) on the machine we used; the outlet air-temperature (T_{outlet}) could only be measured. Spray-drying was performed under the following four sets of conditions: T_{inlet}/T_{outlet} = 90 °C/60 °C; T_{inlet}/T_{outlet} = 110 °C/70 °C; T_{inlet}/T_{outlet} = 130 °C/80 °C; T_{inlet}/T_{outlet} = 150 °C/95 °C. Unless otherwise stated, the spray solution contained 10% w/w total solids (trehalose + LDH + surfactant), giving a maximum theoretical yield of 5 g of powder per 50 mL of spray solution used in one experiment.

Characterization of Spray-Dried Powders—The residual moisture contents of the spray-dried powders were determined by Karl Fischer Titration (Schott Instruments). Powder samples (50−100 mg) were dissolved in water-free methanol/formamide (1:1) prior to titration. The thermal transitions of the powders were examined on a Polymer Laboratories differential scanning calorimeter. Samples (10 mg) were first sealed in Al pans and then repeatedly cooled and heated between −20 °C and 150 °C at 10 °C/min. Each sample's glass transition temperature, T_g, was determined from the midpoint of the endothermic shift on the DSC trace. Wide-angle X-ray diffraction was performed at 25 °C ± 1 °C on a Phillips Model TW 1730, with Cu Kα radiation of λ = 0.15418 nm at 40 kV/30 mA. The external morphology of the spray-dry powders was examined using scanning electron microscopy (SEM) on an Amray 1810 T microscope. The powders were gold sputtered on an Al sample holder.

Laser Diffractometry—The particle size distributions of the spray-dried powders were determined using a Coulter Model LS 130 Laser Diffractometer. Each dry powder sample was initially deaggregated by dispersion in a 1% w/w solution of Span 85 in Miglyol 812 using an ultrasonic bath for 4 min. This dispersion was placed in the small volume accessory of the diffractometer, and the laser light scattering intensity was evaluated by Fraunhofer analysis.[10]

Electron Spectroscopy for Chemical Analysis (ESCA)—This technique was used to quantify the surface coverage of the spray-dried powders with LDH. Using ESCA it is possible to identify quantitatively the elements present in the surface of dried particles.[11] Briefly, the powder sample is exposed to an X-ray beam, and electrons contained in the near-surface region of the solid (approximately 10 nm) that have a binding energy less than the photon energy will be ejected from the atom. The kinetic energy of the ejected electrons will be equal to the difference between photon energy and binding energy, allowing for an instrument response function. As the binding energy is characteristic of the atom from which it is ejected, the elements present in the specimen can be identified quantitatively.[12]

To determine the surface coverages of the spray-dried powders with LDH, we analyzed the surface atomic concentrations of the elements C, O, and N. We assume only that the ratio of elements found in a dried powder sample is a linear combination of the ratio of elements occurring in the pure components comprising the sample.[11] In this fashion the concentration of LDH in the outermost 10 nm-thick layer of the spray-dried powder can be calculated. A photoelectron spectrometer (Physical Electronics) was used with an Al Kα X-ray source. The pressure in the sample chamber was reduced to below 0.1 μbar bar. The detector (electron kinetic energy analyzer) was operated with a pass energy of 188 eV, and the ESCA spectra were determined using a step size of 1.0 eV. Each spray-dried powder sample was placed in the indentation of the machine's sample holder. The result of each ESCA analysis is expressed as a spectrum of counts/s at the detector versus binding energy in eV.

Table 1—Properties of Trehalose Powders Spray-Dried under Different Conditions of T_{inlet}/T_{outlet}[a,b]

T_{inlet} [°C]	T_{outlet} [°C]	yield [%]	water content [% w/w]	T_g [°C]
110	70	58	3.5	72
130	80	65	2.4	86
150	95	78	2.6	84

[a] Spray solution contained 10% w/w total solids. [b] Liquid feed rate was 4 mL/min, and atomizing air flow rate was 0.7 m^3/h.

Process and Storage Stability of LDH—The residual LDH activity in the trehalose powders was determined immediately after spray-drying and also after various storage times at 4 °C, 25 °C, 40 °C, and 60 °C in sealed glass vials over P_2O_5. The LDH activity assay was conducted as follows: 2.5 mL of phosphate buffer (0.1 M, pH 7), 0.1 mL of pyruvate (0.02 M), and 0.05 mL of NADH (11 mM) were first mixed in a quartz cuvette at 25 °C. LDH solution (0.05 mL) to be tested was then added with mixing. The extinction of the solution was measured at λ = 365 nm over 5 min using a Kontron Uvikon 810 UV−vis photometer with water bath for temperature control. The enzymatic activity [units/mL] could be calculated from the measured rate of change in extinction per min [$\Delta E/\Delta t$]. The residual LDH activities were expressed on a scale between 0 and 100% of the LDH activity of the spray solution determined immediately before spray-drying. Both trehalose and polysorbate strongly influenced the LDH assay and were accounted for by running appropriate blank references.

Surface Tension Measurements—The surface tension of LDH in water was measured at 25 °C ± 0.1 °C and at various concentrations using a thermostated Krüss K 10 Tensiometer equipped with a Wilhelmy plate. The surface tension was measured at various time points up to 60 min. The LDH concentrations were determined from UV-extinction of the solutions at λ = 280 nm by using $E^{0.1\%}_{280nm}$ 1.40 cm^{-1} mL mg^{-1}.[13]

Results and Discussion

Spray-Drying of Protein-Free Trehalose—The reported "sticky" nature of trehalose spray-dried at T_{inlet}/T_{outlet} = 90 °C/60 °C[6] could be overcome by the simple expedient of increasing T_{inlet} to improve product quality, as can be deduced from Broadhead's earlier work.[4] At T_{inlet}/T_{outlet} = 150 °C/95 °C a respectable yield (for the Büchi) of almost 80% is obtained, and the product has a residual moisture content of 2.6% with a T_g of > 80 °C (Table 1). Clearly, use of a low T_{inlet} = 90 °C[6] appears intuitively attractive to reduce possible protein inactivation by thermal stress during spray drying. The consequences of increasing T_{inlet} to 150 °C to obtain a drier product on LDH's process and storage stability will be seen presently. The advantage of using trehalose compared with other nonreducing sugars such as sucrose is also evident from Table 1. A residual moisture of 2.6% is still high compared with freeze-drying the same product, and this value would depress the T_g of sucrose down to approximately 40 °C.[9] By virtue of its high T_g in the dried state (T_g = 115 °C),[14] the relatively high residual moisture contents achievable with spray-drying still yield T_g's of >80 °C. This could be of advantage for the process stability of a protein and certainly will be propitious for its storage stability.[9]

Hancock and Zografi[15] showed that the plasticizing effect of water on various amorphous pharmaceutical solids could be accurately described by the simple Gordon−Taylor model of perfect volume-additivity and no interactions between water and the amorphous solid. Figure 1 shows the T_g's of the spray-dried trehalose powders plotted versus weight fraction residual moisture in the range 0 to ap-

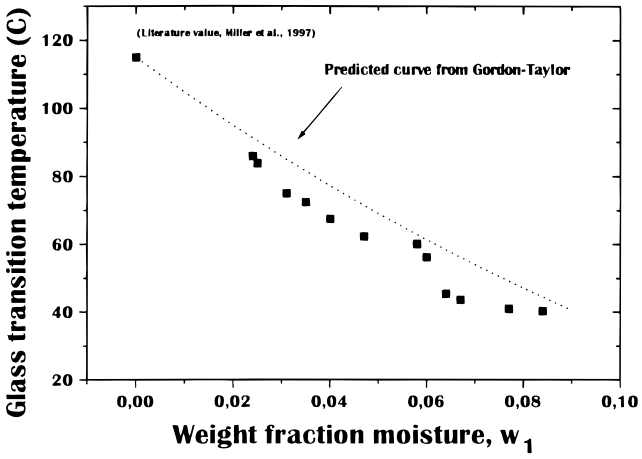

Figure 1—Variation in glass transition temperature (T_g) with weight fraction residual moisture content (w_1) of the spray-dried trehalose powders. Spray solutions contained 10% w/w total solids (trehalose dihydrate). Liquid feed rate was 4 mL/min, and atomizing air flow rate was 0.7 m^3/h. The solid squares are the individual results from the spray-dried powders. The dotted line is the curve calculated from the Gordon–Taylor equation for the water/trehalose system: $T_{g,mix} = (w_1T_g^1 + Kw_2T_g^2)/w_1 + Kw_2$, $K = (T_g^1\rho_1/T_g^2\rho_2)$. The following values were used: water $T_g^1 = 135$ K (–138 °C) $\rho_1 = 1.00 \times 10^3$ kg/m^3; trehalose $T_g^2 = 388$ K (115 °C) $\rho_1 = 1.47 \times 10^3$ kg/m^3; $K_{water/trehalose}$: = 0.237.

proximately 9% w/w water. These different residual water contents were obtained by varying T_{inlet}/T_{outlet} accordingly. The experimentally determined T_g's lie consistently below the curve predicted from the Gordon−Taylor equation (Figure 1). This deviation from ideality is, however, less than that observed for the sucrose−water system.[15] We expect the system trehalose−water to be very nonregular in terms of solution theory by virtue of hydrogen bonding. Bearing this in mind, the relatively small negative deviation from ideality in Figure 1 is surprising. As noted by Hancock and Zografi,[15] however, such nonideality obviously does not have a strong influence on the free volume of the water−glass mixtures.

The scanning electron micrograph (SEM) for trehalose spray-dried at T_{inlet}/T_{outlet} = 150 °C/95 °C (Figure 2a) shows almost perfectly spherical particles with smooth surfaces. This is the typical picture for other spray-dried sugars such as lactose and mannitol[6,7] that are not loaded with higher molecular weight ingredients such as proteins or polymers. No change in particle morphology could be observed with change in T_{inlet}/T_{outlet} in the range examined here. In a literature report, partly fused agglomerates were found with trehalose prepared at T_{inlet}/T_{outlet} = 90 °C/60 °C.[6] Although the product at T_{inlet}/T_{outlet} = 110 °C/70 °C showed no indication of particle fusion, any fused aggregates formed during the process were retained on the inner walls of the cyclone, accounting for the small yield of 58% at this T_{inlet}. Under all spray-drying conditions examined here the trehalose particles were fully amorphous, the wide-angle X-ray diffractograms showing the typical amorphous halo (Figure 2b). Although the particle size determined by laser diffraction was independent of T_{inlet}/T_{outlet}, decreasing the total solids concentration of the spray solution led to reduced particle size of the dried product (Figure 2c). Total solids (10% w/w) give, for example, an average particle diameter of 3.5 μm. If the fine particle dose of a powder is defined as that ≤6 μm,[7] it is approximately 72% with 10% w/w solids content. Such spray-dried powders are, therefore, attractive for pulmonary application, as noted before.[7] This would need to be confirmed, however, by measurements of the aerodynamic particle size using a suitable impactor. If the spray droplet size is independent of the total solids content of the spray solution in the range used

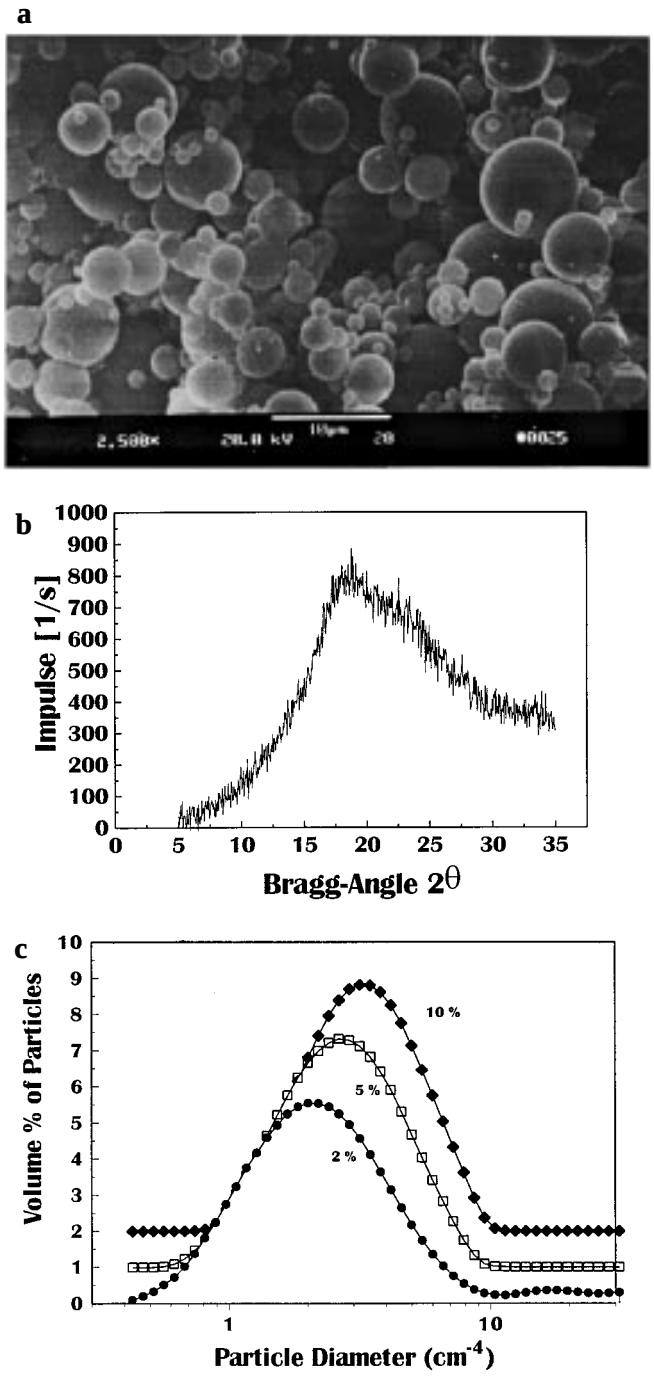

Figure 2—Spray-dried trehalose prepared at T_{inlet}/T_{outlet} = 150 °C/95 °C. (A) Scanning electron micrograph of magnification 2500×. (B) Wide-angle X-ray scattering diffractogram showing characteristic amorphous halo. (C) Influence of total solids content of spray solution on particle size distribution determined by laser diffraction. With decreasing total solid content from 10 through 5 to 2%, the size distribution is shifted to lower diameters.

here, then reducing the total solids content should produce smaller particles, as also observed in Figure 2c.

On dry storage (over P_2O_5) at room temperature, the residual moisture content of the spray-dried particles prepared at T_{inlet}/T_{outlet} = 150 °C/95 °C remained constant over at least 43 days (Table 2). Accordingly, T_g also remained unchanged. The powder remained fully amorphous (X-ray diffractogram not shown, but identical to Figure 2b), indicating that these spray-dried trehalose particles retain their glass properties on suitable dry storage. Uptake of moisture into spray-dried lactose particles[7] induced massive particle aggregation with subse-

Table 2—Properties of Spray-Dried Trehalose Powders on Dry Storage over P_2O_5[a]

storage time [days]	water content [% w/w]	T_g [°C]
0	2.6 ± 0.2	84
1	2.5 ± 0.1	83
8	2.5 ± 0.2	84
15	2.6 ± 0.1	84
43	2.4 ± 0.1	85

[a] Powder prepared at T_{inlet}/T_{outlet} = 150 °C/95 °C and as given in Table 1. n = 3.

quent major reduction in fine particle dose. When used as a protein carrier, it is vital, however, that adjuvents such as trehalose retain their amorphous glassy character on storage.

Spray-Drying of LDH in Trehalose—We distinguish between process stability and storage stability of the model protein LDH in the spray-dried trehalose. *Process stability* defines the extent of inactivation of LDH during spray-drying and can be quantified by measuring residual LDH activity in the powder immediately after spray-drying. Possible causes for protein unfolding and inactivation during spray-drying are shearing stress in the nozzle, thermal stress during droplet drying in the spray-drying tower, and adsorption at the greatly expanded liquid/air interface of the spray solution on atomization.[8] Recent work by Maa et al.[16] indicates that unfolding and aggregation of recombinant human growth hormone (rhGH) during spray-drying was induced primarily by adsorption at the liquid/air interface created during spraying; shearing and thermal stresses were considered to be of minor importance. Figure 3 shows the behavior of the spray-dried LDH/trehalose powders. A low dry-particle protein loading of 0.3% w/w LDH was purposefully chosen to maximize the possible stabilizing effects of the trehalose. Under the mild process conditions of T_{inlet}/T_{outlet} = 90 °C/60 °C (Figure 3a), a loss of approximately 11% LDH activity is caused by the spray-drying process. More vigorous process conditions increase this activity loss up to approximately 25% with T_{inlet}/T_{outlet} = 150 °C/95 °C (Figure 3b–d). It follows that thermal stress must play some part in LDH inactivation, since shearing stress and, presumably, liquid/air interfacial adsorption during the short time required for atomization will be independent of T_{inlet}/T_{outlet}. Only droplet drying time will decrease at higher T_{inlet}/T_{outlet}.[17] The spherical smooth particles of pure trehalose (cf. Figure 2a) are changed with the 0.3% dry-particle LDH loading to show a slightly dimpled appearance (Figure 4a). This is typical for the effects of a high molecular weight additive such as a polymer[18] or a protein.[6] Increasing the dry-particle loading to 5% LDH for T_{inlet}/T_{outlet} = 150 °C/95 °C reduces the percent inactivation of LDH during spray-drying from approximately 25% with 0.3% LDH to approximately 11% (Figure 5a). This represents, however, an increase in the absolute amounts of LDH inactivated from 0.075 mg LDH/mL of spray solution (with 0.3% LDH dry-particle loading) to 0.55 mg LDH/mL of spray solution (with 5% LDH dry-particle loading). Also, the SEM of 5% LDH dry-particle loading shows an extremely wrinkled appearance (Figure 4b). If the primary cause of this LDH inactivation during spray-drying is adsorption at the liquid/air interface of the nebulized spray solution, then the amount adsorbed evidently increases with greater LDH concentration in the spray solution, indicating a diffusion-controlled process.

Some light can be shed on the likelihood of adsorption-induced inactivation by comparing the rates of droplet formation, droplet drying, and LDH adsorption. As shown in the Appendix, the spray droplets formed under the conditions used in these experiments had an average diameter of 8.5 μm and an almost instantaneous formation time, t_f, at the tip of the pneumatic nozzle of 5×10^{-6} ms. The subsequent droplet drying process is slower and occurs in two periods:[19] a constant-rate period until solid phase

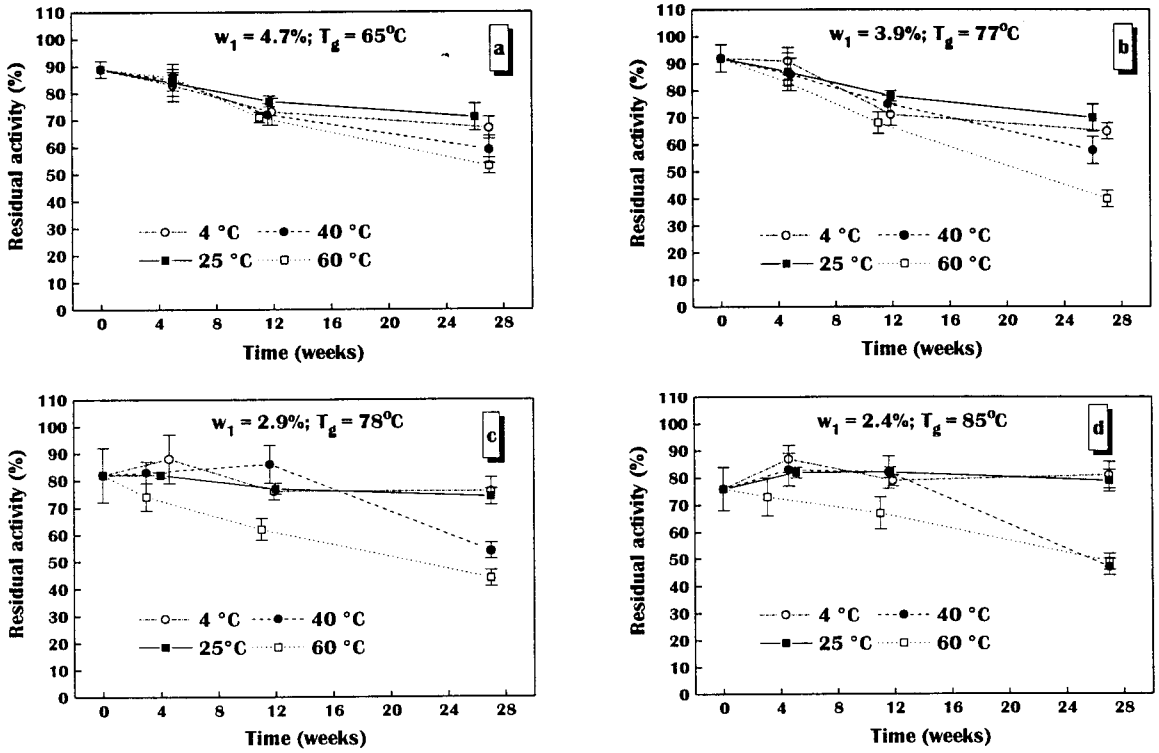

Figure 3—Effect of process temperatures (T_{inlet}/T_{outlet}) on process and storage stability of LDH in spray-dried trehalose powders. The trehalose was initially dry-particle loaded with 0.3% w/w LDH. The spray solution contained 10% total solids (trehalose dihydrate). Liquid feed rate was 4 mL/min, and the atomizing air flow rate was 0.7 m³/h. In each figure the corresponding values for residual water content (w_1) and glass transition temperature (T_g) are given. (A) T_{inlet}/T_{outlet} = 90 °C/60 °C; (B) T_{inlet}/T_{outlet} = 110 °C/70 °C; (C) T_{inlet}/T_{outlet} = 130 °C/80 °C; (D) T_{inlet}/T_{outlet} = 150 °C/95 °C.

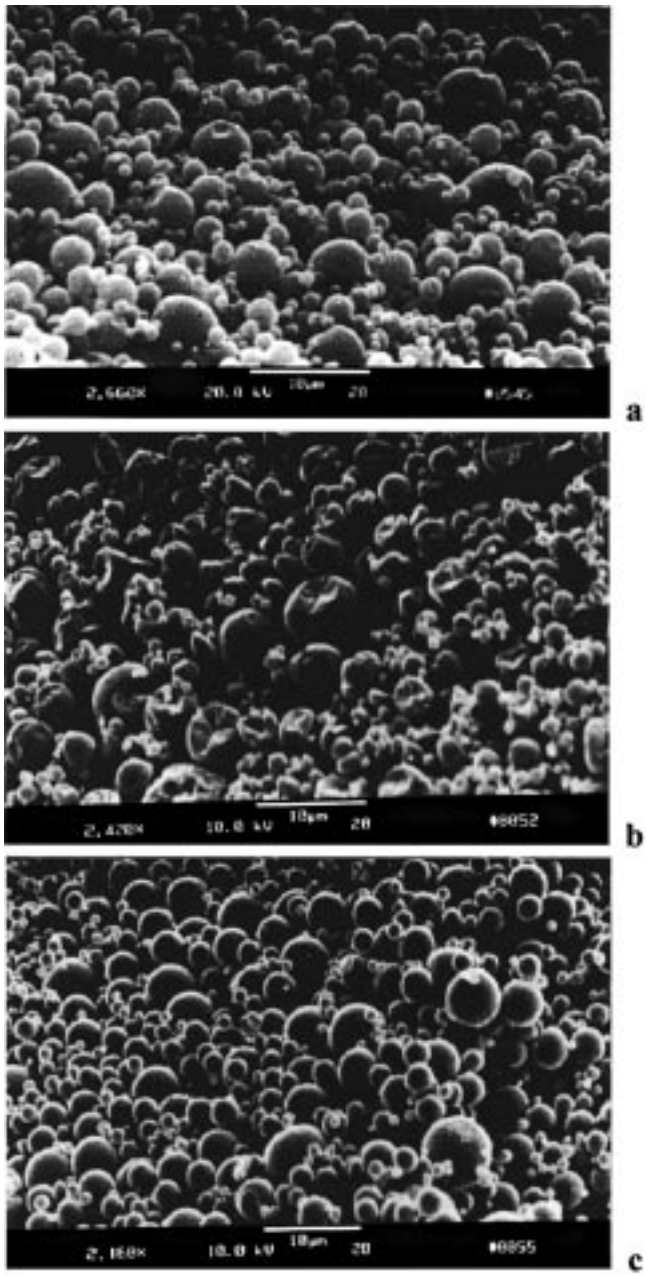

Figure 4—Scanning electron micrographs of trehalose powders spray-dried at T_{inlet}/T_{outlet} = 150 °C/95 °C. The spray solutions contained 10% w/w total solids. (A) Trehalose dry-loaded with 0.3% LDH. (B) Trehalose dry-loaded with 5% LDH. (C) Trehalose dry-loaded with 5% LDH; spray solution also contained 0.1% w/w polysorbate 80.

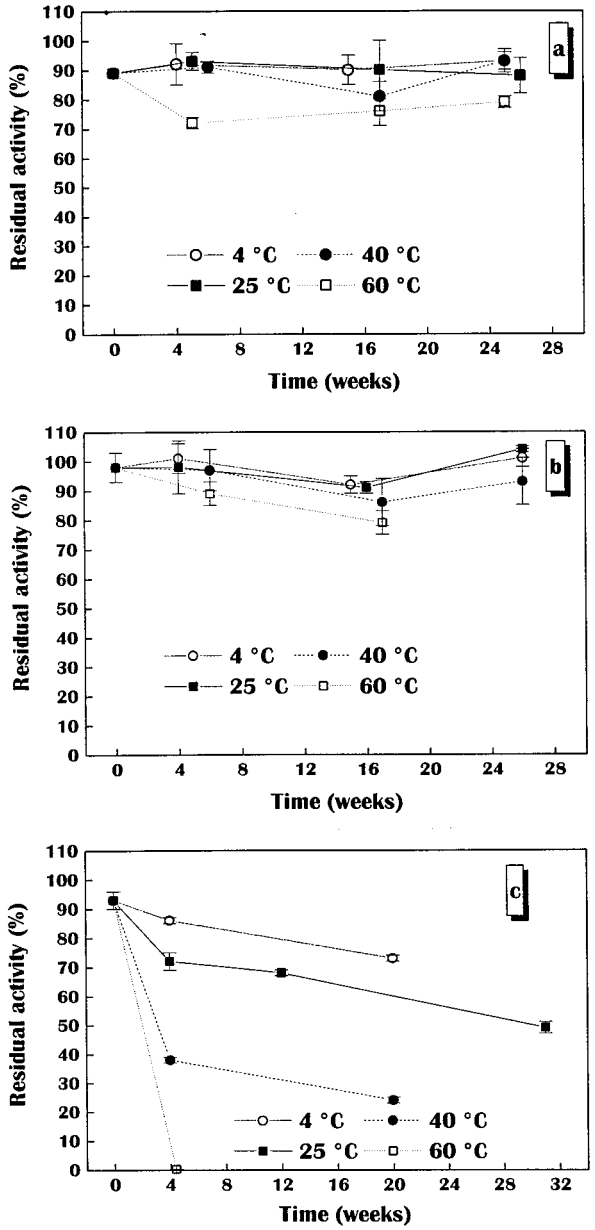

Figure 5—Process and storage stability of LDH in various spray-dried trehalose powders. The process temperatures were T_{inlet}/T_{outlet} = 150 °C/95 °C. The liquid feed rate was 4 mL/min, and the atomizing air flow rate was 0.7 m³/h. (A) 5% w/w dry-particle loading of LDH in trehalose, 10% total solids in spray solution, 0% polysorbate 80 (P 80); (B) 5% w/w dry-particle loading of LDH in trehalose, 10% total solids in spray solution, 0.1% w/w P 80 solution concentration = P 80/LDH molar ratio (27:1); (C) 0.3% w/w dry-particle loading of LDH in trehalose, 2% total solids in spray solution, 0.1% w/w P 80 solution concentration = molar ratio P 80/LDH (1890:1).

starts to form at the droplet surface, followed by a falling-rate period where particle diameter does not change further. As calculated in the Appendix, the droplet evaporation times for an 8.6 μm diameter water droplet containing 10% w/w dissolved solid in the constant-rate period, t_{cr}, and the falling-rate period, t_{fr}, are 0.4 and 1.1 ms, respectively (see Table 3). These process times can be used to calculate the amounts of LDH which could be adsorbed at the liquid/water interface [mg/m²] during droplet formation and drying. Figure 6a shows the air/water surface tension (γ) plot for LDH determined after 0.5 h and 1 h equilibration time. It is clear that this protein is surface active with a surface excess of Γ = 221 mg/m² calculated from the slope using the Gibbs equation. This value is 2 orders of magnitude larger than the saturated monolayer surface concentrations of β-casein (MW = 24000), lysozyme (MW = 14500), and bovine serum albumin (MW = 67000)

Table 3—Results of Calculated Times for Spray Droplet Formation, t_f, and Drying Times in Constant-Rate, t_{cr}, and Falling-Rate, t_{fr}, Periods (see Appendix for calculations)

time	calculated value, ms
t_f	5×10^{-6}
t_{cr}	0.41
t_{fr}	1.07

determined by a radio-tracer method.[20] Despite the higher molecular weight of LDH (144000 for the tetrameter), a Γ of 221 mg/m² is unreasonable. As previously found with human serum albumin, the Gibbs equation evidently cannot be applied to γ versus log C_B data for proteins in this concentration region.[21] It is more useful to examine

Table 4—Calculation of Diffusivity, D, and Surface Excess Concentration, Γ, for LDH in Water from Plot of Surface Pressure, $\Pi(t)$, versus $\sqrt{t}$ According to eq 1

LDH bulk concentration [mg/mL]	slope $d\Pi(t)/dt^{1/2}$ [N/m·s$^{1/2}$]	D [m^2/s]	Γ_f [mg/m^2]	Γ_{cr} [mg/m^2]	LDH adsorbed up to critical point [mg/mL solution]
0.43	1.2×10^{-4}	2.1×10^{-10}	5×10^{-4}	0.14	0.1

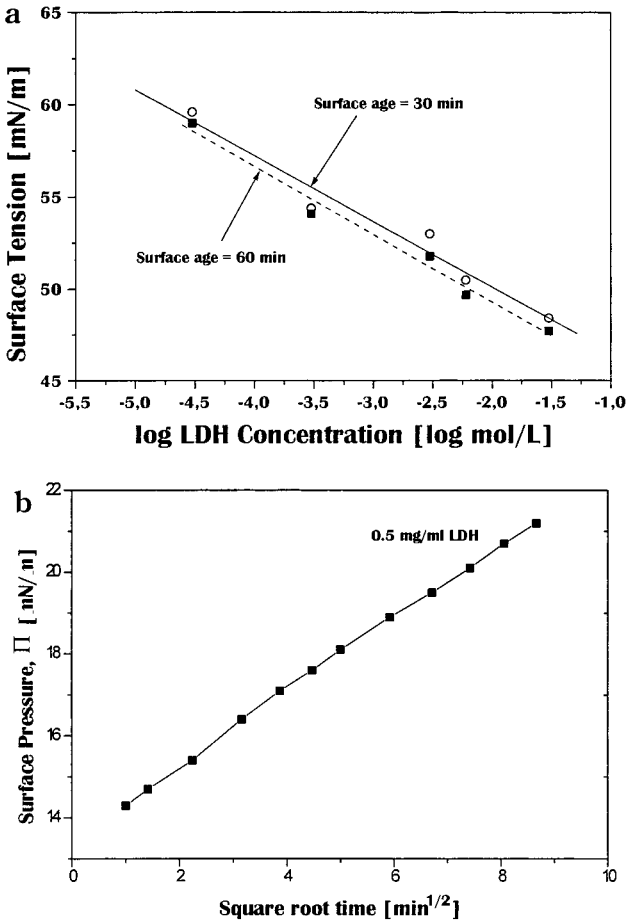

Figure 6—(A) Plot of surface tension versus log LDH concentration in water. From the Gibbs equation, $\Gamma = -[\, d\gamma/d \ln c] \times 1/RT$, the surface excess, Γ, is 221 mg/m^2. (B) Change in surface pressure (Π) with time for 0.43 mg/mL LDH (■) solution in water determined with Wilhelmy plate.

the time-dependence of γ. Adsorption of protein molecules at a liquid/air interface is diffusion-controlled up to approximately 10% surface saturation:[22]

$$\Pi(t) = \Gamma(t)RT = 2RTC_B\sqrt{\frac{Dt}{\pi}} \qquad \Gamma \le 0.1\Gamma_{sat} \quad (1)$$

where Π is the surface pressure ($= \gamma_{solvent} - \gamma_{solution}$), C_B is the protein's bulk concentration, and D is its diffusivity. Figure 6b shows a plot of Π versus $\sqrt{t}$ for an LDH solution in water of $C_B = 0.43$ mg/mL, this being approximately that LDH concentration in the spray solutions used to produce a dry-particle protein loading of 0.3%. The values for $\Pi(t)$ fit well to a straight line in accordance with eq 1 and yield calculated diffusivity of 2.7×10^{-10} m^2/s (see Table 4). This is in the same order of magnitude as found for β-casein and lysozyme.[22] If LDH can diffuse to the liquid/air interface only until the critical point is reached where solid forms at the droplet surface, the total time available for protein adsorption on spraying will be: $t_f + t_{cr}$ (see Table 3). The surface excess concentrations of LDH at the end of droplet formation, Γ_f, and at the critical point, Γ_{cr}, can now be calculated directly from eq 1 and are given in Table 4.

Table 5—Influence of T_g on % LDH-Inactivation Loss on Storage after 27 Weeks at 4 °C, 25 °C, 40 °C, and 60 °C[a]

storage temp [°C]	% LDH-inactivation loss at T_g [°C]: 65 °C	77 °C	78 °C	85 °C
4	25	29	7	0
25	20	24	10	0
40	37	37	34	38
60	40	57	46	36

[a] Values calculated from results in Figure 3.

The calculated total excess amount of LDH adsorbed at the liquid/air interface up to the critical point is clearly more than sufficient to account for the measured LDH-inactivation during spray-drying. With 0.3% LDH dry-particle loading, an LDH-inactivation of 0.075 mg LDH/mL spray solution was measured (Figure 3d), whereas 0.1 mg LDH/mL spray solution could be adsorbed at the spray droplet surface according to this calculation (Table 4). Thus approximately 75% of the theoretical amount of excess adsorbed LDH is therefore inactivated during spray-drying. The interfacial adsorption and inactivation of LDH during spray-drying thus appear feasible.

The *storage stability* of a protein in an amorphous solid will depend in a complex fashion on residual moisture content and T_g.[23] In an early study[3] it was found that those carriers which gave the best protein process stability also gave the best storage stability. The effect on T_{inlet}/T_{outlet} on the balance between process and storage stability has, however, not yet been clarified. Figure 3 shows that the influence of T_{inlet}/T_{outlet} on storage stability is the opposite of that seen with process stability. The high residual moisture content and low T_g of the dried product obtained with T_{inlet}/T_{outlet} = 90 °C/60 °C are associated with a continual decline in LDH activity at all four storage temperatures (Figure 3a). At 25 °C, for example, the LDH loses approximately 15% activity during 26 weeks of storage. Raising T_{inlet}/T_{outlet} reduces the residual moisture content, increases T_g, and improves the storage stability of the LDH, with no loss of LDH activity being seen after 26 weeks of storage at 25 °C for the product spray-dried at T_{inlet}/T_{outlet} = 150 °C/95 °C (Figure 3d). Degradation of proteins in amorphous solids is thought to follow fast kinetics (VTF or WLF) in the rubbery state and slow kinetics (Arrhenius) in the glassy state.[23] Only the samples stored at 4 °C and 25 °C show, however, a trend to less LDH-inactivation with increasing T_g of the carrier (Table 5). Those stored at 40 °C and 60 °C show no dependence of LDH-inactivation on the T_g. These inconsistencies underline the complexity of protein stability in a solid carrier. Protein degradation at storage temperatures below a formulation's T_g can, for example, depend on the presence of non-native protein structure in the dried state,[24] as has been demonstrated for freeze-dried LDH.[25] Also, the mechanism of protein degradation may be temperature dependent, making application of Arrhenius redundant. These aspects were not, however, considered further in this work.

Process and storage stability of LDH in the spray-dried powders are thus seen to be at odds. By decreasing T_{inlet}/T_{outlet} to improve the process stability of LDH, its storage stability (at least at 4 °C and 25 °C) is worsened. This is a result of either reduced T_g[23] or reduced degree of native

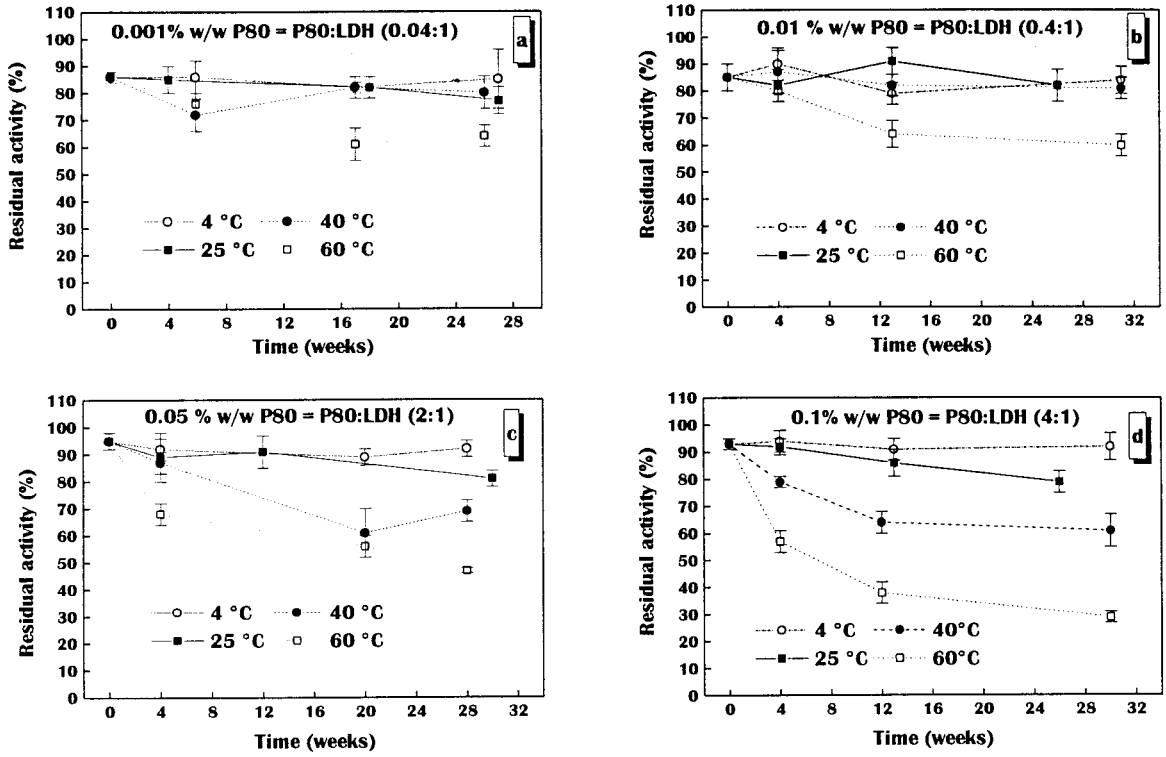

Figure 7—Influence of added Polysorbate 80 (P 80) concentration on process and storage stability of LDH in spray-dried trehalose powders. The trehalose was initially dry-particle loaded with 0.3% w/w LDH. The spray solution contained 10% total solids and was dried at T_{inlet}/T_{outlet} = 150 °C/95 °C. The liquid feed rate was 4 mL/min, and the atomizing air flow rate was 0.7 m³/h. (A) 0.001% w/w P 80 solution concentration = molar ratio P 80/LDH (4.4:1); (B) 0.01% w/w P 80 solution concentration = molar ratio P 80/LDH (44:1); (C) 0.05% w/w P 80 solution concentration = molar ratio P 80/LDH (222:1); (D) 0.1% w/w P 80 solution concentration = molar ratio P 80/LDH (444:1).

structure in the solid immediately after drying.[24] The physicochemical state of the spray-dried powders was stable at all four storage temperatures (over P_2O_5) examined here. There was no change in either residual moisture content (± 0.3% w/w), T_g (± 2 °C), or the X-ray diffractogram up to 27 weeks of storage (cf. Table 2). This was also the case for the powder whose T_g = 65 °C lies only marginally above the highest storage temperature of 60 °C. The incipient formation of a rubbery state without the additional uptake of moisture was evidently insufficient to promote crystallization of the trehalose after 27 weeks. Although not examined in this study, we expect storage under humid conditions to produce major changes in stability of both carrier[7] and protein.[26]

Influence of Polysorbate 80 on LDH Inactivation—It is known that nonionic surfactants can reduce aggregation of proteins during spray-drying at or above the critical micelle concentration of the surfactants in solution.[8,16] The addition of polysorbate 20 to spray solutions of rhGH reduced the total extent of rhGH aggregation during spray-drying at T_{inlet}/T_{outlet} = 90 °C/60 °C from approximately 45% to <18%.[8] Both of these values were reduced at higher protein concentrations in the spray solution. A similar effect is seen with polysorbate 80 on the process stability of LDH in the spray-dried trehalose powders (Figure 7). These results were all obtained for the powder spray-dried at T_{inlet}/T_{outlet} = 150 °C/95 °C. Recall that in the absence of polysorbate 80 some 25% loss in LDH activity occurred during spray-drying under these conditions (cf. Figure 3d). Again we must distinguish between *process stability* and *storage stability* of the LDH. Increasing polysorbate 80 solution-concentration in the spray solution progressively ameliorates the inactivation of LDH during the spray-drying process. At and above a polysorbate 80 solution-concentration of 0.05% w/w, the LDH inactivation has been reduced to approximately 5% during spray-drying (Figure 7c,d). The value of 0,05% w/w surfactant is the same critical surfactant concentration for protein stability found previously for polysorbate 20 and rhGH.[8] The current opinion is that the liquid–air interface of the spray-droplets is preferentially occupied by the surfactant rather than the protein,[8,16] reducing protein unfolding and aggregation during spray-drying. In accord with this idea, the addition of 0.1% polysorbate 80 to the spray solution (Figure 4c) changes the dimpled appearance of trehalose particles dry-loaded with 0.3% LDH (cf. Figure 4a) to the perfect sphericity and smoothness seen with pure trehalose (cf. Figure 2a). This can be explained by a reduction in surface tension of the spray droplets containing surfactant, which alters the balance of surface-to-viscous forces influencing droplet shape during drying.[18]

The effect of polysorbate 80 on the storage stability of LDH in the spray-dried trehalose is unexpected, although its presence in the concentrations examined here influenced neither residual moisture content nor T_g. Recall from Figure 3d that with a T_{inlet}/T_{outlet} = 150 °C/95 °C and a resulting T_g of 84 °C, LDH was storage stable at 4 °C and 25 °C up to 27 weeks. This behavior is retained with 0.001% polysorbate 80 in the spray solution (Figure 7a). Increasing polysorbate 80 solution concentration produces, however, a change in protein stability behavior. The good storage stability at 4 °C remains unaltered; at higher storage temperatures the presence of polysorbate 80 causes a reduction in stability. At polysorbate 80 solution concentrations ≥ 0.05%, we find a clear temperature-dependence of the LDH storage stability (Figure 7c,d). The higher concentrations of polysorbate 80 evidently promote inactivation of LDH within the trehalose glass on storage. The illuminating factor here is the molar ratio of polysorbate 80/LDH present in the dried particles. The low dry-particle LDH loading (0.3% w/w) of trehalose used for the data in Figure 4 makes this ratio large at the higher polysorbate

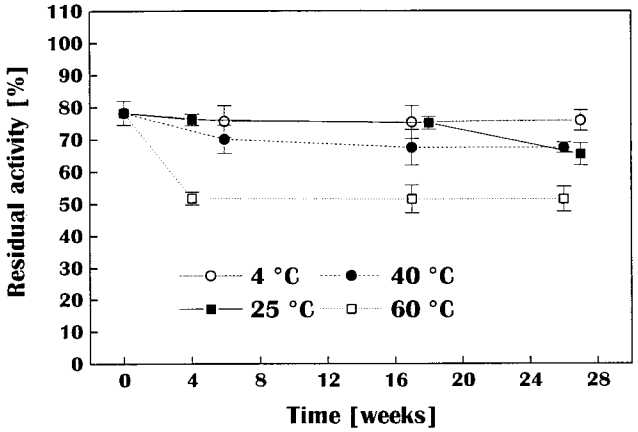

Figure 8—Influence of 0.01% w/w added Lipoid E 80 on process and storage stability of LDH in spray-dried trehalose powders. The trehalose was initially dry-loaded with 0.3% w/w LDH. The spray solution contained 10% total solids and was dried at T_{inlet}/T_{outlet} = 150 °C/95 °C.

80 concentrations. A high molar ratio of polysorbate 80/LDH of 444:1 exists, for example, in the dry product obtained with 0.1% polysorbate 80 in the spray solution, and LDH shows poor storage stability (Figure 7d). By increasing the dry-particle LDH loading to 5% (Figure 5b), 0.1% polysorbate 80 in the spray solution is now equivalent to a mole ratio of 27:1, and LDH is storage stable again. The opposite effect is achieved by reducing the total solids content of the spray solution to 2% with a dry-particle LDH loading of 0.3% and 0.1% polysorbate 80 in the spray solution. This yields the very high molar ratio of polysorbate 80/LDH of 1890:1 in the dry product, which causes extreme LDH instability on storage (Figure 5c). It is conceivable that this instability on storage is a result of peroxide contaminants known to be present in surfactants. These would be present in sufficient quantities to react with LDH in the solid trehalose particles. Care needs therefore to be exercised when adding surfactants to spray-drying solutions. The dependence on the molar ratio of surfactant/protein in the dried product means, however, that protein storage instability caused by the surfactant will not be noticeable with spray-dried pure proteins containing surfactant[8] where the surfactant/protein molar ratio will be smaller than here.

As a negative control we also examined the effect of egg lecithin added to the spray solution on LDH process and storage stability. Lipoid E 80 contains approximately 80% phosphatidylcholine and forms liposomes in water. We chose this material assuming that the single unilamellar vesicles formed would not be adsorbed at the liquid/air interface of the spray droplets and could not therefore stabilize LDH during spray-drying. Subsequent measurements showed, however, that Lipoid 80 reduced the γ of water to approximately 26 mN m^{-1} in the concentration range used in the spray solutions. We attribute this to interfacial adsorption of more water-soluble lyso-derivatives present within the Lipoid E 80. Figure 8 shows how the addition of ≥0.01% w/w solution concentration of Lipoid E 80 indeed fails to ameliorate the approximately 25% loss in LDH activity seen during spray-drying at T_{inlet}/T_{outlet} = 150 °C/95 °C (cf. Figure 3d without colloid). We conclude that the liposomes are not adsorbed at the liquid/air interface of the spray droplets sufficiently to prevent LDH being inactivated. The water-soluble lyso-derivatives evidently also do not stabilize LDH, although it is not clear why this is so. There is a reduction in storage stability of the dry product on addition of Lipoid E 80, but this negative effect (Figure 8) is less pronounced than with polysorbate 80 (cf. Figure 7b).

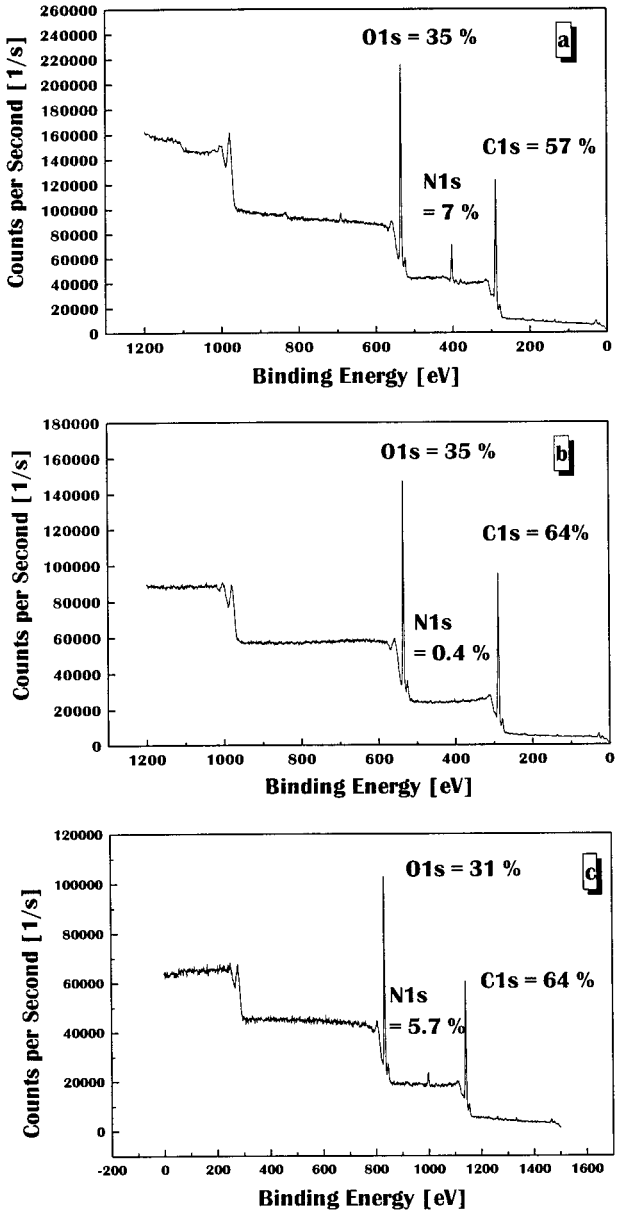

Figure 9—ESCA results for spray-dried trehalose powders dry-loaded with 5% w/w LDH. (A) 0% added polysorbate 80; (B) 0.1% added polysorbate 80 solution concentration; (C) 0.1% added Lipoid E 80 solution concentration.

ESCA Examination of LDH in Trehalose (5:95)—All ESCA measurements had to be carried out with 5% LDH dry-particle loading of the trehalose to ensure sufficient sensitivity to the elements being sought. Figure 9a shows the result for spray-dried LDH/trehalose (T_{inlet}/T_{outlet} = 150 °C/95 °C) in the absence of any added surfactant or colloid. The binding energy profile shows three elemental peaks that are of interest, viz. the 1 s electrons of O, N, and C. From the integrated peak heights the percentage surface-layer coverage of the dried product with each of these elements was calculated and is shown in the figure. The N peak is unequivocally indicative of the presence of LDH in the outer 10 nm of surface of the spray-dried particles. According to the ESCA result, 7 atomic weight % of this surface layer is composed of N (Figure 9a). LDH contains approximately 15 wt % N, although this could not be measured directly by ESCA, since pure solid LDH is not readily obtainable from the LDH-suspension used here. The spray-dried powder is loaded with 5 wt % LDH, so it follows that the surface-layer should contain approximately 0.75 wt % N, if the LDH were homogeneously distributed

throughout each uniformly solid particle. The result is, however, 10 times higher than this value and means that LDH is concentrated within the outer surface-layer of the spray-dried trehalose particles. This cannot be an artifact resulting from the formation of hollow particles, since this would not alter the concentration ratio of trehalose to LDH in the solid phase. The calculations presented above showed that there is sufficient time during droplet formation and drying to allow diffusion-mediated adsorption of LDH to the liquid/air interface. There seems no reason to believe that the rapidly *contracting* liquid/air interface during spray droplet drying up to the critical point would further alter the concentration of LDH at the resulting particle surface. As a result of this process we find the substantial inactivation of LDH during spray-drying seen in Figure 3.

The addition of 0.1% polysorbate 80 to the spray solution reduces the surface coverage with N to <0.4 atomic weight % (Figure 9b). The LDH present in the surface-layer of the spray-dried particles is thus greatly reduced in the presence of the surfactant. The N-coverage of 0.4% is indeed less than that value of 0.75% expected for a homogeneous distribution of LDH throughout a uniformly solid particle. It could also be a result of trace amounts of atmospheric N_2 adsorbed to the particle surface. The presence of surfactant at the liquid/air interface of the spray droplets thus hinders adsorption of LDH there. Owing to its much smaller molecular weight, the polysorbate 80 will diffuse faster to the liquid/air interface than does the LDH. Thus, in that range between 0% and 0.1% solution-concentration where polysorbate 80 progressively reduces LDH inactivation during spray-drying (cf. Figure 7), it also has to a great extent prevented the concentration of LDH in the surface-layer of the dried product. This result provides the first direct and quantitative evidence of the previously accepted stabilizing mechanism of the surfactant on proteins during spray-drying[8,16]

The ESCA result with Lipoid E 80 and LDH is also satisfactory. Recall that addition of Lipoid E 80 to the spray solution in the concentration ≥ 0.01% w/w did not influence inactivation of LDH during spray-drying (Figure 5b). The ESCA result in Figure 9c shows also no reduction in surface coverage of the spray-dried LDH/trehalose particles with N on the addition of 0.1% solution concentration of Lipoid E 80. Lipoid E 80 does not therefore prevent adsorption of LDH at the liquid/air interface of the spray solution and cannot therefore protect LDH against inactivation at T_{inlet}/T_{outlet} = 150 °C/95 °C. This is seen despite the aforementioned reduction in γ of the spray solution with Lipoid E 80. Neither liposomes nor surface-active impurities lead to LDH protection. Whatever the cause, the ESCA results for polysorbate 80 and Lipoid E 80 confirm that surfactants reduce the presence of proteins at the solid particle surface on spray-drying.

Conclusions

The main object of this work was to distinguish between process stability and storage stability of LDH in spray-dried trehalose. The influence of process conditions run contrary to one another: those process conditions that produce good process stability yield poor storage stability. The same behavior is found with addition of surfactant: this improves process stability but is deleterious to storage stability. A particular feature of this work was the use of ESCA to prove that polysorbate 80 prevents LDH appearing in the surface of the spray-dried particles. This could be correlated with a reduction in LDH inactivation during spray-drying. The negative result with Lipoid E 80 confirms this stabilizing mechanism. The relevant equations indicate that the concentrated presence of LDH in the surface of surfactant-free trehalose particles is a result of diffusion-driven adsorption of LDH at the liquid/air interface during spray droplet formation and drying.

Table 6—Comparison of Spraying Conditions and Resulting Spray Droplet Diameter

	from ref 6	in this work
liquid feed rate [m^3/h]	3×10^{-4}	2.4×10^{-4}
air flow rate [m^3/h]	0.9	0.7
air/liquid mass ratio[a]	3.61	3.35
spray droplet diameter [μm]	7.5 (measured)	8.6 (calcd)

[a] $= \dfrac{\text{air flow rate [m}^3\text{/h]} \times \text{air density (1.204)[kg/m}^3\text{]}}{\text{liquid feed rate [m}^3\text{/h]} \times \text{liquid density (1000 or 1407)[kg/m}^3\text{]}}$

Appendix

1. Calculation of Average Spray Droplet Volume—The relation between the diameter of a spray droplet, D_w, and the diameter of the resulting solid particle after drying, D_d, is given by:[27]

$$D_w = 2\left(\frac{\left(\frac{D_d}{2}\right)^3 \rho_2}{W_2}\right)^{1/3} \quad \text{(A1)}$$

where ρ_2 is the density of the solid and W_2 is the total solids' content of the spray solution. For the 10% w/w trehalose solution spray-dried at T_{inlet}/T_{outlet} = 150 °C/95 °C, D_d = 3.5 μm (from Figure 2c), and ρ_2 = 1470 kg/m^3 and W_2 = 100 kg/m^3. Equation A1 predicts a value of 8.6 μm for D_w, which agrees closely with measured values of droplet size at the same air/liquid mass ratio using laser diffraction (see Table 6).[6]

2. Calculation of Spray Droplet Formation Time—The formation time of a single spray droplet, t_f, at the tip of a pneumatic nozzle is given by:

$$t_f = \frac{\text{droplet volume [m}^3\text{]}}{\text{feed rate [m}^3\text{/h]}} \quad \text{(A2)}$$

For a droplet volume of $^4/_3\pi(4.3 \times 10^{-6})^3 = 3.33 \times 10^{-16}$ m^3 and a feed rate of 0.24×10^{-3} m^3/h, eq A2 gives a value for t_f of 5×10^{-6} ms, illustrating the almost instantaneous nature of droplet formation.

3. Calculation of Spray Droplet Drying Time—The drying of spray droplet containing dissolved trehalose in water can be divided into two phases. In the initial constant-rate period, the water concentration at the droplet surface and hence the rate of evaporation, dW/dt, are constant:[19]

$$\frac{dW}{dt}\Big|_{cr} = \frac{2\pi k_d D_{av} \Delta T}{\lambda} \quad \text{(A3)}$$

where ΔT is the log mean temperature difference:

$$\Delta T = \frac{(T_{inlet} - T_{wb}^{inlet})(T_{outlet} - T_{wb}^{outlet})}{\ln(T_{inlet} - T_{wb}^{inlet})/(T_{outlet} - T_{wb}^{outlet})} \quad \text{(A4)}$$

with T_{wb}^{inlet} being the wet-bulb temperature of the spray droplet surface and T_{wb}^{outlet} is the wet-bulb temperature of the dried particle surface. For the spray-dried trehalose, T_{inlet} = 150 °C, T_{wb}^{inlet} = 55 °C (from enthalpy/humidity chart), T_{outlet} = 95 °C, and T_{wb}^{outlet} = 55 °C, giving a value for ΔT of 64 °C. k_d is the thermal conductivity of the water vapor in the stagnant layer around the droplet = 0.567 kcal/m h °C at 64 °C. D_{av} is the average droplet/particle

diameter = 6.05 μm, and λ is the latent heat of vaporization of water = 540 kcal/kg. For these values, $dW/dt = 2.56 \times 10^{-6}$ kg/h according to eq A3. The total mass of water removed in the constant-rate period, ΔW_{cr}, is given by:

$$\Delta W_{cr} = \frac{4}{3}\pi(r_w^3 - r_d^3)\rho W_1 \quad \text{(A5)}$$

where r is droplet/particle radius, ρ is the density of the trehalose/water solution (1047 kg/m^3), and W_1 is the water content of the spray solution (0.9 kg/kg). Equation A5 gives for ΔW_{cr} a value of 2.93×10^{-13} kg. The drying time of the droplet in the constant-rate period, t_{cr}, is then given by:[19]

$$t_{cr} = \frac{\Delta W_{cr}}{dW/dt|_{cr}} = 0.41 \text{ ms} \quad \text{(A6)}$$

In the following falling-rate period, solid is present in the surface and the particle size is assumed not to change further. The rate of evaporation, $dW/dt|_{fr}$, decreases and is given by

$$\frac{\Delta W}{dt}|_{fr} = \frac{dW'}{dt} \times \text{wt of dry particle} \quad \text{(A7)}$$

where:

$$\frac{dW'}{dt} = \frac{12 k_d \Delta T}{\lambda D_c^2 \bar{\rho}_s} \quad \text{(A8)}$$

k_d is the thermal conductivity of the drying air around the particle = 0.0238 kcal/h m °C at approximately 64 °C. D_c is the critical particle diameter = D_d. $\bar{\rho}_s$ is the average particle density during the falling-rate period = 1374 kg/m^3. For these values eqs A7 and A8 give $dW/dt|_{fr} = 6.48 \times 10^{-8}$ kg/h. The mass of moisture removed in the falling-rate period, ΔW_{fr}, is given by the difference between moisture content at the critical point and the end moisture content:

$$\Delta W_{fr} = (2.00 \times 10^{14}) - (8.25 \times 10^{-16}) = 1.92 \times 10^{-14} \text{ kg} \quad \text{(A9)}$$

The drying time of the particle in the falling-rate period, t_{fr}, is then given by:

$$t_{fr} = \frac{\Delta W_{fr}}{dW/dt|_{fr}} = 1.07 \text{ ms} \quad \text{(A10)}$$

The results are summarized in Table 3. The extremely short drying times are a consequence of the small droplet size and high T_{inlet}. As a comparison, the drying time of a pure water droplet of the same diameter[17] yields:

$$t = \frac{\lambda \rho_1}{r k_d \Delta T} \int_0^{D_w} D\,dD = 0.5 \text{ ms} \quad \text{(A11)}$$

Abstract □ Free radical polymerization converts aqueous solutions of methacrylated inulin into cross-linked hydrogels. The purpose of this work was to study the hydrogel formation and to characterize the fully cured hydrogels. The gelation process of aqueous solutions of methacrylated inulin was monitored as a function of time by means of linear oscillatory shear measurements, at a fixed frequency and amplitude. The fully cured inulin hydrogels were characterized by measurement of the frequency-dependency of the linear elastic modulus *G′*. The effects of the degree of substitution and feed concentration of methacrylated inulin on both the gelation kinetics and the rigidity of the obtained hydrogels were determined. The effect of the concentration of the initiators of the radical polymerization reaction has been studied as well. The weight fraction of polymer which was not incorporated in the hydrogel networks was determined using the anthrone reaction, and physical chain entanglements were determined by solution viscosity measurements. The gelation kinetics and the elastic modulus were proportional to the degree of substitution and feed concentration of methacrylated inulin. Increasing concentrations of radical-forming compounds also accelerated the hydrogel formation, but lowered the elastic modulus of the obtained hydrogels. The amount of polymer chains incorporated in the hydrogel network seemed to be especially influenced by the degree of substitution of the derivatized inulin, and for a feed concentration of 27% w/w of methacrylated inulin, entanglements have to be accounted for. The gelation kinetics and the elastic modulus of inulin hydrogels are not only affected by the degree of substitution and the feed concentration of methacrylated inulin, but also by the concentration of the initiators of the free radical polymerization reaction.

Introduction

Inulin hydrogels were developed as carriers for colonic drug targeting. Inulin is a storage polysaccharide found in many plants such as garlic, onion, artichoke, and chicory.[1] It consists of β 2−1 linked D-fructose molecules, and the majority of the fructose chains have a glucose unit at the reducing end. The β 2−1 glycosidic bond is not significantly hydrolyzed by the endogenous secretions of the human digestive tract,[2] but bacteria residing in the colon, and more specifically *Bifidobacteria*, are able to ferment inulin.[3−5] *Bifidobacteria* constitute up to 25% of the normal gut flora of man and animals.[6] Hence, inulin was selected as candidate polymer for the development of a colon-specific drug delivery systems.

Inulin hydrogel formation has been previously described by Vervoort et al.[7] Vinyl groups were incorporated in the fructose chains by reaction of inulin with glycidyl methacrylate at room temperature using 4-(dimethylamino)-pyridine as catalyst. Transesterification occurred during the reaction of inulin with glycidyl methacrylate, since the obtained reaction product was characterized as methacrylated inulin (MA-IN) instead of glyceryl methacrylated inulin. This confirmed the findings which have been published previously by van Dijk-Wolthuis et al.[8] for the derivatization of dextran with glycidyl methacrylate. By varying the molar ratio of glycidyl methacrylate to inulin, the degree of substitution (DS), i.e., the amount of methacryloyl groups per 100 fructose units, of MA-IN could be tuned. Aqueous solutions of MA-IN were subsequently converted into cross-linked three-dimensional networks by free radical polymerization using ammonium persulfate (APS) and *N,N,N′,N′*-tetramethylethylenediamine (TMEDA) as radical generating compounds. Figure 1 gives a schematic representation of the derivatization reaction of inulin with glycidyl methacrylate and MA-IN hydrogel formation.

This work describes the rheological characterization of the synthesized inulin hydrogels as well as the hydrogel formation process. The influence of the degree of substitution and feed concentration of MA-IN, and the concentration of radical-generating compounds, were studied. The rheological data are correlated with previously obtained results with respect to the equilibrium-swelling degree of the inulin hydrogels and the in vitro enzymatic degradation of the devices.

Experimental Section

Materials—Chicory inulin (Raftiline HP; average degree of polymerization between 22 and 25) was kindly provided by Orafti (Tienen, Belgium), and was used for the synthesis of methacrylated inulin. APS was supplied by UCB (Leuven, Belgium) and TMEDA by Sigma (St. Louis, MO). Anthrone was obtained from ICN Biomedicals (Ohio) and D(−)-fructose from Merck (Darmstadt, Germany). For details about the materials used for the synthesis of MA-IN, reference is made to Vervoort et al.[7] For the rheological experiments, MA-IN solutions with feed concentration of 16%, 22%, and 27% w/w were prepared in 0.5 M phosphate buffer pH 6.5. MA-IN with three different degrees of substitution was used: DS = 4.4, 12.1, and 22.3.

Rheological Experiments—Dynamic oscillatory measurements were performed on a strain-controlled rheometer (Rheometrics Mechanical Spectrometer RMS705), equipped with a parallel plate geometry (diameter 25 mm). To avoid slippage of the sample, the plates were covered with sand-paper. The temperature was kept constant at 20 °C by a fluids bath. MA-IN solutions were prepared and immediately after adding the radical-generating compounds, the solutions were poured onto the lower plate (cup) of the rheometer, after which the upper plate was positioned at a gap of 1 mm. The free surface of the sample was

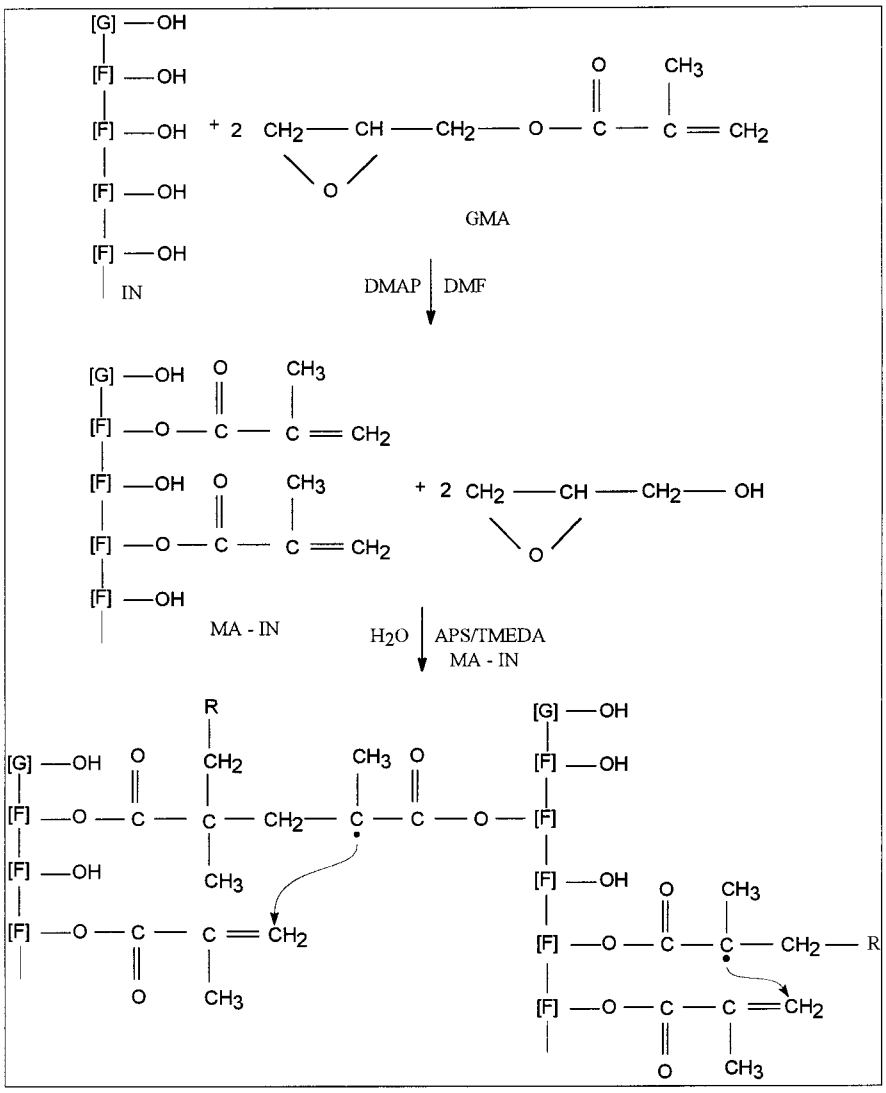

Figure 1—Schematic representation of the synthesis of MA-IN and the formation of inulin hydrogels. ([F]-OH = fructosyl unit; [G]-OH = glucosyl unit; IN = inulin; GMA = glycidyl methacrylate; DMAP = 4-(dimethylamino)pyridine; DMF = *N,N*-dimethylformamide; MA-IN = methacrylated inulin; APS = ammonium persulfate; TMEDA = *N,N,N′,N′*-tetramethylethylenediamine; R = initiator.)

covered with a mineral oil of low viscosity to prevent evaporation of the solvent during the experiment. The loading procedure took 160 s, after which the dynamic measurements started.

Small strain oscillations at a fixed frequency (4 rad/s) were applied to the samples to monitor the hydrogel formation. The strain was kept low enough to avoid interference with the formation of the MA-IN networks. After completion of the gelation process, a frequency sweep experiment was performed to characterize the fully cured MA-IN hydrogels. Before the latter experiment, the excess of gel at the rim of the geometry was removed to minimize errors due to edge effects. The dynamic behavior could be recorded over a frequency range from 0.01 to 10 rad/s. A linearity check was performed on every hydrogel to ensure that all measurements were probing the linear behavior of the hydrogels (results not shown).

Determination of Weight Fraction of Soluble Material (sol fraction)—The weight fraction of soluble material of a hydrogel (sol fraction) is defined as the amount of polymer chains, which are not incorporated in the hydrogel network and which can consequently be extracted and separated from the hydrogel.[9] To determine this sol fraction, MA-IN hydrogels of known dry weight were prepared and washed in demineralized water to extract the polymer chains, which are not attached to the hydrogel network. The sol fraction was calculated as the weight ratio of extracted material to initial material. The amount of extracted sugars was determined by means of the anthrone method,[10,11] and for the calculations, the degree of substitution of MA-IN used to prepare the respective hydrogels was taken into account.

The anthrone reagent was prepared by dissolving 50 mg of anthrone in a mixture of 28 mL of water and 72 mL of concentrated sulfuric acid. This freshly prepared reagent (2.5 mL) was mixed with 0.3 mL of collected samples of the hydrogel washing water containing the polymer chains, which were not incorporated in the hydrogel network. The samples were incubated for 10 min at 100 °C followed by cooling to room temperature. Finally, the absorbance of the samples was read spectrophotometrically with a HP 8452A spectrophotometer (Hewlett-Packard, Santa Clara, CA) at 625 nm. Since the same absorption is given by a sugar compound as if it was first hydrolyzed and then determined,[12] fructose solutions with concentrations ranging from 0.08 to 0.2 mg fructose/mL were used to construct a calibration line. Beside fructose, inulin also contains glucose units, but this does not compromise the anthrone method for sol fraction determination since equal amounts of glucose and fructose give identical absorption values.[12]

Determination of the Intrinsic Viscosity—To investigate whether chain entanglements, which can act as additional intermolecular cross-links, occur in the MA-IN solutions of different feed concentration, the intrinsic viscosity of MA-IN DS 12.1 was determined by solution viscosity measurements using an Ubbelohde suspended-level capillary viscometer (Schott Geräte, Hofheim, Germany). Efflux times of MA-IN solutions in 0.5 M phosphate buffer pH 6.5 were determined at 20 °C, and the respective reduced viscosities were calculated. The intrinsic viscosity was obtained by extrapolating the plot of the obtained values of reduced viscosity against the MA-IN concentration to infinite

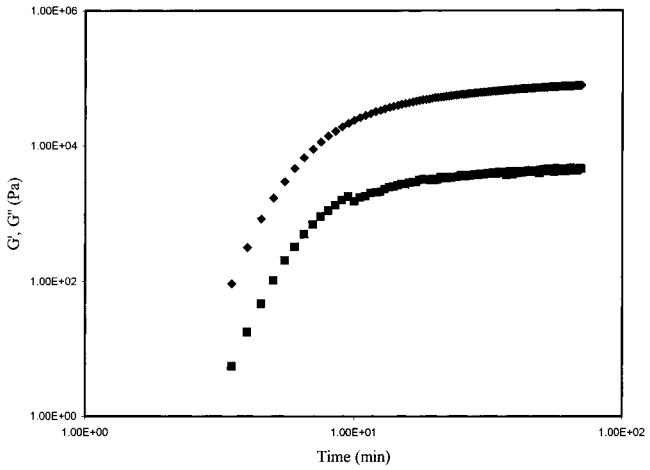

Figure 2—G' (◆) and G'' (■) as a function of polymerization time for hydrogel formation of a 27% w/w MA-IN DS 12.1 solution. (Concentration of APS = 17.5 μmol/mL buffer and TMEDA = 39.4 μmol/mL buffer.)

dilution according to the Huggins equation:

$$\eta_{red} = [\eta] + k[\eta]^2 c \quad (1)$$

with η_{red} the reduced viscosity, $[\eta]$ the intrinsic viscosity expressed in dL/g, k the Huggins constant, and c the concentration of the MA-IN solutions expressed in g/dL.

Results and Discussion

The addition of the radical-generating compounds APS and TMEDA to aqueous MA-IN solutions results in free radical polymerization. Dynamic rheological measurements at a fixed frequency and amplitude were performed during this process in order to follow the gradual formation of a three-dimensional network. The formation of intermolecular cross-links should show up in an increase of the elastic modulus G' as a function of time. G' is a measure of the energy stored and recovered per cycle of oscillatory deformation and represents the elastic behavior of the material.[13] Beside intermolecular cross-links, the radical polymerization reaction probably also introduces loops or intramolecular cross-links, loose ends or chains incorporated in the network by a single bond, unattached material or sol fraction, and physical chain entanglements in the network. These structures hardly contribute to an increase in G'.[14–16] The viscous modulus G'', on the other hand, is a measure of energy dissipation per cycle of sinusoidal deformation[13] and represents the viscous behavior of the system under investigation. The viscosity is known to be sensitive to the molecular weight of polymer chains. Figure 2 shows a plot of G' and G'' versus time, representing the gelation process of a 27% w/w MA-IN DS 12.1 solution. From the point on where the moduli have increased sufficiently to be measurable, G'' is an order of magnitude smaller than G'. This was the case for all hydrogel formulations tested. Since the fully cured hydrogels exhibited no or only a limited frequency dependence of G' (Figure 3), it can be assumed that a network has indeed been formed by the radical reaction. The profile of G' versus time (Figure 2) can thus be interpreted as the gradual formation of a hydrogel network from a MA-IN solution. The three stages commonly encountered in hydrogel formation can be distinguished from the evolution of G' in time: a pregelation period, in which no measurable increase in G' is seen, a gelation period showing a rapid increase in G', and a postgelation period in which G' hardly changes anymore and reaches a constant value. During the pregelation period free radicals are formed and reaction within and between chains starts. The incorporation of the MA-IN polymers in a three-dimensional network takes place during the gelation period while gelation is ending during the post-gelation period.

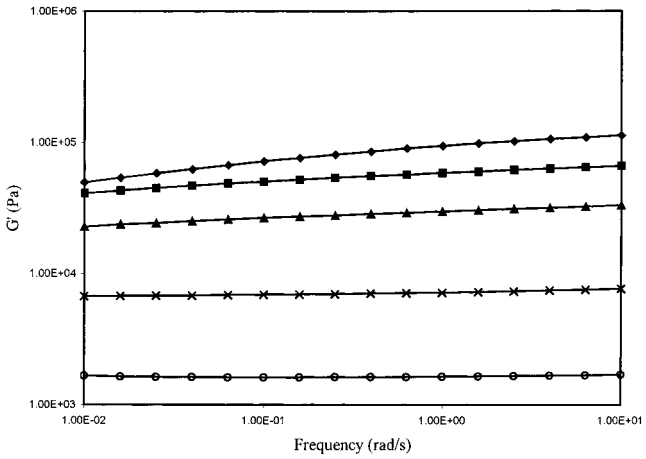

Figure 3—G' as a function of frequency for fully cured MA-IN hydrogels with different degree of substitution and feed concentration (○ = DS 4.4; 27%, × = DS 12.1; 16%, ▲ = DS 12.1; 22%, ■ = DS 12.1; 27%, ◆ = DS 22.3; 27%). (Concentration of APS = 17.5 μmol/mL buffer and TMEDA = 39.4 μmol/mL buffer.)

Table 1—Time (min, loading procedure included) To Reach 50% of G' end for Hydrogels of Different Composition ([APS] = 17.5 μmol/mL buffer, [TMEDA] = 39.4 μmol/mL buffer)

hydrogel composition		
DS	feed concn (% w/w)	time (min)
4.4	27	60.5
12.1	16	21.3
12.1	22	18.8
12.1	27	16.8
22.3	27	15.8

Table 2—Time (min, loading procedure included) To Reach 50% of G' end for Hydrogels Prepared from 16% w/w Solutions of MA-IN DS 12.1 as a Function of the Concentrations of APS and TMEDA (μmol/mL buffer)

[APS]	[TMEDA]	time (min)
17.5	39.4	21.3
17.5	78.7	13.1
17.5	157.4	4.6
70.1	39.4	3.8

To quantify a characteristic time for network formation, the time needed to reach 50% of the final value of G' (G' end) has been determined. Table 1 lists the results as a function of the degree of substitution and the feed concentration of MA-IN. It can be concluded that increasing the degree of substitution or the feed concentration accelerates the gelation process, implying that the radical cross-linking reaction is promoted by increasing concentrations of reactive vinyl groups. The characteristic time for network formation is also influenced by the concentration of the initiators of the polymerization reaction as is shown in Table 2. TMEDA is believed to exert a promoting effect on the vinyl polymerization initiated by persulfate attributed to an acceleration of the homolytic scission of the latter compound.[17,18] Increasing the concentration of the radical-generating compound APS, and thus introducing more free radicals in the reaction solution, also decreases the gelation time. To verify whether the accelerating effect of the

Table 3—Pregelation Period (min, loading procedure included) and Slope (Pa/min) of the Curves of G' versus Time ($0.1 < G'/G'$ end < 0.6), Indicative for the Gelation Period, for Hydrogels Prepared from 16% w/w Solutions of MA-IN DS 12.1 as a Function of Varying Concentrations of APS and TMEDA (μmol/mL buffer)

[APS]	[TMEDA]	pregelation period (min)	slope (Pa/min)
17.5	39.4	6.57	265.70
17.5	78.7	3.86	267.45
17.5	157.4	1.03	709.14
70.1	39.4	0.29	780.00

initiators was caused by shortening either the pregelation or the gelation period, both periods were separately defined, and the effect of the initiator concentration was studied. The pregelation period was defined as the time needed to reach 1% of G' end. The slope of the curves of G' versus time ($0.1 < G'/G'$ end <0.6) was considered as an indication of the rate of gelation. Table 3 illustrates that increasing initiator concentrations accelerate both stages of hydrogel formation: using high concentrations of APS and TMEDA, intermolecular cross-link formation is detectable almost immediately after mixing the two compounds with the MA-IN solutions, and the gelation process is characterized by a steep rise in G'.

From this kinetic study, it was concluded that the formation of MA-IN hydrogels can be performed within 2.5 h, because cross-linking of MA-IN chains will have ended in this period of time, at least for the range of degree of substitution and feed concentration studied.

If an ideal three-dimensional network is formed by the radical polymerization, the elastic modulus G' is independent of frequency. This frequency-independent elastic modulus is called the equilibrium elastic modulus G_e and is a measure of the structure that has been formed by the cross-linking reaction. Several theories, such as the affine theory, the phantom theory, the constrained junction model, or the Langley−Graessley model,[19−21] have been developed to relate the macroscopic elastic modulus of a polymeric network to its molecular structure. From these theories, it can generally be concluded that G_e is proportional to the number of moles of elastic chains, i.e., chains attached to the network with both ends, per volume unit of the network (ν) according to the following equation:

$$G_e \sim \nu RT \qquad (2)$$

with R the gas constant and T the absolute temperature.

Determination of G_e can thus give an idea about the concentration of elastic network strands and hence about the amount of intermolecular cross-links formed.

For the cross-linked materials under investigation, the frequency dependence of the elastic modulus is shown in Figure 3 over three decades in frequency. For hydrogels prepared from MA-IN with low degree of substitution (27% w/w solution with DS = 4.4) or low feed concentration (16% w/w solution with DS = 12.1), the values of G' appear to be almost independent of frequency. To a first approximation, these hydrogels can thus be considered as ideal networks, and the constant value of G' consequently represents the equilibrium elastic modulus G_e. However, the other hydrogels tested show a slight decrease of G' with decreasing frequency, indicating that relaxation (rearrangements) can still occur in the network. For these systems, G_e could not be determined. Nevertheless, it may be concluded that the amount of elastic chains per volume unit of the network increases with increasing degree of substitution and feed concentration, since both parameters definitely have an increasing effect on G'. These observations support the results of the equilibrium degree of swelling study and the in vitro enzymatic degradation study of the MA-IN hydrogels.[22,23] The decreased equilibrium swelling and the decreased enzymatic degradation of the hydrogels with increasing degree of substitution or feed concentration of MA-IN can be attributed to the increased intermolecular cross-linking density (higher G' values) of the networks, which increases the contractility of the hydrogels, resulting in a restriction of expansion upon swelling, and which reduces the permeability of the networks toward degrading enzymes.

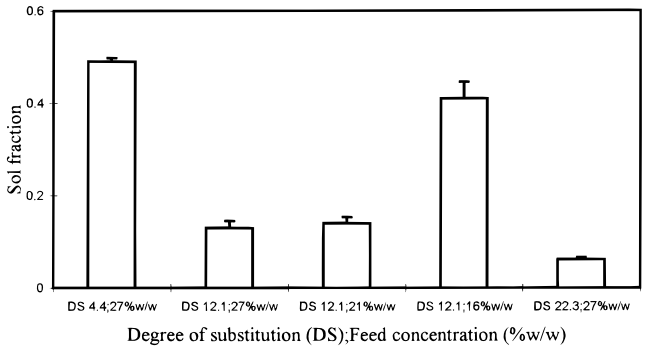

Figure 4—Weight fraction of soluble material (sol fraction) for MA-IN hydrogels with different compositions.

The observed frequency dependence of G' can possibly be attributed to imperfections in the structure of the network.[19] Loose ends, loops, and MA-IN chains which are not incorporated in the network, can relax, causing a decrease in G' at low frequencies.

It was first checked whether the presence of a sol fraction can explain the relaxation in G'. As gelation of the MA-IN solutions took place between the plates of the rheometer, the chains which are not incorporated in the hydrogel network, have not been removed. Figure 4 shows the sol fractions of MA-IN hydrogels of different feed composition. As expected, the sol fraction is reduced with an increasing amount of reactive groups per chain (DS): more chains will participate in the network when there are more groups present which can link them to the network. The effect of concentration on sol fraction can be understood from the promoting effect of dilution on intramolecular cross-linking, which does not incorporate chains in the network. The probability that bonds will be formed between different chains of the system is proportional to the probability that these chains lie in the same small volume-element[14] and therefore increases with concentration. Hence, the hydrogels prepared from a 16% w/w solution (MA-IN DS = 12.1) exhibited a higher sol fraction when compared with the more concentrated solutions (22 and 27% w/w). However, comparison of the data from Figure 3 and Figure 4 clearly indicates that the sol fraction data cannot explain the frequency dependence of G': the samples with the higher sol fraction do not correspond to the samples with the more pronounced frequency dependence of G'.

A second possible explanation for the observed decrease of G' is the relaxation of loose ends and loops. MA-IN solutions of high feed concentration form dense networks in a short period of time compared with more diluted solutions (Figure 3 and Table 1). As mentioned above, intermolecular cross-links are predominantly formed starting from a concentrated solution, whereas intramolecular cross-link formation is promoted by a diluted solution. Due to the higher extent of intermolecular cross-linking in case of a concentrated solution, the mobility of the polymer chains can be restricted to such an extent that full conversion of the vinyl groups can be impeded. Consequently, more loose ends may remain in the hydrogel network, and these are able to relax on the time scales

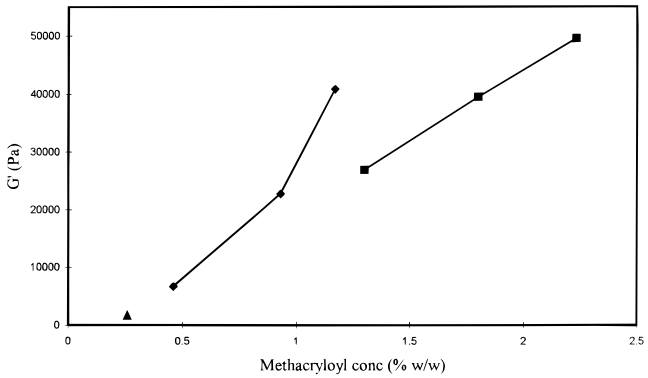

Figure 5—*G′* as a function of the real methacryloyl concentration in the hydrogel network prepared from MA-IN DS 4.4 (▲), DS 12.1 (◆), and DS 22.3 (■).

probed by the oscillatory experiments. In addition, when the feed concentration of MA-IN exceeds the critical concentration at which MA-IN chains start to overlap, physical chain entanglements are formed which promote intermolecular cross-linking even more. Moreover, the entanglements themselves can be considered as additional intermolecular cross-links, contributing to an increase in *G′* and additionally limiting chain mobility thereby restricting full conversion of the vinyl groups.

A rule of thumb for predicting when concentration effects will become important is when the coil overlap parameter $c[\eta]$, with c the concentration of the polymer solution (g/dL) and $[\eta]$ the intrinsic viscosity of the polymer (dL/g), is near unity.[24] Consequently, it can be postulated that:

$c[\eta] < 1$: the polymer coils are isolated one from another, and the solution can be considered as a particle solution;

$c[\eta] = 1$: the polymer coils begin to overlap;

$c[\eta] > 1$: the polymer coils form entanglements, and the solution can be considered as a network solution.

The intrinsic viscosity of MA-IN DS 12.1 is 0.038 dL/g as determined by solution viscosity measurements. This implies that for the highest feed concentration (density = 1.14 g/mL), entanglements have to be accounted for, which may increase the amount of loose ends.

Unfortunately, the degree of conversion of MA-IN during hydrogel formation could not be determined, neither by FT-IR nor by solid state ^{13}C NMR spectroscopy.[7] But van Dijk-Wolthuis et al.[18] described indeed a low final percentage conversion of the methacryloyl groups of methacrylated dextran upon free radical polymerization at a high initial concentration of methacrylated dextran compared with a low initial concentration.

With respect to the effect of degree of substitution on the observed frequency dependence of *G′*, the same remark can be made as for the effect of the feed concentration. Solutions of MA-IN with a high degree of substitution are converted rather fast in rigid networks (high value of *G′*), implying again that full conversion of the double bonds may be impeded and loose ends may remain. A high degree of substitution additionally promotes cyclization or the formation of loops,[25] which can also relax during the rheological experiments.

To investigate the relative amount of inter- to intramolecular cross-links, G_e, being a measure of the intermolecular cross-links, was plotted in Figure 5 as a function of the methacryloyl concentration, a measure of the amount of reactive sites. For the perfect networks, G_e was considered whereas for the imperfect networks *G′* at a frequency of 0.01 rad/s was taken. Since the sol fraction of the systems under investigation is not negligible (Figure 4), the real methacryloyl concentration in the network, i.e., the concentration corrected for the not incorporated polymer

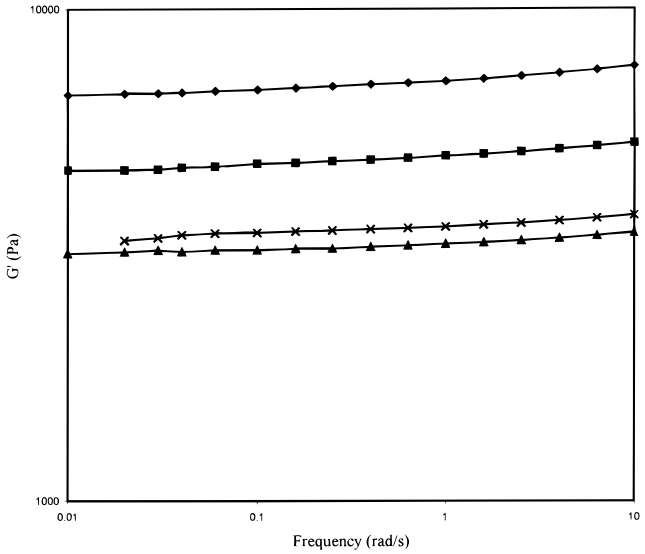

Figure 6—*G′* as a function of frequency for MA-IN hydrogels with DS 12.1 and feed concentration 16% w/w prepared with different concentrations of APS and TMEDA (μmol/mL buffer). ([APS]; [TMEDA] = 17.5; 39.4 (◆), 17.5; 78.7 (■), 17.5; 157.4 (▲), and 70.1; 39.4 (×).)

chains, has been considered. Determination of the sol fraction of hydrogels prepared from 16% and 22% w/w solutions of MA-IN DS 4.4 could not be performed, as these hydrogels were too weak to manipulate. Hence, only one value for DS 4.4 is depicted in Figure 5. Figure 5 clearly illustrates that increasing amounts of reactive vinyl groups in the polymerization reaction (increased feed concentration) results in the increased formation of intermolecular cross-links, confirming the conclusions from Figure 3. In addition, this figure suggests that for the same methacryloyl concentration, hydrogels prepared from MA-IN with a low degree of substitution exhibit higher values of *G′* than hydrogels from MA-IN with a higher degree of substitution. In other words, to form an equal amount of intermolecular cross-links, higher substituted MA-IN may need a higher amount of polymerizable groups, since reactive sites may be lost by intramolecular cross-linking or perhaps may not have reacted at all (lower degree of conversion). These observations agree with the remarks made in order to explain the frequency dependence of *G′*.

Finally, the effect of the concentration of the initiating species APS and TMEDA on the resulting structure of the hydrogel has been investigated. Figure 6 represents the dynamic behavior of fully cured networks prepared from 16% w/w solutions of MA-IN DS 12.1 with various initiator concentrations. Apparently, hydrogels prepared with higher initiator concentrations exhibit lower values of *G′*, at least for the range of concentrations studied. This can be explained by the fact that the higher concentrations of initiators result in the formation of an increased number of radicals in the initiation step of the radical polymerization reaction. Consequently, the number of active centers formed on the inulin chains is also increased, implying that less unreacted vinyl groups are left to cross-link the chains, which results in lower *G′* values.

Conclusions

Oscillatory shear measurements, performed on inulin solutions during the gelation process as well as on fully cured hydrogels, showed that the degree of substitution and feed concentration of MA-IN, and the concentration of the initiating species of the free radical polymerization reaction (APS and TMEDA), all affect the gelation process and the

rigidity of the obtained hydrogels. A higher degree of substitution or feed concentration cause an acceleration of the network formation. The resulting hydrogels are characterized by a higher mechanical strength (higher G' values), arising from the increased amount of intermolecular cross-links formed. Increasing concentrations of APS and TMEDA also shorten the process of hydrogel formation, but result in hydrogels with lower G' values.

Received August 17, 1998. Accepted for publication November 3, 1998.

Abstract □ The release of human immunoglobulin G (IgG) using ethylene–vinyl acetate copolymer (EVAc) as a polymer carrier was studied by fabricating them into two commercially available dosage forms: slab and microsphere. A first-order flux decay model and two hierarchical models concerned with the mass transfer coefficient on the slab surface were used to describe the mechanism of release kinetics and the results compared. These models gave insight to some of the important physical parameters of drug release such as the diffusion coefficient, time constant of release, and initial flux. It was found that the release mechanism varies with time, and hence no single model can be used to predict the release profile for the entire period of study. A controlled release study by matrix coating was also done. The results obtained were utilized to examine the suitability of a particular dosage form (matrix geometry) of IgG for clinical applications. The release data compared with the standard methods of IgG therapy proves localized drug delivery to be a major boon for immunodeficient patients.

Introduction

The survival of the human race depends largely on the body's defense mechanism. Better known as humoral immune response, the production of antibodies in response to foreign bodies or "antigens" determines the state of health of any individual. Individuals falling short of this response are said to be immunodeficient and require immune therapy for treatment. This led to the development of γ-globulin therapy about three decades ago.[1] Immunoglobulin G (IgG), a very high molecular weight protein molecule, constitutes the major fraction of the γ-globulin repertoire, and its mean normal serum concentration is of the order 5.4−16.1 g/L. Replacement therapy using IgG is a common feature for patients suffering from hypogammaglobulinemia[2] and for those patients suffering from cancer, burns, and other disorders due to secondary IgG deficiencies. IgG has also been used in the development of efficient immunotherapeutic agents for the treatment of tumors, by the fusion of genetic engineering and hybridoma technology.[3] They function as carriers of drug molecules, which are directed toward a specific antigenic target site located in various parts of the human body.

Classical methods of IgG therapy are done either by intravenous injection or by intramuscular injection.[1] Intramuscular administration of IgG has been in vogue since the early 1950s. However limitations in this therapy, which include the painful method of injection, the persistence of discomfiture, the reduced elevation of serum IgG levels after injection etc. led to the usage of intravenous injection as an alternative in the 1980s. Although the method proved to be effective in certain areas such as an immediate rise in the serum IgG level after infusion, it had its own detrimental effects by introducing certain painful side effects. Further, the dose required for treatment and the frequency of therapy was substantially high, particularly if the treatment is for a tumor. IgG immunotherapy is employed in coordination with the radiation therapy and surgery for extreme cases of tumor. Inspite of these methodologies, the recurrence of malignancies at a site near the original location could not be prevented.[4] This can, however, be avoided if the tumor-bearing region is exposed to increasing doses of radiation and immunotherapy. However, both methodologies have their own defect. Excessive radiation might also affect the normal tissues, and a higher dose of drug might result in systemic toxicity.

A suitable alternative is the use of drug-incorporated polymer matrixes with controlled release applications, which has attracted considerable attention since its practicality was demonstrated.[5] The method is highly attractive due to its reduced dose handling and the drastic reduction in treatment frequency. Controlled delivery of antibody to the mucosal tissue of rats by topical application has been already studied by Kuo et al.[6] Cleek et al.[7] studied the release characteristics of γ-globulin molecules from biodegradable microspheres. Extensive efforts have been put into searching for a suitable polymer carrier and the variety of factors that affect the release kinetics of drug−polymer systems. A nonbiodegradable and hydrophobic polymer, EVAc (ethylene−vinyl acetate copolymer) has been chosen as a drug carrier in many drug−polymer systems because of its proven biocompatibility.[8,9]

In this report, we study the in vitro release kinetics of IgG by using two commercially available dosage forms: the slab and the microsphere. Due to the geometric difference, the release pattern obtained for the two cases will be different, thereby serving as dosage forms for patients with different dose specificities and natures of compliance. Since IgG is naturally present in humans along with other proteins, the in vitro analysis was carried out based on perfusion immunoassay using a high performance liquid chromatography (HPLC) system. We have chosen this method because of its ability to detect specific proteins in a relatively fast and highly automated fashion, as compared to the method of the enzyme-linked immunosorbent assay.[10] The results obtained from the release kinetics were then compared with the conventional methods of therapy and the features discussed.

Materials and Methods

Methods—*Fabrication of IgG-EVAc Systems*—To prevent the possible denaturation of IgG at high temperatures, which may occur during the classical methods of compression molding and injection molding, a solvent-casting method was chosen for fabrication of drug−polymer systems. The EVAc polymer, which is in the form of pellets, was cleaned as described by Langer et al.[8] It was then dissolved in methylene chloride in a mass ratio of 1:9. IgG crystals were sieved with Endecotts test sieve (250 μm) to obtain the desired size fraction. The amount of IgG powder corresponding to the required drug loading was then weighed out accurately (± 0.0001 g) and added to 10 mL of the resultant EVAc−methylene chloride solution. The drug−polymer suspension was then molded into two geometrical shapes, viz. microsphere and slab as reported in Sefton et al.[11] and Rhine et al.,[12] respectively. Briefly, the drug−polymer suspension was poured into a Petri dish (for slab fabrication) and precooled at −70 °C for 15 min. The dish containing the matrix was initially cooled at −70 °C for 10 min before transferring it to −20 °C. After 2 days, the matrix was kept under mild vacuum for an additional 2 days under room temperature. The resulting matrix was found to be a thin film ~1 mm in thickness. Square slabs with specific dimensions were cut off from the matrix. In the case of microsphere fabrication, the suspension was extruded using a disposable 3 mL syringe fitted with a 16 gauge (BioLaboratories, Singapore) needle into cold absolute ethanol (placed in a container of liquid nitrogen). After leaving for 24 h, the absolute ethanol solution was replaced in order to remove the methylene chloride by liquid−liquid extraction phenomena. The beads that were obtained were finally vacuum-dried for 4 h before using for release study. Microspheres were also prepared using the 19 gauge and 23 gauge sized needles.

Fabrication of Coated IgG−EVAc Matrixes—The slabs that were obtained as per the previous procedure were submerged in 10% EVAc solution for 2 min. Before dipping, one of the 1 × 0.1 cm^2 sides of each slab was covered with a carbon adhesive tape to make it coating free. The slabs were then taken out, and the tape was removed and dried at room temperature for 5 min. Finally, they were dried under mild vacuum at room temperature for 24 h. The same procedure was carried out for slabs coated in 20% and 30% EVAc solution.

In Vitro Release Kinetics Study—Each slice of slab was weighed and submerged in separate beakers containing 2 mL of 0.1 M phosphate buffer, pH 7.4, containing 0.1 M sodium phosphate and 0.15 M sodium chloride (prepared using the PBS pack obtained from Pierce, Rockford, IL) and 4 mg/L gentamicin sulfate (Sigma Diagnostics, St. Louis, MO) which acts as an antibiotic against microbes. A release study was carried out at 37 °C for 1 h. The slices were then removed by forceps, blotted dry by tissue, and then transferred to a fresh buffer solution. Phosphate buffers (2 mL) were analyzed by HPLC to determine the IgG concentration. The same procedure was repeated at specific time intervals. When the releasing was for more than 1 h, the slices were soaked in 10 mL of phosphate buffer to provide the "infinite sink" condition. Buffers (10 mL) were also used to determine the concentrations and to give a clear picture on the percentage of drug that had been released each day. For the case of microspheres, a 50 mg aliquot of microspheres was weighed accurately and subjected to the release study as mentioned above.

HPLC Analysis—The quantification of IgG release was done using the HPLC system (Perkin-Elmer Corporation, Norwalk, CT) and PA Immunodetection sensor cartridge (PerSeptive Biosystems Inc., Framingham, MA). The loading buffer (0.01 M phosphate buffer), pH 7.4, containing 0.12 M sodium chloride and 0.0027 M potassium chloride, was prepared from PBS packs obtained from Sigma Diagnostics while the elution buffer was prepared from 0.15 M sodium chloride, pH adjusted to 2.3 using 6 M HCl. The IgG sample with an injection volume of 50 μL was pumped through the sensor cartridge. The nontarget components of the assay gave the first peak of the chromatography. With the switch of loading buffer to the elution buffer, the IgG−Protein G complexes were dissociated, and IgG was eluted out of the cartridge, which gave the second peak of the chromatography. The sample peak area was obtained by subtracting the chromatogram of the blank from that of the sample. The mass of IgG released was then obtained on comparison with a calibration curve of the peak area plotted against the mass of IgG standard sample taken.

Data Analysis—The decay in the flux of IgG is approximated by a first-order process with a characteristic time constant τ, given by the relation

$$\frac{F}{F_0} = \exp\left(\frac{-t}{\tau}\right) \tag{1}$$

where F is the molar flux as a function of time and F_o is the initial flux. Further, two models of mass transfer were used to analyze the release mechanism of IgG from the polymer matrix. The first one (model I) assumes an infinitely high coefficient of matter transfer on the surface. Hence, making use of the classical Fickian equation for release from slab (thin film):

$$\frac{\partial C_i}{\partial \mathrm{t}} = D_i \frac{\partial^2 C_i}{\partial x^2} \tag{2}$$

where C_i is the IgG concentration in the EVAc matrix as a function of time and position, x is the position within the polymer matrix, and D_i is the diffusion coefficient for IgG transport within the EVAc matrix and assuming that (i) the IgG concentration is uniform throughout the matrix at time $t = 0$ i.e., $C_i = C_i^0$ at $t = 0$, for all x, and (ii) the surface concentration of IgG is maintained at a constant concentration at times $t > 0$, eq 2 can be solved for C_i[13] as a function of x and t. On integrating over the thickness of the film, the amount (mass) of IgG released Q_t from the slab at time t can be obtained. This can be further simplified to obtain the relation for Q_t at short and long times based on the value of Q_t/Q_T

$$\frac{Q_t}{Q_T} = \frac{4}{L}\left(\frac{D_i t}{\pi}\right)^{0.5} \quad \text{for} \quad Q_t/Q_T \le 0.5 \tag{3}$$

$$\frac{Q_T - Q_t}{Q_T} = \frac{8}{\pi^2}\exp\left(-\frac{\pi^2 D_i t}{L^2}\right) \quad \text{for} \quad Q_t/Q_T \ge 0.55 \tag{4}$$

where Q_T is the amount of IgG released at infinite time,[14] and L is the thickness of the slab. The diffusion coefficient D_i for IgG transport in the porous polymer matrix for short and long times were determined by comparing the experimental results to eqs 3 and 4, respectively.

The second model (model II) assumes a finite coefficient of matter transfer on the surface. Starting from eq 2 for a slab of thickness $2L$, the model similar to the previous one, assumes uniform initial concentration of IgG (C_i^0) for all x. The boundary condition representing the loss of IgG at the slab surface is given by eq 5,

$$t > 0 \quad -D_i\left|\frac{\partial C_i}{\partial x}\right| = h(C_s - C_e) \qquad x = \pm L \tag{5}$$

where h is the coefficient of matter (IgG) transfer, C_s is the concentration of IgG at the surface, and C_e is the concentration of IgG required to maintain equilibrium with the medium. Equation 2 can be solved for C_i[13] as a function of x and t making use of the given initial and boundary conditions. On integration over the slab thickness, a relation between the amount (mass) of IgG released Q_t from the slab at time t and the amount released after infinite time Q_T can be obtained.[15]

$$\frac{Q_T - Q_t}{Q_T} = \sum_{n=1}^{\infty} \frac{2N^2}{\beta_n^2(\beta_n^2 + N^2 + N)}\exp\left(-\frac{\beta_n^2 D_i t}{L^2}\right) \tag{6}$$

where N is the dimensionless number given by eq 7

$$N = \frac{Lh}{D_i} \tag{7}$$

and β_n is the positive root of eq 8

$$\beta \times \tan\beta = N \tag{8}$$

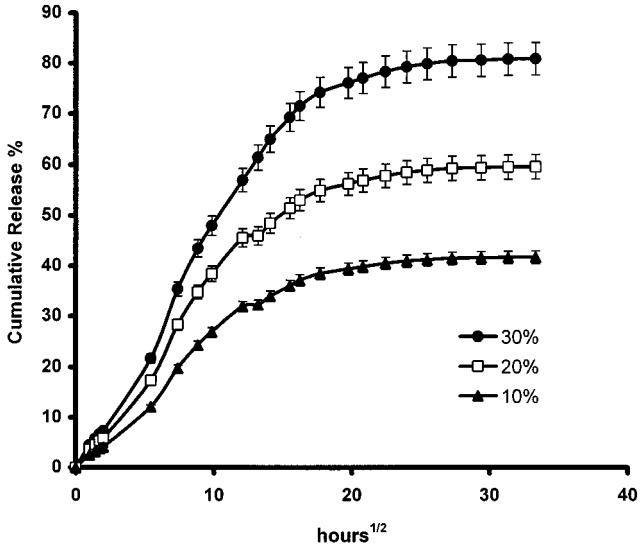

Figure 1—Fraction of IgG released for the 10, 20, and 30% loaded cases, respectively, for the slab geometry. Each point is an average of six data points. Standard error of the mean of release at each time point is 4%.

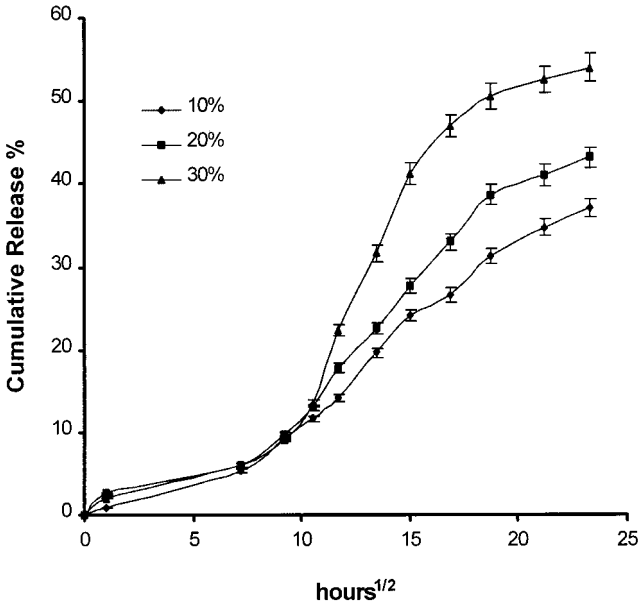

Figure 2—Fraction of IgG released for the 10, 20, and 30% loaded cases, respectively, for the microsphere geometry. Each point is an average of four data points. Standard error of the mean of release at each time point is 3–6%.

The transfer coefficient h and the diffusion coefficient D_i were then determined by fitting the experimental data to eq 6 coupled with eqs 7 and 8.

Results and Discussion

Release Studies—Preliminary studies carried out for different drug loading showed that drug release increased with increased drug loading for both geometries as shown in Figures 1 and 2, respectively. The initial steep slope for the slab geometry is mainly due to the release of drug molecules present on the exterior surface of the matrix that is followed by a stage in which the drug gradually diffuses through the polymer backbone to the exterior of the matrix and therefore a corresponding decrease in the release rate. The possibility of drug dissolution in the buffer followed by diffusion through the solvent-filled pores cannot be completely ignored. Further, since the solubility or the saturation concentration of IgG is less than the drug loading, dissolution in the solvent-filled pores plays a very important role in the initial period of release, whereas the latter period of release is predominated by the diffusion through the pores and channels formed in the matrix.[16]

The very high molecular weight of the IgG molecule restricts its release through the tortuous path within the matrix. Hence, in the presence of the available tortuous path formed by the preceding molecules, the later molecules find their way to the exterior much more easily, and therefore the release rate is gradually maintained but in a decreasing trend because of the increased distance for release. This feature continues until one of the following two limiting cases exist: (1) the path available for the drug to be released becomes more tortuous, and (2) decrease in the available drug content to utilize the existing release path. As a result, the curve tends to be asymptotic at very high time intervals. Thus, the drug release is explained by these two stages, which alternates between each other to give a sustained release. However, this can be avoided by altering the matrix geometry to compensate for the increasing distance for diffusion by increased drug concentration in order to achieve a zero-order release pattern.[17]

On observing the fraction of drug released for slabs from Figure 1, we find that the cumulative drug release rises in proportion with the square root of time for the first 15 days followed by a decline in the release percent. About 81% of the drug was observed to be released after 46 days for the 30% loaded case during which the 10 and 20% loaded cases released approximately 40 and 60% IgG, respectively. It is clearly noted that the drug release follows a square root of time kinetics in the initial period, which might vary for different drug loading and experimental conditions. Since then, the flux deteriorates, following an intermediate transitional order for the next fortnight finally tending toward zero after 45 days. In the case of microspheres, the drug release is initially in the lag period (Figure 2) after which the release gradually improves until an asymptotic behavior exists. The lag period might be due to the role of dissolution playing the rate-limiting step in the release kinetics. An important feature noted in the release profiles is the sigmoidal nature of the curve, and this nature increases for increasing drug loading. Furthermore, the release mechanism of a microsphere approximates that of a slab for smaller drug loading at all times and for higher drug loading at longer times (data not shown). Hence, the geometry of the drug−polymer matrix plays an essential role in deciding the type of release mechanism.

Henceforth, the discussion will be based on the 30% IgG loaded slab and microsphere matrixes (16 gauge size, unless mentioned otherwise) for more rigorous analysis on the release kinetics. In addition, this percentage loading exhibits some agreement with the required dosage levels of drug that has to be maintained in patients suffering from primary immunodeficiency disease.[18] An explanation of this statement is given later in this article.

The decrease in the molar flux of IgG calculated as moles of IgG released perpendicular to a square centimeter of surface area per second from the matrix was found to fit well to the exponential eq 1. F_o and τ were analyzed for slab matrixes with different dimensions (represented by the ratio of surface area to volume [S/V]), with the same thickness using eq 1. The initial flux and time constant for the different cases tabulated in Table 1 agree reasonably well with respect to each other. Further, the release profiles for the slabs with different S/V ratios shown in Figure 3 were in reasonable agreement with each other, thereby confirming the uniformity in drug distribution and the reproducibility of the release kinetics.[12] This is due to the release occurring primarily in the direction perpen-

Table 1—Initial Fluxes and Time Constants Calculated for Slabs of Different Dimensions

S/V (cm^{-1})	initial flux F_0 ($mol/cm^2 \cdot s$) $\times 10^{12}$	time constant (h)
22	1.244 ± 0.03	154.74 ± 1.56
24	1.318 ± 0.025	157.999 ± 2.10
30	1.334 ± 0.026	158.643 ± 1.89

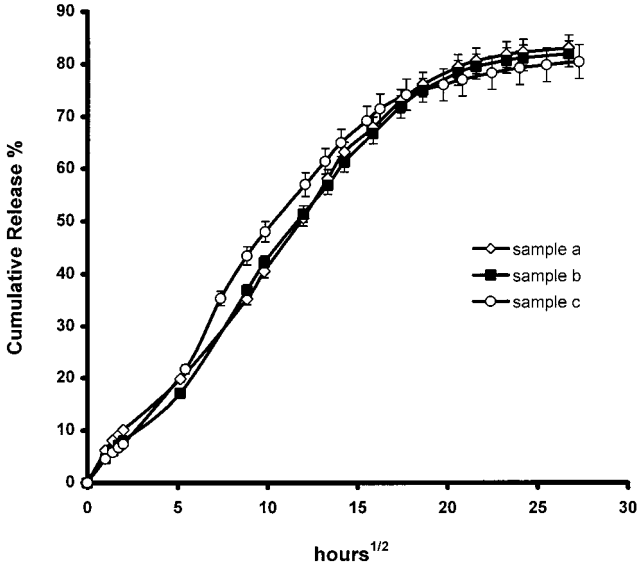

Figure 3—Cumulative percent of IgG release for different sized slab matrixes of 30% IgG loading. (Sample a: 30 cm^{-1}; sample b: 24 cm^{-1}; sample c: 22 cm^{-1}). Each point is an average of four data points, and the error of the mean of the release at each time point is less than 4%.

Table 2—Experimentally Determined Parameter Values for Short and Long Times of Release for the Case of a Slab Using Model One[a]

Q_t/Q_T	D_i (cm^2/s)	tortuosity
≤ 0.50	1.82×10^{-9}	341
≥ 0.55	1.89×10^{-9}	328

[a] $L = 0.1$ cm.

dicular to the thickness of the film. However, this cannot be true for cases in which the thickness is comparable to the other slab dimensions. For example, similar release studies carried out for different sized cubic samples (data not shown) showed variations in their kinetics.

Fitting of the experimental data to model I, i.e., eqs 3−4, show that the diffusion coefficient is almost a constant (see Table 2) with respect to time. The calculated D_i for IgG release through the EVAc backbone agrees reasonably well with the D_{eff} (0.9×10^{-9} cm^2/s) reported by Saltzman et al.[19] for IgG. The slight variation between the two values might be attributed to factors such as the difference in the percentage loading of IgG, the molecular weight of EVAc used, and the matrix geometry. The tortuosity value in the table was obtained on dividing the aqueous diffusion coefficient[20] of IgG (6.2×10^{-7} cm^2/s) by the experimentally determined diffusion coefficient.[21] Hence, it is noted that the path for drug diffusion in the polymer matrix becomes more complicated by an order of ~ 2 on comparison to unrestricted diffusion in free liquid. This seems to be quite practical on comparison with the tortuosity values obtained in similar experimental runs[22] for other biomolecules. The tortuosity value essentially takes into account all the properties of the polymer−drug and their interactions. In the case of model II, the experimental data was fitted to eq 6 by taking the diffusion coefficient developed in model I as an initial estimate, and refining the values of the

Table 3—Experimentally Determined Parameter Values for Model Two[a]

coefficient of matter transfer (h)	6.89×10^{-5} cm/s
diffusion coefficient (D_i)	2.06×10^{-9} cm^2/s
tortuosity	301

[a] $L = 0.05$ cm.

dimensionless number N and its corresponding β_n by using a standard nonlinear optimization tool. The diffusion coefficient and the matter transfer coefficient that are finally obtained are shown in Table 3. The diffusion coefficient shows a slight deviation from that obtained for model I. Figure 4 gives the variation of the predicted model results from the experimental values. It is clearly seen from Figures 4a and 4b, that model II assuming finite coefficient of matter transfer on the surface is a better model on comparison to model I. Considering the fact that the experiment was conducted under stagnant conditions, the assumption that the rate of matter transfer to the surface by diffusion is equal to the rate at which it leaves the surface proves to be a more realistic model on comparison to model I which assumes all the matter brought to the surface to attain equilibrium with the medium concentration in an infinitesimally short time. Hence, model II approximates itself to model I when we assume an infinite

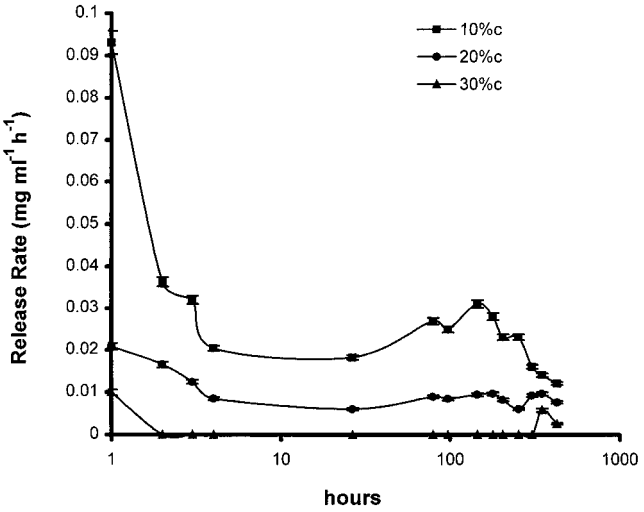

Figure 5—Release rate of IgG from EVAc-coated matrixes. 10, 20 and 30%c refers to 10, 20, and 30% EVAc coating, respectively. Each point is the mean of four data points, and the standard errors of the mean of release at each time point are within 4.5%.

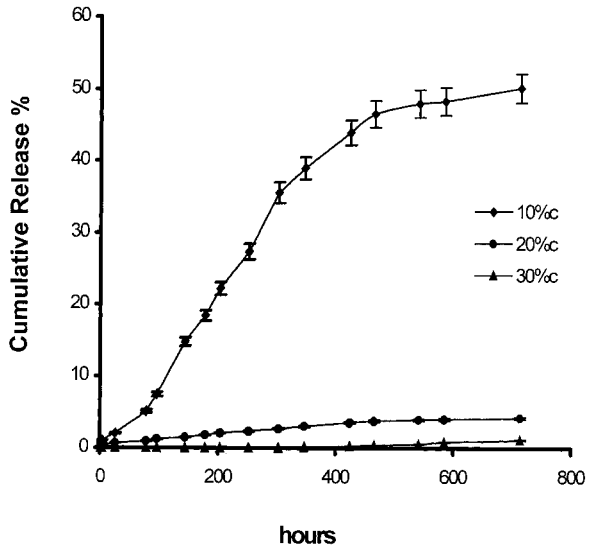

Figure 6—Cumulative percent release of IgG from 10, 20, and 30% coated matrixes. The symbolic representations and the standard errors are the same as those of Figure 5.

matter transfer coefficient ($h \rightarrow \infty$ and $N \rightarrow \infty$) on the surface. However, a slight deviation of the fitting of model II when compared to model I at higher time i.e., $t > 500$ h (Figure 4c) might be due to the experimental conditions involved and the limitations imposed by model II when the surface concentration C_s tends toward the equilibrium concentration C_e. This error observed is practically negligible, considering the fact that more than 76% of IgG has been released at that point of time (Figures 4a and 4b), and the rate of release is so low enough that the fraction of drug released is only 3% during the period greater than 400 h (Figure 4c).

Coating of matrixes (slab) in polymer solution significantly controlled the release rate as seen in Figure 5 which shows the release rate of IgG from matrixes coated in 10%, 20%, and 30% EVAc solution. The profile obtained is not as smooth as that got for uncoated matrixes. The sudden rise and fall in the release rate might be due to the EVAc coating, which, although initially impermeable to the IgG molecules, gradually forms a porous network due to the entry of the buffer solution, thereby bringing about the release of IgG molecules. Hence, a sudden rise in the release rate occurs, which then decreases because of the existence of one of the two limiting cases that have already been mentioned in this paper for uncoated matrixes. From Figure 6, we find that only about 50% and 4% of IgG has been released from the 10 and 20% coated matrixes after 700 h. In fact, the release of IgG from the 20% coated matrix is almost following a time-independent release profile, and this will continue until the coating gives way to porous networks for the IgG molecules to diffuse out. Coating of 30% EVAc polymer solution (or rather a paste because of its highly viscous nature) does not show any measurable release for the first 2 weeks after which the release gradually followed the 20% coating case.

From a clinical viewpoint, one of the primary objectives of sustained release is to maintain the required drug concentration at a reduced dosage level in patients. The usual dose of immunoglobulin for a primary immunodeficiency disease is 200 mg/kg of a patient's body weight[23] normally administered once per month by intravenous infusion (ivi). Although the minimum concentration of IgG necessary for protection has not yet been established, Pirofsky[18] has reported that an ivi of 150 mg/kg to a patient will result in the increase of serum IgG concentration to approximately 300 mg/dL which decays or is used up completely over a span of 28 days. Extrapolating from our experimental data, we find that a slab polymer drug matrix of dose 2.771 mg/kg (assuming an average patient weight as 50 kg) can give the same residual IgG concentration as the 150 mg/kg ivi case and can persist for a period more than one month before resulting in the decrease of concentration for a period of at least 2 months. This dose is found approximately 54 times less than the apparent ivi dose reported by Pirofsky.[18] Therefore a 3.704 mg/kg dose of the polymer–drug matrix can bring about the same effect as the conventional ivi of 200 mg/kg. Since it is a 30% loaded matrix, the total mass of the matrix administered to a 50 kg patient will be 617.5 mg. Hence, approximately six slabs of ~100 mg each will solve the process. Although the comparison above will be valid only if we get the exact relation between the in vitro and in vivo study, this work serves as a preliminary step in identifying the role played by controlled drug delivery to attenuate the problems faced by some of the conventional methods of drug treatment.

The methodology employed in the fabrication of microspheres is a nonaqueous encapsulation protocol in contrast to the commonly used double emulsion encapsulation technique.[24] The nonaqueous methodology is advantageous because it enhances the stability or the structural conformation of IgG, thereby protecting the native structure of the biomolecule as mentioned by Costantino et al.[25] The dehydrated proteins on suspension in organic solvents are conformationally rigid, and the chances of moisture induced aggregation are drastically reduced. Further, the question posed on the deteriorating activity of the protein under such conditions and the ways to overcome them have been discussed by Klibanov.[26] However, the study of IgG stability will be a very interesting topic for future investigations in this field.

All the release kinetics were studied under stagnant conditions (i.e. no shaking), since the implanted materials are localized in a rigid manner as in the case of a drug–polymer matrix being compactly placed and held inside the resection cavity of the pathological site.[27] Studies correlating the in vivo and in vitro release are few, and they greatly depend on the physiological environment in which the wafer has been placed, the presence of fluid remaining around the site, and the type of wafer involved. The initial flux F_o and the time constant of release τ are some of the few in vitro parameters that researchers use in their in

vivo model analysis.[28] The F_o and τ values in the case of slabs are given in Table 1. In the case of microspheres, the 30% loaded case had an initial flux value of 3.13×10^{-13} g·mol/cm^2·s and a time constant of 320.19 h with a deviation of less than 5%. The higher value of time constant and the lower value of F_o are due to the lag period experienced in the initial period of release. Hence, patients who cannot withstand high doses of IgG at the beginning can be recommended for the microsphere dosage form, and the slab dosage form can be recommended for the opposite case.

In general, the exact mechanism by which the IgG molecules are released through the EVAc into the buffer is based on a combination of different factors such as dissolution of the drug in the buffer, the relaxation rate of the polymer chains, the diffusion rate of the drug molecule through the polymer backbone, the experimental conditions involved, and last on the nature of the polymer, drug, and their interactions. This study serves as another step to elucidate the mechanism of release of macromolecules through an EVAc backbone and tries to identify the dosage form suitable for different type of patients.

Conclusions

The in vitro release kinetics of IgG−EVAc system fabricated by a solvent-casting method was studied for slab and microsphere geometry. Mass loading of IgG was found to affect the release rates significantly for both geometries. Release experiments conducted for the 30% loaded slab matrixes showed that the release rate followed a classical Fickian type of diffusion until 75% drug release (or for time $t < 15$ days) and gradually approaches the time-independent release for $t > 30$ days. Experiments conducted with matrixes of different surface areas showed a similar release pattern, and reproducible initial release flux and time constants were obtained. The one-dimensional pattern of drug release was the cause for reproducible results. Coating significantly controls the release rate of IgG from the matrix with the 20% EVAc-coated matrix providing a quasi-zero order drug release. Microsphere geometry gives a release pattern similar to the slab geometry, except for the initial lag time followed by Fickian type of diffusion. A model incorporating the finite matter coefficient of transfer on the surface seems to be more accurate than another model, which has an infinite matter transfer coefficient on the surface. The temporal variation of the diffusion coefficient was not significant. On correlating the experimental results with clinical data, it was worth noting that the polymeric implant dosage form can reduce the dose administration drastically compared with standard dosage forms.

Abstract □ Human immunoglobulin G (IgG) serves as an important chemotherapeutic agent for a number of immunological ailments and as a carrier in the targeted delivery of other therapeutic agents. This paper deals with the characterization of IgG-dispersed monolithic matrixes of different geometries, prepared using a nonbiodegradable polymer carrier EVAc. The morphological changes associated with the matrix during drug release was studied using scanning electron microscopy, polarizing microscopy, atomic force microscopy, and X-ray photoelectron microscopy, and the results were compared. The study answered the burst effect problem significantly and illustrated the potential of these techniques in understanding the morphological structure of matrixes and mode of release kinetics.

Introduction

The topic of controlled drug release has received significant contributions from the scientific world ever since the work of Langer and Folkman in the mid-1970s.[1] A number of different types of polymers[2−6] have been used for the controlled release studies, and the mode of release varies with the polymer type. Although release kinetics studies and the fitting of experimental data to model equations would give us some understanding of the type of release mechanism involved, the results obtained can be ascertained by conducting matrix characterization studies for matrixes during different stages of drug release. Release kinetics of immunoglobulin G (IgG), from a nonbiodegradable EVAc polymer, have been discussed elsewhere.[7] It was noted that dissolution plays a significant role during the initial stages of release, while diffusion predominates in the later period. This variation in the release mechanism necessitated the use of combination of models to describe the release behavior. In this report, an extensive study has been made in the morphological characterization of these matrixes both in the qualitative and quantitative sense. A variety of techniques such as the scanning electron microscopy, atomic force microscopy, polarizing microscopy, and X-ray photoelectron microscopy were used for matrix characterization.

Scanning electron microscopy (SEM) still serves as a preliminary surface characterization technique for numerous drug delivery systems.[3,8−10] The technique is greatly appreciated when applied to biodegradable systems in which marked changes in matrix morphology occur with release. However, in the present study, nonbiodegradable EVAc matrixes of different geometries under varied stages of release were examined under SEM for both the surface and cross-section analysis.

Atomic force microscopy (AFM) is used to study the surface features of polymeric materials by visualizing their morphology, nanostructure, molecular order, and surface compositional mapping in heterogeneous samples with a resolution down to the atomic level.[11] The need to choose AFM for matrix characterization is because of its attractive feature of obtaining two- and three-dimensional topographical features of material surfaces at extremely high resolution in either vacuum, liquid, or ambient atmospheres. AFM is a mechano-optical instrument, which detects atomic-level forces ($\sim nN$) through optical measurements of movements of a very sensitive cantilever tipped with a hard, pyramid-shaped crystal that moves along surfaces. Typical working mode of AFM is the contact mode, where the AFM tip remains (more or less) in contact with the surface (some friction may be observed). Most AFMs have vertical resolution below 0.1 nm range, whereas lateral resolution is usually lower due to the sharp tip and the small loading force involved.

Polarizing microscopy (PM), when equipped with a hot stage, is a valuable tool for measuring phase transitions and crystallization kinetics. When the sample is placed between two crossed polarizing filters, different colors based on varying thickness, texture, stress level, and bond arrangement of polymer chains can be observed. The first polarizing filter polarizes or limits the vibration of light waves to one plane. When the polarized light passes through the polymer, its direction of polarization is altered depending on the thickness and texture of the polymer. The final direction of polarization determines whether light of a certain wavelength can pass through the second polarizing filter. The importance of this technique lies in the fact that it is able to qualitatively analyze the change in IgG concentration on the EVAc matrix surface.

X-ray photoelectron microscopy (XPS) is by far the most widely used surface spectroscopic instrument. When a surface is irradiated with soft X-ray photons, electrons from inner shells can be ejected with a definite binding energy. Therefore, XPS is capable of elemental analysis since no two atoms of the periodic table exhibit the same set of binding energies. Qualitative analysis of the elements can be easily performed by wide scans, in which all the available energy range is explored. Quantitative elemental analysis is performed by detail scans, where a small portion of the binding energy range is acquired with a higher spectral resolution than in the wide scans.

The characterization studies were performed for matrixes in different stages of drug release. The results obtained were then used to get a reasonable explanation for the type of release mechanism and the extent of drug distribution in the matrix.

Materials and Methods

IgG-EVAc systems of different geometries, viz. slabs, microspheres, and cubes, were fabricated as described in a previous

paper.[7] Blank matrixes (without IgG) were also fabricated in a similar manner. The different matrixes were then subjected to release in 0.1 M phosphate buffer, pH 7.4, for a time span of 3 to 8 weeks. They were then removed by forceps, blotted dry by tissue, and subjected to characterization studies.

Scanning Electron Microscopy (SEM)—Samples of slab and microsphere were stuck on to metallic cylinders by making use of a double-sided carbon adhesive tape, which were then sputter-coated using an ion sputtering device (JFC-1100E, JEOL Co., Tokyo, Japan) and observed under SEM (JSM-T330A, JEOL Technics Co. Ltd., Tokyo, Japan).

Atomic Force Microscopy (AFM)—Samples of slab were cut into thin sections using a surgical blade (Hecos, Shanghai, China) and observed under AFM (Topometrix, TMX-2000, Topometrix Corp., Santa Clara, CA). Explorer AFM was used as the stage type and the image resolution was fixed at 200 × 200 pixels under forward scan direction and 0° rotation with system calibration. In addition, this instrument employs a "double cross" cantilever, which restricts the motion of the tip to the "Z" direction (normal to the sample surface). Scanning was done using an E449701 type scanner at the rate 200 μm/s, and the sample bias was fixed at 1 mV. Microspheres, because of their natural curvature, are difficult to be observed under AFM and hence are not shown.

Polarizing Microscopy (PM)—Samples of slab and microsphere were observed under PM-BX50 (Olympus, Japan). A 530 nm sensitive tint plate (U-TP530) was used as a test plate compensator, which resulted in a magenta background for the pictures taken. A hot stage (Cole-Parmer Digital Hot Plate, Model no. 8207C-2 Vernon Hills, IL) was used to increase the specimen temperature at selected rates, and the system was capable of taking a time series of photographs while holding the sample at a constant temperature. Visual observations of specimen transitions and the temperatures at which they occur may be recorded.

X-ray Photoelectron Spectroscopy (XPS)—Samples of slab were observed under XPS (VG ESCALAB MKII spectrometer) with Mg Kα (1253.6 eV, 120W) as X-ray source and neutral C1s (284.6 eV) as BEs reference to determine the elemental composition of the matrix. The take-off angle was set at 75°, and the chamber pressure was maintained at $\leq 1 \times 10^{-8}$ mbar. FWHM was kept constant for all the components. To investigate the distribution of IgG on the surface of IgG/EVAc system, a combined XPS method of wide scan with detail scan was employed. Elemental ratios of O/C and N/C were calculated by the method of detail scan. For the purpose of comparison with 30% IgG film sample, we also grinded it into fine powder using a mortar and pestle and then measured its XPS value.

Results and Discussion

(a) Particle Size Analysis—In the present study, the dependence of microsphere size on the needle size and the drug loading (which affects the viscosity and surface tension of the solution) was examined by maintaining a uniform extrusion rate (2−3 mL/min). The microsphere particle size was measured using the Nikon SMZ-1 microscope. The size distribution was compared for spheres with different drug loadings and for spheres with different diameters prepared using different sized needles. The results are tabulated in Tables 1 and 2. It is quite clear that the size increases as drug loading is increased and as needle size is increased. In spite of the size being in the range of 1000 μm, we can still consider these beads as microspheres since their size is within the range ca. 50 nm−2 mm.[12]

(b) SEM—Observations of the SEM pictures for slabs (Figure 1) show that the EVAc−IgG unreleased (Figure 1a)

matrix surface was uniform without any clear demarcation of the IgG molecules in the matrix. The matrix surface, which can be described as an extended, highly loose globular, viscous, cloudy surface was found to be spread uniformly over and within the matrix (Figure 1b). This could not be seen in the blank sample of EVAc polymer (no drug case) matrix, which was made up of a clear continuous phase. Even the cross-section of the blank showed a clear phase distribution without the presence of any matrix deformities or pores. In the case of EVAc−IgG matrix subjected to release for 45 days (Figure 1c), the deformation of the continuous polymer phase can be clearly observed. The deformation might be due to the swelling of the dispersed IgG particles upon uptake of diffusant.[13] Further, cracks and channels, possibly due to the interconnection of the pores were also observed in the cross-section of Figure 1d. Figures 1e−h are the SEM pictures of 30% loaded cubic samples. Compared with the slab samples, the unreleased sample (Figure 1e) exhibits a similar continuous undeformed phase, whereas the cross-section (Figure 1f) reveals the presence of "pocket-filled IgG cluster" like structures. Surface (Figure 1g) and cross-section (Figure 1h) of the sample subjected to release for two months reveal deformities as expected. However, the cross-section reveals distinct pores rather than channels (seen in Figure 1d), which can be attributed to the difference in geometry between the two cases.

SEM pictures of microsphere are shown in Figure 2. The thready polymer entanglements are clearly visible in Figure 2a. Figure 2b shows a portion of the blank sample cut off. It was noticed that the cross-section of the blank exhibits a hollow region. This feature might be due to the evaporation of methylene chloride from the matrix during its fabrication. The 30% loaded sample in Figure 2c shows certain complications in the surface morphology. Again, the cross-section in Figure 2d of the loaded sample before release shows a hollow region. However, no pores are visible on the matrix surface. The sample subjected to release for three weeks in Figure 2e shows a little bit of swelling, and minute pores or channels can be noticed (possibly due to the relaxation of the polymer chains). Finally, Figure 2f, a cross-section of the loaded sample taken in the transverse direction, after three weeks of release, reveals pores along with the expected hollow region observed along the side. Hence, a common feature noted in all the three geometries is the increase of matrix porosity with prolonged exposure to the release medium. Since the polymer is hydrophobic and nonbiodegradable, the occurrence of such deformities such as pores and cracks can be attributed due to the drug−solvent interaction—dissolution of the drug in the solvent, swelling of the drug due to solvent uptake, and gradual diffusion through the solvent-filled pores and channels.

(c) AFM—AFM pictures of the slab samples are shown in Figure 3. Observation of the blank sample (Figure 3a) shows a smooth, flat surface. The numerous tiny spots, which appear on the figure, are not pores but are rather microscopic depressions on the surface due to the evaporation of the solvent. On observing the IgG-loaded sample

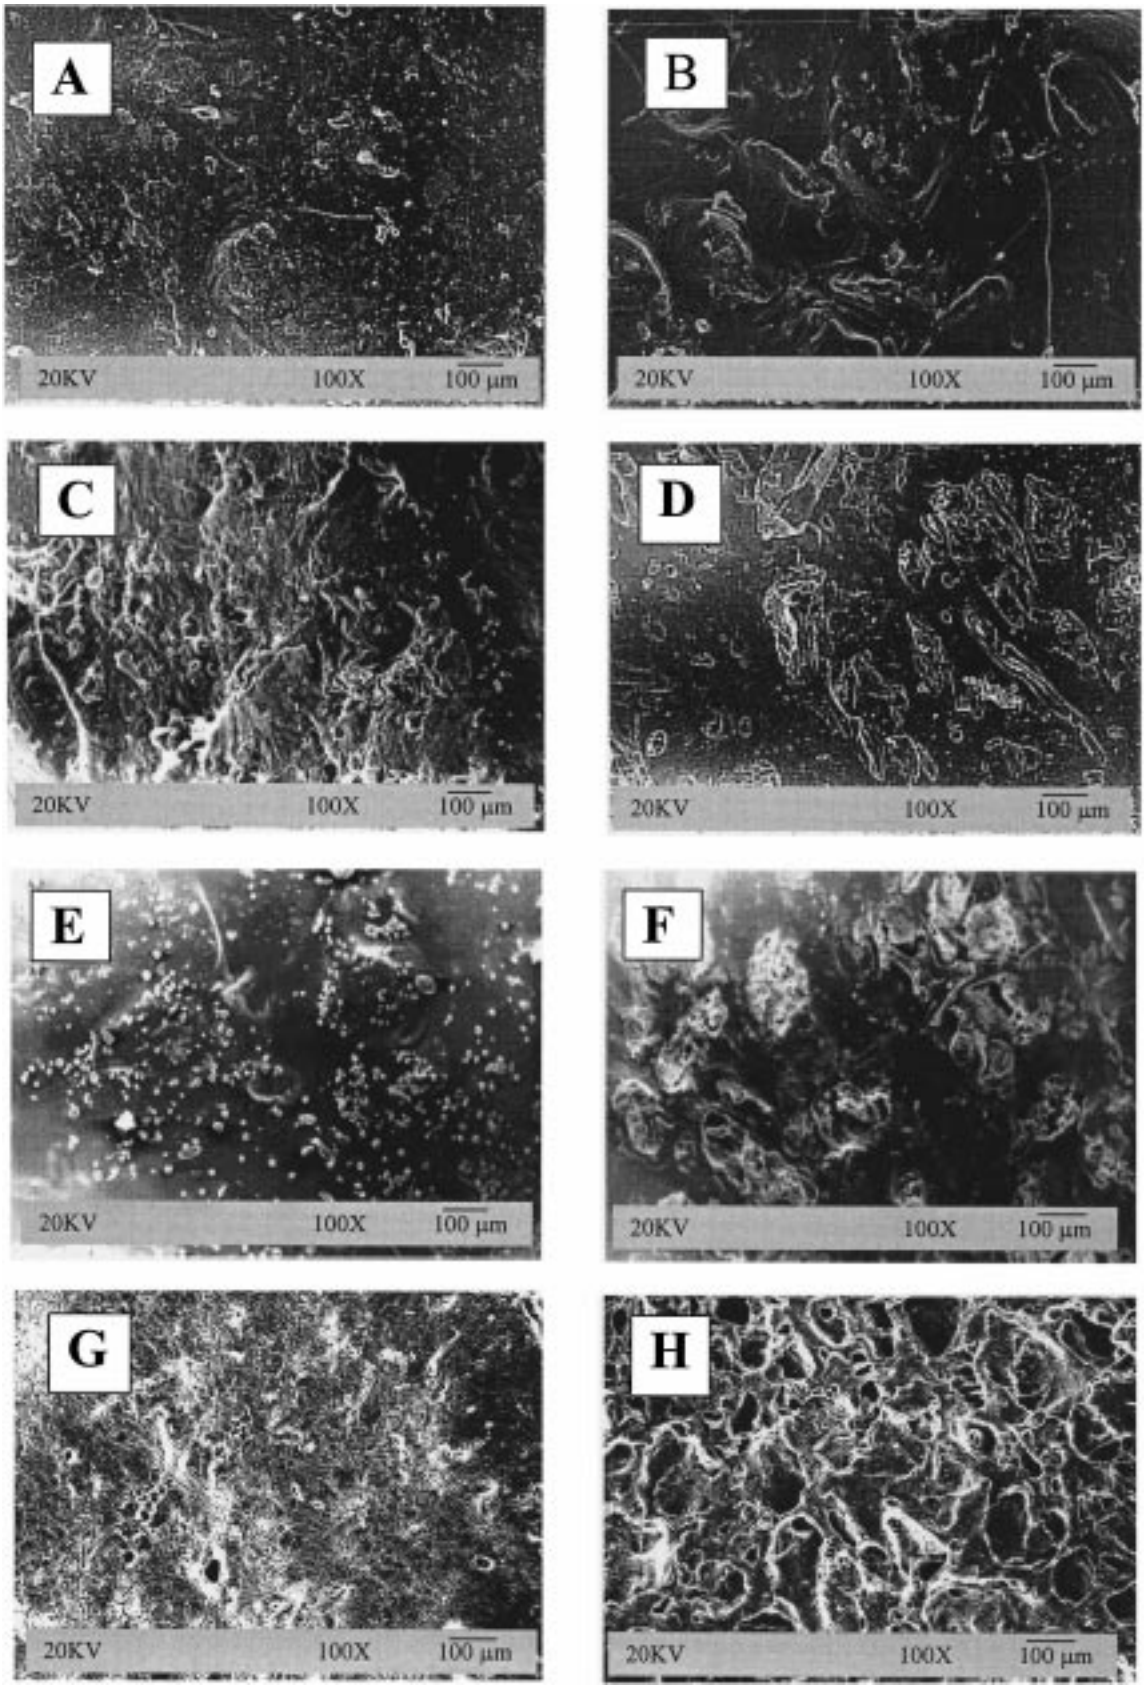

Figure 1—Scanning electron microscopy photographs of 30% IgG loading for (a) slab, before release, (b) slab cross-section, before release, (c) slab, after 45 days of release, (d) slab cross-section, after 45 days release, (e) cube, before release, (f) cube cross-section, before release, (g) cube, after 2 months of release, (h) cube cross-section, after 2 months of release. before release (Figure 3b), we find that the surface has a fluffy appearance with numerous bumps and undulations. The depressions seen on the blank sample have been completely filled up, and a homogeneous matrix surface could be observed. The dark spot appearing on the far corner of the figure is just an artifact created due to the

sectioning of the sample for AFM studies. Figure 3c is an AFM picture of the sample subjected to release for 30 days. We can clearly see pores on the surface, with occasional strips of fluffy mass seen in the before release sample. AFM results confirm the nonbiodegradable nature of the EVAc polymer and backs the SEM results of drug dissolution into the buffer-filled pores followed by diffusion.

(d) PM—The PM pictures of the slab can be viewed in Figures 4a–c. The blank sample can be observed in Figure 4a. The sample placed between two crossed polarizing filters gives different shades of colors depending on the depths at which the light penetrates, and the colors are reflected based on the refractive index of the component. The complexity of the structure increases with the drug loading as shown in the 30% drug-loaded sample before release (Figure 4b). Numerous opaque dark spots could be

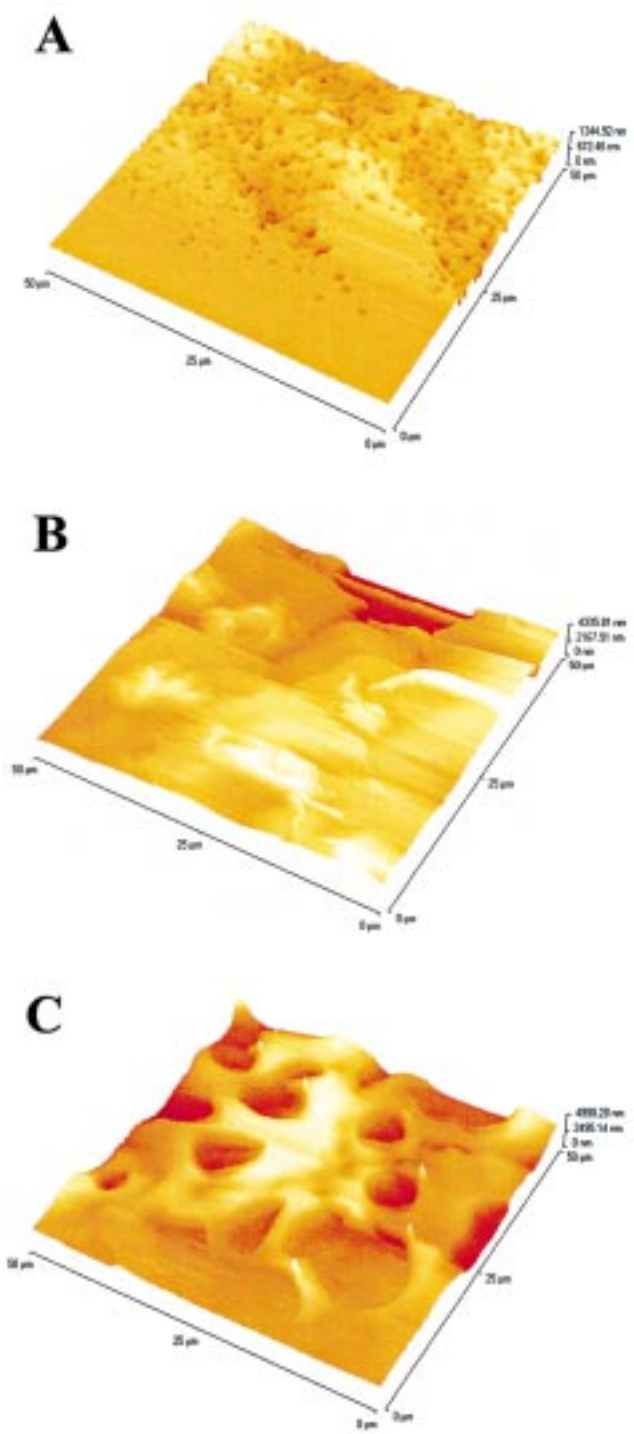

Figure 3—Atomic force microscopy pictures of slabs for (a) blank, (b) 30% IgG loading, before release, (c) 30% IgG loading, after 30 days release.

observed which are not present in the blank sample. The fact that these are IgG clusters cannot be completely ignored. This assumption is further strengthened by the reduction of such a structural feature in the sample subjected to release for 45 days, as shown in Figure 4c. A thorough analysis of the dark spots on Figure 4b was done by magnifying them and comparing with the PM pictures of raw IgG molecules and they did show similar structure (Figure 5). PM pictures of microspheres can be viewed in Figures 4d–f. The blank sample in Figure 4d shows some similarity with the SEM picture in Figure 2a with respect to the external morphology. In fact, higher magnification of Figure 4d reveals the presence of some polygonal structures on the matrix surface, which could also be observed in the SEM at higher magnifications. Similar to Figure 4b, dark spots can be observed in the 30% drug-loaded sample before release (Figure 4e) which are likely to be IgG molecules, but the decreased concentration of these spots when compared to the slab surface (Figure 4b) is attributed to the dosage form involved. The reduced black spot concentration on the microsphere surface also answers the decrease in burst effect observed for this geometry when compared to the case of slab geometry. The black spot concentration decreases with the release of IgG molecules, as shown in the sample subjected to release for 3 weeks (Figure 4f). However, this decrease is not as pronounced with respect to the relative decrease in concentration of black spots from Figure 4b to 4c. This is quite logical looking at the fact that only about 55% of IgG has been released after 3 weeks for a microsphere when compared to the 81% release observed for the slab after 46 days.[7]

(e) XPS—The wide scan and detail scan XPS pictures are shown in Figure 6. Theoretically, the photoelectron binding energy E_b is given by the following relation[14]

$$E_b = h\nu - E_k - \phi \qquad (1)$$

where $h\nu$ is the photon energy of the X-ray source (1253.6 eV in the present case), E_k is the kinetic energy of the photoelectron, and ϕ is the spectrometer work function (defined as the energy required to remove the uppermost electrons).

Examination of blank sample by wide scan XPS showed that the main elements of EVAc were C (carbon) and O (oxygen), without N (nitrogen), as seen in Figure 6a, while the wide scan XPS of pure IgG showed the presence of a N1s peak along with C1s and O1s peaks, thereby indicating the presence of nitrogen in pure IgG (Figure 6d). The peak of N1s is centered near 399.0 eV (Table 3), a value characteristic of the amino group from a protein. Hence, we may assume the concentration of nitrogen determined by the XPS method as an indirect measure of IgG concentration on the surface of the IgG–EVAc system. Interestingly, 30% IgG-loaded samples, exhibited a stronger N1s peak for its grinded version (Figure 6b) than its film version (Figure 6c). Further, detail scans of XPS revealed that the powdered sample had a higher N/C ratio than the film sample (Table 3). The reduced surface concentration of IgG in the film sample can be due to the relatively faster migration of EVAc to the surface compared to IgG during the evaporation of methylene chloride, which was ultimately reflected in the results due to the surface specific detection property of XPS. On the other hand, the sample obtained by grinding the film to a fine homogeneous blend of powder, exhibited an increased concentration of IgG on the surface, resulting in a stronger N1s peak in the wide scan XPS and a corresponding increase in the N/C ratio. Since XPS can be used to measure the elemental composition present on sample surfaces alone, we utilized this aspect to our advantage in trying to get an explanation for the "burst effect" or the increased release rate of drugs at the initial time period. Since most of the element nitrogen (N) is present in the IgG molecule (constituting about 85% wt in the Venoglobulin-I sample[15] used for the release study), an analysis of the N/C composition for the slab sample (top surface) and its grinded version (sample grinded to get a flat layer) will give the approximate IgG composition in the top surface of the slab and the overall IgG composition of the slab. The percentage of IgG present on the top surface calculated in this manner was found almost equal to the fraction of IgG released in the first hour (with an error less than 10%). Hence the burst effect might

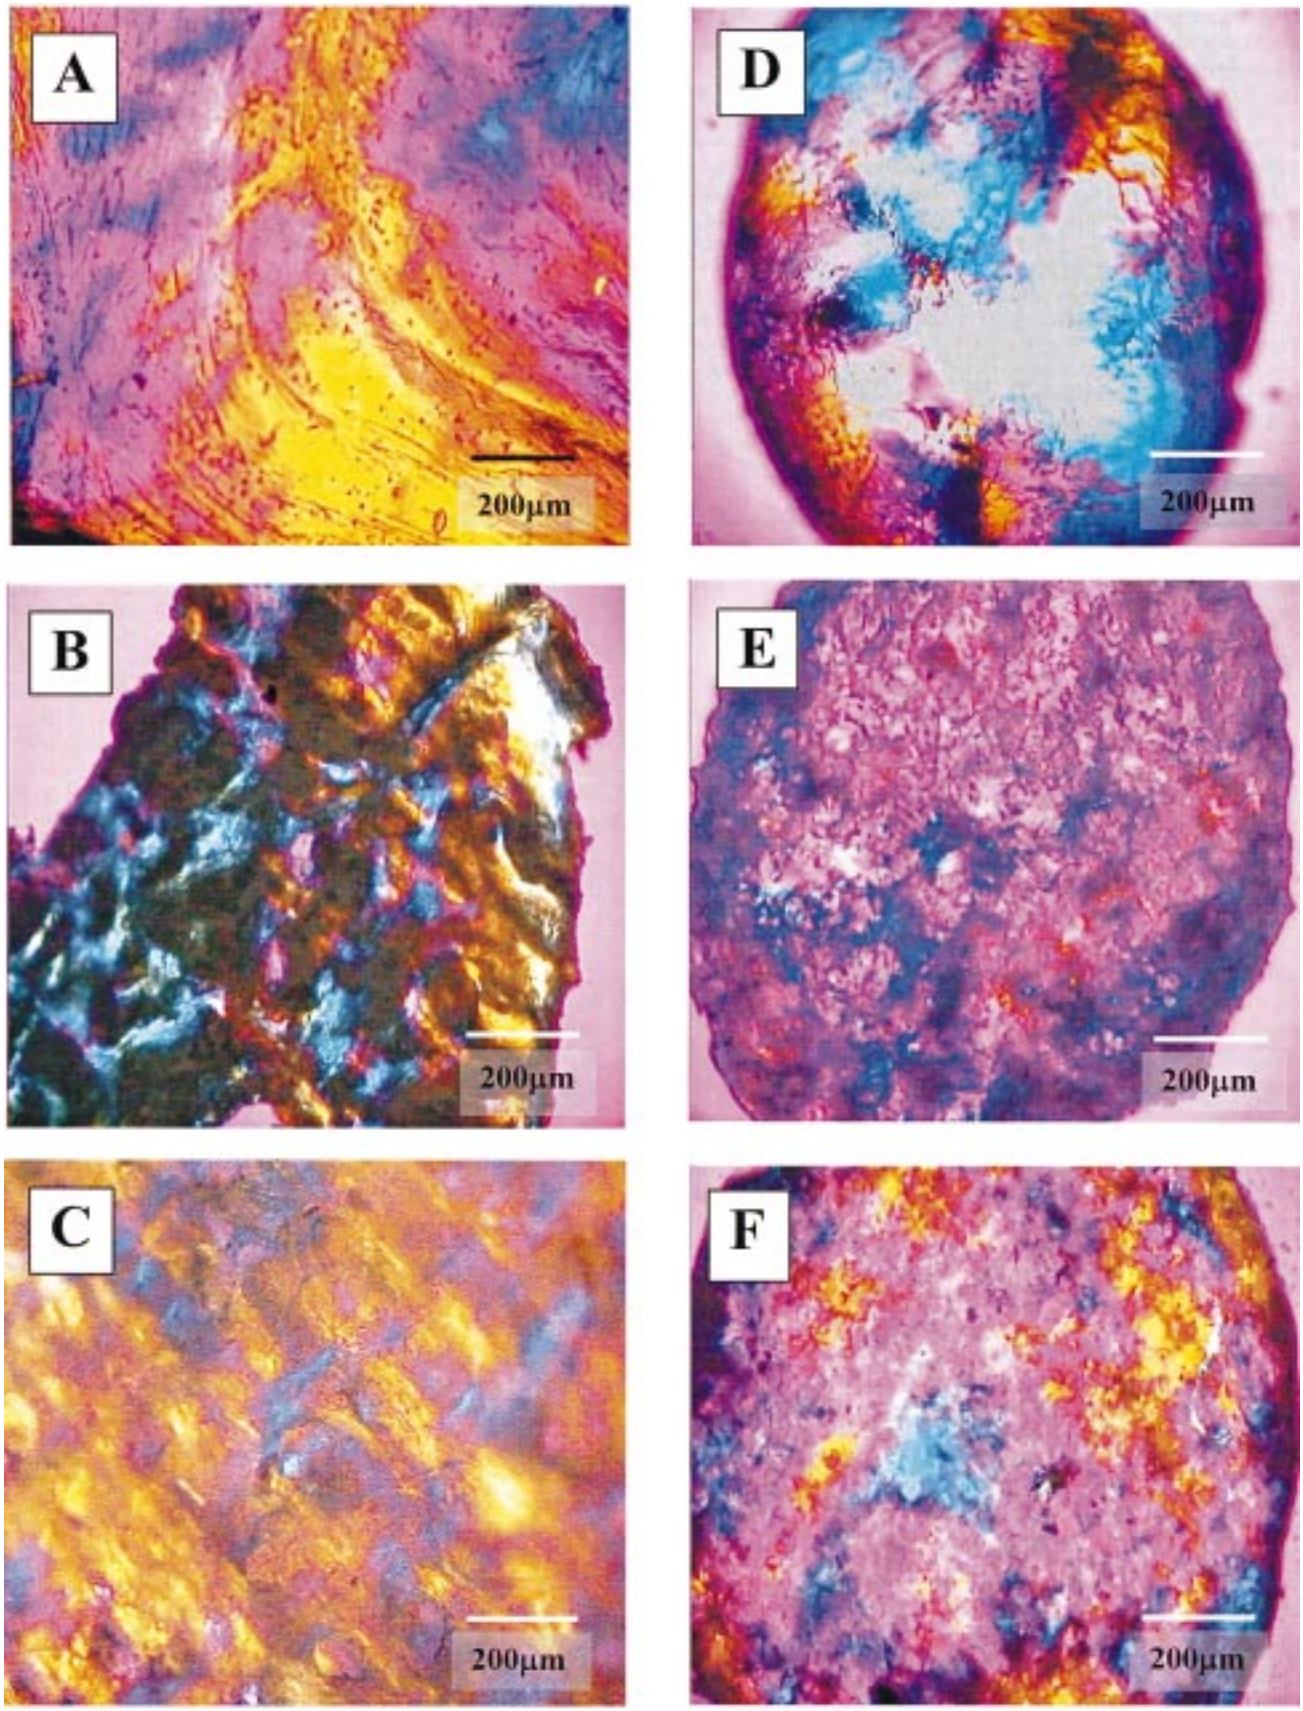

Figure 4—Polarizing microscopy pictures for (a) slab, blank, (b) slab, 30% IgG loading, before release, (c) slab, 30% IgG loading- after 45 days release, (d) microsphere, blank, (e) microsphere, 30% IgG loading, before release, (f) microsphere, 30% IgG loading, after 3 weeks of release.

be primarily due to the surface concentration of IgG molecules, and this can be avoided by the use of coated matrixes.

The utilization of microspheres of size range in the order of 800 to 1100 μm prevents phagocytosis by macrophages. Immunologically speaking, macrophages play an important

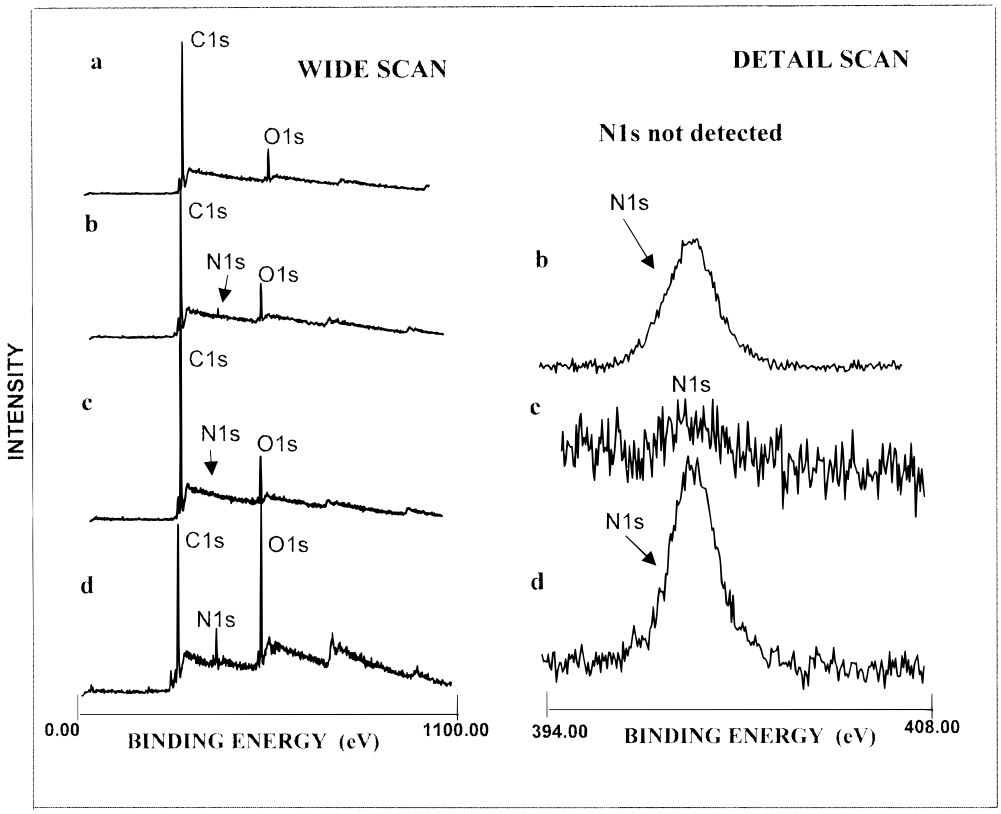

Figure 6—XPS spectrum for (a) blank, (b) 30% IgG loading, before release, powder, (c) 30% IgG loading, before release, film, (d) pure IgG.

Table 3—Detail Scan Data of XPS for Different Samples

sample	binding energy N1s (eV)	N/C	O/C
blank	–	–	0.1249
30% IgG-loaded film	399.10	0.0024	0.1323
30% IgG-loaded powder	399.52	0.0395	0.1799
IgG powder	400.00	0.1361	0.4328

role in the body's defense mechanism by engulfing or phagocytosing foreign bodies or antigenic particles and triggering the formation of antibodies to act against these antigens. Hence, microspheres of size range less than 800 μm have an increased probability of being engulfed by macrophages, which triggers the formation of anti-antibodies, thereby affecting the basic principle of treatment. This explains the role of microsphere size selection for therapeutic purposes.

Conclusions

Matrix characterization studies were performed using SEM, AFM, PM, and XPS. SEM and AFM studies gave a clear picture of the type of morphological changes encountered by the matrix in the release study. The results

indicate that the drug release mechanism is controlled by diffusion−dissolution irrespective of the matrix geometry. PM studies gave insight into the extent of IgG distribution in the polymer matrix while XPS results showed that the burst effect observed in the release studies during the initial period might be due to the surface concentration of IgG molecules. These characterization studies would therefore serve as supporting evidence to the in vitro release kinetics studies for IgG release through an EVAc backbone.

Abstract □ The aim of this study was to determine the efficacy of atom-type electrotopological state indices for estimation of the octanol–water partition coefficient (log *P*) values in a set of 345 drug compounds or related complex chemical structures. Multilinear regression analysis and artificial neural networks were used to construct models based on molecular weights and atom-type electrotopological state indices. Both multilinear regression and artificial neural networks provide reliable log *P* estimations. For the same set of parameters, application of neural networks provided better prediction ability for training and test sets. The present study indicates that atom-type electrotopological state indices offer valuable parameters for fast evaluation of octanol–water partition coefficients that can be applied to screen large databases of chemical compounds, such as combinatorial libraries.

Introduction

The logarithm of the partition coefficient between octanol and water, log *P*, is extensively used to describe lipophilic or hydrophobic properties of chemical compounds. It has been shown that log *P* is a useful parameter to correlate transport properties of drug molecules, interactions between drugs and receptors, and changes in the structure of drugs with various biochemical or toxic effects of these compounds.[1] The measurement of log P throughout the synthesis of the compound and its subsequent experimental determination is time-consuming and expensive. Hence, there is a strong interest in the structure-based prediction of log P for rational development of new drugs before potential drug compounds have been synthesized.

Several approaches for computing log P on the basis of chemical structure have been proposed. Among others there are two essentially empirical methods for the estimation of log P: Rekker's *f* constant method and Leo and Hansch's fragment approach.[3] Both methods divide a compound into basic fragments and calculate its log P by the summation of the hydrophobic contributions of each fragment. However, the difficulties of these methods is how to fragment a molecule, especially large drug molecules, into basic fragments. New fragment methods (atomic fragments) were developed to overcome this problem.[4−6] These methods are conceptually simple and are able to give fast and accurate estimations for diverse organic compounds. However, correction factors are usually needed for complex structures to compensate for the interactions between functional groups.

Recently, Kier and Hall[7,8] introduced electrotopological state (E-state) indices for molecular structure description in which both electronic and topological characteristics are combined together. The E-state can be used in a group contribution manner and has been found to be useful in structure−property relationship studies. Using only these indices and neural network modeling, Hall and Story[9] were able to predict the boiling points and critical temperatures for a set of heterogeneous organic compounds.

In our recent studies we suggested methods for estimations of aqueous solubility, log S, of structurally related[10] and diverse sets[11] of drug compounds based on molecular topology and neural network modeling. The present study shows that the same indices can be successfully used to estimate log P coefficients, another important solubility property of drug compounds for drug design studies.

Experimental Section

Three hundred twenty-six drugs or related compounds from different structural classes were randomly selected from the Hansch−Leo compilation.[12] The partition coefficients of these compounds were represented as logarithm values, log P, and were in the range −2.11−5.9, corresponding to urea and thioridazine, respectively. This data set was divided into a training set of 300 compounds and a test set of 26 compounds (selected at random). An additional test set of 19 compounds[13] was included in the present study to compare our approach with currently available ones.

Structural parameters were calculated by Molconn-Z software (Hall Associated Consulting, Quincy, MA). Molecular weights and 32 atom-type E-state indices were calculated for each analyzed compound by SMILES line notation code. These 33 parameters were analyzed using multilinear regression (MLR) analysis and artificial neural networks (ANNs). MLR analysis was done with the SPSS package (v. 5.1, SPSS Inc., Chicago, IL) running on a Pentium PC. The ANNs employed in this study were fully connected feed-forward back-propagation networks with one hidden layer and bias neurons. ANN training was accomplished using the SuperSAB algorithm.[14] The logistic $f(x) = 1/(1+e^{-x})$ activation function was used both for hidden and output nodes. All calculated parameters and the set of parameters optimized by MLR were used for neural network training. The number of neurons in the hidden layer was optimized as indicated in the *Results* section. One single output node was used to code log P values.

The avoidance of overfitting/overtraining has been shown to be an important factor for improvement of generalization ability and correct selection of variables in neural networks studies.[14,15] The Early Stopping over an Ensemble technique was used in the current study to accomplish this problem. A detailed description of this approach can be found elsewhere.[14,15] In brief, each analyzed ensemble was composed of $M = 100$ networks. The values calculated for analyzed cases were averaged over all M neural networks, and their means were used for computing statistical

coefficients with targets. We used a subdivision of the initial training set into two equal learning/validation subsets. The first set was used to train the neural network, whereas the second one was used to monitor the training process measured by root-mean-square error. An early stopping point determined as a best fit of a network to the validation set was used to stop the neural network learning. It was shown that a neural network trained up to an early stopping point provided better prediction ability than a network trained to the error minimum for the learning set.[10,14] Thus, statistical parameters calculated at the early stopping point were used. The training was terminated by limiting the network run to 10 000 epochs (total number of epochs) or after 2000 epochs (local number of epochs) following the last improvement of root-mean-square error at the early stopping point.

The computer code for the ANN was programmed in ANSI C++. The calculations were performed at HP Workstation Cluster at the Swiss Center for Scientific Computing.

The quality of the models was tested in two ways. An analysis of predictive ability was done in terms of both predictive q^2 and actual prediction. Predictive q^2 in leave-one-out cross-validation was defined as

$$q^2 = (\mathrm{SSY} - \mathrm{PRESS})/\mathrm{SSY} \quad (1)$$

Here, SSY is the sum of squares of the deviation between the observed log P values and their mean value and PRESS is the prediction error sum of squares obtained from leave-one-out (LOO) procedure. The standard deviation s_{LOO} was also considered. This coefficient was defined as

$$s_{LOO} = [\mathrm{PRESS}/n]^{1/2} \quad (2)$$

where n was the number of compounds in the model. In addition, the two test sets already described were used to estimate the actual prediction of the models using square of correlation coefficient r^2 and standard deviation s.

Results and Discussion

A total of 32 atom-type E-state indices (Table 1) and molecular weights were used as parameters for analysis by MLR and ANNs. Stepwise and backward methods were employed in the regression analysis and the following 19 parameters yielded a satisfactory statistical model:

$$\log P = 0.228\ (\pm 0.021)\ \mathrm{SsCH_3} + 0.294\ (\pm 0.072)\ \mathrm{SdCH_2} + 0.275\ (\pm 0.023)\ \mathrm{SssCH_2} + 0.171\ (\pm 0.011)\ \mathrm{SaaCH} + 0.221\ (\pm 0.053)\ \mathrm{SsssCH} - 0.190\ (\pm 0.063)\ \mathrm{SdssC} + 0.215\ (\pm 0.044)\ \mathrm{SaasC} + 0.246\ (\pm 0.047)\ \mathrm{SaaaC} - 0.093\ (\pm 0.016)\ \mathrm{SsNH_2} - 0.198\ (\pm 0.028)\ \mathrm{SssNH} - 0.051\ (\pm 0.013)\ \mathrm{SaaN} - 0.360\ (\pm 0.039)\ \mathrm{SsssN} + 0.013\ (\pm 0.004)\ \mathrm{SdO} - 0.035\ (\pm 0.013)\ \mathrm{SssO} + 0.071\ (\pm 0.006)\ \mathrm{SsF} + 0.264\ (\pm 0.068)\ \mathrm{SdS} + 0.199\ (\pm 0.098)\ \mathrm{SssS} + 0.444\ (\pm 0.185)\ \mathrm{SaaS} + 0.187\ (\pm 0.025)\ \mathrm{SsCl} - 0.468\ (\pm 0.124).$$

$$(n = 300,\ r^2 = 0.87,\ s = 0.68,\ F = 87.5,\ q^2 = 0.83,\ s_{LOO} = 0.71) \quad (3)$$

where n is the number of compounds used in the fit, F is the overall F-statistics for the addition of each successive term, and values in parentheses are the 95% confidence limit of each coefficient. The correlation analysis for parameters in eq 3 showed that all pairwise correlations were $R < 0.5$, indicating a low multicollinearity as well.

For neural network studies, a preliminary analysis using all available parameters was done to determine the optimal number of neurons in the hidden layer chosen in the set 2, 3, 5, 7, 10, 15, and 30. The performance of neural networks was evaluated by LOO statistical coefficients calculated at early stopping point for the training data set. We found that q^2 increased (i.e., $q^2 = 0.824 \pm 0.002$, 0.825 ± 0.002, 0.829 ± 0.003) when the number of neurons in the hidden layer was changed from 2 to 5. However, further increase in the number of hidden neurons from 7 to 30 did not influence the prediction ability of neural networks (i.e., $q^2 = 0.829 \pm 0.002$, 0.828 ± 0.003, 0.829 ± 0.002, 0.830 ± 0.003). Thus, we fixed the number of neurons in the hidden layer equal to 5.

Neural networks represents essentially nonlinear methods of data analysis. However, the use of ANNs for the same set of parameters provided a prediction ability similar to that of MLRs for compounds in the training set. In LOO cross-validation procedures, ANNs gave $q^2 = 0.84$ and $s_{LOO} = 0.69$ for the same set of parameters as in regression analysis, and $q^2 = 0.83$ and $s_{LOO} = 0.70$ for all calculated parameters. The prediction ability of the MLR model given by the PRESS statistics, $s_{LOO} = 0.71$, is only 0.03 log units

[a] According to Hall and Kier.[8] [b] S states for the sum of the E-state values for a certain atom type or group; the sum for the hydroxyl groups is SsOH, for the ether or ester oxygen it is SssO, and for the keto oxygen it is SdO. [c] The formula of the atom type or group; the bond types between the heavy atoms are s = single (—), d = double (=), and a = aromatic (..). [d] The parameters that were eliminated in MLR regression are marked by X. [e] The number of compounds with the index.

Table 2—Comparison of the Predictive Ability of MLR and ANN Models

			training set		test set 1		test set 2	
model	params	#[a]	q^2	s_{LOO}	r^2	s	r^2	s
MLR	regressed	19	0.83	0.71	0.87	0.71	0.83	0.68

[a] This set was originally proposed by Moriguchi et al.[13] [b] The results calculated by XLOGP, CLOGP, and Moriguchi's and Rekker's methods are from ref 4.

higher than for the fitting model. Such a small increase indicates a robustness of the model.

The generalization ability of ANNs for the test sets was higher than that of MLR (Table 2). As in the case of the training set, the best predictions were calculated using all parameters. The results calculated using ANNs for the test set 2 ($n = 19$, $r^2 = 0.87$, $s = 0.57$) are comparable with those found using other known methods, such as CLOGP ($r^2 = 0.94$, $s = 0.44$), XLOGP ($r^2 = 0.89$, $s = 0.54$), and Moriguchi's method ($r^2 = 0.87$, $s = 0.63$), and are better than that of the Rekker's method ($r^2 = 0.84$, $s = 0.79$) (see Table 3).

The analysis of residuals showed that there were several compounds with a large calculation error in the training set. The compounds with a residual >1.4 log units, that is two times the standard deviation, are shown in Table 4. We found that two compounds in the analyzed test sets, loratidine (Test set 1) and flufenamic acid (Test set 2), were also characterized by high ANN prediction errors of 1.82 and 1.44 log units, respectively (Table 3). The elimination of these compounds from the test sets significantly improves prediction ability of ANNs (Table 2).

The low prediction ANN ability for loratidine and flufenamic acid and some other compounds from the training set can be explained by an analysis of the residuals. These two compounds have experimental log P values near to the largest value (5.90) in the training set. Let us note that for log P > 5.0, there were four compounds with large residual errors in the training set. However there were in total only seven compounds with such log P values in our training dataset. Thus, >50% of compounds with log P > 5.0 were poorly predicted. This result suggests that the

[a] Compounds with absolute value of residuals >1.4 log units (two times the standard deviation of the prediction error) for MLR and ANNs are shown.

number of analyzed molecules with high log P values did not provide a representative training data set for correct application of the analyzed methods and the training set should be extended by including more compounds with high log P values.

The atom-type E-state indices are used in a manner similar to group additive schemes. Each atom in the molecular graph is presented by an E-state value that encodes the intrinsic electronic state of the atom perturbed by the electronic influence of all atoms in the molecule within the context of topological character of the molecule. Thus, the E-state for a given atom (or atom type) varies from molecule to molecule and depends on the detailed structure of the molecule. An analysis of residuals (Table 4) provided some hints of which structural features makes difficulties for the proposed method. There were four carboxylic acids (2,4-dihydroxybencoic acid, salicylic acid, mefenic acid, and tolfenamic acid) and hydroxyl-containing compounds (riboflavine, α-methylnoradrenalin, pyridoxamine, and DES), which all have a large calculation error. Also, both of the compounds with a large calculation error in the test sets contain a carbonyl group; that is, loratidine contains the ester carbonyl and flufenamic acid has a carboxylic acid group.

The reason for low prediction results for the compounds just mentioned can be explained by the fact that all E-state values calculated for hydroxyl groups are used to calculate only one parameter, SsOH, and no division for different types (i.e., alcohol, phenols, and carboxylic acids) is made. Likewise, the parameter SdO accounts for carbonyl oxygen, making no distinction between neighbor atom type (i.e., carboxylic acids, amides, ketones, and esters). The effects of the atom group could be considered similarly to the group contribution approach.[5,6,16] In this approach, contribution values are calculated separately for hydroxyl groups in aliphatic and aromatic compounds and for carbonyl oxygen-containing compounds, the division is made between carboxylic acids, esters, aldehydes, ketones, and amides. In both cases, the contribution values varied considerably, depending on the type of the atom group. Nearly all compounds with a large calculation error in our training set contain different types of hydroxyl and carbonyl compounds. Thus, it might be possible that the atom-type E-state index values for hydroxyl (SsOH) and carbonyl (SdO) groups are not enough to discriminate them according to their binding environment. We suggest that the usefulness of E-state formalism could be improved by taking into account the binding environment of an atom type, especially in the case of hydroxyl and carbonyl groups, like in Meylan's atom/fragment contribution method[5] and in Klopman's group contribution approach.[6,16]

The atom-type E-state indices are similar to some extent to the group contribution variables (e.g., numbers of $-CH_2-$ groups instead of $SssCH_2$). It is possible to assume that the same results would be calculated if these variables were used instead of the atom-type E-state indices. The numbers of atom-types computed using Molconn-Z software and the molecular weights were fitted as input parameters for MLR and ANNs. The best MLR model calculated using stepwise and backward methods contained the following 15 indices:

$$\log P = 0.163\ (\pm 0.072)\ ISsCH_3 + 0.164\ (\pm 0.038)\ ISssCH_2 + 0.128\ (\pm 0.037)\ ISaaCH + 0.260\ (\pm 0.062)\ ISaasC + 0.471\ (\pm 0.090)\ ISaaaC - 0.766\ (\pm 0.162)\ ISsNH_2 - 0.454\ (0.126)\ ISssNH - 0.522\ (\pm 0.264)\ ISdsN - 0.457\ (\pm 0.095)\ ISaaN - 0.465\ (\pm 0.119)\ ISsssN - 0.361\ (0.107)\ ISsOH - 0.516\ (0.122)\ ISssO + 0.254\ (\pm 0.111)\ ISsF - 0.472\ (\pm 0.231)\ SddssS + 0.0046\ (\pm 0.0012)\ MW + 0.145\ (\pm 0.234)$$

$$(n = 300,\ r^2 = 0.55,\ s = 1.18,\ F = 23.4,\ q^2 = 0.49,\ s_{LOO} = 1.23) \quad (4)$$

where I refers to the number of groups corresponding to the appropriate atom-type E-state index and MW is the molecular weight (Table 2). The prediction ability of this

equation was $r^2 = 0.59$, $s = 1.26$ and $r^2 = 0.13$, $s = 1.67$ for test sets 1 and 2, respectively. ANNs computed similar results; that is, $q^2 = 0.48$, $s_{LOO} = 1.24$ for the training set and $r^2 = 0.59$, $s = 1.29$ and $r^2 = 0.22$, $s = 1.74$ for test sets 1 and 2, respectively. Thus, both MLR and ANN methods provided significantly worse results if the group contribution variables were used instead of atom-type E-state indices. To understand these results, recall that the atom-type E-state indices account both for electronic and topological characteristics of the molecular structure. It is also important that the range of the atom-type E-state indices (Table 1) is considerably larger than that calculated by counts of the number of corresponding groups. This fact also significantly contributes to the performance and high prediction ability of models based on the atom-type E-state indices.

The most important advantage of the present approach is that only 32 parameters and no corrections factors were used for coding each molecule, whereas other methods require hundreds of parameters.[2−6,17] We are well aware of the shortcoming of the present model. Topological indices cannot account for three-dimensional and conformational effects, which may play a major role for solubility properties of chemical compounds, as recently suggested by Palm and co-workers.[18] However, topological indices are attractive because they can be easily and rapidly calculated from the structures of analyzed compounds. This feature makes it possible to obtain fast estimations of the solubility properties of compounds belonging to large databases, such as virtual combinatorial libraries. Probably, these indices can also be used to improve the prediction ability of other methods that are based on calculation of theoretical descriptors derived from the molecular structures of compounds.[19,20]

The prediction of partition coefficients using atom-type E-state indices is accurate and provides reliable log P estimations that are comparable to those obtained by other methods. An advantage of the proposed approach is that the atom-type E-state indices can be quickly and easily estimated directly from the chemical structure of analyzed compounds. Moreover, the number of parameters is small. Thus, the present approach introduces a fast method for estimation of log P of chemical compounds.

Abstract □ Disopyramide (DP) is known to induce QT prolongation and Torsades de Pointes (TdP) when administered concomitantly with erythromycin (EM). To define and evaluate quantitatively the arrhythmogenic risk of the concomitant administration of DP and EM, we investigated the influence of EM on the pharmacokinetics and pharmacodynamics of DP in rats. The time profiles of change in QT interval and plasma concentration of each drug were evaluated during and after constant intravenous infusion of DP (6.0 or 15.0 mg/kg/h), EM (4.0 or 8.0 mg/kg/h), and coadministration of DP and EM (DP 6.0 mg/kg/h plus EM 4.0 mg/kg/h). Each agent induced QT prolongation at plasma concentrations within the therapeutic range in humans. DP-induced QT prolongation was proportional to its plasma concentration. In the case of EM, the E_{max} model with an "effect compartment" could explain the relationship between plasma EM concentrations and changes in QT interval. Although coadministration of EM with DP gave enhanced QT prolongation compared to dosing with DP alone, EM did not affect the pharmacokinetics of DP. In conclusion, it was shown that a pharmacodynamic interaction contributes to the electrocardiographic adverse reaction (i.e., QT prolongation) induced by coadministration of DP and EM in rats.

Introduction

Disopyramide (DP), a class Ia antiarrhythmic agent, is used for tachyarrhythmia and prolongs action potential duration (APD) in cardiac myocytes. In recent years, it has been reported that concomitant administration of DP and erythromycin (EM), a macrolide antibiotic, induced Torsades de Pointes (TdP) associated with electrocardiographic QT prolongation.[1,2] In humans, DP is metabolized mainly by the liver into the major metabolite, mono-N-dealkylated disopyramide (MND).[3] Since EM, which is known to inhibit CYP3A4,[4] is reported to inhibit the metabolism of DP,[5] this oxdation enzyme is thought to be from the CYP 3A subfamily, paticularly CYP3A4. This inhibition may lead to elevated plasma DP concentration, and resultant toxicity such as QT prolongation. However, one case of TdP associated with QT prolongation resulting from the coadministration of DP and EM without an elevation of plasma DP concentration was also reported.[1] Therefore, the elevation of plasma DP concentration may not completly explain this adverse reaction. In fact, EM itself is known to induce QT prolongation or TdP.[6–8] Lin et al.[9] reported a case of TdP associated with QT prolongation induced by the concomitant use of quinidine and EM without an increase of plasma quinidine concentrations; they concluded that the adverse reaction caused by quinidine and EM coadministration might be based on their pharmacodynamic interaction. However, the significance of the pharmacodynamic interaction between DP and EM remains to be evaluated quantitatively.

Since EM is well-known as a metabolic inhibitor, the interaction between DP and EM might be initially considered based on metabolic inhibition. However, as far as a pharmacodynamic interaction is involved, monitoring of plasma DP concentrations only should underestimate the risk of adverse reactions. In this case, it is necessary to investigate this interaction not only from the pharmacokinetic aspect but also from the pharmacodynamic one. The aim of this study, therefore, was to define and evaluate quantitatively the risk of QT prolongation induced by DP and EM in an animal model, where rats were employed to estimate the ECG abnormality, including QT prolongation.[9]

Materials and Methods

1. Materials and Animals—DP was purchased from Wako Pure Chemical Industries (Osaka, Japan). MND and *p*-chlorodisopyramide were kindly provided from Russel Uclaf (Paris, France). Erythromycin base (EM) was obtained from Dai Nippon Pharmaceutical Co. (Osaka, Japan). Acetonitrile, methanol, and dichloromethane were of HPLC grade from Wako Pure Chemical Industries. Other reagents of analytical grade were also purchased from Wako Pure Chemical Industries. Male Sprague−Dawley rats weighing 250−350 g were purchased from Nippon Bio-Supp. Center (Tokyo, Japan) and used for the experiments.

2. Pharmacodynamic Studies—Drug solutions used for pharmacodynamic studies were prepared as follows: DP was solubilized by physiological salt solution (PSS; NaCl: 135 mM, $NaHCO_3$: 11.9 mM, KCl: 5.4 mM, $CaCl_2$: 1.8 mM, $MgCl_2$: 1.0 mM) with 1 mol equiv of H_3PO_4. EM was easily dissolved in PSS. For coadministration experiments, EM were dissolved in DP phosphate solution described above (nearly pH 7.0). EM was comfirmed to be stable in all the solutions for intravenous administration. Each solution was infused into the jugular vein of rats as below by means of a syringe pump (Model 975, Harvard Apparatus, MA) at an infusion rate of 1.05 mL/h.

Rats were anesthetized with a mixture of urethane and α-chlorarose (1.1 mg/kg and 27.5 mg/kg i.p., respectively). The precordial and limb hair were removed using a hair-removing cream (Hair Remover, Kanebo, Tokyo). The trachea, jugular vein, and carotid artery were cannulated with polyethylene tubing. After cannulation, the animals were restrained in a supine position on a heatpad, and the electrodes were noninvasively fastened. The body temperature was maintained at 37.5 ± 0.5 °C throughout the experiment.

After stabilization of the ECG and body temperature, PSS was infused into the jugular vein for 10 min. Subsequently, DP (6 or

15 mg/kg/h), EM (4 or 8 mg/kg/h), and the mixture of these agents (DP 6 mg/kg/h + EM 8 mg/kg/h) or PSS only (for control) was infused for 90 min. ECG was recorded 10 min before the start of infusion (−10 min), and 0, 1−7, 10, 15, 20, 30, 45, 60, 75, 90−97, 100, 105, 110, 120, 135, 150, 165, and 180 min after the start of infusion. The ECG was examined by a procedure previously reported.[10] Briefly, signals from the bipolar lead II were amplified by means of an electric amplifier (AB-621G, Nihon-Koden, Tokyo), stored in a personal computer (PC-9801VX, NEC, Tokyo) via A/D converter (Analog-Pro Jr., Canopus Electric, Kobe) at a sampling rate of 500 Hz and analyzed with Wave Master II (Canopus Electric, Kobe). Signals from the pressure transducer joined to the cannula of carotid artery were amplified by means of a pressure amplifier (AP-621G, Nihon-Kohden, Tokyo) and recorded by a pen recorder (WI-681G, Nihon-Kohden, Tokyo). ECG parameters such as heart rate and QT interval were derived manually from the average wave shape of recordings for 10 s. Blood was collected after the last recording of ECG to verify that the plasma drug concentration was equivalent to that in pharmacokinetic studies.

3. Pharmacokinetic Studies—*Pharmacokinetics during and after infusion of DP or EM*—Pharmacokinetic studies were performed in animals different from those used in the pharmacodynamic experiments in order to avoid any influence of blood sampling on ECG. Each drug solution was infused in the same manner as the pharmacodynamic experiments. Blood samples were collected from the carotid artery at 2, 5, 15, 45, 90, 92, 95, 105, 135, and 180 min after the start of drug administration. Blood samples were centrifuged to obtain plasma at 1500*g* for 10 min and determined by a procedure described below.

Pharmacokinetics after Portal Vein Administration of DP—Rats were fasted overnight before the experiment. Polyethylene cannula were inserted and fixed into the pyloric vein, the femoral vein and artery under ether anesthesia. The body temperature was maintained at 37.5 ± 0.5 °C throughout the experiment. After recovery from anesthesia, physiological saline or 50 mg/kg of EM was injected into the femoral vein at 5 min before the administration of DP. Then, 20 mg/kg of DP was injected into the portal vein. Each drug solution was prepared as follows: EM was solubilized in phosphate buffer solution (pH 4.0) (0.04 M KH_2PO_4, 0.04 M H_3PO_4), and DP was easily dissolved in physiological saline.

Blood samples (150 μL) were collected at 1, 3, 5, 15, 30, 60, 120, and 180 min after the DP administration and immediately centrifuged at 1500*g* for 10 min. Urine samples were collected for the intervals of 0−3, 3−24, and 24−48 h after the drug administration. The plasma and urine samples were stored at −20 °C until assay.

4. Effects of EM on Plasma Free Fraction (f_p) of DP—The plasma free fraction of DP (f_p) was determined in the presence or absence of EM by an ultrafiltration method. Drug-free blood was collected through the portal vein, heparinized, and centrifuged (1500g, 10 min) to separate plasma. DP was dissolved in plasma to make the concentrations of 0.1, 3.0, 6.0, and 15.0 μg/mL. To examine the influence of EM on f_p of DP, EM was added to the plasma samples containing EM to give a final concentration of 63 μg/mL. After preincubation at 37 °C for 5 min, an aliquot (500 μL) of the sample was put into the reservoir of an ultrafiltration device (Centrifree, Amicon, MA). Thereafter, it was centrifuged at 1000*g* for 2 min at 37 °C to obtain ultrafiltrate. The volume of the ultrafiltrate was measured as less than 15% of the original sample (500 μL). The concentration of DP in each fraction was determined as described below. The f_p value was calculated by dividing the DP concentration in the ultrafiltrate by that in the retained sample.

5. Determination of DP, MND, and EM Concentration—DP and MND concentrations in plasma or urine were determined using an HPLC method reported previously by Mayer et al.[11] with a minor modification. Briefly, an aliquot (50 μL) of plasma or urine sample was pipetted into a 10-mL glass tube. After addition of 50 μL of the internal solution (0.6 μg/mL *p*-chlorodisopyramide solution in 0.01 M HCl) and 2 mL of dichloromethane, the mixture was made alkaline with 5 μL of 1 M NaOH and then shaken for 10 min by a mechanical shaker. After centrifugation (10 min, 1500*g*), the lower organic layer was transferred into a 10-mL glass tube and evaporated to dryness under a stream of dry nitrogen at ambient temperature. The dry residue was dissolved into 50 μL of mobile phase, and 20 μL was applied onto the HPLC system.

HPLC was performed with a UV detector (UV−vis DETECTOR SPD-10A, Shimazu, Kyoto, Japan) and a C_{18} reversed-phase column (Cosmosil-packed column 5-C_{18}, 150 mm × 4.6 mm i.d., particle size 5 μm, Nacalai Tesque, Kyoto, Japan). Assay was carried out at ambient temperature. The mobile phase consisted of aqueous solution (0.125 M HCl, 0.125 M sodium 1-octanesulfonate, 0.072 M triethylamine) and acetonitrile (70:30, v/v). The flow rate was 1.0 mL/min, and the detection wavelength was set at 263 nm. The lower limit of reliable detection of this method was 0.1 μg/mL for DP and 0.05 μg/mL for MND. The plasma EM concentrations were determined by an HPLC-ECD method described previously.[12]

6. Pharmacokinetic−Pharmacodynamic Analyses of QT prolongation—The effects of DP and EM on QT interval were analyzed from both pharmacokinetic and pharmacodynamic aspects. The QT interval was defined as the time from the start of the QRS complex to the end of the T wave, at which the amplitude of the T wave declined to 10% of its maximum. The effect of a drug at each time was expressed as the deviation from the value before the drug administration (ΔQT). Mean QT interval just before the start of drug administration was 61.6 ± 0.98 ms (n = 24). The PR interval was defined as the time from the start of the P wave to the apex of the R wave.

The time profiles of plasma DP concentration (C_p) were analyzed by a conventional two-compartment open with a first-order elimination model described previously.[13] Pharmacokinetic parameters were estimated by simultaneous fitting of the data at each infusion rate.

Then, the relationship between the plasma concentration of DP and the effect of DP on QT prolongation (E_{DP}) was analyzed, assuming a linear relation as follows:

$$E_{DP} = KC_p \quad (1)$$

where C_p is the plasma DP concentration and K is the slope.

The time profiles of plasma EM concentration were also analyzed by a conventional two-compartment model described previously.[13] Pharmacokinetic parameters of α, β, k_{10}, k_{21}, and V_1 were estimated by simultaneous computer-fitting of the data at each infusion rate.

For the pharmacokinetic−pharmacodynamic analysis of EM, the "effect compartment model"[14] was applied because a delay of QT prolongation was observed. The drug concentration (C_e) in the effect compartment is described by equations reported by Holford and Sheiner.[14]

Then the relationship between C_e and the effect of EM on QT prolongation (E_{EM}) was analyzed. The E_{max} model was employed to relate C_e to E_{EM} as follows:

$$E_{EM} = \frac{E_{max}C_e}{EC_{50} + C_e} \quad (2)$$

where E_{max} is the maximum effect, and EC_{50} represents the concentration which gives half-maximal effect.

For coadministration of EM and DP, we assumed that the effect of the coadministration on QT prolongation (E_{DP+EM}) was estimated from the additive model described below.

$$E_{DP+EM} = E_{DP} + E_{EM} \quad (3)$$

Results

ECG Effects and Pharmacokinetics of DP—Figure 1 represents the time profiles of the change in QT interval (ΔQT) and the plasma DP concentration during and after the constant intravenous infusion of DP. The QT interval was prolonged in response to the increase in plasma DP concentration without a lag-time. After the end of the infusion, the QT interval was shortened as the plasma DP concentration declined. DP induced a dose-dependent prolongation of QT interval within the dose range tested; changes in QT prolongation at 90 min after the start of the infusion were 17.50 ± 1.94 ms and 38.50 ± 5.00 ms at the dosing rates of 6 mg/kg/h and 15 mg/kg/h, respectively. In addition, DP induced a significant prolongation of PR

interval and a slight prolongation of QRS interval (data not shown).

ECG Effects and Pharmacokinetics of EM—The time profiles of the change in QT interval (ΔQT) and the plasma EM concentration during and after the constant intravenous infusion of EM are shown in Figure 2. Although EM also evoked an obvious QT prolongation as observed in the case of DP, ceasing the infusion did not give an immediate shortening of the QT interval despite the prompt decrease in the plasma EM concentration. This observation indicates the presence of a delay in QT prolongation against plasma EM concentration. Within the EM concentration range under the present experimental conditions, saturation of the effect on QT interval was observed; changes in QT prolongation at 90 min after the start of the infusion were 28.20 ± 3.65 ms and 33.50 ± 3.75 ms at the dosing rates of 4 mg/kg/h and 8 mg/kg/h, respectively. Other ECG parameters, PR and QRS intervals, were not significantly altered (data not shown).

Pharmacokinetic–Pharmacodynamic Analyses of QT Prolongation—Figure 3 represents the relationship between plasma DP concentration and change in QT interval, and Figure 4 shows the relationship between EM concentration in plasma and change in QT interval. With regard to DP, as neither a delay nor saturation of QT prolongation was observed, the linear model (eq 1) was applied to the relationship between plasma DP concentration and E_{DP} (Figure 3). As judged from the anticlockwise hysteresis and saturation of the relationship in Figure 4, the E_{max} model with the effect compartment (eq 2) was

successfully employed. The pharmacodynamic parameters for DP and EM are listed in Table 1.

Electrocardiographic Interaction on ECG Induced by DP and EM—Figure 5 represents the time profiles of the change in QT interval during and after the infusion of DP, EM, and their combination. The coadministration of DP and EM induced a larger QT prolongation than the administration of each drug alone. The simulation curves line calculated from eq 3 were in good agreement with the observed data. Although an electrocardiographic (ECG) interaction was seen between these drugs (right panel of

Figure 5), EM did not affect the plasma concentration of DP and vice versa. This result led us to further investigate the pharmacokinetics of DP in the coadministration of EM.

Pharmacokinetic Interactions of DP and EM—Figure 6 represents the time profiles of plasma concentrations of DP and its metabolite, MND, after the portal vein administration of DP in the presence or absence of EM. The time profile of DP was described by a conventional two-compartment open model. Although the plasma concentration of MND reached maximum at 5 min after the administration of DP, the concentration of the metabolite was less than one tenth of that of the parent drug. After the administration of DP, 26.2 ± 2.1% of the dose was excreted as unchanged drug, while 4.1 ± 0.9% was excreted as MND in the urine within 24 h. Table 2 lists the pharmacokinetic parameters, which are in agreement with the published data.[15,16]

EM did not significantly change the pharmacokinetic parameters of DP, and both the plasma concentrations and the urinary excretion of the metabolite, MND, were not also significantly changed. Moreover, the plasma free fraction

of DP (f_p), 0.800−0.875, was almost constant over the concentration range of 0.05−15.0 μg/mL and was not significantly changed in the presence of EM.

Discussion

In recent years, QT prolongation induced by noncardiovascular drugs has received much attention. Such drug-

induced QT prolongation may be accentuated by coadministration of an antiarrhythmic agent, which itself prolongs QT interval. For instance, some cases have been reported that DP, coadministered with EM, caused TdP associated with QT prolongation,[1,2] a life-threatening adverse reaction. It is therefore important to investigate the interactions between antiarrhythmics and noncardiovascular agents which have the possibility of prolonging the QT interval.

Correction of QT Interval by Heart Rate—Since heart rate is known to affect the QT interval in humans, QTc, derived from "Bazett's formula", is widely applied in evaluation of QT prolongation. In this study, EM did not change the heart rate, whereas DP induced bradycardia, probably resulting from the blockade of sodium channels. However, Hayes et al. demonstrated that the QT interval is independent of heart rate in rats, in contrast to humans, rabbits, and guinea pigs.[17] In addition, it has been reported that the actual QT interval, without any correction for heart rate, may be preferable the QTc in heralding TdP.[18] Therefore, in this study, we employed the actual QT interval for evaluation of arrhythmogenic potency.

QT Prolongation Induced by DP or EM—In the present study, the administration of DP or EM alone induced a significant QT prolongation. DP is known to block sodium channels and potassium channels of cardiac myocytes and delay repolarization, which leads to prolongation of action potential duration (APD) and QT interval.[19] In our study in rats, DP induced QT prolongation within its therapeutic range (2.0−5.0 μg/mL). This range coincides with the concentrations where APD prolongation was reported on cardiac muscle of guinea pigs or rats by whole-cell voltage clamp technique.[20−23] Although MND, a major metabolite of DP, is documented to possess one-fourth the anticholinergic potency of DP,[24,25] it is virtually inactive in QT prolongation.[23,26] Therefore, MND was excluded from the further kinetic analysis.

EM is also known to inhibit potassium channels in ventricular myocytes.[27−29] This blockade may lead to delayed repolarization and prolongation of QT interval. However, the detailed mechanism has not been thoroughly elucidated.

An anticlockwise hysteresis was observed between plasma EM concentration and effect on QT prolongation, which indicates a delay of QT prolongation. The E_{max} model with "effect compartment" may adequately explain the relationship (Figure 3B). This hysteresis could be due to several factors, including delayed distribution of EM to the effect site, which is assumed to be potassium channels of ventricular myocytes. The binding site for EM in the potassium channel has not been identified yet. However, there is a possibility that the binding site is located in the intracellular or transmembrane domain of the channel and that it may take several minutes for the drug to reach the effect site, as speculated from the delay of QT prolongation. A possible explanation for this anticlockwise hysteresisis is the generation of an active metabolite of EM. While EM is reported to be active in QT prolongation, it is not reported whether the metabolite of EM is active or not. No major metabolites of EM were detected by ECD, so that we could not investigate metabolite pharmacokinetics. However, when we examined the time course of EM concentrations in the ventricle, it showed a delayed distribution of EM into the ventricle at the distribution rate similar with k_{eo} (data not shown).

In this study, EM induced a significant QT prolongation within the therapeutic range of plasma EM concentrations (0.5−3.0 μg/mL). Using the in vitro patch clamp technique, it has been reported that a higher concentration (up to 100 μM; 73.4 μg/mL) is necessary for EM to prolong the action potential duration (APD) or reduce potassium current (delayed rectifier potassium current).[27−29] Rubart et al.[27] discussed that the concentrations of EM required to induce early after-depolarizations (EADs) in vitro are higher than those in vivo. Antzelevitch et al.[29] demonstrated that APD prolongation was evoked at a relatively low concentration of EM (10 μM) in canine M cells, but the concentration was still above the therapeutic range. In the present study, even if the plasma protein binding of EM (16.9% for rats) was taken into consideration, the concentration which evoked QT prolongation in vivo was still lower than that reported in vitro,[27−29] indicating that the potency of EM for APD prolongation or potassium current blockade in ventricular myocytes in vitro may be weaker than that for QT prolongation in vivo. Further investigation is required to clarify the mechanism and sources of this discrepancy. A possible explanation is that the EM concentration near the potassium channels is different between in vivo and in vitro conditions, due to different cellular uptake and/or intracellular distribution under these conditions.

As no saturation was observed for DP-induced QT prolongation, the relationship between plasma DP concentration and change in QT interval was analyzed by a linear pharmacodynamic model (eq 1). Although we also employed the E_{max} model, the linear model showed a better goodness of fit than the E_{max} model. Doses of DP beyond the therapeutic range were not experimentally feasible due to adverse effects on rats. It is of interest that different pharmacodynamic models were applied to DP and EM: the linear model for DP and the E_{max} model for EM. Similar cases have been reported for other agents which induce QT prolongation, i.e., the relationship between drug concentration and change in QT interval was explained by the linear model for quinidine and an E_{max} model for terfenadine.[10] Whiting et al.[30] have also reported that the change in QT interval is linearly correlated with plasma DP concentration. Both DP and quinidine were reported to block several types of potassium channels on ventricular myocytes,[22,31] leading to a complex, stepwise inhibition, which may result in a linear relation between drug concentration and change in QT interval.

Pharmacodynamic Interaction between DP and EM—Enhanced QT prolongation was observed after coadministration of EM and DP compared to that after each administration of these drugs (Figure 5). However, the plasma concentrations of each agent were not changed by each other. This indicates that the interaction on ECG between these drugs can be attributed to their pharmacodynamic interaction, not a pharmacokinetic one, at least in the present experimental setting. Thus, a clinically important pharmacodynamic interaction between EM and DP can be observed without affecting pharmacokinetics.

The observed data after coadministration of EM and DP were simulated by simple addition of QT prolongations after separate EM and DP administrations. The simulated line is below the observed data during the administration. Then, at each point, we compared the ΔQT (ΔQT_{DP+EM}) in concomitant administration with the additional ΔQT (ΔQT_{DP}

$+ \Delta QT_{EM}$) using the Student *t*-test. As a result, significant differences were observed only at 4 and 5 min. Therefore, we cannot completely define this interaction as additive. However, we are not sure that the interaction between DP and EM is antagonistic. The clinical significance of the present study is that enhanced QT prolongation was shown in concomitant administration compared to individual administrations.

Effects of EM on Pharmacokinetics of DP—The pharmacokinetic parameters of DP obtained here were is close agreement with those noted in previous studies.[15,16] Since the total plasma clearance of DP was large and thought to be blood flow-limited, we evaluated the effects of EM on the pharmacokinetics of DP following portal vein administration of DP.

In the portal vein dosing of DP, EM pretreatment did not significantly change the pharmacokinetic parameters of DP (Table 2). In addition, no effect of EM on the plasma protein binding of DP was observed. In addition, the blood-to-plasma concentration ratio of DP (R_B) was also evaluated and it was not significantly changed by EM. While the plasma binding of DP is known to saturate within the therapeutic range in humans,[32] it was almost constant in rats under the current experimental range (0.05−15.0 μg/mL), suggesting interspecies difference in the plasma protein binding of DP, in accordance with a previous reports.[16]

Although it is expected that EM might cause the elevation of DP plasma concentrations in humans by metabolic inhibition, no pharmacokinetic interaction was seen in rats. The most likely explanation for these results may be interspecies differences in the metabolism of DP. In fact, the urinary excretion of MND, a major metabolite yielded by CYP3A, proved to be lower (up to 4% of the dose) in rats than in humans. It has also been reported[16,33] that in rats about 20% of the dose was excreted into urine as phenol and methoxyphenol metabolites, while these metabolites are not detected in humans. Therefore, the contribution of the metabolic pathway of DP, which EM could inhibit, to the total clearance may be lower in humans than in rats. The EM concentration in liver was enough compared to its inhibition constant (IC_{50} = 70 μg/mL) in vitro.[5] Another potential explanation for the lack of pharmacokinetic interaction between EM and DP is a setereoselective metabolism. DP is a racemic mixture of *R*(−) and *S*(+) enantiomers, and those clearances are reported to be different.[34] If EM inhibits one of the enantiomers, increase in AUC of DP as a racemic mixture may not reach significance. Echizen et al.[35] showed that the enantiomers share an enzyme in humans and mice, and that EM inhibited their metabolism equally in mice but not equally in human microsomes. However, no data are available for rats in vivo or in vitro. Since DP is used as a racemic mixture in clinical settings, the clinical significance of our study may not be diminished.

Other explanation is the administration route-dependency. EM was intravenously administered in this study. However, the repeated oral administration of EM might be required to induce the metabolic inhibition of CYP3A.[36] In addition, when orally administered, the intestinal metabolisms by CYP3A may be inhibited, which may lead to further increase in the DP concentrations if DP is metabolized by intestinal CYP3A.

Prediction of QT Prolongation in Humans—It has been reported[26,30,37−40] that DP prolongs the QT interval within the therapeutic range of plasma concentration (2.0−5.0 μg/mL) in humans. The findings obtained in the present study were consistent with the above reports. On the other hand, the plasma concentrations of EM have not been reported where QT prolongation or TdP occurred, possibly because of difficulty in the determination of EM concentration in plasma. Therefore, the quantitative relationship between concentration of EM and its effect on QT interval in clinical settings remains unknown. An EM-induced QT prolongation is reported[5] to occur not only after i.v. administration of a high dose (up to 1 g/body) in many cases, but also after oral administration of EM.[41] In the case of oral administration, plasma EM concentration is considered to be lower than in the case of i.v. injection, suggesting a possibility that EM may also induce QT prolongation within or near therapeutic plasma concentrations (0.5−3.0 μg/mL), which correlates well with the range examined in our present study. In addition, orally administered EM is also known to induce TdP associated with QT prolongation after concomitant treatment with quinidine.[9] Thus, our method presented here may be useful for predicting drug-induced QT prolongation in clinical settings, at least in a qualitative manner.

In conclusion, the present study suggests that pharmacodynamic interaction may increase the risk of QT prolongation after coadministration of DP and EM in humans. In concomitant treatment of DP and EM, therefore, it is our recommendation for patients' safety that ECG should be monitored periodically as necessary.

Received June 9, 1998. Accepted for publication October 19, 1998.

Abstract □ Twelve measured ethylene glycol–heptane partition coefficients, P_{eh}, have been combined with 20 measured literature values and 44 indirectly determined values to give a set of 76 values. Excluding one value for benzamide, the log P_{eh} values are correlated through our general solvation equation, log $P_{eh} = 0.336 - 0.075R_2 - 1.201\pi_2^H - 3.786\ \Sigma\alpha_2^H - 2.201\ \Sigma\beta_2^H + 2.085V_x$ with $r^2 = 0.966$, sd $= 0.28$, and $F = 386$. The solute descriptor R_2 is the excess molar refraction, π_2^H is the dipolarity/polarizability, $\Sigma\alpha_2^H$ and $\Sigma\beta_2^H$ are the overall hydrogen bond acidity and basicity, and V_x is the McGowan volume. The log P_{eh} equation has then been used to obtain descriptors for eleven peptides, all of which are end-protected. It is shown that for these end-protected peptides, hydrogen bond basicity makes a greater contribution to log P_{eh} than does hydrogen bond acidity.

Introduction

Karls et al.,[1] in 1991, showed that the hydrogen bond number of Stein[2] was useful in the correlation of absorption of a series of peptides in rats. The peptides, I−VII, are shown in Figure 1, and the hydrogen bond numbers, H#, are in Table 1. The latter are simply calculated from the total number of C=O and N−H groups, with NH_2 counted as two. Burton et al.[3] used the same seven peptides to study permeability across Caco-2 cell monolayers and showed graphically that there was a reasonable correlation between log k_{caco} and the Δlog P parameter of Seiler.[4] The latter is obtained from water−octanol and water−alkane partition coefficients through eq 1,

$$\Delta\log P = \log P_{oct} - \log P_{alk} \quad (1)$$

Burton et al.[3] did not explore the H# numbers, but investigated the use of a novel partitioning system, that of ethylene glycol−heptane:

$$P_{eh} = [\text{concn in heptane}]/[\text{concn in ethylene glycol}] \quad (2)$$

They showed that for the seven peptides there was a reasonable plot of log P_{eh} against Δlog P, and argued that since Δlog P could be taken as a measure of the hydrogen bond or desolvation potential of a solute, so could log P_{eh}. The various partition coefficients that were determined[3] for the seven peptides are given in Table 1; the alkane used was isooctane. In later work it was shown[5] that permeabilities of the seven peptides across an in vitro model of the blood−brain barrier (BBB) or from physiologic saline to rat brain could be correlated with H# or Δlog P or log P_{eh}. The hydrogen bonding capacity of the peptides was suggested to be the major factor governing both the in vitro and the perfusion in vivo permeabilities.

Table 1—Hydrogen Bond Numbers and Partition Coefficients for Peptides[a]

peptides	H#	log P_{oct}	log P_{iso}[b]	log P_{eh}
I	5	0.05	–4.92	–5.46 (–5.57)
II	7	1.19	–5.29	–6.52 (–6.28)
III	9	2.30	–5.02	–7.10 (–7.16)
IV	8	2.63	–4.20	–6.28
V	7	2.53	–3.10	–5.14
VI	6	2.92	–1.67	–4.20
VII	5	3.24	–0.69	–2.86
VIII	8			(–6.00)
IX	8			(–5.76)
X	7			(–4.35)
XI	5			(–3.44)

[a] log P values from ref 3; values in parentheses from ref 6. [b] P_{iso} refers to partition between water and isooctane.

To characterize the ethylene glycol−heptane partitioning system, Paterson et al.[6] measured log P_{eh} values for a set of 20 standard compounds, and correlated these values with the solvatochromic parameters of Kamlet et al..[7] The log P_{eh} values are in Table 2, nos. 1−20, and the correlation equation was:

$$\log P_{eh} = 0.30 - 1.53\pi^* - 4.41\alpha - 1.69\beta + 2.79V_I \quad (2)$$
$$n = 19,\ r^2 = 0.984,\ \text{sd} = 0.19,\ F = 223$$

In eq 2, π^* is the solute dipolarity/polarizability, α is the solute hydrogen bond acidity, β is the solute hydrogen bond basicity, and V_I is the solute intrinsic volume in (cm^3 mol^{-1})/100. Benzamide was left out of the correlation, hence n, the number of data points, is 19; the only other statistic given[6] was $r^2 = 0.980$, where r is the correlation coefficient. We have rerun the correlation and find $r^2 = 0.984$ (the value of 0.980 is the adjusted value), the standard deviation sd $= 0.19$ and the F-statistic $F = 223$, as shown above.

Paterson et al.[6] pointed out that eq 2 shows that the most important coefficient is the solute hydrogen bond acidity. However, this does not mean that the term in α always dominates; this will depend on the various parameter values for any given solute. Although the solvatochromic parameters of Kamlet et al.[7] are useful, there are difficulties in that parameters for many solutes have to be estimated, and that there is no protocol for the estimation of parameters for new structures such as peptides I−VII. In addition, although Paterson et al.[6] selected a reasonable set of compounds, the number is minimal for a four-

parameter equation, and the range of the various descriptors is not very large.

We therefore set out to expand the number and nature of the solutes, to characterize the ethylene glycol–heptane system through the solvation equation and the solvation parameters of Abraham,[8] and to compare coefficients in the correlation equation with those for many other partitioning systems that have been thus characterized.[9] Once this has been done, our aim is to determine solvation parameters for the peptides I–VII, and then to ascertain the factors that influence partitioning of peptides in the ethylene glycol–heptane system.

Experimental Section

Ethylene glycol was Fisons Analytical Reagent, and heptane was Fisher Scientific Analytical Reagent. Partition experiments were carried out with mutually saturated solvents. The various solutes were from Sigma or Aldrich, except for benzyl alcohol, zolantidine, and clonidine which were in-house specimens. Preliminary experiments showed that the maximum water content of the ethylene glycol was 0.11% by Karl Fischer titration, either with fresh solvent or after shaking the solvent in a separating funnel with a significant air space. Since the ethylene glycol did not appear to be particularly hydroscopic, no special precautions were taken to exclude water. A number of partition experiments were carried out on benzyl alcohol, with different combinations of sonication and tumbling. Results showed that 15 min sonication using a SEMAT ultrasonic bath followed by mixing for 1 h on a mechanical flask tumbler was sufficient to reach equilibrium.

Partition measurements were carried out by dissolving the solute in presaturated ethylene glycol. In the case of compounds obtained as salts (imipramine hydrochloride, mepyramine maleate, and clonidine hydrochloride) solid potassium hydroxide was first dissolved in the ethylene glycol at a concentration of 1.0 mg ml^{-1}. A known volume of the ethylene glycol solution was transferred to a Nalgene FEP bottle, and a known volume of preequilibrated heptane was added. The phases were mixed, as above, and allowed to separate, with centrifugation for 3 min at 3000 rpm, if necessary. The ethylene glycol solutions before and after partitioning were analyzed by UV spectrometry. In all case, determinations were carried out in duplicate, using different volume ratios of ethyene glygol:heptane. The volume ratios were chosen so that the initial and final absorbances were significantly different. In the case of pentachlorophenol and anthracene, solubility in ethylene glycol was very low. The compounds were therefore initially dissolved in heptane, and it was this phase that was analyzed before and after partitioning. Results are in Table 2 under compounds nos. 21–32.

Results and Discussion

Characterization of the Ethylene Glycol–Heptane System—We use the solvation equation of Abraham,[8] as shown in eq 3:

$$\log SP = c + rR_2 + s\pi_2^H + a\Sigma\alpha_2^H + b\Sigma\beta_2^H + vV_x \quad (3)$$

The solute descriptor R_2 is excess molar refraction, π_2^H is the polarizability/dipolarity, $\Sigma\alpha_2^H$ and $\Sigma\beta_2^H$ are the overall or effective hydrogen bond acidity and basicity, and V_x is the characteristic volume of McGowan[10] in units of $(cm^3\ mol^{-1})/100$. As solutes we used the 20 compounds studied by Paterson et al.,[6] nos. 1–20 in Table 2, and we also measured log P_{eh} for another 12 compounds, nos. 21–32 in Table 2, by the standard shake-flask method, as described above. The 12 compounds were chosen specifically to increase the range of the descriptors; inclusion of the drugs nos. 28–32, and of deoxycortisone, very considerably extends the range. However, there is still room for improvement because over solutes nos. 1–32, the lowest value of π_2^H is 0.52 for benzene, and the lowest value of V_x is 0.5470 for propanone. Since the solubility of ethylene glycol in heptane is very small,[6] we felt that the partition coefficient between these equilibrated phases could be obtained through solubility of gases and vapors in the two pure solvents, eq 4:

$$\log P_{eh} = \log L_h - \log L_e \quad (4)$$

where log L_h and log L_e are the Ostwald solubility coefficients (or gas–liquid partition coefficients) in heptane[11–23] and ethylene glycol[13–16,22–29] at 298 K. Values of log P_{eh} could thus be obtained for 44 extra solutes (nos. 33–76 in Table 2) some with zero values of π_2^H, and with V_x as low as 0.0850 for neon; details are in Table 3. The range of descriptors over the total 72 solutes is now very large indeed; values are collected in Table 2. We note that three of the solutes in set 1–32 are duplicated in set 33–76 (benzene, toluene, and butanone) so that we have 76 data points for 73 solutes. Application of eq 3 to the 76 data points in Table 2 showed that again benzamide was a marked outlier. It is hard to believe that both the Kamlet and the Abraham set of descriptors for benzamide are wrong, and so it is possible that the log P_{eh} value is in error. We did not carry out a determination of log P_{eh} for benzamide ourselves, because the value quoted (–3.69) is lower than we can measure by our shake flask and UV analytical method. Omission of benzamide leads to the correlation eq 5; the sd values for the coefficients are also given.

$$\log P_{eh} = 0.336(0.067) - 0.075(0.134)R_2 - 1.201(0.140)\pi_2^H - 3.786(0.177)\Sigma\alpha_2^H - 2.201(0.163)\Sigma\beta_2^H + 2.085(0.097)V_x \quad (5)$$

$$n = 75,\ r^2 = 0.966,\ \text{sd} = 0.28,\ F = 386$$

75	propylbenzene	2.68	4.34	1.66
76	isopropylbenzene	2.59	4.19	1.60

The rR_2 term is statistically not significant and can be omitted to give:

$$\log P_{eh} = 0.343(0.066) - 1.247(0.112)\pi_2^H - 3.807(0.172)\Sigma\alpha_2^H - 2.194(0.162)\Sigma\beta_2^H + 2.065(0.089)V_x \quad (6)$$

$$n = 75,\ r^2 = 0.966,\ \text{sd} = 0.28,\ F = 488$$

These equations confirm the finding of Paterson et al.[6] that the *a*-coefficient is numerically the largest coefficient. However, as pointed out above, this does not necessarily mean that solute hydrogen bond acidity is the major factor that influences log P_{eh}. In any case, solute hydrogen bond acidity is not the only factor, as shown by the large *s*-, *b*-, and *v*-coefficients. Indeed, it is chemically unreasonable to suggest that solute hydrogen bond basicity, for example, will have little effect on log P_{eh}. The *b*-coefficient is related to the difference in solvent hydrogen bond acidity of ethylene glycol and heptane. Since ethylene glycol is a reasonably strong hydrogen bond acid, and heptane has no acidity, there must be a considerable difference in solvent hydrogen bond acidity, and this must give rise to a substantial *b*-coefficient in the solvation equation.

Table 4—Coefficients in Eq 3 for Various Systems

log SP	*c*	*r*	*s*	*a*	*b*	*v*

Table 5—Values of R_2 and V_x, and Calculated Descriptors for Peptides I–VII from Three Simultaneous Equations

peptide	R_2	V_x	π_2^H	$\Sigma\alpha_2^H$	$\Sigma\beta_2^H$
I	1.453	1.6519	4.01	0.64	0.85
II	2.466	2.7979	5.18	0.73	1.60
III	3.479	3.9439	6.41	0.68	2.33
IV	3.441	4.0848	6.46	0.50	2.36
V	3.403	4.2257	6.91	0.12	2.40
VI	3.365	4.3666	7.68	–0.18	2.20
VII	3.302	4.5075	6.33	–0.30	2.66

We can compare the coefficients in eq 5 with those for a number of partitions,[9,30] as shown in Table 4. For convenience we give coefficients for $-\Delta\log P$. There is certainly a connection between the coefficients for log P_{eh} and $-\Delta\log P$, so it is not surprising that log P_{eh} and $-\Delta\log P$ are linearly related for a series of similar solutes, e.g., peptides I–VII, as shown by Burton et al.[3] However, there are considerable differences between the *b*- and *v*-coefficients in the two partition systems. Hence a relationship between log P_{eh} and $\Delta\log P$ for peptides I–VII may not be general, especially as these peptides have particularly large volumes and large basicities (as shown later).

Analysis of the Hydrogen Bonding Capacity of Peptides—To our knowledge, there are no published studies on quantitative determinations of either the hydrogen bond acidity or the hydrogen bond basicity of peptides. It is therefore of some interest to attempt to determine the solvation descriptors, including $\Sigma\alpha_2^H$ and $\Sigma\beta_2^H$, for peptides I–VII. Once the solvation descriptors are known, it is possible to determine quantitatively the factors that influence the distribution of the peptides.

For the peptides I–VII, both R_2 and V_x can be calculated from structure. The former is obtained by the summation of fragments of known R_2 value,[9] and the latter by McGowan's method of atomic fragments.[10] There remain three descriptors that have to be determined, π_2^H, $\Sigma\alpha_2^H$, and $\Sigma\beta_2^H$. Now if there are available for a given peptide log *P* values in three different partition systems for which the coefficients in eq 3 are known, all three descriptors can be calculated from a set of three simultaneous equations. In Table 1 are log *P* values for the peptides in three partition systems, and in Table 4 are the required coefficients. The calculated descriptors are in Table 5, together with the necessary R_2 and V_x values. There is no point in giving any calculated log *P* values, because the descriptors reproduce the three log *P* values exactly. The obtained descriptors can be compared with descriptors calculated by simple addition of fragment values. We take π_2^H, $\Sigma\alpha_2^H$, and $\Sigma\beta_2^H$ as follows: for a primary amide (1.30, 0.55, and 0.70), for a secondary amide (1.30, 0.40, and 0.70), and for the CH_2Ph group (0.51, 0.00, and 0.15). The calculated descriptors for the mono-, di-, and tripeptides I, II, and III are in Table 6. Values of π_2^H from the fragment addition and the simultaneous equations agree quite well, compare Tables 5 and 6, but $\Sigma\alpha_2^H$ and $\Sigma\beta_2^H$ from the simultaneous equations are much lower than those from fragment addition.

Table 6—Calculated Descriptors from Fragment Values

peptide	π_2^H	$\Sigma\alpha_2^H$	$\Sigma\beta_2^H$
I	3.11	0.95	1.95
II	4.92	1.35	2.82
III	6.73	1.75	3.69

Table 7–Revised Descriptors for Peptides I–VII

				calculated log P[a]		
peptide	π_2^H	$\Sigma\alpha_2^H$	$\Sigma\beta_2^H$	oct	iso	eh
I	3.90	0.65	0.89	0.04	–4.94	–5.43
II	5.20	0.67	1.63	1.05	–5.27	–6.38
III	6.60	0.64	2.27	2.30	–5.08	–7.05
IV	6.45	0.50	2.37	2.62	–4.20	–6.26
V	6.60	0.16	2.48	2.59	–3.13	–5.10
VI	6.50	0.00	2.50	3.13	–1.85	–4.12
VII	6.10	0.00	2.55	3.88	–0.82	–3.45

[a] Oct is water–octanol, iso is water–isooctane, eh is ethylene glycol–heptane.

This might be due to peptide conformations in which intramolecular hydrogen bonding takes place, or in which there is restricted access of solvent molecules to hydrogen bond sites. In either case, $\Sigma\alpha_2^H$ and $\Sigma\beta_2^H$ will be lower than expected.

Even taking these effects into account, some of the obtained descriptors by the simultaneous equation method are not very reasonable. The negative $\Sigma\alpha_2^H$ values for VI and VII have no physical meaning, and π_2^H for VI seems too large. There are a number of possible reasons. First, the determination of very negative log P values is difficult, and the observed log P values may have a larger error than usual. Second, there are numerous possible combinations of the three descriptors that will all give calculated log P values in reasonable accord with the observed values. Third, although we have considerably extended the range of descriptors by incorporation of compounds nos. 21−32 (Table 2), some of the peptides still lie outside this range. Hence small variations in the coefficients of the log P_{eh} equation could lead to large differences in calculated descriptors. We therefore take the descriptors in Table 5 as a first estimate only and then calculate a revised set that (i) will reproduce quite well the observed log P values, and (ii) will be chemically more reasonable. In particular we have assigned $\Sigma\alpha_2^H$ as zero for VI and VII, instead of the negative quantities in Table 5. From the fragment values in Table 6, the difference in π_2^H between I and II and between II and III would be around 1.80 units. However, we find that such an adjustment leads to poorer fits of calculated and experimental log P values, and as a compromise we take the difference as 1.5 units. Also, we expect π_2^H for the tripeptides III−VII to be nearly the same. The revised descriptors are in Table 7, together with the calculated log P values using the revised descriptors. Results are very good for peptides I−VI, with observed and calculated log P values being in good agreement, but for peptide VII, the agreement is not so good. The general trend of the descriptors for I−VII, Table 7, now seems more reasonable than those from the simultaneous equations, Table 5, especially regarding π_2^H and $\Sigma\beta_2^H$.

We can test whether the assigned descriptors for I−VII are compatible with those in Table 2 by incorporating the peptides into the log P_{eh} regression. The resulting equations are very close to eq 5 and eq 6. If only peptides I−VI are used, the regression equation coefficients are almost exactly the same as those in eq 5, or in eq 6:

Table 8—Calculated Descriptors for Peptides VIII–XIV

						calculated log P		
peptide	R_2	V_x	π_2^H	$\Sigma\alpha_2^H$	$\Sigma\beta_2^H$	oct	iso	eh
VIII	3.441	4.0848	6.55	0.41	2.35	2.58	–3.93	–6.00
IX	3.441	4.0848	6.40	0.40	2.34	2.77	–3.60	–5.76
X	3.403	4.2257	6.45	0.03	2.45	2.84	–2.26	–4.36
XI	1.263	2.1333	3.50	0.45	1.01	1.77	–2.02	–3.44
XII	1.060	1.2546	1.65	(0.40)	0.82	0.91	–1.89	–2.43
XIII	1.000	1.2546	1.54	(0.30)	0.83	0.95	–1.42	–1.94
XIV	0.960	1.3955	1.60	0.00	0.89	1.18	–0.10	–0.71

$$\log P_{eh} = 0.336(0.061) - 0.063(0.109)R_2 - 1.218(0.070)\pi_2^H - 3.788(0.157)\Sigma\alpha_2^H - 2.192(0.144)\Sigma\beta_2^H + 2.087(0.092)V_x \quad (7)$$

$$n = 81,\ r^2 = 0.986,\ \text{sd} = 0.27,\ F = 1043$$

$$\log P_{eh} = 0.339(0.061) - 1.231(0.066)\pi_2^H - 3.816(0.149)\Sigma\alpha_2^H - 2.206(0.141)\Sigma\beta_2^H + 2.063(0.082)V_x \quad (8)$$

$$n = 81,\ r^2 = 0.986,\ \text{sd} = 0.27,\ F = 1315$$

The range of descriptors in eq 7 and eq 8 is now so large that it is possible to estimate new values of log P_{eh} for a very large number of compounds; we suggest eq 7 or eq 8 rather than eq 5 or eq 6 be used for this purpose.

Paterson et al.[6] also gave values of log P_{eh} (Table 1) and log P_{oct} (the latter graphically) for peptides VIII−XI. We can use the same procedure as that used for peptides I−VII to assign descriptors. Thus for VIII, π_2^H is expected to be around 6.5−6.6 and $\Sigma\beta_2^H$ to be near to 2.4, by analogy with III, VI, and VII. For IX there is a direct analogy with IV ($\pi_2^H = 6.45$ and $\Sigma\beta_2^H = 2.37$), and for X there is an analogy with V ($\pi_2^H = 6.6$ and $\Sigma\beta_2^H = 2.48$). Our assigned descriptors are in Table 8, together with log P values calculated from the descriptors; there is quite good agreement with the expected values. For XI, it is more difficult to estimate descriptors, but by comparison of *N*-alkylamides and alkylcarbamates we expect that π_2^H for XI should be somewhat less than that for I ($\pi_2^H = 3.9$). If we take π_2^H as 3.5, then the descriptors shown in Table 8 for XI are obtained.

Conradi et al.[31] also investigated peptides XII−XIV in terms of hydrogen bond numbers, H#, but gave no partition coefficients. We can use our usual method of addition of fragments, together with known values of log P_{oct} for XII (0.91),[32,33] and XIII (0.95),[33] to estimate the descriptors shown in Table 8. There is not enough data to obtain reliable $\Sigma\alpha_2^H$ values for XII and XIII, and so the calculated values for log P_{iso} and log P_{eh} are provisional only.

Inspection of Table 7 reveals surprising trends especially with the descriptor $\Sigma\alpha_2^H$. For the mono-, di-, and tripeptides I, II, and III, π_2^H and $\Sigma\beta_2^H$ increase regularly with the number of amide groups, but $\Sigma\alpha_2^H$ remains constant even though the number of acidic (CO)N−H bonds is increased. This is not at all due to our assignment of descriptors, because the same trends are shown in Table 5. *N*-Methylation of III decreases the hydrogen bond acidity, as expected, but VI and VII would still be predicted to have some hydrogen bond acidity; yet from the results in Table 5 we have had to assign zero values of $\Sigma\alpha_2^H$. Our calculated descriptors for VIII−X show the same trend: $\Sigma\alpha_2^H$ decreases with increasing *N*-methylation, but the actual values are smaller than expected. Borchardt et al.[34,35] have shown how the secondary β-turn structure of peptides can influence their lipophilicity, as log P_{oct}, but

Table 9—An Analysis of the Factors That Influence Log P_{eh} for Peptides, Based on Eq 5

the most direct evidence of the effect of structure on hydrogen-bonding potential is provided by Price et al.[36] These workers examined the peptide XV and calculated the electrostatic maxima and minima around the van der Waals surface, with the peptide in both an extended conformation and a helical conformation. In the extended conformation, only one substantial electrostatic maximum was found, and in the helical conformation only two maxima were found, yet the peptide possesses three acidic (CO)N−H bonds. The lack of maxima in the extended conformation was attributed to N−H bonds being parallel and coplanar with neighboring C═O groups, resulting in cancelation of potentials of opposite magnitude. In the helical conformation, the N−H in the terminal CONHMe group is in close proximity to the oxygen in the MeCONH group, again producing a cancelation of potentials.[36] Our findings can possibly be explained by similar effects that result in the loss of electrostatic maxima.

Interestingly, in the extended conformation of XV there are three substantial electrostatic minima, corresponding to the three C═O groups, and in the helical conformation there are two very large electrostatic minima corresponding to C═O(1)/C═O(2) and C═O(2)/C═O(3).[36] Hence cancellation of electrostatic potentials can result in almost complete loss of electrostatic maxima while still retaining substantial electrostatic minima. Our calculated descriptors seem to follow this trend; VI and VII have no hydrogen bond acidity, yet $\Sigma\beta_2^H$ gradually increases along the series III − VII, with increasing *N*-methylation.

Once descriptors for the peptides are available, it is possible to assess quantitatively the factors that influence values of log P_{eh} for peptides. In Table 9 is a term-by-term breakdown of eq 5 for a representative selection of peptides I−XIV. The most interesting finding is that solute hydrogen bond acidity is NOT the main factor that influences the value of log P_{eh}. Even for peptides I and III, with large values of $\Sigma\alpha_2^H$, the $a\Sigma\alpha_2^H$ term is numerically smaller than the dipolarity/polarizability and volume terms. And with the sole exception of peptide I, all the peptides I−XIV have a smaller $a\Sigma\alpha_2^H$ term than the hydrogen bond basicity term $b\Sigma\beta_2^H$. This illustrates that examination of coefficients is not enough to assess the contribution of the different terms in eq 5, or in eq 3, generally. Only a term-by-term analysis, such as that in Table 9, allows the contribution of each term to be found.

Paterson et al.[6] and Conradi et al.[31,37] determined permeability of Caco-2 cell monolayers for the fourteen peptides I−XIV, Table 10. For 10 of these peptides, there was a good correlation ($r^2 = 0.943$) of log k_{mono} against the hydrogen bond number H#.[34] We have repeated the correlation for all fourteen peptides and find $r^2 = 0.857$, still quite reasonable. However, such a correlation does not distinguish between effects of hydrogen bond acidity and hydrogen bond basicity. To establish these effects, a correlation equation and descriptors for the solutes concerned are required. Unfortunately, the number and variety of solutes is too small to yield a definitive correlation equation through the solvation equation, eq 3.

Abstract □ We prepared two kinds of surface-coated liposomes and investigated their potencies as oral dosage forms for peptide drugs by focusing on their effects on the gastrointestinal (GI) transit of drugs. The surface of the liposomes was coated with poly(ethylene glycol) 2000 (PEG-Lip) or the sugar chain of mucin (Mucin-Lip). As a model peptide drug, insulin was encapsulated in these liposomes. Coating the surface with poly(ethylene glycol) was found to reduce the transit rate of liposomes in the small intestine after oral administration to rats in vivo. Mucin-Lip was retained in the stomach longer than PEG-Lip or uncoated liposomes. The effect of surface coating on the intestinal transit of liposomes was determined by means of in situ single pass perfusion in the rat small intestine. Statistical moment analysis was applied to the outflow pattern of both liposomes and encapsulated insulin. The mean transit time (MTT) and deviation of transit time (DTT) in the intestinal tract were calculated. The MTT of PEG-Lip was much longer than those of uncoated liposomes and Mucin-Lip and was significantly shortened after removal of the intestinal mucous layer. These results indicated that PEG-Lip interacts strongly with the intestinal mucous layer, leading to its slow transit in the intestine. In contrast, coating the liposome's surface with mucin did not affect either the MTT or DTT of liposomes in the intestine. This result is in accordance with the in vivo observation that Mucin-Lip was highly retained in the stomach, but not in any region of the small intestine in vivo. Both the MTT and DTT values of insulin encapsulated in PEG-Lip and Mucin-Lip were almost the same as those of liposomes themselves, suggesting that surface-coated liposomes retained insulin in the intestinal tract. However, MTT and DTT of insulin were significantly shorter than those of uncoated liposomes because these liposomes degraded and released significant amounts of insulin during single pass perfusion. The ability of surface-coated liposomes, especially of PEG-Lip, to interact with the mucus layer and slow the transit rate in the GI tract is considered desirable for oral delivery of peptide drugs. Modification of the liposomal surface with appropriate materials, therefore, should be an effective method by which to achieve the oral delivery of peptide drugs.

A number of peptide and protein drugs with high therapeutic potency have been developed. Most of these, however, can be administered only by injection due to their instability in the gastrointestinal (GI) tract and poor absorption. Recently, particulate systems such as liposomes, emulsions, and micro- or nanosized polymer particles have attracted a great deal of attention as possible oral dosage forms for such peptide drugs.[1−3] Among these particulate systems, liposomes possess the advantage that they are composed of physiological materials, e.g. phospholipids. Since Patel and Ryman reported the significant hypoglycemic effect of orally administered insulin encapsulated in liposomes,[4] many studies have been carried out to evaluate the potency of liposomes. However, the degradation of liposomes in the GI tract through the interaction with bile salts sometimes obscured the effects of liposomes on drug absorption. To circumvent this problem, we reported previously that liposomes coated with poly(ethylene glycol) 2000 (PEG-Lip) or the sugar chain of mucin (Mucin-Lip) became resistant to digestion by bile salts and were useful for oral delivery of peptide drugs. The oral administration of insulin encapsulated in PEG-Lip, in particular, showed a greatly enhanced and sustained hypoglycemic effect in rats in comparison to insulin encapsulated in normal liposomes.[5] It was revealed that the increased resistance of surface-coated liposomes against digestion by bile salts leads to the increased stability of insulin in the GI tract.

However, it is not possible to explain the enhanced and prolonged hypoglycemic effects of insulin only by the increase in stability because many other factors affect intestinal absorption of peptides. Kimura et al.[6] reported that the oral administration of insulin incorporated in poly(vinyl alcohol)-gel spheres significantly increased its bioavailability due to the decreased gastrointestinal transit rate of insulin. In this study, therefore, the effects of surface-coated liposomes on the oral absorption of peptide drugs were analyzed from the viewpoint of their effects on the gastrointestinal transit of drugs.

Experimental Section

Materials—Dipalmitoylphosphatidylcholine (DPPC), cholesterol (CHOL) and distearoylphosphatidylethanolamine−poly(ethylene glycol) 2000 (DSPE-PEG), were gifts from Nippon Fine Chemical Co., Ltd. (Tokyo, Japan). Bovine insulin (25.7 IU/mg) and stearylamine (SA) were purchased from Sigma Chemical Co. (St. Louis, MO). [^{14}C]DPPC (113.4 mCi/mmol) was obtained from New England Nuclear (Boston, MA). All other chemicals used were of analytical grade. Cetyl-mucin, one of the surface-coating materials, was synthesized as previously reported.[5] Briefly, mucin from pig stomach was trypsinized for 5 h at 37 °C, treated with proteinase K for another 40 h after adjusting to pH 8.0, and centrifuged and filtered to obtain the sugar portion of mucin. Further purification was carried out using Sepharose CL-2B column chromatography. The cetyl group was grafted to the sugar chain domain of mucin using cetyl bromide and triethylamine.

Table 1—Lipid Composition of Liposomes Used in This Study[a]

	DPPC	Chol	SA	cetyl-mucin (mg/mL)	DSPE-PEG
(+)-Lip	10	10	1	–	–
mucin-Lip	10	10	1	1	–
PEG-Lip	10	10	–	–	1

[a] Each value was expressed as a molar ratio.

Preparation of Surface-Coated Liposomes—The sugar chain portion of mucin and poly(ethylene glycol) (PEG) were used as surface-coating materials. The compositions of liposomes are listed in Table 1. Liposomes were prepared according to the method of Bangham[7] with some modifications. Briefly, a mixture of DPPC, cholesterol, and surface-coating material (cetyl-mucin or DSPE-PEG) dissolved in chloroform was evaporated to dryness in a rotary evaporator. The lipid film was further dried in vacuo for 8 h to remove the solvent completely. Then the lipid film was hydrated with phosphate-buffered saline (PBS, pH 7.4) containing insulin. After three cycles of freeze−thawing, the liposomal suspension was diluted with PBS to adjust the lipid concentration. Just before the experiment, the liposomal suspension was centrifuged three times at 15000 rpm for 10 min to remove untrapped drugs. The entrapment efficiency of insulin in uncoated liposome, Mucin-Lip, and PEG-Lip was 31.4 ± 6.0%, 35.3 ± 5.9%, 37.7 ± 4.8%, respectively. The size distribution of liposomes was measured by electrophoretic light scattering photometer, ELS-800 (Otsuka Electronics Co. Ltd., Japan). The mean particle size of uncoated liposome, Mucin-Lip, and PEG-Lip was 348 ± 148 nm, 453 ± 165 nm, 479 ± 187 nm, respectively.

In Vivo Oral Administration Experiment—Male Wistar rats, weighing 250−300 g, were obtained from Japan SLC, Inc. (Shizuoka, Japan). Suspensions of liposomes in which the membranes were labeled with [^{14}C]DPPC were orally administered to rats (1 mL/rat). At predetermined time points, rats were anesthetized with sodium pentobarbital, and then the gastrointestinal tract was excised and divided into eight regions, i.e., stomach, duodenum, proximal jejunum, middle jejunum, distal jejunum, ileum, cecum, and colon. The contents of each region were washed with 10 mL of saline, and aliquots of each sample were placed in scintillation vials. Then, 10 mL of Clearsol (Nacalai Tesque, Kyoto, Japan) was added, and the radioactivity of each sample was measured using a liquid scintillation analyzer, LSA 1600 CA (Packard). The remaining amount of liposomes in each region was calculated and expressed as the mean % against the total recovery. The total recovery of radioactivity was more than 91% of the dose applied for each experiment.

In Situ Single Pass Perfusion Experiment—In situ local intestinal perfusion was carried out according to the method of Kakutani[8] with some modifications. The rats were fasted for 12 h and then anesthetized by intraperitoneal injection of sodium pentobarbital (40 mg/kg body weight). An abdominal incision was made, and both the duodenum and proximal jejunum (20 cm below the duodenum) were cannulated and ligated tightly. After preperfusion with PBS (pH7.4) for 10 min, 0.15 mL of test solutions including 1 mg/mL insulin, insulin in PBS (Solution; pH7.4), or liposomal suspensions were injected into the line of perfusion flow as a pulse using a three-position valve. The outflow perfusate was collected into preweighed tubes. In the early stages of the experiment, the samples were collected every 15 s, while at later stages sampling was performed every 30 s. After weighing each sample, the concentration of intact insulin was determined by HPLC. Bovine serum albumin labeled with Evans' blue (EB-BSA) was used as a nonabsorbable marker.[9] The recovery ratio of EB-BSA in outflow perfusate was more than 95% of the dose applied, and the coefficient of variability was 3.3%. When determining the transit of liposomes, diphenylhexatriene (DPH) was used as a liposomal membrane marker, and the concentration of DPH in the perfusate was measured spectrofluorometrically.

Determination of Insulin—Insulin was assayed by reverse phase HPLC on a LiChrospher 300 RP-8 column (250 × 4.0 mm, 10 μm). The HPLC consisted of a Shimadzu model LC-10As pump, SPD-6A UV spectrophotometric detector, and C-R6A integrator. The mobile phase was a mixture of 0.1% trifluoroacetic acid/acetonitrile = 60/40% (v/v) and was run at a flow rate of 1 mL/min. The UV detector was set at 210 nm.

Interaction between Liposomes and Intestinal Mucous Layer—To remove mucous fluid,[10] dithiothreitol solution (20 mM in PBS, pH 7.4) was injected into the perfused region of the rat jejunum. Thirty minutes after injection, dithiothreitol was washed out with PBS. Thereafter, in situ perfusion was carried out as described above. It was confirmed that 20 mM of dithiothreitol solution did not induce damage to the intestinal epithelial (data not shown).

Moment Analysis—Statistical moment analysis[8] was applied to the data obtained from the single pass perfusion experiment. The mean transit time (MTT) and the deviation of transit time (DTT) of insulin or liposomes were calculated from their outflow patterns. Briefly, the zero order moment (S_0) was calculated from the area under the time versus amount (% of dose) in the perfusate curve. Similarly, the first-order moment (S_1) and the second-order moment (S_2) were calculated from the area under the time versus time × amount curve and the time versus time × amount^2 curve, respectively. Then, MTT and DTT were calculated from the following equations.

$$\mathrm{MTT} = S_1/S_0$$

$$\mathrm{VTT} = (S_2/S_0) + (\mathrm{MRT})^2$$

$$\mathrm{DTT} = (\mathrm{VTT})^{1/2}$$

where VTT is variance of transit time. DTT, the square root of VTT, was used here, since VTT was too large.

Results

GI Transit of Liposomes in Vivo—Figure 1 shows the time course of remaining radioactivity (% of recovered) of [^{14}C]DPPC in each region of the GI tract after oral administration of liposomes to rats. Positively charged liposomes ((+)-Lip) were used as a control because among uncoated liposomes only (+)-Lip enhanced the absorption of insulin.[5] Although all kinds of liposomes examined reached the distal jejunum at 0.5 h postadministration, their transit patterns in the GI tract were markedly different. In the case of (+)-Lip, about 20% of liposomes were detected in the ileum at 1 h, and most were in the cecum at 2 h post-administration. On the other hand, Mucin-Lip was retained in the stomach for a longer time and then spread throughout the whole jejunum. When PEG-Lip was administered, about 30% remained in the distal jejunum even at 2 h post-administration, and 25% was still detected in the ileum at 3 h. The retention of PEG-Lip in both the distal-jejunum and ileum was remarkable compared to those in other regions.

Intestinal Transit of Insulin and Liposomes in Situ—The outflow pattern of insulin administered in liposomal form is shown in Figure 2. Both (+)-Lip and Mucin-Lip showed sharp peaks of insulin outflow, whereas a broad peak was observed after administration of PEG-Lip. In (+)-Lip and Mucin-Lip, insulin was detectable up to 250 and 495 s after administration, respectively. However insulin was continuously detected until the last sampling time point in PEG-Lip. Moment analysis was applied to these data to compare the differences in the intestinal transit patterns of insulin incorporated in the three kinds of liposomes. As summarized in Table 2, the recovery ratio of insulin was the highest in Mucin-Lip and the lowest in (+)-Lip. PEG-Lip showed 2-fold longer MTT than (+)-Lip or Mucin-Lip, reflecting the slow transit of insulin encapsulated in PEG-Lip. From the comparison of DTT, it was demonstrated that insulin encapsulated in PEG-Lip spread widely in the intestinal tract.

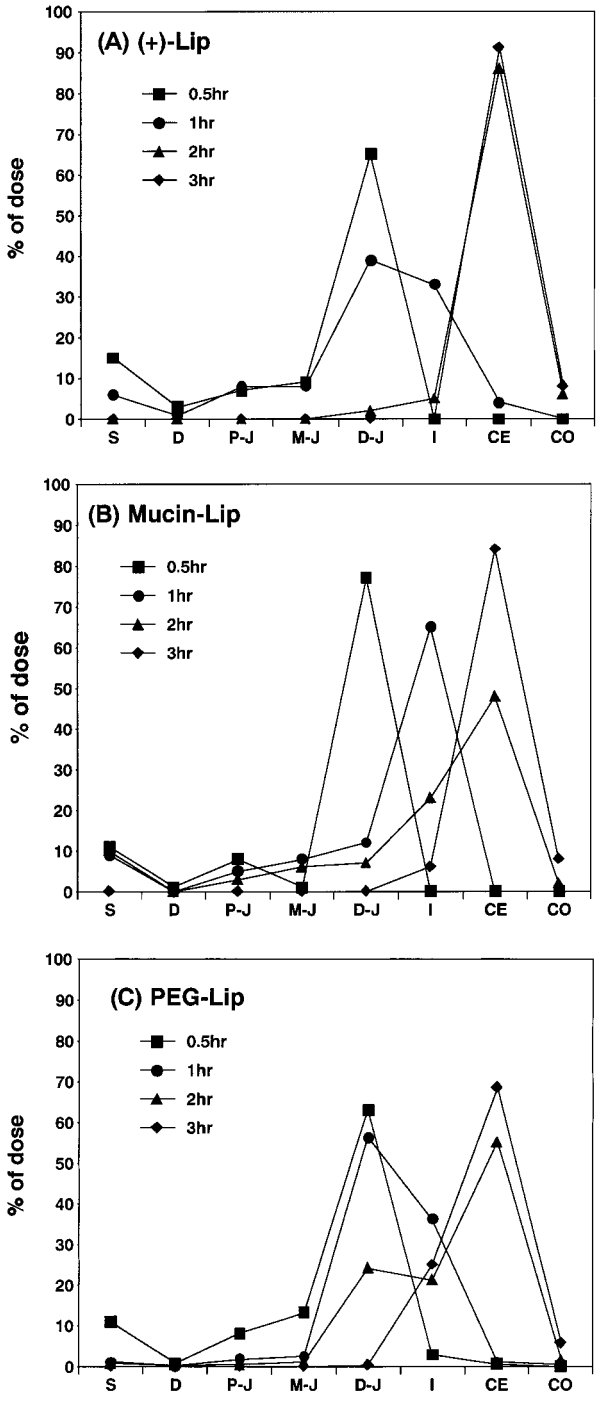

Figure 1—Time course of remaining radioactivity (% of recovered) of [^{14}C]-DPPC in the GI tract (A) (+)-Lip, (B) Mucin-Lip, (C) PEG-Lip. S, stomach; D, duodenum; P-J, proximal jejunum; M-J, middle jejunum; D-J, distal jejunum; I, ileum; CE, cecum; CO, colon. Data are expressed as means of 4–6 experiments.

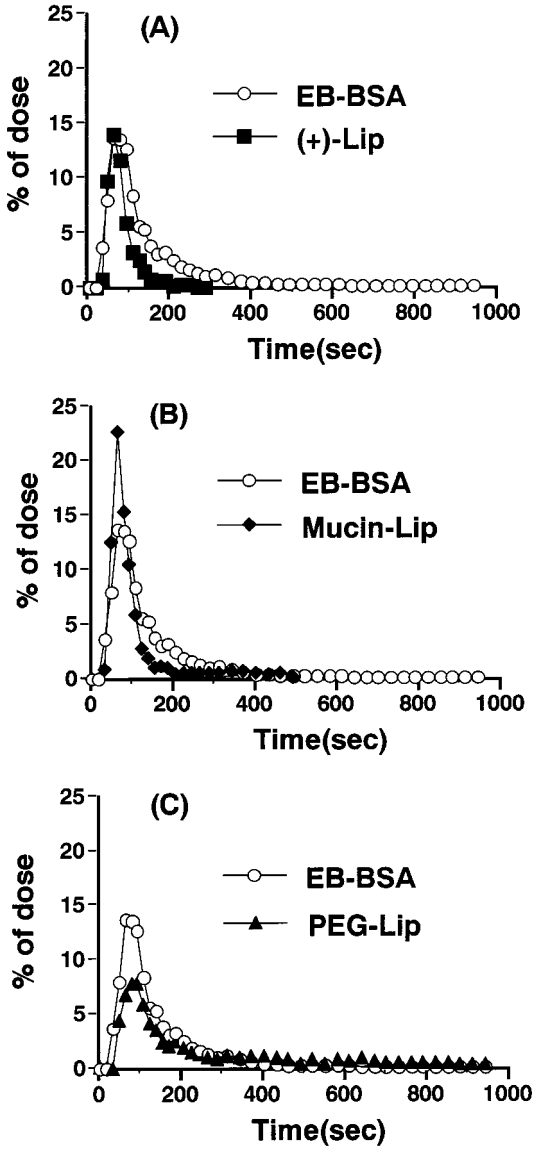

Figure 2—Typical outflow pattern of insulin obtained from in situ single pass perfusion experiment: (A) (+)-Lip, (B) Mucin-Lip, (C) PEG-Lip.

Table 2—Moment Parameters for Intestinal Transit of Insulin and Liposomes

		recovery[c] (%)	MTT[c] (s)	DTT[c] (s)
(+)-Lip	liposome	65.36 ± 4.56	111.96 ± 8.79	107.02 ± 13.41
	insulin	52.57 ± 4.67[b]	86.38 ± 2.63[b]	34.96 ± 1.32[b]
mucin-Lip	liposome	70.43 ± 5.07	99.22 ± 5.90	83.64 ± 17.42
	insulin	80.71 ± 5.29[a]	103.54 ± 12.52[a]	81.11 ± 14.02[a]
PEG-Lip	liposome	77.92 ± 2.93[a]	198.57 ± 22.16[a]	179.85 ± 22.54[a]
	insulin	64.54 ± 1.19[a,b]	201.58 ± 19.44[a]	165.48 ± 8.06[a]

[a] Significant at $p < 0.05$ vs (+)-Lip. [b] Significant at $p < 0.05$ between liposome and insulin. [c] Results were expressed as the mean ± SE of 5–8 experiments.

The intestinal transit of liposomes themselves was also investigated by labeling the liposomal membrane with diphenylhexatriene (DPH). Moment parameters for outflow patterns of liposomes are also listed in Table 2. After administration of Mucin-Lip and PEG-Lip, there were no significant differences in MTT or DTT between liposomes and insulin. In contrast, both MTT and DTT of liposomes were significantly longer than those of insulin in (+)-Lip. These results suggested that most of the insulin passed through the intestinal tract in liposomal form in the surface-coated liposomes, while in (+)-Lip significant amounts of insulin were released from liposomes in the intestinal loop.

Effect of Removal of the Mucous Layer on the Intestinal Transit of Liposomes—The effect of pretreatment of the intestine with dithiothreitol, which can remove the mucous layer from the epithelial surface, on the intestinal transit of surface-coated liposomes was investigated. As listed in Table 3, this pretreatment did not cause any significant changes in the recovery ratio of either type of liposomes. However, a marked decrease was observed

Table 3—Effects of Intestinal Mucous Layer on the Transit of Liposomes

		recovery[b] (%)	MTT[b] (s)	DTT[b] (s)
mucin-Lip	control	70.43 ± 5.07	99.22 ± 5.90	83.64 ± 17.42
	treated	61.20 ± 3.72	81.27 ± 3.97	97.41 ± 16.49

Discussion

We have reported that coating the surface of liposomes with poly(ethylene glycol) or the sugar chain of mucin increased the potency of liposomes as a tool for oral delivery of peptide drugs.[5] Insulin encapsulated in surface-coated liposomes showed enhanced and sustained hypoglycemic effects after oral administration. It was revealed that surface coating resulted in liposomes that resisted digestion by bile salts, leading to the stabilization and slow release of insulin in the GI tract. However, many factors other than drug stability affect the absorption profile of peptide drugs. Surface coating with these materials may also affect the intestinal transit of liposomes through interaction with the intestinal wall. Therefore, we investigated the behavior of surface coated liposomes in the GI tract in vivo and also in situ by focusing on the effect on liposomal transit.

When liposomes were orally administered to rats in vivo, uncoated liposomes, (+)-Lip, showed rapid transit to distal parts of the intestine, suggesting the weak interaction of liposomes themselves with the intestinal wall. Although surface coating reduced the transit rate of liposomes, PEG-Lip and Mucin-Lip showed different behavior in the GI tract (Figure 1). Mucin-Lip was retained in the stomach longer than other liposomes. As the surface of the stomach is completely covered with a mucin layer, this may be caused by the interaction between mucin on the surface of the stomach and that of the liposomes. In contrast, PEG-Lip was markedly retained in the lower region of the intestine rather than in the stomach, suggesting the higher affinity of poly(ethylene glycol) to the surface of the small intestine. These results indicated that the behavior of liposomes in the GI tract depends on the features of the surface-coating materials.

To elucidate this in further detail, we investigated the effect of coating the surface of liposomes on the intestinal transit by means of in situ perfusion experiments. The recovery ratio of insulin after administration of (+)-Lip was significantly lower than that after administration of surface-coated liposomes (Table 2). Furthermore, both the MTT and DTT of insulin encapsulated in (+)-Lip were different from those of the liposomes themselves. On the other hand, there were no significant differences in MTT or DTT between liposomes and insulin after administration of surface-coated liposomes. Therefore, it is obvious that (+)-Lip degraded and released insulin during transit through the intestinal tract, while surface-coated liposomes retained insulin in the intestine. These results are consistent with our observation that insulin encapsulated in surface-coated liposomes was much more stable than that in uncoated liposomes in the intestinal fluid in vitro.[5] Shegal and Rogers et al.[11] reported that coating the surface of liposomes with *O*-palmitoylpullulan was an effective way to avoid the interaction of the liposomal lipid membrane with bile salts. Also, Zeisig et al.[12] reported that the thickness of the fixed aqueous layer on the surface of liposomes was increased by coating the surface with poly(ethylene glycol). This fixed aqueous layer on PEG-Lip could protect the lipid membrane against digestion by bile salts. Since the surface of Mucin-Lip was covered with the long sugar chain, this also prevented the digestion of liposomes in the intestinal tract.

Neither the MTT nor DTT of Mucin-Lip were significantly different from those of (+)-Lip, indicating that surface coating with mucin did not affect the transit rate of liposomes in the small intestine. This result was supported by the observation that Mucin-Lip was highly retained in the stomach rather than in the intestine after oral administration in vivo.

In contrast, it is apparent from the much longer values of MTT and DTT that PEG-Lip strongly interacts with the intestinal wall. The viscosity and mucoadhesiveness of the liposomal formulation may be the most important factors affecting intestinal transit. Since coating the liposome's surface with poly(ethylene glycol) only slightly affected their viscosity (data not shown), it could be speculated that increased mucoadhesiveness decreased the intestinal transit rate and caused the wide spread distribution patterns of PEG-Lip observed in vivo. Hassan et al.[13] reported that the adhesive force of poly(ethylene glycol) to mucin is comparable to that of other neutral polymers. Also, Ascentiis et al.[14] reported that the mucoadhesiveness of methacrylate polymer microparticles was increased by the copolymerization of methacrylate with poly(ethylene glycol). The increased mucoadhesiveness of PEG-Lip was also confirmed by in situ perfusion experiments using rat intestine in which the mucous layer had been removed. Both the MTT and DTT of PEG-Lip were significantly shortened by removal of the intestinal mucous layer, whereas those of Mucin-Lip were changed only slightly (Table 3). This result clearly indicated that poly(ethylene glycol) interacts with intestinal wall through adhesion to the mucous layer. Rao et al. reported that the mucoadhesiveness of glass beads coated with hydrophilic polymers decreased following removal of the mucous layer.[15] Furthermore, since the amounts of mucous fluid in both the distal-jejunum and ileum are richer than those in other regions, the marked retention of PEG-Lip in these regions in vivo (Figure 1) may reflect its strong interaction with the mucous layer. Ilan et al.[16] reported that the intestinal absorption of desmopressin was enhanced by using mucoadhesive submicron emulsion. They speculated that coating the surface of the emulsion with Carbopol-940 caused a strong interaction between the emulsion and the mucous layer and increased the retention of the emulsion in the intestinal tract, resulting in the enhanced absorption of desmopressin. Lehr et al.[17] also reported that the intestinal absorption of 9-des-glycinamide, 8 arginine vasopressin (DGAVP) was enhanced by using mucoadhesive microspheres in the rat intestine in vitro. Thus, for oral delivery of peptide drugs, the slow transit of the formulation in the intestinal tract, such as PEG-Lip in this study, should be desirable.

In conclusion, Mucin-Lip adhered preferentially to the surface of the stomach. PEG-Lip moved along the GI tract slowly and spread widely in the small intestine because of the strong interaction with the intestinal mucous layer, leading to the enhanced and prolonged hypoglycemic effects of insulin. These findings clearly demonstrated that the surface coating of liposomes is a useful method for oral delivery of peptide drugs.

Abstract □ Previous studies have established that a partially quaternized derivative of chitosan, *N*-trimethyl chitosan chloride (TMC), can be used as an absorption enhancer for large hydrophilic compounds across mucosal surfaces. This study evaluates and compares the effects of the degree of quaternization of TMC, in a neutral environment, on the permeability of intestinal epithelial cells in vitro, where normal chitosan salts are ineffective as absorption enhancers. The effects of TMC-H [61.2% quaternized, (0.05–1.5% w/v)], TMC-L [12.3% quaternized, (0.5–1.5% w/v)], and chitosan hydrochloride [0.5–1.5% w/v] on the transepithelial electrical resistance (TEER) and permeability, for the hydrophilic model compound [^{14}C]-mannitol, of intestinal epithelial Caco-2 cell monolayers, were investigated at pH values of 6.20 and 7.40. The viability of the monolayers was checked with the trypan blue exclusion technique. At a pH of 6.20, all the polymers caused a pronounced reduction (37–67% at 0.5% w/v concentrations) in the TEER of Caco-2 cells. On the contrary, at a pH of 7.40, only TMC-H was able to decrease the TEER values, even in a concentration as low as 0.05% w/v (35% reduction). Comparable results were obtained with the permeation of [^{14}C]mannitol. Large increases in the transport rate (18–23-fold at 0.5% w/v concentrations) were found at pH 6.20, whereas only TMC-H was able to increase the permeation of [^{14}C]mannitol at pH 7.40 (31–48-fold at 0.05–1.5% w/v concentrations of TMC-H). For all the polymers studied, no deleterious effects to the cells could be demonstrated with the trypan blue exclusion technique. It is concluded that highly quaternized TMC is a potent absorption enhancer and the potential use of this polymer, especially in neutral and basic environments where normal chitosan salts are not effective, is expected to be an important contribution to the development of effective delivery systems for hydrophilic compounds such as peptide drugs.

Introduction

The potential use of chitosan as an absorption enhancer across mucosal surfaces has been well documented in recent years. Chitosan salts such as chitosan glutamate and chitosan hydrochloride have been shown to increase the absorption of a number of hydrophilic compounds and peptide drugs both in vitro and in vivo.[1−7] Apart from its mucoadhesive properties,[8] chitosan acts mainly by opening the tight junctions between epithelial cells to allow for the paracellular transport of these large hydrophilic molecules. Such an action is believed to be due to an interaction of a positively charged amino group on the C-2 position of chitosan with negatively charged sites on the cell membranes, which results in a structural reorganization of the tight junction-associated proteins.[1,6]

Chitosan has an apparent pK_a value between 5.5 and 6.5, and a certain amount of acid is required to transform the glucosamine units into the positively charged, water-soluble form. At neutral and basic pH values, the chitosan molecules will lose their charge and therefore the potential use of this polymer, especially in more neutral and basic environments such as those found in the large intestine and colon, is limited. It has been shown recently that a partially quaternized (12%) derivative of chitosan, *N*-trimethyl chitosan chloride (TMC), was also able to significantly increase the transport of hydrophilic compounds, such as [^{14}C]mannitol (MW 182.2), fluorescein isothiocyanate-labeled dextran (MW 4400), and [^{14}C]poly(ethylene glycol) (MW 4000), and the peptide drugs buserelin (MW 1300), 9-desglycinamide, 8-L-arginine vasopressin (MW 1412), and insulin (MW 5778) in Caco-2 cell monolayers at acidic pH values (4.40−6.20).[9−11] It was suggested that TMC most likely has the same mechanism of action on the junctional complex as other chitosan salts.[10] The derivative TMC (12% quaternized) was not as effective as other chitosan salts, such as chitosan glutamate and chitosan hydrochloride. This lesser efficacy was explained by its charge density, which was determined by the degree of quaternization, and by a partial hiding of the positive charge on the amino group by the attached methyl groups.[10,11] However, the much higher aqueous solubility of TMC may compensate for its lesser efficacy. TMC has proved to be very soluble over a wide pH range (pH 1−9) up to 10% w/v concentrations, even at degrees of quaternization as low as 10%.[9−10]

Our hypothesis is that TMC with higher degrees of quaternization may be more effective as an absorption enhancer to increase the paracellular transport of hydrophilic compounds at neutral pH values. The aim of the present study was to synthesize TMC with different degrees of quaternization (low and high) and to evaluate and compare the effect of these polymers with the effect of chitosan hydrochloride on the permeability of intestinal

epithelial cells in vitro for increased transport of a hydrophilic compound at slightly acidic and neutral pH values (6.20 and 7.40).

Experimental Section

Synthesis and Characterization of *N*-Trimethyl Chitosan Chloride (TMC)—Two batches of TMC, one with a low and one with a high degree of quaternization, were synthesized from sieved fractions (<500 μm) of chitosan (degree of acetylation ca. 25%; Pronova Biopolymer, Drammen, Norway) based on the method of Domard et al.[12] and Sieval et al.[13] Briefly, the experimental conditions are reductive methylation of chitosan with iodomethane in a strong basic environment at 60 °C. The batch with the lower degree of quaternization (TMC-L) was prepared in a single-step reaction of 60 min. To obtain TMC with the higher degree of quaternization (TMC-H), the basic reaction was repeated twice with the product obtained after the first step.[13] The counterion (I^-) was exchanged to Cl^- by dissolving the quaternized polymers in a aqueous solution of NaCl. The final products were obtained by precipitation and washing with ethanol. The polymers were characterized by nuclear magnetic resonance (NMR) spectroscopy, and the degree of quaternization of the respective polymers was calculated from ^{1}H NMR spectra (600 MHz) obtained with a Bruker DMX-600 spectrometer.[13]

Cell Cultures—Caco-2 cells (passages 88 and 93−94) were seeded on tissue-culture-treated polycarbonate filters (area 4.7 cm^2 and 0.33 cm^2) in Costar Transwell 6- and 24-well plates (Costar Europe Ltd., Badhoevedorp, The Netherlands) at a seeding density of 10^4 cells/cm^2. Dulbecco's Modified Eagle's Medium (DMEM, pH 7.40; Sigma, Bornem, Belgium), supplemented with 1% nonessential amino acids, 10% foetal bovine serum, benzylpenicillin G (160 U/mL), and streptomycin sulfate (100 μg/mL) (all obtained from Sigma), was used as culture medium. The medium was changed every second day. Cell cultures were kept at 37 °C in an atmosphere of 95% air and 5% CO_2. Filters were used for transepithelial electrical resistance measurements (24-well plates) and transport experiments (6-well plates), 21−23 days after seeding.[3,14,15]

Measurement of the Transepithelial Electrical Resistance (TEER)—The effect of TMC-H (0.05−1.5% w/v), TMC-L (0.5−1.5% w/v) and chitosan hydrochloride (0.5−1.5% w/v; SEACURE CL 210 from Pronova Biopolymer, Drammen, Norway) on the TEER of the Caco-2 cell monolayers was measured every 20 min with a Millicell ERS meter (Millipore Corp., Bedford, MA) connected to a pair of thin, side-by-side electrodes suitable for use in the small 24-well culture plates.[3,14,15] The effect of these polymers on the TEER was measured at both pH 6.20 and 7.40. The polymer solutions were prepared in serum-free DMEM, and the pH was adjusted to 6.20 with 0.1 M HCl or to 7.40 with 0.1 M NaOH. Because of the insolubility of chitosan hydrochloride at a pH of 7.40, the resulting polymer preparation was used as a dispersion of chitosan hydrochloride in DMEM. Two hours before the start of each experiment, the medium in the acceptor compartment was removed and replaced with DMEM buffered at pH 7.40 with 25 mM HEPES [*n*-(2-hydroxyethyl) piperazine-*N*-(2-ethanesulfonic acid; Sigma]. Measurements started 1 h prior to incubation on the apical side of the cells with the respective polymer solutions. After 2 h, the polymer solutions were carefully removed, and cells were washed three times with and replaced by serum-free DMEM (pH 6.20 or 7.40). The TEER was measured for an additional hour to study the reversibility of the effect of the polymer solutions. Control experiments were done under the same conditions without polymers. Average TEER values for untreated cell monolayers were in the range 200−300 Ω·cm^2 at both pH 6.20 and 7.40.[6] At the end of each experiment, the solutions in both the apical and basolateral sides of the cell compartments were checked for any changes in pH. Experiments were done in triplicate at 37 °C in an atmosphere of 95% air and 5% CO_2.

Permeability Studies with [^{14}C]Mannitol—[^{14}C]Mannitol (MW 182.2; specific radioactivity 57 mCi/mmol) was obtained from Amersham Life Science (Little Chalfort, UK). The transport of [^{14}C]mannitol across Caco-2 cell monolayers was studied as described previously.[3,9,10] The polymers were dissolved in serum-free DMEM containing the radioactive marker and the pH was adjusted to 6.20 with 0.1 M HCL or to 7.40 with 0.1 M NaOH. Chitosan hydrochloride was used as a dispersion in DMEM at pH 7.40. Solutions with TMC-H (0.05−1.5% w/v), TMC-L (0.5−1.5% w/v), and chitosan hydrochloride (0.5−1.5% w/v) were added on the apical side of the monolayers. The medium in the acceptor compartment was DMEM buffered at pH 7.40 with 40 mmol/L HEPES. Samples of 200 μL were taken every 20 min for 4 h from the basolateral side. Samples taken from the basolateral side were replaced with an equal volume of DMEM with HEPES. Control experiments were run in every experiment with solutions containing the radioactive markers without the dissolved polymers. At the end of each experiment the pH of the solutions from both the apical and basolateral sides were checked for any changes in pH. All experiments were done in triplicate in an atmosphere of 95% air and 5% CO_2 at 37 °C. The radioactivity applied to the cells was determined in 200-μL samples of the solutions tested and background radioactivity was determined in 200-μL samples of DMEM and HEPES without the radioactive marker. The radioactivity present in the samples was determined after adding 3 mL of scintillation cocktail (Ultima Gold) in a liquid scintillation counter (Tri −Carb 1500, Packard Instrument Company, Meridan, CT). Results were corrected for dilution and expressed as cumulative transport at time t.[3,9−11]

Viability of Caco-2 Cell Monolayers—Both the apical and basolateral sides of the cell monolayers were rinsed twice with 0.01 M phosphate-buffered saline (PBS, pH 7.40) after completion of all the TEER and transport experiments. The cell monolayers were incubated apically with a solution of 0.1% trypan blue (Sigma) in PBS.[3,9,10] The basolateral medium was PBS. After 30 min, the medium was removed from both sides of the cell monolayers and examined by light microscopy for exclusion of the marker. Cells excluding trypan blue were considered to be viable. Cells incubated for 5 min with 0.5% w/v sodium dodecyl sulfate in PBS and stained with trypan blue were used as a reference for uptake of the marker.

Data Analysis and Statistical Evaluation—From the permeation profiles of [^{14}C]mannitol, apparent permeability coefficients (P_{app}) were calculated according to the following equation:

$$P_{app} = dQ/dt/(A \cdot 60 \cdot C_0)$$

where P_{app} is the apparent permeability coefficient (cm s^{-1}), dQ/dt is the permeability rate (amount permeated per min), A is the diffusion area of the monolayer (cm^2), and C_0 is the initial concentration of the marker molecule. The regression coefficients (r^2) obtained from the curve fits were generally between 0.9 and 1.00. Transport enhancement ratios (R) were calculated from P_{app} values by:

$$R = P_{app}(\text{sample})/P_{app}(\text{control})$$

Statistical differences were determined using one-way analysis of variance (ANOVA) and Sheffe's F-test for multiple comparisons. Differences between groups were considered to be significant at $p < 0.05$.

Results

Synthesis and Characterization of TMC—The initial chitosan used to prepare TMC was only soluble in acidic solutions, but after quaternization it became highly soluble in water at every pH.[9,10,13] By repeating the reaction steps, polymers with different degrees of quaternization were obtained. The degree of quaternization was calculated from ^{1}H NMR spectra.[12,13] After an initial 60 min, a polymer (TMC-L) with a degree of quaternization of 12.3% was recovered. Longer reaction times (up to 6 h) do not yield polymers with higher degrees of quaternization.[9] Repeating the basic reaction twice, under the same conditions, with the polymer recovered after an initial 60 min, gave a highly quaternized product (TMC-H) with a degree of quaternization of 61.2%. At this degree of quaternization, the^{13}C and ^{1}H NMR spectra showed additionally some extent of methylation on the 3- and 6-hydroxyl groups of chitosan, but the polymer recovered was still perfectly soluble in water at pH values between 1 and 9.[13]

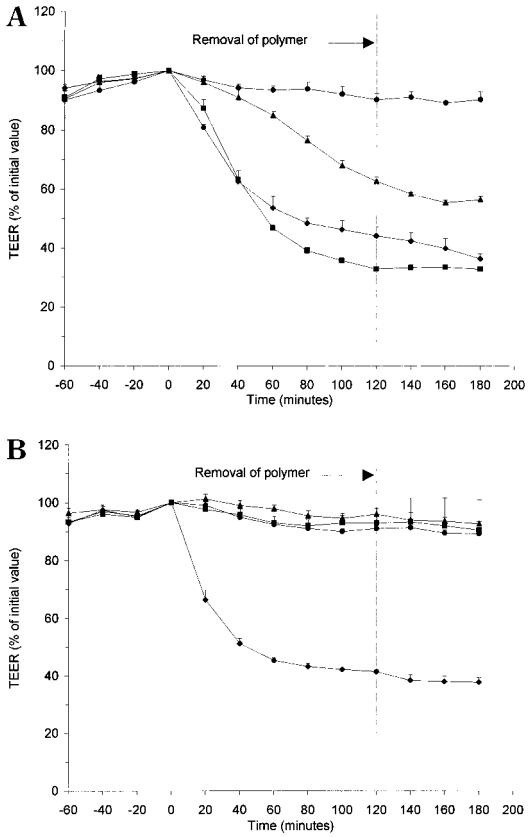

Figure 1—(A) The effects of 0.5% w/v concentrations of TMC-L, TMC-H, and chitosan hydrochloride on the TEER of Caco-2 cell monolayers at a pH of 6.20. (B) The effects of 0.5% w/v concentrations of TMC-L, TMC-H, and chitosan hydrochloride on the TEER of Caco-2 cell monolayers at a pH of 7.40. Each point represents the mean ± SD of three experiments. Key: (●) control; (▲) TMC-L; (◆) TMC-H; (■) chitosan hydrochloride; dotted line (- - -) represents start of reversibility experiment.

Effect on the TEER of Intestinal Epithelial Cells—The effects of 0.5% w/v concentrations of TMC-H, TMC-L, and chitosan hydrochloride on the TEER of the Caco-2 cell monolayers at pH 6.20 and 7.40 are shown in Figures 1A and 1B, respectively. At pH 6.20, incubation with these polymers resulted in a pronounced reduction in TEER values compared with the control group. After 2 h incubation, the reduction in TEER was in the following order: chitosan hydrochloride (67.1 ± 0.6%) > TMC-H (55.9 ± 3.1%) > TMC-L (37.3 ± 1.4%). Higher polymer concentrations (1.0 and 1.5% w/v) did not cause any further significant decreases in the TEER.

At pH 7.40, only TMC-H was able to decrease the TEER of the cell monolayers (Figure 1B). Neither TMC-L nor chitosan hydrochloride, even in concentrations of 1.5% w/v, was able to cause any significant decreases in TEER values compared with the control group. Incubation of the monolayers with TMC-H resulted in a pronounced decrease in the TEER of the cell monolayers. After 2 h incubation, the reduction in TEER was as followed: 43.1 ± 2.5% at 0.1% w/v TMC-H, 45.6 ± 3.7% at 0.25% w/v TMC-H, 58.6 ± 0.7% at 0.5% w/v TMC-H, 60.1 ± 3.1% at 1% w/v TMC-H, and 63.1 ± 2.1% at 1.5% w/v TMC-H. Even in a concentration as low as 0.05% w/v, TMC-H was able to reduce the TEER by 34.8 ± 4.1%.

Reversibility of the effect of 0.5% w/v concentrations of these polymers on TEER could not be demonstrated at any pH value (Figures 1A and 1B). Complete removal of the polymers, without damaging the cells, proved to be problematic due to the high viscosity and mucoadhesivity of the polymer solutions. Furthermore, the repeated washing of the cells and the short time allowed for recovery may also be reasons why significant reversibility of the effect could not be demonstrated. However, in concentrations <0.5% w/v of TMC-H, a clearer tendency to recover to initial values was observed. Staining with trypan blue after completion of all the TEER experiments did not result in any visible intracellular uptake of the marker, indicating that the cells were still viable after incubation with these polymers.

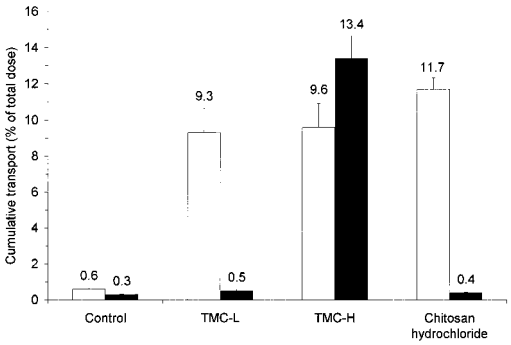

Figure 2—The effect of 0.5% w/v concentrations of TMC-L, TMC-H, and chitosan hydrochloride on the cumulative transport of [^{14}C]mannitol in Caco-2 cell monolayers at pH 6.20 (white bars) and pH 7.40 (black bars). Each point represents the mean ± SD of three experiments.

Effect on [^{14}C]Mannitol Transport—In Figure 2 the cumulative amounts of [^{14}C]mannitol transported after 4 h in the presence of the respective polymers (0.5% w/v) are given at both pH 6.20 and 7.40. From the permeation profiles of [^{14}C]mannitol at the different polymer concentrations and the two pH values, apparent permeability coefficients (P_{app}) values and transport enhancement ratios (R) were calculated (Table 1). Under the conditions described, only negligible amounts of [^{14}C]mannitol were transported in the control groups. At pH 6.20, all the polymers caused a marked accumulation of the marker molecule in the acceptor compartments. As evident from Figure 2, no major differences in the permeability of [^{14}C]-mannitol were found between TMC-L, TMC-H, and chitosan hydrochloride at 0.5% w/v concentrations. At this concentration, the permeability of [^{14}C]mannitol was increased 20-fold (TMC-H), 18-fold (TMC-L), and 23-fold (chitosan hydrochloride) compared with the control group (Table 1). Similar results were obtained at higher concentrations of TMC-L and TMC-H (1.0 and 1.5% w/v). With chitosan hydrochloride, a concentration-dependent increase in [^{14}C]mannitol transport was observed (14.6 ± 1.2% and 19.8 ± 3.8%, of the total dose applied, at 1.0 and 1.5% w/v concentrations, respectively). Apparently, chitosan hydrochloride is more effective than TMC-L and TMC-H at a pH of 6.20.

In agreement with the TEER results, only TMC-H was able to increase the transport of [^{14}C]mannitol at a pH of 7.40. The cumulative amounts of [^{14}C]mannitol transported at 0.05−1.5% w/v concentrations of TMC-H are depicted in Figure 3. These values represent a 31- to 48-fold increase in the permeation of [^{14}C]mannitol (Table 1). The efficiency of TMC-H at this pH value is evident from these results. Even in a concentration as low as 0.05% w/v, the permeability of [^{14}C]mannitol was increased 31-fold.

In all the permeation curves, both at pH 6.20 and 7.40, the transport of [^{14}C]mannitol from the donor to the acceptor compartment was relative steady, as evident from the slope of the individual concentration curves. This result indicates unhindered paracellular diffusion of this hydrophilic compound through opened tight junctions. No evidence of trypan blue inclusion into the intracellular spaces

Table 1—Effect of TMC-H, TMC-L, and Chitosan Hydrochloride on the Permeability of [^{14}C]Mannitol

of the cells was found when cells were stained with this dye after completion of all the transport studies.

Discussion

The results of this study show that both chitosan hydrochloride and TMC, with different degrees of quaternization, are potent absorption enhancers at a pH of 6.20. These polymers were able to decrease the TEER of the Caco-2 cell monolayers markedly. Measurement of TEER is believed to be a good indication of the tightness of the junctions between epithelial cells. The apparent difference in effect between chitosan hydrochloride and TMC could be explained in terms of their respective charge densities. The amino group on the C-2 position of TMC is a much larger unit, due to the attached methyl groups, compared with the amino group on the C-2 position of chitosan hydrochloride. With chitosan hydrochloride, about 10 wt % constitute the salt part and therefore the charge density is much higher as for TMC. Additionally, the attached methyl groups on TMC may partially shield the positive charge and steric effects may also influence the configuration of the TMC molecule where chitosan hydrochloride probably exists in a linear configuration at acidic pH values when the amino group is protonated. A clear comparison between these polymers is not possible because the equivalent amounts of free chitosan base could not be calculated, especially for TMC because NMR spectra showed that some amino groups are still dimethylated, depending on the degree of quaternization of the respective TMC sample.

In agreement with the reduction in TEER at a pH of 6.20, the permeation of the hydrophilic model compound [^{14}C]mannitol was also increased markedly, indicating enhanced paracellular transport. Because of their positive charge, cationic macromolecules such as chitosan and TMC can interact with the anionic components of the glycoproteins on the surface of epithelial cells. Cationic macromolecules can displace cations from electronegative sites on cell membranes, which require coordination with cations for dimensional stability.[16] It is also known that the interior of the tight junction channel are hydrated and contained fixed negative sites. Changes in the concentration of certain ions in the pore could result in alteration in tight junction resistance leading to opening of the pore with increased paracellular permeability.[17] It has been reported that chitosan is able to induce a redistribution in cytoskeletal F-action, thereby resulting in a structural reorganization of tight junction associated proteins such as ZO-1.[1,6] TMC probably acts in a similar way to open the tight junctions.[10]

At a pH of 7.40 only TMC-H was able to decrease the TEER of the cell monolayers. In agreement with this reduction in measured TEER, the permeation of [^{14}C]-mannitol was substantially increased even in concentrations as low as 0.05% w/v. Chitosan hydrochloride has an apparent pK_a value of 5.5−6.5 and, at a pH of 7.40, it probably exists in a more coiled configuration with no protonated amino groups that can interact with the cell surfaces or tight junctions. With TMC-L, the charged density has not reach the threshold concentration to induce interaction with the anionic components of the glycoproteins at the surface of the cells or with the fixed negative charges within the aqueous tight junctions. Additionally, the attached methyl groups may partially shield the positive charge from significant interaction with the cell membranes or tight junctions. TMC-H, on the other hand, has a much higher proportion of quaternary amino groups that seems to be sufficient to interact with anionic components on the cell membranes or the negative sites within the tight junctions.

Because of the high viscosity and mucoadhesive character of chitosan hydrochloride and TMC, it is unlikely that all the polymer solution could be removed without damaging the cells. Therefore, reversibility of the effect of these polymers on the TEER could not be established. Nevertheless, the absence of intracellular trypan blue staining, after prolonged incubation with these polymers, implies that the Caco-2 cells remained undamaged and functionally intact. This implication is in agreement with results obtained in a recent study where Caco-2 cell monolayers were tested with the propidium iodide nucleic stain for their viability after 4 h of incubation with TMC (40 and 60% quaternized) at different concentrations up to 1.0% w/v. In all cases, the monolayers were able to exlude propidium iodide.[18]

In summary, our study shows that the insolubility of chitosan and chitosan salts prevents these polymers from being effective as absorption enhancers at neutral pH values. It has been shown that TMC, already at very low degrees of quaternization, is superior in water solubility compared with chitosan and chitosan salts.[9,10] The degree of quaternization of TMC is demonstrated to play an important role in its ability to open the tight junctions of intestinal epithelial cells. Highly quaternized TMC proves to be a very potent absorption enhancer, especially at neutral pH values. The use of this chitosan derivative may be a valuable contribution to the development of selective and effective delivery systems for hydrophilic compounds such as peptide drugs, especially in neutral and basic environments where normal chitosan salts are ineffective.

Accepted for publication November 11, 1998.

Abstract □ A number of experiments were performed to illustrate the unusual versatility of Polysorbate 80 (Tween 80) as an ionophore. New ions shown to be transported by it from and to water layers through a model membrane (CH_2Cl_2) include H_3O^+, Li^+, Pb^{2+}, Co^{2+}, piperidinium ion, guanidinium ion, and Paraquat, while two complex ions resisted transport under the conditions used. "Reverse" transport of lipophilic guests (azobenzene, azulene, ferrocene) from and to organic solvents through water was also promoted by Tween 80, but C_{60} was not carried. Three water molecules were transported per molecule of KSCN by the Tween.

Introduction

Previous work has shown that Polysorbate 80 (**1**, Tween 80), a popular surfactant and solubilizing agent used in biochemical, chemical, and pharmacological research and in the food and cosmetic industries, is an effective ionophore,[1] can be used as a phase transfer catalyst,[2] and affects the serum concentrations of calcium ions of rats when included in their diets.[3] It also exhibits, as do poly(ethylene glycol) 1000 and 18-crown-6, an unusual inverse temperature effect on the rates of transport of potassium thiocyanate through a model membrane.[4]

The present work was undertaken to illustrate the versatility of Polysorbate 80 as an ionophore. It was already known that it is more stable in basic solutions than the tetraalkylammonium salts, and both cheaper and less toxic than the crown ethers.[1] We set out to expand the number and types of ions carried by it, to settle the question of how ions are carried ("naked" or hydrated), and to discover if the "reverse" transport of lipophilic guests through water could be achieved.

Too often, Polysorbate 80 has been used as a surfactant and solubilizing agent in living systems under the assumption that it was totally inert and had no further physiological activity or influence. To test this assumption, we hope to be able to answer the following questions. Is Polysorbate 80 able to transport, not only benign ions, but also potentially dangerous ones (e.g. heavy metal ions), across a membrane? Is it able to transport organic ions as well? Is it able to, not only solubilize into aqueous bodily compartments neutral organic entities, but also to facilitate their movements through membranes into other aqueous compartments, such as cells? How inert and innocuous is Polysorbate 80?

Experimental Section

Materials—Thiocyanate salts, azobenzene, azulene, ferrocene, Paraquat, Methyl Thymol Blue, and Carbon Soot were purchased from Aldrich and, except for the Soot, used without further purification. Polysorbate 80 was obtained from Fisher Chemical. Spectra were recorded on a Milton Roy Spectronic 301.

Transport Studies—The experimental setup has been described elsewhere.[1] A lower layer of 150 mL of approximately 0.8 mM **1** in CH_2Cl_2 in a 600 mL beaker supports an inner layer of 40 mL of 0.1 M aqueous metal or organic thiocyanate and an outer layer of 0.02 M $Fe(NO_3)_3$ in 0.20 M HNO_3, the latter two layers separated by a glass "cup". The rate of transport is monitored by measuring the increase in the absorbance at 480 nm of the red complex ion $Fe(SCN)^{2+}$ formed in the outer layer with time.

Two exceptions to the above procedure should be noted. Since $Pb(SCN)_2$ is only very slightly soluble in water, $Pb(NO_3)_2$ was used as the salt, and the outer layer changed to a 0.1 mM solution of methyl thymol blue in 0.05 mM succinic acid buffer (pH 5.8).[5]

In the case of the transport of hydronium ions, the inner layer consisted of various concentrations of aqueous HNO_3, and the outer layer of distilled water. Transport was monitored by measuring the pH of the outer layer.

Transport of Water Molecules—These experiments were conducted in a dry bag in an atmosphere of dry N_2. The inner layer consisted of 40 mL of 0.1 M aqueous KSCN and the outer layer of 25 mL of D_2O. At regular intervals, including at time zero, 2.0 mL samples of the outer layer were removed and placed in stoppered NMR tubes. At the end, the tubes were removed from the dry bag and the intensity of the absorption peak for H_2O at 4.65 ppm monitored a minimum of six times. Then, 1.5 mL of each sample was mixed in a UV cuvette with 1.5 mL of 0.02 M $Fe(NO_3)_3$ in 0.20 M HNO_3, and the absorption of the resultant solution followed at 480 nM.

The standard curve used to convert the UV absorptions to concentrations was that used previously.[1] A standard curve to ascertain the transport of H_2O into the D_2O of the outer layer was made by adding microliter samples of distilled, deionized H_2O to 2.0 mL samples of D_2O and measuring the intensity of the absorption in the NMR at 4.65 ppm; its $r = 0.9985$.

Blank experiments were run without KSCN in the inner layer but with Tween in the lower layer, and also without either present.

Transport of Paraquat—The colorless Paraquat can be monitored using the intensely colored radical cation which absorbs at 605 nm formed when it is oxidized by alkaline sodium dithionite.[6] A standard curve was prepared by measuring the absorption of a series of solutions made by adding 1.0 mL of aqueous Paraquat solutions to 1.0 mL of freshly prepared 0.5% sodium dithionite in 0.5 M ammonia buffer (pH 9); its coefficient of correlation was 0.9992. Timely 1.0 mL samples of the distilled water in the outer layer were taken during the experiment and, at the end, all added sequentially to 1.0 mL samples of a freshly prepared dithionite solution and the absorption read at 605 nm (dithionite solutions are unstable and must be prepared just before adding to the transported samples).

"Reverse" Transport of Lipophilic Guests—In these cases, the lower layer consisted of 150 mL of 0.643 mM aqueous Polysorbate 80; the inner layer of 40 mL of 0.100 M solute (azobenzene, azulene, or ferrocene) in the organic solvent (either hexane or isooctane); and the outer layer of 50 mL of the same pure solvent. Transport was monitored by measuring the absorption of the colored species themselves (azobenzene at 436 nm, azulene at 633 nm, and ferrocene at 442 nm) with time in the outer layer. Standard curves were constructed for each of the solutes: for azobenzene, $A = 0.00887 + 0.1834[AZB]$, $r = 0.9945$; for azulene, $A = -0.000963 + 0.3405[Azl]$, $r = 0.9981$; for ferrocene, $A = 0.0113 + 90.65[Fer]$, $r = 0.9928$.

[a] Unless otherwise indicated, using 0.8 mM Tween in CH_2Cl_2 as the lower layer, 0.1 M thiocyanate salt as the inner layer, and 0.02 M $Fe(NO_3)_3$ in 0.20 M HNO_3 as the outer layer at 23 °C and 125 rpm. [b] Number of determinations. [c] Using 0.1 M HNO_3 as the inner layer and distilled, deionized water as the outer layer. [d] Using 0.10 M $Pb(NO_3)_2$ as the inner layer and 0.10 mM methyl thymol blue in 0.05 mM succinic acid buffer (pH 5.8) as the outer layer. [e] Using 0.0778 M Paraquat as the inner layer and distilled, deionized water as the outer layer.

A 0.006 M solution of buckminsterfullerene (C_{60}) in toluene was prepared according to the method of Scrivens et al.[7] and 40 mL of it used as the inner layer. Distilled water constituted the outer layer. A standard curve was constructed using the absorption of C_{60} at 598 nm.[8] Transport was monitored at the same wavelength.

Results and Discussion

Ion Transport—The number and type of ions shown to be transported by Polysorbate 80 was increased considerably. The original work[1] had studied four biochemically important ions (K^+, Na^+, NH_4^+, Ca^{2+}). In this work, smaller ions were used (Li^+, H_3O^+), as well as, for the first time, heavy metal ions (Co^{2+}, Pb^{2+}). Some larger organic ions (piperidinium ion, guanidinium ion) are transported, while several complex ions [hexamminecobalt(III)$^{2+}$ and hexamminenickel(II)$^{2+}$] are not. Methyl viologen, better known as Paraquat (**2**), a divalent cation in which the charges are separated, was also transported, but at a considerably lower rate (about 1/150) than any of the other ions. The fluxes of all these ions are summarized in Table 1.

The reluctance of the complex ions to be transported is probably due to the fact that the charges on the metals are so deeply buried within the six ammine groups that no interaction with the oxygen atoms of the Polysorbate 80 is possible, this despite the fact that the ammonium ion itself is easily transported. Chia et al.[9] reported a similar lack of transport of the hexamminecobalt(III)$^{2+}$ using the sodium salt of lasalocid as the ionophore; they did, however, effect transport if the receiving layer was spiked with ammonium ion (Lindoy et al.[10] also did this). The much lower rate of transport of the Paraquat may be related to the much greater size and weight that it represents; e.g. the length of the Paraquat molecule is about 10.2 Å compared to a length of only 4.9 Å for piperidinium ion. Apparently, the Tween can completely sequester the latter, but not the former. Also, it may be able to envelope only one of the positively charged nitrogen positions on the Paraquat molecule, leaving the other free to resist removal from the aqueous layer (the positive charges are about 7.1 Å apart).

Leaving Paraquat aside, the ions that are transported move at similar rates. An exception is the piperidinium ion, whose flux is three or more times greater than the other monopositive ions. The reason for this may be that this ion has a lipophilic end that can facilitate solution in the model membrane; even the guanidinium ion cannot do this, because the positive charge is distributed throughout the molecule by resonance. Still, this general similarity in fluxes is in contrast to the situation using cyclic ionophores such as the crown ethers, where the correspondence between the size of the cavity and the diameter of the ion is of such importance, so that ions that can fit comfortably within the cavity are transported much more easily than those that are too big or too small for a snug fit. Over a large range of sizes, the poly(ethylene oxide) arms of the Polysorbate 80 are able to envelope many dissimilar ions with similar effectiveness, making it inherently more versatile than the cyclic ionophores.

[a] Mol/s/m^2 ± SD, with a minimum of three determinations at each concentration. [b] Using 150 mL of 0.8 mM aqueous Polysorbate 80 as the lower layer, 40 mL of the guest at the stated concentrations in the stated solvent as the inner layer, and 50 mL of the same pure solvent as the outer layer, at 23 °C and 150 rpm. [c] Coefficient of correlation of the plot of concentration versus flux. [d] Diederich and Dick[14] report a transport rate for azulene from 0.02 M azulene in hexane through a 0.5 mM cyclophane-type ionophore in water to hexane at 20–22 °C of 8.6×10^{-6} mol/L/h; they do not reduce this to a flux.

"Reverse" Transport of Lipophilic Guests—One of the major uses of Polysorbate 80 has been to solubilize in water compounds that are otherwise insoluble in it. This led us to believe that lipophilic guests, with very low solubilities, might be able to be transported by Polysorbate 80 from an initial organic layer through an aqueous layer and into a final organic layer. A few examples exist of such "reverse" transport involving specifically constructed hosts (e.g. calixarenes[11,12] and cyclophanes[13,14]) with limited versatility. We chose as our guests strongly colored organic molecules whose absorptions in the visible region could act as their own means of detection.

The results of these experiments are shown in Table 2. Three quite different types of substances (azobenzene, azulene, and ferrocene) were transported with fluxes comparable to those of the ions transported (cf. Table 1). Initially, hexane was used as the organic solvent, but its relatively high volatility led to problems (an adjustment of volume in the upper layers before each reading). These problems were solved by changing to the less volatile solvent isooctane.[15]

With regular ion transport, the flux is first order in the salt. We determined the orders of the transports of our three organic guests in the usual way (using the slope of the line obtained by plotting ln k versus ln c), with the following results: 0.3−0.4 order for azobenzene, 1.20−1.25 order for azulene, and 0.74 order for ferrocene. This indicates that the rate-determining step of the process, the

formation of the complex at the initial organic solvent–water interface, is not simple, but complex, depending to some extent on the shape and the size of the guest. Further work is needed to explain these orders.

It is apparent that Polysorbate 80 is as adept at transporting hydrophobic molecules through an aqueous layer as it is in carrying ions through an organic layer. Such versatility is not possible with many artificial (e.g. crown ethers and analogues) or naturally occurring (e.g. valinomycin, monensin, etc.) ionophores, whose cyclic or pseudocyclic structures restrict them to one basic conformation featuring a hydrophilic cavity and a lipophilic exterior. In addition, as is the case with other "octopus" compounds,[12] the size of the guests carried by Polysorbate 80 is not limited by a cavity of a specific size. The relatively free poly(oxyethylene) arms of one or more molecules[11] can envelope and carry guests of widely varying dimensions.

These results should act as a caveat in the use of Polysorbate 80 in living systems. There is always the possibility that the movement of organic molecules that are small enough through membranes can be facilitated by the Tween, causing interference at best and risk at worst. One such example, involving a study of the effect of 11-hydroxy-Δ^9-tetrahydrocannabinol on the tachycardia of an excised rat heart, has already been documented.[16]

Are Tween Transported Ions Hydrated or Not—One of the reasons given for the increased rates of reaction produced by phase transfer catalysis (beyond the fact that the reacting species are in the same phase) is the fact that the ions transported to the organic phase are "naked", i.e., not hydrated, or at least are less hydrated, than they were in the aqueous phase. Polysorbate 80 has been used as a phase transfer catalyst,[2] and so an experiment was set up to ascertain whether and to what extent water was transported through an organic layer with the cations and their counterions.

The results are shown in Table 3. Two blanks were run. In the first case, no salt was present in the inner layer and no Polysorbate 80 in the lower layer. Despite this fact, water was transported under the usual conditions of the experiment with a significant flux (16.18×10^{-8} mol/s/m^2). The second blank involved no salt in the inner layer, but Polysorbate 80 in the lower layer; the flux of water rose to 18.88×10^{-8} mol/s/m^2, an increase of about 17%.

When KSCN was present in the inner layer and Polysorbate 80 in the lower layer, the flux of the salt was shown to be 1.11×10^{-8} mol/s/m^2 and that of the water 22.29×10^{-8} mol/s/m^2. Since the flux of the water without the presence of the salt was 18.88×10^{-8} mol/s/m^2, the KSCN would be responsible for a water flux of the difference, 3.41×10^{-8} mol/s/m^2. This means that, for each mole of KSCN transported, about three moles of water are transported [$(22.29 \pm 2.48 - 18.88 \pm 0.68) \div 1.11 \pm 0.12 = 3.07 \pm 1.32$]. It is not clear at present whether this water is transported by the cation, the counterion, or a combination of the two. In a similar case, Dang and Kollman[17] postulate on theoretical grounds that three water molecules adhere to the potassium ion in its complex with 18-crown-6. Still, it is clear that the ions in the organic layer, while not truly "naked", are nonetheless considerably unclothed compared to their situation in water.

Powder Densification. 1. Particle–Particle Basis for Incorporation of Viscoelastic Material Properties

SUSAN K. LUM*,† AND WENDY C. DUNCAN-HEWITT†,‡

Contribution from *Faculty of Pharmacy, University of Toronto, 19 Russell Street, Toronto, Ontario, Canada M5S 2S2.*

Received January 9, 1998. Accepted for publication November 9, 1998.

Abstract □ The present investigation was undertaken to examine the basic unit of densification: the particle–particle indentation. The true interparticle contact area that is established during densification ultimately determines the quality of the tablet compact. By examining the interfacial contact between mutually indenting viscoelastic particles, the process of contact evolution may be represented in mathematical form through extension of the classical Hertzian elastic contact description to encompass material viscoelastic terms. In this way, the time-dependent response of materials to applied loads may be addressed explicitly. The effects of rates of applied loading and maximum load levels were also considered. This analysis was based on viscoelastic stress data collected using an instrumented Instron analyzer during the densification of PMMA/coMMA, a pharmaceutical polymeric coating material. A crossed cylinder matrix compaction geometry was used to simulate the geometry of two mutually indenting spherical particles. Numerical and graphical solutions delineating the relationship between contact area evolution and the prescribed loading force are presented. This particle–particle description of the contacting interface serves as a unit basis for describing the entire powder bed. The powder bed may ultimately be modeled as a collection of these particles in contact.

Introduction

Oral administration is the most common route of drug delivery for systemic circulation. The tablet is the leading oral form; it's simplicity, portability, and economic value enhances patient compliance. Tablets exist in diverse forms, ranging from conventional disintegrating forms to advanced modified-release systems, but all are formed through a common pathway, namely, through powder densification.

Powder densification consists of sequential and concurrent processes where particles are brought into intimate contact, interparticulate bonds are formed, and dimensional changes occur as a result of stress redistribution. Time-dependent phenomena inherent in these processes may govern the ultimate quality of the compact produced. Permanent densification occurs when stress exceeds the elastic strain limit of a given material. The extent of this nonrecoverable deformation depends on the time in which the applied stress exceeds this material yield stress. It is viscoelastic theory that serves to quantitate this time dependence and provide a description of the relationship between the strain rate of the material in a plastic state and the stress required to produce that strain rate.

The compaction of powders is a complex process. The rate at which compacts are formed determines the final tablet strength and viability.[1−4] With the advent of modern processes, the high speeds of compaction emphasize the time-dependent component of material behavior. This complexity is reflected in the large-scale manufacturing of tablets where problems of low tablet strength, capping and sensitivity to material batch variability exist and are translated into costly overruns. Resolution of these problems often involves multiple formulation adjustments based on empirical knowledge rather than the reasoned use of physical data; improving the theoretical understanding of the compaction process would enable a more rational approach to the formulation of tablets.[5]

It is conjectured that problems arise during tablet production as a consequence of viscoelasticity combined with poor interparticle bonding. The amount of elastic recovery of the particles depends on the release of elastic strain during decompression and tends to disrupt interparticle bonds. This stress relaxation is a function of the viscoelasticity of the material, which in turn is influenced by the speed of compression and decompression. At high compaction speeds, the internal stress after compaction is high and the propensity of the material for elastic recovery is considerably higher than at low compaction speeds.

Existing approaches to assess powder compaction have mainly tried to quantify compression in an empirical form. The equations proposed to empirically fit compaction data with parameters such as punch and die wall stresses and tablet porosity[6−9] offer little insight into the physical basis for particle interaction. Therefore, they remain descriptive rather than predictive of powder densification.

A predictive model of compaction must explicitly incorporate material viscoelastic terms into a working description of densification. Analytical models that describe densification from the deformation of particles serve to facilitate the selection of production process parameters such as pressure, temperature, and time. The present investigation was undertaken to examine the basic unit of densification: the particle−particle interaction. By defining the contact between mutually indenting viscoelastic particles, the compact may ultimately be modeled as a collection of these particles in contact and in this way address the time-dependent response of materials to applied loads.

Rationale

In random close packing of a powder bed, point contacts exist between adjacent particles. The density of the powder increases through processes that flatten these contacts between particles. The degree of interparticle bonding and bond strength, which which determines the ultimate quality of a tablet, is assumed to be largely governed by the magnitude of the true interparticle contact area created during densification. This process of contact evolution may be represented in mathematical form through amelioration of the classical Hertzian elastic contact description to encompass material viscoelastic terms. In this way, a

This is valid for cases where deformations are small.

quantitative measure of the contact deformation between mutually indenting viscoelastic particles may be defined.

Theoretical Section

The time-dependent stress and indentation behavior of the test matrixes were modeled in terms of a standard linear viscoelastic rheological form transposed into the classical elastic description of contact. Components of the theory underlying this contact deformation may be found interspersed in the literature for specific geometries.[10,11] The following derivation of the theory describing the contact between spherical particles of a viscoelastic material, as applied to these studies, is developed in detail for the integral understanding of the resultant model.

Boundary Conditions for the Deformation between Two Spherical Bodies in Contact—The geometry of the surface of undeformed spheres near the center of contact are smooth surfaces that can be described with sufficient accuracy, as shown in Figure 1, by

$$z_1 = \frac{r^2}{2R_1} \qquad z_2 = \frac{r^2}{2R_2} \tag{1}$$

and the mutual distance between points is

$$z_1 + z_2 = r^2\left(\frac{1}{2R_1} + \frac{1}{2R_2}\right) = \frac{r^2(R_1 + R_2)}{2R_1R_2} \tag{2}$$

If the spheres are compressed together by a normal force *P*, there will be a local deformation near the point of contact producing contact over a small surface with a circular boundary, hence, the surface of contact arises.

Let w_1 and w_2 be the deformations of the two spheres owing to the contact pressure, *a* the radius of the contact region, and α be the total distance of approach of the two spheres from the state of point contact. The deformed configuration is shown in Figure 2. The condition

$$w_1 + w_2 = \alpha - (z_1 + z_2) \tag{3}$$

is to be satisfied at each point in the contact region. By eq 2

$$w_1 + w_2 = \alpha - \left(\frac{r^2(R_1 + R_2)}{2R_1R_2}\right) \tag{4}$$

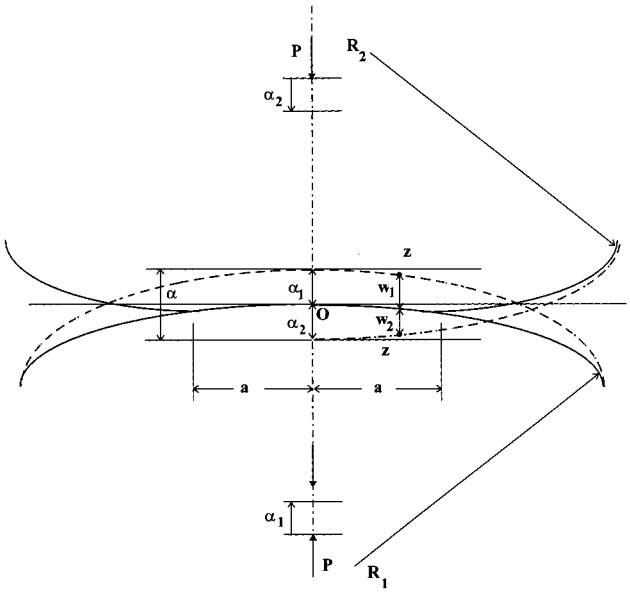

Figure 2—Schematic for the deformation between two spheres from the state of point contact. The deformed configuration is shown with dotted lines indicating the distance of approach of either sphere.

If points lie outside the contact area so that they do not touch it follows that

$$w_1 + w_2 > \alpha - \left(\frac{r^2(R_1 + R_2)}{2R_1R_2}\right) \tag{5}$$

from geometry alone.

Pressure between Two Spheres in Contact—The distribution of pressure transmitted between the two bodies at their surface of contact must be such that the resultant displacements normal to that surface satisfy eq 4 within the contact area and eq 5 outside it. Because the contact region is comparatively much smaller than the dimensions of the bodies ($r \ll R_1$ and R_2), the relation between the surface deflection of each body and the contact pressure can be represented approximately by the solution for surface deflection of a semi-infinite body with pressure distributed on part of its surface. The errors incurred by assuming that the spheres are half-spaces are smaller than those due to the assumption of infinitesimal strains.[12]

Let $a(t)$ be the radius of the contact region and $\alpha(t)$ the total distance of approach. For a given concentrated force acting on a boundary plane of a semi-infinite solid, the displacement is given by[11]

$$w_{z=0} = \frac{q(1 - v^2)}{\pi E r} \tag{6}$$

where *w* is the total displacement, *q* is the intensity of pressure between the bodies in contact, *v* is the Poisson's ratio, *E* is the elastic modulus, and *r* is the distance from the center.

In the case of an uniform load distributed over the area of a circle of radius *a*, if a point D is within the loaded area, the displacement produced is found by superposition. The load on the shaded element in Figure 3 which represents the surface of contact, is $qs\mathrm{d}\psi\mathrm{d}s$. The displacement in the direction of the load is then

$$\frac{(1 - v^2)q}{\pi E}\frac{s\mathrm{d}\psi\mathrm{d}s}{s} = \frac{(1 - v^2)q}{\pi E}\mathrm{d}\psi\mathrm{d}s \tag{7}$$

If there is no pressure between the bodies, we have contact

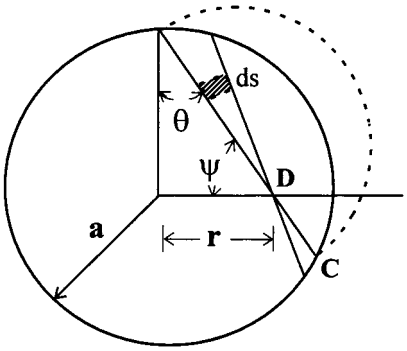

Figure 3—Sketch of a circular contact region of radius *a*. This is the surface of contact over which an uniform load has been distributed.

at one point O. Points D and C are on a meridian section of the spheres, on the plane tangent at O, at a very small distance r (r is small in comparison with R_1 and R_2) from the axis.

The total deflection of a point on the circular contact surface is then obtained by double integration

$$w = \frac{(1 - \upsilon^2)}{\pi E} q \int\int \mathrm{d}\psi \mathrm{d}s \tag{8}$$

because the length of the cord indicated by $bc = 2r = 2a \cos\theta$ and because $r = a \cos\theta = \sqrt{a^2 - r^2 \sin^2\psi}$ the area of the circle $= \pi r^2 = \pi(a^2 - r^2 \sin^2\psi)$ and ψ varies from 0 to $\pi/2$ (see *Appendix I*):

$$\therefore w = \frac{(1 - \upsilon^2)}{\pi E} q \pi \frac{\pi}{4}(2a^2 - r^2) \tag{9}$$

Expressions for the Displacement and Radius of the Contact Surface— Let $(1 - \upsilon^2)/\pi E = k_1 + k_2$ and assume a Hertzian pressure distribution wherein the scale[11] representing the pressure distribution is the constant q_0/a. Thus from eqs 4 and 9, for two same sized spheres in contact,

$$\therefore (k_1 + k_2)\frac{q_0}{a}\frac{\pi^2}{4}(2a^2 - r^2) = w = \alpha - \frac{r^2}{R} \tag{10}$$

Which is then solved by making a term-by-term equivalence between the left- and right-hand sides of this equation

$$\therefore \alpha = \frac{(k_1 + k_2)}{2} q_0 \pi^2 a \tag{11}$$

And because

$$\frac{1}{R} = \frac{(k_1 + k_2)}{4a} q_0 \pi^2 \tag{12}$$

$$\therefore a = \frac{(k_1 + k_2)}{4} q_0 \pi^2 R \tag{13}$$

By adopting the Hertzian pressure distribution assumption (see *Appendix II*),

$$q_0 = \frac{3P}{2\pi a^2} \tag{14}$$

which relates the maximum pressure, q_0, to the loading force, P. We thus find

$$a^3 = \frac{3}{8}\pi(k_1 + k_2)PR \tag{15}$$

by substituting eq 14 into eq 13.

Extension to the Viscoelastic Case—Solutions to the contact problem must accommodate mixed boundary conditions, assigned depending on whether the point in question lies inside or outside of the contacting region. Within the contacting area, the sum of the surface displacements of the two bodies must satisfy constraints to ensure perfect contact, whereas the surface traction must vanish outside of the contact area.

At first reckoning it may appear that Laplace transforms could be useful in addressing the viscoelastic or time-dependent contact case by removing the time variable in the governing equations and boundary conditions. Hence, the problem may be reduced to a corresponding elastic problem with the Laplace transform variable as a parameter. The desired viscoelastic solution would then be an inversion of the solution to the corresponding elastic case.

Viscoelastic contact regions, however, vary with time. Some points initially outside of the region of contact may fall later into the contacting region as the result of the growing indentation area. For these points, neither the traction nor the displacement may be prescribed completely throughout the development of the problem; the transform method may not be used directly to supply a solution to the problem.

Notwithstanding, it has been shown through inductive reasoning that the contact problem in elasticity may be generalized to include the contact of viscoelastic bodies with a restriction that the indentation must be monotonically increasing. Lee and Radok[13] treated a range of problems that fall outside the scope of the transform method by taking a family of solutions of the elastic problem with the parameter time, with the same boundary conditions as the viscoelastic problem, and replacing the elastic constants with the appropriate viscoelastic operators in the expression for stress components. The results comprise tractable mathematical equations for evaluating the stress components for the viscoelastic body.

In the elastic case of mutual indenting spheres, as shown in eqs 11–15, the normal contact pressure $p(r,t)$ of the assumed elastic half space is the relation[14,15]

$$p(r,t) \propto \frac{4}{\pi R}\frac{G}{1 - \upsilon}\sqrt{a^2(t) - r^2} \tag{16}$$

where G is the shear modulus, υ is the Poisson's ratio, and $a(t)$ is the contact area radius. Time appears only as a parameter prescribing the current radius of contact in this quasistatic approach. The elastic constants do not contain time explicitly and so when they are replaced by general linear operators, the solution at any time t depends solely on the instantaneous value of the boundary condition and not on the history of the process.

The viscoelastic counterpart of this Hertzian problem in elasticity as deduced from the elastic solution is then

$$P[p(r,t)] = \frac{4}{\pi R} Q[f(r,t)] \tag{17}$$

where $f(r,t) = \sqrt{a^2(t) - r^2}$, P, and Q are linear operators in the time variable.

The problem is now defined by a normal surface traction $p(r,t)$ and a zero shear traction and is amenable to analysis by the Laplace transform procedure. The transformed

surface pressure

$$\bar{p}(r,s) = \frac{4}{\pi R}\frac{\bar{Q}}{\bar{P}}\bar{f}(r,s) \tag{18}$$

is then related to $\bar{Q}$, $\bar{P}$, the transformed form of the operators. If integral operators are used, the convolution theorem then determines the transformed form.

This procedural manipulation of the operators is valid as long as the contact area does not decrease. In any physically reasonable contact problem of this type, to satisfy the restriction of the Hertz theory, the region of contact will be limited to a finite area. The transformed pressure given by eq 18 is thus nonzero only inside this maximum region of the contact. If the radius of contact increases to a maximum and then decreases to zero, then the normal deflection of the entire surface would reduce to zero, contradicting the reality of viscoelastic material behavior. Delayed elastic and viscous components of strain would be expected to leave a residual indentation after contact has ceased.

The reason for this paradoxical result is that if $a(t)$ passes through a maximum and decreases, then the corresponding $p(r,t)$ usually passes through zero and takes on negative or tensile values. When $a(t)$ then decreases, a residual tensile surface traction is left at the points formerly in the contact region, which violates the contact condition that outside the current region of contact the surface traction should be zero. This dilemma does not arise with nondecreasing $a(t)$ because the zero initial condition for all earlier times guarantee zero traction outside the region of contact.

What follows is a derivation of the formula for the extension of the contact problem to linear viscoelastic spheres. To reduce the complexity of the problem, a number of assumptions were adopted. It was assumed that both bodies in contact were isotropic, homogeneous, and linearly viscoelastic. The material properties were characterized by creep or relaxation functions. Moreover, the surfaces were considered smooth to neglect the effect of friction. Small strains were assumed, as evidenced in the preceding derivations where the area of contact is small in comparison with the dimensions of the contacting bodies. The indentation area should furthermore increase monotonically with time. And finally, shear and dynamic and intermolecular force effects were neglected.

Rheological Model for Viscoelastic Case—The behavior of viscoelastic materials under uniaxial loading may be represented by means of conceptual models composed of elastic and viscous elements. Such rheological forms are useful as analogues for stress and strain. The basic elements of springs and dashpots also assists in the conceptualization of the material behavior.

An ideal helicoidal spring element would be perfectly linear and massless, representing Hooke's Law:

$$\sigma(t) = E\epsilon(t) \tag{19}$$

where E is the modulus of elasticity with dimension (force/length^2). The spring has a creep function $H(t - \tau)/E$ and a relaxation function $EH(t - \tau)$. The dashpot as an ideal viscous element extends at a rate proportional to the force applied, according to Newton's Law:

$$\dot{\epsilon}(t) = \frac{\sigma(t)}{\eta} \tag{20}$$

where $\dot{\epsilon} = \partial\epsilon/\partial t$ is the rate of strain and η is the viscosity coefficient with dimension (force × time × length^{-2}).

Different combinations of springs and dashpots afford flexibility in portraying different responses. Whereas simple

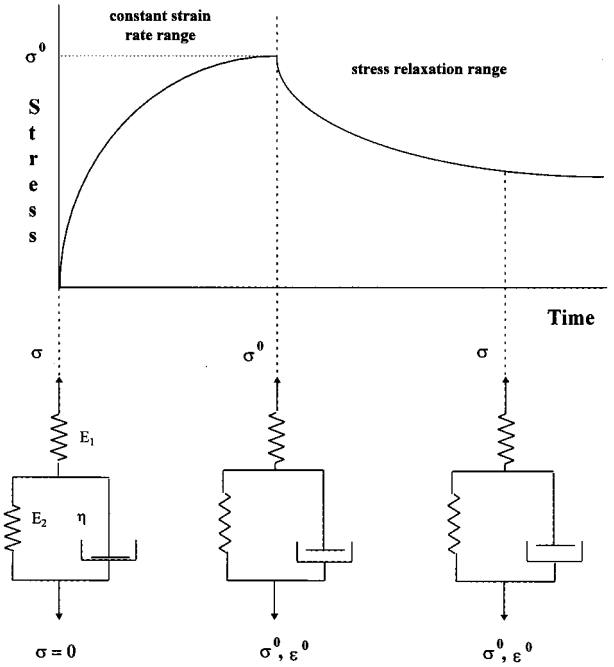

Figure 4—Illustration of the stress–time relation in association with a standard three-parameter rheological model.

models are inadequate representations of real viscoelastic behavior, a three-parameter, standard model consisting of two springs and a dashpot has successfully portrayed real material behavior.[17,18] A standard model was thus employed in the extension of the description of particle contact to the viscoelastic case.

In operational form, this standard model (Figure 4) appears as

$$E_1\eta\dot{\epsilon} + E_1E_2\epsilon = \sigma(E_1 + E_2) + \eta\dot{\sigma} \tag{21}$$

By integrating over a strain history $\epsilon(t)$

$$\therefore \sigma(t) = \epsilon(t)\frac{E_1E_2}{E_1 + E_2} + \frac{E_1^2}{E_1 + E_2}\int_0^t e^{-\frac{(t-\tau)(E_1+E_2)}{\eta}}\dot{\epsilon}(\tau)d\tau \tag{22}$$

Wherein the creep function is

$$\phi(t) = \frac{1}{E_1} + \frac{1}{E_2}(1 - e^{-\frac{tE_2}{\eta}}) \tag{23}$$

and the relaxation function is

$$\Psi(t) = E_1e^{-\frac{t(E_1+E_2)}{\eta}} + \frac{E_1E_2}{E_1 + E_2}(1 - e^{-\frac{t(E_1+E_2)}{\eta}}) \tag{24}$$

Linear Viscoelasticity—Many materials, notably polymers, exhibit time-dependent behavior in their relationships between stress and strain. The common features of a three-parameter or standard solid viscoelastic behavior includes an initial elastic response to an applied or eliminated stress, a delayed elastic response, and a permanent strain that is acquired through the action of creep.

Linear viscoelastic relationships are valid for small strains and assume the principle of superposition holds:[16] a stress history of

$$\sigma(\tau) = \sigma_1(\tau) + \sigma_2(\tau) \qquad \tau \ni (\tau_0,t) \tag{25}$$

corresponds to a strain history of

$$\epsilon(\tau) = \epsilon_1(\tau) + \epsilon_2(\tau) \quad (26)$$

Materials often exhibit linear behavior at low stresses and nonlinear viscoelastic behavior at high stresses.

The stress–strain relations for a linear viscoelastic material are commonly expressed as a relaxation function, $\Psi(t)$. This function, as already deduced from a standard spring-dashpot model, expresses the stress response to a step change in strain.

Viscoelastic Case Analysis—As the preceding contention shows, the interfacial description of two linearly viscoelastic spheres in normal contact may be described mathematically by replacing the elastic constant of the elastic solution by the integral operator from the viscoelastic stress–strain relations. For simplicity, the case of an isotropic, homogeneous, incompressible, and linearly viscoelastic material in the absence of shear is considered. These stipulations facilitate the analytical solution for the case of indentation of smooth viscoelastic spheres; the three-dimensional constitutive equations can be simplified to allow for the application of one pair of viscoelastic operators, p and q, as described by the stress–strain differential equation (see *Appendix III*):[19]

$$\left(\sum_0^m p_k \frac{\mathrm{d}^k}{\mathrm{d}t^k}\right)\sigma = \left(\sum_0^n q_k \frac{\mathrm{d}^k}{\mathrm{d}t^k}\right)\epsilon \quad (27)$$

The condition of very small strains permits the use of linear viscoelastic theory, although it is not a necessary restriction in the treatment detailed by Lee and Radok.[13] The elastic constants can be replaced by viscoelastic terms in the method of analysis for contact of smooth bodies of arbitrary linear viscoelastic materials, just as the Hertz solution applies for arbitrary smooth elastic bodies.[13] The form of the viscoelastic operator can be expressed in terms of the creep compliance or relaxation function found in eqs 23 or 24.

Thus, the contact between spherical particles may be described by substituting the viscoelastic operator ($\Psi(t)$, eq 24) for the elastic constants in the elastic solution found in eq 15. We then have

$$a^3(t) = \frac{3}{8}\pi R \int_0^t \left\{\frac{1}{E_1} + \frac{1}{E_2}\left(1 - \mathrm{e}^{-\frac{(t-t')E_2}{\eta}}\right)\right\}\frac{\mathrm{d}}{\mathrm{d}t'}P(t')\mathrm{d}t' \quad (28)$$

and

$$p(r,t) = \frac{\pi R}{4}\int_0^t \left\{E_1 \mathrm{e}^{-\frac{t-t'}{\tau}} + \frac{E_1E_2}{E_1+E_2}\left(1 - \mathrm{e}^{-\frac{t-t'}{\tau}}\right)\right\} \times \frac{\mathrm{d}}{\mathrm{d}t'}(a^2(t') - r^2)^{1/2}\,\mathrm{d}t' \quad (29)$$

where

$$\tau = \frac{\eta}{E_1 + E_2} \quad (30)$$

is a descriptor of viscoelastic material behavior. These equations, therefore, delineate then an explicit relation between contact area evolution and the applied contact force; a relation that will form the basis for the superposition of such contacts in summation over the entire powder bed.

Experimental Section

Instrumentation—An Instron 4206 stress–strain analyzer, housed in a climate-controlled room (T = 26 °C, RH = 45 ± 6%), was instrumentized through the addition of a 12-bit 10 mV unipolar A/D data acquisition board (PC-LPM-16, National Instruments, Austin, TX). With an op-amp added in line, the voltage signals from up to 8 channels exiting the control console were digitized for collection on a 486-DX clone. The commercial software provided with the board was modified to facilitate signal collection; the testing force was monitored at 250 points per second and averaged over 25 points to reduce spurious fluctuations associated with noise.

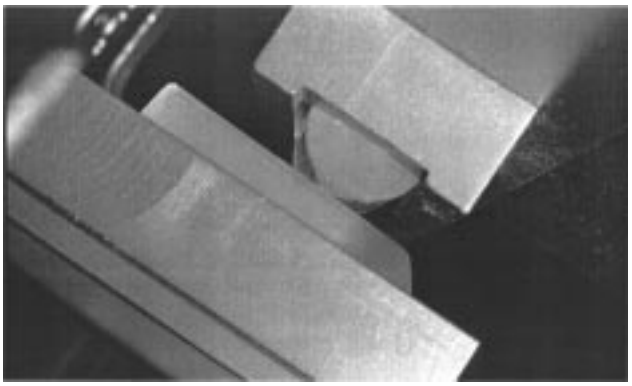

Figure 5—PMMA/coMAA cylinders displayed in crossed cylinder compaction geometry. Matrixes are mounted in stainless steel holders, which in turn are clamped to the platens within the Instron assembly.

Rods to be tested were oriented either axially or radially in stainless steel holders that were machined to fit the contour of the halved rods and that clamped directly onto the upper and lower base platens of the Instron. The test samples were held in compression and the forces experienced by the samples were measured as that transmitted by the load cell. The configuration is displayed in Figure 5.

The 5 kN, 150 kN reversible load cells, and the Instron itself were serviced and calibrated by the source company (Instron) prior to beginning experimental testing. Signal output to the board was calibrated to the force displayed on the console by verifying emitted voltages with a digital multimeter (Beckman 4.5 digit model 800). This calibration extended beyond the experimental applied forces associated with the displacement measurements and served to establish both the calibration factor and the linearity of response ($r^2 > 0.999$).

Materials—Inhibitor-free methyl methacrylate (MMA; Fischer, lot no. 911696) and methacrylic acid (MA; Aldrich, lot no. 07015EZ) were used as they were received. 2,2′-Azobisisobutyronitrile (AIBN; Analychem Corp. Ltd., Markham, Ontario, lot no. 413286) was recrystallized from isopropyl alcohol, and the HPLC grade tetrahydrofuran (THF) (Fischer, lot. no. 904140) was freshly distilled prior to use.

Specimen Synthesis—Ideal contact between two spheres is difficult to achieve experimentally, so the geometry was approximated by the contact of crossed cylinders at 90°. Poly(methyl methacrylate)/comethacrylic acid (PMMA/coMAA), an amorphous acrylic polymer similar to the commercial pharmaceutical Eudragit, was chosen as the model material for study. Although the flow and material properties of PMMA alone are well documented, the copolymer material is more commonly employed in pharmaceutical coating and encapsulation.

PMMA/coMAA cylinders were prepared by free radical bulk polymerization of a 1:1 mole ratio mixture of inhibitor-free MMA and inhibitor-free MAA using recrystallized AIBN as the initiator. The mixture was deaerated by repeated freeze thawing under an argon blanket, and the polymerization was carried out in sealed 13-mm diameter glass molds under Argon at 25°C for 4 weeks (Atmos environmental bag, Sigma Chemical Company, St. Louis, MO). During solidification, the molds were continuously agitated to minimize porosity from trapped gas bubbles (Psycrotherm Incubator shaker model R-27, ser. 8695; NewBrunswick Scientific Company Inc., New Brunswick, NJ). The resulting cylinders were purified by extracting any residual monomer, side products, or initiator by Soxhlet reflux (MeOH/water, 60/40 by volume). Rods were halved longitudinally, polished, and used together as the opposing upper and lower contact elements in compression (wire saw and diamond impregnated wire blades, 0.010" diameter, South Bay Technology, San Clements, CA; Crystal Bay crocus abrasive

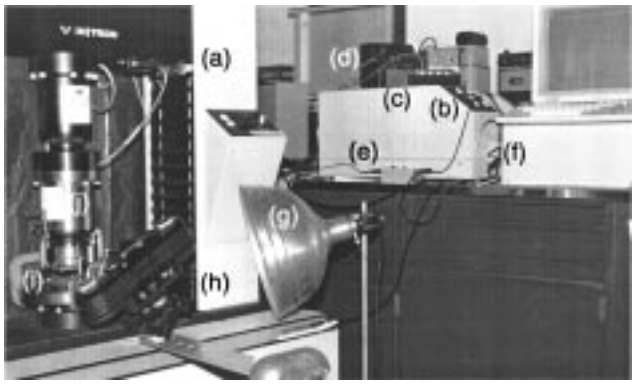

Figure 6—Instrumentation associated with compressional loading of polymer matrixes and concomitant photomicroscopy survey of contacting region: (a) Instron 4206; (b) Instron control console; (c) op-amp for signal transduction; (d) timing relay; (e) single switch or continuous relay; (f) 486DX for automated data acquisition and control, equipped with A/D board; (g) contrast illumination; (h) bulk loaded camera driven through electronic relay; (i) samples mounted within platens; and (j) reversible load cell.

cloth, 3M Canada Inc., London, Ontario, Canada). A nominal aspect ratio (length-to-diameter ratio) of at least 2:1 was chosen to avoid complications of edge effects or barreling during compression. Care was also taken that the material did not come into contact with water or any contaminant while the specimens were being prepared or during subsequent handling and testing; mainly by storage with desiccant under an argon blanket. The samples for this study were annealed at 170 °C for 2 h prior to deformation testing.

Polymer Characterization—Changes in material morphology and properties among sample matrixes were controlled by annealing and monitored by microhardness and acoustic testing as described elsewhere.[20] The mean diameters of five indentations per sample were used to calculate the Knoop hardness values and the corresponding elastic moduli, which averaged 11.3 ± 3.9 MPa and 5.67 ± 0.2 GPa, respectively, at 25 °C. The copolymer was further characterized by a variety of means as reported previously: [21] solid density measurements at various temperatures by stereopycnometer yielded $\rho = 1.20$ g/mL at 20 °C (SE = ±0.001 g/mL), differential scanning calorimetry scans showed a $T_g \sim 175$ °C and no evidence of crystallinity, copolymer composition was checked by Fourier transform infrared (FTIR) spectroscopy, and the viscosity average and weight average molecular weight were determined, respectively, by capillary viscometry and low angle laser light scattering, $M_w \sim 5 \times 10^5$.

Contact Deformation—Compaction between two cylinders was performed on the instrumentized Instron already described at four rates ranging from 1 to 10 mm/min and at four loads ranging from 3.0 to 4.5 kN. Stress relaxation was also monitored for 20 min after the peak load was achieved. At least three runs were performed at each load level and nominal strain rate. The contacting surface radius was determined concomitantly by optical means.

Growth of the contact area, produced by the forces applied to the mutually indenting rods, was measured photomicroscopically with an automated camera system equipped with a custom 10-mm microlens. The camera was mounted on a tripod parallel to the interface of the contacting matrixes, loaded with bulk film, and driven frame by frame by synchronized relay (Nikon F-250, Nippon Kogaku, Japan; TMAX 100 black and white film, Kodak, Canada; Nikon film winder cassette; Intervalomeer HN−I with single or continuous relay and motor driver, HN1 Anglophoto Ltd, Montreal). The timing of the relay and subsequent shutter interval was checked by stopwatch and matched to the timing of the force-data acquisition. High contrast photos were taken of the contact zone at 90° to the axis of compression at 1 s intervals, processed, magnified, and measured (Mitotuyo 500−133 vernier calipers). The instrumentation is depicted in Figure 6 for purposes of visualization. The data from these measurements were analyzed according to methods described next.

Data Analysis—*Force−Time Signal*—Below 0.6 kN on all preliminary and subsequent curves, a distortion was evident in the applied force that produced a replicate kink in the force−time plot across all applied loads and nominal strains. This artifact was attributable to the operational system of the Instron employed. Although hydraulically loaded systems provide an instantaneous force to the testing area, screw-loaded systems must overcome the give or stiffness of the machine before actual loading occurs. The screw-loaded Instron 4206 was employed because of its availability.

The force−time signals relayed to file were smoothed at <0.6 kN. The 0.6 kN value itself corresponds roughly to the 7.5% limit of sensitivity specification for the 5 kN reversible load cell employed for the majority of the experimental runs. Fortran subroutines were written to handle the data sets. The collected force signals were converted by the calibration already noted fitted to a power form by nonlinear regression following a Marquardt algorithm, and back extrapolated at 0.6 kN to the proper abscissa point to offset the time-lag associated with the screw loading.

In the nonlinear least-squares fitting, a chi squared merit function was defined and a best-fit parameter determined by its minimization. The iterative minimization proceeded from trial values input for the parameter following a Marquardt subroutine method (template[22]), which varies smoothly between the extremes of the inverse-Hessian method and the method of steepest descent. Several initial values were iterated through to safeguard against convergence onto a local rather than a global minimum. For each of the 4 × 4 matrix experiments repeated in triplicate, the best fit was assessed by minimization of the sum of squares, comparison of the multiple correlation coefficient, and examination of the residuals and the standard error associated with the estimate of the coefficient to the power form.

The resultant equations for the 4 × 4 design, of the form force $P(\text{time}) = \text{coefficient}*(\text{time-lag time})^{\text{power}}$ were amassed and assessed for correlations with the prescribed load levels and nominal strain rates. Multiple linear regression was applied in both forward and backward substitution forms for various combinations and permutations of the load level and crosshead rates. The best aggregate description was determined on the basis of assessment of the adjusted R, the standard error of the estimate, and the mean square residuals.

Radial Growth Data—The measured contact radii were normalized by the initial apparent contact radius that occurs as a result of the weight of the upper rod resting on the lower. Although the timing relay between photos was calibrated by stopwatch, minor variations accruing from the finite shutter speed time necessitated checking the timing intervals between radii measurements. This calculation was accomplished given the peak force time signal and the number of frames advanced. Accounting also for measurement magnification, and the lag-time associated with screw loading, the radii data provided normalized radius growth with time curves in triplicate for the 4 × 4 design (for various nominal strain rates and ultimate loading levels).

Calculation of Material Viscoelastic Parameters—Relaxation or creep compliance functions are traditionally measured by creep tests, in which constant strain rates or stresses are applied to achieve constant stresses or strain rates, respectively, at various elevated temperatures. These measurements require long loading times to reach steady state, which may change either the geometry of the specimen or the microstructure and hence the stress−strain relation. Changes such as these are especially important in porous powder materials which tend to densify during indentation creep testing.

Following the method of Hsueh,[23,24] the viscosity and the two elastic moduli of a three-parameter model constructed to represent a viscoelastic material were determined from the experimental stress−time curve generated from short-term loading at a constant strain rate ($\dot{\epsilon}_0$) followed by a period of stress relaxation. By decomposing the stress−time curve into the applied periods of strain, then for $\dot{\epsilon} = \dot{\epsilon}_0$,

$$\sigma(t) = \left(\frac{E_1}{E_1 + E_2}\right)^2 \eta\epsilon_0[1 - \exp^{-\frac{(E_1 + E_2)}{\eta}t}] + \frac{E_1E_2}{E_1 + E_2}\dot{\epsilon}_0 t \qquad (31)$$

During the stress relaxation phase, $\dot{\epsilon} = 0$ and

$$\sigma(t) = \sigma_\infty + (\sigma_f - \sigma_\infty) \exp^{-(t - t_i)\frac{(E_1 + E_2)}{\eta}} \qquad (32)$$

where

$$\sigma_\infty = \frac{E_1 E_2}{E_1 + E_2}\dot{\epsilon}_0 t_f$$

$$\therefore \sigma(t) = A[1 - \exp^{-\frac{t}{\tau}}] + \sigma_\infty \frac{t}{t_f} \quad (33)$$

for $t > t_f$, where $\tau = \eta/(E_1 + E_2)$, and $A = (E_1/E_1 + E_2)^2 \eta \dot{\epsilon}_0$.

Examination of the stress–time curve provides estimates for t_f, the time at which stress relaxation begins, σ_∞, the limiting stress, and, by plotting ln $(\sigma - \sigma_\infty)$ vs $(t - t_f)$, an estimate for τ. The subsequent application of nonlinear (Marquardt) regression to the stress data, following the form of eq 33, yields a value for A. Simple algebraic manipulation of A, τ, and σ_∞ therefore returns:[24]

$$E_1 = \frac{1}{\tau \dot{\epsilon}_0}\left(A + \frac{\sigma_\infty \tau}{t_f}\right) \quad (34)$$

$$E_2 = \frac{\sigma_\infty}{\dot{\epsilon}_0 t_f}\left(1 + \frac{\sigma_\infty \tau}{A t_f}\right) \quad (35)$$

and

$$\eta = \frac{1}{\epsilon_0}\left(A + \frac{2\sigma_\infty \tau}{t_f} + \frac{\sigma_\infty^2 \tau^2}{A t_f^2}\right) \quad (36)$$

as estimates for substitution into the equational definition (eq 24) for the relaxation function.

Solution of Viscoelastic Case Equations—The premise of this study was to mathematically describe the link between applied load and the evolution of particle–particle contact area between spherical bodies during densification. In this way, the material response may be incorporated in the mathematical description. The experimental data described in the preceding sections measured specific contact area growth resulting from specified applied loads, which then serve as input boundaries for the mathematical relation described in the set of eqs 27–30.

Decomposition of the stress–time curves into applied periods of strain allowed for the estimation of the variables comprising the relaxation modulus operator ($\Psi(t)$, eq 24). The radius of the contacting area (eq 28) was then to be solved for a prescribed loading force–time with substitution of this viscoelastic operator $\Psi(t)$. Application of integration by parts (see *Appendix IV*) provided a simplified form of the equation

$$a^3(t) = \frac{3}{8}\pi R\left\{\frac{P(t)}{E_1} - \left(\frac{1}{E_1} + \frac{1}{E_2} - \frac{1}{E_2}e^{-\frac{tE_2}{\eta}}\right)P_0\right\} + \int_0^t \frac{P(t')}{\eta} e^{-\frac{(t-t')E_2}{\eta}} dt' \quad (37)$$

which was then processed using the numerical quadrature algorithm of a commercial high-performance numeric computation and visualization software program (MATLAB, The MathWorks, Inc., Natrick, MA). The initial processing was performed with a Fortran numerical quadrature subroutine,[22] which was cumbersome compared with the speed with which the commercial form using a recursive adaptive Newton-Cotes 8 panel rule was able to ameliorate the calculations.

A best-fit polynomial form for the contact area–time description was then returned as input into the equation form describing the pressure distribution within the sphere. Equations 29–30 were likewise simplified to

$$p(r,t) = \frac{8}{\pi R}\left\{(a^2(t) - r^2)^{1/2}E_1 - (a_0^2 - r^2)^{1/2}\frac{(E_1^2 e^{-\frac{t}{\tau}} + E_1 E_2)}{E_1 + E_2} - \int_0^t (a^2(t') - r^2)^{1/2} \cdot \frac{E_1^2}{(E_1 + E_2)\tau} e^{-\frac{(t-t')}{\tau}} dt'\right\} \quad (38)$$

where $\tau = \eta/(E_1 + E_2)$, and processed in MATLAB.

Results and Discussion

The primary motivation for studying the particle level contact was the need to ascertain a time-dependent material function for subsequent modeling analysis. With the focus of this study centered on the interaction zone between two particles under mutual deformation, the loading force under which our experimental matrixes were subjected and the resultant experimental area growths were monitored. The applied loading force curves are depicted in Figures 7 and 8 inclusive. Each displayed curve represents the average of several large experimental datasets; the experimental standard deviation for selected points along a curve are shown in Figure 9 for clarity. In accordance with the geometry of the load application, the applied force experienced within the contact zone matches that which was applied externally through the Instron apparatus. The effect of the applied nominal strain rates is clearly shown in the force versus time series of Figure 7. As expected, the time to achieve a defined maximum load was inversely proportional to the crosshead speed, and, within experimental error, the ratio of such times mirrored the ratios of the respective strains (1:2:5:10) applied.

Force–time curves were replotted in Figure 8 for each nominally applied strain rate. Within experimental error, then, the maximum load level itself may be inferred as a function of the time under which the cylinders are compressed and hence not wholly independent of the applied rate of strain. The fitted coefficients for the power form of the force–time curves are summarized in Table 1. From multiple regression analyses, the prescribed loading force–time, $P(t)$, rate dependence may be embodied in the equational form

$$P(t) = (2.859 \times 10^{-2}\dot{\epsilon} + 3.233 \times 10^{-3}\dot{\epsilon}^2)(t - \text{lagtime})^{1.1} \quad (39)$$

where $\dot{\epsilon}$ is the applied strain rate. The value $R^2_{adj} = 98.34$, SE = 0.0424, mean absolute error equals 0.0246, and the mean square residual is 1.802×10^{-3}.

Radial contact growth curves derived from triplicate runs are displayed with error bars representing the replicate variability in Figures 10a–d inclusive. The effect of the applied nominal strain rates is clearly revealed in the sequence of plots where the strain rate differs in achieving a standard maximum load. This rate dependence is analogous to that which was manifest in the force–time series; that is, the time required to attain a specified dilation was inversely proportional to the applied crosshead speed and, within experimental error, the ratio of these times were roughly 1:2:5:10.

By replotting the radial growth curves in Figures 11a–d for each nominally applied strain rate, the effect of the maximum load level achieved is evidently once again a function of the time spent under compression. Each curve series held at a constant strain rate resembles a collinear plot within experimental error. The errors associated with higher strain rates are larger in relation to the points shown at lower strains because there is a finite time required to measure, process, and handle the photographs capturing the changing radial area.

The experimental radial growth data curves were subjected to simple regression fitting (minimization of least squares), and the coefficients of the normalized radial growth, $a(t)$, fitted to the square root of time are tabulated in Table 2.

The solution of the constitutive differential equation describing the behavior during a stress relaxation experiment to yield the relaxation function parameters is not an easy task. For simple models comprised of one to three

elements, the relaxation function may be formulated using hybrid parameters, which also allows a valid conversion to the creep compliance at the same point and at the same time.[25] In more complex models, the relaxation force equalizes differently in time and direction using parts of the springs, dashpots, and Kelvin elements differentially

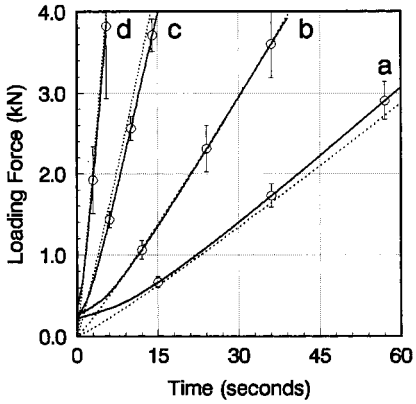

Figure 9—Loading force–time plots of the results obtained from use of the applied strain rates (a) 1 mm/min, (b) 2 mm/min, (c) 5 mm/min, and (d) 10 mm/min, to a maximum of 4.5 kN. Displayed in dotted form are the resultant curves predicted for the prescribed loading at these various strain rates. Selected experimental datapoints depicting the standard deviations between triplicate runs are highlighted.

Table 1—Force–Time Loading Phase of PMMA/CoMAA Matrices[a]

strain rate (mm/min)	maximum load (kN)	average coefficient of fit ($\times 10^{-2}$)	average lag time (s)
1	3.0	4.239 ± 0.57	34.17 ± 3.22
1	3.5	3.431 ± 0.14	19.74 ± 0.10

until a forceless condition arises. Consequently, in the time-dependent domain, no simple relation between the creep compliance and the relaxation function may be found.[25]

Extraction of the relaxation function parameters, based on a standard three-element model from compaction load-time experiments, was preferred over the use of traditional measured creep tests over long times and elevated temperatures. As previously inferred, such tests would necessitate recasting specimen geometry or induce unwonted alterations in the material microstructure. A method used in material science to evaluate the viscosity and the two elastic modules of a three-parameter model during a combined experiment consisting of deformation with a constant strain rate followed by stress relaxation was adopted as a suitable means of evaluation of the PMMA/coMAA $\Psi(t)$ parameters. The crossed cylinder compactions performed consisted of the prerequisite deformation, load-time monitoring under a set crosshead speed, and relaxation monitoring under constant strain. The assumption of the equivalence of a constant crosshead speed with a constant nominal strain rate is a best first approximation. This method is consistent with an engineering definition of strain[26] ($\epsilon = \Delta l/l_0$, where Δl is the change in distance, l is the postfacto length, and l_0 is the original specimen length) rather than that of true strain [$\epsilon_t = \int dl/l_0 = \ln(l/l_0)$].

Table 2—Normalized Radial Growth with Time during Loading Phase of PMMA/CoMAA Matrices[a]

strain rate (mm/min)	maximum load (kN)	intercept of fit ($\times 10^{-2}$)	coefficient of fit ($\times 10^{-1}$)
1	3.0	–0.198 ± 2.0	1.201 ± 0.04

[a] $a(t)$ = intercept + coefficient × $\sqrt{t}$. Average fitted coefficients reported are calculated from triplicate runs in each case. Standard errors reported reflect the matrix–matrix variability.

Others[25] have used solely numerical means for decomposing tabletting load–time curves. In both convolution and deconvolution processes of estimating viscoelastic model parameters, the numerical stability of the regression methods are problematic. The limited accuracy of the numerical transactions and the uncertainty of the initial condition estimates necessitates validation with well-defined, known theoretical material data. This necessity is especially true in the case of powder-type consolidation because volume reduction itself augments viscoelastic features.[25]

Figure 12 serves to illustrate the use of the decomposition method for the determination of the three-parameter viscoelastic terms for one specific case. The procedure is visually elucidated in terms of the decomposition of the stress relaxation curve into components in the development and provides an example of the nonlinear regression analysis used to determine the estimates in the summation process.

The derived parameters required for the relaxation modulus calculation are then summarized in Tables 3 and 4 per the method already described. These parameters serve as input variables in merely defining the viscoelastic operator over a limited time frame and by no means can be used to define $\Psi(t)$ over the time spectrum in its entirety.

Evaluation of the relaxation modulus (eq 24) with the parameters derived in Table 4 is shown in Figure 13. In physical terms, the relaxation modulus represents the time-dependent analogue of the equilibrium shear modulus, which in itself is a ratio of a stress to a corresponding strain measured in an experiment with a specific time pattern. The shape and magnitude of the log–log plots are consistent with that expected for an un-cross-linked polymer network of high molecular weight:[18] at short times, $\Psi(t)$ approaches a limiting value that represents the rigidity of the chain in the absence of backbone rearrangements, and at long times, $\Psi(t)$ falls rapidly for the un-cross-linked networks and eventually vanishes. A mechanical model analogue would translate this behavior as the relaxation of all the springs in an array. Alternatively, in molecular terms, this configuration corresponds to the resumption of random average configurations by the macromolecular coils that have been divested from the constraints originally imposed on them. The external dimensions of the sample in question may remain deformed at long times during this

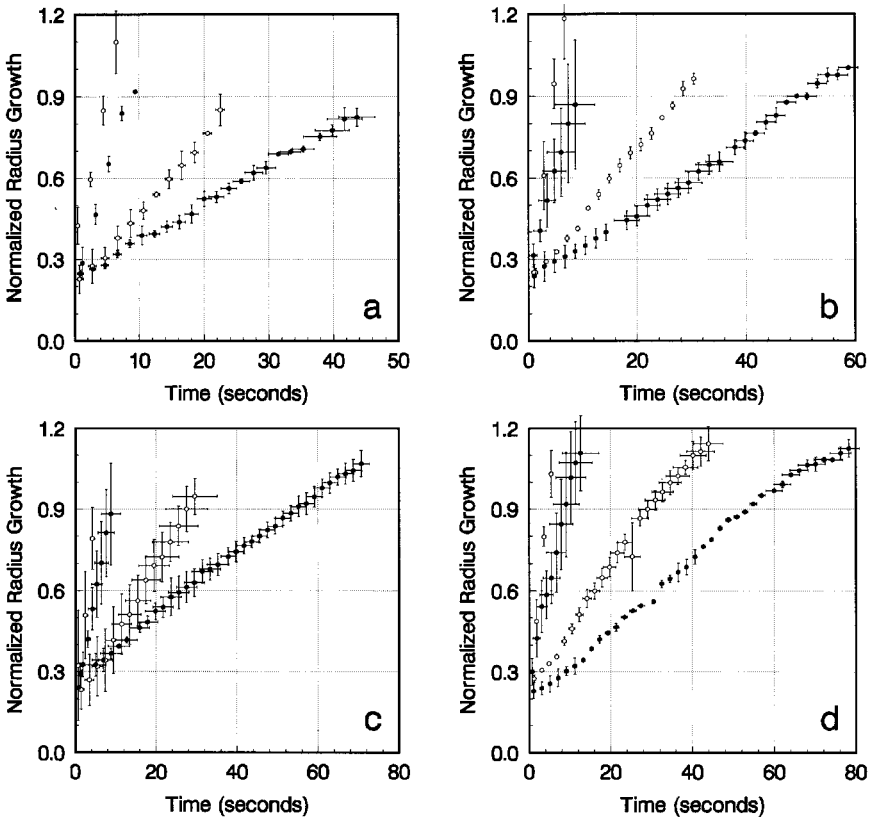

Figure 10—Averaged radial contact growth-time series for various strain rates measured concomitantly: to a maximum load level of (a) 3.0 kN; (b) 3.5 kN; (c) 4.0 kN; and (d) 4.5 kN.

resumption of molecular motion; the residual deformation is the result of the flow contribution to what is essentially a creep experiment.

The magnitude of the compressionally derived modulus depicted in Figure 13 is lower than that reported for PMMA[14] achieved by tension experimentation. This dif-

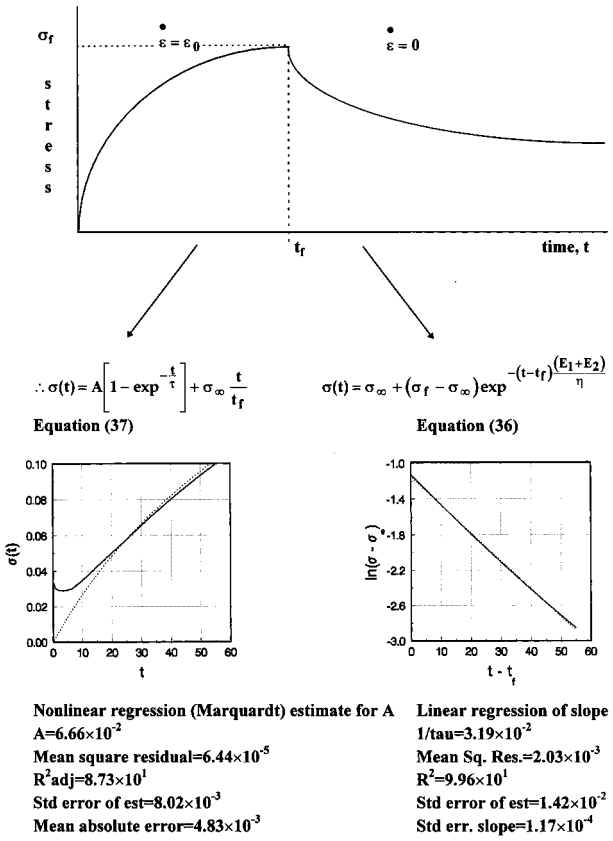

Figure 12—Schematic of the decomposition of the stress–time curve for the case of a load level of 3.0 kN achieved through loading at 1 mm/min. Evaluation of the viscosity and modulus components of a three-parameter model follows that described by Hsueh.[23]

ference is not unexpected, because of the experimental configurational differences and the differences between the two experimental time patterns. At intermediate times depicted in each curve of the figure, the stress shown gradually falls as the distortion of the chain backbones compensates through Brownian motion; segments would adjust first with respect to other closely neighboring segments and then with respect to those farther removed. The modulus falls off sharply thereafter in the region time scale of the terminal zone.

The time dependent operator $\Psi(t)$ displays the effects of the applied strain rates 1, 2, 5, and 10 mm/min shown through the superposition of curves a−d. The trend is in accord with the anticipated rate effect, that is, the inflection time marking the terminal zone is abbreviated with higher strain rates, while the inflection times are elongated with lower strains.

The parameters tabulated in Table 4 served as input for the calculation of the relaxational modulus and thereby the predicted radial contact growth for a prescribed load−time application. Numerical quadrature of the transformed eq 37 predicts a resultant contact growth that has been superimposed on the experimental dataset in Figure 14. The predicted curves are further tabulated using simple least squares regression in Table 5. Although the predicted curve lies within the range of experimental error, deviation from the measured growth may be due to error in the steps taken for the approximation of the specific relaxational modulus form. Indeed, assessing the fit of the predicted curves to this experimental set would not be a valid means of evaluating the utility of the model form as a predictive tool. An independent particle densification series based on stepped load, which was not itself used in the evaluation of the stress relaxation curves from which the relaxation operator was interpolated, would be required; such an assessment will form the basis for subsequent study.

In assessing the viscoelastic operator parameters derived in Table 4, it is clear that the value of the arbitrary maximum load level at which replicate runs were held is a complex function of the time under which loading occurs in a fashion similar to that deduced for load−time and radial growth−time curves. The nominal strain rate under which the matrixes were subjected serves as a better independent measure of the time-dependent behavior of each of the modulus parameters that comprise the $\Psi(t)$ operator. Multiple regression analysis of these tabulated parameters offers a best fit for E_1, E_2, and η when stratifying for specific load levels achieved. For the 4.5 kN levels, as an example,

$$E_1 = 1.70 \times 10^{-3} + 1.60 \times 10^{-3}\dot{\epsilon} - 4.47 \times 10^{-4}\dot{\epsilon}^2 + 3.62 \times 10^{-4}\dot{\epsilon}^3 - 5.58 \times 10^{-7}\dot{\epsilon}^4$$

$$E_2 = 5.21 \times 10^{-4} + 4.28 \times 10^{-5}\dot{\epsilon} - 5.69 \times 10^{-5}\dot{\epsilon}^2 + 6.96 \times 10^{-6}\dot{\epsilon}^3 - 1.15 \times 10^{-7}\dot{\epsilon}^4$$

$$\eta = 5.30 \times 10^{-1} - 1.71 \times 10^{-1}\dot{\epsilon} + 3.67 \times 10^{-2}\dot{\epsilon}^2 - 2.91 \times 10^{-3}\dot{\epsilon}^3 + 4.47 \times 10^{-5}\dot{\epsilon}^4$$

represents a parametrization set that may be used for interpolative prediction within the experimental boundaries delineated in the origin of the dataset. The values of E_1, E_2, and η represent theoretical estimates of the stiffness and flowability of the viscoelastic material. Together, these values form a mathematical construct of the viscoelastic behavior of the material that allows for prediction of the material behavior under different testing conditions. In a viscoelastic body, all of the stresses, strains, and displacements occurring are time dependent, whereas in an elastic solid under constant load, these parameters are independent of time. The values of these spring moduli and dashpot viscosity may provide an estimate of elastic parameters that represent the limiting case of a viscoelastic material. This theory is elucidated in *Appendix V*. Obviously, caution must be exercised in attempting to extrapolate beyond the strain rates prescribed because the size of the dataset lends insufficient power to that function.

The pressure distribution within the two mutually indenting viscoelastic three-parameter model spheres was also found by substituting the relaxation modulus function solved from eq 24 and $a(t)$ as derived from eq 37 into eq 38 and performing the integrations. The computations were carried out for each of the cases indicated in Table 4; the results are plotted in Figures 15a and b for the case of 4.5 kN at both 1 and 10 mm/min loading. These simplified sketches display a two-dimensional projection of the matrix solution which forms a three-dimensional contour (radius, time) in the Cartesian plane. From this schematic, one may infer that immediately following load application, there is an instantaneous elastic response from which the initial contact radius arises. This contact size then grows with time as discussed in preceding sections. It is apparent that the pressure distribution is similar to the Hertz elastic form given by

$$p = p_0\left(1 - \left(\frac{r}{a}\right)^2\right)^{-1/2} \qquad (40)$$

in which the maximum pressure is in the center of the contact area. As time progresses during loading, the balance of relaxation, contact, and load growth favors an

[a] Average fitted coefficients reported are calculated from triplicate runs in each case. Standard deviations reported reflect the matrix–matrix variability.

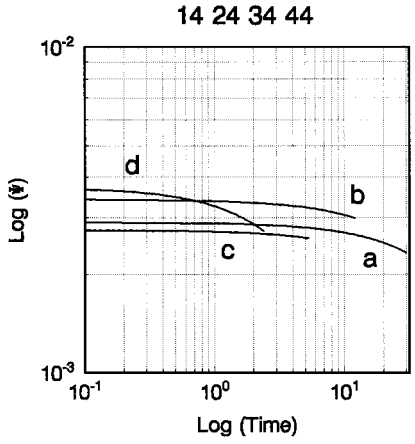

Figure 13—log–log plot of the relaxational modulus–time curves calculated for compaction at the rates of loading at (a) 1 mm/min, (b) 2 mm/min, (c) 5 mm/min, and (d) at 10 mm/min, to a maximum load of 4.5 kN.

expanding pressure distribution. Variation in the loading rate results in a marginally greater magnitude of pressure distributed in a similar fashion. The time-dependent effect, therefore, would appear to consist of the growth in the contact from its initial to its final size; the stresses at any instant in the process being distributed according to elastic theory.

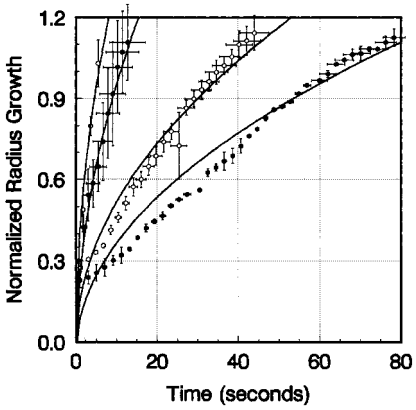

Figure 14—Predicted radial growth curves for various strain rates imposed on the compact to a loading level of 4.5 kN: loading at (a) 1 mm/min, (b) 2 mm/min, (c) 5 mm/min, and (d) 10 mm/min.

10	–0.941 (0.18)	42.564 (0.15)

[a] Average fitted coefficients and standard errors reported are calculated for a maximum loading level of 4.5 kN.

Conclusions

The present investigation was undertaken to examine the basic unit of densification: the particle–particle interaction. Emphasis was placed on the contact interface between two spheres under compression as interparticulate bonding inherently occurs whenever an area of true contact is established between two solids; the interfacial energy is always less than the surface energy of the two surfaces which form the interface. The degree of cohesion within a tablet was assumed to be largely governed by the magnitude of this true interparticle contact area created during densification.

The interfacial description of two linearly viscoelastic spheres in normal contact was described mathematically by replacing the elastic constant of the elastic solution by the integral operator from the viscoelastic stress–strain relations. An explicit relation was delineated between contact area evolution and the applied or prescribed contact force in a 4 × 4 matrix of varying strain and load level. The analysis of the extended Hertzian solution with experimentally determined input parameters yielded two-dimensional surface plots which map the evolution of these variables of local contact force, area growth, and pressure functions with time and applied strain rate at specified maximum loads. Within the context of the experimental time frame, these relations form the basis for the superposition of such contacts in summation over the entire powder bed.

By defining the contact between mutually indenting viscoelastic particles, the compact may ultimately be modeled as a collection of these particles in contact and in this way address the time-dependent response of materials to applied loads. This summation to describe a tabletting powder is the subject of the second paper in this series.

Acknowledgments

This work was abstracted in part from a dissertation submitted by S.L. to the Graduate School, University of Toronto, in partial fulfillment of the Doctor of Philosophy degree. The authors thank and acknowledge the financial assistance of MRC in the form of a grant (to W.D.H.) and a studentship (to S.L.) in supporting this study.

Appendix I

As the length of the cord $bc = 2r = 2a \cos\theta$, $r = a \cos\theta$ since $a \sin\theta = r \sin\psi$

$$a^2 \sin^2\theta = r^2 \sin^2\psi$$

$$a^2(1 - \cos^2\theta) = r^2 \sin^2\psi$$

$$a^2 - a^2 \cos^2\theta = r^2 \sin^2\psi$$

$$a^2 \cos^2\theta = a^2 - r^2 \sin^2\psi$$

$$\therefore a \cos\theta = \sqrt{a^2 - r^2 \sin^2\psi}$$

$$\therefore \text{area of circle} = \pi r^2 = \pi(a^2 - r^2 \sin^2\psi)$$

$$\therefore w = \frac{(1 - \upsilon^2)}{\pi E} q\pi \int_0^{\pi/2} (a^2 - r^2 \sin^2\psi)\mathrm{d}\psi$$

Appendix II

Pressure Applied to a Circular Region—When axisymmetrical pressure distributions of the form

$$q = q_0\left(1 - \frac{r^2}{a^2}\right)^n$$

are applied to a circular region of radius a, the displacements at surface points and the stresses at internal points due to this pressure distribution may be found in closed form.

In the particular case where $n = 1/2$, the pressure distribution is referred to as the "Hertz pressure" given by Hertz theory. This pressure is exerted between two frictionless purely elastic solids of revolution in contact.

As the total loading or compressive force, P, relates to this pressure, q, via

$$P = \int_0^a q(r) 2\pi r \mathrm{d}r$$

then

$$p = \frac{2\pi q_0}{a} \int_0^a (a^2 - r^2)^{1/2} r \mathrm{d}r$$

let $u = a^2 - r^2$, $\mathrm{d}u = -2r\mathrm{d}r$, $r\mathrm{d}r = -1/2\ \mathrm{d}u$, and $a^2 = u + r^2$

$$\therefore P = \frac{2\pi q_0}{a} \int_0^1 u^{\frac{1}{2}}\left(-\frac{1}{2}\right)\mathrm{d}u = \left[-\frac{2\pi q_0}{3a} u^{\frac{3}{2}}\right]_0^a = \left[-\frac{2\pi q_0}{3a}(a^2 - r^2)^{\frac{3}{2}}\right]_0^a = \frac{2}{3}\pi q_0 a^2$$

$$\therefore \text{force} \propto \text{maximum pressure}$$

$$\therefore q_0 = \frac{3P}{2\pi a^2}$$

Appendix III

Derivation of Simplified Three-Dimensional Form for Viscoelastic Constitutive Description[19]—When a problem has more than one stress component, then a generalization of the viscoelastic law to the three-dimensional form may be needed. If a viscoelastic material is

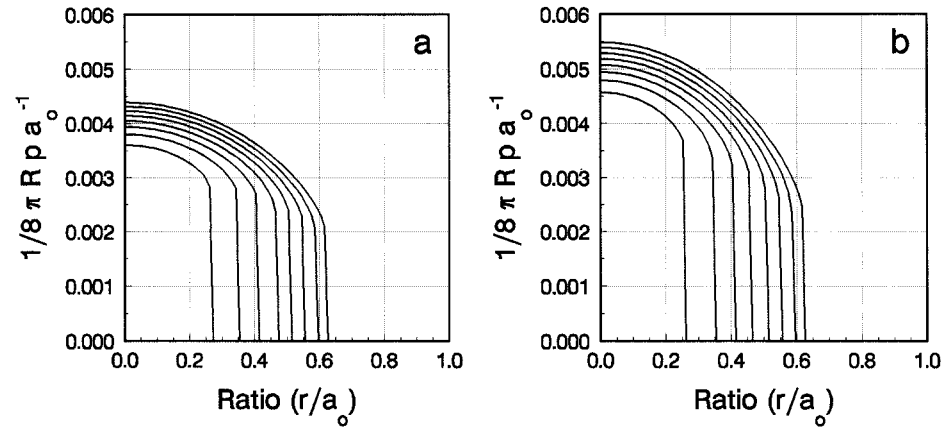

Figure 15—Solution of the pressure equations predicts a stress distribution similar to the elastic form. (a) two-dimensional surface contour plot of the pressure distribution for loading at 1 mm/min to the 4.5 kN level; and (b) loading at 10 mm/min to the 4.5 kN level.

isotropic, a hydrostatic stress must produce a dilatation and no distortion. The stress and strain are related by the differential equation

$$\sigma + p_1\dot{\sigma} + p_2\ddot{\sigma} + \ldots = q_0\epsilon + q_1\dot{\epsilon} + \ldots \qquad \text{(III.1)}$$

$$\left(\sum_0^m p_k \frac{\mathrm{d}^k}{\mathrm{d}t^k}\right)\sigma = \left(\sum_0^n q_k \frac{\mathrm{d}^k}{\mathrm{d}t^k}\right)\epsilon \qquad \text{(III.2)}$$

or, shorter, by

$$P''\sigma = Q''\epsilon \qquad \text{(III.3)}$$

On the other hand, if shear is present, then the shear strain coupled with isotropy of the material requires that

$$\left(\sum_0^{m'} p'_k \frac{\mathrm{d}^k}{\mathrm{d}t^k}\right)\hat{\sigma} = \left(\sum_0^{n'} q'k \frac{\mathrm{d}^k}{\mathrm{d}t^k}\right)\hat{\epsilon} \qquad \text{(III.4)}$$

or

$$P'\hat{\sigma} = Q'\hat{\epsilon} \qquad \text{(III.5)}$$

where $\hat{\sigma}$ and $\hat{\epsilon}$ correspond to the components of the stress and strain deviators.

The operator pairs P'', Q'', and P' and Q', which describe the viscoelastic material, are entirely independent of each other. To each pair, the relation stated in eq 23 or 24 is applicable for a standard three element model.[19] These operator pairs for different rheological models are also summarized in Flugge (Table 1.2; pp 22−23)[19] and in Muller (pp 108, 110, 112, 119, 121).[25]

In uniaxial tension, there is only one stress, σ_x; and strain has three components, the axial strain ϵ_x and the lateral contractions $\epsilon_y = \epsilon_z$. As the operators are assumed linear and time invariant, the commutative properties yields

$$(P''Q' + 2Q''P')\sigma_x = 3Q''Q'\epsilon_x \qquad \text{(III.6)}$$

$$(\mathrm{P}''\mathrm{Q}' - Q''P')\sigma_x = 3Q''Q'\epsilon_y \qquad \text{(III.7)}$$

for applied uniaxial stress. By analogy,

$$(Q''P' + 2P''Q')\epsilon_x = 3P''P'\sigma_x \qquad \text{(III.8)}$$

$$(Q''\mathrm{P}' - P''Q')\epsilon_x = 3P''P'\sigma_y \qquad \text{(III.9)}$$

follows for applied uniaxial strain (in stress relaxation experiments).

Equations III.6−III.9 serve as the viscoelastic equivalent of a complete statement of Hooke's law for uniaxial tension. Interpretation requires special choices for the operators.

As stated by Flugge (p 167),[19] although the shear deformation may be rather large, the change of volume measured by E is always very limited. It seems therefore, reasonable to neglect the latter completely and to assume $E = 0$. This corresponds to $P'' = 0$ and $Q'' = 1$. The constitutive equations for uniaxial stress in tension are then

$$2P'\sigma_x = 3Q'\epsilon_x \text{ and } -P'\sigma_x = 3Q'\epsilon_y \qquad \text{(III.10)}$$

and for applied uniaxial strain,

$$2Q'\epsilon_x = 3P'\sigma_x \text{ and } -Q'\epsilon_x = 3P'\sigma_y \qquad \text{(III.11)}$$

Appendix IV

$$a^3(t) = \frac{3}{8}\pi R\int_0^t\left\{\frac{1}{E_1} + \frac{1}{E_2}(1 - \mathrm{e}^{-\frac{(t-t')E_2}{\eta}})\right\}\frac{\mathrm{d}}{\mathrm{d}t'}P(t')\mathrm{d}t' \qquad (28)$$

integration by parts $uv - \int v\mathrm{d}u$: let

$$u = \frac{1}{E_1} + \frac{1}{E_2} - \frac{1}{E_2}\mathrm{e}^{-\frac{(t-t')E_2}{\eta}} \quad \therefore \mathrm{d}u = -\frac{1}{E_2}\cdot\frac{E_2}{\eta}e^{-\frac{(t-t')E_2}{\eta}}\mathrm{d}t'$$

$$\mathrm{d}v = \frac{\mathrm{d}}{\mathrm{d}t'}P(t')\mathrm{d}t' \quad \mathrm{v} = P(t')$$

$$\therefore a^3(t) = \frac{3}{8}\pi R\left[\left(\frac{1}{E_1} + \frac{1}{E_2} - \frac{1}{E_2}\,\mathrm{e}^{-\frac{(t-t')E_2}{\eta}}\right)(P(t'))\right]_0^t - \int\frac{P(t')}{-\eta}\mathrm{e}^{-\frac{(t-t')E_2}{\eta}}\mathrm{d}t'$$

$$\therefore a^3(t) = \frac{3}{8}\pi R\left\{\frac{P(t)}{E_1} - \left(\frac{1}{E_2} + \frac{1}{E_2} - \frac{1}{E_2}\mathrm{e}^{-\frac{tE_2}{\eta}}\right)P_0\right\} + \int_0^t\frac{P(t')}{\eta}\mathrm{e}^{-\frac{(t-t')E_2}{\eta}}\mathrm{d}t'$$

calculate $a(t)$ per given $P(t)$.

Similarly,

$$p(r,t) = \frac{4}{\pi R}\int_0^t\left\{E_1\mathrm{e}^{-\frac{t-t'}{\tau}} + \frac{E_1E_2}{E_1+E_2}(1 - \mathrm{e}^{-\frac{t-t'}{\tau}})\right\}\times \frac{\mathrm{d}}{\mathrm{d}t'}(a^2(t') - r^2)^{1/2}\,\mathrm{d}t'$$

where

$$\tau = \frac{\eta}{E_1 + E_2} \tag{30}$$

let

$$u = \frac{1}{E_1 + E_2} \cdot E_1^2 e^{-\frac{(t - t')}{\tau}} + \frac{E_1 E_2}{E_1 + E_2}$$

$$\therefore \mathrm{d}u = \frac{E_1^2}{(E_1 + E_2)\tau} \mathrm{e}^{-\frac{(t - t')}{\tau}} \mathrm{d}t'$$

and

$$\mathrm{d}v = \frac{\mathrm{d}}{\mathrm{d}t'}(a^2(t') - r^2)^{1/2} \mathrm{d}t' \quad \therefore v = (a^2(t') - r^2)^{1/2}$$

$$p(r,t) = \frac{8}{\pi R}\left\{(a^2(t) - r^2)^{1/2} E_1 - (a_0^2 - r^2)^{1/2} \frac{(E_1^2 e^{-\frac{t}{\tau}} + E_1 E_2)}{E_1 + E_2} - \right.$$

$$\left. \int_0^t (a^2(t') - r^2)^{1/2} \frac{E_1^2}{(E_1 + E_2)\tau} \mathrm{e}^{-\frac{(t - t')}{\tau}} \mathrm{d}t' \right\}$$

Appendix V

Derivation of Elastic Parameters as a Limiting Case[19]—In a viscoelastic body, all of the stresses, strains, and displacements occurring under load are time dependent. The elastic solid is then a limiting case of a viscoelastic material. The moduli of the springs of the rheological model do not correspond simply to Young's modulus because time, temperature, and stress dependence are overt considerations. If, for example, one considers a material tested in tension, the plot of the compliance would show that the ratio $\epsilon_x/-\epsilon_y$ varies with time. This time dependence indicates that the concept of Poisson ratios etc. are not very meaningful for a viscoelastic material.[19]

The linear elastic law (Hooke's law) in the form (III.1; see *Appendix III*) would render the four operators as multiplicative constants and the formulation of the stress deviation as[19]

$$\sigma_x = \frac{E}{(1 + \nu)(1 - 2\nu)}[(1 - \nu)\epsilon_x + \nu(\epsilon_y + \epsilon_z)] \tag{V.1}$$

The differential operators P and Q can be replaced by polynomials $\rho(s)$ and $\vartheta(s)$ in considering an elastic body, hence,[19]

$$\rho''(s)\bar{\sigma} = \vartheta''(s)\bar{\epsilon} \tag{V.2}$$

$$\rho'(s)\bar{\sigma} = \vartheta'(s)\bar{\epsilon} \tag{V.3}$$

where $\bar{\sigma}$ and $\bar{\epsilon}$ are the Laplace transforms of the time-dependent stresses and strains. These algebraic relations define the limits of their elastic counterparts if[19]

$$3K \rightarrow \frac{\vartheta''(s)}{\rho''(s)} \quad 2G \rightarrow \frac{\vartheta'(s)}{\rho'(s)} \tag{V.4}$$

$$E \rightarrow \frac{3\vartheta'\vartheta''}{2\rho'\vartheta'' + \vartheta'\rho''} \quad \nu \rightarrow \frac{\rho'\vartheta'' - \vartheta'\rho''}{2\rho'\vartheta'' + \vartheta'\rho''} \tag{V.5}$$

For a standard (three-parameter material), a reduced or effective modulus $E_R(t, \tau)$ offers estimates of an instantaneous $E_R(\tau_0,\tau_0)$ and an asymptotic modulus $E_R(\infty,\tau)$:[17]

$$E(\tau_0,\tau_0) = \frac{1}{E_1} \quad E(\infty,\tau_0) = \frac{E_1 E_2}{E_1 + E_2} \tag{V.6}$$

List of Symbols

$\dot{\epsilon}_0$	constant strain rate
$\dot{\epsilon}$	rate of strain
τ	interval within domain t, also designated $\eta/(E_1 + E_2)$
υ	Poisson's ratio
σ_∞	limiting stress during stress relaxation
$\Phi(t)$	creep function
$\epsilon(t)$	strain which varies with time
$\sigma(t)$	stress which varies with time
$\Psi(t)$	the relaxation modulus function, a viscoelastic operator
α, α_1, α_2	total distance of approach of two spheres, of each sphere designated 1 and 2
σ_f	stress at time corresponding to beginning of stress relaxation (strain rate = 0)
Δl	change in distance
ϵ_t	true strain
A	coefficient = $(E_1/E_1 + E_2)^2\eta\dot{\epsilon}_0$
a, $a(t)$	particle contact radius (radius of circular contact region) varying with time
E	elastic modulus
E_1, E_2, η	elastic moduli of the springs and viscosity coefficient of the dashpot of a standard rheological model
K, G	bulk, and shear modulus
$k_1 + k_2$	elastic constant term = $(1 - \upsilon^2)/\pi E$ upon substitution
l	length
l_0	original specimen length
$P(t)$	applied compressive force acting normal to the surface
p, $p(r,t)$	normal contact pressure which varies with contact radius and time
q, q_0	concentrated pressure, maximum pressure
r	distance from sphere center, x coordinate of point (r,z) of indenting sphere, $r \ll R$
R, R_1, R_2	radius of curvature, of the indenting spheres designated 1 and 2, respectively
t'	dummy time variable within interval t
t_f	time at which stress relaxation begins, total strain is held constant
w_1, w_2	deformation of sphere 1 and 2 owing to contact pressure
x, y, z	Cartesian coordinates
z_1, z_2	Cartesian coordinate projection of deforming surface points, designated 1 and 2

Accepted for publication October 2, 1998.

Abstract □ After intravenous administration of MK-826, a new carbapenem antibiotic, the compound exhibited nonlinear pharmacokinetics in rats and monkeys. In both species, time-averaged plasma clearance (based on total concentrations) increased about 5-fold over the 10- to 180-mg/kg dose range. MK-826 was extensively plasma protein bound in rat and monkey plasma, and the extent of binding was concentration dependent at plasma concentrations achieved after administration of these doses. Rosenthal analysis of the plasma protein binding indicated that there were two classes of binding sites. The binding capacity of the primary site was comparable to the plasma albumin concentration, which suggested that this primary site consisted of a single site on albumin. The extent of binding of MK-826 to rat albumin was similar to that in whole plasma. Clearance values based on unbound concentrations appeared independent of dose from 10 to 180 mg/kg, which is consistent with saturation of protein binding as the primary cause of the nonlinear pharmacokinetic behavior.

Introduction

MK-826 is a carbapenem antibiotic intended for the parenteral treatment of bacterial infections (see Figure 1).[1] Preliminary studies indicate that MK-826 is bound extensively to plasma proteins. Saturable plasma protein binding can lead to nonlinear pharmacokinetic behavior.[2,3] In the present studies, dose-dependent clearance of MK-826 was observed following intravenous (iv) administration to rats and monkeys. This clearance was explained by concentration-dependent protein binding to two different classes of plasma binding sites that probably reside on albumin.

Experimental Section

Synthesis—MK-826 (formula weight of monosodium salt, 497.4) was synthesized at Merck Research Laboratories (Rahway, NJ).

Animal Studies—Male Sprague–Dawley rats weighing 0.240 to 0.280 kg were purchased from Taconic Farms (Germantown, NY) and housed under standard conditions with free access to food and water. On the day prior to drug administration, a silicone rubber/polyethylene cannula was implanted in a jugular vein while the rats were under pentobarbital [40 mg/kg, intraperitoneally (ip)] anesthesia.[4]

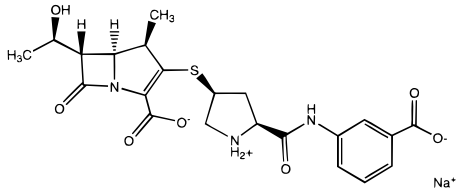

Figure 1—Chemical structure of MK-826.

Intravenous doses of MK-826 (monosodium salt dissolved in saline) of 10, 30, 60, and 180 mg/kg were administered by bolus injection into the jugular vein cannula to four rats per dose level. Male rhesus monkeys weighing 4.2 to 6 kg (Charles River, Key Lois, FL, $n = 4$) received the same dose levels as in the rat study, iv via a cephalic or saphenous vein. The rat study was of noncrossover design, but the monkeys received the MK-826 doses in a crossover fashion at least 1 week apart. Blood samples were drawn from rats before and 1, 3, 5, 15, and 30 min, and 1, 2, 3, and 4 h after the iv administration of MK-826. In the monkey studies, blood samples were obtained predose and at 5 and 30 min, and 1, 2, 4, 6, 12, 16, and 24 h post dose. Heparin was added to the blood samples to prevent clotting, and the resultant plasma was immediately frozen on dry ice. When stored at −70 °C, the compound was stable in plasma for at least 44 days; all assays were completed within that time.

Protein Binding—Protein binding of MK-826 was measured in triplicate in rat and monkey plasma by ultrafiltration over the 10- to 2000-μg/mL concentration range as previously described.[5] This range includes the concentrations observed in vivo; after the administration of the a 180-mg/kg dose to rats and monkeys, the concentration in plasma at the initial sampling time was about 1000 μg/mL. Briefly, stock solutions of MK-826 in water were added to freshly drawn plasma (pH 7.4) at 1% of total volume. After incubation at 37 °C for 10 min, aliquots of plasma were transferred to ultrafiltration devices (30 000 molecular weight cutoff; Centrifree, Amicon, Danvers, MA) and centrifuged at 1500 x g for 15 min. The binding of MK-826 to albumin was assessed similarly using solutions of rat (fraction V, fatty acid free) and rhesus (fraction V, not fatty acid free, Sigma) albumin (40 mg/mL). Concentrations of MK-826 in plasma and ultrafiltrate were determined by a liquid chromatographic method. A preliminary study showed that nonspecific binding of MK-826 to the ultrafiltration device was minor (<4%).

The binding capacity and association constants were estimated by fitting the protein binding data to the following equation that describes two classes of sites:

$$\frac{B}{U} = \frac{n_1P_1 \times K_1}{1 + K_1 \times U} + \frac{n_2P_2 \times K_2}{1 + K_2 \times U} \quad (1)$$

where B and U are the concentration of bound and unbound MK-826; n_1P_1 and n_2P_2 are the binding capacities or concentrations of

[a] Shown as the mean (SD) of $n = 4$ per group. Dose-normalized AUC, *CL*, and terminal $t_{1/2}$ were evaluated by one-way ANOVA and Tukey's multiple comparison test. Values bearing the same superscript were judged to be different at $p < 0.05$. Abbreviations: AUC, area under the concentration–time curve from time 0 to infinity; *CL*, time-averaged plasma clearance. Values for half-lives are harmonic mean. Standard deviation was calculated using the jackknife method.[10]

the first and second classes of binding sites, respectively; and K_1 and K_2 are the association constants for the first and second classes of binding, respectively.[6] This analysis assumes that the classes of binding sites are mutually independent. The nonlinear regression analysis was performed with the RS/1 computer program (version 4.2, BBN Software) using a weighting factor of $1/y^2$.

Pharmacokinetic Analysis—Because of blood sample volume constraints, unbound concentrations were calculated from total concentrations in plasma (measured in vivo after administration of MK-826) using the binding capacities and association constants for the binding of MK-826 to plasma proteins. The relationship between bound and unbound concentrations for two classes of binding sites is described by

$$B = \frac{n_1P_1 \times K_1 \times U}{1 + K_1 \times U} + \frac{n_2P_2 \times K_2 \times U}{1 + K_2 \times U} \quad (2)$$

Substitution for bound concentration (Bound = Total − Unbound) permits calculation of unbound concentrations from total concentrations. In this study, $K_2 \times U \ll 1$, so eq 2 reduces to

$$(n_2P_2 \times K_2 \times K_1 + K_1) \times U^2 + (n_1P_1 \times K_1 + n_2P_2 \times K_2 - T \times K_1 + 1) \times U - T = 0 \quad (3)$$

which is a quadratic equation with one positive solution for unbound concentration. This equation for calculating the unbound concentrations for a drug that has two classes of binding sites is similar to that reported previously for a drug with single binding site.[2]

The terminal $t_{1/2}$ of MK-826 was determined by linear regression of the log-linear portion of the plasma concentration—time profile. Clearance (*CL*), based on either total or unbound plasma concentrations, was calculated as

$$CL = \text{Dose/AUC} \quad (4)$$

where AUC is the area under the curve from time zero to infinity. Clearance based on total concentration was shown to be dose-dependent, so these are time-averaged values. The standard method of calculating the volume of distribution at steady state (Vd_{ss}) based on total drug concentrations is invalid when nonlinear protein binding exists because it overestimates the steady-state distribution volume of total drug.[7,8] However, a corrected distribution volume $\overline{Vd^{t}_{ss}}$ may be calculated that theoretically better reflects the distribution volume of total drug at steady state:[8]

$$\overline{Vd^{t}_{ss}} = \overline{f_p} \times \overline{Vd^{n}_{ss}} \quad (5)$$

where $\overline{f_p}$ corresponds to the area-weighted average fraction unbound in the plasma[7] and $\overline{Vd^{u}_{ss}}$ is the steady-state distribution volume for unbound drug calculated by the standard method from the unbound concentrations.[7,8]

Liquid Chromatographic Method for MK-826—Plasma concentrations of MK-826 were measured by a direct-injection, column-switching method with UV absorption detection at 298 nm. Briefly, two columns connected by a switching valve provided automated sample cleanup and analysis; the columns were a Phenomenex (Torrance, CA) C18 Maxil-10 extraction column (50 × 4.6 mm) and a Whatman (Clifton, NJ) C18 Partisphere analytical column (125 × 4.6 mm). Plasma, buffered by the addition of one volume of 1 M 2-[*N*-morpholino]ethanesulfonate (pH 6.5) buffer, was injected directly onto the extraction column. Endogenous interfering components were diverted to waste for 5 min, and then from 5 to 10 min the mobile phase was switched to transfer MK-826 from the extraction column to the analytical column. Mobile phase for the extraction column consisted of 0.025 M sodium phosphate (pH 6.5) buffer at a flow rate of 2 mL/min. The analytical mobile phase consisted of the preceding buffer and acetonitrile (95/5, v/v) at a flow rate of 2 mL/min. Under these conditions, the retention time of MK-826 was 12 min. Replicate analysis of calibration standards and spiked quality control samples ($n = 5$ per concentration) indicated that the method provided >90% accuracy and variability of <10% over the 0.1- to 100-μg/mL concentration range.

Statistical Analysis—One-way analysis of variance (ANOVA) was used to assess the effect of dose on pharmacokinetic parameters. A log transformation of data was made when unequal variances across dose levels were detected. Differences between dose levels were evaluated using the Tukey multiple comparison test.[9]

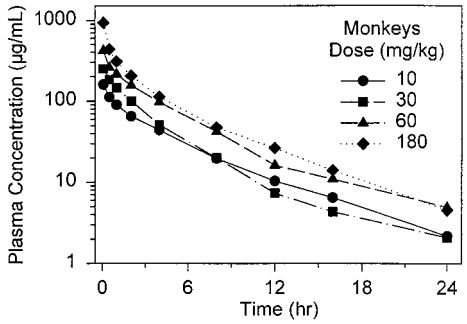

Figure 2—Mean plasma concentrations of MK-826 in rhesus monkeys after iv administration of 10 to 180 mg/kg.

Table 2—Binding Capacities and Association Constants for the Protein Binding of MK-826 in Rat and Monkey Plasma[a]

rat	2.89×10^{-4}	9.07×10^{4}	8.50×10^{-3}	2.17×10^{2}
monkey	6.52×10^{-4}	11.5×10^{4}	1.36×10^{-3}	1.37×10^{2}

[a] Symbols: n_1P_1 and n_2P_2 are the binding capacities or concentrations of the first and second class of binding sites, respectively; K_1 and K_2 are the association constants for the primary and secondary classes of binding sites, respectively.

Results and Discussion

Following the iv administration of MK-826 to rats, plasma concentrations increased less than dose-proportionally, as shown by the dose-normalized AUC that decreased with dose (Table 1). Over this 18-fold range of doses, the dose-normalized AUC decreased by 5- to 6-fold. This decrease was due to a 5-fold increase in the time-averaged plasma clearance. A similar dose-dependent trend was observed in monkeys. Because for drugs with a low extraction ratio the plasma clearance is proportional to the

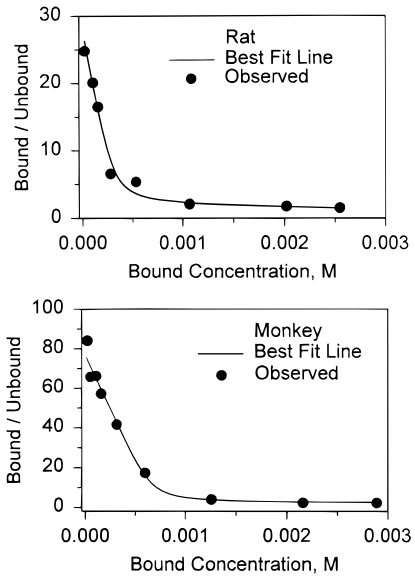

Figure 3—Rosenthal analysis of the protein binding of MK-826 in rat and monkey plasma.

unbound fraction in plasma, the concentration dependence of plasma protein binding was examined as a potential mechanism for the nonlinear clearance.

MK-826 was bound extensively to rat and monkey plasma proteins and the extent of protein binding was concentration dependent. In rat plasma, the unbound fraction was ca. 4% and remained constant up to 75 μg/mL; however, the unbound fraction increased to 40% at 2000 μg/mL. In monkey plasma, the unbound fraction in the linear range was 1.5% and then increased to 32% at 2000 μg/mL. The nonlinear binding range extended to concentrations achieved in the dose proportionality study (Figure 2). Rosenthal plots of the bound/unbound concentration ratio versus bound concentration were biphasic, consistent with two different classes of binding sites (Figure 3). When the data were fit to the equation describing two classes of binding sites, there was good agreement between the theoretical and observed values (the residual errors were ≤11% and there was no systematic deviation between the observed and calculated values). The binding capacities of the primary binding sites (n_1P_1) in rat and monkey plasma were 289 and 652 μM, respectively (Table 2), values which are comparable to physiological albumin concentrations.[11] Binding capacity is the product of the number of binding sites per protein molecule times the protein concentration, so this similarity implied that the higher affinity binding was to a single site on albumin. The binding of MK-826 (25 μg/mL) to rat albumin was assessed directly and found to be extensive (2.0 ± 0.1% unbound fraction, $n = 3$). Binding of MK-826 to monkey albumin also was extensive, however, the unbound fraction was higher than the free fraction in plasma (18 ± 0.5% versus 1.5 ± 0.2%). The reason for this result is unknown but could be due to the presence of endogenous competitive displacers, such as fatty acids, that form during the isolation of albumin.

Pharmacokinetic parameters based on unbound concentrations would be independent of dose if saturation of plasma protein binding was the primary cause of the dose-dependent plasma clearance. Determination of the association constants and binding capacities for the plasma protein binding permitted the calculation of unbound pharmacokinetic parameters from total plasma concentrations. In rats, dose-normalized AUC and clearance based on calculated unbound concentrations in plasma appeared independent of dose, confirming that the concentration-dependent plasma protein binding was the primary cause of the nonlinear plasma clearance (Table 3). The unbound clearance in rats was very high (110−159 mL/min/kg) and exceeded hepatic blood flow. However, preliminary studies in rats indicate that dehydropeptidase-I, an enzyme that is present in highest concentration in rodent lungs and kidneys, is important to the clearance of MK-826 in this species (data not shown). Kinetic analysis of unbound concentrations showed similar results in monkeys over the dose range examined, although the unbound clearance at 30 mg/kg appeared slightly higher than in the other dose groups. During the initial period after administration of MK-826 (30 min in mice and 4 h in monkeys after 180 mg/kg), the unbound fraction in the nonlinear dose range was increased because the concentrations achieved saturated the primary albumin binding site. Clearance based on total concentrations increased because of the higher unbound fraction available for elimination.

Despite the dose-dependent plasma clearance, terminal half-life was dose independent because this parameter reflected decline during a period when concentrations were within the linear protein binding range. The calculated steady-state distribution volume (Vd_{ss}^{t}), corrected for the nonlinear protein binding, was relatively unchanged with dose (ranges of means across the dose levels were 145−151 and 84−122 mL/kg in rats monkeys, respectively). This result suggested that despite the saturation of plasma protein binding, the net shift of MK-826 out of the plasma into the tissues was minor.

In summary, the dose-dependent increases in plasma clearance of MK-826 in rats and monkeys were shown to be the result of concentration-dependent plasma protein binding. Initial clinical studies suggest that after high doses of MK-826, the AUC in plasma also increases less than dose proportionally.[12]

Abstract □ The effects of various classes of additives on the stability of a protein with a relatively hydrophobic surface, *Humicola lanuginosa* lipase (HLL), during lyophilization and storage in the dried solid, were investigated. Prior to lyophilization, it was found that 1 M trehalose or 1% (wt/vol) Tween 20 caused the protein to precipitate. Infrared spectroscopy indicated that trehalose "salted-out" native HLL, whereas Tween 20 induced non-native aggregates. Optimal recovery of native protein in the initial dried solid was obtained in the presence of additives which formed an amorphous phase and which had the capacity to hydrogen bond to the dried protein (e.g., trehalose and sucrose). Additives which crystallized during lyophilization (e.g., mannitol) or which remained amorphous, but were unable to hydrogen bond to the dried protein (e.g., dextran), afforded less stabilization relative to that seen in the absence of additives. Optimal storage stability in the dried solid required that both protein unfolding during lyophilization was minimized and that the formulation was stored at a temperature below its T_g value. Crystallization of sucrose during storage greatly reduced the storage stability of HLL. This was attributed to the increased moisture content and the reduced T_g value in the remaining amorphous phase containing the protein. Sucrose crystallization and the resulting damage to the protein were inhibited by decreasing the mass ratio of sucrose:protein.

Introduction

Mechanisms that are proposed to account for stabilization of proteins acutely during lyophilization and long-term during storage in the dried solid are based mainly upon studies using globular proteins with a typical hydrophilic surface. It has been found that, in addition to formation of an amorphous phase in the dried solid, the ability of the additive to hydrogen bond to the dried protein and thus act as a water substitute also is required for optimal protection of a protein during the lyophilization process.[1] Furthermore, it has been found that long-term storage stability depends on two factors: (1) formation of a an amorphous phase containing protein and additive and maintenance of the formulation glass transition temperature (T_g) above the storage temperature, and (2) preservation of native, aqueous protein secondary structure during lyophilization.[2−4]

To determine if the same mechanisms may account for stabilization of a soluble, globular protein which has a much more hydrophobic surface than proteins typically studied, the current study investigates the effects of additives with selected properties on the acute and long-term stability of lyophilized *Humicola lanuginosa* lipase (HLL). HLL is a well-characterized protein[5,6] that has a predominantly hydrophobic surface exposed to the solvent, as determined by hydrophobicity plots.[7] HLL is used as an

enzymatic detergent additive[8] and has shown potential as a therapeutic protein for exocrine pancreatic insufficiencies.[9] The additives tested were mannitol, dextran, trehalose, and sucrose.

Sugars are often used to stabilize proteins during lyophilization and during subsequent storage in the dried solid. However, similar to other reports,[10−12] we have recently observed that crystallization of a sugar from the amorphous state during storage can drastically reduce protein storage stability.[2] Crystallization of amorphous sugars is usually only observed on a reasonable time scale of weeks to months during storage at temperatures close to or above the formulation T_g value.[13] Crystallization can be due to increased moisture contents (e.g., because of moisture transfer from the vial stopper to the dried formulation)[14,15] or simply due to prolonged storage.[16] Recently, it has been shown that proteins, at an adequately high protein:sugar mass ratio, are able to prevent crystallization of either sucrose[17] or trehalose[18] from the dried solid. However, since the T_g value of sucrose is much lower than that of trehalose at similar moisture contents,[19,20] it is expected that sucrose may crystallize at lower temperatures than trehalose. Thus, another objective of the current study is to determine the effects of varying protein: sugar mass ratios on the capacity of HLL to inhibit crystallization of sucrose or trehalose during storage.

In addition to issues involving sugar crystallization, it is generally of interest to investigate the relative stabilizing effects of sucrose or trehalose on the acute and long-term stability of proteins. This topic has been the subject of many publications.[12,19−21] Trehalose has been shown to provide improved storage stability at high storage temperatures to proteins[2,22] and to liposomes[20] compared to that provided by sucrose. However, no study to date has addressed the relative effectiveness of the disaccharides as stabilizers for a protein with a relatively hydrophobic surface, such as HLL.

Materials and Methods

Materials—Recombinant *Humicola lanuginosa* lipase (HLL), expressed in *Aspergillus oryzae*,[5] was a kind gift from Novo Nordisk A/S (Bagsværd, Denmark). The protein was obtained as a lyophilized, additive-free powder containing >95% HLL (by activity assay). Potassium phosphate, mannitol, dextran (*Leuconostoc mesenteroides*, Strain no. B-512, Average MW 162 kDa) and poly(oxyethylene) sorbitan monolaurate (Tween 20) were obtained from Sigma Chemical Co. (St. Louis, MO). Sucrose and trehalose were purchased from Pfanstiehl Laboratories (Waukegan, IL). All other chemicals and reagents were obtained from Sigma Chemical Co. (St. Louis, MO), except as indicated below.

Formulation Preparation—HLL was dissolved in 10 mM potassium phosphate buffer (pH 10, at 23 °C) at 4 mg/mL ($E_{280\ nm}$ (1%) = 14.68)[6] and mixed in a 1:1 (vol:vol) ratio with the respective additive solutions (prepared at twice the desired concentration using phosphate buffer) to obtain a final HLL concentration of 2 mg/mL and the final desired additive concentration. Formulations were subsequently aliquotted (1.0 mL) into 5 mL lyophilization vials (21 mm ID) (West Company, Lionsville, PA).

Lyophilization—The protein formulations were lyophilized in a FTS Durastop μP microprocessor controlled freeze-drier (Stoneridge, NY) as previously described.[2] After drying was complete, the vials were capped under vacuum using butyl stoppers from the West Company (formulation no. 4416) (Lionsville, PA). None of the formulations showed any evidence of cake collapse following lyophilization.

Storage Studies—Following lyophilization, vials were incubated at 40 or 60 °C and analyzed following 0, 14 days, 1 and 3 months. Control formulations were stored at −80 °C and analyzed following 3 months. Following storage, formulations were rehydrated to 1 mg/mL HLL with deionized, distilled water and filtered to remove insoluble aggregates, and the filtrate was analyzed as described below. Triplicate vials from each formulation were assayed at each time point. No differences were seen between formulations assayed at $t = 0$ and the control formulations stored at −80 °C (results not shown).

Analytical Methods—*Size exclusion high performance liquid chromatography (HPLC-SEC)* was performed by using a Dionex HPLC (Sunnyvale, CA) equipped with a GP40 gradient pump and an AD20 detector, using a detection wavelength of 215 nm. The amount of native, monomeric protein molecules and non-native soluble aggregates were quantitated using a Zorbax G250 column (MACMOD Analytical Inc., Chadds Ford, PA) eluted with 1 M sodium phosphate in phosphate-buffered saline solution (120 mM sodium chloride, 2.7 mM potassium chloride, 10 mM monobasic potassium phosphate; pH 7.4, at 23 °C) at a flow rate of 1.0 mL/min. Between 1 and 20 μg of protein were injected onto the column. The masses of native, monomeric HLL and soluble aggregates were calculated based on peak areas eluting at 11.2 min and between 9.1 and 11.0 min, respectively. Results were expressed as percentage of the native, monomeric protein mass present in solution prior to freeze-drying.

The amount of the protein-forming insoluble aggregates was calculated and reported as previously described.[2] To test whether protein could also be lost from solution due to adsorption to the vial or stopper during lyophilization and rehydration, the total protein content was estimated by a Bradford assay using bicinchoninic acid (BCA) (Pierce, Rockford, IL) as a reagent. For all preparations, 100% of the protein was recovered in the rehydrated formulations (data not shown), indicating that minimal protein was lost due to adsorption to surfaces.

HLL Activity Assay—HLL activity was assessed by the ability of the protein to hydrolyze tributyrin according to a slightly modified method originally described by Holmquist et al.[5,6] The amount of sodium hydroxide (Merck, Damstadt, Germany) required to neutralize hydrolyzed tributyrin (Merck, Damstadt, Germany) was monitored as a function of time employing a pH-stat titrator. The substrate solution (pH 7, at 30 °C) containing tributyrin (0.159 M) and gum arabic (0.094%, wt/vol) in water was emulsified using a blender for 20 s and subsequently stirred using a magnetic stir plate for 20−30 min. The HLL formulations were dissolved in 0.01 M glycine (Merck, Damstadt, Germany) (pH 10.6, at 23 °C) to yield a final concentration of approximately 1 mg/mL. The reaction was started by the addition of HLL solution to a stirred, thermostated (30 °C) substrate solution. The pH was maintained automatically with sodium hydroxide (0.05−0.1 M) using a Titralab 90 (Radiometer, Copenhagen, Denmark) equipped with an ABU900 autoburet (Radiometer, Copenhagen, Denmark) connected to a Titration Manager TIM900 (Radiometer, Copenhagen, Denmark). The amount of base required to maintain pH at 7.0 during 5 min of titration was recorded and used to calculate the hydrolytic activity of a given HLL formulation. Results are reported as mean values (± standard deviation) of three vials assayed in duplicate.

The enzymatic activity of HLL in solution prior to lyophilization was not determined. However, acute recovery of enzymatic activity in the lyophilized and rehydrated formulations averaged 97% ± 5% compared to a standard solution of freshly prepared HLL (1 mg/mL), and this value was therefore used as initial recovery of enzymatic activity at $t = 0$.

Karl Fisher Moisture Analysis—The relative amount of moisture was determined by preparing samples in a dry nitrogen purged glovebox and assaying for water content using a Mettler DL37 KF coulometer (Hightstown, NJ) as previously described,[2] except that slightly larger aliquots (2−5 mL) of a 1:1 (vol:vol) methanol: formamide mixture were used to dissolve the dried formulations compared to that previously used (1 mL aliquots).

X-ray Diffraction—X-ray powder diffraction was recorded with a Guinier powder diffraction camera, XDC-700 (Incentive Research & Development AB), using Cr $K\alpha_1$ (l = 2.290 Å) radiation. Small amounts of dried solid (5−10 mg) was placed in a sample disk, and the sample was subjected to radiation for approximately 30−45 min. The film was developed, and crystallization was detected as distinct band patterns characteristic for the crystallized material (sucrose).

Sodium dodecyl lauryl sulfate polyacrylamide gel electrophoresis (SDS−PAGE), using nonreduced and reduced samples, was performed as previously described.[2] The gels showed a faint band corresponding to the molecular weight of a dimer in all stored and rehydrated formulations which had more than 20% soluble aggregates, as determined by size-exclusion chromatography (data

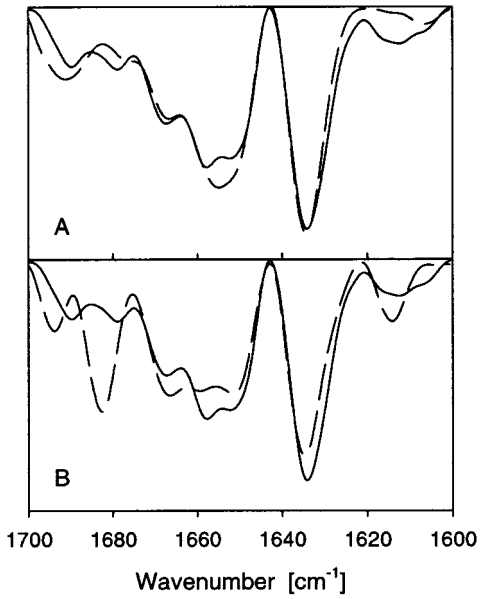

Figure 1—Area-normalized, second derivative infrared amide I spectra of native, aqueous HLL in buffer alone (10 mM phosphate buffer, pH 10, at 23 °C) (—) and of HLL precipitate (---) induced by 1 M trehalose (A) or 1% (wt/vol) Tween 20 (B).

not shown). The band was present in both nonreduced and reduced samples assayed by SDS−PAGE, indicating that the covalently bonded dimer is formed by mechanisms other than disulfide scrambling. No bands corresponding to low molecular weight fragmentation products were observed (not shown).

Infrared (IR) Spectroscopy—Infrared spectra of liquid and dried HLL formulations were recorded at 23 °C using a Nicolet Magna 550 infrared spectrometer (Madison, WI) as previously described.[2] Spectra were processed according to previously established criteria.[23]

Differential scanning calorimetric (DSC) analysis was also conducted as previously described[2] using a Perkin-Elmer DSC-7 (Norwalk, CT). Briefly, samples were heated at 10 °C/min to a final temperature of 180 °C. Selected samples were then cooled and reheated to 50−100 °C above the glass transition temperature to ensure reversibility of the glass transition. The degree of crystallinity of PEG or mannitol was calculated by dividing the enthalpy per gram of PEG or mannitol in an experimental formulation by the value obtained for the respective reference material and multiplying the result by 100.[2] Reference materials were taken from the supplier's bottle (Sigma Chemical Co., St. Louis, MO).

Results and Discussion

Effect of Additives on Secondary Structure in Solution—To determine if the presence of an additive induced secondary structural changes in HLL prior to lyophilization, protein infrared spectra in the conformationally sensitive amide I region were compared. The second derivative spectrum for the protein prepared in buffer alone is shown in Figure 1. The component bands can be assigned as follows:[24] bands at 1631, 1635, and 1689 cm^{-1} are due to β-sheet, the band at 1649 cm^{-1} is due to random elements, the band at 1657 cm^{-1} is due to α-helix, and the bands at 1668 and 1679 cm^{-1} are often assigned to turn structures. The spectra for the protein prepared in the presence of 1 M sucrose, 0.5 M mannitol, or 5% (wt/vol) dextran were essentially identical to that for the protein in buffer alone (data not shown). Thus, these additives do not alter the secondary structure of the protein in solution.

However, unexpectedly, in the presence of 1 M trehalose or 1% (wt/vol) Tween 20, the protein formed a white precipitate. Such behavior has not been reported previously in several studies of more typical globular proteins with relatively hydrophilic surfaces and may thus be attributed to the surface hydrophobicity of HLL. To gain insight into the process causing precipitation, we used infrared spectroscopy to study the protein secondary structure. The spectrum for the precipitate formed in 1 M trehalose was very similar to that for native, soluble protein, indicating that precipitation did not alter protein secondary structure (Figure 1A). Diluting the solution with buffer caused the precipitate to dissolve completely (data not shown). Thus, it appears that trehalose can "salt-out" HLL. Reversible precipitation and retention of native protein secondary structure in precipitates have previously been noted for interferon-γ salted-out with PEG,[25] and for lactate dehydrogenase, chymotrypsinogen, bovine serum albumin, and insulin salted-out with poloxamer.[26]

Salting-out of proteins by additives can be explained by the Timasheff preferential exclusion mechanism. The salting-out agents are preferentially excluded from the protein surface, which increases protein chemical potential and reduces solubility.[27] Interestingly, HLL remained soluble in 1 M sucrose but was salted-out with 1 M trehalose. Sucrose and trehalose have both been shown to be preferentially excluded to a similar degree from the surface of ribonuclease A, a protein with a more typical predominantly hydrophilic surface.[27,28]

The preferential interactions of sugars with a protein with a more hydrophobic surface such as HLL have not been studied. However, trehalose has been found to interact less favorably with poly(ethylene glycol) (PEG) than does sucrose.[29] PEG attains a more hydrophobic surface at higher temperatures due to conformational alterations.[30] Izutsu and colleagues found that trehalose depressed the cloud point of PEG (i.e., the temperature above which PEG separates as a precipitate from an aqueous solution) to a greater degree than sucrose. The lower solubility of PEG in the presence of trehalose is thought to be due to a greater repulsion between PEG and trehalose than between PEG and sucrose.[29] In turn, this difference has been attributed to differences between sucrose and trehalose stereochemistry.[30,31] That of trehalose fosters a larger volume of hydration and thus a more favorable interaction with water and a less favorable interaction with apolar molecules. Therefore, trehalose is expected to interact less favorably with hydrophobic molecules such as PEG or HLL than does sucrose.

Contrary to the trehalose-induced precipitate, the precipitate induced by Tween 20 did not dissolve upon dilution in buffer (data not shown), and the infrared spectrum of the protein precipitate was substantially altered compared to that of native HLL (Figure 1B). The presence of large infrared bands at 1614 and 1696 cm^{-1} are due to an intermolecular β-sheet,[32,33] suggesting that the precipitated protein was composed of non-native aggregates. Aggregation via the formation of non-native β-sheet structure is commonly seen for proteins under denaturing conditions such as high temperature, extremes in pH, or the presence of chaotrophs such as urea, guanidine hydrochloride, or thiocyanate.[32,33] Thus, in contrast to the "salting-out" noted in the presence of trehalose, Tween 20 alters the native conformation to a sufficient degree that the non-native molecules form intermolecular contacts and precipitate. Interaction of HLL with the Tween 20 micelle−water interface and/or direct binding of Tween 20 to the protein's surface may be responsible for perturbation of the native protein structure. For proteins with a more typical hydrophilic surface such as Factor XIII[2] and subtilisin,[34] Tween 20 does not alter the native structure of the protein.

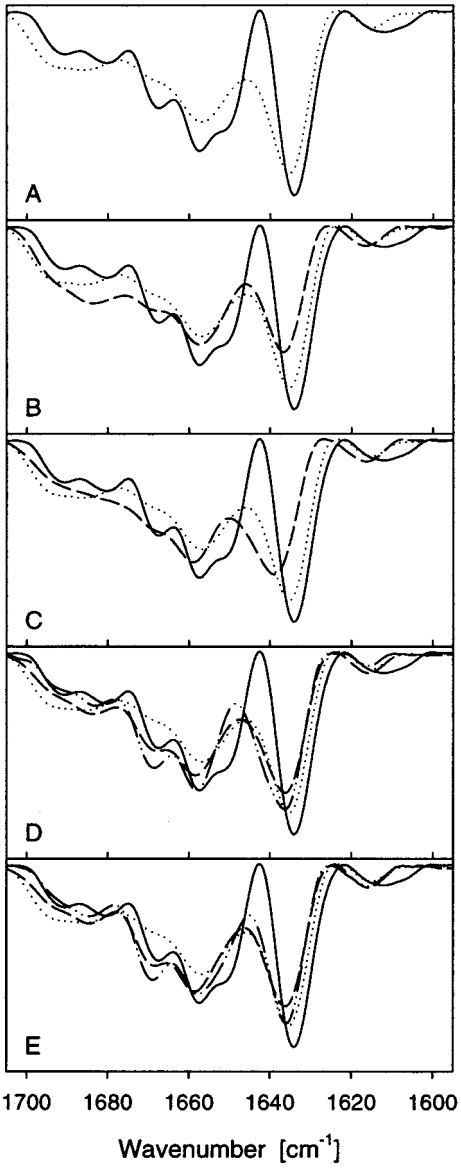

Figure 2—Area-normalized second derivative infrared amide I spectra of HLL in the native, aqueous state (—) and when lyophilized in the absence of additives (•••), or in the presence of additives (---): No additives (A), 300 mM mannitol (B), 5% (wt/vol) dextran (C), 50 mM (---) or 300 mM (–••–) trehalose (D), or 50 mM (---) or 300 mM (–••–) sucrose (E).

Thus, it appears that the effects of additives on the structure and solubility of the hydrophobic protein HLL in aqueous solution are quite different from those noted with more typical soluble, globular proteins that have a more hydrophilic surface exposed to the solvent. The next question we addressed is whether different behaviors also are manifested during the lyophilization process.

Acute Stability during Freeze-Drying and Rehydration—To assess initially the effects of freeze-drying, HLL was lyophilized in the absence of additives. Figure 2A shows that the infrared spectrum of the dried protein was substantially altered relative to that of the native, aqueous protein. In general, the components bands in the amide I region for the spectrum of the dried protein appeared broader and had decreased resolution. This is typical of many lyophilized proteins.[2,35] In addition, there was a decrease in absorbance of the bands at 1635, 1649, 1657, and 1668 cm^{-1} which was compensated for by an increase in absorbance at 1645 cm^{-1} and in the region from 1684 to 1694 cm^{-1} (Figure 2A). Together, these changes indicated that HLL was unfolded in the dried solid. Upon rehydration, however, 100% native, monomeric protein was recovered (Table 1). Thus, it appeared that refolding of HLL was favored over aggregation during rehydration.[35]

Table 1—Lyophilized Formulation Characteristics

formulation	% native monomer[a]	glassy[b]	T_g,[b] °C	% moisture[a]
no additives	100 ± 0.5	yes	nd[c]	<0.5
300 mM mannitol	93 ± 1.8	no	na[d]	1.3 ± 0.5
5% (wt/vol) dextran	96 ± 1.8	yes	nd[c]	0.6 ± 0.3
50 mM trehalose	98 ± 1.6	yes	95	0.9 ± 0.7
300 mM trehalose	95 ± 1.2	yes	100	0.5 ± 0.1
50 mM sucrose	102 ± 1.2	yes	70	1.0 ± 0.5
300 mM sucrose	99 ± 0.3	yes	70	1.2 ± 0.6

[a] Values are reported as mean of three vials from each formulation (±standard deviation). Native, monomer recovery was determined by size exclusion chromatography. Moisture content was determined by Karl Fisher titration and reported as % (g H_2O/100 g dried solid). [b] Determined by differential scanning calorimetry (see Methods). [c] nd = no glass transition detectable. Previous literature[42,43] indicates that the T_g may be above the highest storage temperature (60 °C). [d] na = not applicable, mainly crystalline material.

To determine if the water replacement mechanism shown to account for protection of more hydrophilic proteins during lyophilization[2–4] also accounts for protection of more hydrophobic proteins, HLL was lyophilized in the presence of representative additives, which previously have been shown to (1) remain amorphous and hydrogen bond to the dried protein (trehalose or sucrose),[1] (2) fail to protect due to crystallization (mannitol),[10] or (3) remain amorphous, but fail to protect the protein because steric hindrance eliminates effective hydrogen bonding to the dried protein (dextran).[36]

The second derivative amide I infrared spectra for the protein dried with 300 mM mannitol or 5% (wt/vol) dextran were more perturbed than that for HLL lyophilized without additives (Figure 2B,C). There was a further decrease in absorbance at 1635 cm^{-1} and greater band broadening. In addition, the recovery of native, monomeric protein was slightly less with mannitol than that noted for the protein lyophilized without additives (Table 1). Dextran had little effect on the recovery of native, monomeric protein (Table 1).

Differential scanning calorimetric analysis (see Methods) documented that 85% of the mannitol mass was crystallized in the dried solid (not shown). Apparently the remaining 15% of mannitol, corresponding to a 4:1 mass ratio of mannitol:HLL, did not afford protection to the protein during lyophilization. This is consistent with results observed for more hydrophilic proteins.[2,10]

In contrast, differential scanning calorimetry showed that dextran was completely amorphous in the dried solid containing HLL (data not shown). The failure of amorphous dextran to inhibit protein unfolding may be due to steric hindrance making it unable to hydrogen bond with the dried protein. In addition, potential separation of dextran and protein into separate dextran-rich and protein-rich amorphous phases[37] could have caused greater damage to the protein during lyophilization.

Finally, the effects of sucrose and trehalose were tested. Both disaccharides formed amorphous phases (Table 1) during lyophilization and are known to have the ability to hydrogen bond to the protein during dehydration.[1,35] Infrared spectra of HLL lyophilized in the presence of either concentration (50 or 300 mM) of trehalose (Figure 2D) or sucrose (Figure 2E) were more nativelike than those of HLL lyophilized without additives (Figure 2A). The bands near 1648, 1657, and 1668 cm^{-1} were better resolved, and the absorbance in the region from 1684 to 1694 cm^{-1}

was reduced to a level more closely resembling that seen in the spectrum of the native, aqueous protein (Figure 2D,E). The spectrum of HLL lyophilized with sucrose (Figure 2E) had slightly less broadening of the 1635 cm^{-1} band compared to that seen in the spectrum of HLL lyophilized with trehalose (Figure 2D), suggesting that structural preservation by sucrose was somewhat better than that by trehalose. Thus, despite the less favorable interaction between HLL and trehalose than between HLL and sucrose in aqueous solution, similar levels of structural protection are noted during freezing-drying and rehydration. Also, slightly better band resolution was achieved in spectra of HLL lyophilized in the presence of 300 mM disaccharide compared to formulations prepared in 50 mM disaccharide (Figure 2D,E). Preliminary studies showed band resolution in the spectra of the dried protein increased when HLL was lyophilized with increasing disaccharide concentrations ranging from 10 to 300 mM (unpublished results). Finally, more than 95% of native, monomeric protein was recovered after rehydration of HLL formulations lyophilized with either disaccharide (Table 1). Taken together, these results indicate that sucrose and trehalose are far superior to mannitol and dextran at inhibiting lyophilization-induced unfolding of HLL.

Long-Term Storage Stability—It has been proposed that storage stability of a protein in the dried solid only depends on using an amorphous additive and on maintaining the formulation at a temperature below its T_g value.[38] However, in the only three published studies (with interleukin-1 receptor antagonist, Factor XIII, and interleukin-2), in which both protein structure and glass transition temperature of the dried solid have been determined,[2–4] it was found that long-term stability of a protein in the dried solid depended both on minimizing protein unfolding during the lyophilization process as well as on storage at a temperature below the formulation T_g value. If the only requirement for storage stability of HLL is that formulations must be stored in the amorphous solid at temperatures below the T_g value,[38] then formulations containing either dextran, trehalose, or sucrose should show optimal stability (Table 1). If, in addition, preservation of native structure in the dried solid is also important,[2–4] then only trehalose and sucrose should provide optimal stability (Figure 2).

However, storage stability of a dried protein may also be compromised if the sugar additive crystallizes during storage.[11,12] Sugar crystallization usually occurs at temperatures close to or above the formulation T_g value and can be minimized by increasing the mass ratio of protein to sugar.[17,18] Since the initial T_g values of the trehalose containing HLL formulations were 25–30 °C higher than those of the sucrose-containing formulations (Table 1), it would be expected that during storage at 40 and 60 °C, HLL formulations containing sucrose (especially at the higher initial sucrose concentration) would be more prone to sugar crystallization than those containing trehalose.

HLL was stored without additives to assess the storage stability of the protein alone. The additive-free formulation had a residual moisture level of less than 0.5% (g H_2O/g dried solid) (Table 1). Similar to what has been observed for other proteins,[2,17] a glass transition for the HLL formulation was not discernible by differential scanning calorimetric analysis (data not shown). The glass transition temperature of dried HLL was probably well above either storage temperature, since dried protein T_g values have been estimated to be between 100 and 200 °C.[39] Thus, if storage in the amorphous solid at temperatures below the T_g value was the only important factor accounting for long-term storage stability of the hydrophobic protein, it would be expected that HLL without additives would exhibit good storage stability.

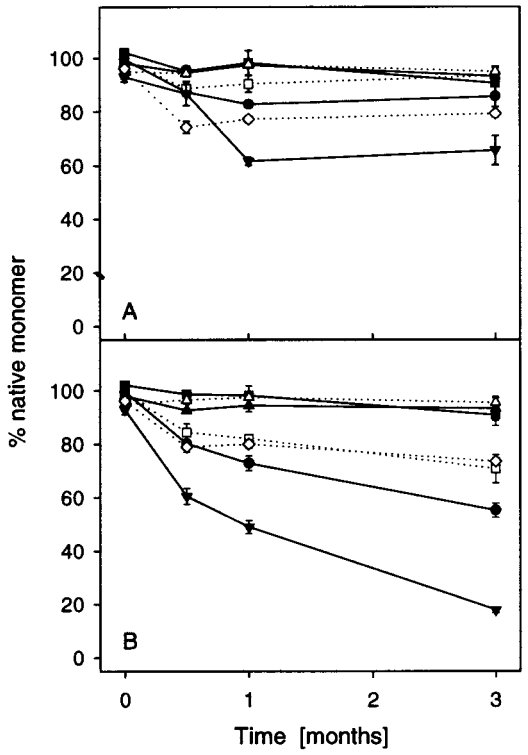

Figure 3—Recovery of native, monomeric HLL as a function of time as determined by size exclusion chromatography. The recovery was determined as the percentage of native, monomeric protein relative to that present in solution prior to lyophilization. Formulations were stored at 40 °C (A) or 60 °C (B) in the absence of additives (solid circle) or in the presence 300 mM mannitol (solid triangle, down), 5% (wt/vol) dextran (open diamond), 50 mM trehalose (solid triangle, up), 300 mM trehalose, (open triangle, up), 50 mM sucrose (solid square), or 300 mM sucrose (open square). Each data point represents the mean of 3 vials ± standard deviation.

Following rehydration of the formulation, which had been stored for 14 days at either 40 and 60 °C, loss of native, monomeric HLL (Figure 3) was seen. This was mainly due to formation of insoluble aggregates in the formulation stored at 40 °C (Figure 5A) and formation of approximately equal amounts of soluble and insoluble aggregates at 60 °C (Figures 4B, 5B). Larger effects were noted in the formulation stored at 60 °C than at 40 °C (Figures 3–6). There was a much larger loss of hydrolytic activity (Figure 6) compared to loss of native, monomeric protein (Figure 3) after 3 months storage. This suggested that chemical degradation in addition to physical degradation (aggregation) was taking place. Chemical degradation such as deamidation and oxidation has previously been observed in lyophilized protein formulations during storage of the dried solid.[40] Taken together, these results document that storage of HLL at temperatures below the T_g value was not sufficient to ensure optimal storage stability, similar to that noted for several other more hydrophilic proteins.[2,3,40,41]

To determine if the damage assessed after storage and rehydration was accompanied by structural alterations in the dried solid, infrared spectra of the dried formulations stored at either temperature were recorded. Figure 7A shows that the structural alterations initially induced during the lyophilization process were augmented after storage for 3 months at either 40 or 60 °C. Absorbances of the bands at 1635 and 1657 cm^{-1} were further decreased, and this was compensated for by a further increase in absorption in the 1684 to 1694 cm^{-1} region. The modest increase in absorbances at 1694 cm^{-1} might be due to an

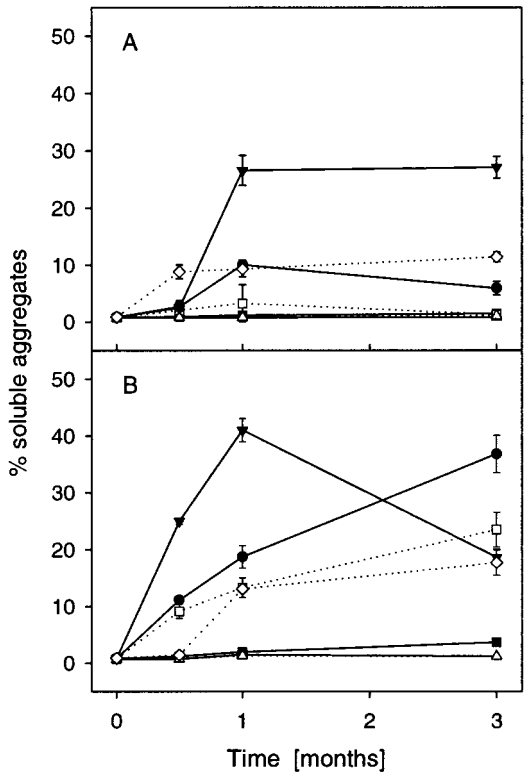

Figure 4—Formation of soluble aggregates as a function of time as determined by size exclusion chromatography. The amount of soluble aggregates formed was determined as the amount of soluble aggregates present in the stored and rehydrated formulations relative to the initial amount of native, monomeric protein present in solution prior to lyophilization. Formulations were stored at 40 °C (A) or 60 °C (B) in the absence of additives (solid circle) or in the presence 300 mM mannitol (solid triangle, down), 5% (wt/vol) dextran (open diamond), 50 mM trehalose (solid triangle, up), 300 mM trehalose, (open triangle, up), 50 mM sucrose (solid square), or 300 mM sucrose (open square). Each data point represents the mean of 3 vials ± standard deviation.

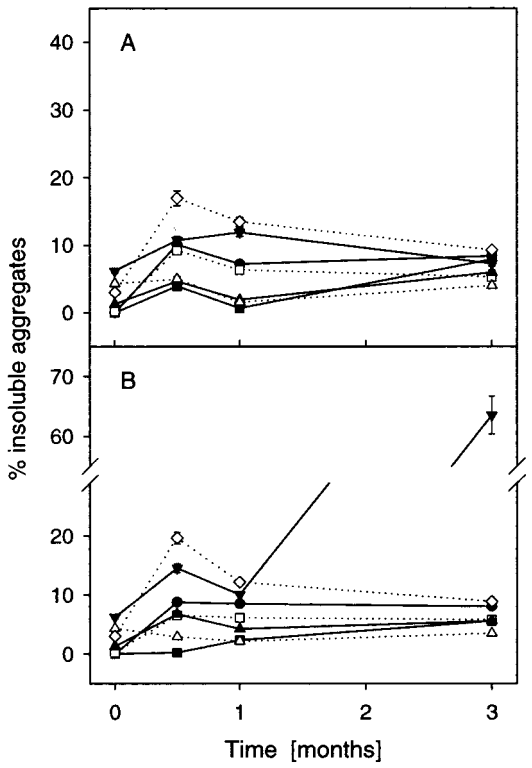

Figure 5—Formation of insoluble aggregates as a function of time. The amount of insoluble aggregates present in the stored and rehydrated formulations was calculated as the difference between the initial mass of native, monomeric protein present in solution prior to lyophilization minus the mass of recovered soluble protein (native, monomeric protein and soluble aggregates). Formulations were stored at 40 °C (A) or 60 °C (B) in the absence of additives (solid circle) or in the presence 300 mM mannitol (solid triangle, down), 5% (wt/vol) dextran (open diamond), 50 mM trehalose (solid triangle, up), 300 mM trehalose, (open triangle, up), 50 mM sucrose (solid square), or 300 mM sucrose (open square). Each data point represents the mean of three vials ± standard deviation.

intermolecular β-sheet, reflective of the formation of protein aggregates in a small fraction of the dried protein molecules.[32,33,35] However, the much greater formation of soluble aggregates noted after rehydration of the formulation stored at 60 °C compared to that measured for the formulation stored at 40 °C (Figure 4) was not reflected in the infrared spectra of the dried protein, which were very similar. Thus, it appears that aggregation during rehydration was more pronounced for the formulation stored at 60 °C.

Compared to the formulation prepared without additive, the formulation prepared with 300 mM mannitol had a greater loss of native, monomeric protein (Figure 3) and of hydrolytic activity (Figure 6) and increased formation of both soluble and insoluble aggregates during storage at either 40 or 60 °C. The one exception was the formulation stored at 60 °C which showed a decrease in the amount of soluble aggregates (Figure 4B) between 1 and 3 months storage concomitant with a large increase in the amount of insoluble aggregates (Figure 5B). Similar to that seen in the absence of additives, there was a larger decrease in recovery of hydrolytic activity (Figure 6) than that of native, monomeric protein (Figure 3), indicating that chemical degradation, in addition to physical degradation, was taking place.

Interestingly, secondary structural changes were not observed following storage for 3 months at either temperature (Figure 7B). It may have been that the amorphous mannitol in the formulation provided spatial separation between the protein molecules, thus preventing protein structural changes, resolvable by infrared spectroscopy, in the dried solid. The extensive aggregation noted after rehydration, however, indicated that mannitol was not able to inhibit aggregation during rehydration.

The poor storage stability of HLL lyophilized in the presence of mannitol is consistent with previous studies, which have shown that additives, which crystallized during lyophilization, afforded poor storage stability to several proteins.[2,10–12] The cause of the increased degradation of HLL in the mannitol formulation compared to that in the formulation without additives was not clear. There was not any increase in mannitol crystallinity during storage, based on analysis of the formulation with differential scanning calorimetry (data not shown). However, even though a glass transition was not apparent in the thermograms of the mannitol formulations, it may be that the T_g value of the amorphous solid of this formulation was lower than that for the formulation prepared without additives, resulting in reduced storage stability of the mannitol formulation.

To assess the effect of forming an amorphous solid with a T_g value above the storage temperature, HLL was stored in the presence of 5% (wt/vol) dextran. The amorphous solid formed in the presence of dextran had a moisture content of 0.6% (Table 1). No glass transition was detected by differential scanning calorimetric analysis (data not shown). Dextrans are known to form amorphous solids with T_g values increasing with the molecular weight of the dextran.[42] Since dextran with an average molecular weight of 40 kDa and a moisture content of 4% has previously been shown to exhibit a glass transition at temperatures corresponding to 90−100 °C,[43] it is assumed that the T_g value

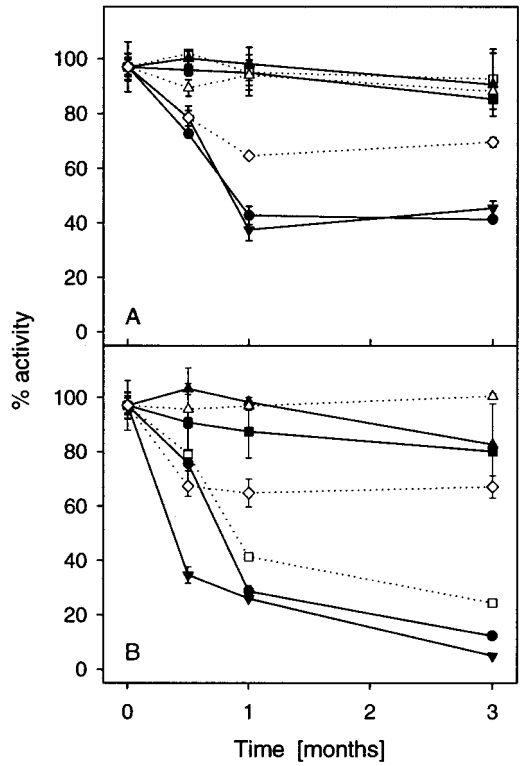

Figure 6—Recovery of hydrolytic activity as a function of time as determined by the activity assay. The recovery of hydrolytic activity was determined as the hydrolytic activity of the stored and rehydrated formulations relative to the initial hydrolytic activity of a given formulation prior to lyophilization. Formulations were stored at 40 °C (A) or 60 °C (B) in the absence of additives (solid circle) or in the presence 300 mM mannitol (solid triangle, down), 5% (wt/vol) dextran (open diamond), 50 mM trehalose (solid triangle, up), 300 mM trehalose, (open triangle, up), 50 mM sucrose (solid square), or 300 mM sucrose (open square). Each data point represents the mean of 3 vials ± standard deviation.

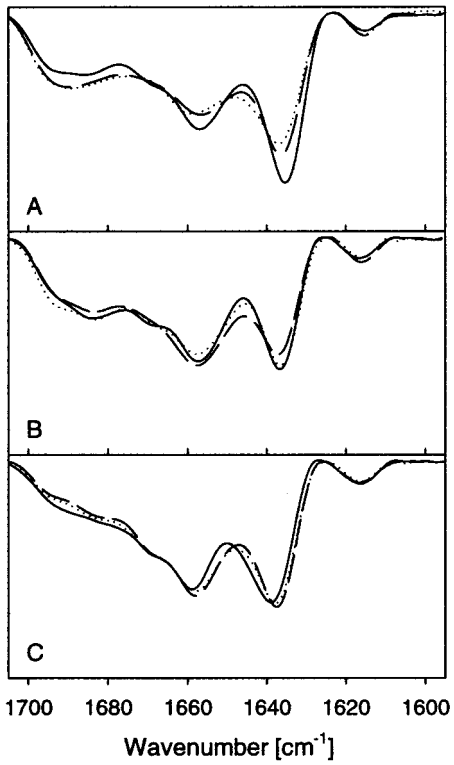

Figure 7—Effect of 3 months storage at 40 °C (•••) or 60 °C (---) on the area-normalized, second derivative amide I infrared spectra of lyophilized HLL. Changes were compared to those induced during lyophilization (—). Formulations were lyophilized and stored in the absence of additives (A), or in the presence of 300 mM mannitol (B), or 5% (wt/vol) dextran (C).

of the current dextran formulation (average molecular weight of dextran = 162 kDa) was well above either storage temperature used in the current study.

Dextran did not substantially improve recovery of native, monomeric protein (Figure 3) nor decrease the formation of aggregates (Figures 4, 5) following rehydration of the formulation stored at 40 °C compared to that observed for the formulation without additives. However, a slight improvement in recovery of hydrolytic activity (Figure 6) was observed in the dextran-containing formulation stored at 40 °C. In addition, dextran slightly improved storage stability of the formulation stored at 60 °C compared to that observed in the formulation without additives (Figures 3–6). At both storage temperatures, loss of hydrolytic activity (Figure 6) following storage and rehydration was not much larger than the loss of native, monomeric protein (Figure 3), suggesting that dextran may stabilize against putative chemical degradation to a greater degree than that seen in the absence of additives.

Figure 7C shows that potential secondary structural changes arising during storage in the dried solid were not detectable with infrared spectroscopy. This is consistent with the results observed for Factor XIII[2] and interleukin-2.[4] Dextran may inhibit structural transitions in the dried solid because it forms an amorphous phase with a high T_g value, which restricts alterations in protein conformation, and also because amorphous dextran is able to spatially separate protein molecules in the dried solid.[38]

The partially improved stability of HLL in the presence of dextran is attributed to storage in an amorphous solid at temperatures substantially below the T_g value of the dextran formulation, suggesting that the same criterion, which is necessary for storage stability of hydrophilic proteins, also is important for hydrophobic proteins. However, also similar to that observed for hydrophilic proteins,[2] this mechanism alone did not appear to be sufficient for optimal storage stability of HLL.

Both concentrations of trehalose (50 mM or 300 mM) formed an amorphous cake with a low moisture content and a T_g value substantially greater than either storage temperature (Table 1), and afforded optimal stability following 3 months storage at either temperature (Figures 3–6). Minor structural alterations were induced during storage in the dried solid in the presence of either concentration of trehalose (Figure 8A,B). These alterations, however, were not reflected in the recovery of either native, monomeric (Figure 3) nor hydrolytically active molecules (Figure 6) in the stored and rehydrated formulations. This may have been because trehalose afforded an environment conducive to refolding upon rehydration.[4]

The increased storage stability relative to that noted with dextran is attributed to the greater retention of native protein structure during the initial lyophilization process (Figure 2). Thus, as has been documented for more hydrophilic proteins, for the relatively hydrophobic HLL, storage at a temperature below the T_g value of the amorphous phase as well as preservation of native structure during lyophilization are critical for storage stability.

Sucrose at either concentration (50 mM or 300 mM) formed an amorphous solid with an initial T_g value above the highest storage temperature (Table 1). In addition, sucrose was able to minimize lyophilization-induced structural alterations (Figure 2E). Figures 3–6 show that the formulation containing 50 mM sucrose stored at either temperature and also the formulation containing 300 mM sucrose stored at 40 °C were as effective at stabilizing HLL

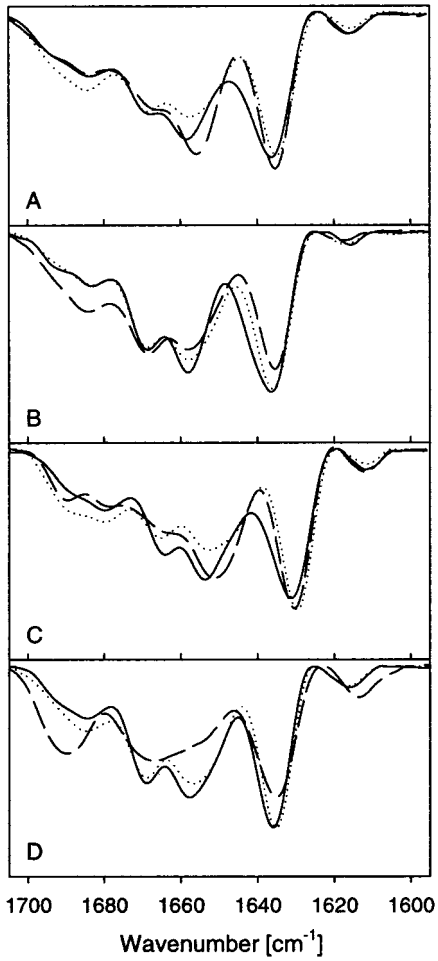

Figure 8—Effect of 3 months storage at 40 °C (•••) or 60 °C (---) on the area-normalized, second derivative amide I infrared spectra of lyophilized HLL. Changes were compared to those induced during lyophilization (—). Formulations were lyophilized and stored in the presence of 50 mM trehalose (A), 300 mM trehalose (B), 50 mM sucrose(C), or 300 mM sucrose (D).

as either concentration of trehalose. However, at 60 °C, 300 mM sucrose afforded minimal stability.

Relatively small secondary structural changes were seen in the formulation containing 50 mM sucrose following storage at either temperature and in the formulation containing 300 mM sucrose stored at 40 °C (Figure 8C,D). However, the infrared spectrum of the protein stored with 300 mM sucrose at 60 °C showed substantial alterations (Figure 8D). Decreases in absorbances at 1635 and 1657 cm^{-1} were indicative of loss of native structure. In addition, increased absorbances at 1614 and 1695 cm^{-1} were due to intermolecular β-sheet formation, which suggested that aggregation was occurring in the dried solid during storage.[35] These changes were consistent with the large amount of aggregates formed upon rehydration.

Thus, at the higher storage temperature (60 °C) sucrose was able to stabilize HLL at high protein:sucrose ratio corresponding to 12% protein [g protein/g (protein+sucrose)] but not at low protein: sucrose ratio (2% protein). Differential scanning calorimetric analysis showed similar initial T_g values for the sucrose containing HLL formulations (Table 1), independent of initial protein:sucrose ratio. Similarly, Sarciaux and Hageman[17] also found that somatotropin (rbSt) did not affect the T_g value of an rbSt formulation containing sucrose at protein weight fractions below 30% (g protein/ g dried formulation). However, they did notice that increasing the concentration of rbSt at lower protein weight fractions (4−10% protein) resulted in an

Table 2—Moisture Content and Glass Transition Temperatures following 3 Months Storage

formulation	% moisture[a] (40 °C)	% moisture[a] (60 °C)	T_g,[b] (40 °C)	T_g,[b] (60 °C)
no additives	13.2 ± 0.8	11.3 ± 2.0		
300 mM mannitol	1.7 ± 0.4	1.4 ± 0.2		
5% (wt/vol) dextran	4.9 ± 0.3	6.5 ± 0.8		
50 mM trehalose	7.1 ± 0.8	4.7 ± 0.5	81	85
300 mM trehalose	2.6 ± 0.2	3.3 ± 0.4	79	87
50 mM sucrose	5.1 ± 1.3	5.9 ± 0.9	46	50
300 mM sucrose	3.1 ± 0.5	1.1 ± 0.2	52	nd[c]

[a] Moisture content of formulations stored at either 40 or 60 °C were determined by Karl Fisher titration (% [g H_2O/100 g dried solid]) and are reported as mean of three vials from each formulation (±standard deviation). [b] Glass transition temperatures (T_g) of formulations stored at either 40 or 60 °C were determined by differential scanning calorimetry (see Methods) and are reported as an average temperature of two vials from each formulation. [c] nd = no glass transition detectable.

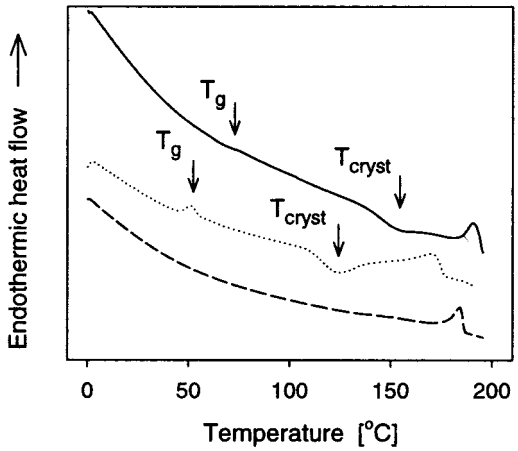

Figure 9—Differential scanning calorimetric thermograms of HLL formulations lyophilized with 300 mM sucrose: Immediately after lyophilization (—), or after 3 months storage at 40 °C (•••) or 60 °C (---). Formulations containing amorphous sucrose prior to thermal scans (top and middle thermograms) exhibited a second-order transition corresponding to a glass transition (T_g) and an exothermic peak (T_{cryst}) corresponding to sucrose crystallization during heating in the calorimeter. The formulation containing crystalline sucrose prior to thermal scanning did not exhibit either of these thermal events (lower thermogram). The endothermic peak at the glass transition of the formulation stored at 40 °C (•••) is due to enthalpic relaxation.

increase in the crystallization temperature of sucrose. Thus, for the current study, although no measurable effect were resolved based on the initial T_g values (Table 1), the differences in storage stability of the two sucrose formulations may be due to inhibition of sucrose crystallization in the formulation containing the greatest weight fraction of HLL.

Crystallization of a sugar commonly requires storage at or above the formulation T_g value.[13] Although the initial T_g values of the dried disaccharide formulations were all above the highest storage temperature (Table 1), during storage the formulations showed an increase in moisture content and a concomitant decrease in the T_g values (Table 2), presumably due to moisture transfer from the stopper.[44]

Differential scanning calorimetric analysis indicated that the decrease in T_g values for both of the trehalose formulations and for the formulation containing low concentrations of sucrose was not accompanied by crystallization of sugar (not shown). In contrast, after 3 months of storage at 60 °C, the 300 mM sucrose formulation did not show a glass transition nor was a crystallization exotherm observed in the thermogram (Figure 9). For comparison, these features were clearly apparent in thermograms for the corresponding formulation immediately after lyophilization or after

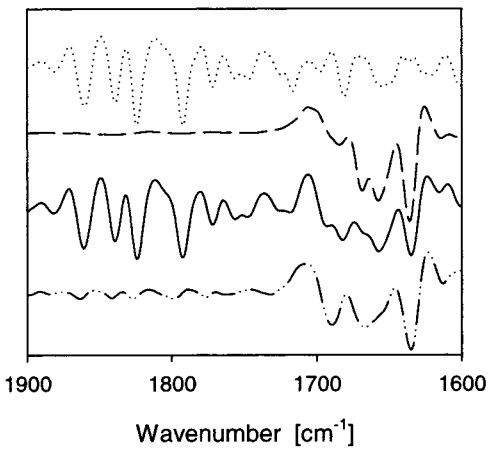

Figure 10—Area-normalized second derivative infrared spectra (1900 cm^{-1} to 1600 cm^{-1}) of crystalline sucrose obtained from the supplier's bottle (•••) and of HLL, lyophilized in the presence of 300 mM sucrose, immediately after lyophilization (---), and after 3 months storage at 60 °C (—). Subtraction of the crystalline sucrose spectrum from the spectrum of HLL lyophilized with 300 mM sucrose, stored at 60 °C for 3 months, resulted in a nearly flat baseline from 1900 cm^{-1} – 1700 cm^{-1} (–••–), ensuring that absorbance in the amide I region (1700 cm^{-1} – 1600 cm^{-1}) was due only to protein.

storage at 40 °C (Figure 9). Thus, for the 300 mM sucrose formulation, the amorphous saccharide had crystallized during storage at 60 °C. This conclusion was confirmed with X-ray powder diffraction, which showed that sucrose crystallization was initiated in the formulation containing 300 mM sucrose following 1 month storage at 60 °C and increased further after 3 months of storage (data not shown). There was not any crystalline sucrose detectable by X-ray powder diffraction in the 300 mM sucrose formulation immediately after lyophilization. And there was no indication of crystalline sucrose in the formulation containing 50 mM sucrose, even after 3 months of storage at 60 °C (data not shown).

Further evidence for sucrose crystallization was obtained by infrared spectroscopy. We have previously shown that sucrose crystallization can be detected by analyzing the second derivative IR spectra in the 1900−1700 cm^{-1} region.[2] Figure 10 shows the second derivative IR spectra of crystalline sucrose obtained from the supplier's bottle and of noncrystalline and crystalline sucrose containing HLL formulations. Both the spectrum of pure crystalline sucrose and that of the HLL formulation containing crystalline sucrose (300 mM sucrose formulation stored for 3 months at 60 °C) had strongly absorbing bands at 1860, 1839, 1824, and 1792 cm^{-1}. In contrast to this, spectra of HLL containing only amorphous sucrose (e.g., immediately after lyophilization) showed a straight baseline in the 1900−1700 cm^{-1} region (Figure 10). Since crystalline sucrose also absorbed slightly in the amide I region (1700−1600 cm^{-1}), it was necessary to subtract the spectrum of crystalline sucrose from that of the HLL formulation containing crystalline sucrose. The subtraction result showed a relatively flat baseline between 1900 and 1700 cm^{-1}, indicating that absorption of the resultant spectrum in the amide I region was due to protein only (Figure 10).

The increased damage to HLL associated with crystallization of sucrose most likely is due to the fact that crystalline sucrose is anhydrous.[45] Thus, as sucrose crystallizes the relative mass of water remaining in the amorphous phase will increase. As a result, the T_g value of the remaining amorphous material will decrease, resulting in compromised protein stability. Similar results were noted with formulations of Factor XIII in which sucrose crystallized.[2]

Finally, the formulation containing 50 mM sucrose stored at 60 °C for 3 months had a final T_g value below the storage temperature (Table 2), yet no sucrose crystallization was observed. This may have been due to several factors. First, when stored at a temperature near the T_g value, the formulation may collapse, but not crystallize.[42] Second, as explained above, increased weight fractions of protein in a dried solid may increase the crystallization temperature without affecting the T_g value.[17,18] Thus, it may have been that the crystallization temperature of sucrose in the current HLL formulation remained above the highest storage temperature (60 °C).

Conclusion

The precipitation of HLL—by salting-out action of trehalose and denaturing action of Tween—documents that the effect of excipients on this relatively hydrophobic protein are much different than those seen with proteins with more typical predominantly hydrophilic surfaces. Despite this difference, the same mechanisms accounting for both acute and long-term storage stability of hydrophilic proteins also accounted for stability of HLL. First, optimal acute stability during lyophilization of HLL required the formation of an amorphous phase containing protein and additive. In addition, the additive should possess the ability to hydrogen bond and thus act as a water substitute during dehydration. However, since the protein favored refolding over aggregation upon rehydration, damage to HLL during lyophilization was best resolved in the dried solid by infrared spectroscopy. Next, formation of an amorphous phase with a T_g value above storage temperature and preservation of native structure during lyophilization were both necessary criteria for storage stability. However, as was seen for hydrophilic proteins,[10−12] crystallization of an amorphous saccharide during storage resulted in poor storage stability. Crystallization of sucrose could be prevented by increasing the protein:sucrose mass ratio, which presumably resulted in an increase in the crystallization temperature. Finally, the superior stabilization afforded by trehalose compared to that afforded by sucrose was attributed to the higher T_g value of the trehalose-containing formulation.

Abstract □ The crystallization kinetics of amorphous lactose in the presence and absence of seed crystals were investigated at 57.5% relative humidity. Isothermal crystallization studies were conducted gravimetrically in an automated vacuum moisture balance at several temperatures between 18 and 32 °C. The crystallization rate constants were then determined from Johnson–Mehl–Avrami (JMA) treatment and isothermal activation energies were obtained from Arrhenius plots. Based on microscopic observations, a reaction order of 3 was used for JMA analysis. The nonisothermal activation energies were determined by differential scanning calorimetry using Kissinger's analysis. Isothermal activation energies for amorphous lactose with and without seed crystals were 89.5 (±5.6) kJ/mol and 186.5 (±17.6) kJ/mol, respectively. Nonisothermal activation energies with and without seed crystals were 71 (±7.5) kJ/mol and 80.9 (±8.9) kJ/mol, respectively. The similarity of the isothermal and nonisothermal activation energies for the sample with seeds suggested that crystallization was occurring by growth from a fixed number of preexisting nuclei. Markedly different isothermal and nonisothermal activation energies in the absence of seeds suggested a site-saturated nucleation mechanism, and therefore allowed calculation of an activation energy for nucleation of 317 kJ/mol.

Introduction

Increases in the dissolution rate and bioavailability of poorly soluble drugs can often be achieved by using metastable amorphous preparations.[1−4] Nevertheless, the use of amorphous oral dosage forms, such as solid dispersions, has seen very limited commercial application. One reason for this limited use is undoubtedly the physical instability of such formulations. Since the amorphous state is thermodynamically unstable compared to the crystalline state, there is a tendency for conversion to the crystalline form. When the conversion occurs during manufacturing or normal storage, product failure can result from the reduced dissolution rate of the crystalline form. If the advantages of metastable amorphous drugs in solid oral dosage forms are to be fully utilized, it is vital to understand the crystallization process, develop methods to stabilize the amorphous phase, and evaluate potential crystallization inhibitors in a timely manner.

The crystallization of amorphous materials can also be detrimental to parenteral products. For example, in protein lyophilization, disaccharides have been shown to stabilize the tertiary structure during the removal of water.[5] One requirement for this stabilizing effect is that the disaccharide form an amorphous phase with the dried protein. It follows that crystallization of the amorphous disaccharide would result in increased protein denaturization. Thus, understanding the transition from amorphous to crystalline states and the stabilization of amorphous phases is also important for parenteral product development.

Spray-dried lactose is widely used in solid dosage forms, and it is probably the most commonly used metastable amorphous material in the pharmaceutical industry. The crystallization of amorphous lactose, particularly during tableting operations[6] and storage of micronized powders,[7] has been reported as an industrial problem. Recent reports in the pharmaceutical literature have discussed amorphous lactose crystallization; however, these studies have not addressed the kinetics.[8−10] This may be a result of the complicating issue of mutarotation between the α- and β-forms of lactose and the ensuing crystal form issues.

Sucrose, another disaccharide, is much less complicated and fairly well studied. Over the years, the crystallization of amorphous sucrose alone and with additives has been studied by various isothermal and nonisothermal techniques including X-ray diffraction,[11] gravimetry,[12−14] and differential scanning calorimetry.[11,15] It is somewhat surprising that other than the statistical approach taken by Van Scoik and Carstensen,[13] crystallization rate constants, and the separation of kinetic parameters for nucleation and growth, are not readily obtained from the literature. Johnson−Mehl−Avrami theory has been used for the determination of crystallization rate constants of materials in frozen solution[16] and for the crystallization of amorphous lactose[17] and amorphous indomethacin;[18] however, none of these studies focused on the separation of nucleation and growth processes.

Determination of the kinetic parameters associated with crystallization of amorphous lactose with and without seed crystals is the focus of the current investigation. The use of isothermal and nonisothermal techniques, combined with microscopic observations, allowed elucidation of the nucleation mechanisms and calculation of activation energies associated with nucleation and growth. The methods and results reported here for lactose form the foundation for later studies on potential crystallization inhibitors.

Theoretical Section

Johnson−Mehl−Avami (JMA) theory describes many solid-state reactions that occur through a process of nucleation and growth such as crystallization.[19−23] For isotropic growth in m dimensions, the general form of the JMA equation is:

$$\alpha(t) = 1 - \exp[-\int_0^t g[\int_\tau^t Y(\Theta)\mathrm{d}\Theta]^m I(\tau)\mathrm{d}\tau] \qquad (1)$$

where α is the fraction crystallized, $Y(\Theta)$ represents the growth rate for all m dimensions of growth, g is a geometric

Table 1—Summary of the Meanings of Isothermal and Nonisothermal Apparent Activation Energies from Woldt[26] [a]

nucleation mechanism	reaction order (n)	isothermal apparent E_a	nonisothermal apparent E_a
continuous	$m+1$	$(E_a^N + mE_a^G)/(m+1)$	$(E_a^N + mE_a^G)/(m+1)$
fixed number	m	E_a^G	E_a^G
site saturated	m	$(E_a^N + mE_a^G)/m$	E_a^G

[a] The superscripts N and G refer to nucleation and one-dimensional growth, respectively.

constant, and $I(\tau)$ is the nucleation rate. Equation 1 can be reduced to the following simplified form:[24−26]

$$\alpha = 1 - e^{-(k(t - t_o))^n} \quad (2)$$

where, k is the crystallization rate constant (time^{-1}), t is time, t_o is the induction time, and n is the reaction order which depends on the nucleation mechanism and the number of dimensions in which growth is occurring. After assigning the appropriate order, the linearized form of eq 2

$$[-\ln(1 - \alpha)]^{1/n} = k(t - t_o) \quad (3)$$

can be used for determining isothermal induction times and rate constants.

If nucleation and growth rates are functions of temperature only (i.e. not position or time dependent), then three general mechanisms of nucleation can be considered: continuous (which reduces to constant rate under isothermal conditions), fixed number of nuclei, and site-saturated nucleation.[26] Continuous nucleation means that nuclei continue to form and grow throughout the transformation. Fixed number nucleation occurs when growth proceeds from a fixed number of preexisting nucleation sites. The number of nuclei is independent of the experimental conditions. The term site-saturated nucleation is a hybrid of the previous two cases. In this situation all nuclei are present at the beginning of the isothermal process, and additional nuclei do not form during the transformation, but the absolute number of nuclei depend on the temperature. One example of this would be if the rate of growth was much greater than the rate of nucleation.

Starting with eq 1 and assuming only Arrhenius dependence of growth and nucleation rates, Woldt derived the meanings of activation energies determined from isothermal and nonisothermal experiments.[26] After corrections for the differences in the units of k between Woldt's representation and eq 3, the meanings of reaction orders and apparent activation energies determined isothermally and nonisothermally can be summarized as shown in Table 1. Thus, if growth occurs in the same number of dimensions, the apparent E_a obtained isothermally and nonisothermally should be identical under fixed number and continuous nucleation. A more interesting situation arises if nucleation occurs through a site-saturated mechanism. In this case different apparent activation energies will be obtained under isothermal and nonisothermal conditions, and the underlying activation energies for nucleation and growth, E_a^N and E_a^G, can be determined. Therefore, the combination of isothermal and nonisothermal methods of determining activation energies for crystallization can, in theory, provide insight into the underlying mechanism of crystallization.

Experimental Section

Materials—Anhydrous lactose was purchased from Quest International (Norwich, NY). Lactose monohydrate was purchased from Van Waters and Rogers (Bedford Park, IL).

Crystallization Conditions—The International Conference on Harmonization (ICH) has recommended 60 ± 5%RH as a humidity condition for long-term stability testing of pharmaceutical products.[27] Since 57.5% RH is easily achieved at 25 °C using saturated aqueous solutions of NaBr, this was the humidity condition chosen for crystallization studies. Preliminary studies showed that amorphous lactose absorbed ca. 14% water at 57.5% RH, resulting in a glass transition temperature (T_g) for the hydrated material of ca. 5 °C. For comparison, the T_g of dry amorphous lactose is ca. 114 °C. Since all crystallization experiments were conducted at least 13 °C above the T_g, the assumption of Arrhenius dependence of nucleation and growth rates employed in Woldt's analysis should be valid.

Preparation and Characterization of Amorphous Lactose—All amorphous samples were prepared by spray-drying (Buchi mini spray dryer, model B-191) freshly prepared aqueous solutions of anhydrous lactose (10% w/v). The inlet air temperature was set to 150 °C and the other parameters were adjusted to give an outlet air temperature of ca. 80 °C. Spray drying was started exactly 4 min after addition of water to the lactose powder and lasted for 12.5 min. The amorphous nature of the product was assessed by X-ray powder diffraction (XRPD) and differential scanning calorimetry (DSC). The amorphous product was then observed by polarized light microscopy (PLM) at a magnification of 332× to check for the presence of seed crystals. One batch of amorphous lactose showed no evidence of crystals by any of the techniques. A second batch appeared amorphous by XRPD and DSC, but small crystallites could be observed by PLM indicating that nucleation occurred during processing stage. Therefore, two batches of amorphous lactose were studied: one which had previously nucleated designated as "with seeds" and one which did not show evidence of nucleation designated as "without seeds".

Polarimetry—The proportion of α and β diastereomers in the raw material, spray-dried product, and recrystallized amorphous material was estimated by polarimetry (Jasco DIP-370 digital polarimeter). Briefly, a standard curve was constructed from the literature values for specific rotation of pure α and β forms.[28] Solutions (1% w/v) were prepared and optical rotation measurements made as a function of time. The specific rotation values were plotted versus time and the y-intercept, which gave the specific rotation at $t = 0$, was used in the standard curve to estimate the α/β content of the solid materials.

Differential Scanning Calorimetry—The DSC experiments employed a Mettler DSC 30 (Mettler-Toledo Inc., Highstown, NJ) or a TA Instruments model 2920 DSC (TA Instruments, Inc. New Castle, DE). Both instruments used aluminum sample pans and were purged with dry nitrogen at 50 mL/min. The DSC cell constants were calibrated with indium and temperature calibrations were performed using indium (single point) or indium, lead and zinc (three point). For nonisothermal crystallization studies, amorphous lactose samples (ca. 2−3 mg) were weighed into sample pans and stored over a saturated aqueous solution of NaBr. After exactly 2 h, the pans were hermetically sealed and immediately scanned in the DSC. The nonisothermal E_a was determined by Kissinger analysis[29,30] at scanning rates of 7.5, 10, 15, 20, and 25 °C/min.

A comparison of the crystallization products from isothermal and nonisothermal crystallization was also performed by DSC. Crystals obtained from isothermal crystallization were scanned from 25 to 300 °C at rates between 7.5 and 25 °C/min using DSC pans with a pinhole. The pinhole was used so that any water could be removed in a reproducible manner and not interfere with the melting transitions. The nonisothermal crystallizations were conducted at rates of 7.5−25 °C/min in hermetically sealed pans as used in Kissinger analysis. However, immediately after the crystallization exotherm a pinhole was placed in the pan and the scan continued to observe the dehydration and melting behavior of the product. The composition of the crystallization products obtained during Kissinger analysis and gravimetric analysis were then compared by using the magnitudes of the α-monohydrate dehydration peak at ca. 145 °C and the α-anhydrous melting peak at ca. 215 °C.

Gravimetry—Crystallization kinetics were determined gravimetrically at 57.5% RH using a vacuum moisture balance (VTI Corporation, Hialeah, FL). The balance was calibrated prior to each run, and the accuracy of the relative humidity was periodically checked by measuring the water uptake of PVP K-90 at 80% RH. Samples weighing approximately 15 mg were used for all but

one experiment with seeds at 29 °C which used a 6 mg sample to check for possible sample size effects. All samples were dried under vacuum at 50 °C until a constant weight was maintained. After the instrument reached the desired experimental temperature, the humidity was rapidly increased to 57.5% and maintained at that level for the duration of the experiment. Sample weight was monitored as a function of time, and the weight loss associated with crystallization was used for the determination of crystallization kinetics. The first step in data reduction was transforming the raw data into fraction crystallized (α) versus corrected time as follows:

$$\alpha = \left(\frac{\mathrm{Wt}_{\max} - \mathrm{Wt}_t}{\mathrm{Wt}_{\max} - \mathrm{Wt}_{\mathrm{final}}}\right), \quad t_{\mathrm{corrected}} = t - t_{\mathrm{drying}} \qquad (4)$$

The α and $t_{\mathrm{corrected}}$ values in the region between $\alpha = 0.15$ and $\alpha = 0.85$ were then fit using eq 3. Crystallization rate constants determined between 18 and 32 °C were used to calculate the apparent activation energies of samples with and without seed crystals.

Microscopy Studies—The crystallization process was observed with a polarized light microscope fitted with a video camera, VCR, and video printer. Constant humidity chambers were constructed using a standard microscope slide, a cover slip, and an O-ring as follows: A greased O-ring was placed on a slide and a small drop of a saturated salt solution placed inside the O-ring. A thin layer of amorphous lactose was pressed on the inside surface of the cover slip, which was then placed on top of the O-ring forming a closed constant humidity chamber suitable for microscopic analysis. The crystallization at room temperature and 57.5% RH was then recorded on the VCR at magnifications of 166× and 332×.

Results and Discussion

Polarimetry—The extrapolated specific rotation values and calculated α/β compositions of various types of lactose are given in Table 2. An increase in α content of 4% is observed on going from crystalline anhydrous lactose to the spray-dried amorphous product. Crystallization of the amorphous material at 57.5% RH results in another 5% increase in α content. Errors in the determination of α content primarily result from different moisture contents of the samples which, based on prior experience, we estimate to be on the order of ca. 2%. The equilibrium distribution of α and β anomers in aqueous lactose solutions has been reported as 37.3% α and 62.7% β at 20 °C.[28] The data in Table 2 suggest that exposure of lactose samples to liquid water or 57.5% RH results in a drift toward the equilibrium composition. However, the increase in α content during isothermal crystallization is small and therefore its impact on the kinetic parameters is considered to be insignificant.

Microscopy—The crystallization of amorphous lactose was observed using polarized light microscopy. For the sample without seeds, visible crystallites formed after a short induction time. Subsequent crystal growth occurred from these "nuclei" with no new "nuclei" appearing in the amorphous regions. Similar observations were made in the presence of seed crystals. Since new crystals should constantly form during the growth phase with continuous nucleation, these findings served to rule out the possibility

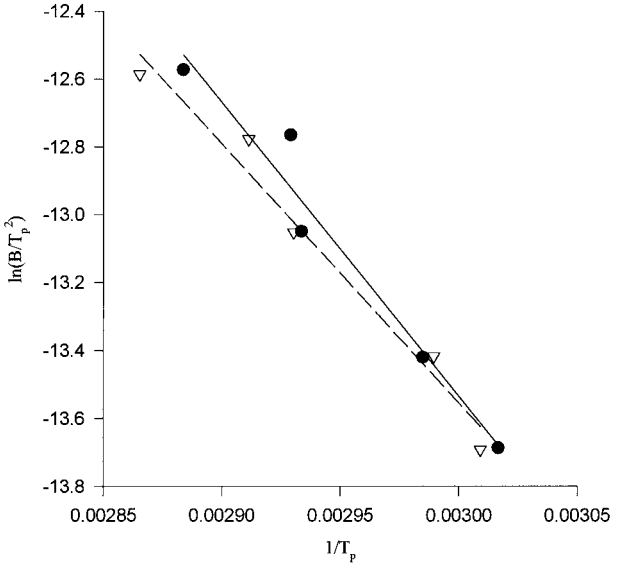

Figure 1—Kissinger plot of the nonisothermal crystallization of amorphous lactose equilibrated at 57.5% RH. Circles, solid line = without seeds; triangles, dashed line = with seeds.

of this mechanism. Table 1 shows that for both fixed number and site-saturated nucleation mechanisms the reaction order is equal to the dimensions of growth. We assume three-dimensional crystal growth and therefore use an order (n) of 3 for fitting gravimetric data to eq 3. Combining this information with the analysis described in the theoretical section should allow elucidation of the nucleation mechanisms in the presence and absence of seed crystals.

Differential Scanning Calorimetry—In Kissinger's analysis, E_a is determined by measuring peak crystallization temperature (T_p) at several heating rates (β), in K/s. The slope of a plot of $\ln(\beta/T_p^2)$ versus $1/T_p$ is $-E_a/R$. Figure 1 shows representative Kissinger plots for lactose at 57.5% RH. Each point in Figure 1 represents a single DSC experiment. The nonisothermal activation energies were 71 (±7.5) and 81 (±8.9) for samples with and without seed crystals, respectively. The reported values represent the averages of three or four Kissinger plots, and the uncertainties are the standard deviations.

As discussed in the theoretical section, the actual meaning of this activation energy may be elucidated by comparing the isothermal and nonisothermal determinations. However, it is possible that effects such as changes in the relative humidity inside the DSC pan during heating could affect the process. Therefore, before a comparison can be made we must have some assurance that the same process is occurring under isothermal and nonisothermal conditions. To support this requirement, DSC thermograms of isothermally recrystallized amorphous lactose and nonisothermally recrystallized amorphous lactose are shown in Figure 2. Both recrystallized lactose samples show an endotherm at ca. 145 °C which is indicative of the dehydration of α-lactose monohydrate. Integration of these endotherms gives values of 55.4 and 58.7 J/g for the isothermal and nonisothermal crystallization products, respectively. A comparison of the previous dehydration endotherms to that obtained for pure α-lactose monohydrate under identical experimental conditions indicates that approximately 33−35% of the sample crystallized as α-lactose monohydrate under both isothermal and nonisothermal conditions.[31] This is in excellent agreement with the proportion of α-lactose in the crystallized product as estimated by polarimetry (29%). The small endotherm at ca. 215 °C represents melting of the α-anhydrous crystal and is

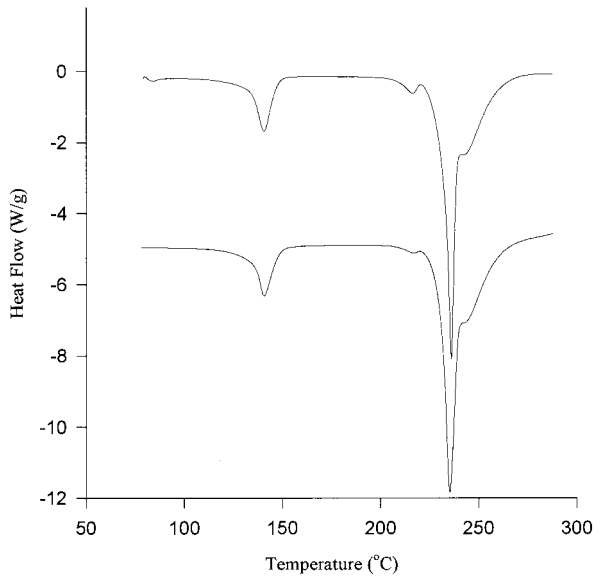

Figure 2—DSC thermograms of amorphous lactose crystallized at 57.5% RH under isothermal and nonisothermal conditions.

slightly larger in the nonisothermal crystallization products. Using a method similar to that described for estimating the amount of α-lactose monohydrate it is estimated that less than 2% α-anhydrous is formed isothermally and that slightly more, but less than 5%, is formed nonisothermally. The DSC-estimated composition of the crystallization products did not depend on the presence of seeds or the heating rate used during nonisothermal crystallization. Given that the difference in crystal composition between isothermal and nonisothermal crystallizations is only on the order of a few percent a significant affect on the activation energy determinations is not expected.

Gravimetry—Isothermal crystallization processes can be followed by techniques including X-ray powder diffraction, isothermal calorimetry, and gravimetry. The large difference in hygroscopicity between the amorphous and crystalline lactose at 57.5% RH made gravimetry an acceptable technique for this study. Other methods such as isothermal calorimetry or X-ray powder diffraction may be better suited for more hydrophobic drug molecules where the difference in hygroscopicity between amorphous and crystalline states is negligible. A representative plot of the raw moisture balance output obtained at 25 °C is shown in Figure 3a. The raw data transformed into fraction crystallized as a function of time shown in Figure 3b give the typical sigmoidal curve expected for reactions occurring through nucleation and growth. Figure 3c shows the experimental data and fit of eq 3 with $n = 3$ in the region $0.15 < \alpha < 0.85$.

One important assumption when determining crystallization kinetics from gravimetric data is that the weight loss is crystallization rate limited, and not limited by evaporation. This assumption was tested by comparing crystallization rate constants at 25 °C and 52.5, 57.5, and 62.5% RH. Since evaporation will occur at a slower rate at higher RH, the observed crystallization rate constants should decrease with increasing RH if weight loss is evaporation limited. Table 3 shows that the rate constants increased markedly with RH as is expected for crystallization rate limited weight loss. The similarity of rate constants obtained for two different sample sizes (Figure 4, 29 °C with seeds) also supports crystallization limited weight loss and suggests sample size has minimal effects on the observed rate constants.

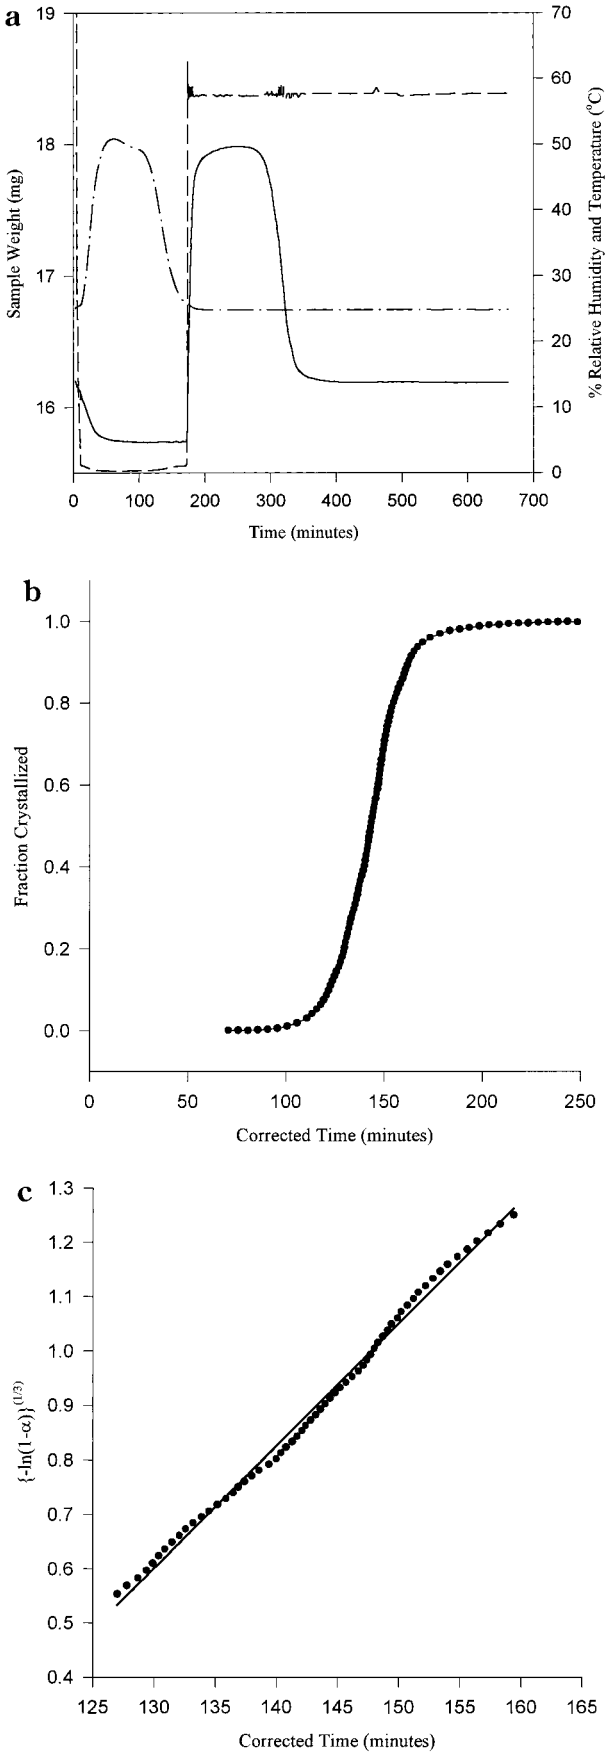

Figure 3—(a) Plot of typical gravimetric data showing sample temperature (dash–dot), sample weight (solid), and percent relative humidity (dashed) as a function of time. (b) Plot of transformed raw data. (c) JMA plot of transformed gravimetric data.

Table 3—Crystallization Rate Constants Determined at 25 °C as a Function of Relative Humidity

% relative humidity	k (min^{-1})
52.5	0.0056
57.5	0.0155, 0.0224
62.5	0.0466

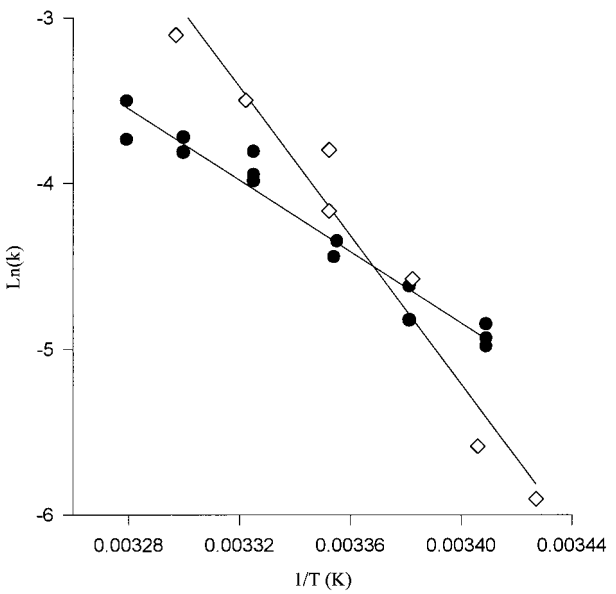

Figure 4—Arrhenius plots of JMA rate constants determined gravimetrically at 57.5% relative humidity. Solid circles = with seeds; open squared = without seeds. The solid lines show the least squares linear fit.

Arrhenius plots of the crystallization rate constants (Figure 4) gave isothermal activation energies with and without seeds of 89.5 (±5.6) and 187 (±17.6) kJ/mol, respectively. The uncertainties represent one estimated standard error obtained from regression analysis.

Comparison of Isothermal and Nonisothermal Activation Energies—Table 4 shows that amorphous lactose containing seed crystals gives essentially the same activation energies by isothermal and nonisothermal techniques. Remembering that continuous nucleation has been ruled out by microscopy, reference to Table 1 reveals that equivalent isothermal and nonisothermal activation energies are expected for growth from a fixed number of preexisting nuclei. Under the fixed number nucleation mechanism, the activation energy determined isothermally or nonisothermally is that for growth. In the absence of seed crystals there is a marked difference between activation energies obtained from isothermal and nonisothermal experiments (Table 4). As shown in Table 1 this result supports a site-saturated nucleation mechanism. Both fixed number and site-saturated nucleation mechanisms should give an activation energy for growth under nonisothermal conditions, and the results obtained with and without seeds (71 ± 7.5 and 81 ± 8.9, respectively) support this assertion.

The process of crystal growth can be separated into bulk diffusion and surface integration steps.[32] It has been shown experimentally that for sucrose crystallization from solution, the activation energies for diffusion are on the order of 25−33 kJ/mol while activation energies for surface incorporation are 67−84 kJ/mol.[33] The activation energies for lactose crystal growth determined here compare very favorably with the range cited for surface incorporation. This comparison suggests that under the conditions studied the crystal growth rate of lactose is limited by surface incorporation rather than diffusion.

Table 4—Comparison of Isothermal and Nonisothermal Activation Energies Determined in the Presence and Absence of Seed Crystals

sample	isothermal E_a (kJ/mol)	nonisothermal E_a (kJ/mol)
seeds present	89.5 ± 5.6	71 ± 7.5
seeds absent	187 ± 18	81 ± 8.9

With site-saturated nucleation and three-dimensional growth, the E_a values obtained isothermally and nonisothermally are given by $(E_a^N + 3E_a^G)/3$ and E_a^G, respectively. Using the experimentally determined apparent E_a values for samples without seeds we can calculate the activation energy for nucleation as $E_a^N = 317$ kJ/mol. The relative value of this activation energy compared to that obtained for growth seems intuitively correct; however, no literature values are available for a direct comparison of the magnitude. By separating the activation energies for nucleation and growth it may be possible to ascertain how various excipients affect nucleation and growth processes during crystallization. This knowledge could allow directed inhibition of nucleation, growth, or both during product development.

Another method for determining an apparent E_a^N involves using the reciprocal of the induction time in an Arrhenius plot.[34] When the induction time data calculated from the intercept and slope of the JMA plots were analyzed in this manner, apparent activation energies of 112 (±15) and 104 (±7.5) kJ/mol were obtained. The fact that equivalent activation energies were obtained with and without seeds seriously calls into question the use of this apparent activation energy for evaluating nucleation. These results may suggest that activation energies determined from induction times may be related to the slow growth of initial nuclei, so-called germ nuclei, into growth nuclei rather than the actual nucleation step as recently discussed by Jacobs.[35]

Conclusions

Under the crystallization conditions used in this report, amorphous lactose appears to give a mixed product consisting of ca. 30% α-monhydrate, 70% β-anhydrous, and possibly a small amount of α-anhydrous crystal forms. Growth rates appear to be limited by surface incorporation rather than diffusion, and in the absence of seed crystals nucleation appears to occur though a site-saturated mechanism. Gravimetry was shown to be useful method for determining crystallization rate constants and induction times of lactose. The combination of isothermal and nonisothermal activation energies allowed investigation of both crystal growth and nucleation mechanisms and led to the separation of activation energies for nucleation and growth. Finally, the relationship between induction-time-based activation energies and nucleation has been questioned. Additional studies employing additives are needed to determine if the separation of activation energies for nucleation and growth allows a more mechanistic understanding of the role of additives in stabilizing or destabilizing amorphous phases.

25. Two different forms of the JMA equation are found in the literature, eq 3 and $-\ln(1-\alpha) = k^*(t-t_o)^n$. Maffezzoli et al.[23] have advocated using the form given in eq 3 so that rate constants will have consistent units of time^{-1}. Care should be taken when comparing kinetic parameters in the literature to ensure the same forms of the JMA equation are being used. The results are different but can be converted using $k^{*1/n} = k$ and $E^*_a/n = E_a$. The physical meaning of the two constants is that k^* is an overall value for all dimensions and k is for one dimension.[18]

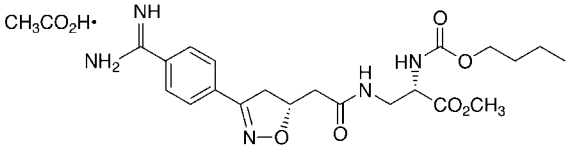
Abstract □ Unit cell parameters of two polymorphs of roxifiban have been determined by a combination of transmission electron microscopy (TEM) single-crystal and synchrotron X-ray powder diffraction techniques. While it was difficult to differentiate the two forms by their standard X-ray diffraction patterns, the high-resolution synchrotron patterns clearly showed striking differences. Unit cells for the two forms required the use of cell parameters derived from TEM diffraction patterns. The two unit cells are, not surprisingly, very similar except for a doubling of one of the axes for form II. The combined use of TEM and synchrotron patterns appears to be a good general approach for characterizing complex (low-symmetry, large unit cell) polymorphs.

Introduction

The term polymorph refers to substances that have the same chemical formula but different crystal structures. Polymorphism has played an important role in drug development, production, and litigation. Synthesized and crystallized under different conditions, polymorphs may have different physical and chemical properties as well as bioavailabilities. Steroids, sulfonamides, and barbiturates are some well-known examples[1] of compounds that have two or more polymorphs. Recently, the polymorphic behavior of Abbott-79175 was detailed.[2] The conventional techniques used to identify polymorphs are X-ray diffraction, optical microscopy, DSC, IR, and solid-state NMR. However, these techniques sometimes fail to differentiate definitively between two structurally similar polymorphs, so more advanced techniques are required. The advanced techniques were applied to roxifiban:



The GP IIb/IIIa receptor antagonist, roxifiban, is a very promising cardiovascular drug discovered recently at DuPont Pharmaceuticals.[3,4] Extensive human clinical trials are presently in progress. It was suspected at one point that different crystalline phases, labeled form I and form II, were being obtained when the synthesis/crystallization conditions were varied. Bulk and tapped densities, for example, were found to vary from 0.23 and 0.37 g/mL for form I to 0.07 and 0.19 g/mL for form II, respectively. These differences were of some concern given the low drug load in the solid dosage form.

Conventional X-ray single-crystal diffraction and polarized microscopy, two traditional methods employed to characterize the physical forms of drug compounds in development, were of no value in distinguishing between the two forms because of the relatively small crystallite sizes of the materials. Even powder diffraction patterns of forms I and II of roxifiban showed few differences when collected on a commercial diffractometer; although there is some intensity variation among peaks in general, there were only 1−2 additional peaks that were truly unique to form II. These differences in the two patterns could easily be explained away either as an effect of preferred orientation (since the crystals have a needle habit) or by the presence of impurity phases.

Unit cell parameters and atomic coordinates of crystalline polymorphs can routinely be determined by single-crystal X-ray diffraction techniques if suitably large crystals are available. However, many organic compounds tend to grow needle and platelike crystals that never achieve a large enough volume for single-crystal studies. Such was the case with forms I and II of roxifiban: diffraction patterns from a few small "single-looking" crystallites produced just enough spots to clearly show that these crystals were generally twinned or agglomerated. Because the single-crystal technique was not available in this case, both TEM and synchrotron powder diffraction techniques were employed in the hope of at least determining the unit cells for the two forms. If all of the peaks in the individual powder patterns of forms I and II can be accounted for by appropriate indexing of the peaks based on their unit cell parameters, then one can assume with high probability (a) that the two forms do indeed exist and, therefore, can be distinguished and (b) that the peaks are not from contaminant phases.

While it is possible to obtain unit cell information from powder X-ray diffraction data by "trial-and-error" techniques either manually or through the use of automated indexing software, chances for successful determination are less likely if the unit cell has low symmetry and a large volume. Unit cells are easily determined by single-crystal techniques because the diffraction spots are spread out in a three-dimensional pattern. Because the powder spectrum is a projection of these spots into a one-dimensional set of peaks, wrong unit cells are often determined when low-resolution commercial powder patterns are used as input.

High-resolution powder diffractometers at synchrotron sources produce patterns that are more easily indexed, but complicated patterns of the type produced by many organic crystals are still difficult to analyze. In electron diffraction, two-dimensional patterns can be obtained from crystals which are very small (submicron or less in size). This is a big advantage in determining some of the unit cell parameters, but generally it is difficult (crystals are generally plates or needles) to obtain all three of the necessary projections to determine all the parameters. Another disadvantage is that organic materials are usually beam sensitive and, for this reason, electron diffraction has not been extensively used on pharmaceuticals. Recently, however, the development of very sensitive CCD detectors has allowed electron diffraction patterns of beam-sensitive materials to be recorded in a few seconds using very low electron currents. In this report, we describe the utility of our newly developed "hybrid" characterization technique[5,6] to pharmaceuticals, coupling the analysis of the synchrotron powder data with information obtained from TEM diffraction patterns to characterize the unit cell parameters of the two forms of roxifiban.

Experimental Section

High-resolution, X-ray powder diffraction patterns for various samples of roxifiban were obtained at the Advanced Photon Source, a DOE User Facility located at Argonne National Laboratory, Chicago, IL. The samples were initially mounted in capillaries although flat-plate samples were later used to obtain patterns with increased Bragg intensities. Patterns were collected on a Huber diffractometer at beamline DND-5BMB. A Si(111) double-crystal monochromator, a Si(111) analyzer, and slits on the order of 1 × 8 mm were used in conjunction with a scintillation counter to achieve the highest possible resolution and signal/noise ratio. Peaks in the patterns were deconvolved using GPLSFT, and indexing was attempted using the program TREOR. GSAS was used to test possible unit cells.

A JEM-2000EX (at 200 kV accelerated voltage) microscope, equipped with a Gatan 1024 × 1024 CCD camera, was used to characterize these materials. The samples were directly deposited on conventional TEM grids. The TEM technique has the primary advantage of being able to examine individual crystallites, and thus it can circumvent the problems of contaminant phases. This technique can exploit the special geometric shapes of these crystallites, many of which have plate and fiberlike habits. In particular, unit cell information perpendicular to the plate direction can be obtained: a typical diffraction pattern might contain the *h*0*l* zone, for example, from which the *a**, *c**, and β* parameters can be obtained.

While these two techniques were individually valuable for partial definitions of the unit cell, neither give data from which the complete unit cell could readily be determined. The determination of roxifiban polymorphs required a combination of transmission electron microscopy (TEM) and synchrotron X-ray diffraction capabilities.

Results

Electron Microscopy (EM)—Figure 1 shows scanning electron microscopy images comparing the morphologies of forms I and II. Both forms I and II contain very small crystals which prevent the use of conventional single crystal X-ray techniques. It is clear that the crystals of form II are more fiberlike. Figure 2 is a low magnification TEM view of form I and II crystals, confirming the SEM results. Figure 3 shows a higher magnification image of a single Form II crystal and its diffraction pattern. TEM results indicate that *d*(100), *d*(001), and β* of both forms I and II are, respectively, around 5.0 Å, 9.2 Å, and 81°.

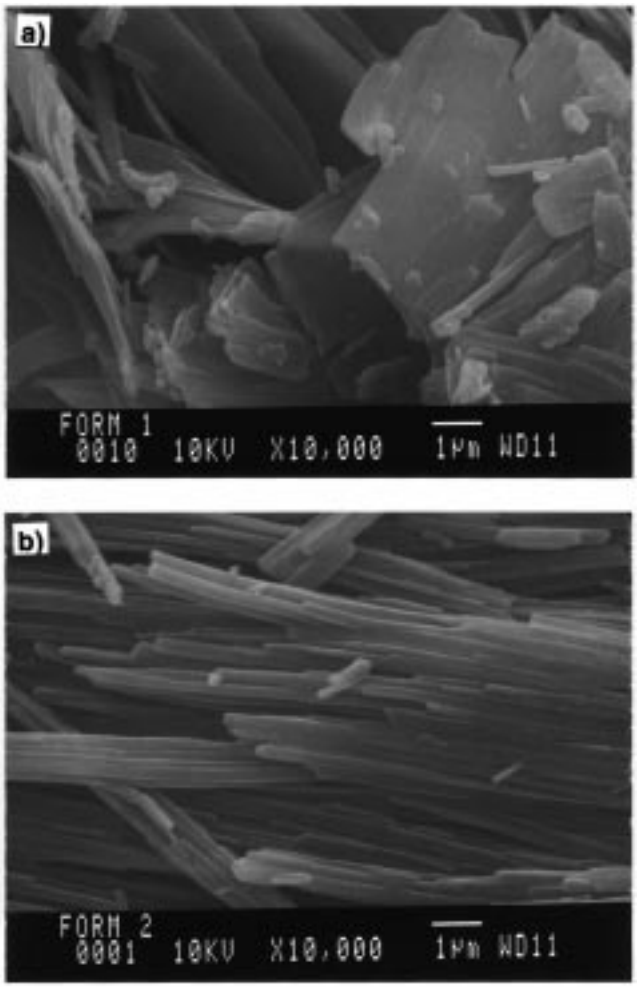

Figure 1—Scanning electron microscopy images of forms I and II. The crystals of form II are seen to be much more fiberlike.

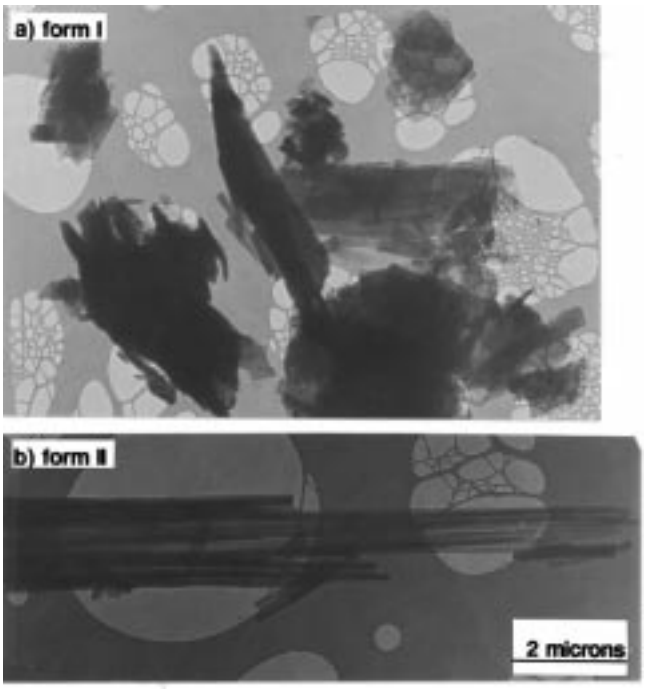

Figure 2—Low magnification TEM images of (a) form I and (b) form II crystals.

Synchrotron X-ray Powder Diffraction (S-XRPD)—*Transmission Mode*—It was revealed that the S-XRPD

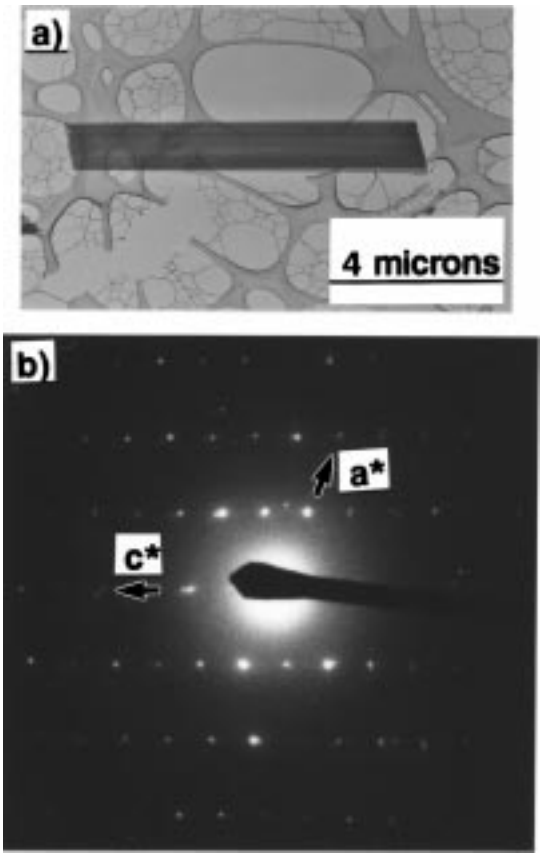

Figure 3—(a) TEM image and (b) diffraction pattern of a single form II crystal.

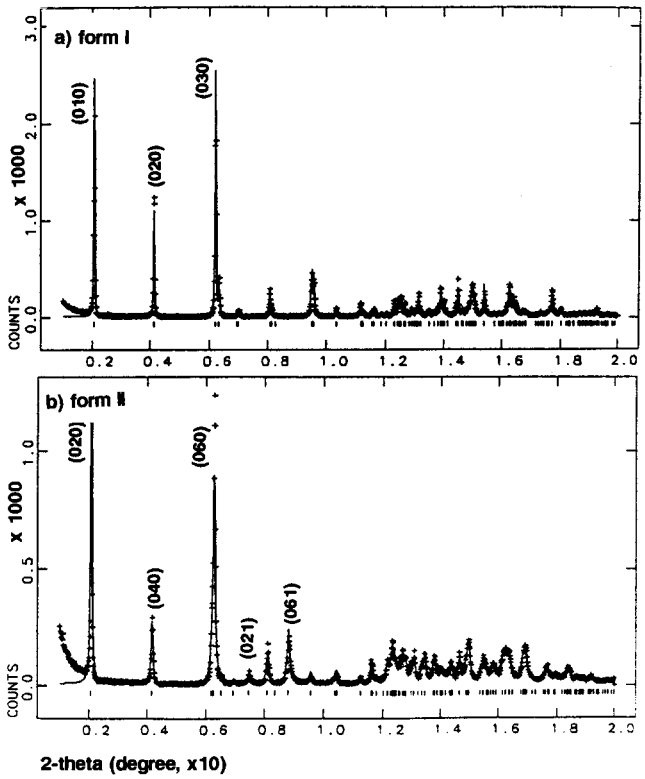

Figure 4—Synchrotron X-ray diffraction patterns (wavelength of 1.00006 Å) of (a) form I and (b) form II. In both cases, the "+" marks represent the observed data points; the solid line is the result of a LeBail fit using the unit cell parameters. The "tick" marks are the locations of the expected reflections. The two extra peaks in the low-angle region of the form II pattern which clearly differentiate it from the pattern of form I are labeled as the (021) and (061) reflections. It can clearly be seen that the match of the derived unit cells and the experimental data points is excellent.

diffraction pattern of form I and form II run with a 1.5 mm capillary were indeed different with two extra diffraction peaks in the lower angle range. Since the large capillary samples should be relatively free of preferred orientation, it was assumed at this point that the major differences in the patterns were a clear indication that the extra peaks in form II were not simply due to preferred orientation effects.

Reflection Mode—Because the intensities of the diffraction lines using the capillary mode were relatively weak, we recollected the patterns in reflection mode using large and deep flat-plate sample holders on samples that were carefully ground. Figure 4 shows the resulting S-XRPD patterns for forms I and II and points out the two extra peaks in the low-angle region of form II which (vide infra) distinguish it from form I. Although we had expected serious problems from preferred orientation effects, the relative intensities of the peaks in the reflection mode were, in fact, very similar to those measured in the capillary mode (without grinding the samples, the relative intensities in reflection mode were very different and strong, preferred orientation effects were very obvious).

Unit Cell of Form I—An attempt was made to determine the unit cell of form I since the peaks were reasonably sharp and the phase appeared pure. TEM work had suggested that the cell was probably of low symmetry, either monoclinic or triclinic, with two of the three cell axes in the neighborhood of 5.0 and 9.2 Å with an interaxial angle of 81°. Synchrotron patterns had shown that the third axis was very long, ca. 27−28 Å. Given the number of atoms in the molecule, one can estimate that the volume per molecule is in the vicinity of 648 Å^3 which would be compatible with two molecules per cell. Indexing was attempted first in the triclinic study giving several hits with one in particular that had dimensions of 6 × 9 × 28 Å. Placing the trial cell into the program RMANDEX showed a nearly perfect fit to all of the peaks. The cell parameters were then refined with CELLREF, and ultimately these numbers were used in a LeBail fit routine in GSAS. Figure 4a shows the quality of the fit for the full pattern. The refined triclinic ($Z = 2$, with space group P1 because the compound is stereochemically pure) unit cell parameters are given below:

	a	*b*	*c*	α	*β*	*γ*	*V*
value:	5.0235	28.075	9.2954	98.533	98.498	92.244	1279.7
σ:	0.0005	0.002	0.0009	0.006	0.009	0.008	0.2

Unit Cell of Form II—Several lines in the low-angle regions of the pattern are unique to the form II pattern, and if their origin could be established, then it might be possible to determine its unit cell. The form II pattern was displayed in RMANDEX[7] using the same unit cell established for form I as a starting point because TEM results indicated that a^*, c^*, and β^* values of forms I and II were very similar. It became immediately clear that the unique peaks in the pattern could not be indexed unless one of the cell edges was doubled. Doubling the volume requires that four molecules must reside in the cell, and, in that case, the cell would likely be monoclinic with space group $P2_1$. The long axis, ca. 28 Å, was the obvious choice for *b* (the unique axis of the monoclinic cell) because the TEM diffraction pattern suggested that 5−9 Å projection still had the 81° angle. Fixing the α and *γ* angles to 90° and adjusting the *a* and *c* axes as well as the *β* angle soon gave a cell which could account for the unique lines in the form II pattern. This cell was then refined using the LeBail fit

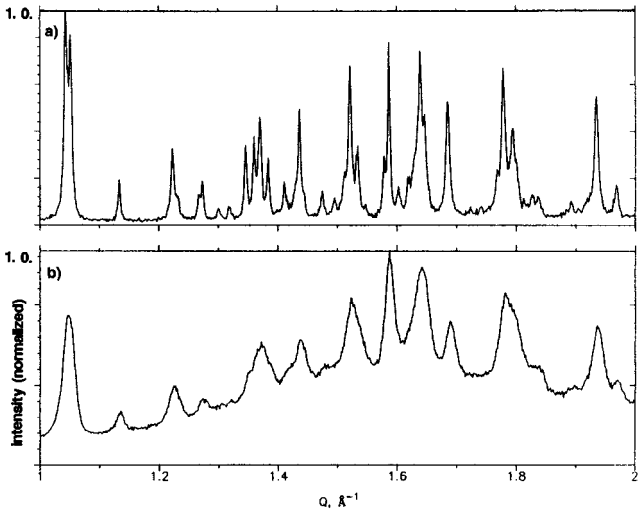

Figure 5—A partial comparison of a (a) synchrotron pattern of form II collected using a wavelength of 1.00006 Å with a (b) conventional X-ray diffraction pattern using Cu Kα radiation in a region where there are many overlapping peaks. The patterns are plotted as a function of $Q = 2\pi/d = 4\pi \sin \theta/\lambda$ to removal the effects of using different wavelengths.

routine in GSAS. The fit is shown in Figure 4b. The final monoclinic unit cell is:

	a	*b*	*c*	*β*	*V*
value:	4.992	54.77	9.372	99.15	2529.9
σ:	0.002	0.02	0.003	0.04	1.5

Conclusions

Conventionally, there are two ways to differentiate polymorphs: single-crystal or powder X-ray diffraction. The former requires fairly large crystals which, in many cases, are very difficult to obtain; the latter is often ambiguous if only visual comparisons of the patterns are made. Successful indexing of a powder pattern, however, strongly suggests that a pattern represents a single, pure phase and can be used as strong evidence for the existence of individual polymorph. We have used a combination of electron and X-ray diffraction techniques to differentiate the polymorphs of roxifiban by demonstrating that they have different, but closely related, unit cell parameters. To our knowledge, this represents the first time this combination of techniques has been used to differentiate two polymorphs of a pharmaceutical drug substance.

The success of this study was critically dependent on the use of a synchrotron diffraction pattern to obtain reliable indexing and accurate lattice parameters. Figure 5 compares the diffraction patterns of form II using (a) S-XRPD and (b) commercial X-ray diffractometer (C-XRD). The much higher resolution of the S-XRPD pattern is clear: the separation of the nearly overlapped peaks was critical to the indexing and to the refinement of the unit cell parameters of the two polymorphs.

Given that the patterns match so closely in the low-angle region, it is not surprising that the unit cell parameters of forms I and II are quite similar. The two extra peaks found in the low-angle region of form II are a consequence of the fact that the *b*-axis, and hence the unit cell volume, is approximately double that of form I. A schematic representation of the two unit cells is shown in Figure 6. It is reasonable to suggest that the long axis of the molecules must be aligned with the *b* axis in both cases. In fact, given that the form I cell is triclinic with space group *P*1 (and hence the origin of the cell is arbitrary), it might be possible to determine its structure by placing a pair of "optimized"

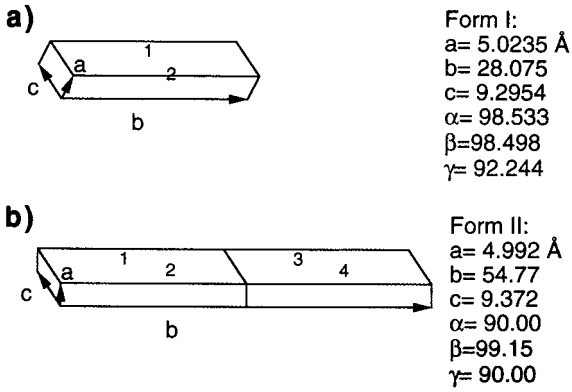

Figure 6—Schematic representation of unit cells of (a) form I with two molecules per cell and (b) form II with four molecules per cell. The molecules presumably align themselves approximately parallel with the very long *b*-axes.

molecules of roxifiban in the unit cell and adjusting their orientations. The task would be complicated by the number of flexible torsion angles in the molecule and by the fact that it is actually a salt, but it may be possible.

Because most crystallites which fail to grow to sizes that would make them amenable to routine single-crystal diffraction techniques have either platelike or needlelike habits, this combined use of TEM and synchrotron powder diffraction techniques should be applicable to similar structural problems in the pharmaceutical industry. Although access to synchrotron powder diffraction beamlines is presently somewhat limited, the use of synchrotron data for the differentiation of these two polymorphs was absolutely critical to the success of this study. In the future, access to such beamlines will be more readily available as more synchrotrons come on line and as better detector systems for powder diffraction are developed.[8]

Abstract □ We have developed a highly sensitive enzyme immunoassay for 6-monoamino-β-CD (mono(6-amino-6-deoxy)cyclomaltoheptaose) and its parent compound (β-CD) with a detection limit in the 100 pg/mL range. The polyclonal antibodies obtained are highly specific for the β-cyclodextrin core and do not recognize other cyclic cyclodextrins (i.e., α- and γ-CD) or linear analogues. This enzyme immunoassay can be used to quantify 6-monoamino-β-CD in rat urine and plasma. Using this immunoassay, we have evaluated the main pharmacokinetic parameters of 6-monoamino-β-CD after iv administration to the rat of a 25 mg/kg dose. Since this method is strictly specific to the native β-CD form, we have demonstrated that the molecule rapidly disappeared from plasma but is probably distributed in the tissues. The urinary route appears as the predominant way of elimination since almost all the administered drug is recovered in urine. Finally, analysis of the same molecule after oral administration to the rat (25 mg/kg) demonstrates low plasma levels and that about 1% of the administered dose is excreted in urine. These experiments demonstrate the high stability of the β-CD core irrespective of the method of administration. This immunological method could provide relevant information on the fate of β-CD and some derivatives for drug delivery using different modes of administration (oral, parenteral, transmucosal, or dermal).

Introduction

Cyclo-malto-oligosaccharides (cyclodextrins or CDs) are natural molecules with the unique feature of trapping small organic compounds in their hydrophobic cavity. Such inclusion complexes induce modifications of the physical properties of the "guest" molecules, particularly in terms of their solubility and stability.[1] Pharmaceutical applications of cyclodextrins and derivatives are aimed at increasing the bioavailability and reducing the side-effects of drugs.[2] CDs can overcome formulation problems encountered with some drugs using classical pharmaceutical excipients, which explains the increasing number of CD-based formulations appearing on the market. Some CD derivatives may prove useful in delivery of hydrophilic compounds such as peptides[3] or oligonucleotides.[4,5]

However, the use of CD molecules as drug carriers or stabilizers requires safety evaluation. Investigation of the biological fate of CDs as well as toxicological issues must be considered before approval of these new excipients by regulatory agencies. Nephrotoxicity of α- and β-CD[6] as well as the hemolytic character of β-CD[7] severely hamper their potential use in pharmaceutical applications, at least for parenteral administration. However, the availability of different substituted analogues with better safety profiles (as recently reviewed[8]) broadens the range of administration. We recently described the decreased hemolytic properties of 6-monoamino-β-CD compared with the parent compound.[9] Using a competitive enzyme immunoassay which is both sensitive and specific for the cyclic structure of 6-monoamino-β-CD, we have investigated the fate of this compound after iv and oral administration to the rat (both at a single 25 mg/kg dose). After parenteral administration, the main pharmacokinetic parameters of 6-monoamino-β-CD were determined and indicated little metabolism and major elimination by the urinary route. It was shown that in the rat, after oral intake, a small but not inconsiderable proportion of 6-monoamino-β-CD is detected in plasma and eliminated in urine.

The data presented support the potential use of 6-monoamino-β-CD and demonstrate the efficiency of immunological methods in specifically monitoring such compounds for safety evaluation.

Published on Web 02/11/1999

three steps from the parent CD as described elsewhere.[14] Maltoheptaose was obtained from Fluka AG (Basel, Switzerland). Heptakis-(2,6-di-*O*-methyl)cyclomaltoheptaose was obtained from Janssen (Beerse, Belgium) and was recrystallized five times in MeOH to over 99% purity. The chemical and optical purity of the different compounds was checked by ^{1}H NMR, mass spectroscopy, and chemical analysis.

Acetylcholinesterase (AChE, EC 3.1.1.7) from the electric organs of the electric eel *Electrophorus electricus* was purified by affinity chromatography[15] and used in its G4 form for 6-monoamino-β-CD labeling. AChE activity was measured using the colorimetric method of Ellman et al.[16]

All reagents used for immunoassays were diluted in the following buffer (EIA buffer): 0.1 M potassium phosphate buffer pH 7.4 containing 0.9% NaCl, 1 mM EDTA, 0.1% bovine serum albumin (BSA), and 0.01% sodium azide. The washing buffer was a 10 mM phosphate buffer containing 0.05% Tween 20.

Apparatus—Solid-phase EIA was performed in 96-well microtiter plates (Immunoplate Maxisorb with certificate, Nunc, Denmark) using automatic Titertek microtitration equipment (washer, dispenser and reader) from Labsystems (Helsinki, Finland).

Antiserum Production—For the production of antibodies, 6-monoamino-β-CD was covalently linked to bovine serum albumin (BSA) by means of glutaraldehyde as previously described.[17]

Preparation of the Enzymatic Tracer—6-Monoamino-β-CD was covalently coupled to AChE using the heterobifunctional reagent *N*-succinimidyl-4-(*N*-maleimidomethyl)-cyclohexane-1-carboxylate (SMCC) as previously described.[17] This method involved the reaction of thiol groups previously introduced into 6-monoamino-β-CD (by reaction of its primary amino group with *N*-succinimidyl-*S*-acetylthioacetate (SATA) in alkaline medium) with maleimido groups incorporated into the enzyme.

Competitive EIA Procedure—Competitive EIA was performed as described elsewhere for various molecules.[18−20] Microtiter plates were coated with mouse monoclonal anti-rabbit IgG antibodies in order to ensure separation of bound and free moieties of the enzymatic tracer during the immunological reaction. Before use, the plates were washed with 0.01 M phosphate buffer (pH 7.4) containing 0.05% Tween 20. The total volume of the immunological reaction was 150 μL, each component (enzymatic tracer, diluted rabbit polyclonal antisera, and cyclodextrin standard) being added in a 50 μL volume. 6-Monoamino-β-CD-AChE enzyme conjugate was used at a concentration of 2 Ellman units/mL (for Ellman unit definition, see ref 19). The working dilution for the rabbit antiserum was determined by performing serial dilution experiments.

After 18-h incubation at 4 °C, the plates were washed and the enzyme activity of the bound immunological complex was revealed by addition of 200 μL of enzymatic substrate and chromogen (Ellman's reagent[16]) to each well. After 1 h of gentle shaking in the dark at room temperature, the absorbance at 414 nm in each well was measured automatically. Results are given in terms of $B/B_0 \times 100$ as a function of the dose (logarithmic scale), B and B_0 representing the bound enzyme activity in the presence or absence of competitor, respectively. A linear log−logit transformation was used to fit the standard curve.[21] The sensitivity of the assay was characterized by the dose of 6-monoamino-β-CD inducing a 50% lowering of the binding observed in the absence of competitor (B/B_0 50%). Nonspecific binding represented less than 0.1% of the total enzyme activity. Finally, the minimum detectable concentration (MDC) was taken as the concentration of competitor inducing a significant decrease (three standard deviations in B_0). All determinations were made in duplicate and quadruplicate for B_0.

To characterize the specificity of the antibodies, standard curves were plotted using various derivatives of malto-oligosaccharides. The results are expressed in terms of percentage cross-reactivity (CR) [(dose of 6-monoamino-β-CD B/B_0 50%/dose of analogue B/B_0 50%) × 100].

For rat plasma samples, a methanol precipitation procedure was performed before the assay. Four volumes of cold methanol were added to the sample before centrifugation (2500 rpm, 10 min). The pellet was discarded and the supernatant dried under vacuum using a SpeedVac apparatus (Savant, Farmingdale, NY) before reconstitution with EIA buffer. Standard curves were plotted by spiking control plasma samples with known amounts of 6-monoamino-β-CD and demonstrated more than 95% recovery of the molecule in the supernatant.

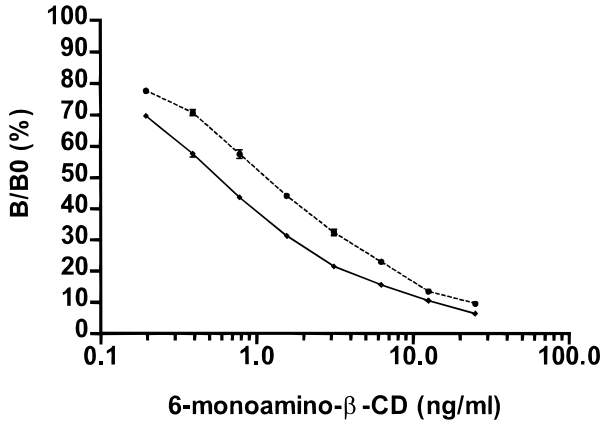

Figure 1—Standard curve for 6-amino-β-cyclodextrin enzyme immunoassay performed in rat urine (full line) and EIA buffer after methanol extraction of rat plasma (dotted line).

Animal Experiments—Experiments were performed on 10-week-old (325 ± 60 g) male Sprague−Dawley rats (Iffa Credo, Les Oncins, France) which throughout the study had free access to water and to a commercial feed (DO4, UAR, Villemoisson, France). The rats were acclimatized for 4 days in individual metabolic cages before experiments. Rats were anaesthetized (one-third O_2, two-thirds NO_2, and 4% fluothane) and catheters were placed in the right femoral artery and vein, passed up into the abdominal vessels, and their free extremity exteriorized at the back of the neck. One day after surgery, a single intravenous dose of 6-monoamino-β-CD (25 mg/kg) in saline solution (47.4 mg/mL) was injected into four rats via the venous catheter. Oral administration of 6-monoamino-β-CD (25 mg/kg) in saline solution (50.1 mg/mL) was performed on four other rats using a 1 mL tuberculin syringe and a 16 gauge gavage needle.

Blood (200 μL) was sampled at various times (0, 5, 10, 15, 20, 30 min, 1 h, 2 h, 4, 8, and 24 h) at the arterial catheter. The blood was centrifuged, and the resulting plasma kept frozen at −20 °C until assay. The pellets containing red blood cells were reinjected after dilution (1/2) with saline dilution through the venous catheter. During the experiment, the rats were housed individually in glass metabolic cages which allowed separate collection of urine and feces. Urine was collected at 4, 8, and 24 h.

Pharmacokinetic Evaluation—A specific computer program (Siphar from SIMED, Créteil, France), designed for nonlinear regression of pharmacokinetic data, was used to fit plasma concentrations. Pharmacokinetic parameters were evaluated using a noncompartmental approach as previously described.[22] The area under the plasma concentration curve (AUC) was determined using the trapezoidal lin-log rule and extrapolated to infinity. The apparent elimination rate constant (k_e) was determined by the decay of the plasma concentration at the four last values (between 30 min and 4 h). Clearance was calculated from the dose divided by the AUC. The apparent volume of distribution was determined using the relation Cl/k_e. Quantities eliminated in urine (Q_e) were evaluated over 0−24 h. Urinary clearance was calculated on the basis of $Cl_u = Q_e/AUC$. Values are expressed as mean ± SD.

Results

Sensitivity and Specificity of the Assay—Using the 6-amino-β-CD-AChE tracer, we optimized the antiserum dilution for the assay. A typical routine standard curve for this assay in EIA buffer using antiserum (no. L1076SAB) at 1/50000 initial dilution is presented in Figure 1. The sensitivity at B/B_0 50% is about 550 pg/mL (25.4 fmol/well) with a minimum detectable concentration close to 110 pg/mL (4.8 fmol/well). The specificity of this assay was demonstrated by testing against different compounds. Parent cyclodextrin (β-CD) gave a full response (90% of cross-reactivity), whereas neither substituted β-CD (i.e. heptakis(2,6-di-*O*-methyl)-β-CD) nor other native or modified CD (i.e. α-CD, γ-CD, and 6-monoamino-γ-CD) displayed any significant cross-reactivity (<0.1%). Linear maltoheptaose was not recognized at all by the antibodies.

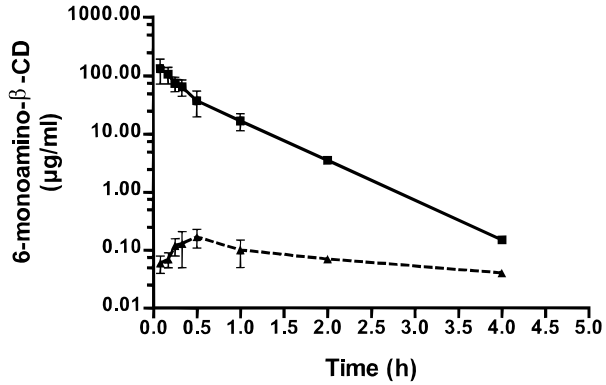

Figure 2—Analysis of plasma levels using specific immunoassay after administration of 6-monoamino-β-cyclodextrin (25 mg/kg) to rats by iv (full line) or oral intake (dotted line). Each value represents the mean ± SD of four rats.

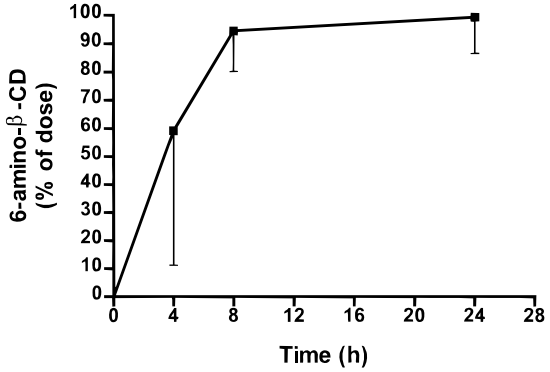

Figure 3—Cumulative urinary excretion of 6-monoamino-β-cyclodextrin after iv administration (25 mg/kg) to rats. Each value represents the mean ± SD of four rats.

All these experiments demonstrated the strict specificity of this assay for the cyclic core of β-CD. Recognition of the molecule by the antibodies seems to involve the secondary hydroxyl rim since the 2,6-di-methyl-β-CD derivative was not detected.

Before performing the pharmacokinetic experiments, we tested the analytical characteristics of the immunomethod in different biological fluids. Rat urine and plasma samples were spiked with known concentrations of 6-monoamino-β-CD. While the assay works properly for urine samples, we observed a lack of reproducibility for undiluted plasma samples. We thus applied a methanol precipitation protocol (see Methods), which provided good reproducibility with only a small change in sensitivity (Figure 1; minimum detectable concentration close to 180 pg/mL). Under these conditions, the precision of the assay is very satisfactory since the coefficients of variation (%) were 8.7, 5.6, and 9.6 within assays and 9.1, 6.1, and 9.8 between assays, for 10, 2, 0.3 ng/mL of 6-amino-β-CD, respectively.

Pharmacokinetic Measurements for 6-Monoamino-β-CD after iv Administration—After a single injection at 25 mg/kg, 6-monoamino-β-CD was detected for up to 4 h in plasma. The 8 and 24 h plasma samples presented no detectable immunoreactivity (except for a single rat for which we measured values of 60 ± 20 ng/mL and 50 ± 30 ng/mL of 6-monoamino-β-CD in the 8 and 24 h samples, respectively). In urine, meaningful concentrations were observed, remaining higher than 20 μg/mL in the 8−24 h collection period. The mean plasma concentration curve and cumulative urinary excretion of iv administered 6-monoamino-β-CD are presented in Figures 2 and 3, respectively. The main pharmacokinetic parameters are listed in Table 1. 6-Monoamino-β-CD disappears rapidly from plasma, as demonstrated by a short half-life (21 min) and MRT (28 min). The apparent volume of distribution (V_d) corresponds to 20% of the total body weight and is close to the plasma and the interstitial volume. This indicates that 6-monoamino-β-CD probably penetrates into tissues to some extent. Most if not all administered compound is eliminated in urine (100% at 24 h) with an apparent urinary clearance close to the systemic clearance. This clearance value is close to the renal glomerular filtration rate.[23]

Table 1—Main Pharmacokinetic Parameters[a] of 6-Monoamino-β-CD after Intravenous Administration (25 mg/kg) to Rats

parameters		rat 1	rat 2	rat 3	rat 4	mean ± SD
$T_{1/2}$	min	20	24	20	19	21 ± 2
MRT	min	28	34	19	29	28 ± 5
Cl_s	mL·min^{-1}·kg^{-1}	5.3	6.3	5.4	10.5	6.9 ± 2.1
AUC (0–inf)	μg·mL^{-1}·h	83.9	72.2	80.8	40.4	69.3 ± 17.2
V_d	mL·kg^{-1}	149	220	153	287	202 ± 56
Q_{el} (0–24 h)	% dose	85	103	95	115	100 ± 11
Cl_u (0–24 h)	mL·min^{-1}·kg^{-1}	4.5	6.4	5.1	12.2	7.1 ± 3.1

[a] Abbreviations: $T_{1/2}$, half-life; MRT, mean residence time; Cl_s, systemic clearance; AUC (0–inf), area under the curve from 0 to infinity; V_d, apparent volume of distribution; Q_{el} (0–24 h), eliminated quantity during 24 h; Cl_u (0–24 h) urinary clearance.

Table 2—Main Pharmacokinetic Parameters[a] of 6-Monoamino-β-CD after Oral Administration (25 mg/kg) to Rats

parameters		rat A	rat B	rat C	rat D	mean ± SD
C_{max}	μg·mL^{-1}	0.15	0.14	0.25	0.13	0.17 ± 0.06
T_{max}	min	30	30	30	30	30
AUC (0–inf)	μg·mL^{-1}·h	0.15	0.25	0.58	0.40	0.35 ± 0.19
Q_{el} (0–24 h)	% dose	0.76	0.68	1.80	0.12	0.84 ± 0.70

[a] Abbreviations: C_{max}, maximal concentration; T_{max}, time of maximal concentration; AUC (0–inf), area under the curve from 0 to infinity; Q_{el} (0–24 h), eliminated quantity during 24 h.

Oral Administration of 6-Monoamino-β-CD—We detected 6-monoamino-β-CD in plasma and urine of all the rats who had received a single oral 25 mg/kg dose. The plasma kinetics measurements are presented in Figure 2 (dotted line), and the main pharmacokinetic parameters are listed in Table 2. The plasma concentration exhibited a maximal value of 170 ± 60 ng/mL at 30 min after administration. 6-Monoamino-β-CD data were presented over the 4 h after oral intake, since it was undetectable in the 8 and 24 h samples. Cumulative urinary elimination of 6-monoamino-β-CD represented 0.84 ± 0.7% of the initial dose. 6-Monoamino-β-CD could still be assayed in the 8−24 h urine (concentration and amount ranging from 0.16 to 11.53 μg/mL and from 1.5 to 71.8 μg, respectively). The bioavailability of 6-monoamino-β-CD was 0.5% and 0.89% as calculated from AUC(0−inf) and Qel (0−24 h), respectively.

Discussion

We have determined the main pharmacokinetic parameters of a β-CD derivative, 6-monoamino-β-CD, which was shown to be less hemolytic than the parent compound, after iv administration at a single 25 mg/kg dose. These results were obtained using a sensitive and specific enzyme immunoassay. Due to the high specificity of this method toward the intact β-CD core, we have demonstrated that little metabolism of this compound occurs. Indeed, 6-monoamino-β-CD is rapidly eliminated from the systemic circulation and is almost totally eliminated via the urinary route, rather like the parent compound.[24] However, in contrast with previous observations for β-CD,[24] 6-monoamino-β-CD has an apparent volume of distribution of 202 mL/

kg, pointing to a probable extravascular distribution, in select tissues or storage pools. The urinary clearance is close to the systemic clearance and appeared close to the glomerular filtration rate.

Using the same immunoanalytical method, we also analyzed the fate of 6-monoamino-β-CD in the rat after oral intake (25 mg/kg). We demonstrated the presence of detectable amounts of the intact molecule in plasma, with a maximal concentration observed 30 min after administration. The molecule is then eliminated via the urinary route. Although 6-monoamino-β-CD was detected in both plasma and urine of the 4 treated rats, large variations were observed; the extent of gastrointestinal absorption of this molecule depends on the individual animal. The cumulative amount of intact CD excreted represents 0.84 $\pm$ 0.7% of the dose. These observations are in agreement with previous reports on orally administered β-CD[25,26] using either radiolabeled compound or a sensitive HPLC technique.[27] Thus, chemical modification does not seem to induce major changes in the pharmacokinetic behavior of the molecule compared with the parent compound. Finally, we have calculated a low oral bioavailability for this molecule, indicating only minimal absorption.

To our knowledge, this is the first full description of the pharmacokinetic analysis of this β-cyclodextrin derivative after iv and oral administration to the rat. A specific analytical method such as the presently described enzyme immunoassay may yield valuable information on the fate of cyclodextrin(s) used for pharmaceutical applications, irrespective of the mode of administration (parenteral and oral for the present study but dermal or transmucosal applications can also be investigated). Moreover, we have observed that this assay retains its analytical characteristics when applied to human urine and plasma samples (data not shown). We are currently developing similar specific immunoassays for methyl derivatives of β-CD, i.e., heptakis-(2, 6-di-*O*-methyl)cyclomaltoheptaose (DIMEB) and heptakis-(2,3,6-tri-*O*-methyl)cyclomaltoheptaose (TRIMEB) which may provide further important data for pharmaceutical applications.

Abstract □ The aim of this study was to investigate the feasibility of a quantitative structure–pharmacokinetic relationships (QSPKR) method based on contemporary three-dimensional (3D) molecular characterization and multivariate statistical analysis. For this purpose, the programs SYBYL/CoMFA, GRID, and Pallas, in combination with the multivariate statistical technique principal component analysis were employed to generate a total of 16 descriptor variables for a series of 12 structurally related adenosine A_1 receptor agonists. Subsequently, the multivariate regression method, partial least squares, was used to predict clearance (CL), volume of distribution (Vd_{SS}) and protein binding (fraction unbound, f_U). The QSPKR models obtained could account for most of the variation in *CL*, Vd_{SS}, and f_U ($R^2 = 0.82$, 0.61 and 0.78, respectively). Cross-validation confirmed the predictive ability of the models ($Q^2 = 0.59$, 0.41 and 0.62 for *CL*, Vd_{SS}, and f_U, respectively). In conclusion, we have developed a multivariate 3D QSPKR model that could adequately predict overall pharmacokinetic behavior of adenosine A_1 receptor agonists in rat. This methodology can also be used for other classes of compounds and may facilitate the further integration of QSPKR in drug discovery and preclinical development.

Introduction

Since the pioneering work of Hansch and co-workers,[1] quantitative structure−activity relationships (QSAR) analysis has become a widely used tool in the design of modern drugs. In recent years, sophisticated alternatives for traditional "Hansch-type" QSAR methods have been developed, in particular in the area of three-dimensional (3D) molecular characterization and multivariate data analysis.[2−4] In contrast to these developments in the QSAR field, the vast majority of quantitative structure−pharmacokinetic relationships (QSPKR[5]) studies have only focused on univariate correlations of individual pharmacokinetic parameters with lipophilicity and ionization, and it has been well established that log *P* and pK_A are important determinants of drug absorption, distribution, protein binding and elimination (for example[3,6−10]). A major drawback of such QSPKR models is that they provide no insight into the influence of other physicochemical properties and therefore their conceptual and predictive value is rather limited. However, despite these limitations, only a few attempts have been made to develop more comprehensive multivariate QSPKR models that predict pharmacokinetics on the basis of various molecular physiocochemical descriptors.[11,12] Furthermore, most QSPKR studies have primarily focused on the prediction of single parameters instead of multivariate modeling of overall pharmacokinetic behavior.[6] Therefore, in the present study we have started to explore the possibilities of generating QSPKR models based on contemporary QSAR methods of 3D molecular characterization and multivariate statistical analysis. The 3D molecular descriptor methods, SYBYL/CoMFA[13] and GRID,[14] in combination with the multivariate statistical techniques, principal component analysis (PCA) and partial least squares (PLS[15,16]), were used to build models for simultaneous prediction of the primary pharmacokinetic parameters, clearance (*CL*), volume of distribution at steady-state (Vd_{SS}), and protein binding (fraction unbound, f_U) for a series of structurally related adenosine A_1 receptor agonists in rat. The pharmacokinetic data were obtained during the course of a program focused on the design of partial agonists for the adenosine A_1 receptor[17,18] as reported previously.[19−23]

Materials and Methods

Chemicals—All compounds used in this study are analogues of the endogenous purine nucleoside, adenosine (Figure 1). Compound **1** is the reference adenosine A_1 receptor agonist, N^6-cyclopentyladenosine (CPA[19]). Compounds **2**−**4** and **5**−**9** are deoxyribose[20] and 8-alkylamino-substitued CPA analogues,[22] respectively. In addition to the CPA analogues, another widely used adenosine A_1 receptor agonist, R−N^6-phenylisopropyladenosine (R−PIA,[21] **10**) was included as well as the novel compounds **11** and **12** as hydrophilic and lipophilic non-CPA analogues, respectively.[23]

Pharmacokinetic Experiments—Details of the pharmacokinetic experiments have been published previously.[19−23] Briefly, 2 days before experimentation, the right femoral artery and the right jugular vein of male Wistar rat (200−250 g) were cannulated for the collection of blood samples and administration of drugs, respectively. Conscious, freely moving rats received an intravenous infusion of vehicle (20% DMSO/water) or compound over 15 min. Serial arterial blood samples were taken over a period of at least 100 min, hemolyzed immediately, and stored at −35 °C until HPLC analysis of blood concentrations.

Compartmental analysis of blood concentration−time profiles was performed by fitting the data to a biexponential equation from which systemic clearance (*CL*) and volume of distribution at steady state (Vd_{SS}) were calculated.[19] The fraction unbound drug in blood (f_U) was determined using standard ultrafiltration methods. The pharmacokinetic parameters for all 12 compounds included in the study are summarized in Table 1.

Molecular Modeling—The 3D structures of the compounds were provided by Dr A. P. IJzerman (Division of Medicinal Chemistry, Leiden/Amsterdam Center for Drug Research), based on the adenosine A_1 receptor model published before.[24]

Generation of Molecular Descriptors—In both the SYBYL/CoMFA[13] (Molecular Modeling Software 6.3, Tripos Inc., St. Louis,

MO) and GRID[14] (Molecular Discovery Ltd., University of Oxford, U.K.) programs, a grid large enough to enclose all the aligned ligands is utilized. In each grid point, interactions between a probe atom and the target molecules are calculated. SYBYL/CoMFA and GRID use different force fields and different types of probe atoms, and the interactions are calculated differently. Interactions accounted for in the GRID force field are steric, electrostatic and hydrogen bonding interactions represented by the Lennard−Jones energy (E_{ste}), the Coulombic energy (E_{ele}) and a hydrogen bonding (E_{hb}) term, respectively. In contrast to SYBYL/CoMFA, where the interaction energies (i.e., E_{ste} and E_{ele}) are considered separately, the sum of all the different interaction energies is calculated in each grid point with GRID. An attractive interaction between the probe atom and the ligand produces a negative field (E_{tot}), whereas a repulsive interaction is positive

$$E_{tot} = E_{ele} + E_{ste} + E_{hb} \quad (1)$$

Different probes reflect different types of interactions and may selectively be included to mimic specific interactions between the ligand and the target protein,[14,25,26] and often more than one probe is necessary for a complete description of the interactions involved in the ligand−protein interaction.

The second type of descriptors considered were molecular surface volumes, such as, POP1, POT0, and POM1 (see Table 2), corresponding to the volumes (Å^3) of the electrostatic potential surfaces at the charge levels plus one, zero, and minus one, respectively (SYBYL 6.1, Molecular Modeling Software 6.3, Tripos Inc., St. Louis, MO).

The third type of descriptors were the electronic descriptors [heat of formation (HEFO), electronic energy (ELEN), dipole moment (DIPO), filled levels (FILE), and ionization potentials (IOPO)], obtained from Mopac 6.0 (SYBYL 6.1) AM1 single point calculations[27] with the keywords SCF1, MULLIK, AM1 and T = 3600 activated (Table 2). Four steric descriptors were included in the present investigation, namely the core−core repulsion (COCO), molecular weight (MW) and the areas and the volumes enclosed by the Connolly surfaces, COAR and COVO, respectively. The Connolly surface area (solvent accessible area) is defined as the area a theoretical water molecule (1.4 Å in diameter) produces when it moves over the van der Waals surface of a ligand.

Finally, the log *P* descriptor (the logarithm of the partition coefficient, *P*, between 1-octanol and water) was estimated with the Prolog *P* module (CDR database) of the Pallas program (version 1.2, CompuDrug Chemistry Ltd., Budapest, Hungary), which utilizes a modification of the method presented by Rekker and De Kort,[28] where the contributions of the hydrophobic molecular fragment constants are added. It is well-known that different methods of calculation may yield different theoretical estimates of log *P*. Therefore, we also calculated log *P* with the ATOMIC5 database of the Pallas program, which is based on a modification of the work of Ghose and Crippen.[29] Although the estimates varied slightly between the two methods, the correlation was high (r = 0.88) and the slope and intercept of the best-line fit were not significantly different from unity and zero, respectively. Hence, for the sake of simplicity only estimates based on the CDR database were used in the present analysis, and the log *P* parameter should be interpreted as such. In other cases, however, it might be advantageous to include several log *P* estimates calculated by different methods in the model.

Principal Component Analysis (PCA)—Principal component analysis (PCA) was used in the first stage of the study to replace the original molecular descriptors generated in the GRID program by so-called "3D principal properties" (3DPPs, see *Results*) and to summarize in a graphical manner the information contained in the dataset. Details of PCA can be found in numerous references.[15,16] Briefly, let **X** be a matrix with *m* rows and *n* columns, representing a dataset of *m* compounds with *n* descriptor variables ($\mathbf{X} = [\mathbf{x_1}, \mathbf{x_2}, ..., \mathbf{x_n}]$). In PCA, the original *n* descriptors in **X** are replaced by a limited number (*a*) of new variables, called principal components (PCs), which are linear combinations of the columns in **X**. Algebraically, PCA decomposes **X** in *a* PCs as follows

$$\mathbf{X} = \mathbf{t_1}\,\mathbf{p_1}^T + \mathbf{t_2}\,\mathbf{p_2}^T + ... + \mathbf{t_a}\,\mathbf{p_a}^T + \mathbf{E} \quad (2)$$

where the $\mathbf{t_i}$ and $\mathbf{p_i}$ vectors are known as the principal components scores and variable loadings, respectively, and **E** is the residual matrix not described by the model. Each consecutive PC is calculated orthogonal to all previous PCs and accounts for a decreasing percentage of the variation in **X**. The purpose of PCA is to describe the complete dataset with less PCs than original descriptors without significant loss of information. Plots of scores and loadings obtained from the first few PCs can then be made to reveal the relationships between objects (compounds) and variables (descriptors), respectively.

Partial Least Squares (PLS) Regression—Partial least squares (PLS) is a relatively new multivariate statistical method that has become the most widely used regression tool in the area of QSAR.[16] PLS is a generalization of ordinary multiple linear regression (MLR) and can be seen as a least-squares regression extension of PCA. Like MLR, PLS aims to provide a statistical model that describes biological properties (**y**) in terms of the descriptor variables in matrix **X**. In contrast to MLR, PLS can deal with high correlations between the descriptor variables in **X** (collinearity) and with the situation where the number of descriptors exceeds the number of compounds ($n > m$), which is often the case in QSAR/QSPKR). A detailed description of the PLS algorithm can be found in the review by Geladi and Kowalski.[15]

For the interpretation of the model, it is particularly useful that PLS models can be expressed in terms of regression coefficients ($\mathbf{b_{PLS}}$):

[a] Compound numbers refer to the chemical structures shown in Figure 1. [b] Abbreviations: 3DPP, three-dimensional principal property; COAR, area enclosed by Connolly surface; COCO, core–core repulsion; COVO, volume enclosed by Connolly surface; DIPO, dipole moment; ELEN, electronic energy; FILE, filled levels; HEFO, heat of formation; IOPO, ionization potential; log *P*, logarithm of partition coefficient; MW, molecular weight; POM1, volume of electrostatic potential surface at charge level minus one; POP1 volume of electrostatic potential surface at charge level plus one; and POT0, volume of electrostatic potential surface at charge level zero.

$$\mathbf{y} = \mathbf{X}\mathbf{b}_{\mathbf{PLS}} + \mathbf{F} \tag{3}$$

where **F** is the residual matrix. As in the case of MLR, the regression coefficients can be used to determine the influence of each variable in **X** in the model.[30]

A crucial step in the development of PLS models is the determination of the number of significant components.[4,15] Although it is possible to calculate as many PLS components as the number of descriptors in the **X** matrix, the use of too many components will result in a model that fits the data well but has poor predictability. Cross-validation has become the method of choice to determine the optimal number of components in PLS[25,26,30] and was also used in the present study. Briefly, with cross-validation, a PLS model is developed with a group of compounds omitted from the dataset. Subsequently, the model is used to predict the dependent variable (y_{pred}) for the omitted compounds and the differences between actual (y_{obs}) and predicted values are calculated. This procedure is repeated several times until all compounds have been omitted once. The predictive ability of the model can then be quantified with the Q^2 statistic:[25,26,30]

$$Q^2 = 1 - \sum (y_{ipred} - y_{iobs})^2 / \sum (y_{iobs} - y_{mean})^2 \tag{4}$$

The optimum number of PLS components is given by the number of components that maximizes Q^2. A model with good predictive capability will have a Q^2 close to unity, whereas a negative value for Q^2 indicates that the model does not predict better than random. Formally, real predictability can only be validated with an external test set, which is not included in the calibration process of the model. However, even in QSAR studies in which it is usually easier to test a large number of compounds than in pharmacokinetic experiments, it is common to test predictability by cross-validation because the dataset is often too small to be split into a training and test set. A compromise between an external test set and leave-one-out cross-validation as used in the present study is leave-more-out cross-validation where multiple compounds are left out simultaneously several times, like in bootstrapping. However, this method still requires rather large datasets and we therefore decided to use the leave-one-out method; that is, compounds were omitted one by one.

The Q^2 value can be compared with the R^2 statistic which indicates the fraction of the variation accounted for by the model:[25,26,30]

$$R^2 = 1 - \sum (y_{icalc} - y_{iobs})^2 / \sum (y_{iobs} - y_{mean})^2 \tag{5}$$

The R^2 values range between zero (meaningless model) and unity (perfect correlation). The value of R^2 increases with the number of components included in the model, and the PLS regression model converges toward the MLR solution when the number of components is identical to the number of variables in the **X** matrix. In that case, the fraction explained variance is maximal but the model is usually overfitted, that is, the predictability is poor (low Q^2). On the other hand, an underfitted model with too few PLS components does not account for sufficient variation (low R^2). Eriksson and Johansson[30] have suggested that a difference between R^2 and Q^2 values of >0.3 is indicative of an inappropriate model.

The outcomes of PCA and PLS are dependent on the scaling of the variables. In the present study we always employed the autoscaling procedure, that is, all variables were scaled to unit variance and centered around the mean.[15]

All PLS and PCA calculations were performed with the PLS_Toolbox version 1.5.2 (Eigenvector Research, Inc., Manson WA) using the MATLAB software package version 4.2c.1 (The MathWorks Inc., Natick MA).

Computer Hardware—The generation of the 3D molecular descriptors was carried out on a R4600 Indy Silicon Graphics workstation. All other calculations were done on standard Pentium personal computers.

Results

Generation and PCA of Molecular Descriptors—The grid created in GRID enclosed all the aligned ligands with 4 Å with a resolution of 1 Å in all directions and consisted of 9025 points. For each of the 12 compounds, interactions with three probes (CA2+, C3, and OH2) were calculated at each grid point, thus yielding three grids with 9025 data points for each compound (i.e., a total of 27 075 data points per compound). Prior to the multivariate analysis, the grids were unfolded to row vectors, which were subsequently combined to form a 12 × 27 075 matrix. A PCA was performed on this matrix to reduce this large set of data into a smaller number of new, orthogonal (uncorrelated) variables. The first three PCs explained 91% of the total variance in the data, indicating that the original 27 075 GRID variables could be replaced by the score vectors associated with these PCs without significant loss of information. These scores vectors can be regarded as "principal properties" (PP) of the compounds and, because they were derived from a 3D structure analysis, will be referred to as "3DPPs". The 3DPPs for the first, second, and third PC (3DPP1, 3DPP2, and 3DPP3, respectively) are given in Table 2 together with the other descriptors, which were obtained as described in the *Methods* section.

Subsequently, a PCA was performed on the combined data of Table 2 to obtain insight into the relationships between descriptors and compounds. One-, two-, and three-component models described 60, 79, and 94% of the total variance, respectively. The plot of the scores of the compounds for the first two PCs reveals three clusters: the first one with the reference ligand CPA (**1**), the deoxyribose

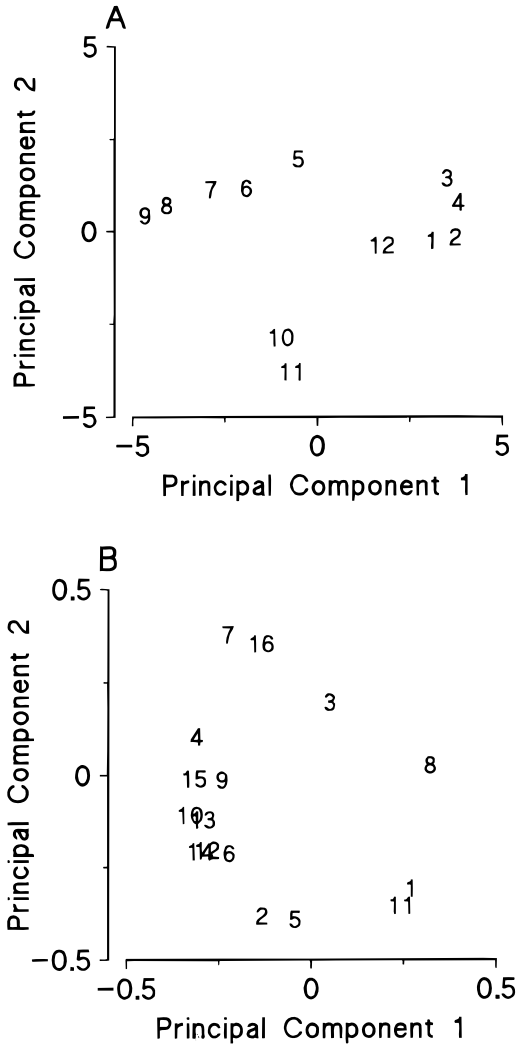

Figure 2—Graphical representation of the first two principal components, which explained 79% of the total variance of the data given in Table 2. (A) Plot of the scores of the 12 adenosine A_1 receptor agonists. Numbers correspond to the compounds shown in Figure 1. (B) Plot of the loadings of the 16 molecular descriptors. Numbers correspond to the descriptor variables in Table 2.

analogues **2**, **3**, and **4**, and the lipophilic non-CPA analogue **12**; a second cluster with the 8-alkylamino-substitued CPA analogues **5**, **6**, **7**, **8**, and **9**; and a third cluster with R−PIA (**10**) and the hydrophilic non-CPA analogue **11** (Figure 2A). From the loading plot for the first two PCs, one clear cluster can be recognized that contains the steric descriptors 12 (COAR), 13 (COVO), 14 (MW), and 15 (COCO), the electronic descriptors 9 (DIPO) and 10 (FILE), and the molecular surface volumes 4 (POP1) and 6 (POM1, Figure 2B). The clustering of the remaining descriptors is less clear. It is of interest to note, however, that 3DPP1 and 3DPP2 seem to be closely associated with IOPO and POT0, respectively (Figure 2B).

Correlation between Pharmacokinetic Parameters and Molecular Descriptors—Correlation coefficients were calculated between the pharmacokinetic parameters and each of the molecular descriptors using the MATLAB program. All three pharmacokinetic parameters were significantly correlated ($P < 0.05$) with HEFO ($r = 0.63$, 0.63, and −0.75 for *CL*, Vd_{SS}, and f_U, respectively) and log *P* ($r = 0.66$, 0.80 and −0.74 for *CL*, Vd_{SS} and f_U, respectively). In the case of Vd_{SS}, no other significant correlations were found, whereas *CL* displayed additional significant correlations with 3DPP1 ($r = -0.62$) and IOPO ($r = -0.68$), and f_U had significant correlations with 3DPP1 ($r = 0.81$), IOPO ($r = 0.81$), POP1 ($r = -0.75$), ELEN ($r = 0.73$), FILE ($r = -0.68$), COAR ($r = -0.61$), COVO ($r = -0.69$), MW ($r = -0.59$), and COCO ($r = -0.74$).

Table 3—Summary of the Results of the Prediction of *CL*, Vd_{SS}, and f_U of the Adenosine A_1 Receptor Agonists (Table 1) using PLS

pharmacokinetic parameter	no. of components[a]	Q^2	R^2
CL	4	0.59	0.82
Vd_{SS}	2	0.41	0.61
f_U	2	0.62	0.78

[a] Number of PLS components were determined using leave-one-out cross-validation (see *Methods* for details).

PLS Regression—PLS regression models to predict *CL*, Vd_{SS}, and f_U were built using the 16 descriptor variables listed in Table 2. The results of the analysis are summarized in Table 3 and plots of the observed versus predicted values are shown in Figure 3. With the exception of Vd_{SS} for **1** and f_U for **12**, most of the variation in the pharmacokinetic parameters could be accounted for by the PLS models (R^2 values 0.6−0.8). Furthermore, the moderate differences between R^2 and Q^2 (∼0.2 for each model) found using cross-validation indicate adequate model predictability and number of PLS components (Table 3). The relationship between R^2 and Q^2 with increasing number of PLS components is exemplified for *CL* in Figure 4.

Figure 5 shows the weighted PLS regression coefficients, which provide insight into the contribution of each descriptor to the modeling of the pharmacokinetic parameters. For example, 3DPP2 (descriptor 2) has a high impact on *CL* but is relatively unimportant in the models for Vd_{SS} and f_U. On the other hand, lipophilicity has considerable, but opposite, influence on both Vd_{SS} and f_U; that is, the log *P* regression coefficient is positive for the former and negative for the latter.

Discussion

To date, QSPKR studies have mainly focused on the relationship between pharmacokinetic properties and single, conventional physiocochemical parameters. To our knowledge, this study is the first example of the application of the molecular descriptor techniques, SYBYL/CoMFA and GRID, in combination with multivariate analysis methods, PCA and PLS, for the prediction of pharmacokinetic properties. Our multivariate approach has several advantages compared with the conventional methodologies employed in previously published QSPKR studies. First, the use of a whole series of advanced molecular descriptors instead of a single "classical" physicochemical property may yield more comprehensive 3D QSPKR models that can provide better insight into the relationship between chemical structure and pharmacokinetic behavior and a better and more robust prediction. Second, our approach can be used to predict multiple parameters and thus overall pharmacokinetic profile. Third, this approach could allow for integrated QSPKR−QSAR analysis and thus for simultaneous optimization of pharmacodynamic and pharmacokinetic properties at a very early stage of drug discovery. This integration could become a feasible strategy in the light of the emerging in vivo high-throughput screening technologies[31−33] that could provide considerable savings of laboratory animals, time, and money.

In the current study, QSPKR models were obtained for the prediction of three main pharmacokinetic parameters (*CL*, Vd_{SS}, and f_U) of a series of 12 adenosine A_1 receptor agonists. It should be noted that the present study was primarily focused on the development of methodology and

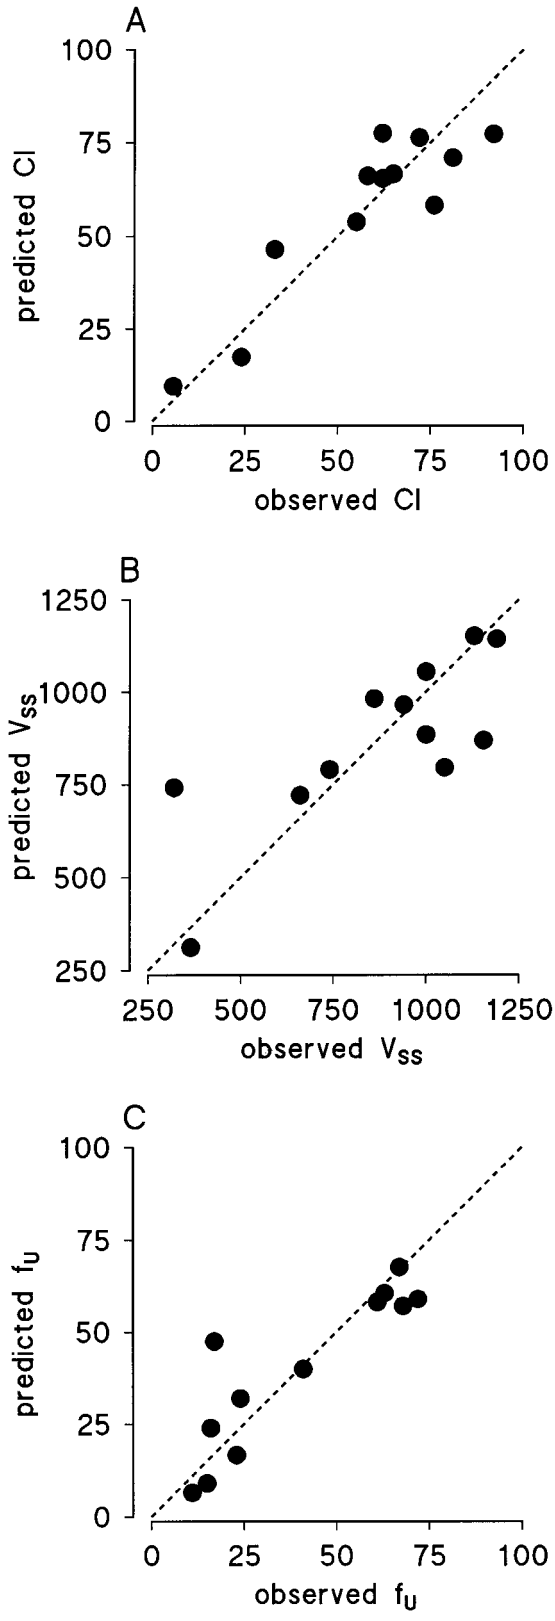

Figure 3—Relationship between observed and predicted (A) *CL*, (B) Vd_{SS}, and (C) f_U using the PLS models summarized in Table 3. The dashed lines represent lines of identity.

the number of compounds used for the modeling was limited. However, despite the relatively small dataset, the predictive ability of the QSPKR model as judged by leave-one-out cross validation was fair (i.e., difference between R^2 and Q^2 was ~0.2 in each case). The between-ligand variation in the pharmacokinetic parameters was accounted for in an adequate manner by the models in most cases (Figure 3). The exceptions were the predictions of Vd_{SS} for CPA (**1**, predicted 742 mL/kg, observed 320 mL/kg) and f_U for **12** (predicted 47%, observed 17%). At present we have no explanation for these outliers, but in the case of CPA, the overestimation of Vd_{SS} may at least in part be due to variability in the experimental estimate because we have recently[23] obtained a >30% higher value (421 mL/kg). Furthermore, the use of the standard PLS algorithm implies the assumption of a linear relationship between molecular descriptors and pharmacokinetic parameters. If this assumption would not be valid, nonlinear variations of PLS might provide better predictions. However, the nonlinear algorithms with polynomial, spline, or neural-network inner relations as implemented in the MATLAB PLS_Toolbox have not yet been widely applied and require further validation.

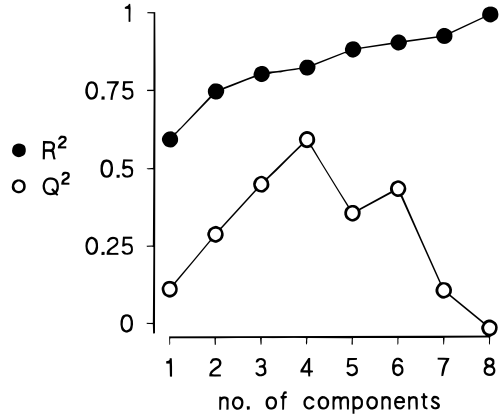

Figure 4—Effect of increasing the number of PLS components in the model for *CL* on the values of R^2 and Q^2. In this case, the optimum number of components was found to be 4 (Table 3).

The GRID program was used to generate 3D molecular descriptors in this study. Because GRID generates datasets with a very large number (27 075 in the present study) of highly correlated variables, it is desirable to employ some form of data pretreatment to reduce the number of datapoints in the descriptor matrix. Because it was found that three principal components could describe >90% of the total variance in the GRID matrix, we decided to replace the original variables with these principal components (3DPPs). An advantage of the use of principal properties, particularly when the number of compounds is relatively small, is that it is much more efficient in reducing the number of variables than other data pretreatment methods generally used in conjunction with GRID, such as D-optimal variable preselection.[25,26] Furthermore, being principal components, the 3DPPs display no collinearity. Another advantage is that the 3DPPs can be related to other molecular descriptors, which allows for a physicochemical interpretation of the GRID analysis. In the present study, it was found that the first and second 3DPP were closely associated with IOPO and POT0, respectively (Figure 2B). To our knowledge, this is the first example where such a relationship between GRID and physicochemical properties is shown.

A qualitative interpretation of the QSPKR models can be made on the basis of the PLS weighted regression coefficients (Figure 5). High values of 3DPP2 and the related descriptor POT0, and to a lesser degree 3DPP1 and the related descriptor IOPO, are associated with low *CL*. In contrast, high values of 3DPP3 and POM1 result in an increase of *CL*. The influences on *CL* of the remaining molecular properties, including log *P* (as calculated), appear to be less important (Figure 5A).

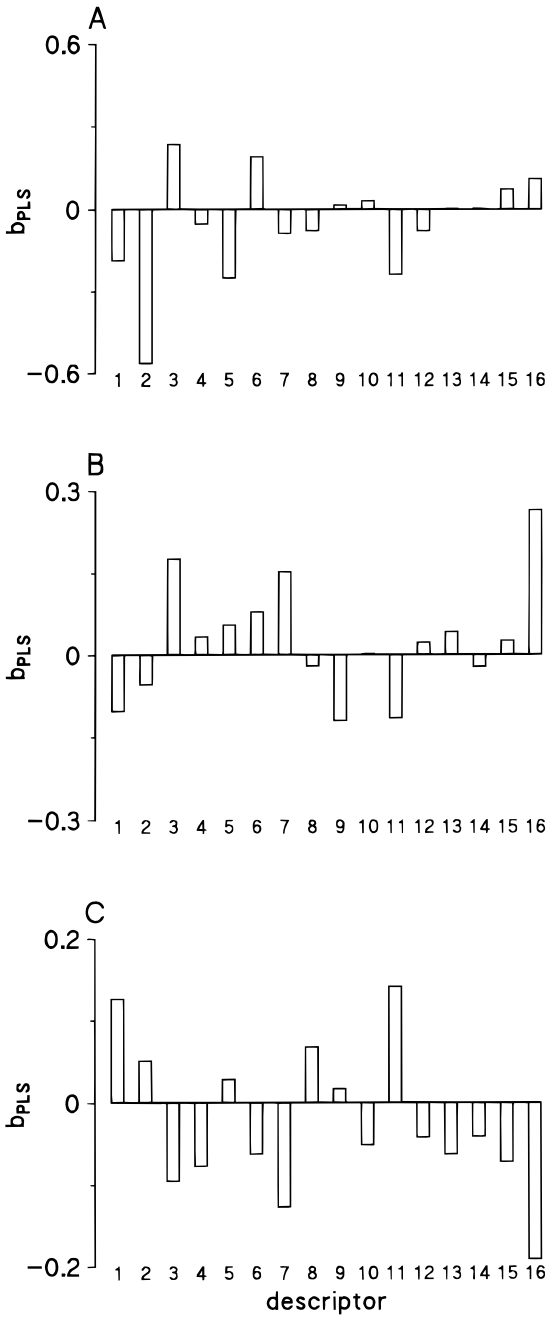

Figure 5—Weighted PLS regression coefficients (b_{PLS}) for (A) *CL*, (B) Vd_{SS}, and (C) f_U. Numbers correspond to the descriptor variables in Table 2.

In the case of Vd_{SS}, the high value of the regression coefficient for log *P* is consistent with many previously published reports that high lipophilicity is associated with large Vd_{SS}.[7] However, from Figure 5B it can be seen that 3DPP3 and HEFO are also important factors that are positively correlated with Vd_{SS}, whereas increased values of 3DPP1, IOPO, and DIPO will reduce Vd_{SS}.

Figure 5C shows that many factors contribute to the model for f_U, which would be expected on the basis of the high number of significant correlations found previously (see *Results*). The most influential factors are log *P* and to a lesser degree HEFO, which are negatively correlated, and the two related descriptors 3DPP1 and IOPO, which are positively correlated with f_U. This result confirms the conclusion made by others that lipophilicity is a key determinant of protein binding but that other physicochemical features, in particular electronic properties, also play an important role.[7]

To date, MLR has been used successfully as a regression technique in many QSPKR studies. The main disadvantage of MLR compared with PLS is that it performs very poorly in the case of collinearities among descriptor variables and that it can only be applied when the number of compounds exceeds the number of descriptors by at least a factor 3−5.[15,30] Therefore, PLS has replaced MLR as method of choice in modern QSAR studies and it may be expected that this will also happen in the area of QSPKR when the methods presented in this paper are developed further and applied to large datasets with even more molecular descriptors (for example original GRID points) and pharmacokinetic properties. The main appeal of MLR is that it may yield models that are apparently easy to interpret. When a dependent variable is strongly correlated with one of the independent variables, it should, in general, be possible to generate a simple MLR model based on the influential descriptor and one or two additional orthogonal variables that explain a fraction of the variation similar to that explained by PLS. For example, on the basis of the strong influence of log *P* on Vd_{SS} and f_U, one can calculate the simple MLR relationships $Vd_{SS} = 236.2 + 181.6 \log P + 1.2$ MW and $f_U = 92.4 - 15.4 \log P - 6.4$ DIPO which yield R^2 values (0.67 and 0.77, respectively) that are as good as the ones obtained with PLS (Table 3). However, the molecular diversity of the ligands in this study was limited, and it may be expected that the chances of finding such simple relationships will decrease with increasing complexity of the dataset. Furthermore, multivariate QSPKR modeling should aim to predict overall pharmacokinetic behavior, whereas MLR on the basis of a few descriptors may only provide an adequate alternative for PLS for some of the parameters of interest. In the present case, for example, the best MLR model for *CL* on the basis of log *P* and one other descriptor ($CL = 156.5 + 12.9 \log P - 0.01$ POT0) predicted poorly compared to PLS ($R^2 = 0.65$ and 0.82, respectively).

Herman and Veng-Pedersen[11] have suggested that QSPKR models need not be limited to congeneric series but can be used to predict distribution kinetics of a wide variety of drugs. However, in our view, QSPKR and QSAR models should generally be regarded as having "local validity" only, that is, their utility is restricted to series of chemically related ligands with similar biological properties. Hence, we believe that QSPKR modeling may be particularly useful to analyze pharmacokinetic databases of structural analogues obtained in the early stages of drug development programs. Obviously, the aim is always to develop a model that predicts the pharmacokinetic parameters of the whole set of compounds as well as possible. However, the limitations of a QSPKR model may be just as valuable and the outliers that are poorly predicted may provide new insight into the mechanisms underlying the pharmacokinetic processes. For this purpose, however, a more physiological approach than the one used in the present study should be adopted in which the dependent variables represent intrinsic pharmacokinetic properties of individual organ systems rather than overall pharmacokinetic behavior.[10,34]

In conclusion, in the present paper we have described a QSPKR method based on 3D molecular characterization and multivariate statistical analysis. By using this method, we obtained a model that could adequately predict overall pharmacokinetic behavior of 12 adenosine A_1 receptor ligands in rat. Notwithstanding the fact that analysis of a larger dataset would be required to draw any general conclusion about the pharmacokinetic behavior of adenosine analogues, these first results obtained with a relatively small number of ligands warrant further validation and application of multivariate 3D QSPKR on larger datasets of other classes of compounds. In combination with emerg-

ing methods for high-throughput in vivo pharmacokinetic screening of mixtures of structurally related compounds[31−33] and with novel approaches in physiologically based pharmacokinetic modeling,[10,34] multivariate 3D QSPKR may become a useful tool in drug discovery and preclinical development.

Received July 20, 1998. Final revised manuscript received November 30, 1998.
Accepted for publication December 1, 1998.

Abstract □ The purpose of this work was (1) to determine if useful in vivo pharmacokinetic data could be obtained after simultaneous administration of 5–22 compounds of a chemically congeneric series to dogs and (2) to determine if structure–pharmacokinetic relationships could be derived from such studies. Mixtures of structurally related α-1 antagonist compounds (**5**–**22**) were administered intravenously to conscious dogs. Blood samples were taken over the next 24 h and analyzed by LC/MS to determine plasma levels and pharmacokinetics of each compound. The pharmacokinetics of 17 of these compounds were also determined after individual administration. Results obtained in the N-in-One format for 17 compounds correlated well with results obtained when these same compounds were administered individually. The N-in-One method is a useful method for obtaining pharmacokinetic data on 5–20 molecules in a single animal at one time. The increased throughput in obtaining important pharmacokinetic information should enhance the drug discovery process. In addition, it was possible to determine the extent to which various chemical substitutions did or did not affect pharmacokinetic parameters.

Introduction

Success in drug discovery increasingly relies on the ability to rapidly identify quality molecules that possess the desired attributes of bioavailability, chemical tractability, selectivity, and potency. Combinatorial chemistry and high throughput biochemical screening techniques should have a major impact on the process of generating and identifying potent and selective compounds in drug discovery.[1] The identification of compounds that possess the desired pharmacokinetic (oral bioavailability, clearance, volume of distribution, and half-life) and pharmacodynamic profile has become a time-consuming process in drug discovery programs. While in vivo studies are expensive to conduct, they are also extremely informative. Thus, substantial enhancements in the capacity to characterize molecules in vivo could help relieve a bottleneck in the current drug discovery process.

Increased throughput in in vivo pharmacokinetic screening has recently been reported by (a) dosing mixtures of compounds to a single animal and (b) by pooling samples from singularly administered compounds prior to analysis.[2–8] Both methods capitalize on tandem liquid chromatography/mass spectrometry (LC/MS) as a sensitive and specific method for analysis. We have referred to the former method as N-in-One dosing, where N is the number of compounds coadministered. The N-in-One approach provides an opportunity to study the pharmacokinetics of several compounds under identical conditions while minimizing sample processing time, analysis time, and the number of animals required. Initial reports have shown the method applicable to (a) a wide range of structural classes of compounds, (b) iv and oral dosing, (c) compounds that are renally and/or metabolically eliminated, and (d) a wide variety of species including mice, rats, dogs, and monkeys.

This contribution expands on a previous report of increased capacity of in vivo pharmacokinetic evaluations.[2] This paper reports results of N-in-One studies of 5−22 α-1a antagonist compounds that provided sufficiently good estimates of pharmacokinetic such that compound progression decisions could be made. In addition, structure-pharmacokinetics relationships were developed to help define molecular changes that do and that do not alter pharmacokinetics.

Methods

Compounds—All compounds were synthesized at Glaxo Wellcome and gave satisfactory analysis by TLC, ^{1}H NMR, mass spectrometry, and elemental analysis.[11]

Pharmacokinetic Study—*N-in-One Dosing*—Male mongrel dogs (weight range 15−20 kg) were fasted overnight and fitted with two temporary cephalic vein cannulae on the day of study. Each dog received 5−22 compounds per dose session. Dose solutions involving mixtures of five or less compounds were prepared by dissolving compounds in 50 mM sodium acetate buffer (pH 4.5). Dose solutions with more than five compounds were prepared by dissolving compounds in 100 mM sodium acetate buffer containing 30% propylene glycol and 1% Tween 80 at a concentration of 0.3 mg each compound/mL. The dose solution was infused over 5 min into the right cephalic vein cannula. Each compound was given at a dose level of 0.25 mg/kg body weight (5-in-One) or 0.3 mg/kg body weight (>5-in-One). Blood samples (4 mL) were obtained from the left cephalic vein cannula in heparinized syringes at 0 (predose), 5, 15, 30, 45 min, 1, 1.5, 2, 4, 6, 8, and 24 h after the infusion began. The plasma was separated from the red blood cells by centrifugation and frozen until APCI LC/MS/MS or APCI LC/MS analysis.

Individual Dosing—Male mongrel dogs (weight range 15−21 kg) were fasted overnight and then fitted with two temporary cephalic vein cannulae on the day of study. Each compound was dissolved in 50 mM sodium acetate buffer (pH 4.5) at a concentration of 1.0 mg/mL and administered at a dose of 1 mg(base)/kg body weight via a 5 min intravenous infusion into the right cephalic vein. Blood was sampled, and plasma was obtained and stored as described above until analysis by HPLC with fluorescence detection. Each compound was studied in one dog, except for compounds **19** and **59** which were studied in four and two dogs, respectively. This

research complied with national legislation and with company policy on the Care and Use of Animals.

Sample Analysis—*N-in-One Dosing*—Calibration standards were prepared at each calibration level for each compound by spiking blank dog plasma over the range of 1 to 2300 ng/mL. Aliquots of the standards and samples (200 μL) were precipitated with 400 μL of acetonitrile that contained an internal standard (compound **18** or **9**) at a concentration of 400 ng/mL. After vortexing and centrifugation, the resulting supernatant was transferred to a clean tube and evaporated to dryness under nitrogen at 35 °C.

The analysis was performed on a Finnigan TSQ-700 mass spectrometer with Atmospheric Pressure Chemical Ionization (APCI). The residues were reconstituted in mobile phase (200 μL), centrifuged, and injected onto either a 3 μm, 50 × 4.6 mm (5-in-One study) or a 5 μm, 250 × 4.6 BDS Hypersil C18 column (>5-in-One studies). The mobile phase consisted of 5 mM ammonium acetate (pH 4.0) and acetonitrile at a flow rate of 1 mL/min. The percentage of acetonitrile was adjusted in each study to retain the mixture from the column void volume and elute all compounds within a k' range of about 1−10. The first 2 min of the HPLC effluent were diverted to waste to minimize contamination of the APCI source. Detection was by selected reaction monitoring (SRM) in positive ion mode for the 5-in-One study. A more generic approach using MS rather than MS/MS was used for quantitation of larger mixtures by scanning in selected ion monitoring mode (SIM). A longer column was necessary for mixtures >5 compounds to increase selectivity and afford more specificity because SIM was used. The run time per sample was 6 min for the 5-in-One study and a maximum of (approximately) 30 min for the other N-in-One studies.

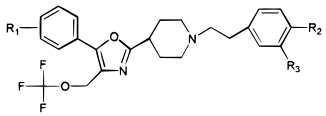
Individual Dosing—Plasma calibration standards were constructed from 5 to 200 ng/mL for each compound. Aliquots of standards and samples (50−100 μL) were precipitated with two volumes of acetonitrile (no internal standard) and prepared as described above. Samples above 200 ng/mL were diluted prior to protein precipitation. The plasma extracts were reconstituted in mobile phase (100 mL) and injected onto a Keystone BDS Hypersil C18 (150 × 3 mm, 3 μm) HPLC column at a temperature of 30 °C. The compounds were eluted with a 25 mM ammonium acetate buffer (pH = 4.5) and acetonitrile mobile phase at a flow rate of 0.5 mL/min. The compounds were detected using a fluorescence detector. The mobile phase composition and wavelength settings were varied to optimize conditions for each compound.

Pharmacokinetic and Statistical Analysis—The clearance (CL), steady-state volume of distribution (V_{ss}), and elimination phase half-life ($t_{1/2}$) of each compound were derived from the respective plasma concentration versus time curve using noncompartmental methods. Statistical comparisons between groups were done by an unpaired *t* test. Results in Tables 2−6 reflect pharmacokinetic data from 1 to 4 dogs in individual or N-in-One format.

Results

Comparison of Pharmacokinetics after Individual and N-in-One Dosing—Table 1 compares the pharmacokinetic parameters of compound **19** when dosed individually to those obtained when coadministered with 4−21 other compounds. There was no statistical difference for any parameter between the two methods. Figure 1 shows the linear regression analyses for the plasma elimination half-life, clearance and steady-state volume of distribution of 17 compounds when measured by both individual and N-in-One methods. There was good agreement in the pharmacokinetic parameters, particularly clearance, obtained from N-in-One dosing and individual dosing.

Table 2—Pharmacokinetic Data for Compounds 1–15[a]



Cmpd	R1	R2	R3	CL (mL/min/kg)	t1/2 (min)	Vss (mL/kg)
1	4H	OMe	H	14	59	785

15	4F	OMe		12	204	2907

[a] Data are present as the mean ± the standard deviation. Compound 19 data is mean of $n = 4$ individual dogs, compounds 26, 27, 31, 33, 48, and 59 are $n = 3$ observations from either individual dogs or from an N-in-One study; the remaining means are $n = 2$ (if standard deviation is shown) otherwise $n = 1$.

Pharmacokinetic data from all studies (individual and N-in-One dosed) are compiled in Tables 2−6. Mean data are presented in cases where the compound was dosed in more than one dog or was studied by both N-in-One and individual dosing. The range of pharmacokinetic values obtained from this chemical series was fairly large. For example, CL ranged from 0.3 to 44 mL/min/kg (146-fold); $t_{1/2}$ ranged from 45 to 1072 min (24-fold); and V_{ss} ranged from 41 to 14178 mL/kg (346−fold). The extent of protein binding was determined for 21 molecules. These were highly protein bound molecules which ranged from 92−99.94% bound (133-fold variation in unbound fraction).

Effect of Chemical Modifications on Pharmacokinetic Properties—*Effect of 4-F on Left-Hand Phenyl Ring*—There are several examples of pairs of molecules (**11, 12; 14, 15; 18, 19; 30, 31; 35, 36; 55, 56; 19, 21**) where the

[a] See footnote of Table 2.

only structural difference was the presence or absence of a F-substitution in the 4-position of the phenyl ring at the 5-position of the oxazole ring. In each case, the effect of the 4-F substitution was to reduce CL, although the magnitude varied from a 36% decrease (**55, 56**) to greater than 5-fold decrease (**18, 19**). CL was reduced in all cases despite the fact that CL of the non-F molecules varied from 2.8 to 44 mL/min/kg. Similar effects on CL were obtained when a chlorine was placed in the 4-position. The CL of **21,** the 4-chloro compound, was similar to **19**, the 4-F analogue (0.9 vs 0.8). In contrast, a 4-methyl substitution did not reduce clearance. The CL of compound **22** increased with 4-methyl substitution compared to its di-F analogue (**26**) (2.0 vs 5.4 mL/min/kg). The position of the halogen appeared to be important in determining the CL of the compound. The presence of F in the 3-position (**20**) did not decrease CL as much as a 4-position F- or Cl-substitution. The CL for **19** was 6 times less than its 3-F homologue (**20**). The importance of 4-position halogenation in lowering CL was also evident in a series of compounds with multiple halogenations on the left-hand side phenyl. The CL of the 2,4-F compound (**27**) was one-half that of the 2,3-F (**23**) and one-quarter that of the 2,5-F compound (**24**). Compounds **19**−**21**, **23**−**24**, and **26**−**29** contain one or more halogen substitutions on the left-hand phenyl ring (either F or Cl) with R_2 = methoxy and R_3 = SO_2NH_2. Of these nine compounds, three compounds (**20**, **23**, and **24)** have H in the 4-position with 0−3 fluorines in other positions on the ring. The remaining six compounds are all 4-halogen compounds. The CL values for **20, 23**, and **24** are 5.0, 2.5, and 5.3 mL/min/kg, respectively, whereas the CL of the other six compounds are lower, ranging from 0.7 to 2.3 mL/min/kg. On the basis of metabolites identified from bile samples of dogs dosed with compound **11**, it is likely that the halogen-substitution on the 4-position blocked a common hydroxylation pathway of metabolism on the left-hand side phenyl ring resulting in a decrease in metabolic clearance.

The effect on V_{ss} of F-substitution on the left-hand phenyl varied. V_{ss} decreased in five pairs of examples of 4-position halogenation from 16 to 66%; however, V_{ss} increased 50% for **12** compared to **11**. The net effect of 4-F substitution on $t_{1/2}$ was mixed depending on the magnitude of change in CL and volume. For example, compounds **11** and **19** experienced a 200% increase in their $t_{1/2}$ whereas **36** and **56** saw essentially no change. 4-Chloro or 4-methyl substitution did not change V_{ss}. No trends were observed in the modest changes in V_{ss} for multiply halogenated compounds. Changes in $t_{1/2}$ thus followed from the changes in CL for these compounds.

*Effect of F-Substitution on Right-Hand Phenyl Ring (**16, 17**; **40, 41**; **41, 42**)*—The placement of F on the right-hand phenyl ring at R_2 or R_3 led to changes in pharmacokinetic parameters that were inconsistent with what was observed with left-hand phenyl ring substitution. Comparisons of **16, 17** as well as **40, 41** and **41, 42** show that putting F in both the R_3 (meta) position with R_2 = methoxy (**16, 17**) or

[a] See footnote of Table 2.

at R_3 with R_2 = H (**40, 41**) had either no effect on or increased CL (CL = 7.9 vs 6.7 mL/min/kg; 4.1 vs 7.4 mL/min/kg, respectively). However, putting F in both the R_3- and R_2-position (**41, 42**) reduced CL by 55% (7.4 vs 3.3 mL/min/kg). The addition of F to R_2 (**40, 41**) or addition of F to both R_2 and R_3 (**40**, **42**) decreased V_{ss}. A modest decrease in V_{ss} was also observed when F was substituted at R_3 in the R_2 = methoxy series (**16**, **17**).

*Effect of Adding SO_2NH_2 to R_3 or R_2 (**1, 18; 25, 27; 19, 47**).* Placing a sulfonamide in the R_3 position decreased CL from 14 to 4.5 mL/min/kg (comparing **1** and **18**, respectively). The V_{ss} also decreased (51%), and $t_{1/2}$ was increased from 59 to 85 min. When this same chemical modification was made to **25**, a larger decrease in CL was observed (from 8.9 to 1.0 mL/min/kg for compounds **25** and **27**, respectively). V_{ss} also decreased from 1595 to 344 mL/kg and there was little effect on $t_{1/2}$. In sharp contrast, when the sulfonamide was placed at the R2 position (**47**) CL increased from 0.8 to 34 mL/min/kg, a 42-fold increase compared to **19**. V_{ss} was also dramatically increased from 202 (**19**) to 14178 mL/kg (**47**), a 70-fold increase. However, the dramatic alterations in CL and V_{ss} led to a relatively modest 31% decrease in $t_{1/2}$ from 248 to 324 min.

Effect of Substituted SO_2NH_2 in R_3-position—Substitution on the sulfonamide in the R_3-position when R_2 = methoxy (**2**−**11**, **13**, **14**, **18**) resulted in higher CL values for all compounds compared to the unsubstituted **18** with the exception of **2** which had a CL about one-half that of **18**. The V_{ss} also tended to be higher for substituted compounds (523 mL/kg for **18** and ranging from 600 to 3464 mL/kg for all others) except for compounds **2** and **6** which had lower V_{ss} values of 151 and 210 mL/kg, respectively. Similar effects (increased CL and V_{ss}) were observed with substituted sulfonamides in the 4-F series (**12, 15** compared to **19**) when R_2 = methoxy. For example, compound **15** had a larger CL (12 mL/min/kg) and a larger V_{ss} (2407 mL/kg) than its unsubstituted counterpart **19** (0.8 mL/min/kg, 202 mL/kg). Similarly, substitution on the sulfonamide in the R_2-position in the R_3 = ethoxy series **(30, 35; 31, 35, 36**−**39)** usually led to increases in CL (0.8−2 mL/min/kg compared to 5.5−18 mL/min/kg) and an increase in V_{ss} (1992 compared 375 mL/kg; or 516−1806 compared to 186 mL/kg). The notable exception in this case was **33,** an *N*-methyl sulfonylurea, which had the lowest CL (0.3 mL/min/kg) of not only all of the substituted sulfonamides, but also of all the 66 compounds presented in this paper, and a very low V_{ss} of 123 mL/kg. Protein binding was determined on five of the compounds in this N-substituted sulfonamide series and free fraction was greater for all the substituted molecules compared to that of the unsubstituted analogue. This may partly explain the larger volumes and the higher clearances. The higher clearances may also arise from increased metabolism (N-dealkylation) of the sulfonamide substitution, a metabolic pathway that was

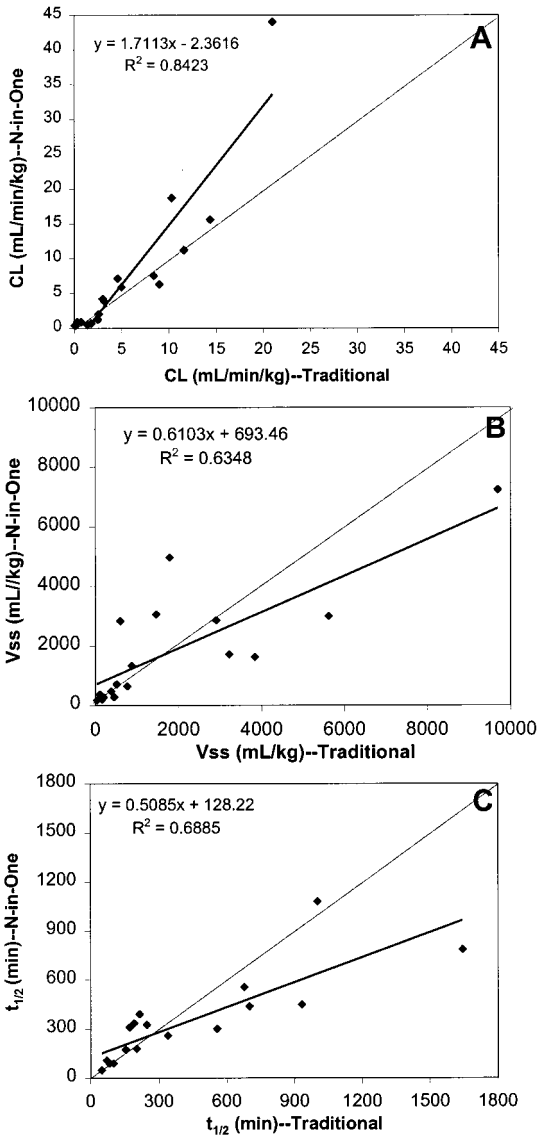

Figure 1—Linear regression (bold line) of CL, V_{ss}, and $t_{1/2}$ data for 17 compounds by both individual and N-in-One methods.

observed in in vitro dog microsomal metabolism studies of several compounds including compound **11**. Finally, one pair of enantiomers was synthesized by substituting *R*- or *S*-alanine on the R_3 sulfonamide. One enantiomer (**8**) had 50% lower CL compared to its opposite enantiomer (**9**). V_{ss} was 27% lower and $t_{1/2}$ was little changed (114 vs 107 min for **8** vs **9**, respectively).

Effect of Chemical Modifications to R3-Sulfonamide Substitutions—Methylation of the sulfonamide nitrogen (**37**) or the acetamide nitrogen (**39**) or both (**38**) increased the CL of the compound compared to that of **36**. When both nitrogens were methylated (**39**), CL was increased more than that of a single methylation (18 vs 9.0 or 14 mL/min/kg). V_{ss} was also increased when the sulfonamide nitrogen is methylated (**37** or **38**), but not when the acetamide alone was methylated (**39**). The net effect on $t_{1/2}$ was a consistent decrease of about 50% comparing **36** to **37**–**39**.

When the amide nitrogen was methylated (**13**), CL was not changed much (22%) compared to the unmethylated compound (**11**). When both the amide and sulfonamide nitrogens were methylated (**14**), the CL was still similar to when one nitrogen was methylated (**11**). However, comparing the 4-F compounds **12** and **15,** CL was unaffected when both nitrogens were methylated (11 to 12 mL/min/kg). No consistent changes were noted in V_{ss}, and no major differences in $t_{1/2}$ were observed in these series. Finally**,** replacement of a methyl group with a trifluromethyl group on the R_3 sulfonamide (**4, 5**) resulted in a 160% increase in CL, 239% increase in V_{ss}, and a 50% reduction in $t_{1/2}$.

*Comparison of Ethoxy- vs Methoxy-Substitution at R_2 (**4, 35; 18, 30; 19, 31; 25, 32**)*—No consistent change in pharmacokinetic properties was observed when the size of the alkyl group on R_2 was increased from methyl to ethyl. The notable structural difference between these compounds is that **30**–**32** are unsubstituted sulfonamides, whereas **35** has a ethylene acetamide moiety on its sulfonamide nitrogen. The direction and magnitude of change in pharmacokinetic parameters may be related to the size of the R_3 substituent. For the pair of substituted sulfonamides (**4**, **35**) the CL increased by 60% and the V_{ss} increased by 232% when the methoxy was changed to ethoxy. For the unsubstituted sulfonamides **(18, 30; 19, 31)**, the CL and V_{ss} decreased or were unchanged. The net effect of these changes on $t_{1/2}$ was minimal, except in the case of **30**.

Effect of Adding an N-Methyl Group to R_2 Amide[56–58]—In this example of *N*-methylation, addition of a methyl group to the amide of **56** to generate **57** had little effect on CL, V_{ss}, or on $t_{1/2}$. In contrast to the earlier two examples of methylation at the R_3-substituent, adding a second methyl group (**58**) dramatically reduced the CL from 33 mL/min/kg (**57**) to 8.4 mL/min/kg (about 4-fold). V_{ss} also drops by more than 50% (from 5085 mL/kg to 2102 mL/kg) which attenuates the increase in $t_{1/2}$ to 138% (from 126 to 252 min).

Effect of Adding an N-Methyl Group to Right-Hand Aniline: Comparing NH_2 to NO_2—When the aniline nitrogen was methylated (**49**), CL was not greatly altered compared to **48** (6.3 to 6.6 mL/min/kg). V_{ss} and $t_{1/2}$ were unaffected as well. Adding a second methyl group (**50**) caused CL to increase by almost 4-fold (from 6.3 to 24 mL/min/kg) with a further decrease in V_{ss} (from 8052 to 1725 mL/kg) and a decrease in $t_{1/2}$ by 94% to only 66 min. Oxidation of the amine to a nitro group (**51**) also increased CL by 59% and decreased V_{ss} by 90% compared to **48** and hence also resulted in a large decrease in $t_{1/2}$ of 84%.

*Effect of Alkyl Substitution on the Terminal Nitrogen of the Phenylmethyleneurea on R_2 (**59**–**64**)*—Single methylation of the proximal nitrogen resulted in an increase in CL of 136% (**59** compared to **60**), a modest decrease in V_{ss}, and a large decrease in $t_{1/2}$ of 52% (from 982 to 468 min). When the terminal nitrogen was methylated, the effect on CL was even greater going from 2.5 to 26 mL/min/kg (**59** compared to **61**), and there was little effect on V_{ss} (from 3128 to 3375 mL/kg). The net effect on $t_{1/2}$ was a dramatic reduction from 982 to 95 min (**59**, **61**). When larger alkyl groups were added to the terminal nitrogen of **59**, the effect was still a net increase in CL and decrease in $t_{1/2}$, but the magnitude of the changes were not as great compared to the effect of adding a single methyl group.

*Comparing Methylene Acetamide to Methylene Sulfonamide or Acetal at R_2 (**40**, **43**–**45**)*—Placing an acetal group at R_2 (**45**) increased CL from 4.1 to 17 mL/min/kg relative to no substitution (**40**). V_{ss} was not greatly affected (2743 vs 2419 mL/kg) and $t_{1/2}$ was, therefore, greatly reduced (78 vs 720 min). Extending the acetal to a methylene acetamide (**44**) resulted in a lower CL value of 5.7 mL/min/kg and a higher V_{ss} value of 3350 mL/kg leading to an intermediate $t_{1/2}$ of 486 min. When the methylene acetamide was replaced with a bulkier methylene sulfonamide (**43**), CL (6.2 mL/min/kg) remained essentially the same as **44** and V_{ss} increased still further to 5101 mL/kg. The $t_{1/2}$ is 653

min, which is the longest $t_{1/2}$ of this group of compounds, yet still less than the unsubstituted compound (**40**).

Effect of Other R_2 Substitutions—Comparing the pharmacokinetics of the sulfonamide to the sulfone in the R_2-position, the sulfonamide (**47**) had a 5-fold higher CL and 2-fold higher V_{ss} than the methyl sulfone (**46**). The $t_{1/2}$ was lowered by a factor of 1.6-fold, comparing **47** to **46**. Oxidation of the thioether (**53**) to its sulfoxide (**54**) resulted in a slight increase in CL (from 11 to 14 mL/min/kg) whereas V_{ss} quadrupled, going form 828 to 3632 mL/kg. The effect on $t_{1/2}$ was a 171% increase going from 78 to 211 min. Extension of the urea in the R_2-position (**65**) with a methylene group (**59**) led to a >3-fold increase in CL (2.5 to 9.3 mL/min/kg) and a 37% increase in V_{ss}. The $t_{1/2}$ was decreased by 42%.

Discussion

The original goal of this effort was to determine if N-in-One studies could be used to rapidly determine pharmacokinetic consequences of changes in chemical structure within a congeneric chemical series. In essence, that goal was achieved. This conclusion is supported by the linear regression analysis on the pharmacokinetic parameters for 17 compounds studied by the individual method of one compound in one dog or in various N-in-One studies. It is also supported by the work with **19** which was examined in all nine N-in-One studies and in four separate single drug studies (Table 1).

A second feature of this work was to permit the development of structure−pharmacokinetic relationships with the 66 compounds tested using this method. Of the 66 compounds, 22 were examined in at least two dogs as mixtures or individually. The general robustness of the data afforded the opportunity to make hypotheses about structure−pharmacokinetic relationships that would suggest further study or the resynthesis of compounds to investigate the hypothesis. There are some caveats and limitations to using this method. It is not clear if it applies uniquely to this set of compounds or if the method applies to all compound mixtures. More studies by us and others will be needed to answer this question. A number of limitations have been previously cited[2] and those apply here as well.

In the research program from which these compounds were derived, the desired criteria for the three PK variables were: CL < 5 mL/min/kg, $t_{1/2}$ > 240 min and V_{ss} < 1000 mL/kg. At the other extreme, compounds having either CL > 15 mL/min/kg, $t_{1/2}$ < 120 min, or V_{ss} > 3000 mL/kg were judged unacceptable. Of the 66 compounds studied, there were only five molecules which met all three pharmacokinetic criteria (four in the R_2 = methoxy series, and one in the R_2 = ethoxy series). On the other hand, only two compounds had unacceptable values for all three parameters and these were in the series where R_2 = H. This led to the conclusion that continued modification of compounds with R_2 = methoxy or ethoxy would lead to compounds with the best pharmacokinetic profile. In addition, halogen substitution at the 4-position of the left-hand-side phenyl and removal of substitutions on the R_3-sulfonamide consistently resulted in compounds with lower CL. However, the latter did not appreciably increase the half-life of the compound, since removal of the sulfonamide substitution also consistently led to compounds with reduced volumes of distribution. Compound **33** appears to be unique in pharmacokinetic terms since most N-substituted sulfonamides (**2**−**15; 35**−**39**) had CL values between 2 and 34 mL/min/kg, yet for **33** the CL was 0.3 mL/min/kg, the lowest value obtained for all of the molecules examined. Compound **33** was studied in three dogs with consistent results and therefore raises the question as to why this methylsulfonylurea had such a low (and desirable) CL.

Another example with unexpected results is compound **46** and **47**, which differ only in one being a methyl sulfone, whereas **47** is a sulfonamide in that position. Despite this similarity, there is a 5-fold difference in CL. The explanation for this difference is not clear. Neither the clogP values (3.4 and 3.2, respectively), nor different electron-withdrawing effects (σ values of 0.68 vs 0.62 via Hammett equation) seem likely explanations. One possibility is that glucuronidation may be an additional elimination pathway for the sulfonamide thus contributing the higher clearance. This example highlights the value in doing the N-in-One approach to generate data that can lead in directions that would not have been anticipated from first principles.

Both in vitro drug metabolism and cell permeation studies and in vivo pharmacokinetic experimentation will be needed in order to more fully expand our current understanding of the various factors governing pharmacokinetics.[9,10] It is envisioned that the enhanced capacity to generate qualitative and quantitative pharmacokinetics and drug metabolism data will provide information that will enable the iterative generation and refinement of predictive rules regarding the many factors that govern pharmacokinetics.

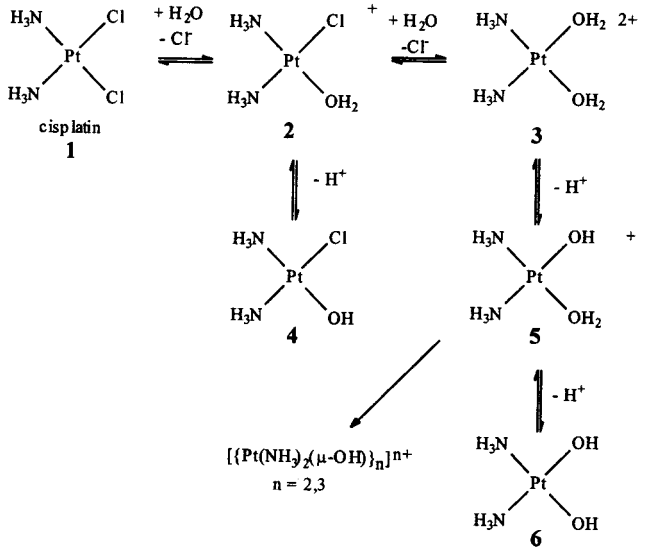
Abstract □ In water, the antineoplastic drug cisplatin, *cis*-[$PtCl_2(NH_3)_2$] (**1**) hydrolyses slowly to the aqua complexes *cis*-[$Pt(NH_3)_2Cl(H_2O)]^+$ (**2**) and, to a small extent, *cis*-[$Pt(NH_3)_2(H_2O)_2]^{2+}$ (**3**), which are thought to play an important role in the metabolism of cisplatin. HPLC is a useful technique for monitoring **2** and **3**, but only if the components of the mobile phase used in the reverse phase HPLC technique are unreactive toward these aqua complexes under the conditions of the experiment. ^{15}N Nuclear magnetic resonance (NMR) with samples highly enriched (>98%) in ^{15}N has been used to check the reactivity of **2** and **3** toward substances commonly used as components of the mobile phase. The results reported herein indicate that acetonitrile, often used as an organic modifier, reacts readily with **2** and **3**. Methanol, also commonly employed, is much less reactive. Carboxylic acids RCO_2H (R = CH_3, H, CF_3), which are frequently used to adjust pH of the mobile phase, also react readily with **2** and **3**. Trifluoromethanesulfonic acid ("triflic acid"), CF_3SO_3H, is unreactive. Neither hexanesulfonic acid nor sodium dodecyl sulfate (SDS), used as "ion-pairing agents", reacts significantly with **2** or **3** under the experimental conditions, but SDS gives better peak separation. Commercial SDS must, however, be purified from chloride contamination. From our studies, optimal conditions for HPLC separation of **1**, **2**, and **3**, with a C_{18} stationary phase at 37 °C, require an aqueous mobile phase with 3% v/v methanol, 0.05 mM SDS, and pH 2.5 (adjusted with triflic acid). This technique was then used to measure levels of **1**, **2**, and **3** in ultrafiltered serum after incubation for various times with cisplatin at 37 °C.

Introduction

Cisplatin (*cis*-diamminedichloroplatinum(II), *cis*-[$PtCl_2(NH_3)_2$] (**1**)) is a widely used antineoplastic drug which is effective against a number of tumors, although its beneficial effects are balanced by significant toxicities.[1] There have been a number of studies of the pharmacokinetics of intact cisplatin,[2,3] but very little is yet known about the pharmacokinetic disposition of the metabolites and hydrolysis products of cisplatin.

The solution chemistry of cisplatin and its analogues has now been extensively explored. The hydrolysis reactions of cisplatin, for example, have been well-studied[4−9] and are summarized in Scheme 1. In an aqueous solution of cisplatin (**1**) with pH < 5, one of the bound chloride ions dissociates, to give *cis*-[$Pt(NH_3)_2Cl(H_2O)]^+$ (**2**), until an equilibrium is set up between **1**, **2**, and the liberated chloride ion. A second chloride ion may dissociate, to give *cis*-[$Pt(NH_3)_2(H_2O)_2]^{2+}$ (**3**), but little of this complex will form unless chloride ion is removed from the solution (e.g., with silver ion).[7] The coordinated water molecules in **2** and **3** may be deprotonated to give hydroxo complexes *cis*-[$Pt(NH_3)_2Cl(OH)$] (**4**), *cis*-[$Pt(NH_3)_2(OH)(H_2O)]^+$ (**5**), and *cis*-[$Pt(NH_3)_2(OH)_2$] (**6**). The acid dissociation constants of **2** and **3** are such that, under physiological conditions, the hydrolysis products will be predominately, but not totally, in the forms **4** and **5**,[6,9,10] with equilibria lying more toward the hydrolysis products than in acid solution. The solution chemistry near pH 7 can be further complicated by the tendency to form hydroxo-bridged oligomers, [{$Pt(NH_3)_2(\mu\text{-}OH)\}_n]^{n+}$ (n = 2,3)[4,5,11−13] and [{$Pt(NH_3)_2\}_2(\mu\text{-}Cl)(\mu\text{-}OH)]^{2+}$.[6] Such species are unlikely to form from mononuclear compounds in solutions with pH < 5, or at the low concentrations of platinum compounds used in vivo, but if present in the initial formulation of platinum compounds dinuclear compounds may persist in both these situations.[5]



Scheme 1

The rate constants for these hydrolysis reactions, in both acidic and alkaline solutions, have been measured by Miller and House.[7−9] The reactions are relatively slow, with many hours required after cisplatin is dissolved before equilibrium is established. There will also be little change in the composition of a solution during the time required for a HPLC run or for a ^{15}N NMR spectrum to be obtained (up to 20 min).

The reactions which cisplatin undergoes in vivo may be divided into three main classes:

(1) Simple hydrolysis reactions of the type shown in Scheme 1.

(2) Reactions involving coordination of small molecules (and ions) to platinum. The species involved may be inorganic, such as phosphate, or small organic molecules such as amino acids or peptides.

(3) Binding of platinum to macromolecules, such as DNA (believed to be primarily responsible for the antitumor activity of platinum drugs).[14−16]

Rather different techniques are required to study the products of these three types of reactions. HPLC techniques are well-suited for study of both small molecule adducts and hydrolysis products. Because of the fundamental role played by hydrolysis in much of the reaction chemistry of cisplatin, and because of the challenge presented by the high reactivity of platinum aqua complexes, we considered it desirable to develop techniques to reliably detect the hydrolysis products in vitro and in vivo. This is the subject of this paper, with later contributions focusing on small molecule adducts.

A number of papers have described reversed-phase HPLC conditions for detecting and monitoring cisplatin hydrolysis products.[17−19] Necessary components of the HPLC system are the stationary phase, the mobile phase, and the detection system. From this previous work, it is clear that a stationary phase consisting of silica particles bonded to C_8 or C_{18} hydrocarbon is suitable. Convenient UV detection is adequate for development of HPLC techniques and checking retention times for model compounds. The use of anionic hydrophobic ion-pairing reagents in the mobile phase, such as sodium dodecyl sulfate (SDS) or hexanesulfonate,[17,19] is clearly effective in giving good peak separation for cationic species. However, the mobile phases used by these workers have been chosen without sufficient regard for the high reactivity of the cisplatin hydrolysis products, so that they contain components that are capable of reacting with platinum aqua complexes. For example, Andersson et al.[18] used a mobile phase containing phosphate buffer, although phosphate is known to react readily with platinum aqua complexes.[5,20,21] De Waal et al.[22] and, more recently, Heudi et al.[23] showed that on-column reactions occur between phosphate and cisplatin hydrolysis products. Wenclawiak and Wollman[24] used micellar electrokinetic capillary chromatography to separate cisplatin from other platinum antitumor drugs (carboplatin and lobaplatin) as well as cisplatin hydrolysis products, using SDS and phosphate−borate or phosphate buffers. Shearan et al.[25] also used phosphate buffers in the separation of cisplatin and hydrolysis products on alumina. It is very likely that some of the peaks observed in each of these studies were actually due to platinum phosphate complexes. Daley-Yates and McBrien[17] used acetonitrile as an organic modifier in their mobile phase, yet acetonitrile is known to interact with platinum aqua complexes, with the well-known "platinum amide blues" forming as the ultimate products under some circumstances.[26] Zhao et al.[19] used mobile phases containing carboxylic acids (trifluoroacetic, formic) although acetate is known to react readily with platinum aqua complexes,[5] which raises the possibility that carboxylato complexes were formed while solutions were passed down the column, in the experiments reported by Zhao et al.[19] Heudi et al.,[23] however, obtained no evidence for reaction of formic acid with cisplatin hydrolysis products in their experiments.

The ambiguities in interpretation of results arising from the possibility of reactions between platinum aqua complexes and the mobile phase may be responsible for some literature conclusions which are surprising in the light of evidence from other sources. For example, Zhao et al.[19] concluded that *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$ (**3**) was present in significant proportions with *cis*-$[PtCl_2(NH_3)_2]$ (**1**) and *cis*-$[Pt(NH_3)_2Cl(H_2O)]^+$ (**2**) when **1** was allowed to stand in acidic aqueous solution. This does not agree with the result of Miller and House,[7] that only small quantities of **3** are present with **1** and **2** under these conditions. Andersson et al.[18] reported that clearance time of **2** (in equilibrium with *cis*-$[Pt(NH_3)_2Cl(OH)]$ (**4**)) in vivo is greater than that of intact cisplatin (**1**), even though the aqua complex **2** would be expected to be more reactive toward potential ligands than **1**. Daley-Yates and McBrien[17] concluded that the concentration of the diaqua complex **3** increased markedly in plasma (despite the rich ligand environment) and suggested that the hydrolysis reaction was catalyzed in plasma! The possibility of accidental equality of retention times of different species was not considered.

In the present work, potential components of the mobile phase were carefully checked for reactivity with **2** and **3**, both by monitoring HPLC traces and by obtaining ^{15}N nuclear magnetic resonance (NMR) spectra of solutions containing the platinum ammine complexes highly enriched in ^{15}N (>98% ^{15}N, nuclear spin quantum number I = $^1/_2$). ^1H-decoupled ^{15}N NMR lines are characteristically very sharp, and the ^{15}N chemical shift, δ_N, is very sensitive to the ligands bound to platinum, especially the ligand trans to the ammine group.[27] Conditions were then determined which optimized the separation of HPLC peaks from **1**, **2**, and **3** with the use of a mobile phase containing only substances which are unreactive toward these complexes under the conditions used. These conditions were then used to monitor concentrations of *cis*-$[Pt(NH_3)_2Cl(H_2O)]^+$ (**2**) in solutions of ultrafiltered plasma incubated with cisplatin (**1**) at 37 °C.

Experimental Section

Platinum Ammine Complexes—Literature methods[4,5] were used for the preparation of *cis*-$[PtCl_2(NH_3)_2]$ (**1**), *cis*-$[Pt(NH_3)_2(ONO_2)_2]$, with both normal isotopic composition and with high enrichment (>98%) in ^{15}N, with $(^{15}NH_4)_2SO_4$ used as the source of labeled ammonia. As previously described,[4,5] warming *cis*-$[Pt(NH_3)_2(ONO_2)_2]$ with water gives a solution of *cis*-$[Pt(NH_3)_2(H_2O)_2](NO_3)_2$, with a trace only of *cis*-$[Pt(NH_3)_2(ONO_2)(H_2O)](NO_3)$ present in dilute solution.[5] To avoid the presence of traces of unreacted silver ion, preparations of *cis*-$[Pt(NH_3)_2(ONO_2)_2]$ were usually carried out with a slight deficiency of silver nitrate, so that a small quantity of *cis*-$[Pt(NH_3)_2Cl(H_2O)]^+$ (**2**) was also present in these solutions. As noted in Results below, samples of *cis*-$[Pt(NH_3)_2(ONO_2)_2]$ for HPLC use must be freshly prepared (within 24 h) to avoid the appearance of additional HPLC peaks. A solution containing >90% *cis*-$[Pt(^{15}NH_3)_2Cl(H_2O)]^+$ (**2**), with *cis*-$[PtCl_2(^{15}NH_3)_2]$ (**1**) as an impurity, was prepared by a refinement of the procedure previously described.[6] *cis*-$[Pt(^{15}NH_3)_2(ONO_2)_2]$ (30 mg, 85.0 μmol) was dissolved in 2 mL of distilled water. Solid sodium chloride (6.0 mg, 102.5 μmol) was dissolved in 10 mL of distilled water. The sodium chloride solution was added very slowly to the stirred solution of *cis*-$[Pt(^{15}NH_3)_2(H_2O)_2](NO_3)_2$ (dropwise, over 2.5 h). The solution was then filtered, and the composition of the solution was checked by ^{15}N NMR. The total platinum concentration of this solution was 7.08 mM. The composition of this solution (far from equilibrium) did not change significantly on standing at 25 °C for 4 h, but after longer times the concentration of **2** decreased as concentrations of **1** and **2** increased. Cooling the solution hastened the loss of **2** through this chloride ion redistribution.

Other Materials—HPLC-grade methanol and acetonitrile (EM Science), trifluoromethanesulfonic acid ("triflic acid")(Aldrich, 98%, appropriately diluted), trifluoroacetic acid (Merck, >98%), formic acid (Ajax), acetic acid (Ajax), and sodium hexanesulfonate (Sigma, 98%) were used without further purification. Sodium dodecyl sulfate (SDS) from different suppliers (e.g., ICN) contained sufficient chloride to affect the HPLC results (notified on labels as 0.01%), and so a chloride-free solution was prepared as follows. Solid SDS (5 g) was dissolved in 20 mL of deionized water, and 17 mg of silver trifluoromethanesulfonate ($Ag(CF_3SO_3)$) was added to precipitate choride as silver chloride. The solution was filtered and then passed down a column of cation-exchange resin (Amberlite IR120) in the H^+ form. The eluted solution was diluted to 1 L with deionized water to give a chloride-free solution with SDS concentration 17.35 mM. It was stored in a refrigerator at 5 °C and diluted as required for use in HPLC. Since semimicro

combination electrodes used for pH determination leaked significant quantities of chloride ion into solutions in which they were immersed, the adjustment of pH to 2.5 was carried out with the aid of narrow-range indicator strips (Merck Acilit) with the colors on the strip calibrated against solutions whose pH was measured with the use of a glass electrode.

HPLC Instrumentation—The HPLC system consisted of a pump (Waters model 510), an automatic injector (Waters model 712 WISP), a Waters stainless steel analytical column (3.9 mm i.d. × 300 mm), packed with Bondapak C18, 10 μm particle size, a variable-wavelength detector (Waters model 484), and a chart recorder (Omniscribe, Houston Instruments). The column was maintained at 37 °C.

HPLC Experiments—In a typical experiment, 0.8−1.0 mg of the platinum complex was dissolved in 4 mL of the mobile phase, and 100 μL of the solution was injected onto the column. Flow rate was 0.5 mL min^{-1} and column temperature 37 °C. The wavelength for the detector was set at 305 nm. At this wavelength, the platinum complexes absorb strongly, but many organic molecules in plasma absorb weakly. To determine the relationship between the integrated area of the HPLC peak and concentration for the platinum compounds, solutions were prepared over a range of concentrations, and a 100 μL aliquot was injected onto the column. Elution was with the mobile phase described above, with SDS concentration 0.5 mM. For **2** and **3**, the solutions were prepared by diluting stock solutions respectively of **2** (prepared as described above) and of *cis*-$[Pt(NH_3)_2(H_2O)_2](NO_3)_2$ (prepared by dissolving a weighed quantity of solid *cis*-$[Pt(NH_3)_2(ONO_2)_2]$). For cisplatin (**1**), each solution was prepared by dissolving a weighed quantity of *cis*-$[PtCl_2(NH_3)_2]$ in a measured volume of water. To minimize hydrolysis, an aliquot was injected onto the column immediately after the solid dissolved.

NMR Experiments—^{1}H-Decoupled 20.2-MHz ^{15}N NMR spectra were obtained with a Bruker ACF-200 spectrometer, equipped with a 5-mm QUAD (^{1}H, ^{13}C, ^{19}F, ^{15}N) probe, with conditions as previously described, including use of the DEPT pulse sequence to enhance signal sensitivity.[28] Spectra are referenced relative to a 5 M solution of $(^{15}NH_4)_2SO_4$ in 1 M sulfuric acid, in a coaxial capillary. Shifts to lower nuclear shielding (higher frequency) are positive. In a typical experiment using *cis*-$[Pt(^{15}NH_3)_2(ONO_2)_2]$ as the starting material, 40 mg of the compound was dissolved in 1 mL of warm water, followed by addition of the mobile phase component.

Incubation of Cisplatin with Ultrafiltered Serum—A sample of human plasma was ultrafiltered from substances with molecular weight >10000 in a Millipore ultrafree MC centrifuge at 6000 G for 30 min. The plasma was incubated at 37 °C with cisplatin at a concentration of 0.2 mg/mL. After the appropriate time, 100 μL of the solution was injected onto the HPLC column. For comparison, samples of plasma without added cisplatin were incubated under identical conditions.

Results

^{15}N NMR Spectra of 2 and 3 in Aqueous Trifluoromethanesulfonic Acid Solution—It is desirable that HPLC separations on platinum(II) aqua complexes be carried out in acid solution. The pK_a values for water bound to platinum(II) in such complexes lie between 5 and 8,[6] so that, at pH-values greater than 5, the protonation state of the complex may be uncertain unless conditions are precisely controlled. Furthermore, hydroxo-bridged oligomers may form, causing undesirable complications.[4−6,11−13] The effectiveness of the anionic hydrophobic ion-pairing agent used in the HPLC mobile phase would also be expected to be optimal when the coordinated aqua ligands are fully protonated, giving maximum positive charge to the complexes. To adjust the pH to a suitable value (e.g., 2.5) it is desirable that an acid be used whose anion is known to be incapable of binding to platinum(II) in aqueous solution. We have previously shown[5] that perchlorate ion does not react with platinum(II) aqua complexes. Although the likelihood of forming potentially explosive compounds from the aqueous solutions studied is remote, as a matter of principle, we prefer to use alternatives if available. Thus,

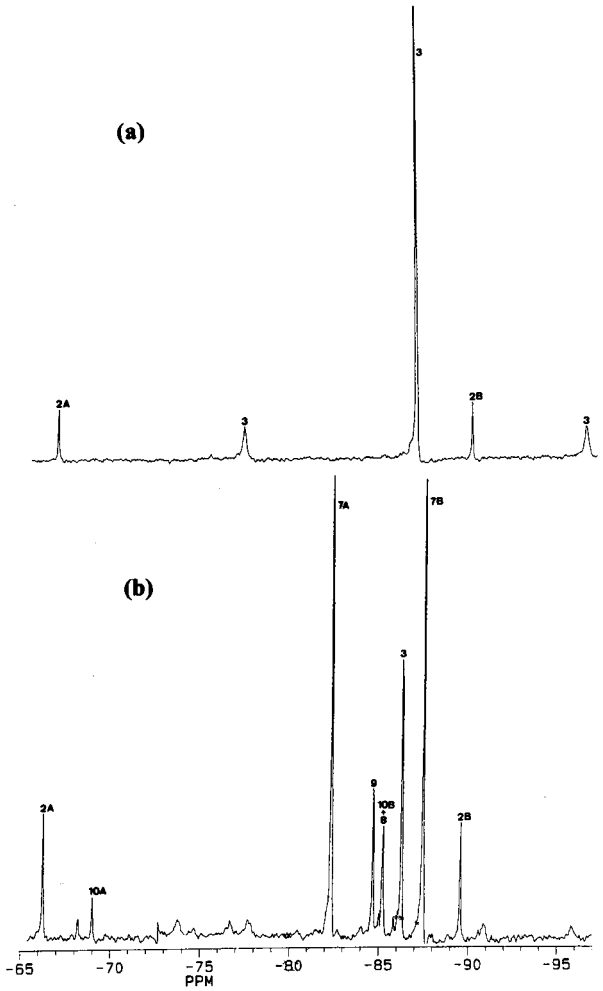

Figure 1—^{1}H-Decoupled 20.2-MHz ^{15}N NMR spectra of solutions obtained by dissolving *cis*-$[Pt(^{15}NH_3)_2(ONO_2)_2]$ in 1 M aqueous solutions of (a) triflic acid, (b) acetic acid. Labels correspond to those in the schemes.

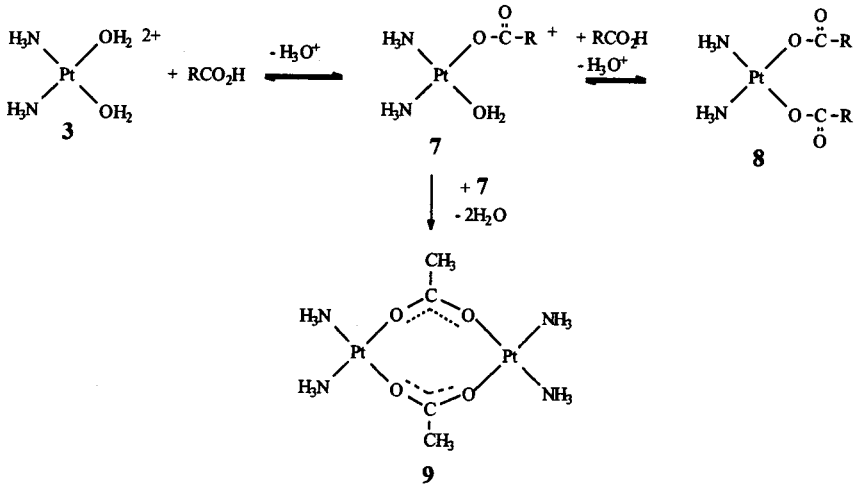
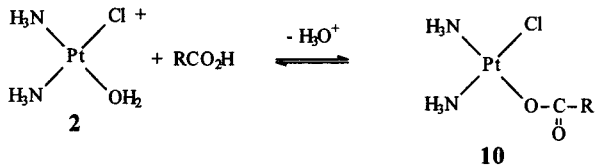
a 1 M solution of triflic acid was used to dissolve a sample of *cis*-$[Pt(^{15}NH_3)_2(-ONO_2)_2]$ containing a small proportion of *cis*-$[Pt(^{15}NH_3)_2Cl(-ONO_2)]$. The ^{15}N NMR spectrum of the resultant solution (Figure 1a) was readily interpreted as showing a singlet from *cis*-$[Pt(^{15}NH_3)_2(H_2O)_2]^{2+}$ (**3**) at −86.8 ppm with "satellite peaks" from coupling with ^{195}Pt (I = $^1/_2$, 34% abundance) ($J(^{195}Pt-^{15}N)$ 385 Hz). The satellite peaks were somewhat broadened through chemical shift anisotropy-induced relaxation of the ^{195}Pt nucleus.[29] These ^{15}N NMR parameters are close to those previously reported for **3**,[4,5] with the usual small dependence on "medium effects" (different counterions etc.). Weaker ^{15}N NMR peaks of equal intensity at −66.9 (labeled **2a** in Figure 1a) and −90.0 ppm (labeled **2b** in Figure 1a) were readily assigned to ^{15}N nuclei trans to chloride and to water in *cis*-$[Pt(^{15}NH_3)_2Cl(H_2O)]^+$ (**2**).[4,6,27] Even when the concentration of triflic acid was greatly increased, no peaks were observed that could be assigned to species containing coordinated triflate.

^{15}N NMR Spectra 2 and 3 in Aqueous Carboxylic Acid Solutions—Previously, it was shown[5] that *cis*-$[Pt(NH_3)_2(H_2O)_2](NO_3)_2$ reacts readily with acetate ion, forming predominantly *cis*-$[Pt(NH_3)_2(-OC(O)CH_3)(H_2O)]^+$ (**7**, R = CH_3), and *cis*-$[Pt(NH_3)_2(-OC(O)CH_3)_2]$ (**8**, R = CH_3) in solution, with $[\{Pt(NH_3)_2\}_2(\mu\text{-}OH)(\mu\text{-}O_2CCH_3)](NO_3)_2$ crystallizing from solution.[30] To determine whether carboxylate complexes are formed when free carboxylic acids are added to solutions of **3** and **2**, ^{15}N NMR spectra were obtained of solutions in 1 M aqueous solutions of RCO_2H (R = CH_3,



Scheme 2

H, CF_3). The spectrum of the solution containing acetic acid is shown in Figure 1b. In light of results obtained on related systems,[5] the major features of this spectrum may be explained in terms of the reactions shown in Scheme 2. The strongest peaks in the spectrum are assigned to ^{15}N trans to acetate (labeled **7A**, −82.1 ppm) and water (labeled **7B**, −87.2 ppm) in **7**. The peak at −85.0 may be assigned to **8**. The nearby peak at −84.5 ppm has not been reported previously. Since both of the ^{15}N nuclei appear to be equivalent, and in view of the propensity of acetate to form a bridge between platinum(II) atoms,[30] this peak has been assigned to the dinuclear complex $[\{Pt(^{15}NH_3)_2(\mu\text{-}O_2CCH_3)\}_2]^{2+}$ (**9**). The presence of a small proportion of *cis*-$[Pt(^{15}NH_3)_2Cl(H_2O)]^+$ (**2**) in the solution also allowed the simultaneous monitoring of the reaction of acetate with this species. It is clear from the spectrum that **2** reacted less overall with acetate than **3**, but the peak labeled **10A** (−68.8 ppm) could be assigned to ^{15}N trans to chloride in *cis*-$[Pt(^{15}NH_3)_2Cl(O_2CCH_3)]$ (**10**, R = CH_3) (Scheme 3). In additional experiments using higher proportions of **2** in the initial solution, the peak from ^{15}N trans to acetate in this complex was clearly observed at −84.7 ppm. In the spectrum shown in Figure 1b this peak (**10B**) is partially obscured by the peak from **8**. The spectrum also contained a small peak at −68.2 ppm from *cis*-$[PtCl_2(^{15}NH_3)_2]$ (**1**).



Scheme 3

The ^{15}N NMR spectra of analogous solutions with formic (R = H) and trifluoroacetic (R = CF_3) acids showed peaks analogous to those from the acetate complexes (R = H: **7**, −82.5, −88.3 ppm; **8**, −84.3 ppm. R = CF_3: **7**, −83.7, −87.5 ppm; **8**, −85.0 ppm). Although relative intensities indicated that there was less reaction with **2** and **3** than for acetate, the reaction was still significant.

^{15}N NMR Spectra of Solutions of 3 and 2 with Hydrophobic Ion-Pairing Agents—The agents which are in common use are sodium dodecyl sulfate, $Na^+(^-O_3SO(CH_2)_{11}CH_3)$, (SDS), and hexanesulfonic acid, $HO_3S(CH_2)_5CH_3$. Commercially available SDS usually contains traces of chloride (two brands tried each were labeled as containing up to 0.01% w/w chloride). Both HPLC experiments and NMR spectra showed that sufficient chloride was present to convert a significant amount of *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$ (**3**) into chloro complexes **2** and **1**. It was therefore necessary to remove chloride from the SDS solution before it could be used with the aqua complexes (see Experimental Section). Addition of excess chloride-free SDS to solutions containing *cis*-$[Pt(^{15}NH_3)_2(H_2O)_2]^{2+}$ (**3**) and *cis*-$[Pt(^{15}NH_3)_2Cl(H_2O)]^+$ (**2**) at pH 2.5 (adjusted with triflic acid) caused no additional peaks to appear from species containing coordinated SDS. Commercially available hexanesulfonic acid did not contain detectable chloride. With excess hexanesulfonic acid added to a solution of *cis*-$[Pt(^{15}NH_3)_2(H_2O)_2]^{2+}$ (**3**), a very small additional ^{15}N NMR peak appeared at −85.5 ppm which was probably from ammine trans to hexanesulfonate in a complex *cis*-$[Pt(^{15}NH_3)_2(-O_3S(CH_2)_5CH_3)(H_2O)]^+$ (the peak from ammine trans to water was probably obscured by the large peak from **3**). The extent of reaction was too small to affect significantly the HPLC experiments.

^{15}N NMR Spectra of Solutions of 3 and 2 with Aqueous Acetonitrile—Addition of even a small quantity of acetonitrile to an aqueous solution of *cis*-$[Pt(^{15}NH_3)_2(H_2O)_2]^{2+}$ (**3**) caused complete conversion to *cis*-$[Pt(^{15}NH_3)_2(NCCH_3)_2]^{2+}$ (^{15}N NMR singlet with satellites, δ_N −70.3 ppm, $J(^{195}Pt-^{15}N)$ 351 Hz). The monochloro complex **2** was similarly converted completely to *cis*-$[Pt(^{15}NH_3)_2Cl(NCCH_3)]^+$ (^{15}N trans to Cl^- −66.9 ppm, trans to acetonitrile −69.9 ppm). Although polynuclear paramagnetic "amide blues" form with more concentrated solutions of diammineplatinum(II) with aqueous acetonitrile,[24] these ^{15}N NMR spectra did not change over several days, probably because the solutions were too dilute for significant amide bridging to occur. Clearly, any acetonitrile used as an organic modifier would be expected to react completely with platinum(II) aqua complexes in HPLC experiments.

^{15}N NMR Spectra of Solutions of 3 and 2 with Aqueous Alcohols—The ^{15}N NMR spectrum of a solution of *cis*-$[Pt(^{15}NH_3)_2(H_2O)_2](NO_3)_2$ in a 2:1 (v/v) mixture of methanol and water showed an intense singlet with satellites from *cis*-$[Pt(^{15}NH_3)_2(H_2O)_2]^{2+}$ (**3**) at −87.0 ppm. A peak at −86.5 ppm assignable to ammine trans to nitrate in *cis*-$[Pt(^{15}NH_3)_2(-ONO_2)(H_2O)]^+$ was stronger than in a pure water solution,[5] but remained weak (from peak heights, the concentration of the nitrato complex was 7.5% of that of **3**; the peak from ammine trans to water in the nitrato complex would be expected to be obscured by that from **3**). Two small peaks with equal intensities, at −84.6 and −88.0, could be assigned to the complex with coordinated methanol, *cis*-$[Pt(^{15}NH_3)_2(CH_3OH)(H_2O)]^{2+}$. From peak heights, the concentration of the methanol complex was

Table 1—Variation of Retention Times for Cisplatin (1), *cis*-$[Pt(NH_3)_2Cl(H_2O)]^+$ (2), and *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$ (3) with Ion-Pairing Agent[a]

ion-pairing agent	concn (mM)	retention times (min)		
		1	2	3
SDS	0.05	6.2	12.0	5.2
SDS	0.50	6.4	18.0	4.4
hexanesulfonic acid	0.05	6.0	6.0	5.4
hexanesulfonic acid	0.50	8.1	7.2	6.2

[a] pH adjusted to 2.5 with triflic acid, 3% (V/V) methanol, column temperature 37 °C, flow rate 0.5 mL/min, detection wavelength 305 nm.

13% of that of **3** under these conditions. This ratio of methanol to water was very much greater than that used in our HPLC experiments. With methanol concentration of 5% v/v, the peaks from the methanol and nitrato complexes were of negligible intensity (<1% of the intensity of peaks from **3**). No peaks from methanol coordination were observed from a solution of *cis*-$[Pt(^{15}NH_3)_2Cl(H_2O)]^+$ (**2**) in 2:1 methanol/water.

In 2-propanol/water mixtures no peaks were observed from alcohol coordination, although there was again a small increase in the intensity of the peak from ammine trans to nitrate in the nitrato complex.

Separation of 1, 2, and 3 by Reversed-Phase HPLC—Solutions containing ^{15}N-labeled cisplatin, *cis*-$[PtCl_2(^{15}NH_3)_2]$ (**1**), *cis*-$[Pt(^{15}NH_3)_2Cl(H_2O)](NO_3)$ (**2**) (>90%), *cis*-$[Pt(^{15}NH_3)_2(H_2O)_2](NO_3)_2$ (**3**), and solutions containing mixtures of these complexes, were checked by ^{15}N NMR spectra, so that their compositions were known, and then injected onto the HPLC column. The mobile phase used in each case contained 3% (v/v) methanol, and the pH of the solution was adjusted to 2.5 with triflic acid. The ion-pairing agent used was either SDS (purified from chloride) or hexanesulfonic acid, at various concentrations. When the starting materials used were freshly prepared, the HPLC trace obtained in each case gave the number of peaks corresponding to the number of species present in solution, as revealed by the ^{15}N NMR spectra. Table 1 shows retention times for **1**, **2**, and **3** under some of the conditions used. Figure 2a is a chromatogram obtained for a solution containing all of the species, **1**, **2**, and **3**, with 0.5 mM SDS, and Figure 2b a chromatogram obtained for another solution, with 0.05 mM SDS. Figure 2c shows the chromatogram of a mixture of **1**, **2**, and **3** with 0.5 mM hexanesulfonate, and Figure 2d with 0.05 mM hexanesulfonate.

As expected, the retention time for the neutral compound cisplatin (**1**) was almost independent of the identity and concentration of the ion-pairing agent. With SDS as the ion-pairing agent, the retention time for **2** (which carries a single positive charge) was much longer than for **1** and also increased dramatically as the concentration of SDS was increased. The peak from **2** was always significantly broader than that from **1**. The retention time for **2** corresponding to a particular SDS concentration was reproducible if the column was thoroughly washed with mobile phase and then allowed to equilibrate for several hours between injections. With more rapid throughput of samples, there was some variation in the retention time for **2** (up to 2 min). With SDS as the "ion-pairing agent", **2** therefore effectively became a nonpolar species. By contrast, the retention time for **2** was relatively short when hexanesulfonate, with its shorter aliphatic chain, was used as the "ion-pairing agent". The retention time for **3** was short with both SDS and hexanesulfonate as the "ion-pairing agent", so that **3**, dipositively charged, remained a relatively polar species. The separation between peaks from

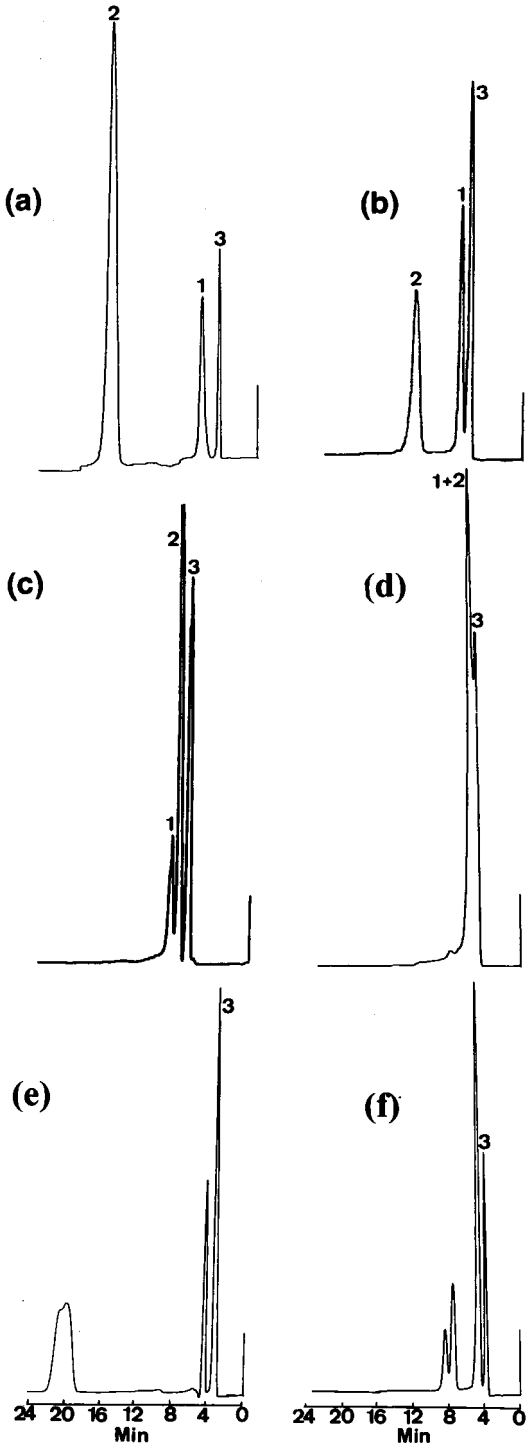


Figure 2—Chromatograms from aqueous solutions containing *cis*-$[PtCl_2(NH_3)_2]$ (**1**), *cis*-$[Pt(NH_3)_2Cl(H_2O)]^+$ (**2**), and *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$ (**3**) (total Pt concentration 0.5 mM), with mobile phase containing 3% (v/v) methanol, pH adjusted to 2.5 with the acid indicated, flow rate 0.5 mL/min (a) triflic acid, 0.5 mM SDS; (b) triflic acid, 0.05 mM SDS; (c) triflic acid, 0.5 mM hexanesulfonate; (d) triflic acid, 0.05 mM hexanesulfonate; (e) acetic acid, 0.5 mM SDS; (f) acetic acid, 0.05 mM SDS

1 and **3**, although always small, was always resolved (baseline resolution in Figure 2a). When chromatograms were obtained from solutions of *cis*-$[Pt(NH_3)_2(H_2O)_2](NO_3)_2$ made up using freshly prepared *cis*-$[Pt(NH_3)_2(ONO_2)_2]$, a single peak from **3** was observed when either ion-pairing agent was used. However, when a sample of *cis*-$[Pt(NH_3)_2(ONO_2)_2]$ was used which had been allowed to stand for 24 h or more, even when refrigerated and protected from light, chromatograms obtained using SDS showed a number of

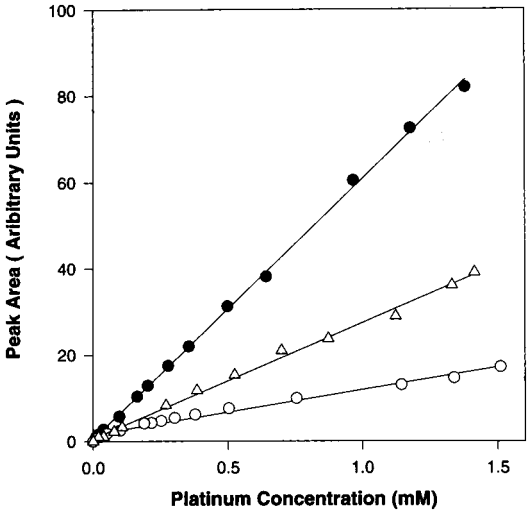

Figure 3—Relationship between integrated peak area and concentration of platinum complex in injected solution, under conditions described in text. In each case the line of best fit is drawn. (●) cisplatin (**1**); (○) *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$, (**3**); (△) *cis*-$[Pt(NH_3)_2Cl(H_2O)]^+$ (**2**).

broad peaks at very long retention times (>20 min). When hexanesulfonic acid was used, the same solutions showed a single, sharper peak, with longer retention time than peaks from **1**, **2**, or **3**. When ^{15}N-labeled sample was used, the ^{15}N NMR spectra of these solutions showed only the peaks from **3**. It is likely that reactions on the surface of solid *cis*-$[Pt(NH_3)_2(ONO_2)_2]$ formed traces of intensely absorbing oligomeric paramagnetic complexes which were responsible for these HPLC peaks. Since this problem could be avoided by the use of freshly prepared material, it was not further investigated. No such HPLC peaks were observed from solutions prepared from fresh *cis*-$[Pt(NH_3)_2(ONO_2)_2]$ which were then allowed to stand for long periods.

Figure 2e shows a chromatogram obtained from a solution initially containing **1**, **2**, and **3**, with the mobile phase containing 0.5 mM SDS and 3% (v/v) methanol, with the pH adjusted to 2.5 with acetic acid rather than triflic acid. For Figure 2f, the SDS concentration was 0.05 mM. Compared with the chromatograms obtained with triflic acid, there is an additional peak. Three of the observed peaks undoubtedly corresponded to **1**, **2**, and **3**, with the additional peak most likely representing a carboxylate complex formed on the column during elution. No attempt was made to assign these peaks to individual species, as, after these results, mobile phases containing carboxylic acids were simply avoided.

Quantitative Determination of 1, 2, and 3 by HPLC—HPLC traces were obtained for solutions which contained known concentrations of **1**, and the integrated area of the HPLC peak from **1** was measured under the standard conditions outlined above (mobile phase containing 3% methanol, 0.5 mM SDS, pH adjusted to 2.5 with triflic acid, column temperature 37 °C, detection wavelength 305 nm). A linear relationship was obtained between peak area and concentration (Figure 3). Similar relationships were obtained for **2** and **3** (Figure 3). The different line slopes are, of course, a result of the differing molar absorptivity coefficients of the three complexes at 305 nm. Such linear plots would not be expected if there were any covalent bonding interaction between the platinum aqua complexes and the stationary phase.

HPLC Detection of *cis*-$[Pt(NH_3)_2Cl(H_2O)]^+$ (2) from Ultrafiltered Plasma Incubated with Cisplatin—Samples were periodically removed from a solution of ultrafiltered human plasma incubated at 37 °C with cisplatin (**1**) and analyzed by HPLC using mobile phases

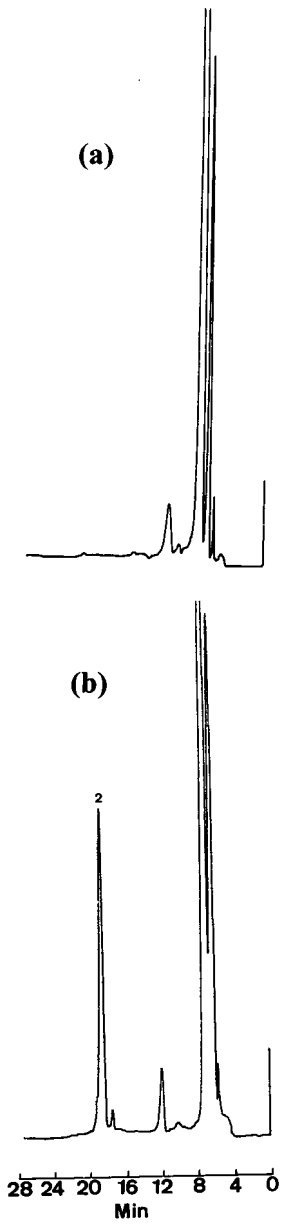

Figure 4—Chromatograms from ultrafiltered human plasma (100 μL injection, mobile phase 3% (v/v) methanol, pH adjusted to 2.5 with triflic acid, 0.05 mM SDS, detector wavelength 305 nm): (a) plasma allowed to stand 24 h at 37 °C; (b) plasma incubated with cisplatin (**1**) (0.2 mg/mL) for 24 h. The peak labeled "**2**" corresponds to *cis*-$[Pt(NH_3)_2Cl(H_2O)]^+$.

as described above (3% (v/v) methanol, pH adjusted to 2.5 with triflic acid) with SDS concentrations of 0.05 or 0.5 mM. Figure 4b shows a chromatogram (obtained with SDS concentration 0.05 mM), from ultrafiltered plasma incubated with cisplatin (**1**) at 37 °C for 24 h, while Figure 4a shows the chromatogram from a sample of plasma allowed to stand at 37 °C for the same time. At the detector wavelength, 305 nm, platinum complexes absorb strongly, but many organic molecules present in plasma have weak absorption. The chromatograms showed the growth, and then decline over several days, of a peak (labeled "**2**" in Figure 4b) with a retention time corresponding to that of *cis*-$[Pt(NH_3)_2Cl(H_2O)]^+$ (**2**). From Figure 4a, it is evident that platinum-free plasma did not give any significant peaks near this retention time, under the same conditions. The assignment of the peak to **2** was confirmed from the chromatogram obtained for the same solution with SDS concentration 0.5 mM, as a peak was now observed at retention time 34.4 min which corresponded to **2** under

these conditions (see Table 1). "Spiking" the plasma with a solution of **2** also caused a large increase in the intensity of the peak. It was, therefore, relatively easy to detect and monitor this species by HPLC analysis of the ultrafiltered plasma. Again, it should be mentioned that at the pH of the plasma, **2** would be largely deprotonated to *cis*-[Pt-$(NH_3)_2Cl(OH)]$ (**4**).

Although there were a number of intense peaks at short retention times from the plasma, there were no peaks in any of the chromatograms at a retention time corresponding to *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$ (**3**). This species and its partially deprotonated form *cis*-$[Pt(NH_3)_2(OH)(H_2O)]^+$ (**5**) are, therefore, not present in detectable concentrations in ultrafiltered plasma incubated with cisplatin.

Discussion

Many previous attempts to detect and monitor cisplatin hydrolysis products and metabolites by HPLC have been marred by a lack of appreciation of the reaction chemistry of these compounds. In the Introduction of this paper, reference has been made to a number of studies in which components were used in mobile phases which react readily with the platinum aqua complexes. There has seldom been unequivocal assignment of HPLC peaks to particular compounds. Checks for accidental superposition of peaks from different compounds have seldom been applied. If results are to be interpreted unambiguously we propose that the following conditions must be applied scrupulously:

(1) The use of any substance in a mobile phase which may react with one of the analytes under the analysis condition should be avoided. This includes the need to check for interfering impurities (such as the chloride present in commercially available SDS or which may leak from electrodes used to measure pH).

(2) Assignment of HPLC peaks to particular compounds should be based on check runs using solutions of known composition. For platinum(II) ammine complexes, ^{15}N NMR spectroscopy provides an excellent means for analysis of such solutions. If sufficient sample is obtainable from HPLC elution, analysis of this purified sample may be an acceptable alternative.

(3) There should be routine checks for accidental equivalence of retention times for different compounds. This may be done by HPLC analysis of the solution with two different mobile phases, which are known to give different retention times for the compound(s) of interest. This also provides confirmation of the assignment of a peak to a particular compound.

Our results have shown that it is possible to analyze for *cis*-$[Pt(NH_3)_2Cl(H_2O)]^+$ (**2**) and *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$ (**3**) (and their deprotonated forms) in aqueous solution and in ultrafiltered plasma while meeting these necessary conditions. The purpose of the experiments on ultrafiltered plasma described here was to show that HPLC peaks corresponding to **2** can be detected in ultrafiltered plasma. The cisplatin concentration used (0.2 mg/mL) was therefore relatively high—higher than would be present when cisplatin is administered as a drug. We are currently carrying out analyses in vitro and in vivo in which the platinum concentration is much lower.

Received July 9, 1998. Accepted for publication November 24, 1998.

Abstract □ The aggregation behavior of FK906, which is a peptide like hypertensive agent, in aqueous solution was studied by static light scattering, ^{1}H-nuclear magnetic resonance (NMR), and surface tension. These experiments showed a clear critical micelle concentration (cmc) at around 6.3×10^{-3} to 1.3×10^{-2} M of FK906 aqueous solution. The result of ^{1}H NMR experiments revealed that FK906 aggregates primarily by hydrophobic interactions involving the benzyl moiety. The Debye plots from light-scattering studies showed that the apparent molecular weight of aggregated FK906 molecule is 1670 which corresponds to 2–3 molecules of FK906. The effect of α- and β-cyclodextrins on the surface tension of FK906 aqueous solution was investigated. It appeared that the addition of α-cyclodextrin showed very small shift of cmc, but that of β-cyclodextrin shifted the cmc to much higher concentration. The investigation on the surface tension of FK906 aqueous solution in the presence of β-cyclodextrin indicated that FK906 forms a 1:1 complex with β-cyclodextrin. On the basis of these experiments, it appears that β-cyclodextrin has an ability to change the surface active property of FK906 in its aqueous solution. Therefore, it is expected that the addition of β-cyclodextrin to FK906 aqueous solution may prevent the adsorption onto container walls and/or reduce the local irritancy.

Introduction

Pharmaceuticals with both hydrophilic and hydrophobic groups show a surface active property. Surface active pharmaceuticals usually show critical micelle concentration (cmc) above that at which they tend to aggregate to form micelles in their aqueous solutions. This aggregation behavior of pharmaceuticals sometimes causes a completely different activity below and above the cmc, because the drug molecules exist as monomer below cmc and form aggregates above cmc. For example, the anesthetic potency as a function of drug in solution shows a decrease in activity at the cmc.[1] Furthermore, these surface active drugs sometimes present problems in pharmaceutical formulation. Typical examples are the adsorption of surface active drugs on to container walls, which may result in a loss of free drug at low concentration,[2] and erythrocytes from hemolysis.[3]

To overcome these pharmaceutical problems, many additives have been studied to change the molecular interaction of surface active drugs in their aqueous solutions. Methyl *p*-hydroxybenzoate is one of the example which has been regarded as an effective additive to prevent the gel formation caused by stacking self-association of doxorubicin at the aromatic rings and to shorten the dissolution time of its freeze-dried product.[4] Cyclodextrins also have been regarded as beneficial additives in the pharmaceutical area because they have an ability to protect erythrocytes from hemolysis and shape changes induced with surface active drugs.[5,6] Furthermore, some hydrophilic cyclodextrins, including maltosyl-β-cyclodextrin, inhibit the adsorption of bovine insulin to containers and its aggregation by interacting with hydrophobic regions of the peptide.[7]

Recently, the number of new drug candidates which have peptide-like structure has been increasing due to their specific biological activities. However, they have a risk of the above-mentioned problems in aqueous solution because they have hydrophilic as well as hydrophobic moieties in their structures.[8] Therefore, whether newly developed drugs are surface active or not is particularly significant in early stage since the concept of the preformulation should be established by taking into account the correlation between biological activities and physicochemical properties for these compounds.

In this report, FK906 ($C_{40}H_{63}N_7O_7$·HCl; mw: 790.44), which is a peptide-like synthetic rennin inhibitor, was used as a model compound since FK906 has polar and nonpolar groups, and its aqueous solution foams readily upon agitation. Thus, the aqueous solution properties of FK906 as a surface active drug were investigated by surface tension measurement, a light scattering study, and chemical shift observations in NMR spectra of samples in aqueous solution. The interaction between FK906 and cyclodextrins was also investigated to know whether cyclodextrins have an ability to change the surface active property of FK906.

Experimental Section

1. Materials—FK906 ($C_{40}H_{63}N_7O_7$·HCl; mw: 790.44), (2*S*,3*S*)-cyclohexyl-3-hydroxy-6-methyl-2-[Na-methyl-[(*S*)-2-[*N*-methyl-N-[2-(*N*-methyl-*N*-morpholinocarbonylamino)ethyl]-3-phenylpropinoil]-L-histidyl]aminoheptane hydrochloride, was synthesized at Fujisawa Pharmaceutical Co., Ltd. and used without further purification. The purity determined by area % with HPLC was 99.1%. All other reagents used were reagent grade.

2. Measurement of Static Light Scattering—Static light scattering of FK906 aqueous solution was measured at 25 °C using a light-scattering spectrophotometer (model DSL-7000, Otsuka Electronics Co., Osaka) equipped with an argon laser (488 nm). FK906 solution filtered through a membrane filter (pore size 0.2 μm) was used for static light scattering at a scattering angle of 45−135°. The refractive index increment of FK906 was measured at 25 °C using a differential refractometer (model DRM-1021, Otsuka Elecrtrocics Co., Osaka) at 633 nm. Solutions of FK906 ranging in concentration from 4 μg/mL to 80 mg/mL were prepared for static light-scattering measurement.

3. Measurements of ^{1}H-Nuclear Magnetic Resonance Spectra—^{1}H NMR spectra were measured at 25 °C on a 200 MHz nuclear magnetic resonance spectrometer (model AC 200P, Bruker) in deuterium oxide (D_2O) over a concentration range from 1 mg/mL to 50 mg/mL.

4. Measurement of Surface Tension—The surface tension was measured based on the Wilhelmy plate method with an automatic surface tensiometer (model CBVP-Z, Kyowa Seimitsu, Tokyo). The platinum plate was heated by an oxidizing flame before use. For the calculation of the surface tension of aqueous solution, the value of 72.0 mN/m was used as the surface tension

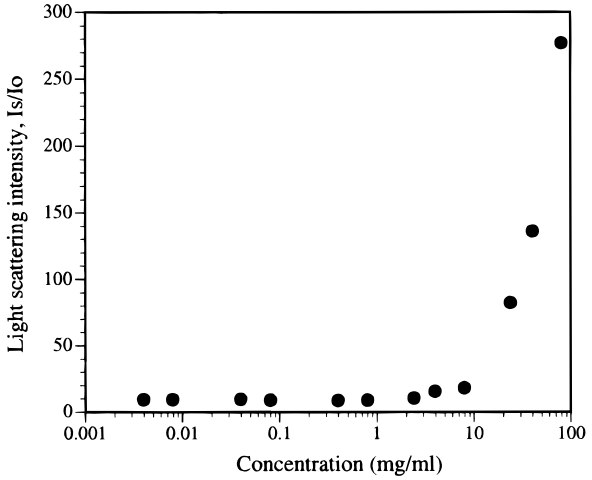

Figure 1—Effects of FK906 concentration on light-scattering intensity.

of pure water at 25 °C. The surface tension data for FK906 aqueous solution ranging from 1 μg/mL to 25 mg/mL were plotted against the logarithm of the concentration as the abscissa, and the intersection of the descending line and another one close to the horizontal was taken as the cmc. The effect of α- and β-cyclodextrins on the surface tension data for FK906 aqueous solution was also investigated according to the above-mentioned conditions.

Results and Discussion

1. Light Scattering Studies on Micelle Formation—Figure 1 shows the effects of FK906 concentration on light-scattering intensity at an angle of 90°. A rapid rise in the curve at around 10 mg/mL (1.3×10^{-2} M) is evidence of the aggregate formation of FK906 molecule.

This light-scattering method has another advantage of being able to obtain the molecular weight of a self-associated drug substance. Debye plots which are obtained from the light-scattering experiments were used to evaluate the apparent molecular weight of aggregated FK906. In this calculation, the following equations were used.

$$R\vartheta = A(n^2 I / {n_b}^2 I_0) \quad (1)$$

Where $R\vartheta$ is the Rayleigh ratio, A is the calibration constant of the apparatus, n and n_b are the refractive indices of water and toluene used for calibration, and I and I_0 are the intensities of scattered and introduced laser light, respectively. The apparent molecular weight of FK906 aggregates, mw, was determined according to eq 2:[9]

$$K(C - C_0)/(R\vartheta - R_0) - 2A_2(C - C_0) = 1/\mathrm{mw} \times P(\vartheta) \quad (2)$$

Where K is the optical constant, R_0 is the Rayleigh ratio at critical micelle concentration, C_0 is the second virial coefficient, and $P(\vartheta)$ can be assumed to be 1 when the particle size is small enough.

The apparent molecular weight of aggregated FK906 molecules obtained from Debye plots was 1670 which corresponds to 2 or 3 molecules of FK906. Although the aggregation number of FK906 molecules was much smaller than that of a reported drug substance such as a leukotriene D_4 receptor antagonist which aggregates more than 16000 molecules,[10] similar results to those from FK906 have been reported for some antibiotics[11] and nicotinamide.[12]

2. ^{1}H-Nuclear Magnetic Resonance Study—Figure 2 shows the ^{1}H NMR spectrum of FK906 in D_2O. Signal assignments of main moieties are also shown in Figure 2.

To evaluate the effect of aggregation on chemical shifts of the proton signals, the protons of benzyl, imidazoil, and

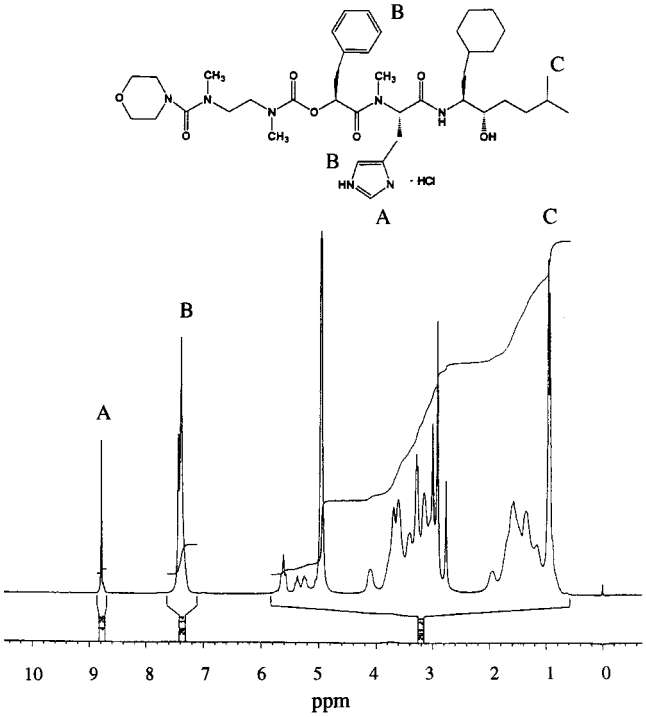

Figure 2—^{1}H NMR spectrum of FK906.

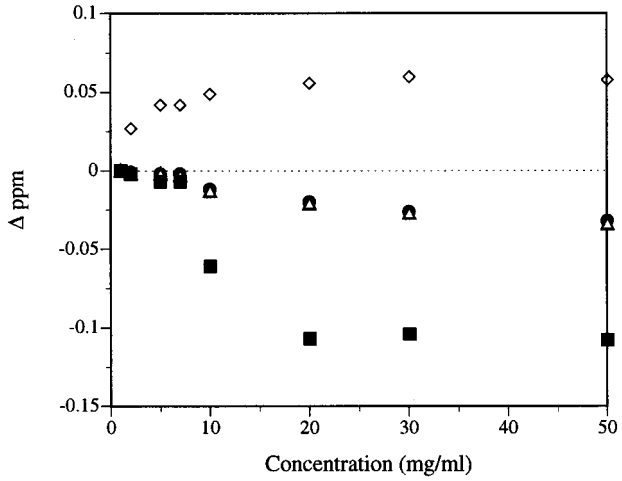

Figure 3—Concentration dependence of proton chemical shifts of FK906 in D_2O. ●, 0.76 ppm; △, 0.79 ppm; ■, 7.33 ppm; ◇, 8.52 ppm.

methyl groups were selected, since they are considered to have an important role to form micelle.[13,14] The concentration dependence of chemical shifts of above-mentioned protons are shown in Figure 3.

It appeared that by increasing the concentration of FK906 in solution, large upfield shifts were found for aromatic ring protons as compared with other protons. Furthermore, NMR studies also proved the existence of cmc for FK906 aqueous solutions, since plots of proton chemical shifts in Figure 3 showed a marked break at 10 mg/mL FK906 aqueous solution. From these chemical shifts of protons, the cmc value seems to be about 1.3×10^{-2} M. These results suggest that FK906 aggregates primarily by hydrophobic interaction involving the benzyl moiety.

3. Surface Tension Studies—Figure 4 shows the relation between the surface tension and the concentration of the aqueous FK906 solution.

The curve shows a general decline in surface tension with increase in drug concentration. The value of cmc was estimated as the point of intersection of the extension of

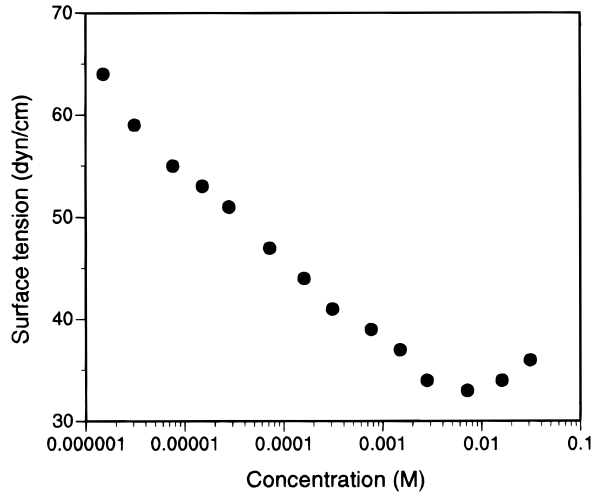

Figure 4—Effects of FK906 concentration on surface tension.

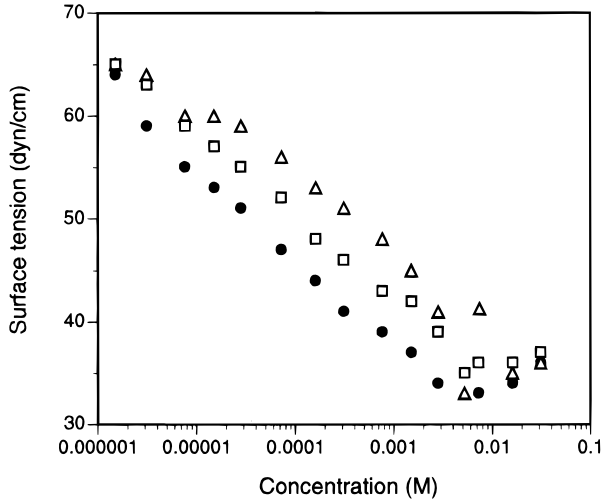

Figure 5—Dependence of FK906 concentration on the surface tension in the presence of cyclodextrins. ●, CyDs (0 M); △, β-Cy (5.0×10^{-3} M); □, α-CyD (6.7×10^{-3} M).

the gentle curve and the horizontal line. The cmc of FK906 in water was about 5 mg/mL (6.3×10^{-3} M) by the surface tension measurement.

These static light-scattering, NMR, and surface tension measurements apparently indicated that FK906 is a typical surface active product, and these experiments showed similar cmc values for FK906 in aqueous solution.

4. Effects of Cyclodextrins on Self-Association Behavior—It was expected that the surface tension measurement would indicate the formation of an inclusion complex of FK906 with cyclodextrins, because Funasaki et al.[15] reported that the binding constants of cyclodextrin–surfactant complexes were evaluated by surface tension data. Thus, surface tension measurements were used to evaluate the effects of α- and β-cyclodextrins on the surface tension property for FK906 aqueous solutions. Figure 5 shows the dependence of surface tension on the FK906 concentration in the presence of α- and β-cyclodextrins.

From Figure 5, some shifts of the surface tension curve can be seen when β-cyclodextrin was added to FK906 aqueous solution. Therefore, it was proved that β-cyclodextrin has an interaction with FK906 molecule. On the contrary, α-cyclodextrin showed only small shifts of surface tension curve, which indicated that the cavity size of α-cyclodextrin is too small to form a inclusion complex with FK906.

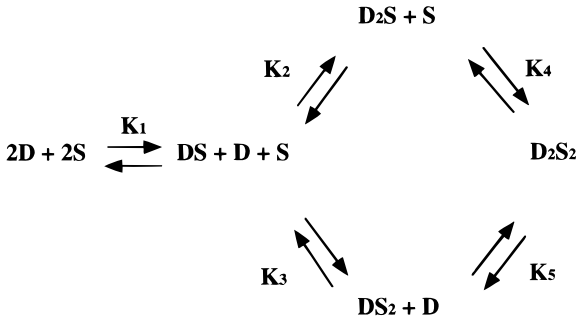

Figure 6—Scheme for the formation of the inclusion complex.

The following scheme (Figure 6) with regard to the complex formation between FK906 and β-cyclodextrin was introduced from a paper describing the complex formation between cyclodextrin and surfactants.[15]

In this scheme, β-cyclodextrin and FK906 were designated as D and S, respectively, and K_1 through K_5 represent the stability constants.

The each stability constant presented in Figure 6 is defined as follows:

$$K_1 = [DS]/[D][S] \quad (3)$$

$$K_2 = [D_2S]/[DS][D] \quad (4)$$

$$K_3 = [DS_2]/[DS][S] \quad (5)$$

$$K_4 = [D_2S_2]/[D_2S][S] \quad (6)$$

$$K_5 = [D_2S_2]/[DS_2][D] \quad (7)$$

where [D] represents the concentration of β-cyclodextrin and [S] is the concentration of FK906. In the case of FK906–β-cyclodextrin complex, a 2:2 complex of FK906 and β-cyclodextrin was assumed to be excluded because the binding constants of K_4 and K_5 reported for surfactant–cyclodextrin complex were almost zero. Thus, the total concentrations of β-cyclodextrin, C_D, and FK906, C_S, in the testing solution are expressed as follows:

$$C_D = [D] + [DS] + 2[D_2S] + [DS_2] = [D] + K_1[D][S] + 2K_1K_2[D]^2[S] + K_1K_3[D][S]^2 \quad (8)$$

$$C_S = [S] + [DS] + 2[D_2S] + [DS_2] = [S] + K_1[D][S] + 2K_1K_2[D]^2[S] + K_1K_3[D][S]^2 \quad (9)$$

By using the above equations, the next four cases are represented as follows:

Case 1: only DS is present.

$$\{C_D[S] - (C_S - [S])[S]\}K_1 = C_S - [S] \quad (10)$$

Case 2: DS and D_2S are present.

$$\{1 + 4K_1K_2C_D[S] - K_1^2[S]^2 - (1 - K_1[S])^2 + 8K_1K_2C_D[S]^{1/2}\}/8K_1K_2[S] + [S] - C_S = 0 \quad (11)$$

Case 3: DS and D_2S are present.

$$K_1K_3[S]^3 - K_1[1 + K_3(2C_D - C_S)][S]^2 + [1 + K_1(C_D - C_S)][S] - C_S = 0 \quad (12)$$

Case 4: DS, D_2S, and DS_2 are present.

$$\{1 + 4K_1K_2C_D[S] - K_1(K_1 + 2K_3)[S]^2 - 4K_1^2K_3^2[S]^4 - 3K_1^2K_3^2[S]^4 - (1 - K_1[S] - 3K_1K_3[S]^2) - [(1 + K_1[S] + K_1K_3[S]^2)^2 + 8K_1K_2C_D[S]^{1/2}\}/8K_1K_2[S] + [S] - C_S = 0 \quad (13)$$

Since the addition of β-cyclodextrin to the FK906 aqueous solution does not decrease the surface tension of water, the inclusion complexes can be expected to show less surface action than free FK906. Therefore, it can be assumed that the surface tension depends on only the concentration of free FK906 [S] even in the solution including β-cyclodextrin. As there is a good linearity between the surface tension and the concentration of FK906 below the cmc (see Figure 4), the concentration of free FK906 [S] is obtained from the surface tension of the sample solution.

From Figure 4, the concentration dependence of the surface tension for FK906 solution is written as the following equation.

$$\sigma = -3.77 \ln[S] + 11.5 \quad (14)$$

In this equation, σ represents the surface tension.

As the total concentration of β-cyclodextrin (C_D), the total concentration of FK906 (C_S), and the concentration of free FK906 [S] are known values, the best fit value for each stability constant was estimated from Akaike information criterion (AIC).[15]

The estimation of binding constants was carried out by minimizing the AIC value which is expressed in the following equation.

$$AIC = n \times \ln(ss) + 2r \quad (15)$$

$$ss = \sum_{i=1}^{n} (\sigma_{i,obsd} - \sigma_{i,calcd})^2 \quad (16)$$

In this equation, n, ss, and r represent that the number of data, sum of squares, and the number of constants, respectively. The minimum value of AIC obtained from this equation was selected and tabulated in Table 1.

It appeared that type 3 is the best of them in the case of β-cyclodextrin. However, this is an unrealistic model, since the value of K_3 is negative. Thus, it is concluded that FK906 forms a 1:1 inclusion complex with β-cyclodextrin, since type 1 is the second fit model among these models (K_1 = 2000). Spectroscopic (circular dichrorism spectra) analysis was performed to confirm the formation of inclusion complex of FK906 with β-cyclodextrin. As a result, the obtained spectra strongly supported the complex formation of FK906 with β-cyclodextrin. However, it was difficult to determine the exact molar ratio of FK906/β-cyclodextrin complex, since there were some deviations in the magnitude of circular dichrorism spectra. On the contrary, it is expected that surface tension method gives us rather detailed information to discuss the model of complex formation, since quantitative treatment for cyclodextrin−FK906 interactions including 1:1, 1:2, 2:1, and 2:2 complexes was taken into account.[15]

Conclusion

It was confirmed that FK906 shows aggregation behavior in aqueous solution. Three different experiments, ^{1}H NMR spectrometry, light scattering, and surface tension, showed almost the same cmc at 6.3×10^{-3} to 1.3×10^{-2} M. It appeared that the addition of β-cyclodextrin strongly affected the surface tension of FK906 aqueous solution. Furthermore, the surface tension measurement suggested that the aggregation of FK906 was prevented by the formation of an inclusion complex with β-cyclodextrin.

Therefore, it is expected that the addition of β-cyclodextrin to FK906 aqueous solution may solve the pharmaceutical problems such as toxicity which comes from the surface active property of FK906.

Table 1. Best Fit Value of Binding Constants for FK906 and β-Cyclodextrin

complexes	K_1	K_2	K_3	ss	A

Received June 22, 1998. Final revised manuscript received December 8, 1998.
Accepted for publication December 9, 1998.

Abstract □ The covalent insulin–protamine product molecules formed by heat stress in Neutral Protamine Hagedorn formulations of insulin and the insulin analogue [Lys^{B28},Pro^{B29}] were examined by mass spectrometry. The results demonstrated that the covalent cross-link between insulin and protamine was not caused by linkage through the protamine N-terminal amino group, as had been previously thought. Our results indicate that the linkage was formed between the side chain of a protamine arginine and a histidine in the insulin B chain, resulting in a net mass change of –5 Da, compared to the sum of the protamine and insulin molecular masses. A mechanism for this new type of covalent cross-linking reaction is proposed.

Introduction

The Neutral Protamine Hagedorn (NPH) formulation of insulin is the oldest and most successful example of a sustained release protein pharmaceutical product.[1] NPH[2] consists of insulin cocrystallized with a defined amount of the very basic protein protamine. The resulting microcrystalline suspension is administered to a patient parenterally. The crystals dissolve very slowly in the subcutaneous depot site, resulting in a protracted release of free insulin. The pharmacological properties of NPH have been thoroughly studied.[3]

The long history of the NPH formulation has led to careful examination of the products that form during long-term storage of this pharmaceutical preparation. Brange and co-workers[4−6] have examined these products in detail and determined that they fall into two general classes: modification of side chain moieties of insulin, and polymerization reactions that form both covalently cross-linked insulin dimers (CID) and covalently cross-linked insulin−protamine products (CIPP). The nature of the polymerization reactions that cause the insulin dimer products could not be directly determined by these studies. Brange et al.[4−6] speculate that the polymers were produced by the attack of an N-terminal amino group on a side chain amide group, resulting in the loss of ammonia and the formation of an isopeptide bond. This cross-linking reaction was referred to as either aminolysis or transamidation. It was further speculated that any of the six amide-containing residues of insulin could participate in these reactions leading to the observed chromatographic multiplicity of insulin dimer peaks. Formation of insulin−protamine polymer products was assumed to proceed by the same mechanism, i.e., transamidation between the N-terminus of protamine and any of the amide groups in insulin. The protamine used in pharmaceutical preparations of NPH does not have any amide moeities,[7] so there can be no reactions of this type between protamine and the N-termini of mature insulin.

Anderson and co-workers[8−10] have suggested a different reaction mechanism for the formation of covalent insulin dimers. Their mechanism requires the formation of a succinyl anhydride by the loss of ammonia from the C-terminal asparagine residue on the A-chain of insulin. Succinyl anhydride can then react with water to form $desamido_{A21}$-insulin. Alternatively, succinyl anhydride can react with a free amino group on the N-terminus of insulin's A or B chain to form a covalently linked dimer. This reaction can result in either a peptide or isopeptide bond linking the two chains together. Their work does not directly consider the formation of insulin−protamine products; however, it would be reasonable to assume that a highly reactive succinyl anhydride should cause a similar transacylation reaction with the free N-terminus of protamine.

Conventional reversed-phase HPLC methods result in many CID peaks and a rather ambiguous set of CIPP peaks. A size exclusion method has been recently developed to separate insulin from any covalent cross-linked products, in a solution formed by dissolving NPH insulin crystals in an acidic solution.[11] This method results in three resolved peaks: (1) monomeric insulin; (2) containing all CID species; and (3) containing all CIPP species. In this work, we have used this method to purify relatively large amounts of CIPP. The isolated material was characterized using a combination of mass spectrometry and standard protein chemistry techniques. Our results show that the CIPP peak consists of a mixture of many different insulin−protamine covalent dimers. We show that CIPP dimers are not linked by either a peptide or isopeptide bond. Instead, we propose that a condensation reaction occurs, involving any arginine group in protamine and the histidine groups on the B chain at position B5 or B10. This proposed reaction results in the loss of 5 Da, compared to the sum of the starting materials.

Experimental Section

Chemicals—NPH and NPL[12−14] (a similar preparation to NPH that uses the [Lys^{B28},Pro^{B29}] analogue of insulin) suspensions were obtained in house from Eli Lilly and Company (Indianapolis, IN) supplies. Chum salmon (*Oncorhynchus keta*) protamine was also obtained in house from Eli Lilly and Company (Indianapolis, IN). All chromatographic solvents were HPLC grade, except the water, which was obtained from a Milli-Q Plus water purification system (Millipore, Bedford, MA). Burdick & Jackson (Muskegon, MI) high purity grade water and acetonitrile were used for mass spectrometric sample preparation. The trifluoroacetic acid used was Sequanal grade (Pierce, Rockford, IL). *trans*-α-cyano-4-hydroxycinnamic acid[15] (Acros, Pittsburgh, PA) was dissolved as an ammonium salt, recrystallized with dilute hydrochloric acid and repeatedly washed with water prior to use as a MALDI matrix. Porcine trypsin was obtained from Promega (Madison, WI), and

10.1021/js9802603 CCC: $18.00
Published on Web 01/20/1999

endo-Glu-C was obtained from Sigma (St. Louis, MO). Ammonium bicarbonate (Fisher Scientific, Pittsburgh, PA) and dithiothreitol (Aldrich Chemical Co., Milwaukee, WI) were used in digesting the CIPP fractions.

Sample Preparation and Storage—One vial of NPH suspension contains the following ingredients: biosynthetic human insulin (3.5 mg/mL); protamine free base (0.27 mg/mL); dibasic sodium phosphate (3.78 mg/mL); glycerol (16 mg/mL); phenol (0.65 mg/mL); *m*-cresol (1.60 mg/mL); zinc oxide (to yield 0.025 mg/mL Zn^{2+}); water for injection. One vial of NPL suspension contains the following ingredients: biosynthetic [Lys^{B28},Pro^{B29}] human insulin analogue (3.5 mg/mL); protamine free base (0.30 mg/mL); dibasic sodium phosphate (3.78 mg/mL); glycerol (16 mg/mL); phenol (0.72 mg/mL); *m*-cresol (1.76 mg/mL); zinc oxide (as needed to yield 0.025/ml mg Zn^{2+}); water for injection.

CID and CIPP molecular species were generated in these vials of suspended crystals by heat stressing the sealed containers in normal atmospheric air for 3−6 months at 30−37 °C. These conditions normally promote mild oxidation of the tested protein, such as the formation of methionine sulfoxide, if methionine residues are present in the sequence.

Size Exclusion Chromatography—The method used has been previously described.[11] The chromatography system was composed of an AS-100T autosampler (BIO-RAD, Mountain View, CA), a Protein-Pak 125, 10 μm, 7.8 × 300 mm size exclusion column, a ConstaMetric 3500 pump (LDC Analytical, Riviera Beach, FL), and a variable wavelength UV detector (Applied Biosystems, Foster City, CA). The mobile phase was 65:20:15 5.74 mM l-arginine:acetonitrile:glacial acetic acid (v/v/v). The volume flow rate was 0.5 mL/min, the injection volume was 100 μL, and the column temperature was room ambient. The total run time for the method was approximately 40 min, and all peaks were collected manually. To improve CIPP recovery from dried fractions, the arginine was left out of the mobile phase for some sample collections. The absence of arginine from the mobile phase did not affect the method's ability to resolve the CIPP or CID peaks from monomeric insulin.

Enzymatic Digestion—Purified CIPP fractions were digested with trypsin by first vacuum evaporating 10 μL of a fraction in a 0.5 mL polypropylene Eppendorf tube, using a SpeedVac drying apparatus (Savant Instruments, Holbrook, NY), with no heating applied during drying. The resulting deposit was dissolved in 20 μL of 50 mM ammonium bicarbonate (pH = 8.0), and 1 μL of 0.1 g/L trypsin was added. The tube was incubated for 1 h at 37 °C. If the sample was to be reduced, sufficient dithiothreitol was added to bring its concentration to 10 mM and incubated for 20 min at 20 °C. For endo-Glu-C digestion, the same procedure was followed, except that 1 μL of 0.1 g/L endo-Glu-C was substituted for trypsin. All other relevant factors remained the same. Pharmaceutical grade biosynthetic human insulin was used as the control in all of the studies mentioned in this paper, with parallel digestions and analyses performed. The results of these controls were not included explicitly in the Results section, because they did not demonstrate any unexpected results.

Mass Spectrometry—ESI mass spectrometry was performed using an API-III triple quadrupole (PE-Sciex, Foster City, CA) equipped with a nanospray ion source. Data analysis of the ESI spectra was performed using *BioMultiView* (PE-Sciex, Foster City, CA), version 1.2. The MS/MS experiment described in the Results section was performed with *m*/*z* steps of 0.24 and 0.14 on the first and third quadrupoles, respectively. The collision gas used was argon.

MALDI mass spectrometry was performed using a Voyager linear time-of-flight mass spectrometer (PerSeptive Biosystems, Framingham, MA). The matrix material used was *trans*-α-cyano-4-hydroxycinnamic acid. Typical sample preparation[16] consisted of first preparing a stock solution of the matrix material—a saturated solution of the matrix in 2:1:0.001 water:acetonitrile: trifluroacetic acid (v/v/v), prepared at room temperature. This solution was mixed with the sample at a ratio of 10 parts matrix solution to 1 part sample solution (v/v), and a 1 μL aliquot of the mixture was dried on the sample stage of the mass spectrometer. Data analysis of the MALDI spectra was performed using *m*/*z* (ProteoMetrics, New York, NY), version 8.6. Molecular mass calculations were performed using *PAWS* (ProteoMetrics, New York, NY), version 8.3. All masses shown as labels in figures or in tables below are the true molecular mass for the peptide, calculated from the experimental *m*/*z* value by the following formula: $m = z \times (m/z - 1.0079)$. All peptide masses calculated correspond to the isotopically averaged, chemical mass of the peptide.

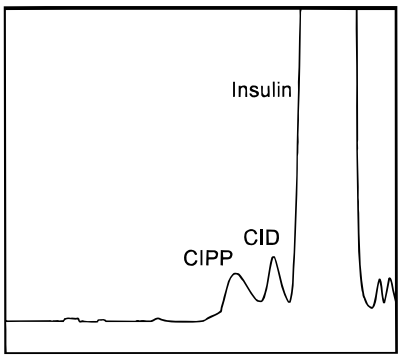

Figure 1—A typical size exclusion chromatogram of stressed NPH insulin, using the method described in the text. Free protamine was not recorded in this chromatogram because at the detector wavelength used (276 nm), protamine is transparent.

Table 1—The Molecular Masses of Chum Salmon Protamine

protamine variant	measured mass[a] (Da)	calculated mass[b] (Da)
1	4237	4236
2	4320	4319
3	4250	4250
4	4064	4064
5	4163	–
6	4418	–

[a] The measured masses were obtained by MALDI. [b] The calculated masses were obtained using the sequences and numbering system found in Hoffman,[7] except variants 5 and 6, which are reported here for the first time.

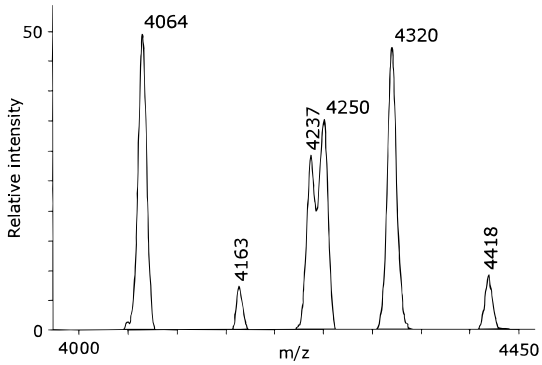

Figure 2—MALDI spectrum of protamine. See Table 1 for a comparison with known protamine sequences. The mass accuracy for the labeled peaks was ±1 Da.

Results

Figure 1 is a representative size exclusion chromatogram, demonstrating the resolution of the CID and CIPP species from insulin. Protamine, which is also present in the preparation, elutes just to the left of the CIPP peak. The detector wavelength used (276 nm) was chosen so that protamine itself is transparent, making the interpretation of the intensity of the CIPP peak unambiguous: the only absorption is the consequence of the presence of insulin[17] attached to one or more protamine molecules.

Even though protamine has considerable microheterogeneity[7] (see Table 1 and Figure 2), the size exclusion method produces only one peak corresponding to a dimer of itself with insulin. The presence of a single peak suggests that this product is the result of the addition of only one protamine molecule per insulin molecule. The mass spec-

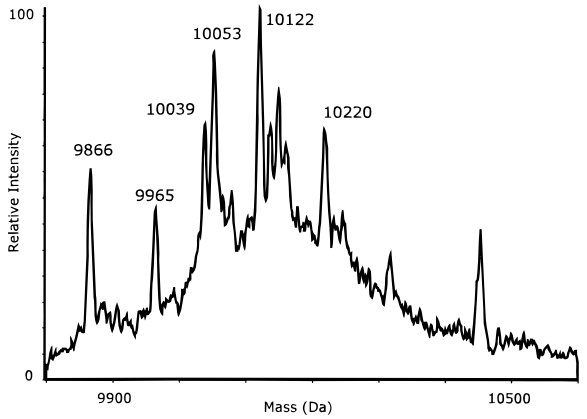

Figure 3—ESI spectrum of intact CIPP molecules. This spectrum was reconstructed from the multiply charged ion intensity pattern. The mass accuracy for the labeled peaks was ±1 Da.

Table 2—A Comparison of the Mass of the CIPP Dimer Observed by Electrospray Mass Spectrometry and the Molecular Mass Calculated by Simply Adding the Mass of Insulin to the Mass of a Protamine Variant (see Table 1)

observed dimer mass (Da)	assigned variant	protamine + insulin (Da)	Δ (Da)
10039	1	10044	–5
10122	2	10127	–5
10053	3	10058	–5

9965	5	9971	–6
10220	6	10226	–6

trum in Figure 2 shows that the protamine used for the current study corresponded to known protamine sequences, although two new sequence variants (5 and 6) were discovered.

The reconstructed mass spectrum of the complete mixture of species found in the CIPP peak (see Figure 1) is shown in Figure 3. There are clearly many molecular species present in this mixture. Comparing the intensity distribution and molecular mass differences found in Figure 2 with those found in Figure 3, it was straightforward to assign which variant gave rise to a particular signal. For example, the lowest mass peak in Figure 3 (9866) is 99 Da lighter than the next peak (9965). This result corresponds to the same mass difference observed between the first two peaks in Figure 2. Table 2 shows the results of this correlation analysis. The first column is the observed mass of the CIPP species, column 2 is the assigned protamine variant, column 3 is the result of simply adding the mass of the protamine variant and insulin (5807.6 Da), and column 4 is the difference, $\Delta =$ (column 1) − (column 3). Examination of column 4 shows that the average mass loss in forming a CIPP dimer is ≈5 Da, regardless of which protamine variant is present in the CIPP dimer.

The spectrum shown in Figure 3 is the best electrospray spectrum obtained from CIPP material, but it still represents a very low intensity signal, relative to the baseline noise. MALDI produced much higher relative signal intensities for all CIPP samples, and it was the method of choice for analyzing these materials. In this case, however, the mass accuracy of the electrospray spectrum was sufficiently superior to the MALDI spectrum that it was used for the calculation shown in Table 2. The ionic species represented in Table 2 were those that were observed unambiguously in both the MALDI and electrospray spectra.

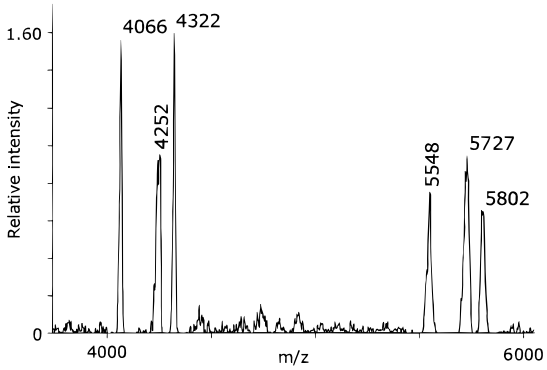

Figure 4—MALDI spectrum of CIPP, after treatment with endo-Glu-C and reduction with DTT. The mass accuracy for the labeled peaks was ±2 Da.

It is worth noting that even the purest CIPP fractions contained a significant amount of free protamine. The CIPP peak shown in Figure 1 elutes in the tail of the free protamine peak, which does not appear in the chromatographic trace because of the long wavelength chosen for the UV detector. All of the sample examined contained at least 30% free protamine, as estimated by MALDI-MS. Free protamine does not produce a useful signal in ESI-MS, so it could not be estimated by this method.

The nature of the cross-linking reaction was further investigated by performing a series of specific cleavages on the CIPP molecules and analyzing the results by mass spectrometry. The first of these cleavage reactions was to treat CIPP with the disulfide bond reducing reagent dithiothreitol and then cleave the resulting insulin A and B chains with the enzyme endo-Glu-C. This enzyme cleaves rapidly at the carboxy side of the peptide bond of glutamic acid residues, and more slowly at aspartic acid residues. Protamine does not contain any acidic residues, so it remains intact. The results of this cleavage are shown in Figure 4. The peaks in the mass range 4000−4400 Da correspond to unmodified protamine. The peaks in the mass range 5500−5900 Da correspond to protamine attached to the proteolytic fragment of insulin B chain, B[1−13]. These peaks also have $\Delta \approx -5$ Da. This result localizes the site of protamine attachment to somewhere in the first thirteen residues of the insulin B chain. Disulfide bond reduction was used to simplify the interpretation of the resulting molecular masses: the conditions used for this digestion reaction can promote disulfide shuffling.

One reasonable hypothesis regarding the attachment of protamine to insulin would be that the N-terminal amino group of protamine is involved in the cross-linking reaction. This hypothesis was tested by adding trypsin to the CIPP fraction, with the intention of cleaving all of the R−X (X ≠ P) bonds in protamine. The known protamine sequences[7] predicted that complete cleavage of all trypsin susceptible bonds would result in the dipeptide "PR" remaining attached to the insulin B chain. Dithiothreitol was added to the mixture after trypsin digestion to confirm that the modification was on the B chain.

Figure 5 shows the results of trypsin digestion followed by disulfide bond reduction. The signal $m/z = 2488$ and 3430 correspond to unmodified insulin B[1−22] and B[1−30], respectively. Table 3 assigns the signals for $m/z > 3430$ to possible tryptic fragments of the protamine sequences, along with the Δ value for each one of these assignments. Protamine produces many partially digested tryptic fragments with the same amino acid composition: the multiplicity per protamine molecule of possible fragments is given in the 4th column of Table 3, averaged over the known protamine sequences. The pattern of masses in the range $m/z = 2488-3327$ correspond to the same sequence

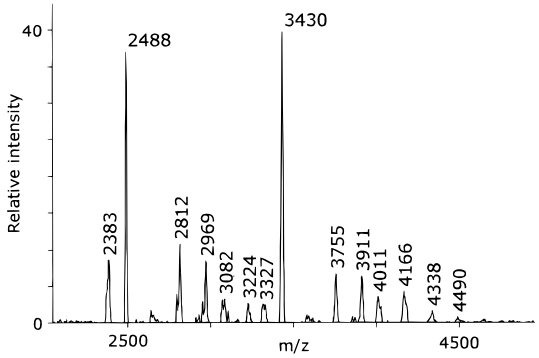

Figure 5—A portion of the MALDI mass spectrum of CIPP, following trypsin digestion and reduction with DTT. The mass accuracy for the labeled peaks was ±1 Da.

Table 3—Assignment of Tryptic Fragments of Protamine That Are Covalently Cross-Linked to the Human Insulin B Chain

measured mass (Da)	B chain + sequence	Δ (Da)	multiplicity[a]
3755	RR	–5	14

4011	PRRR	–5	2
4166	PRRRR; *or* RPRASR	–5	2
		–5	2
4338	RRRRGGR	–5	4

[a] Multiplicity indicates the number of different ways that a tryptic fragment with the same amino acid composition can be generated from the sequence of protamine.

and Δ assignments as in Table 3, except they are cross-linked to the tryptic fragment of insulin, B[1−22]. The signal at $m/z = 2383$ is the A chain of insulin.

The same types of experiments were performed using NPL formulations of the biosynthetic [Lys^{B28},Pro^{B29}] human insulin analogue. Identical results were obtained with the NPL formulation (data not shown).

Using the hypothetical reaction deduced in the section below, an MS/MS experiment was performed on CIPP material that had been subjected to a trypsin digestion, followed by a disulfide bond reduction and an endo-Glu-C digestion. The quadruply charged ion that would correspond to the B[1−13] cross-linked to the dipeptide RR less 5 Da ($m/z = 453.1$) was selected and MS/MS sequencing performed on that ion. The MS/MS data showed that the RR peptide was attached in the interval B[4−5]: the ion signals excluded all but these two residues as possible attachment sites. The interpretation of the signals from this MS/MS experiment was made possible by the deductions made below, rather than aiding in the formulation of these deductions, and therefore the data was not included in this study.

Discussion

The general strategy of using mass spectrometry on mixtures of peptides produced by enzymatic and chemical digests has been used to generate the main results in this study. The heterogeneity of the analytes and their physical properties make this approach the most viable method of gaining an understanding of the chemistry involved. Protamine and the protamine-insulin cross-linked species are very heterogeneous: there are at least 6 distinct protamine sequences and as many as 23 possible side chains that may participate in the proposed cross-linking reaction described below. Therefore, there are approximately 140 distinct molecular species that are being generically referred to as "CIPP". The samples that were analyzed in the course of this research were near the limits of detection for the mass spectrometric methods used, so any additional peak dilution caused by separating the individual components would compromise the quality of the data obtained from those peak fractions. Protamine-containing molecules do not separate well using reversed-phase separations because of the high solubility of protamine. Amino acid analysis was not useful for generating either positive or negative results because of the heterogeneity of the samples, their low concentrations, and the unusually high relative abundance of arginine in protamine-containing molecules, which leads to dynamic range problems in conventional amino acid analysis equipment.

Our results show that covalent CIPP species are present in stressed NPH insulin preparations and that they are very heterogeneous. The grossest level of heterogeneity results from the different sequences of protamine present in the initial preparation. The attachment site of protamine molecules to insulin is in the B chain of insulin. The results of endo-Glu-C digestion show that the protamine is linked to a residue somewhere within the first 13 amino acid residues of the insulin B chain. Tryptic digestion shows that the linkage can be made between B[1−13] and any arginine residue in protamine.

The value $\Delta = -5$ Da rules out the dimer formation reactions discussed by other authors[4−6,8−10] (see the Introduction). Transamidation reactions[4−6] result in the value $\Delta = -17$ Da. Succinyl anhydride-mediated reactions[8−10] result in $\Delta = -18$ Da. Cross-linking reactions resulting from the presence of low concentrations of aldehydes[4] would result in $\Delta \geq +12$ Da ($\Delta = +12$ is for the smallest aldehyde, formaldehyde). Protamine does not contain any cysteine residues, so disulfide cross-linking cannot occur.

The tryptic fragment assignments made in Table 3 rule out any dimer formation reaction involving the N-terminal amino group of protamine. If a free amino group was required to form the cross-link, then all of the sequences should begin with the N-terminal proline of the protamine sequence,[18] i.e., sequences beginning with the residues "PR ...". The observed sequences do not conform to this pattern. Instead they could come from any part of the protamine molecules, with fragments characteristic of both the N- and C-terminal region. Therefore, the protamine's N-terminal amino group cannot be involved in the dimer formation mechanism.

The fact that cross-linking to a single arginine residue is not observed (there is no signal at m/z = B chain + "R" − 5 Da) suggests that the cross-linking reaction involves the side chain of arginine in some way. The size of Δ suggests that the reaction involves the loss of 5 hydrogen atoms. This reaction would therefore not belong to the general class of condensation reactions typically found in protein chemistry. This different mechanism is probably brought about by the fact that this reaction is not a low temperature, solution phase reaction. Instead, this reaction occurs at elevated temperatures in the solid phase, i.e., within protamine-insulin crystals.

Inspection of the amino acid residues in the insulin B chain peptide B[1−13] can rule out a number of the residues for reaction with protamine. The sequence[16] is as follows:

FVNQHLCGSHLVE....

The side chains of phenylalanine, valine, leucine, and glycine residues are chemically inert under the conditions used to form CIPP. Therefore, the side chains of B1, B2, B6, B8, B11, and B12 do not participate in the reaction. The specificity of endo-Glu-C for cleaving at the carboxy side of glutamic acid residues implies that if B13 was modified there would be no cleavage at that site. The cleavage does occur; therefore B13 is not modified and does

not participate in the cross-linking reaction. Reactions known to occur with serine, asparagine, and glutamine residues all involve condensation reactions of their side chain amide groups, resulting in the loss of ammonia or water ($\Delta = -17$ or -18 Da). The results shown in Tables 2 and 3 rule out this type of reaction. Therefore residues B3, B4, and B9 do not participate in the formation of the CIPP observed in this study.

This simple process of elimination leaves the histidine residues, B5 and B10, and the cystine residue, B7-A7, as candidates to form of a cross-link with $\Delta = -5$ between a protamine guanidino group and insulin's B chain in a neutral pH, mildly oxidizing environment. There are no reactions that the authors are aware of (or can imagine) between an arginine guanidino group and a cystine residue that would result in this type of cross-linking under these conditions. Any reaction involving the oxidation of the sulfur atoms leading to a reactive product, such as cystine *S*-dioxide,[19] would result in $\Delta > 0$. A β-elimination reaction[20] involving that cystine could leave a reactive dehydroalanine at B7, but any reaction of that dehydroalanine with a guanidino group would result in $\Delta \leq -32$. These considerations eliminate the cystine residue and point to the involvement of at least one of the histidine residues.

Any dimer-forming reaction that occurs in the solid-state would be either assisted or inhibited by the geometry of insulin and protamine molecules in the NPH crystals. X-ray crystallographic examination of NPH crystals[21] shows that protamine does not occupy a single, well-oriented site in these crystals, due to its repetitive and heterogeneous structure. Electron density maps of these crystals show a region of protamine density at the interface between monomer 1 and the symmetry equivalent of monomer 3. It was suggested that the interactions between insulin and protamine molecules occurred via the guanidino groups of protamine's arginine residues and carboxylic acid containing residues in the insulin molecule. Contrary to this supposition, the actual structure shows that the most stable portions of the protamine electron density occur near the two histidine residues in the B chain, B5 and B10. The histidine residue B10 was also found to be responsible for the coordination of the zinc atoms in the assembled insulin hexamers.

Hydrogen bonding interactions between arginine and histidine side chains probably produce the localization observed in the X-ray crystal structure. Both histidine and arginine contain hydrogen bond donor and acceptor nitrogen atoms, because both contain singly bonded and doubly bonded nitrogens separated by one carbon atom. Therefore, there is the potential of forming two hydrogen bonds between these residues, which would lead to a significant stabilization of conformers that would allow the formation of these bonds in NPH crystals.

The most likely cross-linking reaction involves the imidazole group of histidine and the guanidino group of arginine, based on the combination of the known geometric association of insulin histidine and protamine arginine residues and the process of eliminating all of the other residues in the B[1−13] peptide. The mass lost during the reaction strongly suggests that two bonds are formed: a loss of four hydrogens leads to $\Delta = -4$, which is very close to the measured experimental value. However, the mechanism for this type of bond formation could not be probed directly in this system. Subsequently, the location of the cross-linking bridge was confirmed by LC/MS/MS (see Results) to be within the region B[4−5], supporting this hypothesis.

A number of reactions were considered for forming this cross-link, given the experimental constraints. Reactions involving the formation of a bridged tetrazine ring, and a

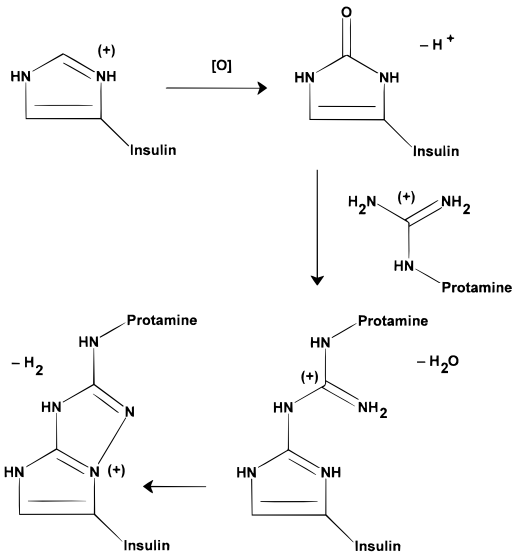

Figure 6—The proposed mechanism for the formation of the protamine-insulin cross-link, via an oxidation–reduction to form an imidazo[2,3-*b*]-1,2,4-triazolinium fused ring.[28]

number of other possible bridged rings were rejected because they would all result in violations of Bredt's rule.[22] One reasonable pathway to the formation of an appropriate cross-link is to postulate an initial oxidation of the histidine imidazole, as shown in Figure 6. This reaction, which forms imidazolone, is known to occur in histidine-containing peptides under oxidizing conditions.[23−25] This reaction has also been identified as a necessary step in the cross-linking of crystallins under oxidizing conditions.[26] The resulting imidazolone ring can be modified in several different ways, resulting in 2(3*H*)-, 2(5*H*)-, or 4(5*H*)-imidazolone.[27] Each of these exists as several tautomers,[26] by shifting a hydrogen to or from the keto group to form the tautomeric alcohol. The following discussion will center on the 2-imidazolone form because it has been observed in peptides.[23−25] Once the imidazolone derivative has been formed by oxidation, it is susceptible to a nucleophilic attack by one of the nitrogens in a protamine arginine side chain guanidino group. The final step in this tentative cross-linking mechanism is a further oxidation, as shown at the bottom of Figure 6.

This final step is necessary to explain the observed $\Delta = -5$ Da. The net result of the proposed reaction is the addition of oxygen (+16 Da), the loss of water (−18 Da), and the loss of H_2 (−2 Da), giving an overall $\Delta = -4$ Da. However, because the final product is positively charged, the additional proton that is normally assumed when making molecular mass calculations from experimentally determined *m/z* values is not necessary, resulting in the apparent loss of an additional proton, i.e., $\Delta = -5$ Da.

Conclusions

Whatever the exact mechanism, the results given in this paper clearly demonstrate that in the NPH formulation of insulin, the CIPP species formed are caused by a novel cross-linking reaction that occurs most rapidly under heat-stressed, mildly oxidizing conditions. Our observations do not agree with previous propositions as to the mechanism of CIPP formation, and they rule out most common condensation reactions that are known to occur between amino acid side chains. The site of the cross-linkage is proposed to be between any arginine side chain in protamine and the B[1−13] residues of insulin. We propose the reaction pathway indicated by Figure 6 as being consistent

with the experimental evidence. This mechanism may be the cause of dimer formation in other proteins, when they are stressed under similar conditions. Further work is ongoing to test this hypothesis.

Abstract □ The identification of the racemic species, as a racemic compound, a racemic conglomerate, or a racemic solid solution (pseudoracemate), is crucial for rationalizing the potential for resolution of racemates by crystallization. The melting points and enthalpies of fusion of a number of chiral drugs and their salts were measured by differential scanning calorimetry. Based on a thermodynamic cycle involving the solid and liquid phases of the enantiomers and racemic species, the enthalpy, entropy and Gibbs free energy of the racemic species were derived from the thermal data. The Gibbs free energy of formation, $\Delta G^{\circ}_{T_f}$, is always negative for a racemic compound, if it can exist, and the contribution from the entropy of mixing in the liquid state to the free energy of formation is the driving force for the process. For a racemic conglomerate, the entropy of mixing in the liquid state is close to the ideal value of R ln 2 (1.38 cal·mol^{-1}·K^{-1}). Pseudoracemates behave differently from the other two types of racemic species. When the melting points of the racemic species is about 30 K below that of the homochiral species, $\Delta G^{\circ}_{T_f}$ is approximately zero, indicating that the racemic compound and racemic conglomerate possess similar relative stabilities. The powder X-ray diffraction patterns and ^{13}C solid-state nuclear magnetic resonance spectra are valuable for revealing structural differences between a racemic compound and a racemic conglomerate. Thermodynamic prediction, thermal analysis, and structural study are in excellent agreement for identifying the nature of the racemic species.

Introduction

Chiral drugs comprise more than one-half of drugs approved worldwide.[1,2] In recent years, enantioselective production of chiral drugs has continued to grow at a rapid pace. Although catalytic asymmetric syntheses and biocatalytic resolutions have advanced steadily, resolution of racemates by crystallization (enantioselective crystallization) remains an important and the most economic process for the industrial-scale production and purification of single enantiomers.

A racemic species (also termed a racemate) can exist as a racemic compound, a racemic conglomerate, or a pseudoracemate (racemic solid solution), through different arrangements of equal numbers of moles of the opposite enantiomers in the crystalline state.[3] Characterization of the racemic species is a prerequisite for the design of industrial-scale resolution processes. Depending on the nature of the racemic species, different resolution techniques may be employed for the separation of the opposite enantiomers. Formation of a racemic conglomerate, consisting of homochiral crystals (same chirality),[4] facilitates resolution by crystallization. The outcome of a crystallization process, homochiral or heterochiral (differing chiralities), is governed by the nature of the solid−liquid-phase equilibrium that occurs in mixtures of enantiomers.[5] The formation of these different types of crystals is a result of difference in the structure and energetics between the homochiral and heterochiral crystals, which is the origin of chiral discrimination in the solid state.[6] For this reason, understanding the thermodynamic basis of the stereoselective interactions in these systems is essential for predicting and optimizing the course of resolution.

Construction of the binary phase diagram from simple measurements of the melting temperatures of the racemic species and of the corresponding enantiomers has traditionally been used for identifying the nature of the racemic species, usually a racemic compound (Figure 1a or 1b), or a racemic conglomerate (Figure 1c), or rarely a pseudoracemate (Figure 1d).[7,8] However, examination of melting temperatures alone may not be adequate in some cases, in particular when the racemic species exists either as a metastable racemic compound or as a metastable racemic conglomerate as in Figure 1c. The definitive identification of the structural differences between a racemic compound and the enantiomers usually comes from powder X-ray diffraction patterns, or from spectroscopic techniques, such as infrared and solid-state nuclear magnetic resonance (SSNMR) spectroscopy.

Questions arise as to the thermodynamic basis for the formation of different racemic species and as to the ability of the thermodynamic properties of chiral systems to serve as a reliable tool for the identification of racemic species. In view of the significant differences in the melting behavior of these racemic species (Figure 1), their thermodynamic properties must differ. These differences may be used to characterize the racemic species and may furthermore reveal the driving force for the formation of a racemic compound versus that of a racemic conglomerate or a pseudoracemate.

Although some studies on a number of chiral organic compounds have been carried out,[3,5] no investigation of this type has been reported for chiral pharmaceuticals. Therefore, the specific aims of this work are (1) to characterize various racemic species of chiral drugs using thermodynamic properties derived from calorimetric measurements, (2) to explore the thermodynamic factors determining the formation of homochiral and racemic crystals, (3) to identify the solid racemic phase by powder X-ray diffraction and by SSNMR, and to correlate the structural differences with the calculated thermodynamic quantities.

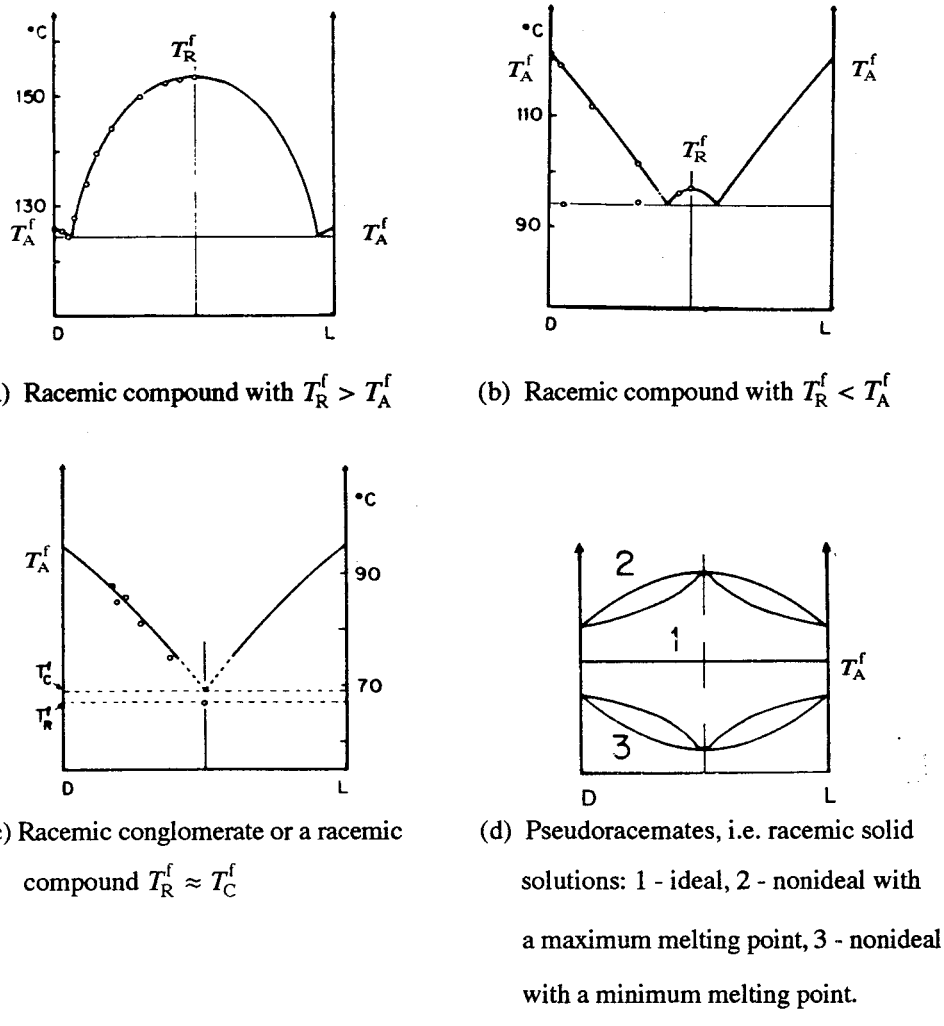

Figure 1—Typical phase diagrams of various racemic species[3] (reprinted with the permission of the copyright owner, Krieger Publishing Co.)

Twenty five chiral compounds of pharmaceutical interest were selected (see Table 1). Several compounds, specifically ephedrine and its derivatives and their salts, were prepared in this work, while others were collected from previously reported thermal analytical data of chiral drugs. These chiral compounds have various molecular structures and therapeutic applications, including several β-adrenergic antagonists, mucoregulating agents, and diagnostic agents. The overall goal of this work is to reveal unique thermodynamic properties of chiral solids of pharmaceutical interest.

Thermodynamics of Racemic Species—*Various Racemic Species.* Figure 1 shows three types of racemic species, sometimes termed racemates. However, because the term racemate has also been applied to racemic compounds only, use of the word racemate is avoided in this paper. A racemic conglomerate is an equimolar physical mixture of the individual homochiral crystals of the two opposite enantiomers. A racemic compound consists of crystals in which the two enantiomeric molecules of opposite chirality are paired up in the unit cell of the crystal lattice. A pseudoracemate consists of the two enantiomeric molecules of opposite chirality arranged more or less randomly in the same crystal lattice. All these three types are collectively termed racemic species in this work.

These structural differences in the solid state give rise to a difference in the energetics of the solid, which can be described by various thermodynamic properties that are either experimentally determined or derived quantities. To calculate the differences in the thermodynamic quantities between a racemic compound and its corresponding racemic conglomerate, Jacques et al.[3] developed a thermodynamic approach, using thermodynamic cycles. In the present work, the thermodynamic cycles of Jacques et al.[3] are modified and applied to the 25 racemic species studied. The thermodynamic cycle involving the two enantiomers, D and L, and their corresponding racemic species, R, is shown in Figure 2 for the enthalpy changes and in Figure 3 for the corresponding entropy changes.

Racemic Conglomerate—In a racemic conglomerate, if the enantiomers are perfectly immisible in the solid state, $\Delta H_s^m = 0$. Because of the structural similarity of the enantiomeric molecules, their liquid mixture is close to ideal, so that $\Delta H_l^m \approx 0$. The entropy of mixing of the enantiomers in the liquid state can be derived as described by Jacques et al.[3] and may be stated as follows:

$$\Delta S_l^m = \frac{\Delta H_R^f}{T_R^f} - \frac{\Delta H_A^f}{T_A^f} - \frac{\Delta H_R^f - \Delta H_A^f}{T_R^f - T_A^f} \ln\frac{T_R^f}{T_A^f} \qquad (1)$$

Equation 1 allows us to calculate the entropy of mixing of the liquid enantiomers from the enthalpies of fusion and

melting points, as measured by differential scanning calorimetry (DSC). If the enantiomeric molecules are randomly mixed in the liquid state, the entropy of mixing is ideal and its value is given by:

$$\Delta S_l^{\mathrm{m}} = R \ln 2 = 1.38 \text{ cal·mol}^{-1}\text{·K}^{-1} \qquad (2)$$

For a number of racemic conglomerates, the average entropy of mixing of the enantiomers in the liquid state was found to be 1.33 ± 0.14 cal·mol^{-1}·K^{-1}, indicating that mixing of the enantiomers is nearly ideal in the liquid state.[3] The small deviation from the ideal value may be attributed to the possibility that the corresponding enthalpy of mixing, ΔH_l^{m}, may not be exactly zero.

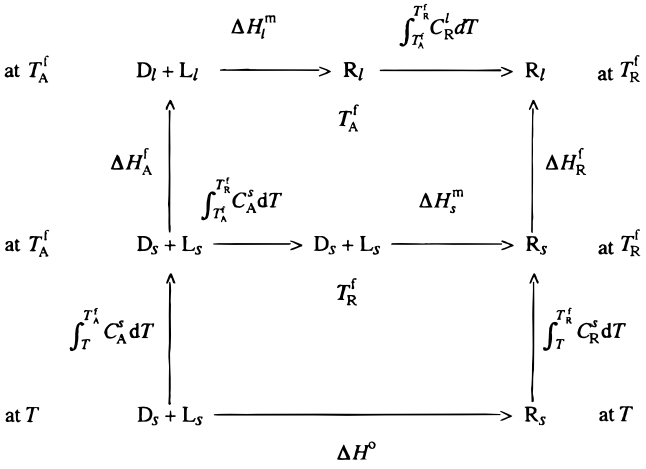

Figure 2—The enthalpy changes during various stages of a thermodynamic cycle involving the enantiomers, D and L, and the racemic species, R, where ΔH^{f}, C^{l}, C^{s} and T^{f} represent the enthalpy of fusion, heat capacity of the liquid and solid, and melting temperature, respectively. The subscript A denotes the enantiomer and R the racemic species; and the subscripts *l* and *s* denote the liquid and solid state, respectively. ΔH^{m} and ΔH° represent the enthalpy of mixing and the enthalpy of formation, respectively.

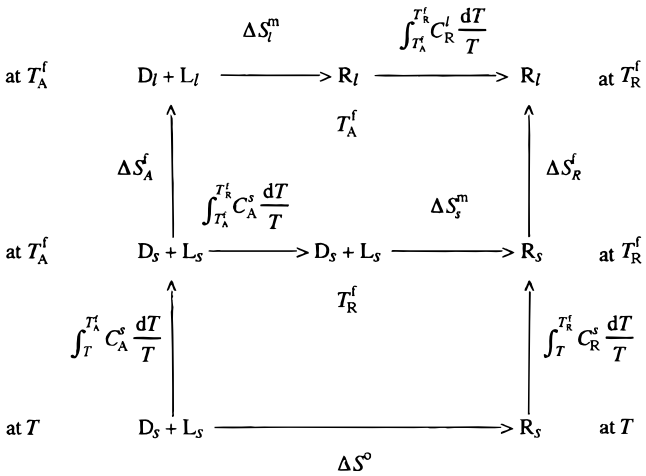

Figure 3—The entropy changes during various stages of a thermodynamic cycle involving the enantiomers, D and L, and the racemic species, R, where ΔS^{f}, C^{l}, C^{s}, and T^{f} represent the entropy of fusion, heat capacity of the liquid and solid, and melting temperature, respectively. The subscript A denotes the enantiomer and R the racemic species; the subscript *l* and *s* denote the liquid and solid state, respectively. ΔS^{m} and ΔS° represent the entropy of mixing and the entropy of formation, respectively.

Racemic Compound—The stability of a racemic compound can be defined by the Gibbs free energy change, $\Delta G°$, of solid-state transformation, corresponding to the "reaction" between the crystals of the two enantiomers, D and L, in the racemic conglomerate to yield crystals of the racemic compound, R:

$$\mathrm{D_s} + \mathrm{L_s} \rightarrow \mathrm{R_s}$$

where the left-hand side refers to the racemic conglomerate, which consists of an equimolar mixture of crystals of D and L, and the subscript, s, refers to the solid, i.e., the crystalline state. For a stable racemic compound, *this free energy change must be negative*. For this purpose, $\Delta G°$ is the Gibbs free energy of formation of the racemic compound from the two opposite enantiomers. $\Delta G°$ may be also expressed as a function of the corresponding enthalpy of formation, $\Delta H°$, and entropy of formation, $\Delta S°$:

$$\Delta G° = \Delta H° - T\Delta S° \qquad (3)$$

The thermodynamic quantities in eq 3 are not directly measurable, but can be determined from calorimetry data using eqs 4a−7b, as discussed below.

Assuming that the above "reaction" occurs at the melting point of that species (racemic species or enantiomer) which has the lower melting point, eqs 4a−7b may be derived to calculate the thermodynamic properties for the formation of a racemic compound. The enthalpies of fusion, ΔH^f, and the melting temperature, T^f, of both the racemic compound, R, and its enantiomer, A (in subscript), are determined experimentally. As shown in Figure 1a and 1b, the two situations, $T^f_A < T^f_R$ and $T^f_A > T^f_R$, are presented separately.

Enthalpy of formation:

$$\Delta H^\circ_{T^f_A} = \Delta H^f_A - \Delta H^f_R + (C^l - C^s_R)(T^f_R - T^f_A), \quad \text{when } T^f_A < T^f_R \quad (4a)$$

$$\Delta H^\circ_{T^f_R} = \Delta H^f_A - \Delta H^f_R + (C^l - C^s_A)(T^f_R - T^f_A), \quad \text{when } T^f_A > T^f_R \quad (4b)$$

Entropy of formation

$$\Delta S^\circ_{T^f_A} = \Delta S^f_A - \Delta S^f_R + R \ln 2 + (C^l - C^s_R)\ln \frac{T^f_R}{T^f_A}, \quad \text{when } T^f_A < T^f_R \quad (5a)$$

$$\Delta S^\circ_{T^f_R} = \Delta S^f_A - \Delta S^f_R + R \ln 2 + (C^l - C^s_A)\ln \frac{T^f_R}{T^f_A}, \quad \text{when } T^f_A > T^f_R \quad (5b)$$

Substituting the enthalpy of formation and the entropy of formation into eq 3 affords the free energy of formation, $\Delta G°$. The contribution from the terms containing the heat capacities in eqs 4 and 5 is always small and is effectively negligible.[3] Taking the difference in the melting points, $\Delta T = T^f_R - T^f_A$, and neglecting the small difference in the heat capacities, the free energy of formation is given by:

$$\Delta G^\circ_{T^f_A} \cong -\Delta S^f_R \Delta T - T^f_A R \ln 2, \text{ when } T^f_A < T^f_R, \text{ i.e., } \Delta T > 0 \quad (6a)$$

$$\Delta G^\circ_{T^f_R} \cong -\Delta S^f_A \Delta T - T^f_R R \ln 2, \text{ when } T^f_A > T^f_R, \text{ i.e., } \Delta T < 0 \quad (6b)$$

When, as in Figure 1a, the racemic compound melts at a higher temperature than its enantiomers, represented by eq 6a, $\Delta G° < 0$, suggesting that the formation of the racemic compound is always thermodynamically favorable in this situation. Figure 1b and eq 6b, however, present a more complicated situation. When $\Delta T < 0$, eq 6b is applicable and the first term on the right becomes positive. As ΔT becomes increasingly negative, $\Delta G°$ becomes less negative, eventually approaching zero (as ΔT approaches −30 K, to be considered later following eqs 7a and 7b). When $\Delta G°$ is zero or positive, there is no driving force for the formation of a racemic compound, and the racemic species remain as a racemic conglomerate as shown in Figure 1c. In other words, no "reaction" occurs between the enantiomers, when the racemic species is a racemic conglomerate.

Equations 4a−6b are valid only at the melting temperature of the enantiomers (or of the racemic species). In the pharmaceutical sciences, however, we are more interested in the thermodynamic values, especially $\Delta G°$, below the melting temperatures, e.g., at 25 °C or 37 °C. Extrapolation of the thermodynamic quantities from the melting temperature to another temperature, T, requires knowledge of the heat capacity terms. Accordingly, $\Delta G°$ at any temperature T, ΔG°_T, can be derived from the thermodynamic cycles in Figures 2 and 3:

$$\Delta G^\circ_T = \Delta G^\circ_{T^f_A} + \Delta\Delta S(T^f_A - T) + (C^l - C^s_R)\left[T^f_R - T^f_A - T \ln \frac{T^f_R}{T^f_A}\right] + (C^s_A - C^s_R)\left[T^f_A - T - T \ln \frac{T^f_A}{T}\right]$$

where

$$\Delta\Delta S = \Delta S^f_A - \Delta S^f_R + R \ln 2, \text{ when } T^f_A < T^f_R \quad (7a)$$

$$\Delta G^\circ_T = \Delta G^\circ_{T^f_R} + \Delta\Delta S(T^f_R - T) + (C^l - C^s_A)\left[T^f_R - T^f_A - T \ln \frac{T^f_R}{T^f_A}\right] + (C^s_A - C^s_R)\left[T^f_R - T - T \ln \frac{T^f_R}{T}\right]$$

where

$$\Delta\Delta S = \Delta S^f_A - \Delta S^f_R + R \ln 2, \text{ when } T^f_A > T^f_R \quad (7b)$$

The magnitude of the last three terms is relatively small. In the case of eq 7a, ΔG°_T is likely to remain negative over a wide temperature range below the melting point. However, when the free energy of formation at T^f_R in eq 7b has a small negative value close to zero (see examples in Tables 3), the sign of ΔG°_T may become positive depending on the sign of the sum, i.e., the relative magnitudes, of the last three terms. This possibility, arising from eq 7b, provides a thermodynamic basis for the melting point phase diagrams, shown in Figure 1c, and for the solubility diagrams of chiral systems that display a transformation from a racemic compound to a racemic conglomerate at certain temperatures.[3,9]

Materials and Methods

Materials—The names, acronyms, and sources of the chiral compounds used in this study are listed in Table 1. Some of these compounds were prepared by the methods described in the next paragraph. Others were purchased from chemical suppliers, with reported purity exceeding 99%, and were used as received.

Crystallization—(+)-Norephedrinium salicylate, (+)-NE·S, was obtained by dissolving equimolar quantities of (+)-norephedrine and salicylic acid in anhydrous ether followed by complete drying to yield a solid mass. The purity of (+)-NE·S was verified by a single sharp exotherm in the DSC curve and also by a single thermal event in the derivative of heat flow versus temperature. (+)-Pseudoephedrinium salicylate, (+)-PE·S, was prepared by crystallization.[10,11]

The racemic species of NE, E, PE, NE·S, PE·S, and ME, listed in Table 1, were prepared by dissolving equimolar quantities of the two enantiomers in methanol or ethanol and allowing the solvent to evaporate completely at room temperature (22.5 °C).

Differential Scanning Calorimetry (DSC)—Measurement of melting point and enthalpy of fusion of the crystalline chiral compounds was performed using a Du Pont 910 differential scanning calorimeter equipped with a data station (Thermal

[a] Numbers are given to identify the entries; code names are the acronyms explained in Table 1. [b] R and A denote the racemic species and its enantiomers, respectively. For entries 1–10, thermal analysis was carried out in this work, the standard deviation being less than 2.5%. [c] Entropy of fusion was obtained as $\Delta H^f/T^f$ of the corresponding homochiral or racemic species, but only the differences, $\Delta\Delta S^f$, are given.

Analyst 2000, TA instruments, New Castle, DE). The temperature axis and the cell constant were calibrated with indium (~3 mg, 99.99%, peak maximum at 156.6 °C and heat of fusion 28.4 J/g). Samples of 3.5 ± 0.5 mg in crimped aluminum pans were heated at a rate of 10 °C/min, and the peak melting temperature was recorded. All samples were measured in triplicate, and the standard deviations were less than ± 2.5%. Any small variations in the enthalpy of fusion as a result of differences in crystallinity of the homochiral and racemic species were expected to be negligible. The errors in determining the enthalpy of fusion when followed by possible decomposition were practically canceled out in the calculations, because small deviations in the baseline after melting occurred in the melt state for both the pure enantiomers and the racemic species.

Powder X-ray Diffraction (PXD) Pattern—Experimental PXD patterns of the compounds, both racemic and homochiral crystals, were determined at room temperature using a powder diffractometer (Model D-500, Siemens, Germany) with Cu Kα radiation at 30 mA, 45 kV. The sample was packed into an aluminum holder and scanned with the diffraction angle 2θ increasing from 2 to 30°, with a step size of 0.02°/min and counting time of 1 s per step.

^{13}C Solid-State Nuclear Magnetic Resonance (SSNMR) Spectroscopy—^{13}C SSNMR spectra were acquired at 75.743 MHz using a Chemagnetics CMX-300 spectrometer (Fort Collins, CO) and a Chemagnetics Pencil probe equipped with a 7.5 mm magic-angle spinning system using zirconia rotors. All spectra were acquired with cross polarization, magic-angle spinning, and high power ^{1}H decoupling. Spinning speeds were typically 5–6 kHz. Between 1024 and 2048 transients were acquired with a repetition delay of 3 s, contact time of 5 ms, and pulse width of 4 ms. No apodization was applied to the free induction decay prior to the Fourier transform.

Results and Discussion

Thermal Properties and Thermodynamic Calculations—To compare the thermodynamic properties of the enantiomers and their racemic species, the melting temperatures and enthalpy of fusion of the 25 chiral compounds are compiled in Table 2. The difference in melting temperature, ΔT^f, enthalpy of fusion, $\Delta\Delta H^f$, and entropy of fusion, $\Delta\Delta S^f$, of the two species are also given in Table 2 and are illustrated in Figure 4. Entry numbers, instead of compound names, are used for unbiased analysis and

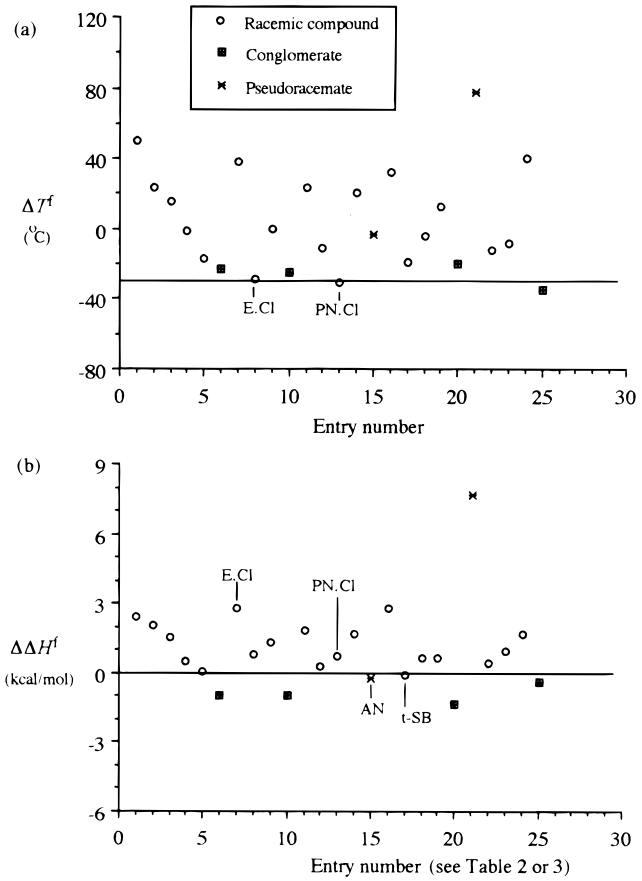

Figure 4—Differences between homochiral and racemic species in (a) the melting points, ΔT^f, and (b) the enthalpies of fusion, $\Delta\Delta H^f$.
