Although we have demonstrated the feasibility of MCP IP transdermal delivery from an input rate standpoint, local skin irritation has been observed at the delivery site. This local side effect could jeopardize clinical acceptability of this transdermal system. The goal of the present study was to investigate the feasibility of codelivery of HC with MCP and evaluate the inhibitory effect of HC on the skin response. MCP is a low molecular weight, cationic, water-soluble drug salt. Although most MCP transport is accomplished via migration of ionized drug molecules in the electric field, HC transport is mainly the result of passive diffusion and electroosmosis (i.e., migration of nonionized molecules in an electric field).[25] IP through the skin occurs chiefly through aqueous pathways (i.e., sweat glands and hair follicles).[26] As a result, the stratum corneum, which accounts for most of the reservoir effect observed during transdermal steroid delivery,[27] is bypassed; this routing should result in a reduced transport lag time of HC compared with passive delivery. We did not attempt to measure HC flux during this clinical study because theoretical calculations indicated that the resulting HC blood levels would be indistinguishable from endogenous levels. In the in vitro flux experiment, HC steady-state flux was achieved within less than 4 h transport under an anodic current of 0.1 mA/cm^2, indicating that IP effectively bypasses the reservoir effect of the stratum corneum with respect to HC delivery. In addition, we found that HC flux is affected by current and the presence of MCP. A current of 0.1 mA/cm^2 results in a more than 1 order of magnitude increase over the passive flux of HC. This result is consistent with transport of HC by electroosmosis and increased skin permeability resulting from IP, as was demonstrated with other neutral molecules.[28,29] Increase in HC flux in the presence of MCP may be explained by the increase in HC solubility in the presence of MCP. MCP is a very water-soluble drug that does not seem to present significant colloidal properties (in this study, it did not decrease significantly the surface tension of water at up to 0.5 M). Therefore, the observed increase in HC solubility in the presence of MCP cannot be the result of solubilization of hydrocortisone in MCP aggregates as has been observed with surfactants and compounds presenting colloidal properties.[30] Increase in HC solubility is probably the result of a salting-in phenomenon that commonly occurs when organic-substituted ammonium salts are added to aqueous solutions of nonelectrolytes.[31] In any case, the flux of a solute (electrosmotic as well as passive diffusion) has been reported to be directly dependent on its concentration.[28] Consequently, the increase in HC flux observed in the presence of MCP is consistent with the increase in HC solubility.

Neither the plasma concentration profile nor any of the pharmacokinetic parameters of MCP differed when it was delivered by IP, with or without HC, indicating that MCP input rate and its clearance from the skin were unaltered by HC. However, HC inhibited erythema as well as edema resulting from IP delivery of MCP. This result indicates that HC was delivered in vivo at a rate sufficient to exert its local pharmacological effect. Inhibition of erythema was very effective, as assessed visually and by skin color reflectance, and could be the result of the vasoconstrictive effect produced by HC, while the inhibition of edema probably reflects the antiinflammatory action of HC. Vasoconstriction is known to retard drug clearance from the delivery site.[32] Codelivery of HC could therefore impact the pharmacokinetic profile of MCP. No such effect of HC was observed possibly because of the high transport rate of MCP through the skin by IP and saturation of the skin binding sites. Alternatively, this could be explained by the low potency of HC. Indeed, HC is the weakest GC available; stronger GCs could possibly modify the pharmacokinetics of a codelivered drug by increasing local vasoconstriction at the delivery site.

GCs are broad-based antiinflammatory agents; they are expected to exert their activity on any type of inflammation, regardless of the triggering mechanism.[33] As a result, GCs are among the most universal agents for counteracting skin reactions. Using GCs when an inflammation mechanism is unknown or poorly understood provides a definitive advantage compared with using more specific antiinflammatory strategies described in the literature.[9,10,12,13]

The use of topical steroids more potent than HC can be more beneficial from an antiinflammatory standpoint in cases of extreme inflammation.[33,34] However, an increase in potency implies that potential side effects may also be observed. In normal subjects, adrenal suppression did not

occur with high-potency corticosteroid ointment formulations applied to 75% of the body surface once a day for six consecutive days.[35] However, in clinical practice, mild adrenal suppression has been observed after intensive use in patients who required rigorous treatment of their skin disease.[36] This observation indicates that the risk of systemic side effect with high-potency steroids is not completely negligible. Local side effects such as skin thinning resulting from local administration of steroids are also related to potency.[37] The usefulness of high-potency steroids, therefore, may be limited by the potential for systemic and local side effects.

The beneficial effect of HC has been reported only with weak sensitizers or moderate irritants.[15,16] Since IP delivery of MCP results in only moderate inflammation, it is thought that HC is more appropriate than stronger steroids for codelivery with it. The use of HC may be a good alternative to more potent GCs for inhibition of mild to moderate inflammatory responses for three reasons. First, HC is an endogenous compound; the amount needed to produce local antiinflammatory effects is a small fraction of the endogenous production. (In this study, the total calculated flux of HC per subject was about 0.1 mg after 4 h IP delivery, whereas endogenous HC production is reported to be about 10 mg/d.[33] Even if the amount of HC delivered is extrapolated to 24 h, this daily total is still a small fraction of the endogenous HC production. Therefore, systemic activity of HC is probably not responsible for the antiinflammatory effects observed in this study. Second, to the best of our knowledge, local side effects such as skin thinning have never been observed with HC. Finally, water solubility of HC is higher than that of most GCs and, if needed, solubility can be increased by the addition of solvents such as propylene glycol in concentrations compatible with IP delivery.[38] Therefore, the effect observed with MCP can probably be extended to the delivery of other irritating or sensitizing drugs, making this strategy a very powerful tool for achieving safe and acceptable transdermal delivery of drugs.

Abstract □ The major challenge faced during the development of implantable dosage forms for site-specific delivery is monitoring the local concentration of the drug at or around the site of action. The tissue concentration at the site is generally measured by either sacrificing the animal at different points in time or by determining the amount of drug left in the implants at various time intervals. Unfortunately, there are no official in vitro dissolution methods available to study the release characteristics of drugs from this drug delivery system. The objective of this investigation was to develop a simple method using microdialysis sampling technique to serve as an in vitro dissolution method for implantable drug delivery systems. Ciprofloxacin implants were prepared by compressing ciprofloxacin microcapsules in poly(lactic acid) (PLA) and poly(lactic-glycolic acid) (PLGA). A sensitive HPLC method was developed and validated for the assay of Ciprofloxacin. An in vitro dissolution method was developed to study the release characteristics of drug from these implants. The method used a microdialysis sampling technique and a small sample volume of release medium. The various advantages and disadvantages of this method over other USP methods are discussed.

Introduction

In vitro dissolution testing of pharmaceuticals is not a guarantee of therapeutic efficacy, but it is the best available in vitro method that can reveal qualitatively the physiological availability of a drug. Furthermore, the FDA Generic Drugs Advisory Committee has recently recommended the use of dissolution testing as an in vitro surrogate marker for bioavailability and bioequivalence.[1] Unfortunately, no such methods are officially available for implantable dosage forms. An in vitro method which may correlate to the local concentration of drug near the target site(s) will be invaluable for the design and evaluation of implantable dosage forms. Implantable dosage forms are gaining tremendous interest for the treatment of bone cancer, osteomyelitis, and for the delivery of short half-life polypeptides.[2−4] Therefore, a need to develop an in vitro dissolution method for these dosage forms will be an important contribution to the area of pharmaceutical dosage form design and analysis.

Microdialysis is a very useful technique because it permits continuous monitoring of drug concentration in extracellular spaces and has been used extensively in pharmacokinetics and pharmacodynamics studies.[5−7] In vitro microdialysis sampling technique has also been used to determine the protein binding of a drug,[8,9] partition coefficient,[10] and dissolution testing of pharmaceutical formulations.[11,12] The overall goal of this study is to develop an in vitro dissolution method using a microdialysis sampling technique to study the release characteristics of drugs from implantable dosage forms and compare the in vitro release profiles obtained from an established USP dissolution method. The idea of microdialysis is to mimic the passive function of a capillary blood vessel by perfusing a perfusate solution through a thin dialysis tube implanted in the tissue near the site of the implant. Therefore, the objectives of this investigation are to (i) develop and validate a sensitive HPLC method for the assay of ciprofloxacin, (ii) design a biodegradable implant for ciprofloxacin, (iii) design an in vitro dissolution apparatus using microdialysis as the sampling technique to study the release characteristics of ciprofloxacin from the implants, and (iv) compare the in vitro release profiles of drugs obtained from this method with an established USP dissolution method.

Experimental Section

Materials—Ciprofloxacin (Miles Pharmaceutical, West Haven, CT), a broad-spectrum antibiotic of the fluoroquinolone group, was used as a model compound. Poly DL-lactide-*co*-glycolide (PLGA) (50:50) and poly-lactic acid (PLA) (Birmingham Polymer, Birmingham, AL) were used as the biodegradable polymeric matrix materials. Citric acid, sodium phosphate (dibasic), acetonitrile, methanol, perchloric acid, and water (HPLC grade) were used as received (Fisher Scientific, Fair Lawn, NJ).

Preparation of Microcapsules and the Implants—Coacervation-phase separation method was used for the preparation of the microcapsules. The PLGA/PLA polymer (1 g) was dissolved in 30 mL of methylene chloride. Ciprofloxacin hydrochloride powder was dispersed in 600 mL of cyclohexanes. The polymer solution was then added, dropwise, over a period of 5 min to the cyclohexanes containing the dispersion of the drug. Methylene chloride was then evaporated off over a period of 2.5 h. After the microcapsules were formed, the solution was vacuum-filtered and dried overnight. Implants were made by compressing ciprofloxacin microcapsules in a Carver press using stainless steel dies and punches. The compression force used was 1000 psi for 5 s.

Scanning Electron Microscopy (SEM)—Samples were mounted onto the SEM specimen stub using transparent adhesive tabs. They were coated with gold and palladium, for 3 min, using a Polaron (model-E511) sputter coater and examined under a JEOL-JSM840 SEM (JEOL, Tokyo, Japan) operated at 10 kV.

Assay of Ciprofloxacin—The HPLC method developed by Bauer et al. was extensively modified and used for the analysis of the drug.[13] The mobile phase consisted of a citrate buffer: acetonitrile:methanol mixture (85:10:5 v/v/v). The apparent pH of the mobile phase was adjusted to 2.4 with perchloric acid. The citrate buffer (pH 3.8) was prepared by mixing 64.6% (v/v) of 0.1 M citric acid to 35.4% (v/v) 0.2 M Na_2HPO_4 solution. The flow rate was maintained at 1.5 mL/min (Shimadzu LC-6A pump). A Spherisorb C18 pH stable column (Phase Separations, Norwalk, CT), 15 cm in length, was used, and the column effluents were monitored at 280 nm (Shimadzu SPD-6A UV detector, Shimadzu. Koyoto, Japan).

Microdialysis System—This system consisted of a Harvard-22 syringe pump, Hamilton gastight (3.26 mm diameter) 500 μL

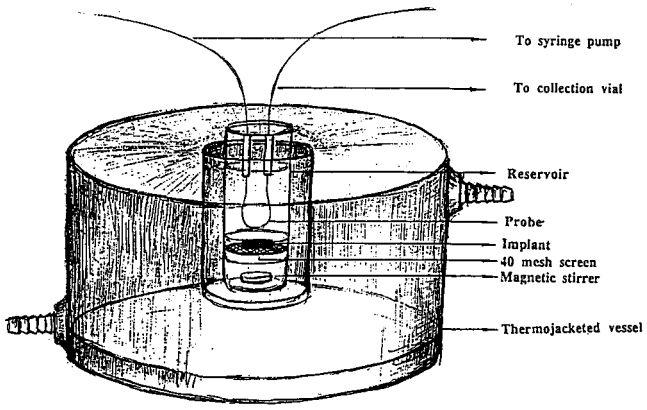

Figure 1—In vitro dissolution apparatus with microdialysis sampling technique designed in our laboratory for implantable drug delivery system.

syringes, and flexible microdialysis probes (made in house).[8] Flow-through loop-type probes were constructed using fused-silica tubing (Polymicro Technologies, Phoenix, AZ) with 75 μm i.d. and 150 μm o.d. Regenerated cellulose Spectro/Pro microdialysis hollow fibers (Spectrum Medical Industries, Los Angeles, CA) with a molecular weight cut-off of 1300 Da and 28−36 mm long were used as the dialysis membrane. The inner diameter of the dialysis fiber was 150 μm with a wall thickness of 9 μm. Probes were connected to the perfusion syringe with fused silica tubing. Initially, the probes were soaked and perfused with 80% (v/v) ethanol in water. Prior to experimentation, all of the probes were soaked and perfused with Sorensen's phosphate buffer (pH 7.4). These experiments were carried out at 37 °C with constant stirring (50 rpm) of the dissolution medium.

In Vitro Dissolution Apparatus with Microdialysis Sampling Technique—An in vitro dissolution apparatus which utilizes a microdialysis sample collection technique was developed in our laboratory and a schematic representation of the apparatus is depicted in Figure 1. The diameter of the reservoir was 15 mm, and its height was 45 mm. A 40 mesh screen was kept at a height of 5 mm from the bottom of the reservoir. The implantable delivery system was placed on the screen, and the microdialysis probe was placed at a fixed distance (10 mm) from the implant. Sorensen's phosphate buffer (pH 7.4) was used as the perfusate and the dissolution medium. The release medium was constantly stirred with the aid of a magnetic stirrer (50 rpm) placed at the bottom of the release medium as shown in Figure 1. The flow rate of the perfusate varied from 0.5 to 1 μL/min. At 25−40 min time intervals, the perfusate samples were collected directly into the HPLC autosampler injection vials with 200 μL inserts. To avoid evaporation, the vials were rapped with Parafilm. After the end of sample collection the Parafilm was immediately replaced with the cap containing the rubber septum. The concentration of the drug in the perfusate was determined using the HPLC method.

Microdialysis Probe Calibration—The in vitro calibration was performed at 37 °C in a Sorensen's phosphate buffer in a special thermojacketed Plexiglass microdialysis chamber containing 8.0 mg/L of ciprofloxacin. Probe recovery was measured before each experiment.

Factors Affecting the in Vitro Microdialysis Recovery—Probe flow rate was validated gravimetrically using preweighed collection vials. The effect of the flow rate and probe length on recovery of the drug during the microdialysis studies were evaluated.

Data Analysis—The in vitro recovery of the probes was calculated as the ratio of the ciprofloxacin concentration in the dialysate to that in the Sorensen's phosphate buffer in the reservoir vial, expressed as the peak height ratio (PHR) of drug to the internal standard (IS), represented by eq 1:

$$\text{recovery}_{\text{in vitro}} = \frac{C_{\text{dial}}}{C_{\text{res}}} = \frac{\text{PHR}_{\text{(drug/IS) dialysate}}}{\text{PHR}_{\text{(drug/IS) reservoir}}} \qquad \text{(eq 1)}$$

USP Dissolution Apparatus 3[14]—Sorensen's phosphate buffer pH 7.4 (150 mL) was used as the dissolution medium and equilibrated to 37 °C. The ciprofloxacin implant was then placed on the plastic wire mesh of the reciprocating tube and dipped at a rate of 20 dips per minute into the dissolution medium. At predetermined time intervals, 1 mL of the sample was collected and an equal volume of fresh phosphate buffer was replaced after each sample collection. The drug content in the release medium was determined by the HPLC method.

Results and Discussion

Formulation of the PLGA Implants Containing Ciprofloxacin—The drug is highly water soluble and has been reported to be stable in solution.[15] The pK_as of ciprofloxacin are 6 and 8.8 with a molecular weight of 385.8 (g/mol). These physicochemical properties indicate that the drug can easily pass through the microdialysis membranes used in this investigation and, therefore, be utilized as the model drug. Initial attempts to make the PLGA/PLA implants by direct compression of the physical mixture of the drug and polymer in a Carver press was unsuccessful. Therefore, the drug was first microencapsulated in the polymer and then compressed into cylindrical implants. The microstructure of the drug both before and after microencapsulation is shown in Figure 2. The scanning electron micrographs indicated that the free drug (Figure 2a) is crystalline and rod-shaped in nature, whereas the microcapsules (Figure 2b) are agglomerates with a different microstructure. Such a change in microstructure was essential for the direct compression of these polymers (PLA and PLGA) and the drug (ciprofloxacin) into implant. The detailed dimensions of the implants made and their composition are provided in Table 1.

HPLC Method Validation—Representative chromatograms of the internal standard (phenacetin), ciprofloxacin, and both the drug and internal standard are shown in Figure 3. No interfering peaks were observed in the chromatograms. The linearity, precision, accuracy, and sensitivity of the assay were determined as indicated below.

Linearity—The standard curves were linear over the concentration range of 0.0−9.5 mg L^{-1}. The equation of the standard curve relating the peak height ratio (P) to the ciprofloxacin hydrochloride concentration (C in mg l^{-1}) in this range was:

$$P = 0.27578C + 0.00147, \qquad r^2 > 0.999$$

Precision—Within-day precision was determined by analysis of four different standard curves on the same day. Day-to-day precision was determined from the standard curves prepared on each seven different days during 60 days. The precision of the assay was determined from the variability in the peak height ratio at each concentration. The RSD for the within-day and day-to-day precision were 0.6−2.6% and 1.9−4.3%, respectively, and are depicted in Table 2.

Accuracy—Known amounts of ciprofloxacin were added to the mobile phase to make the quality control samples. Three quality control samples and the standard solutions were kept at 4 °C for 60 days. These solutions were analyzed seven times during this period, and the accuracy of the assay was determined by comparing the measured concentration to its true value of the drug. The RSD for the accuracy measurement for this method was between 3.8 and 4.7% as shown in Table 3.

Sensitivity—The sensitivity criteria was determined from seven different standard curves using the lowest limit of reliable assay measurement guidelines described by Oppenheimer et al.[16] In this study, the critical level is defined as the assay response above which an observed response is reliably recognized as detectable. The critical level is also considered a threshold value, thus, defining

[a] Mean ± SD; $n = 7$. [b] Accuracy = (measured concentration/actual concentration) × 100.

In addition to the critical value, another important parameter is the detection level defined as the actual net response, which may, a priori, be expected to lead to detection. This response is defined as the smallest value of the true concentration that is "nearly sure" to produce a measurement value that results in detection.[17] The detection level in this analysis was found to be 0.069 ± 0.013 μg mL^{-1} (mean ± SD).

The determination level is defined as the concentration at which the measurement precision will be satisfactory for quantitative analysis. This level was determined as 0.191 ± 0.035 μg mL^{-1} (mean ± SD) to obtain a 10% RSD level of precision.

Microdialysis Probe Calibration—The recovery of the probes was determined prior to each in vitro release study. The effects of probe length and perfusion flow rate on the in vitro recovery of ciprofloxacin were then determined and shown in Table 4. As expected, decreasing the length of the probe decreased the in vitro recovery of the drug.

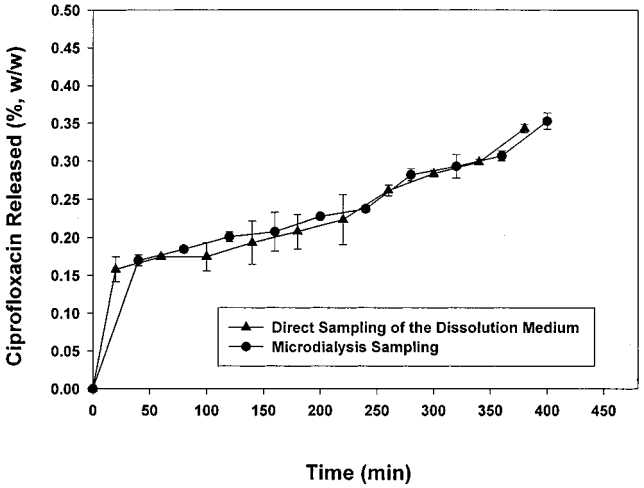

Figure 4—In vitro release profiles of Ciprofloxacin from PLGA implants (9.4% w/w drug load) determined by direct sampling of the dissolution medium and sampling by microdialysis.

However, the perfusate flow rate had an inverse relationship with the in vitro recovery of the drug. Through the analysis of the results of these studies, the optimal perfusate flow rate was determined to be 0.75 μL/min and the length of the microdialysis probe was kept within the range of 30−32 mm for the entire study. Probe flow rate was validated gravimetrically using preweighed collection vials. Within sample precision of the microdialysis sampling was determined in seven microdialysate samples collected using the same probe and same flow rate. The RSD for this precision determination was within 5%.

In Vitro Release of Ciprofloxacin from the Implants—The in vitro release of ciprofloxacin from these implants was then determined by two separate and independent methods. The drug was first analyzed using the method developed in our lab with microdialysis sampling technique and second by utilizing USP dissolution method 3.

Using the dissolution method developed in our lab, the ciprofloxacin concentration in the release medium was determined by two different sampling methods. At appropriate time intervals, 30 μL of the sample was collected directly from the dissolution medium and injected into the HPLC for assay of ciprofloxacin. Simultaneously, 30 μL of fresh phosphate buffer was replaced in the chamber. In the second sampling method, the microdialysis probes were used to monitor the concentration of the drug in the dialysis chamber. Before using the probes for monitoring the in vitro drug concentration, they were calibrated to determine their in vitro recovery. The perfusate (30 μL) was collected every 40 min at a flow rate of 0.75 μL/min, and the concentration of the drug in the microdialysate was determined by HPLC. The drug concentration in the dissolution medium was then calculated using the in vitro recovery of the probe. Figure 4 depicts the in vitro release profiles of

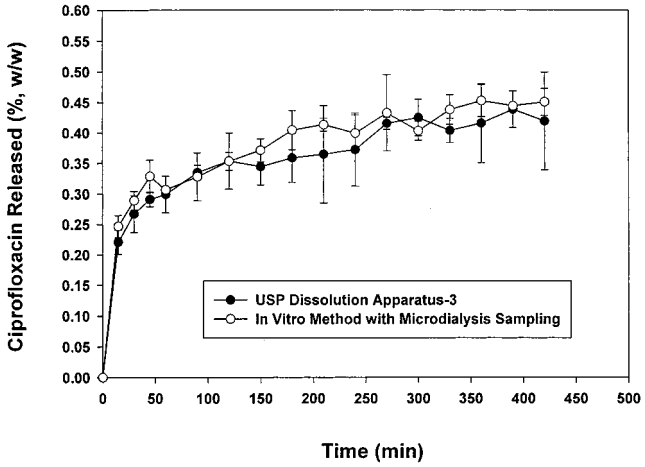

Figure 5—Comparison of the in vitro release profiles of Ciprofloxacin from PLGA implants (9.4% w/w drug load) determined by the use of microdialysis sampling method and the USP dissolution method 3.

implant type	microdialysis using direct sampling	microdialysis using microdialysis probe	USP apparatus 3
PLA	0.15 ± 0.003[a]	0.15 ± 0.004	0.17 ± 0.02
PLGA	0.40 ± 0.01	0.44 ± 0.05	0.41 ± 0.02

[a] Mean ± SD; $n = 3$.

the drug from a PLGA implant determined by the two sampling techniques. The method by which the samples were collected had no effect on the release profiles of the drug. Therefore, this study clearly indicated that this microdialysis sampling technique could be used to monitor the concentration of various drugs in the release medium if the determination of the in vitro recovery of the probe is correct.

The in vitro release characteristics of ciprofloxacin from the implants were then studied using the two independent methods. We selected the USP dissolution method 3 for the following reasons: (i) a low volume (150 mL) of release medium is required as compared to the 900 mL in the case of USP methods 1 and 2, (ii) low rate of evaporation of the release medium during dissolution studies over a prolonged period of time as compared to the USP methods 1 and 2, and (iii) in our laboratory, we have already compared and reported the in vitro release characteristics of other dosage forms using both USP apparatus 2 and 3 without any significant differences in their release profiles.[18] The in vitro release profiles of the drug from various implants containing similar drug loads were then obtained by both methods and are shown in Figure 5. The rate and extent of drug release determined by both of these methods were in close agreement. The burst effect shown during the in vitro release studies could arise due to the presence of free drug on the surface of the implants. This free drug might have originated during compaction of the microcapsules or due to the presence of uncoated drug in the formulation. Table 4 summarizes and compares the extent of ciprofloxacin released from various implants with similar drug loads in 6 h. This study indicated that the release of ciprofloxacin from the PLGA implants was higher than the PLA implants (release profiles not shown here). Moreover, the preparation of PLGA microcapsules was easier than the PLA microcapsules. The former microcapsules were compact, whereas the latter were fluffy and difficult to handle during compression. Comparison of the in vitro

release profiles of drug from the implants within a batch was found to be in close agreement and independent of the sampling (Figure 4) and dissolution methods (Figure 5) used. However, a slight difference in the release profiles was noticed between batches (Figure 4 and Figure 5) even though the drug load was kept constant in both the batches. This difference in the release profiles could possibly be attributed to batch-to-batch variations.

Conclusions

(1) A sensitive HPLC method was developed and validated for the analysis of ciprofloxacin.

(2) An in vitro dissolution method using a microdialysis sampling technique was developed and used to determine the release characteristics of ciprofloxacin from various implants.

(3) The proposed method has the following advantages: (i) it is simple, (ii) it requires a very small volume of dissolution medium, (iii) on-line analysis of the drug is possible, (iv) continuous monitoring of the drug over a prolonged period of time is possible, and (v) this method could be used to determine the local concentrations of the drug near the implant site.

(4) The rate and extent of ciprofloxacin release determined by both methods were in close agreement.

(5) In the future, this method could be used in evaluating the in vitro dissolution characteristics of potent drugs and dosage forms (microcapsules and microspheres of proteins and peptides) requiring a small volume dissolution medium.

Accepted for publication July 9, 1999.

Abstract □ A novel method for quantifying hemolysis is described. This method uses a spin filter to separate the free hemoglobin from the red blood cells suspended in the test solution. This procedure enables the use of a closed loop system that continuously measures hemolysis spectrophotometrically. It is shown that hemolysis does not always stop after the solution has been quenched with normal saline. In fact, the process of hemolysis induced by chemicals such as potassium oleate is relatively slow.

1. Introduction

Hemolysis is defined as the destruction of red blood cells in such a manner that hemoglobin is liberated into the medium in which the cells are suspended.[1] Increases in free hemoglobin in the plasma resulting from hemolysis are associated with serious medical conditions such as renal dysfunction, splenomegaly, jaundice and kernicterus.[2]

In 1936, Wokes[3] defined the hemolyzing concentration of a solution as the concentration that will produce a supernatant liquid that is faintly pink after half of an hour of contact time with freshly shed normal human blood. This method for detecting hemolysis does not quantify the amount of hemolysis produced and is not sensitive enough to detect hemolysis that could not be seen by the naked eye. Husa and Adams[4] developed an in vitro method for evaluating hemolysis that became the standard parenteral screening method for many years. This method involves the incubation of red blood cells with a large excess of test solution. In this method the supernatant is measured for absorbance at 540 nm (the absorbance maximum for hemoglobin). The use of a spectrophotometer provides a sensitive method for quantifying the extent of hemolysis. Although the Husa and Adams method is generally quite useful, three main problems have been noted.[5] The first problem with this procedure is that the presence of nonaqueous solvents and metal ions produce changes in the absorbance spectrum of hemoglobin and therefore can give inaccurate results. The second problem with this method is that the formulation:blood ratio of 50 is unrealistically high for modeling intravenous injections. The third problem is that this method used a very long contact time (30 min) of formulation with blood before separation and analysis of hemoglobin. This contact time does not mimic the dilution that occurs naturally after injection of the formulation into the human vein.

In 1985, Reed and Yalkowsky[6] developed a more physiologically realistic model using a formulation:blood ratio of 0.1 and a 2-min contact time of blood with the test solution. However, this contact time is still too long to accurately model hemolysis that occurs after an intravenous injection.[2] Reed and Yalkowsky also addressed the issue of alterations in the absorbance spectrum of hemoglobin caused by the presence of nonaqueous solvents and metal ions that are sometimes present in parenteral injections by washing the red blood cells and ghosts that remained after mixing the test solution with blood. The intact red blood cells were then lysed with water, and the fraction of healthy cells was determined. This procedure, which is analogous to a back-titration, allowed all spectral analysis of hemoglobin to be performed in a purely aqueous medium.

Obeng and Cadwallader[7] were the first to develop a dynamic method that mimics hemolysis occurring in the body following an intravascular injection. Their method utilizes an in vitro flow system that provided a reasonable simulation of the mixing that occurs at the intravenous injection site, taking into consideration tubing diameter, blood flow rate, injection volume, and injection time. In this method, Obeng and Cadwallader injected the formulation into a flowing stream of red blood cells. Then the formulation and blood mixture entered a large volume of saline, which was assumed to quench the hemolytic reaction. The saline mixture was then centrifuged and the supernatant was analyzed with spectrophotometer. Although this method is capable of measuring the effect of contact time, this was not done to any significant extent. Krzyzaniak and coworkers[8] developed a dynamic in vitro method that is able to quantify hemolysis at short contact times (1 s) with a formulation:blood ratio of 0.1. This contact time of 1 s provides a more physiologically realistic model of the injection site.

Both the Reed and Yalkowsky and the Obeng and Cadwallader methods assume that quenching the test solution with saline stops the hemolytic reaction. However, some red blood cells that are slightly damaged could still break some time after the solution has been quenched. This reaction could not be detected by the previous methods because all other methods quantify hemolysis at one point of time after the reaction has been quenched. Another problem with all previous methods is that they determine the degree of hemolysis at a relatively long time after quenching because of a lengthy centrifugation step. They cannot be used to evaluate the very early reaction between red blood cells and the test solution.

The aim of this investigation is to develop a method for quantifying hemolysis that is physiologically realistic and that is able to evaluate the very early reaction between red blood cells and the test solution.

2. Materials and Methods

2.1 Materials—The blood used in this investigation was obtained from the American Red Cross (Tucson, AZ). Sodium lauryl sulfate, (SLS), poly(ethylene glycol) 400 (PEG 400), propylene glycol (PG), and sodium chloride were purchased from Sigma Chemical Company. Tween 80, glycerine, potassium oleate, and

red food color (red dye) were purchased from Biotech, Mallinckrodt, TCI America, and McCormick & Company Inc., respectively. All chemicals were used as received. These compounds were chosen because they are commonly used in pharmaceutical formulations. Each of these were admixed with normal saline to the concentration listed in Table 1.

2.2 Methods—*2.2.1. Spin Filter Method*—Figure 1 illustrates the experimental apparatus. Whole blood was washed three times with normal saline to remove the damaged red blood cells, buffy coat, and free hemoglobin. The washed red blood cells were reconstituted to a 40% hematocrit with Sorensen phosphate buffer (pH 7.4). The intact red blood cells were then pumped through Tygon tubing (1/32 in. i. d.) with a syringe pump. The vehicles were injected into the blood flow with the aid of syringe pump. The formulation-blood mixture at the ratio of 0.1 remained in contact for one second. These formulation:blood ratio and contact time were obtained by a blood flow rate of 6 mL/min, a formulation flow rate of 0.6 mL/min, and a mixing distance of 5 cm in the approximately 1 mm i. d. tubing. The mixture then was diluted with a large amount of normal saline. The normal saline containing the formulation:blood mixture was continuously sampled with a centrifugal filtering system (0.3 μm Whatman, Gamma-12 high efficiency in-line units) as described by Shah.[9] The spin filter allows only the contents of lysed red blood cells mixed with normal saline to enter the spectrophotometer. The spin filter, which rotates at a speed of ~142 rpm, throws off by centrifugal force erythrocytes, ghosts, and other matter that would clog a stationary filter. Using this spin filter apparatus, the supernatant and the cells are rapidly separated without centrifugation. The filtered solution was then allowed to circulate through the spin filter until the hemolytic reaction has terminated. Red dye was used to determine the lag-time in this method. A pump was used to circulate the solution through the spin filter and flow cell in the spectrophotometer. Hemolysis was then calculated with the following formula:

$$\%\text{Hemolysis} = \frac{A_F - A_0}{A_{100} - A_0} \times 100 \qquad (1)$$

where A_F = absorbance of hemoglobin in the filtered solution after injecting test solution, A_0 = absorbance of hemoglobin in the filtered solution after injecting normal saline, and A_{100} = absorbance of hemoglobin in the filtered solution after total cell lysis with water. Because the filtered solution is continuously sampled, a percent hemolysis versus time profile is generated. This profile describes both the extent of hemolysis and the time frame of the hemolytic reaction.

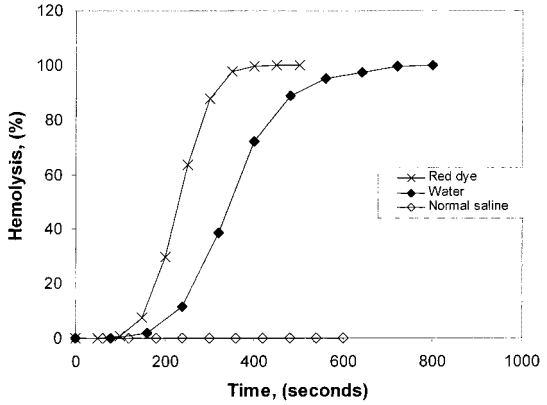

Figure 2—Percent hemolysis versus time profile for the blanks used on the spin filter method; that is, normal saline and water. The Y axis for red dye was obtained considering its absorbance at the plateau as 100% hemolysis and eq 1.

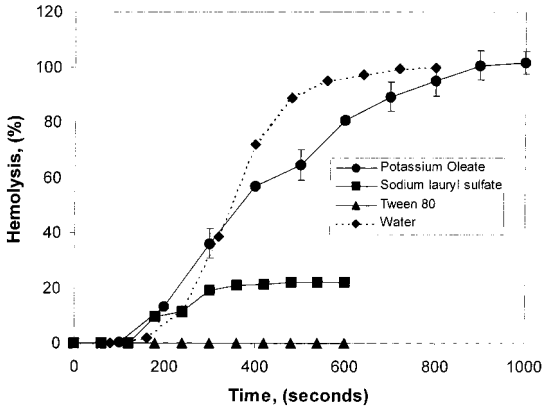

Figure 3—Hemolysis induced by surfactants.

3. Results

Figure 2 shows the percent hemolysis versus time profile for normal saline and water. The Y axis data for the red dye were obtained by the normalization of the absorbance data at 540 nm with the absorbance at t_{100} (A_{100} or absorbance at the plateau) and eq 1. All samples were run in triplicate at room temperature.

The six pharmaceutical vehicles were divided into two categories, surfactants and cosolvents. The first category includes SLS, potassium oleate, and Tween 80. The second category includes PG, PEG 400, and glycerine. The percent hemolysis produced by each vehicle at each time point was measured three times and their mean and standard deviation was determined. A cumulative graph of the percent hemolysis versus time for the surfactants and cosolvents are presented in Figures 3 and 4, respectively.

4. Discussion

Red dye data (Figure 2) indicate that the spin filter method has a lag-time of ~100 s. This figure also shows 0% hemolysis at 600 s for normal saline, indicating that red blood cells are not destroyed during the experiment. Interestingly, this figure shows that the hemolysis produced by water is a time-dependent process. The time to reach 100% hemolysis is ~700 s (almost 2 min longer that

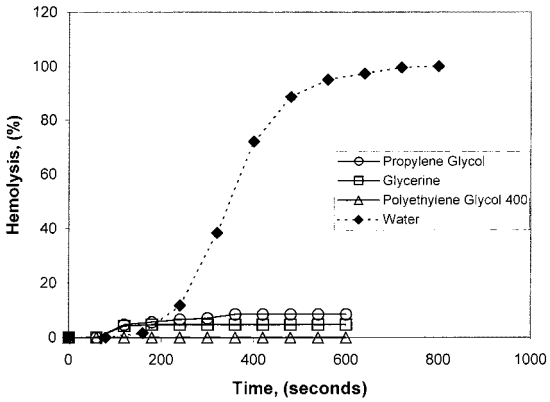

Figure 4—Hemolysis induced by cosolvents.

the red dye). These data indicate that hemolysis is not stopped instantaneously by quenching, and that the spin filter method is able to measure both the extent of hemolysis and the time required for the hemolysis process to occur.

Figures 3 and 4 show that the hemolytic reactions for the cosolvents PG and glycerine are less complete and more rapid than the reactions produced by the surfactants potassium oleate and SLS, at the tested concentrations. Also, these figures indicate that the cosolvent PEG 400 and the surfactant Tween 80 are not hemolytic, at the tested concentrations, which is consistent with the results of previous investigations.[2,10]

Figure 3 shows that the hemolytic reaction produced by potassium oleate is slower than the reaction produced by water. Potassium oleate takes longer to produce complete hemolysis than does water. However, Figure 3 shows that potassium oleate is as hemolytic as water at longer times. In addition, Figure 3 shows that although SLS is less hemolytic than water, it reaches its maximum value in less time than does water.

5. Conclusions

Unlike other methods, the spin filter method for evaluating hemolysis provides a means of assessing hemolysis that occurs after quenching. If it is assumed that the mixture of the blood from an injected vein with blood from other parts of the body is equivalent to quenching of hemolysis, then the spin filter method provides a more realistic simulation of the process of hemolysis, as it would occur in the body following an intravascular injection, than other methods. This method is able to determine not only the extent of hemolysis but also the estimated time frame of the reaction.

Pore Charge Distribution Considerations in Human Epidermal Membrane Electroosmosis

S. KEVIN LI,* ABDEL-HALIM GHANEM, AND WILLIAM I. HIGUCHI

Contribution from *301 Skaggs Hall, Department of Pharmaceutics and Pharmaceutical Chemistry, University of Utah, Salt Lake City, Utah 84112.*

Received November 10, 1998. Accepted for publication July 13, 1999.

Abstract □ The aim of this study was to assess the extent to which a model with pores having only net negative charges would adequately describe transdermal electroosmosis in human epidermal membrane (HEM) at neutral pH. Such information would enhance the predictive value of the modified Nernst–Planck model for transdermal iontophoresis, in addition to providing insights regarding the likelihood of significant pore charge distribution in HEM. Baseline results (the control) obtained from 0.1 to 0.4 V anodal and cathodal electroosmosis experiments with synthetic polycarbonate membranes (Nuclepore membranes), using radiolabeled urea and mannitol as the model permeants, demonstrated that such a membrane system can be modeled by the electrokinetic (electroosmosis) theory with the assumption of the pores possessing only negative charges. The studies with HEM were carried out at low voltage ($\leq$0.5 V) where alterations in the barrier properties of HEM were minimal and at higher voltages ($\gtrsim$1.0 V) where significant field-induced pore formation in HEM occurred. In both the low and high voltage studies, radiolabeled urea, mannitol, and water were employed as permeants in cathodal and anodal iontophoresis experiments. The results of the low voltage iontophoresis experiments suggest significant pore charge distribution in HEM (a significant deviation between the predictions from the single pore charge type assumption and the experimental data). Under the higher applied voltage conditions ($\gtrsim$1.0 V), results from anodal and cathodal electroosmosis studies were consistent with the model in which the HEM has only pores that are net negatively charged.

Introduction

There has been important progress in our understanding of the mechanisms of transdermal iontophoresis with human epidermal membrane (HEM). The modified Nernst–Planck model (Nernst–Planck equation with corrections for convective solvent flow due to electroosmosis) has been tested with HEM under low voltage iontophoresis conditions,[1,2] and semiquantitative agreement between the experimental results and predictions from the model has been generally observed. In other studies with HEM, the effective sizes of the pores involved in passive permeation and of the pores induced during low to moderate voltage iontophoresis have been deduced from the hindered transport theory and found to be in the range of ~6 to 25 Å.[3,4] More recently, a method based on square-wave alternating current (ac) iontophoresis was developed to study the induction of pores (electroporation) in HEM during iontophoresis at low to moderate voltages without interference from electroosmosis.[5] With this method, direct evidence of new pore induction as an iontophoretic flux enhancing mechanism was presented, and the effective pore sizes of the induced pores were assessed.

* To whom corespondent should be addressed. E-mail: kevin.li@m.cc.utah.edu.

As part of an effort to establish a more comprehensive understanding of the mechanisms of iontophoresis in HEM and to maximize the predictive value of the modified Nernst–Planck model, some independent quantitative assessment of electroosmosis in HEM is necessary. Burnette and Ongpipattanakul[6] previously examined the permselectivity of human cadaver skin at current densities of ~0.08–0.2 mA/cm^2 and showed that skin has an apparent net negative charge at neutral pH. Later studies by Pikal and by Pikal and Shah[7–9] on iontophoretic transport across hairless mouse skin at current densities $\gtrsim$0.3 mA/cm^2 have suggested that negatively charged pores dominate at neutral pH, but the presence of positively charged and neutral pores was also hypothesized. In these hairless mouse skin studies, pore size, pore charge, and their distributions were estimated with a theoretical model using experimental iontophoretic fluxes and electrical resistance measurements made as a function of pH, NaCl concentration, and current density. In an HEM study conducted in our laboratory,[10] the direction of the net electroosmotic convective solvent flow at neutral pH was anode-to-cathode; this direction is consistent with the HEM pores being net negatively charged. However, we have not previously examined the question of the importance of possible positively charged and/or neutral pores in HEM electroosmosis.

The aim of the present study was to examine the extent to which HEM electroosmosis data obtained at neutral pH could be described/predicted by the presence of only negatively charged pores (i.e., that convective solvent flow in the pores would be only in the anode-to-cathode direction). Electroosmotic flux enhancements of urea and mannitol in both anodal and cathodal iontophoresis and iontophoretic water fluxes were determined under different applied voltage conditions (in pH 7.4 and 0.1 M ionic strength phosphate buffered saline) for model analysis. These results were compared with theory predictions assuming a single pore charge (negative), and an assessment was made as to the need to involve positively charged and/or neutral pores in interpreting HEM electroosmosis data. A point of particular interest in this study is the comparison of results obtained with pores newly induced in HEM (induced by applied electric fields) with those from the preexisting pores.

Experimental Section

Materials—[^{14}C]Urea, [^{3}H]mannitol, and [^{3}H]water were obtained from New England Nuclear (Boston, MA) and American Radiolabeled Chemicals (St. Louis, MO). Human epidermal membrane (HEM) was provided by TheraTech, Inc. (Salt Lake City, UT). The epidermal membrane was prepared by heat separation as previously described[10] and immediately frozen for later use. Millipore GVWP filters (0.22 μm pore diameter) were obtained from Millipore Corp. (Bedford, MA). Nuclepore polycarbonate membranes with a nominal pore radius of 7.5 nm and porosity of

Published on Web 09/16/1999

0.001 were purchased from Costar Scientific Corporation (Pleasanton, CA). Phosphate-buffered saline with 0.02% sodium azide (PBS), ionic strength 0.1 M and pH 7.4 (0.077 M NaCl and 0.0074 M phosphate buffer), was prepared from reagent grade chemicals and distilled deionized water.

Theory and Model Analysis—The steady-state iontophoretic flux ($J_{\Delta\psi}$) of a nonionic permeant across a homogeneous porous membrane can be described by the modified Nernst−Planck model:[3]

$$J_{\Delta\psi} = \epsilon\left(-HD\frac{dC}{dx} + W'vC\right) \quad (1)$$

where v is the average velocity of the convective solvent flow (positive v denotes flow from donor to receiver and negative v denotes flow from receiver to donor), ϵ is the combined porosity and tortuosity factor for the membrane; C, x, and D are the concentration, the position in the membrane, and the diffusion coefficient of the permeant, respectively; and H and W' are the hindered transport factors for passive diffusion and for transport due to electroosmosis, respectively. Assuming a single pore size (radius, R_p) and a cylindrical pore geometry in the membrane and when the ratio of solute radius to pore radius (r/R_p) is small (i.e., $r/R_p < 0.4$), the hindrance factor for Brownian diffusion (H) and the hindrance factor for pressure-induced parabolic convective solvent flow (W) can be expressed by:[11]

$$H = (1-\lambda)^2(1 - 2.104\lambda + 2.09\lambda^3 - 0.948\lambda^5) \quad (2)$$

$$W = (1-\lambda)^2(2 - (1-\lambda)^2)(1 - 0.667\lambda^2 - 0.163\lambda^3) \quad (3)$$

where $\lambda = r/R_p$. For convenience, W' is assumed to be equal to W as discussed previously.[3] The diffusion coefficients and Stokes−Einstein radii of the permeants in the present study were taken from literature.[4,12] Integrating eq 1 results in

$$J_{\Delta\psi} = \frac{C_D\epsilon Wv}{1 - \exp[-Wv(\Delta x)/(HD)]} \quad (4)$$

where C_D is the donor concentration and Δx is the effective thickness of the membrane. At the convection limit (electroosmotic transport ≫ passive diffusion), eq 4 reduces to

$$J_{\Delta\psi} = \epsilon WvC_D \quad (5)$$

The total flux enhancement (E_{total}) is defined as the ratio of iontophoretic flux to the passive flux at the same donor concentration:

$$E_{total} = \frac{J_{\Delta\psi}}{J_{passive}} \quad (6)$$

where

$$J_{passive} = \frac{DC_D\epsilon H}{\Delta x} \quad (7)$$

Under an applied potential of ≳1 V, when the electrical resistance of HEM decreases due to pore induction, the total transport enhancement can be expressed by eq 8:

$$E_{total} = E_{\Delta R}E_v \quad (8)$$

where $E_{\Delta R}$ is the enhancement due to pore induction and is defined as the ratio of the porosity-tortuosity factor in iontophoretic transport to the porosity-tortuosity factor in passive transport:

$$E_{\Delta R} = \frac{\epsilon_{ion}}{\epsilon_{pass}} \quad (9)$$

E_v is the transport enhancement due to electroosmosis as described by

$$E_v = \frac{Pe}{1 - \exp\{-Pe\}} \quad (10)$$

where Pe is the Peclet number, which characterizes the contribution of convective transport due to electroosmosis. Pe is expressed as

$$Pe = \frac{Wv\Delta x}{HD} \quad (11)$$

Previous studies[5,13] have demonstrated a proportional relationship between the HEM electrical conductance and HEM permeability under the iontophoresis conditions of a few volts when the sizes of the conducting ions in the solution are comparable to those of the permeants. Thus, the $E_{\Delta R}$ values will be estimated from changes in HEM conductance during iontophoresis in the present study. For the Nuclepore membranes, $E_{\Delta R}$ is equal to unity, and E_{total} equals E_v. Effective pore radii for HEM during iontophoresis and in passive diffusion experiments will be estimated by the flux ratios of the model permeants as described previously,[2−5] with the assumption that the permeant pairs follow the same polar transport pathway in a given run.

In the present study, eq 10 will be used with experimental data obtained from both the anodal and cathodal configurations. The analysis should provide an assessment of the extent to which the model with only negatively charged pores may hold.

Transport Experiments: General Procedure—Transport experiments with HEM and with Nuclepore membranes were conducted using a side-by-side diffusion cell (with a diffusional area of ~0.75 cm^2 and cell volume of 2 or 4 mL) and a four-electrode potentiostat system (JAS Instrument Systems, Inc., Salt Lake City, UT) with Ag-AgCl counter electrodes as described previously.[3] Square-wave ac iontophoresis experiments were carried out with a waveform programmer (JJ 1276, JAS Instrument Systems, Inc., Belmont, NC) with the four-electrode potentiostat setup just described. The electrical resistance of the membranes was calculated with Ohm's law and the current was measured by the potentiostat system in direct current (dc) iontophoresis experiments or with an oscilloscope (Model 2211, Tektronix Inc., Beaverton, OR) in the ac experiments. Transport runs were conducted at 37 °C, which was maintained with a circulation water bath. Before each run, the receiver and donor chambers were filled with PBS and PBS premixed with appropriate amounts (tracer levels) of radiolabeled permeants, respectively. Urea/mannitol and urea/water were the permeant pairs employed. At predetermined time intervals, a 1-mL sample was withdrawn from the receiver chamber and replaced with fresh PBS. At the same time, a 10 μL sample was taken from the donor. The samples were then mixed with 10 mL of scintillation cocktail (Ultima Gold, Packard, Meriden, CT) and assayed in a liquid scintillation counter (1900 TR Liquid Scintillation Analyzer, Packard, Meriden, CT). The permeability coefficients for iontophoretic transport ($P_{\Delta\psi}$) and for passive transport ($P_{passive}$) were calculated by

$$P_{\Delta\psi} \text{ or } P_{passive} = \frac{1}{AC_D}\frac{dQ}{dt} \quad (12)$$

where A is the membrane surface area, t is time, Q is the cumulative amount of permeant transported into the receiver chamber, and

$$P_{\Delta\psi} = J_{\Delta\psi}/C_D \quad (13)$$

$$P_{passive} = J_{passive}/C_D \quad (14)$$

Experiments with Nuclepore Membranes—Nuclepore membranes were presoaked and sonicated in PBS to remove any entrapped air in the membranes. Then, 50 of the membranes were assembled into a single composite membrane in the diffusion cell. The Nuclepore membrane studies were divided into two stages: passive permeation experiments and iontophoresis experiments. Anodal and cathodal iontophoresis experiments were conducted at 0.1, 0.2, 0.4, and/or 0.75 V dc. Passive permeation runs were carried out before and after each iontophoresis run. The same sets of Nuclepore membranes (from the same lot) were used without disassembling to avoid variabilities arising from membrane-to-membrane variations.

Experiments with HEM—HEM was equilibrated in PBS for 12 to 24 h at 37 °C before starting a transport experiment. The

initial electrical resistances were 41 ± 26 kΩ cm^2, average ± SD, $n = 50$. HEM studies were divided into two parts: Studies I and II.

Study I was a baseline study with low applied voltage iontophoresis (0.25 and/or 0.5 V dc) where alterations in the barrier properties of HEM were minimal (generally within 15% of the original HEM electrical resistance). Experiments in Study I were divided into five stages. With each HEM sample, passive permeability coefficients were determined in Stages I, III, and V. Stage II was an iontophoresis run at an applied potential of 0.25 or 0.5 V dc. In Stage IV, the iontophoresis run was carried out with the same applied voltage as in Stage II but with the opposite electrode polarity. Anodal iontophoresis was conducted first (Stage II) with about half of the HEM samples and cathodal iontophoresis was first with the other half.

Study II involved higher applied voltage conditions where significant pore induction occurred in HEM. The initial experimental design in this study was a 4.0 V dc prepulse for 1 min followed by 1.0, 2.0, or 3.0 V dc exposure during which transport experiments were conducted. The 1-min 4.0 V dc prepulse preceding the 1.0, 2.0, or 3.0 V dc iontophoresis run was an attempt (with only variable success) to enhance the extent of pore induction and to minimize differences in the pore conditions between the anodal and cathodal runs. With this experimental protocol, cathodal iontophoresis generally induced a greater extent of pore induction than anodal iontophoresis at the same applied voltage and duration (>3 times in some cases; data not shown). Also, the $E_{\Delta R}$ values in some experiments were <10, suggesting a >10% contribution from preexisting pores to transport in these experiments. Thus, this initial protocol was problematic as we desired simultaneously (a) to compare the anodal and cathodal electroosmotic fluxes under conditions of comparable electroporation and (b) not to have significant flux contributions from preexisting pores compromising data analysis. A new protocol was introduced at this point that was designed to overcome or minimize these problems. This protocol involved superimposing 12.5 Hz square-wave ac onto cathodal or anodal dc iontophoresis with the aim to maintain comparable HEM electrical conductance (pore induction) during the anodal and cathodal electroosmosis runs and to achieve a high extent of pore induction ($E_{\Delta R} > 10$). In this arrangement, 0.5, 1.0 or 2.0 V dc was employed as the driving force for electroosmosis, and the 12.5 Hz square-wave ac with adjustable voltage between 0 and 3 V was used to manually control the extent of pore induction ($E_{\Delta R}$). The outcome of this arrangement was that there was always a >10-fold increase in HEM electrical conductance during iontophoresis (relative to the initial conductance) and a <30% variation in conductance during the combined anodal and cathodal iontophoresis runs. The particular ac frequency of 12.5 Hz was chosen only because of our previous experience with it in the dc/ac superposition iontophoresis.[5]

The experiments of Study II with this new protocol were divided into four stages. Similar to Study I, Stage I was a passive permeation run before the application of the electric field. Stage II was the iontophoresis run superimposing 12.5 Hz square-wave ac (0−3 V) with 0.5, 1.0, or 2.0 V dc for electroosmosis. Stage II was followed by rinsing the receiver chamber two to three times with fresh PBS. In Stage III, the same protocol of superimposing ac and dc was carried out as in Stage II but with opposite electrode polarity. HEM electrical resistance in Stages II and III was regulated by adjusting the ac voltage to obtain a >10-fold increase in electrical conductance (relative to the initial resistance in Stage I) and a <30% variation in resistance throughout the anodal and cathodal iontophoresis runs (Stages II and III). Stage IV was a passive diffusion run after iontophoresis.

Results and Discussion

Analysis of the Urea/Mannitol Dual-Permeant Data—Figure 1 presents the experimental results with the Nuclepore membrane, where the enhancement factor (E_v) for cathodal iontophoresis is plotted against that for anodal iontophoresis. The predictions from the electroosmosis theory (eq 10) with the assumption of a single pore charge are given by the curved line. It is evident that transport data obtained in the experiments with the Nuclepore membrane are consistent with the ideal, single pore charge

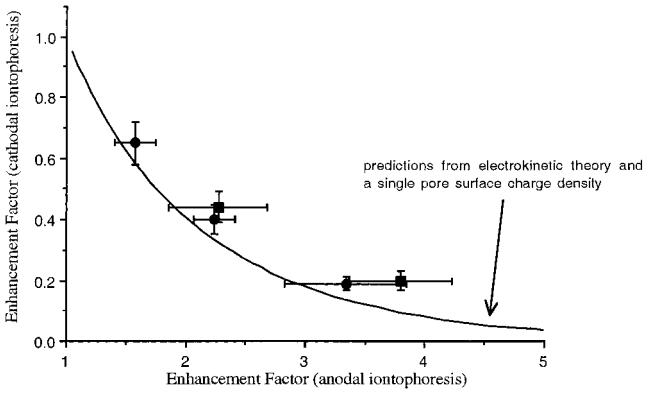

Figure 1—Relationship between cathodal and anodal electroosmotic flux enhancement for Nuclepore membranes at 0.1, 0.2, and 0.4 V dc. The curve represents predictions from electrokinetic theory with the assumption of a single pore surface charge density: E_v for anodal transport is plotted against E_v for cathodal transport (eq 10). Key: (circles) urea; (squares) mannitol. Each data point represents the mean and standard deviation of $n \geq 3$.

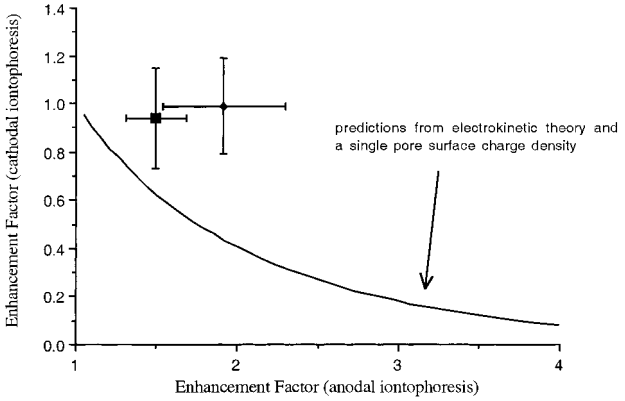

Figure 2—Relationship between cathodal and anodal electroosmotic flux enhancement for urea with HEM at 0.25 and 0.5 V dc. The curve represents predictions from electrokinetic theory with the assumption of a single pore surface charge density. Key: (square) 0.25 V; (diamond) 0.5 V. Each data point represents the mean and 90% confidence interval ($n = 6$).

theory. This result validates the theory and demonstrates that the Nuclepore membrane (a synthetic hydrophilic, poly(vinylpyrrolidone)-coated, polycarbonate membrane) can be modeled accordingly.

Figure 2 presents the low voltage (0.25 and 0.5 V dc) results with HEM (Study I) for urea. The changes in HEM electrical resistance in these low voltage experiments were generally <15% relative to the initial resistance before the iontophoresis runs; thus, these results may be interpreted as being essentially for the preexisting pores of HEM. Significant deviations can be noted between the predictions from electrokinetic theory with a single pore charge type assumption (the curve) and the experimental data with HEM (diamonds and squares). These deviations between the actual transport behavior of HEM and the theory predictions (in the positive direction from the theory) demonstrate that the preexisting pores of HEM, although predominantly negatively charged, may include some positively charged and/or some neutral pores.

Figure 3 summarizes the results of Study II where significant pore induction was involved and when the ac/dc superimposition protocols (0.5, 1.0, and 2.0 V dc plus ac) were employed to control the extent of pore induction ($E_{\Delta R}$) during electroosmosis transport experiments. In Figure 3, the enhancement factors due to electroosmosis (E_v) for urea were calculated from eq 8. An important outcome here is that the experimental results are consistent with theoretical predictions based on a single pore

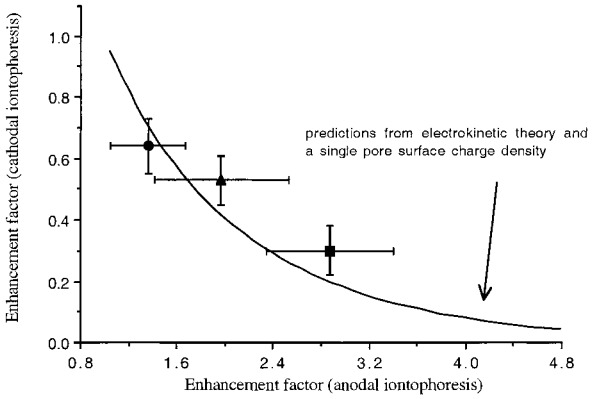

Figure 3—Relationship between transport enhancement due to cathodal and anodal electroosmosis for urea with HEM in 12.5 Hz square-wave ac and dc superposition iontophoresis experiments (Study II). The curve represents predictions from electrokinetic theory with the assumption of a single pore surface charge density. Key: (circle) 0.5 V dc plus 1–3 V ac; (triangle) 1.0 V dc plus 0–3 V ac; (square) 2.0 V dc plus 0–3 V ac. Each data point represents the mean and 90% confidence interval ($n = 7$).

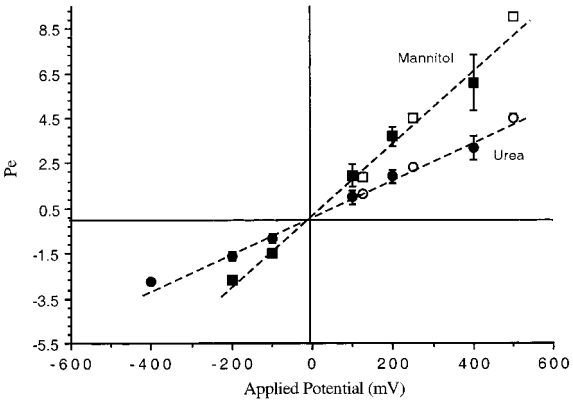

Figure 4—Relationship between the apparent *Pe* and the applied voltage for Nuclepore membranes. Key for closed (present study) and open (data from Peck et al.[2]): (circles) urea; (squares) mannitol. Each data point represents the mean and standard deviation of $n \geq 3$.

(charge) model, suggesting that newly induced pores are essentially all net negatively charged. Although preexisting positive and/or neutral pores may have still been present, the high $E_{\Delta R}$ values in these higher voltage experiments likely reduced their importance during 0.5, 1.0, and 2.0 V electroosmosis to a very small or negligible level.

Figures 4 and 5 present the relationships between the apparent *Pe* and the applied voltage obtained with the Nuclepore membrane and with HEM, respectively. The *Pe* values in Figure 4 were calculated from the urea and mannitol flux data with eq 10. Figure 4 includes data from a previous Nuclepore membrane study.[2] The linear relationship of *Pe* and the applied voltage and the close to zero ordinate intercept in Figure 4 for the Nuclepore membrane system are consistent with what would be expected from electrokinetic theory assuming an effective single pore charge type and density. The greater slope for the mannitol results than for the urea results reflects the smaller diffusion coefficient of mannitol (see eq 11). The *Pe* data in Figure 5 for HEM were determined from the urea flux and HEM electrical resistance data in Studies I and II by eqs 8 and 10. There are likely two separate relationships between *Pe* and the applied voltage in Figure 5. One relationship is for the situation at low voltages (0.25 and 0.5 V dc) where there are predominantly preexisting pores. The second relationship is for the situation at the higher voltages (0.5, 1.0, and 2.0 V dc for electroosmosis plus 0−3 V ac to maintain a high extent of pore induction) where

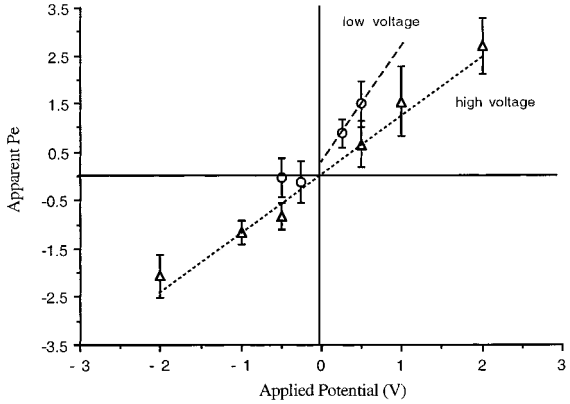

Figure 5—Relationship between the apparent *Pe* for urea as the permeant and the applied voltage with HEM. Key: (circles) low voltage, ≤0.5 V dc; (triangles) high voltages, ≥0.5 V dc plus 0–3 V ac. Each data point represents the mean and 90% confidence interval ($n \geq 6$).

the newly induced pores dominate electroosmosis. The steeper slope under the low voltage anodal conditions (0.25−0.5 V dc) relative to that under the higher voltage anodal and cathodal conditions (−2.0, −1.0, −0.5, 0.5, 1.0, and 2.0 V dc plus ac) is consistent with the interpretation that the effective pore charge density of the negatively charged induced pores is less than that of the preexisting pores. This interpretation is in agreement with the previously observed smaller than expected (based on low voltage studies) electroosmotic enhancement with 2.0 V dc iontophoresis.[3] The approximately linear relationship in Figure 5 for the low voltage anodal electroosmosis without pore induction (0.25−0.5 V dc) is consistent with what will be expected from the electrokinetic theory and the preexisting pores being dominated by negatively charged pores. The deviation from this linear relationship of the data for cathodal iontophoresis (especially at −0.5 V) is a departure, however, from the idea of preexisting pores being only negatively charged (as was also concluded from the data in Figure 2). This low voltage behavior contrasts with the high voltage results (of newly induced pore) that are essentially linear in Figure 5 in both the anodal and cathodal regions and consistent with the induced pores being essentially only negatively charged.

An alternate explanation for the lower slope of the high voltage data in Figure 5 might be based on pore sizes of the newly induced pores being significantly different from those of the preexisting pores. However, electroosmotic flux ratios of urea and mannitol determined as part of the present study at ≥1.0 V have yielded (from the hindered transport theory) pore sizes comparable to those found in similar experiments conducted at low voltages (∼8 Å). Therefore, it appears unlikely that pore size differences can contribute importantly to the slope differences in Figure 5.

Although the results from the higher voltage cathodal/anodal HEM electroosmosis studies are consistent with a model based on only negatively charged pores, one obviously needs to be cautious in making any detailed mechanistic conclusions. Considering the complicated morphology of the stratum corneum, it is only safe to state that HEM electroosmosis behavior under these circumstances is effectively equivalent to that of a membrane with only negatively charged pores. Nonetheless, this information is quite useful in assessing and in correcting for electroosmosis effects in various iontophoretic situations involving HEM.

Analysis of the Water/Urea Dual-Permeant Data—The passive permeability coefficient ratio, tritiated water-to-urea, for the Nuclepore membrane (average ± SD: ratio

$= 2.1 \pm 0.2$, $n = 5$) is consistent with what would be expected (ratio = 1.8) from the urea and water molecular diffusion coefficients with a small correction arising from hindered diffusion effects and with there being no significant difference between the diffusion coefficients (or the effective diffusion coefficients) of ordinary water and tracer tritiated water under the present experimental conditions.[12,14,15] During 0.75 V anodal dc iontophoresis with the Nuclepore membranes, water and urea fluxes were essentially the same at the same donor concentration (permeability coefficients of urea and water $= 1.1 \pm 0.4 \times 10^{-5}$ and $1.2 \pm 0.3 \times 10^{-5}$ cm/s, respectively, average ± SD, $n = 3$), demonstrating that the water velocity was essentially the same as the average velocity for urea and that the electroosmotic transport was at the convection limit.[2]

Tritiated water has been used to study the barrier properties of skin[16–18] and the electroosmosis behavior of skin.[19] The study of water transport across HEM during iontophoresis was expected to provide some independent insights into the mechanism of electroosmosis because liquid water is the carrier in electroosmotic transport. In the present study, the water passive permeability coefficients for HEM (average ± SD: $1.2 \pm 0.3 \times 10^{-6}$ cm/s, $n = 9$; HEM electrical resistance $= 30 \pm 19$ kΩ cm^2, ranging from 12 to 74 kΩ cm^2) are consistent with the permeability coefficients in a previous study.[20] The relatively high passive permeability coefficients of water for HEM compared with that of urea may be due to the accessibility of water to both the pore and the lipoidal pathways of HEM. This hypothesis is supported by present and previous studies: (a) the transport of water across HEM in the present study does not demonstrate an inverse proportionality between HEM permeability (P) and HEM electrical resistance (R) (slope of log P versus log R plot $= -0.26$ with $r^2 = 0.293$) as observed for urea in the present study and literature;[3,5,21] (b) the diffusional activation energy for water transport in HEM was reported to be ~17 kcal/mol,[22] which contrasts with the value of 7 kcal/mol for the transport of polar permeants across HEM[21] and the value (~4 kcal/mol) for unhindered diffusion in an aqueous medium; and (c) transport of water across lipid bilayers has been observed to be much higher than that for polar nonelectrolytes and ions.[23]

No significant difference between the transport rates of water across HEM during 0.25 V dc iontophoresis and during passive diffusion was found [ratios of iontophoretic flux to passive flux during anodal and cathodal iontophoresis (average ± SD) were 1.08 ± 0.05 ($n = 3$) and 1.03 ± 0.07 ($n = 3$), respectively]. This result is direct evidence of the lipoidal pathway being the dominant transport pathway for water in HEM in the absence of pore induction (i.e., low voltage iontophoresis). Under higher voltage conditions (e.g., a prepulse of 4.0 V dc for 1 min followed by 2.0 V dc iontophoresis) when significant pore induction occurred ($E_{\Delta R} > 10$), the pore pathway became dominant for water transport across HEM.

The permeability coefficient of the pore pathway for water in passive diffusion was estimated by the urea passive transport data of each individual HEM sample and eq 7:

$$P^{\text{pore}}_{\text{water,p}} = \frac{H_{\text{water}} D_{\text{water}}}{H_{\text{urea}} D_{\text{urea}}} P_{\text{urea,p}} \qquad (15)$$

The permeability coefficient of the pore pathway in HEM for water during 2.0 V dc iontophoresis was estimated by a parallel pore and lipoidal pathway model:

$$P^{\text{pore}}_{\text{water,i}} = P^{\text{total}}_{\text{water,i}} - (P^{\text{total}}_{\text{water,p}} - P^{\text{pore}}_{\text{water,p}}) \qquad (16)$$

where the subscripts "p" and "i" represent the passive and the iontophoresis experiments, respectively; the superscripts "*total*" and "*pore*" represent the total permeability coefficient and the permeability coefficient of the pore pathway, respectively; and $P_{\text{urea,p}}$ is the experimental permeability coefficient for urea in passive transport. Equations 15 and 16 assume (a) that transport via the lipoidal pathway is the same in passive transport and during iontophoresis, (b) an effective pore radius of 12 Å (the average R_p value deduced in the present passive transport experiments in the *Analysis of the Urea/Mannitol Dual-Permeant Data* section) for the calculation of H_{water} and H_{urea}, and (c) independent lipoidal and pore pathways in HEM. It should be noted that, with eq 16, water transport via the lipoidal pathway was generally small compared with the total iontophoretic flux of water with the application of 2.0 V dc.

With eq 16 and correcting for pore induction with eq 8, the enhancement due to electroosmosis (E_v) for water was estimated to be 2.0 ± 0.7 (average ± SD, $n = 5$) during 2.0 V anodal electroosmosis and 0.4 ± 0.2 (average ± SD, $n = 5$) during cathodal electroosmosis. This result corresponds to water Pe of ~1.6 and −1.5 and apparent water volumetric flow rates (ϵWvA) of $6 \pm 3 \times 10^{-6}$ and $-5 \pm 2 \times 10^{-6}$ cm^3/s across 1 kΩ cm^2 HEM at 2.0 V dc (average ± SD, $n = 5$; calculated using eq 4 and the experimental water P values normalized to 1 kΩ cm^2 HEM) during anodal and cathodal iontophoresis, respectively. These results are consistent with significant convective solvent flow and a net negatively charged HEM under the 2.0 V dc conditions. With the assumption that water and urea follow the same pore pathway in HEM and a R_p value of 8 Å (the average R_p calculated from the present anodal electroosmosis experiments in the *Analysis of the Urea/Mannitol Dual-Permeant Data* section), the water velocity and the velocity of urea convective transport across the pore pathway were compared using eq 4. The ratio of water velocity to that for urea was estimated to be ~1.2. This close-to-unity ratio is direct evidence of water being the carrier for urea during electroosmosis. The slightly higher water velocity than that for urea estimated here (the factor of 1.2) is consistent with differential hindered transport effects if pore radii of ~6 Å is assumed. This 6 Å value is of the same order of magnitude as that deduced from urea/mannitol flux data (i.e., the average R_p of 8 Å). Results from this analysis independently show that water is the carrier in electroosmotic transport during iontophoresis.

Conclusion

By conducting both anodal and cathodal electroosmosis experiments with polar nonionic permeants, the predictivity of a model of pores with a single charge was examined for the preexisting pores and the newly induced pores (due to applied electric fields) in HEM. The electrokinetic model was first checked with a synthetic polycarbonate membrane system, and the experimental results with this model membrane system were consistent with what would be expected of pores possessing only negative charges. Results from experiments with HEM at low voltages (little or no electroporation) showed that although negative pore charges dominate, there were effectively some positive or positive and neutral pores at neutral pH. At higher voltages (>1.0 V), where new pores dominated, there seemed to be contributions only from negatively charged pores at neutral pH. Results from the water transport experiments provide further support that water is the carrier in electroosmotic transport during iontophoresis.

Abstract □ This paper presents systematic analyses by the finite element method of release kinetics of a dispersed solute from various matrixes (i.e., slab, sphere, cylinder, and convex tablet), with or without boundary-layer resistance, into a finite or an infinite external volume. In the case of sink conditions, the numerical results agree well with the existing analytical solutions. For the problems of solute release into a finite external volume, where the analytical solutions are not available, this work has provided numerical solutions of the differential equations describing the release kinetics, moving boundaries, and concentration profiles. This work has also revealed the dependence of release kinetics on the initial solute loading, the external volume, and the boundary-layer thickness. The method presented here can describe the entire process of diffusional release before and after the dispersed solute has been dissolved without the pseudo steady-state assumption and it is applicable to both small and large ratio of initial solute loading to the solute solubility in the matrix.

Introduction

The kinetics of diffusional release of a dispersed solute, i.e., the initial solute loading (A) is higher than the solute solubility in the matrix (C_s), has been a subject of practical importance in controlled drug delivery. Drug delivery systems such as pharmaceutical solid dosage forms often contain dispersed biologically active agents, which makes it difficult to solve the differential equations and thus predict the release kinetics of the agents because of a moving boundary of the dispersed solute. The task becomes more complicated when the solute is released from a multidimensional dosage form, such as a convex tablet, with boundary-layer resistance into a finite external medium. So far, no analytical solution has been made available for investigation of such a complex system.

In the past decades, a number of mathematical models have been developed to describe the release kinetics of dispersed solutes[1−17] mainly for one-dimensional release except for ref 6. The majority of the models postulate infinite well-agitated sink, that is, no boundary layer resistance and no solute accumulation in the release medium due to the mathematical complication. A few groups have considered boundary-layer resistance under the sink condition[2,3,11] and in a finite external medium.[12] It must be noted that the analytical or semianalytical solutions of the above models are only applicable to the release process up to the time, t^*, for all the dispersed solute to dissolve,[3,4,17] except for those with a pseudo steady-state assumption.[1,2,6,10,12] This is because the concentration distribution in the matrix at t^* is nonuniform and unknown ahead of time. For a matrix with a small A/C_s ratio, a considerable amount of dissolved solute remains in the matrix at time t^*, whose contribution to the release kinetics is not described by the models without a pseudo steady-state assumption.[3,4,17] To overcome the difficulty, a linear distribution is assumed in the pseudo steady-state approach.[1,2,6,10,12] This approach has been applied extensively for $A \gg C_s$ and sink conditions or near-sink conditions with success especially for planar geometry.[3,4,16] Nevertheless, when the A/C_s ratio is small, for example, when $A/C_s = 2$ or approaches 1, the real concentration distribution deviates from the linear one noticeably. As a consequence, prediction by the pseudo steady-state approach becomes less accurate.[3,4]

In practice, drug release from a dosage form into a finite volume of surrounding medium is often found. In this case, the release rate may be reduced as a consequence of drug accumulation in the medium, deviating from the prediction by the models for sink conditions. Such an effect can be expected when the drug removal from the medium is slow or the drug solubility in the medium is minimal, typified by drug release in the lower gastrointestinal tract where liquid content and absorption rate are relatively low, or from an implant or an insert into a confined cavity such as solid tumors and root canals. Therefore, prediction of release kinetics for these dosage forms in a finite external volume is of more practical importance than that for sink conditions, although both may be governed by the same release mechanism.

The analytical solutions for solute release into a finite volume can be found for one-dimensional release from slab, sphere, and cylinder with a loading, $A \leq C_s$. Nevertheless, there is no analytical solution available for release kinetics of sphere, cylinder, and convex tablet with a boundary layer and $A > C_s$ in a finite volume, except that for a sphere with assumptions of pseudo steady-state and boundary-layer thickness much smaller than the radius of the sphere.[12] This is perhaps because of the above-mentioned difficulty involving the moving boundary of the solute, time-dependent boundary condition, and nonuniform solute concentration in the matrix at t^*. Therefore, numerical methods must be applied in order to solve the differential equations for such systems.

The objective of this work is to study the kinetics of the entire process of diffusional release of an initially dispersed solute from polymeric matrixes into a finite external volume with or without the boundary-layer effect. The finite element method, a computer-aided numerical approach, is employed to solve the differential equations. The release profiles for matrixes of various shapes (i.e., slab, sphere, cylinder, and convex tablet) are presented for different A/C_s ratios and various external volumes ranging from infinite to a small liquid/matrix volume ratio. The evolution of solute concentration in these matrixes and the

effect of boundary-layer resistance are discussed based on the numerical results.

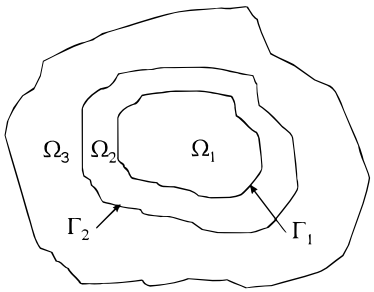
Theoretical Background

It is assumed that dissolution of a dispersed solute is rapid compared with the subsequent depletion of the solute by diffusion. The process of diffusional release of a dispersed solute from a matrix can be physically visualized[18] as a process of solute extraction, i.e., the solution of the dispersed solute followed by the diffusion of the dissolved solute. Initially, the dispersed solute is dissolved and diffuses out from the surface layer; after a certain time, the solute concentration in the surface layer is reduced to the saturated level (C_s), and the extraction of the solute in the next layer is initiated. Between the just-extracted layer and the next layer, there exists a sharp concentration gradient, i.e., the moving boundary of the dispersed solute, and the concentration difference between the two layers is $A - C_s$. The boundary will move inward layer by layer continuously until all the dispersed solute is dissolved.

Since the process is diffusion-controlled, the governing equation of the diffusion is held for the whole process no matter whether the solute is dispersed or dissolved. The general expression of the governing equation for a problem of three-dimensional and homogeneous material with boundary layer resistance in a well-mixed finite external medium is given as follows,

$$\frac{\partial C_i}{\partial t} = \nabla\cdot(D_i \nabla C_i) \qquad i = 1, 2 \tag{1}$$

where ∇ is the differential operator, the suffixes 1 and 2 denote the polymeric matrix and the boundary layer, D_i and C_i are the diffusion coefficient (cm^2/s) and solute concentration (g/cm^3) in these two domains, respectively. Definition of these domains and relevant boundaries for an arbitrary geometry is illustrated in the following schematic diagram:



The corresponding initial and boundary conditions are

$$C_1 = A, \text{ in } \Omega_1, t = 0 \tag{2}$$

$$C_2 = C_3 = 0, \text{ in } \Omega_2 \text{ and } \Omega_3, t = 0 \tag{3}$$

$$D_1\frac{\partial C_1}{\partial n} = D_2\frac{\partial C_2}{\partial n}, \text{ on } \Gamma_1, t > 0 \tag{4}$$

$$C_1 = KC_2, \text{ on } \Gamma_1, t > 0 \tag{5}$$

$$(A - C_s)\frac{d\xi}{dt} = D_1|\nabla C_1|, \text{ on } \xi(t), 0 < t < t^* \tag{6}$$

$$C_1 = C_s, \text{ on } \xi(t), 0 < t \le t^* \tag{7}$$

$$V\frac{\partial C_3}{\partial t} = D_2\frac{\partial C_2}{\partial n}S_2, \text{ on } \Gamma_2, t > 0 \tag{8}$$

where A is the initial solute loading (g/cm^3), K is the partition coefficient, $\xi(t)$ is the moving boundary, Ω_1, Ω_2, and Ω_3 are the domains of the matrix, boundary layer, and the finite external medium, respectively. Γ_1 and Γ_2 denote the boundaries of Ω_1 and Ω_2, S_2 is the area of the interface between Ω_2 and Ω_3. V is the volume of the finite external medium, and t^* is the time for all the dispersed solute to dissolve. In eqs 4 and 8,

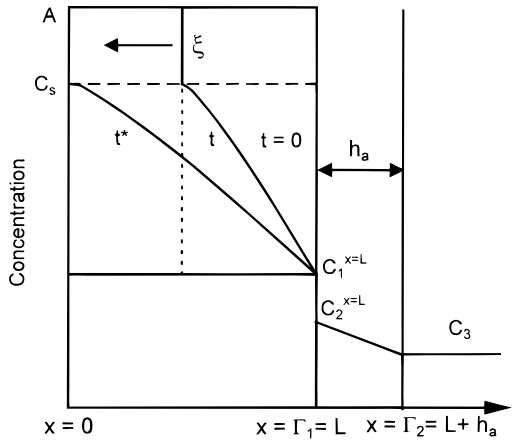


Figure 1—Schematic diagram of moving boundary, boundary layer, and concentration profile for a one-dimensional slab, sphere, and cylinder, where L denotes either the half-thickness of a slab, or radius of a sphere or a cylinder; $x = 0$ stands for the midplane or the center of the matrixes.

$$\frac{\partial C}{\partial n} = n_x\frac{\partial C}{\partial x} + n_y\frac{\partial C}{\partial y} + n_z\frac{\partial C}{\partial z} \tag{9}$$

where n_x, n_y, and n_z are the directional cosines of the outward normal n to the closed boundary Γ_i.

For a sink condition, the boundary condition described by eq 8 is replaced by eq 10,

$$C_3 = 0 \qquad \text{on } \Gamma_2 \qquad t \ge 0 \tag{10}$$

For the matrixes with one-dimensional release such as a sphere, an infinite slab or an infinitely long cylinder, the above equations can be simplified to conventional presentations[2-4] as illustrated in Figure 1, where ξ is the moving boundary of the dispersed solute, x is the distance, L is the half thickness of a slab or the radius of a sphere or a cylinder, h_a is the thickness of the boundary layer, $C_1^{x=L}$ is the concentration in the matrix at x = L, $C_2^{x=L}$ is the concentration in the boundary layer at $x = L$, C_3 is the concentration in the bulk solution. For a system with no boundary-layer resistance, $C_2 = C_3$; a system in a sink with boundary layer, $C_3 = 0$; and a system in a sink without boundary layer, $C_2^{x=L} = C_2 = C_3 = 0$.

As aforementioned, the whole release process is diffusion-controlled. Therefore, the computational procedures of the finite element method developed in the previous work[19-22] for dissolved solute are still applicable to the release of dispersed solute except that eqs 6 and 7 need to be incorporated into the computation. Mathematically these equations represent the instantaneous mass balance at the diffusion moving front. Physically they can be viewed as that, in order for the diffusion front to move a distance δx in a time δt per unit area perpendicular to x, an excess amount of solute, $(A - C_s)\delta x$, must be removed by diffusion. Based on this interpretation, the computational procedures were correspondingly modified to incorporate eqs 6 and 7. The whole matrix domain was divided into many thin layers. The diffusion was initiated from the most outer layer. The solute concentration in the current thin layer was examined at very small time intervals using an iteration checking subroutine. Once the excess amount of

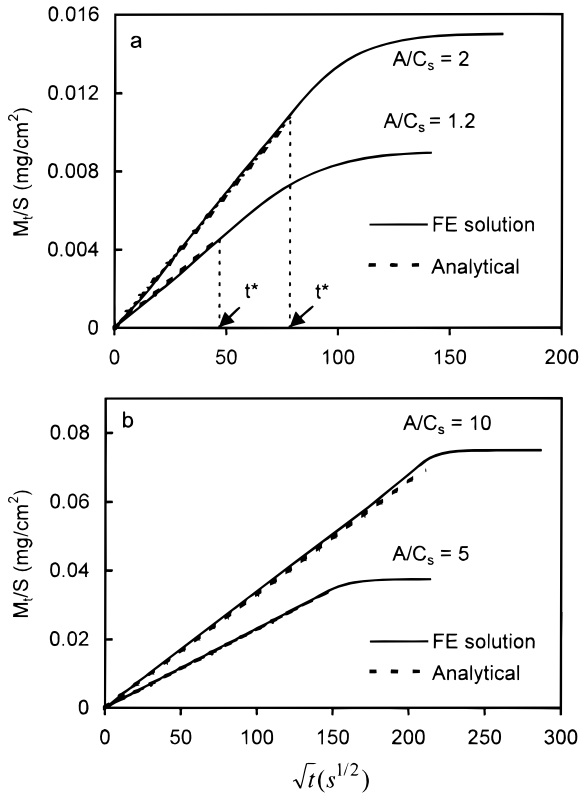

Figure 2—Cumulative amount of a dispersed solute released per unit surface area from a slab into a perfect sink ($L = 0.1$ cm, $D_1 = 1 \times 10^{-6}$ cm^2/s). (a) $A/C_s = 1.2$ and 2; (b) $A/C_s = 5$ and 10.

solute, $(A - C_s)\delta x$, had been depleted, i.e., $C_1 = C_s$ in the current layer, the solute diffusion in the next thin layer was allowed. Otherwise the iteration continued until the saturation level was reached. The amount of solute released (M_t) at time t was obtained by subtracting the amount of solute remained in the matrix from the initial amount of solute. The remaining was calculated by multiplying the solute concentration in each finite element at time t by the volume of the element.

Results and Discussion

To verify the computational procedures and results, release profiles of a dispersed solute from a one-dimensional slab, sphere, and cylinder into a sink were first calculated and compared with the available analytical solutions. Release kinetics for three basic geometries and convex tablet in different external volumes and its dependence on the boundary-layer resistance and initial solute concentration were then studied.

One-Dimensional Release and Verification—*(a) Slab*—Figure 2 depicts the amount of the drug released per unit surface area of a slab as a function of square root of time. Evidently, the results of this work agree well with the analytical solution by Paul and McSpadden[3] at earlier stage, i.e., $t \leq t^*$. At a later stage, i.e., $t > t^*$, the analytical solution is no longer applicable, whereas the finite element solution continuously describes the rest of the release process. When the A/C_s ratio is large, e.g., $A/C_s = 10$ or 5, the analytical solution may be extended to $t > t^*$ with an acceptable error, as only a small portion of the solute remains in the matrix. Nevertheless, the error can be significant when the A/C_s ratio is small. As will be discussed in section d), there is still about 50% of the solute unreleased at t^* for $A/C_s = 1.2$ and 28% for $A/C_s = 2$. This implies that up to 50% of the solute is released by a

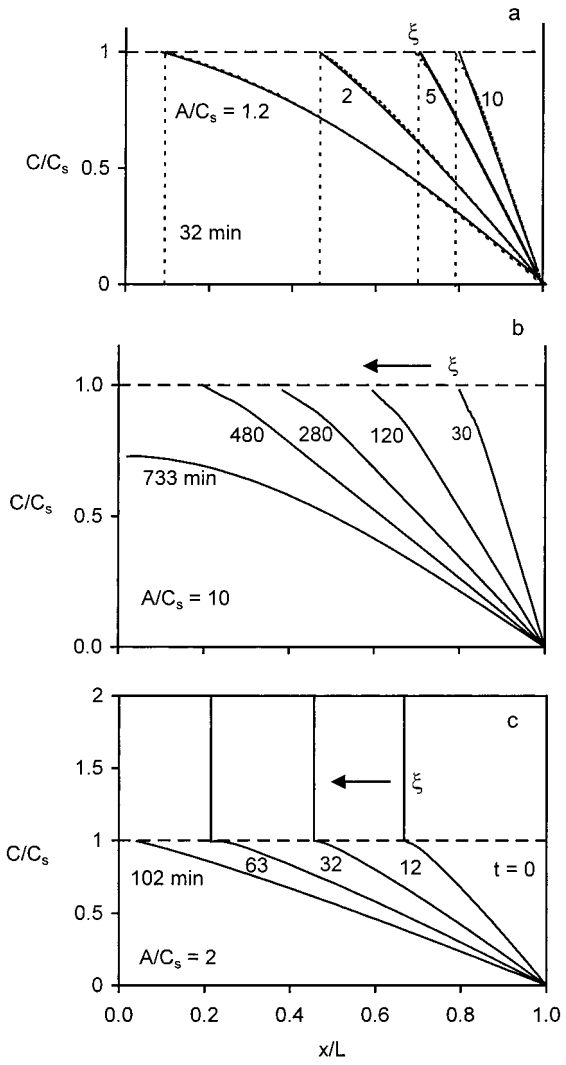

Figure 3—Moving boundary of a solid solute and concentration profile for a sphere with various A/C_s ratios in a perfect sink ($L = 0.1$ cm, $D_1 = 1 \times 10^{-6}$ cm^2/s). (a) Time = 32 min, $A/C_s = 1.2$, 2, 5, and 10, (- - - -) Paul and McSpadeen,[3] (—) FEM; (b and c) $A/C_s = 10$ and 2, respectively, at various time intervals.

different mechanism (i.e., no moving boundary). The release kinetics of this portion of the solute cannot be described by the analytical solution. Therefore, the straight line predicted by the model was linearly extrapolated and linked with the horizontal line of 100% release.[3] The experimental data showed that the release profile is a asymptotic curve approaching to the 100% line,[3] especially for small A/C_s ratios. This experimental observation is predicted by the numerical solutions of this work (Figure 2a).

Figure 3a compares the concentration distribution of a solute in the matrix for different A/C_s ratios at the same time (32 min). A good agreement between this work and the analytical solution[3] is evidenced. Apparently, the smaller the A/C_s ratio, the more advanced the moving boundary of the dispersed solute, due to smaller excess amount of solute to be removed by diffusion. Figures 3b and 3c illustrate the progress of the moving boundary and concentration distribution at different times for $A/C_s = 10$ and 2, respectively. It is noticed that more linear distribution curves are obtained at $A/C_s = 10$ than those at $A/C_s = 2$, supporting Higuchi's pseudo steady-state assumption for $A \gg C_s$.[1]

The amount of solute released into a well-mixed finite medium with the effective volume ratio, $\lambda = V/(V_1K) = 5$,

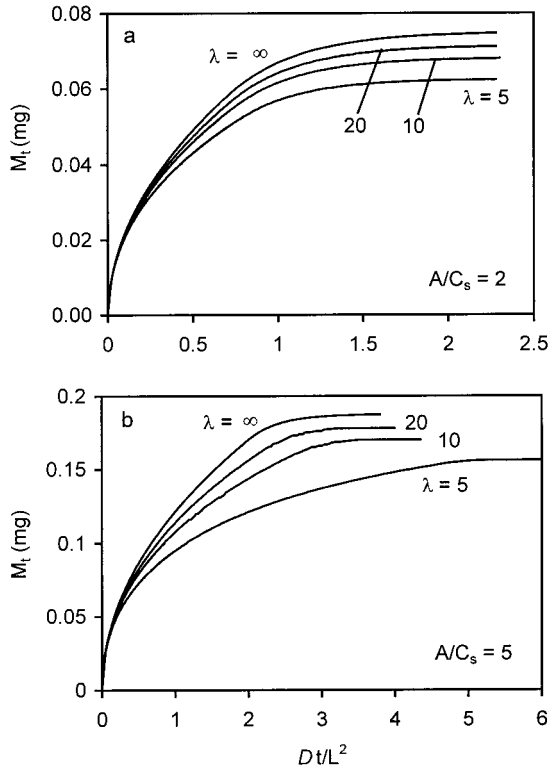

Figure 4—Influence of effective volume ratio on the amount of solute released from a slab into a well-mixed liquid of finite volume ($L = 0.1$ cm, $D_1 = 1 \times 10^{-6}$ cm^2/s, $K = 1$). (a) $A/C_s = 2$ and (b) $A/C_s = 5$. The 100% solute released is indicated by the plateau of the release curve for $\lambda = \infty$.

10, 20, and ∞, is plotted against D_t/L^2 in Figure 4 for (a) $A/C_s = 2$ and (b) $A/C_s = 5$, where $K = 1$, V and V_1 are the volume of the liquid and the matrix, respectively. The influence of the effective volume ratio on the release rate is consistent with previous analytical and experimental results.[19,21] It is shown that the release rate and the final amount of the solute decrease with the decrease in λ value. Given a fixed partition coefficient, this observation can be attributed to quicker concentration build-up and consequently higher diffusional resistance in a smaller volume. Note that at $A/C_s = 5$, the influence of λ becomes more profound as indicated by larger differences among the curves in Figure 4b compared to those in Figure 4a. In addition, more abrupt change in the curves before reaching the plateau is observed for $A/C_s = 5$. This is an indication of inhibition of release by the saturation of the solute in the liquid at higher A/C_s ratios. The analysis can also be carried out in the same way for the effect of K value and for the solute released into a poorly mixed external finite volume.[20]

(b) Sphere—Figure 5 shows the amount of the released solute versus D_t/L^2 for a spherical matrix in a perfect sink by this work compared with the approximate analytical solutions derived by Lee[4] and by Baker and Lonsdale.[5] It is depicted that this work agrees well with Lee's solution at $A/C_s = 2$ and with Baker and Lonsdale at $A/C_s = 5$ and 10. It should be pointed out that the latter, with pseudo steady-state assumption, is restricted to A/C_s ratio > 3 or 4,[16] while the former is suitable for small A/C_s ratios and $t \leq t^*$. In contrast, the numerical method presented in this work, with no restriction, can predict the entire release process for various A/C_s ratios.

As delineated by Figure 6, the progress of the moving boundary is much faster in spheres than that in slabs. Interestingly, due to the spherical geometry, the concentration profiles are considerably nonlinear compared with that in the slab even at a high A/C_s ratio. The distribution curve

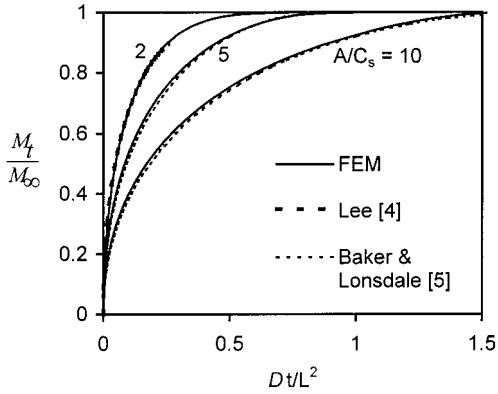

Figure 5—Fractional release of a dispersed solute from a sphere into a perfect sink ($L = 0.1$ cm, $D_1 = 1 \times 10^{-6}$ cm^2/s). Comparison of finite element solution with semianalytical solution from Lee[4] and solution from Baker and Lonsdale with pseudo steady-state assumption.[5]

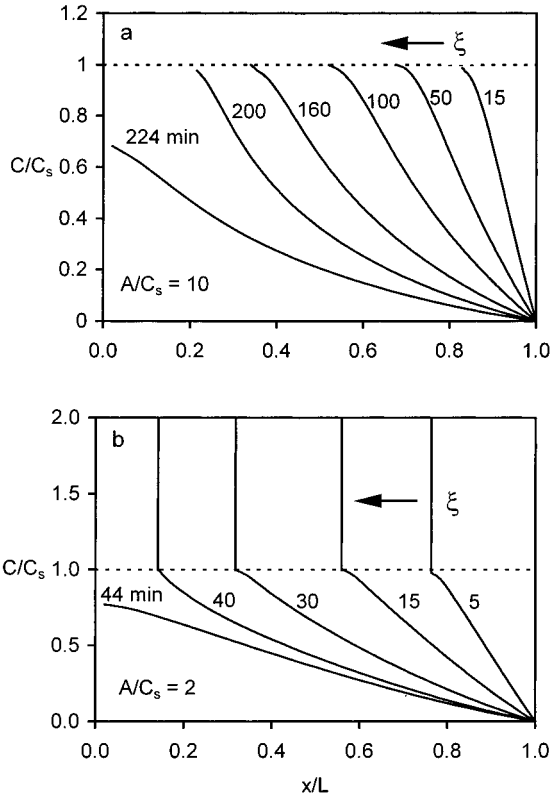

Figure 6—Moving boundary of a solid solute and concentration profile for a sphere in a perfect sink ($L = 0.1$ cm, $D_1 = 1 \times 10^{-6}$ cm^2/s). (a) $A/C_s = 10$ and (b) $A/C_s = 2$.

is gradually changed from convex to concave due to the relative change rate between the surface area of the dispersed solute core and the diffusional distance which is the distance from the moving boundary to the matrix surface.

The amount of the solute released into a well-mixed finite volume with the effective volume ratio, $\lambda = 5$, 10, 20, and the sink condition is presented in Figure 7. The dependence of the release kinetics on the volume ratio and initial loading is similar to that in planar geometry.

(c) Cylinder—The only available analytical solutions for the cylindrical geometry were developed by Crank[23] and Roseman and Higuchi.[2] The former is applicable to $A/C_s \leq 1$ and the latter is an approximate solution and only suitable for $A \gg C_s$ under the sink condition. No analytical solution is available for a cylindrical matrix with a small A/C_s ratio ($A > C_s$) in either a perfect sink or a finite

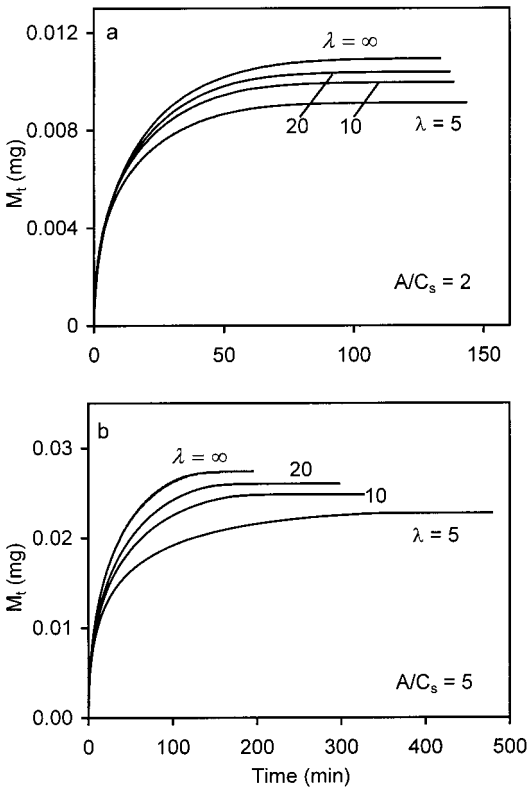

Figure 7—Influence of effective volume ratio on the amount of solute released from a sphere into a well-mixed liquid of finite volume ($L = 0.1$ cm, $D_1 = 1 \times 10^{-6}$ cm^2/s, $K = 1$). (a) $A/C_s = 2$ and (b) $A/C_s = 5$. The 100% solute released is indicated by the plateau of the release curve for $\lambda = \infty$.

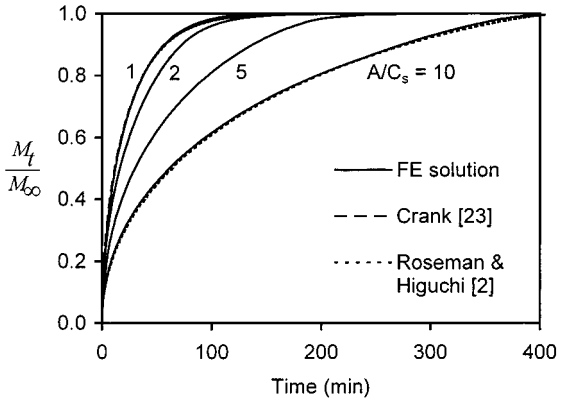

Figure 8—Fractional release of a dispersed solute from a cylinder into a perfect sink ($L = 0.1$ cm, $D_1 = 1 \times 10^{-6}$ cm^2/s, $A/C_s = 1$, 2, 5, and 10).

volume, and there is little knowledge of the concentration distribution in the cylinder. Therefore, Crank's and Roseman and Higuchi's solutions are used here as bounding cases to verify the finite element results. As shown in Figure 8, a very convincing agreement has been obtained between the finite element solutions and the analytical ones in both lower ($A/C_s = 1$) and upper ($A/C_s = 10$) bounding cases. For the A/C_s ratios between these two extremes, where the analytical solutions are not applicable, the solutions of this work have filled the gap. It is expected that the present numerical approach can provide reliable solutions for a broad range of A/C_s ratios from $A/C_s \leq 1$ to $A \gg C_s$.

The progress of the moving front versus time and the concentration distribution in the cylinder for $A/C_s = 2$ and 10 are presented in Figure 9. By comparison of the concentration profiles of slab, sphere, and cylinder, i.e., Figures 3b, 6a, and 9a, some interesting features are

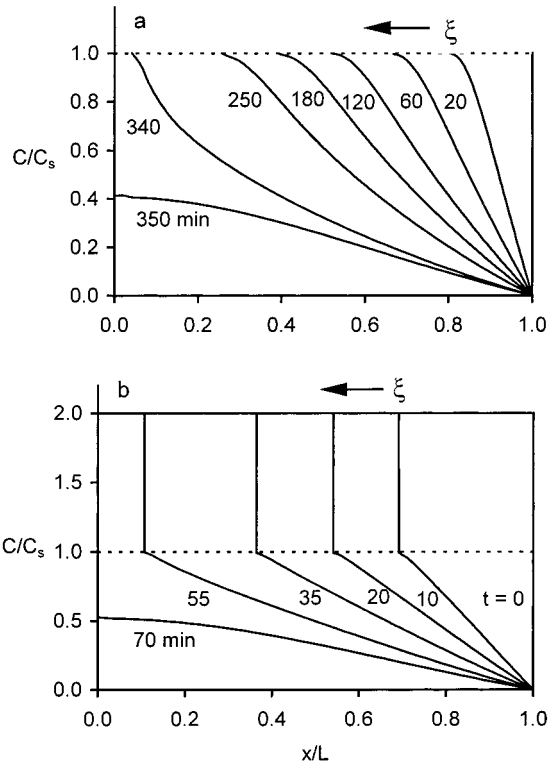

Figure 9—Moving boundary of a solid solute and concentration profile for a cylinder in a perfect sink ($L = 0.1$ cm, $D_1 = 1 \times 10^{-6}$ cm^2/s). (a) $A/C_s = 10$ and (b) $A/C_s = 2$.

noticed. In the slab, the concentration distribution is near linear and always convex. The concentration profile becomes nonlinear and is gradually changed from convex to concave with time in the cylinder. The more nonlinear concentration profile is observed in the sphere with a faster change from convex to concave than in the cylinder. This phenomenon can be ascribed to the inherent difference in the geometry. For diffusional release from matrixes with a dispersed solute, the concentration distribution depends on the relative change rate of the surface area of the solid core and the diffusional distance. The former determines the supply of the solute for diffusion, and the latter determines the time for the solute to leave the matrix. Although surface area and diffusional distance are functions of the moving front in all three geometries, the dependence of the area on the distance is zero for slab, linear for cylinder, and quadratic for sphere. In other words, the relative rate of reduction in the surface area of the undissolved core is the highest in the sphere and the lowest in the slab. Consequently, the change from convex to concave occurs more dramatically in the sphere due to insufficient solute supply for diffusion.

Figure 10 presents the amount of the drug released into different external volumes for cylinders with (a) $A/C_s = 2$ and (b) $A/C_s = 5$. The figures reveal that the influence of volume ratio on the release kinetics for cylinder is similar to that for planar and spherical geometries (Figures 4 and 7). These results are particularly useful for prediction of in vivo release kinetics based on the information of in vitro release.

(d) Correlation of t^* and $(M_r/M_0)^*$ with A/C_s—As aforementioned, the fraction of a solute remaining in the matrix at t^* can be noticeable at small A/C_s. Figure 11 illustrates the remaining fraction at t^*, $(M_r/M_0)^*$, as a function of A/C_s for three geometries, where M_r and M_0 denote the remaining and the initial amount of the solute in the matrix, respectively. $(M_r/M_0)^*$ drops drastically as A/C_s increases from 1 to 2 and then decreases gradually till $A/C_s = 5$,

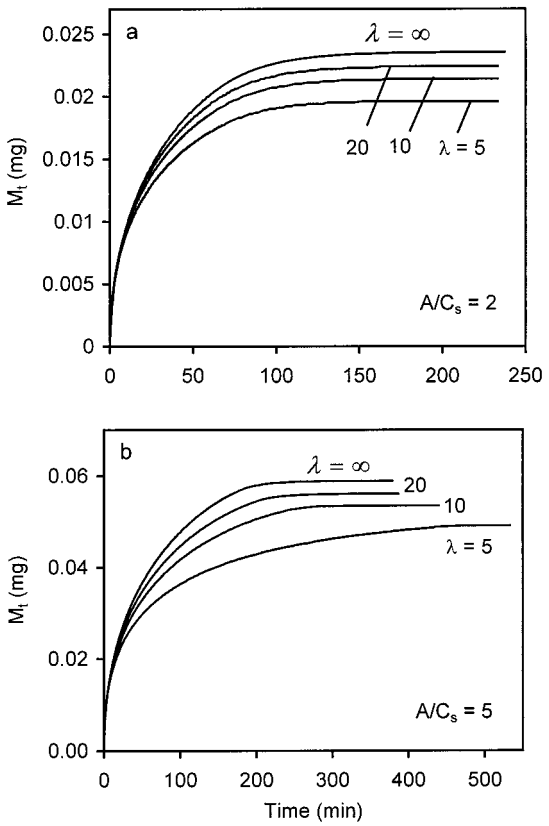

Figure 10—Influence of effective volume ratio on the amount of solute released from a cylinder ($L = 0.1$ cm, $D_1 = 1 \times 10^{-6}$ cm^2/s, $K = 1$). (a) $A/C_s = 2$ and (b) $A/C_s = 5$. The 100% solute released is indicated by the plateau of the release curve for $\lambda = \infty$.

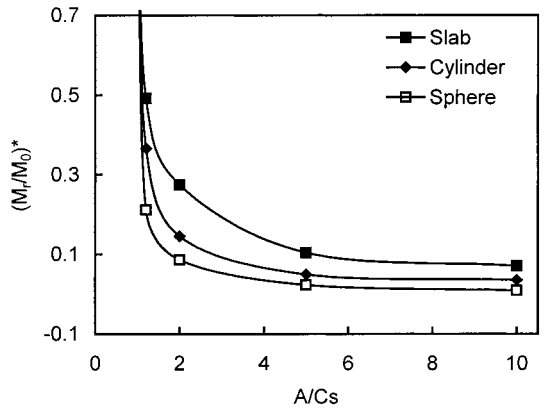

Figure 11—The fraction of a solute remaining in the matrix at t^* for three geometries in a perfect sink ($L = 0.1$ cm, $D_1 = 1 \times 10^{-6}$ cm^2/s).

beyond which the reduction in $(M_r/M_0)^*$ becomes insignificant. The remaining fraction of the solute is the largest for the slab and the smallest for the sphere, suggesting that $(M_r/M_0)^*$ is a function of diffusion rate. One may infer that the remainder could increase as the diffusion coefficient, or the external volume decreases because of the reduced release rate. $(M_r/M_0)^*$ can be correlated with A/C_s by

$$(M_r/M_0)^* = B[A/C_s]^{-\alpha} \qquad (11)$$

where B and α are constants. The values of B and α for three basic geometries were obtained from the nonlinear regression of the data in Figure 11 and are listed in Table 1.

A good linear relationship between the t^* and A/C_s is revealed by Figure 12 for all three geometries. Table 1 summarizes the slope (β) and intercept (γ) of the linear function (eq 12) together with the correlation coefficients of the linear regression.

Table 1—Parameters in Eqs 11 and 12 Evaluated from the Data in Figures 11 and 12 for Three Basic Geometries in a Perfect Sink

geometry	β (slope)	γ (intercept)	r^2 (correlation coefficient)	B	α
slab	75.57	58.69	0.9986	0.7098	1.086
cylinder	36.76	23.72	0.9949	0.5696	1.348
sphere	25.34	14.60	0.9951	0.4678	1.810

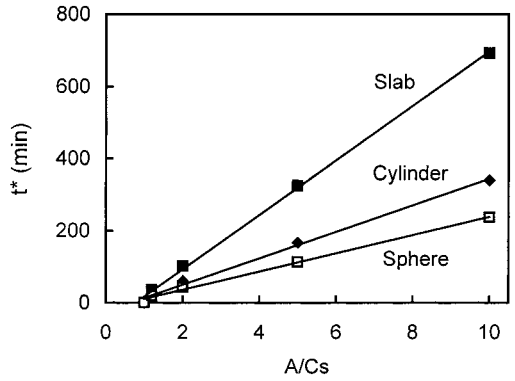

Figure 12—Dependence of t^* on A/C_s for three geometries in a perfect sink ($L = 0.1$ cm, $D_1 = 1 \times 10^{-6}$ cm^2/s).

$$t^* = \beta[A/C_s] - \gamma \qquad (12)$$

Again, the influence of A/C_s on t^* is the greatest for the slab and the least for the sphere, suggesting that, like $(M_r/M_0)^*$, t^* is also dependent on the diffusion rate.

(e) Boundary Layer Effect—It has been demonstrated that the stagnant boundary layer is responsible for the reduced release rate.[2,13] It was intended here to develop a model with consideration of the effect of boundary layer rather than elaborating its mechanism. From the simulation point of view, the boundary layer acts as a thin layer coating. Hence, a thin layer element with corresponding material properties was introduced to the surface of the matrix of interest. The computed release profile was compared with the theoretical solution reported by Roseman and Higuchi[2] for a cylinder in a sink. As depicted in Figure 13a, the finite element solution matches the analytical solution well for a solute with diffusion coefficients in the matrix and in the boundary layer, $D_1 = 1 \times 10^{-6}$ cm^2/s, and $D_2 = 5 \times 10^{-6}$ cm^2/s, respectively, and the thickness of the boundary layer, $h_a = 0.01$ cm. Figure 13b shows that the release rates of a solute from three basic geometries ($L = 0.1$ cm, $A/C_s = 5$) into a finite volume of liquid ($V/V_1 = 10$, $K = 2$) is reduced in the presence of a boundary layer of thickness, $h_a = 0.01$ cm, i.e., $h_a/L = 0.1$. This trend agrees with general observations. The degree of the reduction for the cylinder is slightly greater than the prediction by Roseman & Higuchi's model.[2] For example, at $t = 100$ min, the reduction in the fractional release calculated in this work is ~4% in the presence of a boundary layer, whereas it is ~1% by their model for the same cylinder in a perfect sink. This is likely a result of the difference in the volume of surrounding medium, which is infinite in the analytical solutions and is finite ($V/V_1 = 10$) in the numerical solutions. In a finite volume of liquid, the drug concentration builds up, contributing to a slower release rate and a greater boundary-layer effect.

It is interesting to notice a geometry dependence of the boundary-layer effect. The effect appears the most marked

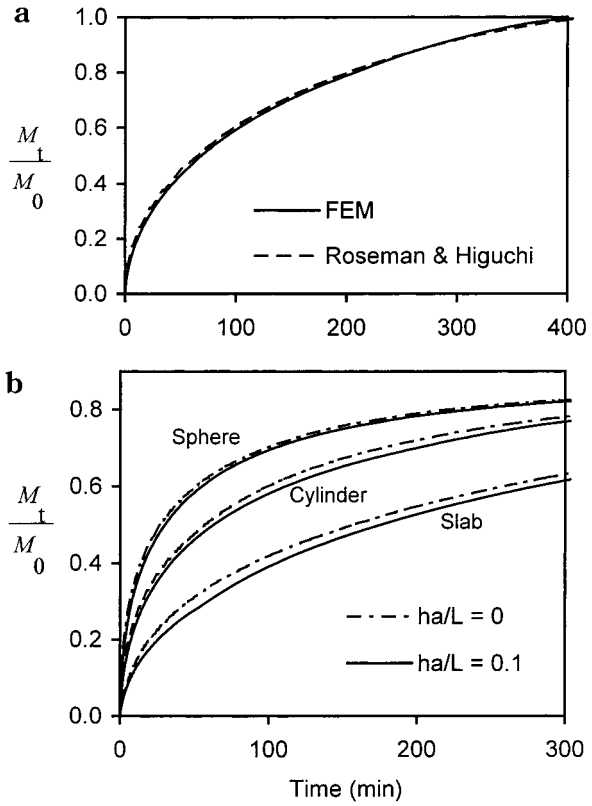

Figure 13—(a) Fractional release of a dispersed solute from a cylinder into a perfect sink with boundary layer resistance ($A/C_s = 10$, $L = 0.1$ cm, $h_a/L = 0.1$, $D_1 = 1 \times 10^{-6}$ cm^2/s, $D_2 = 5 \times 10^{-6}$ cm^2/s, $K = 2$). Comparison of FE solution with the solution from Roseman and Higuchi with pseudo-steady-state assumption.[2] (b) Effect of boundary layer resistance on the release rate of a solute from three geometries in a well-stirred liquid of finite volume ($\lambda = 10$, $A/C_s = 5$, $L = 0.1$ cm, $D_1 = 1 \times 10^{-6}$ cm^2/s, $D_2 = 5 \times 10^{-6}$ cm^2/s, $K = 2$).

for the slab and the least for the sphere. For example, at $t = 100$ min, the reduction in the fractional release in the presence of a boundary layer is 7.2%, 4.1%, and 1.2% for the slab, cylinder, and sphere, respectively. This suggests that the boundary layer effect depends on the relative release rate in the matrix to that in the boundary layer. The solute release from the slab is the slowest and thus is affected most by the boundary layer.

Multidimensional-Release Convex Tablets—The finite element method presented here can model complex matrix dosage forms of virtually any shape. However, the emphasis was placed on matrix tablets here in the hope that the efforts of this work could facilitate the design of this popular controlled-release dosage form for oral administration. For convex tablets with three-dimensional release, dispersed initial drug loading, and the boundary layer resistance, no analytical solution has been reported. This original work provides insight into the release kinetics in relation to design parameters such as A/C_s ratio and environmental conditions. The fractional release, M_t/M_∞, of a drug from convex tablets with different A/C_s ratios into a well-mixed finite volume is depicted in Figure 14, where M_∞ is the amount of drug released at the final stage, $V/V_1 = 10$, $K = 1$, and $D_1 = 1 \times 10^{-6}$ cm^2/s. Clearly, the time for the completion of the release increases with increasing A/C_s ratio, which is consistent with the observation of other geometries.

Figure 15 shows the moving boundary and concentration distribution within a tablet with $A/C_s = 2$ in a well-mixed finite volume ($V/V_1 = 10$, $K = 1$, and $D_1 = 2 \times 10^{-7}$ cm^2/s). The concentration profiles are similar to those in the slab. However, unlike the release into a perfect sink (Figures 3, 6, and 9), the concentration near the surface of the tablet increases with time, reflecting concentration build-up in the bulk solution of a limited volume. Such concentration build-up leads to a smaller driving force for diffusion, i.e., the concentration gradient between the matrix and the medium, and thus lower release rate. This result explains partly why the in vivo release is slower than the in vitro one.

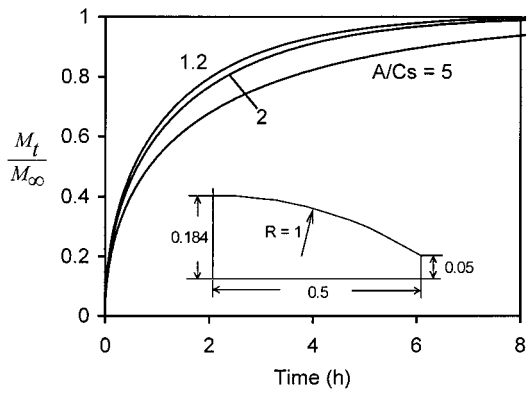

Figure 14—Fractional release of a dispersed drug from a convex tablet with $A/C_s = 1.2$, 2, and 5 into a well-mixed finite volume ($\lambda = 10$, $D_1 = 1 \times 10^{-6}$ cm^2/s, $K = 1$).

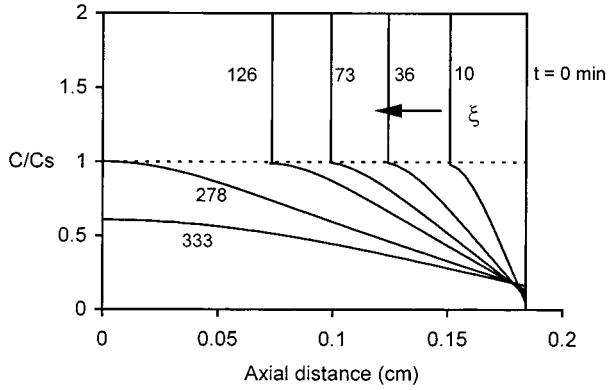

Figure 15—Moving boundary and concentration profile of a dispersed drug for a convex tablet in a well-stirred liquid of finite volume ($\lambda = 10$, $D_1 = 2 \times 10^{-7}$ cm^2/s, $K = 1$).

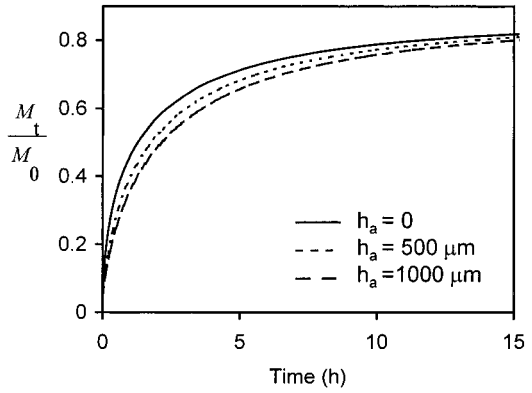

Figure 16—Influence of boundary layer resistance on the fractional release of a dispersed drug from convex tablets into a well-stirred finite volume ($A/C_s = 5$, $\lambda = 10$, $D_1 = 1 \times 10^{-6}$ cm^2/s, $D_2 = 5 \times 10^{-6}$ cm^2/s, $K = 2$).

Another factor that is often associated with the lower in vivo release rate is the diffusion boundary layer. The boundary-layer effect on the fractional release, M_t/M_0, where M_0 is the initial amount of the solute, is illustrated in Figure 16 for a tablet with $A/C_s = 5$ in a well-mixed finite volume ($V/V_1 = 10$, $K = 2$, $D_1 = 1 \times 10^{-6}$ cm^2/s, and $D_2 = 5 \times 10^{-6}$ cm^2/s). As shown by the figure, the release rate

decreases as the boundary-layer thickness increases. It should be indicated that the curves in Figure 16 could only reach ~83% of the initial loading at a much longer time, e.g., 25 h, as a result of saturation of the medium.

In reality, polymeric matrix tablets involve not only the moving boundary of a dispersed drug, but also the moving boundaries of swelling and erosion. The finite element model for matrix tablets with swelling and erosion has been developed by our group for $A/C_s \leq 1$.[22] Further work on incorporation of all three moving boundaries into the model is in progress.

Conclusions

The numerical solutions of differential equations have been obtained by the finite element method for diffusional release of a dispersed solute from slab, sphere, cylinder, and convex tablet into various external volumes. The kinetics of the entire release process have been presented for these matrixes with a broad range of A/C_s ratios and boundary conditions varying from a perfect sink to a finite volume with boundary-layer resistance. The evolution of solute concentration profiles in the matrixes has been revealed. The shape of the concentration profiles depends on the geometry of the matrixes. The nonlinearity of the profiles is found to be sphere > cylinder > slab, in the same order of the release rate. The numerical results for the sink conditions agree well with the existing analytical solutions. The existence of boundary-layer resistance reduces the release rate, and the degree of the reduction increases with increasing thickness.

Solid Dispersion of Poorly Water-Soluble Drugs: Early Promises, Subsequent Problems, and Recent Breakthroughs

ABU T. M. SERAJUDDIN†

Contribution from *Pharmaceutics R & D Department, Bristol-Myers Squibb Pharmaceutical Research Institute, New Brunswick, New Jersey 08903-0191.*

Received October 7, 1998. Accepted for publication July 15, 1999.

Abstract □ Although there was a great interest in solid dispersion systems during the past four decades to increase dissolution rate and bioavailability of poorly water-soluble drugs, their commercial use has been very limited, primarily because of manufacturing difficulties and stability problems. Solid dispersions of drugs were generally produced by melt or solvent evaporation methods. The materials, which were usually semisolid and waxy in nature, were hardened by cooling to very low temperatures. They were then pulverized, sieved, mixed with relatively large amounts of excipients, and encapsulated into hard gelatin capsules or compressed into tablets. These operations were difficult to scale up for the manufacture of dosage forms. The situation has, however, been changing in recent years because of the availability of surface-active and self-emulsifying carriers and the development of technologies to encapsulate solid dispersions directly into hard gelatin capsules as melts. Solid plugs are formed inside the capsules when the melts are cooled to room temperature. Because of surface activity of carriers used, complete dissolution of drug from such solid dispersions can be obtained without the need for pulverization, sieving, mixing with excipients, etc. Equipment is available for large-scale manufacturing of such capsules. Some practical limitations of dosage form development might be the inadequate solubility of drugs in carriers and the instability of drugs and carriers at elevated temperatures necessary to manufacture capsules.

Introduction

The enhancement of oral bioavailability of poorly water-soluble drugs remains one of the most challenging aspects of drug development. Although salt formation, solubilization, and particle size reduction have commonly been used to increase dissolution rate and thereby oral absorption and bioavailability of such drugs,[1] there are practical limitations of these techniques. The salt formation is not feasible for neutral compounds and the synthesis of appropriate salt forms of drugs that are weakly acidic or weakly basic may often not be practical. Even when salts can be prepared, an increased dissolution rate in the gastrointestinal tract may not be achieved in many cases because of the reconversion of salts into aggregates of their respective acid or base forms. The solubilization of drugs in organic solvents or in aqueous media by the use of surfactants and cosolvents leads to liquid formulations that are usually undesirable from the viewpoints of patient acceptability and commercialization. Although particle size reduction is commonly used to increase dissolution rate, there is a practical limit to how much size reduction can be achieved by such commonly used methods as controlled crystallization, grinding, etc. The use of very fine powders in a dosage form may also be problematic because of handling difficulties and poor wettability.

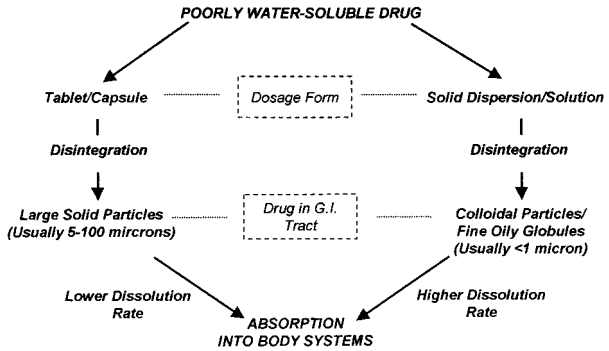

Figure 1—A schematic representation of the bioavailability enhancement of a poorly water-soluble drug by solid dispersion compared with conventional tablet or capsule.

In 1961, Sekiguchi and Obi[2] developed a practical method whereby many of the limitations with the bioavailability enhancement of poorly water-soluble drugs just mentioned can be overcome. This method, which was later termed solid dispersion,[3] involved the formation of eutectic mixtures of drugs with water-soluble carriers by the melting of their physical mixtures. Sekiguchi and Obi[2] suggested that the drug was present in a eutectic mixture in a microcrystalline state. Later, Goldberg et al.[4,5] demonstrated that all the drug in a solid dispersion might not necessarily be present in a microcrystalline state; a certain fraction of the drug might be molecularly dispersed in the matrix, thereby forming a solid solution. In either case, once the solid dispersion was exposed to aqueous media and the carrier dissolved, the drug was released as very fine, colloidal particles. Because of greatly enhanced surface area obtained in this way, the dissolution rate and the bioavailability of poorly water-soluble drugs were expected to be high.

The advantage of solid dispersion, compared with conventional capsule and tablet formulations, is shown schematically in Figure 1.[6] From conventional capsules and tablets, the dissolution rate is limited by the size of the primary particles formed after the disintegration of dosage forms. In this case, an average particle size of 5 μm is usually the lower limit, although higher particle sizes are preferred for ease of handling, formulation, and manufacturing. On the other hand, if a solid dispersion or a solid solution is used, a portion of the drug dissolves immediately to saturate the gastrointestinal fluid, and the excess drug precipitates out as fine colloidal particles or oily globules of submicron size.

Because of such early promises in the bioavailability enhancement of poorly water-soluble drugs, solid dispersion has become one of the most active areas of research in the pharmaceutical field. Numerous papers on various aspects

of solid dispersion were published since 1961; Chiou and Riegelman[3] and Ford[7] reviewed the early research in this area. Despite an active research interest, the commercial application of solid dispersion in dosage form design has been very limited. Only two products, a griseofulvin-in-poly(ethylene glycol) solid dispersion (Gris-PEG, Novartis) and a nabilone-in-povidone solid dispersion (Cesamet, Lilly) were marketed during three decades following the initial work of Sekiguchi and Obi in 1961. The objectives of the present article are to critically review some of the limitations of solid dispersion that prevented its wider commercial application and to discuss how the situation is now changing because of the availability of new types of vehicles and the development of new manufacturing technologies.

Limitations of Solid Dispersion Systems

Problems limiting the commercial application of solid dispersion involve (a) its method of preparation, (b) reproducibility of its physicochemical properties, (c) its formulation into dosage forms, (d) the scale up of manufacturing processes, and (e) the physical and chemical stability of drug and vehicle. Some of the issues are discussed next.

Method of Preparation—In their pioneering study, Sekiguchi and Obi[2] prepared solid dispersions of sulfathiazole in such carriers as ascorbic acid, acetamide, nicotinamide, nicotinic acid, succinimide, and urea by melting various drug–carrier mixtures. To minimize melting temperatures, eutectic mixtures of the drug with carriers were used. Yet, in all cases, except acetamide, the melting temperatures were >110 °C, which could chemically decompose drugs and carriers.[3] High temperatures (>100 °C) were also utilized by Goldberg et al. in preparing acetaminophen–urea,[4] griseofulvin–succinic acid,[4] and chloramphenicol–urea[8] solid dispersions. After melting, the next difficult step in the preparation of solid dispersions was the hardening of melts so that they could be pulverized for subsequent formulation into powder-filled capsules or compressed tablets. Sekiguchi and Obi[2] cooled the sulfathiazole–urea melt rapidly in an ice bath with vigorous stirring until it solidified. Chiou and Riegelman[9] facilitated hardening of the griseofulvin–PEG 6000 solid dispersion by blowing cold air after spreading it on a stainless steel plate and then storing the material in a desiccator for several days. In preparing primidone–citric acid solid dispersions, Summers and Enever[10] spread the melt on Petri dishes, cooled it by storing the Petri dishes in a desiccator, and finally placed the desiccator at 60 °C for several days. Allen et al.[11] prepared solid dispersions of corticosteroids in galactose, dextrose, and sucrose at 169, 185, and 200 °C, respectively, and then placed them on aluminum boats over dry ice. Timko and Lordi[12] also used blocks of dry ice to cool and solidify phenobarbital–citric acid mixtures that had previously been melted on a frying pan at 170 °C. The fusion method of preparing solid dispersion remained essentially similar over the period of time. More recently, Lin and Cham[13] prepared nifedipine–PEG 6000 solid dispersions by blending physical mixtures of the drug and the carrier in a V-shaped blender and then heating the mixtures on a hot plate at 80–85 °C until they were completely melted. The melts were rapidly cooled by immersion in a freezing mixture of ice and sodium chloride, and the solids were stored for 24 h in a desiccator over silica gel before pulverization and sieving. Mura et al.[14] solidified naproxen–PEG melts in an ice bath and the solids were then stored under reduced pressure in a desiccator for 48 h before they were ground into powders with a mortar and pestle. In another study, Owusu-Ababio et al.[15] prepared a mefenamic acid–PEG solid dispersion by heating the drug–carrier mixture on a hot plate to a temperature above the melting point of mefenamic acid (253 °C) and then cooling the melt to room temperature under a controlled environment.

Another commonly used method of preparing a solid dispersion is the dissolution of drug and carrier in a common organic solvent, followed by the removal of solvent by evaporation.[9,16,17] Because the drug used for solid dispersion is usually hydrophobic and the carrier is hydrophilic, it is often difficult to identify a common solvent to dissolve both components. Large volumes of solvents as well as heating may be necessary to enable complete dissolution of both components. Chiou and Riegelman[9] used 500 mL of ethanol to dissolve 0.5 g of griseofulvin and 4.5 g of PEG 6000. Although in most other reported studies the volumes of solvents necessary to prepare solid dispersions were not specified, it is possible that they were similarly large. To minimize the volume of organic solvent necessary, Usui et al.[18] dissolved a basic drug in a hydro alcoholic mixture of 1 N HCl and methanol, with drug-to-cosolvent ratios ranging from 1:48 to 1:20, because as a protonated species, the drug was more soluble in the acidic cosolvent system than in methanol alone. Some other investigators dissolved only the drug in the organic solvent, and the solutions were then added to the melted carriers. Vera et al.[19] dissolved 1 g of oxodipine per 150 mL of ethanol before mixing the solution with melted PEG 6000. In the preparation of piroxicam–PEG 4000 solid dispersion, Fernandez et al.[20] dissolved the drug in chloroform and then mixed the solution with the melt of PEG 4000 at 70 °C. Many different methods were used for the removal of organic solvents from solid dispersions. Simonelli et al.[16] evaporated ethanolic solvent on a steam bath and the residual solvent was then removed by applying reduced pressure. Chiou and Riegelman[9] dried an ethanolic solution of griseofulvin and PEG 6000 in an oil bath at 115 °C until there was no evolution of ethanol bubbles. The viscous mass was then allowed to solidify by cooling in a stream of cold air. Other investigators used such techniques as vacuum-drying,[20,21] spray-drying,[22–25] spraying on sugar-beads using a fluidized bed-coating system,[26] lyophilization,[27] etc., for the removal of organic solvents from solid dispersions. None of the reports, however, addressed how much residual solvents were present in solid dispersions when different solvents, carriers, or drying techniques were used.

Reproducibility of Physicochemical Properties—In their pioneering studies, Sekiguchi and Obi[2] observed that manufacturing conditions might greatly influence the physicochemical properties of solid dispersions formed. They cooled drug–carrier melts under vigorous stirring conditions to obtain fine and uniform drug particles in solid dispersions. Various investigators observed that heating rate, maximum temperature used, holding time at a high temperature, cooling method and rate, method of pulverization, and particle size may greatly influence the properties of solid dispersions prepared by the melt method. McGinity et al.[28] prepared solid dispersions of tolbutamide in urea and PEG 6000 by flash cooling in a bath of dry ice and acetone or by gradual cooling over a period of several hours by immersion in an oil bath. The powder X-ray diffraction patterns of the tolbutamide–urea solid dispersion differed markedly depending on the cooling rate. The slow-cooled solid dispersion of tolbutamide in urea demonstrated a complete lack of crystallinity for both the drug and urea, whereas the flash-cooled dispersions showed only the absence of drug crystallinity. In the powder X-ray diffraction patterns of tolbutamide–PEG 6000 solid dispersions, peaks for both tolbutamide and PEG 6000 were observed; however, their degree of crystallinity in flash-cooled samples was less than that in the slow-cooled

samples. In another study, a metastable amorphous form of nifedipine was formed in its solid dispersions in PEG 4000 and PEG 6000 when the drug–carrier melts were cooled rapidly, whereas slow cooling of melts or powdering of solidified mass resulted in the crystallization of drug.[29] Ginés et al.[30] studied the effect of fusion temperature on oxazepam–PEG 4000 solid dispersions. Microscopic examination revealed the presence of crystalline oxazepam and the spherulitic form of PEG 4000 in solid dispersions prepared by fusion at 100 °C. In contrast, a fusion temperature of 150 °C produced a solid dispersion with no crystalline form of the drug and the presence of PEG 4000 in a hedritic form. Complete dissolution of drug in the carrier at 150 °C in contrast to 100 °C was reported to be responsible for such a difference in physicochemical properties of the solid dispersions produced. Dordunoo et al.[31] also observed a change of triamterene and temazepam from crystalline to amorphous form in poly(ethylene glycol) solid dispersions when the fusion temperature was increased from 100 to 150 °C. Such changes in physical states of drugs in solid dispersions result into differences in drug dissolution rates in aqueous media.[30] Drug-to-carrier ratio and particle size of solid dispersions were also reported to influence the dissolution rate of drug.[32]

The properties of solid dispersions prepared by the solvent method may also vary depending on manufacturing conditions. The solvent method usually leads to amorphous forms of drugs. However, some crystallinity of drug may be observed depending on the drug-to-carrier ratio used.[33] Although no detailed studies were reported in the literature, it is expected that the nature of solvent used, drug-to-solvent and carrier-to-solvent ratios, drying method, and drying rate may significantly influence the physicochemical properties of solid dispersions formed.

Dosage Form Development—Solid dispersion must be developed into convenient dosage forms, such as capsules and tablets, for their clinical use and successful commercialization. As already mentioned, solid dispersions produced by the melt method are usually hardened at very low temperatures and then pulverized with mortars and pestles. Similarly, solid dispersions produced by the solvent method are also pulverized after solvent removal and hardening. Some of the challenges in the dosage form development of such materials are difficulty of pulverization and sifting of the dispersions, which are usually soft and tacky, poor flow and mixing properties of powders thus prepared, poor compressibility, drug–carrier incompatibility, and poor stability of dosage forms. However, there are very few reports in the literature addressing these important issues.[7] Even the limited number of reports describing any dosage form developmental aspects of solid dispersions only confirm that the task of formulating solid dispersions into capsules or tablets may be a very complex and difficult one. In developing a tablet formulation for the indomethacin–PEG 6000 solid dispersion, Ford and Rubinstein[34] reported that the solid dispersion was not amenable to wet granulation because water could disrupt its physical structure. In addition, the dispersion was soft and tacky. To overcome these problems, the authors adopted an in situ dry granulation method where the excipients (calcium hydrogen phosphate and sodium starch glycolate) were preheated and rotated in a water-jacketed blender at 70 °C, and the indomethacin–PEG 6000 mixture that melted at 100 °C was then added to the moving powder. After mixing, the granules were passed through a 20-mesh sieve and allowed to harden at 25 °C for 12 h. Then, the granules were mixed with a relatively high concentration of magnesium stearate (1%) and compressed into tablets. To process 100 mg of solid dispersion, 506 mg of other excipients were used, thus making the final weight of a 25-mg indomethacin tablet 606 mg. Yet, the tablet did not disintegrate in water despite the use of a large amount of excipients. It dissolved slowly by erosion, and the dissolution rate decreased on aging of the tablet. In another study, the same investigators used an essentially similar in situ dry granulation method for the preparation of tablet dosage forms for a chlorpropamide–urea solid dispersion, where the drug, the carrier, and the excipients were mixed in a rotating flask on a water bath maintained at 100 °C.[35] The properties of these formulations also changed with time, and the authors concluded that aging could "limit their usefulness as prospective dosage forms". During the development of a tablet formulation for a furesemide–poly(vinylpyrrolidone) (PVP) solid dispersion, Akbuga et al.[36] observed that method of preparation, choice of disintegrant and particle size of solid dispersions were critical factors in determining the properties of tablets produced. Despite the use of relatively large amounts of disintegrants, the tablets did not disintegrate. Rather, they dissolved by erosion only, and the erosion rate varied depending on the disintegrant used. In addition, the dissolution rate of tablets prepared by double compression (slugging and recompression of dry granules) was much slower than that of the tablets prepared by single compression. The dissolution rate of tablet was also dependent on the particle size of solid dispersion used; the rate decreased by a factor of 5 when 100-mesh particles were used in place of 80-mesh particles. Also, the compressibility of solid dispersion decreased with a decrease in particle size. In another study, Sjökvist and Nystrom [37] overcame the compression difficulties due to sticking of griseofulvin–xylitol solid dispersions to dies and punches by lubricating die wall and punch faces with 1% (w/w) magnesium stearate suspension before the compression of each tablet. The authors observed that the dissolution rate of tablet was highly sensitive to compression pressure. The sticking of solid dispersion to dies and punches might become so problematic that Kaur et al. [38] resorted to placing small pieces of grease-proof paper between metal surfaces and granules before the compression of tablets.

The lack of disintegration and the slow dissolution of tablets prepared from solid dispersions could be related to the soft and waxy nature of carriers used (e.g., PEG) in many of the reported studies. Such carriers essentially act as strong binders within tablets. During compression, the carriers could plasticize, soften, or melt, filling the pores within tablets and thus making them nondisintegrating. It is also possible that the softened and melted carriers coat the disintegrants and other ingredients used in tablets, and such a coating, along with the reduction of porosity of tablets, make the disintegrants ineffective. Use of a very high ratio of solid dispersion to added excipient might alleviate the problem. In one study,[15] 270 mg of microcrystalline cellulose (Avicel) was used to formulate 30 mg of mefenamic acid–PEG solid dispersion into a tablet with good dissolution. The use of such a high ratio of added excipient would, however, greatly increase the size of tablet and might, therefore, be impractical in most formulations.

Scale Up of Manufacturing Processes—Because very few solid dispersion products prepared by melt or solvent methods have been marketed, there are practically no reports on the scale up of such products. It is apparent from the discussion just presented that the scale up of the methods of preparation of solid dispersions and their dosage forms could be very challenging. In most of the studies reported in the literature, solid dispersions by the melt method were prepared in a small scale by heating drug–carrier mixtures in beakers, frying pans, etc. that were placed on hot plates and then cooling the melts in an ice bath, a dry ice-acetone mixture, etc.[2–5,7–14] Because there could be condensation of moisture over solid disper-

sions during cooling to low temperatures, strict protection from moisture was necessary in all cases. The scale up challenges may be illustrated with the example of the preparation of a phenytoin−PEG 4000 solid dispersion by Yakou et al.[39] The drug−carrier mixture was heated at 250 °C under constant stirring until a clear homogeneous melt was obtained, and the melt was air-cooled by spreading on stainless steel trays. The trays were stored in a desiccator for 3 days to enhance solidification of the solid dispersion. The resulting material was then crushed in a cutter mill, and the powders were sieved to collect a sieve fraction of 105−177-μm particle size for use in the dosage form. The scale up of such a method would be difficult and it might even be impractical in many cases because of possible degradation of both drug and carrier at high temperatures used. The scale up might also necessitate a large capital investment because a chemical plant-like facility, rather than a common pharmaceutical dosage form manufacturing plant, would be required to process and manufacture the products. For scale up of the cooling process, Lefebvre et al.[40] recommended such continuous operation as cooling on the surfaces of moving belts or rotating cylinders, and spray congealing. The practical application of the methods, however, was not demonstrated. Kennedy and Niebergall[41] described a hot-melt fluid bed method whereby nonpareils could be coated with PEGs having molecular weights between 1450 and 4600. A similar method can possibly be used to deposit solid dispersions on nonpareils and might in the future find application in the manufacture and scale up of solid dispersion formulations.

The physicochemical properties and stability of solid dispersions may also be affected by scale up because heating and cooling rates of solid dispersions under large-scale manufacturing conditions may differ greatly from that in small beakers.[28,29] Drug−carrier compatibility at a high temperature also requires careful consideration. Dubois and Ford[42] reported the chain scission of PEG 600 during fusion with disulfiram, furosemide, chlorthiazide, and chlorpropamide.

The scale up of the solvent method of preparing solid dispersions may also be very challenging. A chemical plant environment would be necessary to evaporate hundreds and even thousands of liters of organic solvents necessary to prepare solid dispersions for kilogram quantities of drugs.[17,20] The cost of recovery of these solvents may be very high. Removal of residual amounts of potentially toxic organic solvents such as chloroform and methanol from large masses of material may be difficult because the solid dispersions are usually amorphous and may exist in viscous and waxy forms. Solvates may also be formed with drugs and carriers. Because most dosage form manufacturing facilities are not equipped to handle large volumes of organic solvents, one way to resolve the issue might be the designation of solid dispersion as an active pharmaceutical ingredient or bulk drug substance. In that case, the responsibility of the manufacture of solid dispersion can be shifted to the chemical plant. It would be necessary to conduct all developmental activities using the solid dispersion, so this approach might not be suitable for situations where active pharmaceutical ingredients have multiple uses (e.g., oral and parenteral).

The final step in the manufacturing process, which is the conversion of solid dispersions into stable and marketable dosage forms, may be the most difficult one to scale up, optimize, and validate. Most of the commonly used solid dispersion vehicles are soft and sticky and, as a result, the pulverized forms of solid dispersions produced by such vehicles may not be amenable to processing by high-speed capsule or tablet filling machines.

Stability—The physical instability of solid dispersions due to crystallization of drugs was the subject of most published reports in the literature.[3,7] In a solid dispersion prepared by the melt method, a certain fraction of the drug may remain molecularly dispersed, depending on its solubility in the carrier used, thus forming a solid solution. How the excess drug exists may greatly depend on the method of manufacture of the system; it may, as a whole or in part, form a supersaturated solution, separate out as an amorphous phase, or crystallize out. The supersaturated and amorphous forms may, in turn, crystallize out on aging. Similarly, certain carriers may also exist in thermodynamically unstable states in solid dispersions and undergo changes with time. Chiou[43] reported that griseofulvin precipitated out in an amorphous form in a griseofulvin−PEG 6000 solid dispersion during the time of its preparation. The amorphous material crystallized out on aging, except when the drug concentration in the dispersion was 5% or less. Ford and Rubinstein[44] attributed similar crystallization as the cause for a decrease in dissolution rate of drug from indomethacin−PEG 6000 solid dispersions with time. The decrease in the dissolution rate of indomethacin was also dependent on drug concentration in the solid dispersion. The decrease was greater for a higher drug concentration because a larger fraction of drug crystallized out. In another study, Suzuki and Sunada[45] observed that on exposure of a nifedipine−nicotinamide−hydroxypropylmethylcellulose (HPMC) solid dispersion to 60% RH at 30 °C or 75% RH at 40 °C for 1 month, nifedipine converted from the amorphous to the crystalline state, thus lowering the dissolution rate of nifedipine drastically. No conversion of nifedipine to the crystalline state was observed when the solid dispersion was stored at an elevated temperature in the absence of humidity. Although the presence of HPMC facilitated the conversion of nifedipine to an amorphous state during the cooling of drug−nicotinamide melt to room temperature at the time of manufacturing, it did not prevent the subsequent crystallization of drug under humid conditions. Pronounced decreases in dissolution rates due to drug crystallization were also reported for tablets prepared from solid dispersions.[34,35] No such decrease in dissolution rate on aging was observed by Khalil et al.[46] in corticosteroid−PEG solid dispersions prepared with a drug-to-carrier ratio of 1:99, possibly because most of the drug was molecularly dispersed in the carrier. The corticosteroid, however, exhibited chemical degradation due to oxidation by the peroxides present in PEG. The cooling rate of solid dispersions may also significantly influence their aging behavior. It has been reported that the crystallinity of drug in solid dispersions is less influenced by aging when a slow cooling rate is used because thermodynamically more stable systems are produced during the time of preparation.[47,48]

The conversion of drug to crystalline state is also the primary stability issue with solid dispersions prepared by the solvent method. PVP, which is commonly used as a carrier in such solid dispersions, is amorphous and does not convert to a crystalline state. However, certain other carriers may convert from their amorphous states to crystalline states in solid dispersions. Zografi and coworkers[49,50] extensively studied the physicochemical properties of the amorphous states of drugs and excipients and observed that the crystallization of amorphous materials is facilitated by moisture. This effect is why strict protection from moisture is necessary during the preparation and storage of most solid dispersions. Doherty and York[51] studied the stability of furosemide−PVP solid dispersion in the temperature range of 6 to 45 °C and 40% RH for up to 1 year. They did not observe any crystallization of furosemide and suggested that PVP may indeed act as a

stabilizer in the solid dispersion by retarding crystallization of drug at a relatively low humidity. Rapid crystallization of furosemide in the solid dispersion was, however, evident when the humidity was raised to 75% RH. Similar observations were also made by Guillaume et al.[52] for an oxodipine−PVP solid dispersion where no crystallization of oxodipine was observed in 18 months when samples were stored under 55% RH at various temperatures, but the drug crystallized out at 80% RH. The stabilization of drugs in amorphous forms in solid dispersions is an active area of research in the pharmaceutical field. For an indomethacin−PVP solid dispersion system, Taylor and Zografi[53] suggested that hydrogen bonding between the drug and PVP might offer an explanation for the absence of drug crystallization. Lu and Zografi[54] recently demonstrated that indomethacin forms a completely miscible amorphous mixture with citric acid and PVP when the weight fraction of PVP in the ternary mixture exceeds 0.3 weight fraction. Thus, both the choice of carrier and the drug-to-carrier ratio are important considerations in the stabilization of solid dispersions.

Breakthroughs in Solid Dispersion Technology

Because of the various limitations just mentioned, it is not surprising that the solid dispersion system, despite its many potential advantages, has not been widely used in pharmaceutical dosage forms. Under the present health care economic climate, the goal of any drug development program in the pharmaceutical industry is to rapidly progress a new chemical entity from the discovery stage to clinical testing to determine whether it is safe and clinically effective. The limited supply of the bulk drug substance at the early drug development phase and the accelerated time line would not allow a formulator to address most of the challenges (vide supra) of a solid dispersion formulation. Most importantly, if a compound proves promising in early clinical testing, the scale up of complex manufacturing processes for the development of marketable dosage forms cannot be ensured.

Two recent breakthroughs in the formulation of solid dispersion systems involve (1) the development of technologies to fill solid dispersions directly into hard gelatin capsules and (2) the availability of surface-active and self-emulsifying carriers. As a result, there is renewed interest in such systems for use in commercial development of drug products.[6,55]

Direct Capsule-Filling—Although the filling of semisolid materials into hard gelatin capsules as melts, which solidify at room temperature, was first described by Francois and Jones in 1978,[56] it was not until much later that the potential application of the technique for solid dispersions was fully realized. Chatham[57] reported the possibility of preparing PEG-based solid dispersions by filling drug−PEG melts in hard gelatin capsules. By using PEG with molecular weights ranging from 1000 to 8000, Serajuddin et al.,[58] however, demonstrated that a PEG by itself might not be a suitable carrier for solid dispersion of poorly water-soluble drugs intended for direct filling into hard gelatin capsules. They dissolved a poorly water-soluble drug, REV5901, in molten PEG 1000, PEG 1450, and PEG 8000 and filled the hot solutions into hard gelatin capsules such that each size 0 capsule contained 100 mg of drug and 550 mg of PEG. At room temperature, solid plugs were formed inside the capsules, where the drug remained molecularly dispersed in the carriers. Although a sink condition existed for the dissolution of 100 mg of the weakly basic REV5901 ($pK_a \sim 3.6$) in 900 mL of simulated gastric fluid (drug solubility = 0.7 mg/mL at 37 °C), the dissolution of drug from all PEG-based solid dispersions was incomplete.

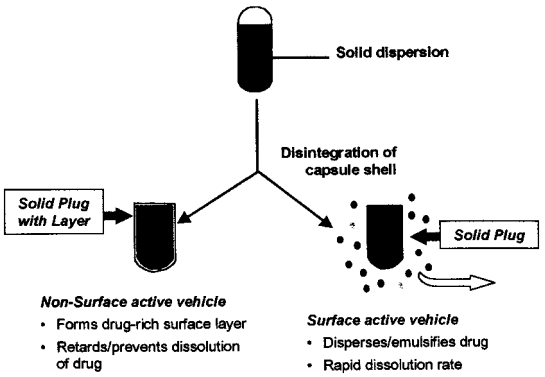

Figure 2—A schematic representation of the comparative dissolution of a poorly water-soluble drug from surface-active versus nonsurface-active vehicles.

Because the water-soluble carrier dissolved more rapidly than the drug, drug-rich layers were formed over the surfaces of dissolving plugs, which prevented further dissolution of drug from solid dispersions. The dissolution was practically zero at pH > 2, where the solubility of drug was low and a drug layer coated the surface of the solid plug as soon as the capsule shell disintegrated. Corrigan[59] also reported the possibility of such a retardation of drug dissolution from solid dispersions.

Surface-Active Carriers—The direct filling of melts into hard gelatin capsules would not be a viable method for the preparation of solid dispersions unless the formation of drug-rich layers on the surfaces of dissolving plugs could be prevented. Serajuddin et al.[58,60] achieved a complete dissolution of drug from solid dispersions by using surface-active or self-emulsifying carriers. The vehicles acted as dispersing or emulsifying agents for the liberated drug, thus preventing the formation of any water-insoluble surface layers. Although the liberated drug remained undissolved in the dissolution medium when its concentration exceeded its saturation solubility, it was dispersed or emulsified in a finely divided state because of surface activity of the dissolved vehicle.[58,60] The high surface area of a drug produced in this way would facilitate its dissolution in the gastrointestinal fluid, especially in the presence of bile salts, lecithin, and lipid digestion mixtures.[61]

The advantage of a surface-active carrier over a nonsurface-active one in the dissolution of drug from a capsule formulation is shown schematically in Figure 2.[6] The physical state of drug in a solid dispersion must, however, be carefully considered in evaluating the advantage of a surface-active vehicle. As mentioned earlier, the drug can be molecularly dispersed in the carrier to form a solid solution or it can be dispersed as particles. It can also be both partially dissolved and partially dispersed in the carrier. The potential for the formation of a continuous drug-rich surface layer is possibly greater if the drug is molecularly dispersed, whereas the drug dispersed as particulates may be more prone to dissociation from the water-soluble matrix. It is, however, rare that the drug is dispersed just as particulates and is not at least partially dissolved in the vehicle. Therefore, a surface-active carrier may be preferable in almost all cases for the solid dispersion of poorly water-soluble drugs.

The interest in surface-active and self-emulsifying carriers for solid dispersion of poorly water-soluble drugs increased greatly in recent years.[58,60,62−67] For ease of manufacturing, the carriers must be amenable to liquid filling into hard gelatin capsules as melts. The melting temperatures of carriers should be such that the solutions do not exceed ~70 °C, which is the maximum acceptable temperature for hard gelatin capsule shells.[68] Some of the manufacturing difficulties mentioned earlier may be en-

countered if solid dispersion products using surface-active carriers are prepared by methods other than direct filling into hard gelatin capsules; for examples, the solvent evaporation method,[69] compaction into tablets from granules,[37] etc.

One surface-active carrier that has commonly been used in solid dispersion for the bioavailability enhancement of drugs is Gelucire 44/14 (Gattefossé Corp., France).[58,62–65,67] It is a mixture of glyceryl and PEG 1500 esters of long-chain fatty acids and is official in the European Pharmacopeia as lauryl macrogolglycerides; the suffixes 44 and 14 in its name refer, respectively, to its melting point and hydrophilic–lipophilic balance (HLB) value. Another surface-active carrier that generated certain interest in recent years is Vitamin E TPGS NF (Eastman, Kingsport, TN),[70] which is prepared by the esterification of the acid group of *d*-α-tocopheryl acid succinate by PEG 1000. The material has an HLB value of 13 and is miscible with water in all parts. Its melting point is, however, relatively low (38 °C) and it may require mixing with other carriers to increase melting temperatures of formulations.

In search of alternative surface-active carriers, Serajuddin and co-workers[60,71] demonstrated that a commonly used surfactant, polysorbate 80, could be used in solid dispersions by mixing it with solid PEG. Although polysorbate 80 is liquid at room temperature, it forms a solid matrix when it is mixed with a PEG because it incorporates within the amorphous regions of PEG solid structure. As high as 50% (w/w) polysorbate 80 could be incorporated in a PEG with a lowering of <6 °C in its melting point. Even when 75% (w/w) polysorbate 80 was incorporated, PEG remained semisolid, and the lowering of the melting temperature of the PEG used was <12 °C.[71] The crystalline structure of solid PEG was minimally affected by polysorbate 80 because the two compounds have low miscibility in each other. Other investigators also reported enhanced dissolution[72] and bioavailability[65] of drugs from PEG–polysorbate carriers. Law et al.[73] reported a >2-fold increase in the dissolution rate of nifedipine from a PEG-based solid dispersion after incorporation of 5% (w/w) phosphatidylcholine. Increased dissolution rate of drug from solid dispersions in PEG containing varying amounts of ionic and nonionic surfactants, including sodium dodecyl sulfate and polysorbate 80, were also reported by Sjökvist et al.[74] The authors, however, pulverized the waxy material instead of filling them into hard gelatin capsules as melts.

Ease of Manufacturing—Cadé and Madt[75] and Shah et al.[76] reviewed various formulation and processing considerations for liquid-filled hard gelatin capsules. Initial formulation development studies can be conducted by filling hot solutions or dispersions into hard gelatin capsule shells manually by using pipets or by using laboratory scale semiautomatic equipment.[77] Equipment is also available to scale up the manufacturing process and for large scale manufacturing.[78] As mentioned earlier, the temperature of solutions during the filling of hard gelatin capsules should not exceed 70 °C.[68] Solutions can also be filled into soft gelatin capsules for which the solution temperature should remain <40 °C.[79] Several hard gelatin[80,81] and soft gelatin[82] capsule products prepared according to these techniques have been marketed in recent years.

Bioavailability Enhancement—The reports on the bioavailability enhancement by solid dispersion in surface-active carriers are promising. The human bioavailability of the poorly soluble REV5901 from a solid dispersion in Gelucire 44/14 under a fasting regimen was much higher than that of a tablet formulation even though the micronized form of drug and a wetting agent were used in the tablet.[83] The bioavailability of ubidecarenone in dogs from solid dispersion in Gelucire 44/14 and the Gelucire 44/14–lecithin mixture were, respectively, two and three times higher than that of commercially available tablet.[63] The bioavailability of another poorly water-soluble drug, RP69698, in dogs was 4.5 times higher (27.6% versus 6%) from its solid dispersion in a PEG 3350–Labrasol–polysorbate 80 system than from an aqueous suspension in 0.5% methylcellulose.[65] Aungst et al.[67] reported that the bioavailability of an HIV protease inhibitor, DMP323, in dogs from a PEG-based formulation decreased from 49.6 to 5.2% when the dose was increased from 100 to 350 mg. No such drastic decrease in bioavailability was observed in a Gelucire 44/14-based formulation of DMP323; the bioavailability values were 68.9 and 49.5% after doses of 85 and 350 mg, respectively. The bioavailability of ritonavir (Norvir, Abbott), another poorly soluble HIV protease inhibitor (solubility <1 μg/mL at pH >2), was enhanced by formulation as a solid dispersion in a mixture of such surface-active carriers as Gelucire 50/13, polysorbate 80 and polyoxyl 35 castor oil.[84]

Special Considerations for Surfactant-Based Solid Dispersions—Solid dispersion in surface-active carriers may not be the answer to all bioavailability problems with poorly water-soluble drugs. One of the limitations of bioavailability enhancement by this method might be the low solubility of drug in available carriers.[64,85] The desired doses of a drug cannot be solubilized and filled into hard gelatin capsules if adequate solubility in a carrier cannot be obtained. Dordunoo et al.[64] reported that the particle size of a drug in a solid dispersion remained unchanged if it is just mixed with the carrier instead of dissolving in it. On the other hand, if the drug is dissolved by heating in excess of its solubility in the carrier under normal storage condition, it may subsequently crystallize out from the solid dispersion. Either situation would defeat the purpose of bioavailability enhancement of poorly water-soluble drugs by solid dispersion, as described in Figure 1.

The crystallization of ritonavir from the supersaturated solution in a solid dispersion system was responsible for the withdrawal of the ritonavir capsule (Norvir, Abbott) from the market.[86] The crystallization of drug adversely influenced the dissolution of the ritonavir capsule, and the product was switched to a thermodynamically stable solution formulation. Aungst et al.[67] also stressed the importance of drug solubility in carriers in the development of capsule formulations. They prepared high-dose formulations of a water-insoluble HIV protease inhibitor by dissolving it in carriers at an elevated temperature only, and the formulations were used for bioavailability testing in dogs within 24 h of preparation when no crystallization occurred. The authors cautioned that precipitation of drug could occur upon storage at room temperature over a longer period of time, and that lowering of drug concentration in the carrier would be necessary to ensure long-term physical stability of the formulation.

To ensure that a drug would not crystallize out of solid dispersion at the desired storage temperature, it is important to screen the drug solubility in different carriers at such a temperature. However, no practical method for determining or estimating drug solubility in a carrier at a relatively low temperature, where the carrier exists in a solid state, has been reported in the literature. The relative solubility of a drug in different carriers may be determined by equilibrating the drug at an elevated temperature where all the carriers exist in a liquid state.[67] If the solubility of a drug in a carrier at an elevated temperature is much higher than the concentration required for solid dispersion, an accurate estimation of solubility at room temperature might not be necessary and a reasonable assumption might be made that the drug would not precipitate out. When a better estimation of solubility is needed, one practical

approach is the determination of solubility−temperature relationship of drug in a chemically related carrier that exists as liquid at a wider range of temperature. For example, for the purpose of estimating the solubility of a drug in a solid PEG at room temperature, the solubility may be determined at an elevated temperature where the PEG exists in a liquid state. Then the solubility of drug at a lower temperature may be estimated from the solubility−temperature relationship in a related vehicle, PEG 400, which remains liquid at a wider range of temperature. This method assumes, however, that similar temperature−solubility relationships for the drug would exist in both PEGs and that the relationship would not change when one of them solidifies. The solubility may also be estimated by microscopic examination of solid solutions with increasing drug concentration for any possible crystallization of drug, assuming that the drug does not exist as a separate amorphous phase and the crystallization occurs in a relatively short period of time. A similar microscopic technique was use for determining the solubility of diazepam in liquid crystalline phases of lecithin.[87]

Another possible limitation of the use of surface-active carrier reported by Aungst et al.[67] is that the bioavailability of a drug may vary depending on the amount of carrier administered along with it. This variation is because different amounts of a surface-active carrier may have different solubilization or dispersion effects on a drug in the gastrointestinal fluid. Serajuddin et al.[58,60] reported a method whereby the rate and efficiency of dispersion of drug in aqueous media from different formulations can be studied.

In addition to the solubility, careful attention must be given to the drug-to-carrier ratio in the successful development of a formulation. When the solubility of a particular drug is relatively low, a high drug-to-carrier ratio is necessary to deliver it in a solubilized state, and, therefore, the dose has to be low if it is desired that the total dose is delivered as a single unit. As mentioned earlier, any attempt to supersaturate the drug in solid dispersion to reduce drug-to-carrier ratio may lead to stability problems and, ultimately, to product failure.

Attention should also be given to optimization and validation of the manufacturing process. It is not only that the physicochemical properties of the drug is affected by the cooling rate, the properties of carriers in a solid dispersion might also be influenced by the solidification rate of the product.[88,89] The implication of this observation on bioavailability and stability of drug product is not known.

Future Prospects

Despite many advantages of solid dispersion, issues related to preparation, reproducibility, formulation, scale up, and stability limited its use in commercial dosage forms for poorly water-soluble drugs. Successful development of solid dispersion systems for preclinical, clinical, and commercial use have been feasible in recent years due to the availability of surface-active and self-emulsifying carriers with relatively low melting points. The preparation of dosage forms involves the dissolving of drugs in melted carriers and the filling of the hot solutions into hard gelatin capsules. Because of the simplicity of manufacturing and scale up processes, the physicochemical properties and, as a result, the bioavailability of solid dispersions are not expected to change significantly during the scale up. For this reason, the popularity of the solid dispersion system to solve difficult bioavailability issues with respect to poorly water-soluble drugs will grow rapidly. Because the dosage form can be developed and prepared using small amounts of drug substances in early stages of the drug development process, the system might have an advantage over such other commonly used bioavailability enhancement techniques as micronization of drugs and soft gelatin encapsulation.

One major focus of future research will be the identification of new surface-active and self-emulsifying carriers for solid dispersions. Only a small number of such carriers are currently available for oral use. Some carriers that are used for topical application of drug only may be qualified for oral use by conducting appropriate toxicological testing. One limitation in the development of solid dispersion systems may the inadequate drug solubility in carriers, so a wider choice of carriers will increase the success of dosage form development. Research should also be directed toward identification of vehicles or excipients that would retard or prevent crystallization of drugs from supersaturated systems. Attention must also be given to any physiological and pharmacological effects of carriers used. Many of the surface-active and self-emulsifying carriers are lipidic in nature, so potential roles of such carriers on drug absorption, especially on their inhibitory effects on CYP3-based drug metabolism and *p*-glycoprotein-mediated drug efflux, will require careful consideration.[90]

In addition to bioavailability enhancement, much recent research on solid dispersion systems was directed toward the development of extended-release dosage forms. Although a review of literature on this aspect of solid dispersion is outside the scope of the present article, it may be pointed out that this area of research has been reinvigorated by the availability of surface-active and self-emulsifying carriers and the development of new capsule-filling processes. Because the formulation of solid dispersion for bioavailability enhancement and extended release of drugs may employ essentially similar processes, except for the use of slower dissolving carriers for the later use,[91] it is expected that the research in these two areas will progress simultaneously and be complementary to each other.

Physical and chemical stability of both the drug and the carrier in a solid dispersion are major developmental issues, as exemplified by the recent withdrawal of ritonavir capsules from the market,[86] so future research needs to be directed to address various stability issues. The semisolid and waxy nature of solid dispersions poses unique stability problems that might not be seen in other types of solid dosage forms. Predictive methods will be necessary for the investigation of any potential crystallization of drugs and its impact on dissolution and bioavailability. Possible drug−carrier interactions must also be investigated.

Although, as mentioned earlier, the direct filling of solid dispersion into hard gelatin capsules is a relatively simple process, there are very limited reports on the scale up of the technology. Further studies on scale up and validation of the process will be essential. Many problems and challenges still remain with solid dispersion systems. Nevertheless, as a result of recent breakthroughs, it will continue to be one of the exciting frontiers of drug development.

Accepted for publication June 26, 1999.

Abstract □ It has been shown in vivo and in vitro that P-glycoprotein (P-gp) may be able to influence the permeability of its substrates across biological membranes. However, the quantitative contribution of the secretion process mediated by P-gp on the overall permeability of membranes has not been determined yet. In particular, observations need to be clarified in which substrates showing high affinity to P-glycoprotein, e.g., verapamil, apparently do not seem to be greatly influenced by P-gp in their permeability and consequently also with respect to their extent of GI-absorption after oral administration, whereas weaker substrates of P-gp, e.g., talinolol, have clearly shown P-gp-related absorption phenomena such as nonlinear intestinal permeability and bioavailability. Experiments with Caco-2 cell monolayers and mathematical simulations based on a mechanistic permeation model should aid in clarifying the underlying mechanism for these observations and quantifying the influence of passive membrane permeability and affinity to P-gp to the overall transmembrane drug flux. In addition, the concentration range of drug at which P-glycoprotein-mediated transport across the biological membrane is relevant should be examined. The permeability of various drugs in Caco-2 monolayers was determined experimentally and modeled using a combination of passive absorptive membrane permeability and a Michaelis–Menten-type transport process in the secretory direction. The passive permeabilities were experimentally obtained for the apical and basolateral membrane by efflux experiments using Caco-2 monolayers in the presence of a P-gp inhibitor. The Michaelis–Menten parameters were determined by a newly developed radioligand-binding assay for the quantification of drug affinity to P-gp. The model was able to accurately simulate the permeability of P-glycoprotein substrates, with differing passive membrane permeabilities and P-glycoprotein affinities. Using the outlined approach, permeability vs donor–concentration profiles were calculated, and the relative contribution of passive and active transport processes to the overall membrane permeability was evaluated. A model is presented to quantitatively describe and predict direction-dependent drug fluxes in Caco-2 monolayers by knowing the affinity of a compound to the exsorptive transporter P-gp and its passive membrane permeability. It was shown that a combination of high P-gp affinity with good passive membrane permeability, e.g., in the case of verapamil, will readily compensate for the P-gp-mediated reduction of intestinal permeability, resulting in a narrow range in which the permeability depends on the apical drug concentration. On the other hand, the permeability of compounds with low passive membrane permeability (e.g., talinolol) might be affected over a wide concentration range despite low affinity to P-gp.

Introduction

The presence of the exsorptive multidrug transporter P-glycoprotein (P-gp) in the apical membrane of absorptive cells throughout the gastrointestinal tract has been identified as a possible source of low or erratic absorption of drugs after peroral dosing. Furthermore, the possibility for drug–drug and drug–food interaction on this level has been pointed out.[1]

It is known that P-gp is abundant in several tissues under physiological conditions, especially in organs and tissues physiologically involved with excretion or distribution to specific organs, e.g., the liver, kidneys, and the blood–brain barrier.[2] In human tissues P-gp has been shown to be mainly expressed in two isotypes, MDR-1 and MDR-3, with distinct differences in substrate specificity.[3] MDR-3 is likely to be involved in the biliary excretion of phosphatidylcholine,[4] whereas the MDR-1 isoform is expressed in the human gastrointestinal tract and is responsible for interference with the intestinal absorption of a number of drugs.[5]

Recently, a model has been introduced to quantitate the affinity of compounds to human P-gp, based on the radioligand displacement principle.[6,7] Several drugs have been classified by this technique with respect to their affinity toward this secretory carrier. Nevertheless, until today, the relevance of the P-gp affinity for the overall transport rate of a P-gp substrate across a biological membrane remains unresolved.

For example, some authors have concluded from a small secretory P-gp-mediated drug efflux, that the respective compound may be a "noncompetitive" inhibitor or an "inhibitor but not a substrate" to P-gp, neglecting, however, the possibility that the P-gp-mediated, saturable secretory transport could be minimized due to high drug concentrations and/or high passive membrane permeability.[8]

Based on the information available today on P-gp-mediated drug secretion, a transport model can be constructed, which contains the relevant parameters controlling drug flux of P-gp substrates across biological membranes expressing the glycoprotein. The use of such a model should enable us to elucidate the quantitative contribution of the P-gp-mediated secretion to the overall membrane permeability of a P-gp substrate.

A scheme of the transport model is shown in Figure 1. As parameters, the model contains the affinity of a compound to P-gp and its passive permeability across the cell membrane. As a model membrane the human colonic carcinoma cell line (Caco-2) overexpressing P-glycoprotein was used. A general outline which describes the experimental approach applied for obtaining data for *passive drug permeability* (by efflux experiments for each compound) and for the *affinity to P-gp* (by a radioligand-binding assay (RBA)[6,7]) is outlined in Figure 2. In a first step, the passive permeation of the apical and basolateral membranes comprising the Caco-2 monolayer was determined, and the permeability was simulated for compounds exhibiting no affinity to P-gp and for P-gp substrates under permeation conditions, where the P-gp "pump" was inhibited by verapamil. In a second step, the model was extended to include

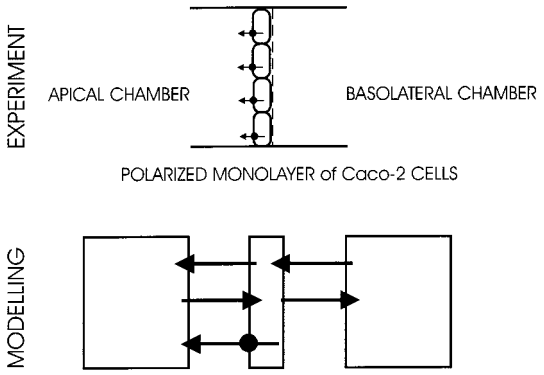

Figure 1—Outline of experimental and modeling approach depicting the compartments as well as passive fluxes and active, P-gp-mediated secretion between the three compartments.

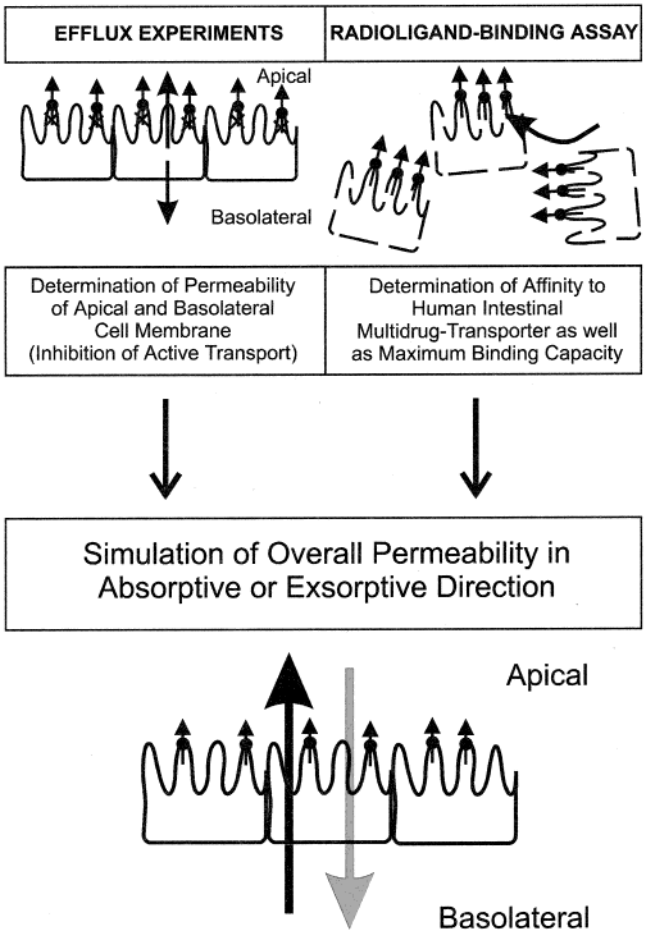

Figure 2—Scheme of experimental approaches used to obtain passive apparent permeablities of apical and basolateral membranes in Caco-2 monolayers by efflux studies as well as affinity to P-gp by radioligand-binding assay.

a saturable, carrier-mediated flux from the intracellular compartment to the apical compartment using affinity data obtained from RBA and estimates of V_{max} obtained from the carrier density and substrate turnover rates. These results were then correlated to data from transport experiments in order to investigate the predictive performance of the model.

Materials and Methods

Cell Culture—Dulbecco's Modified Eagle Medium, fetal calf serum (FCS), L-glutamine 200 mM, penicillin/streptomycin (10000 U/mL, 10 mg/mL), trypsin/EDTA, MEM nonessential amino acids (NEAA), Hanks's Balanced Salt Solution (HBSS), and phosphate-buffered saline (PBS) were from Life Technologies, Paisley, UK. Transwell cell culture inserts used for transport experiments (24 mm, 0.4 μm pore size, polycarbonate membrane) and all other cell culture materials were from Costar, Cambridge, MA. The Caco-2 cells obtained from the American Type Culture Collection (ATCC), Rockville, MD (starting with passage 74), were grown in the presence of 10 nM vinblastine sulfate for induction of P-gp expression. This vinblastine-adapted cell line has been characterized previously with respect to the extent and specificity of P-gp overexpression as well as to growth characteristics of monolayers.[6] For conducting the transport experiments, 90–95% confluent monolayers of vinblastine-induced Caco-2 cells were trypsinized and seeded into Transwell (24 mm, 0.4 μm pore size, polycarbonate membrane) (Costar, Cambridge, UK) cell culture inserts (300000 cells/well) and cultured for 14–17 days. Vinblastine-free medium was provided to the cells 8–16 h before performing binding or transport studies.

Compounds—[^{3}H]Atenolol, [^{3}H]metoprolol, pafenolol, and metoprolol were from Astra Hässle, Mölndal, Sweden. [^{3}H]Verapamil (25 μCi, 84 Ci/mmol) was purchased from New England Nuclear (Boston, MA), and [^{3}H]vinblastine (50 μCi, 16 Ci/mmol) and [^{3}H]-vincristine (50 μCi, 8 Ci/mmol) were from Amersham (Buckinghamshire, UK). Talinolol was a kind gift from Arzneimittelwerk Dresden (Radebeul, Germany). 2-(Morpholino)ethanesulfonic acid (MES) was from Fluka (Gothenburg, Sweden). All other compounds and reagents used were from Sigma (Malmö, Sweden) or BDH (Poole, UK).

Radioligand Binding Assay—The MultiScreen 96-well plate assay system was from Millipore (Eschborn, Germany), MultiScreen 96-well plates with Durapore membrane of 0.22 μm pore size were provided by Millipore (Malmö, Sweden). Liquid scintillation counting was performed by a WinSpectral 1414 counter from Wallac (Turku, Finland), using scintillation fluid Optiphase "Hisafe" 3 from Wallac (Loughborough, UK).

Transport and Efflux Experiments—An Electrical Voltage-Ohm-Meter (EVOM) equipped with "chopstick" electrodes (World Precision Instruments, Sarasota, FL) was used for monitoring transepithelial resistance of Caco-2 monolayers growing in Transwell inserts.

HPLC Analysis—The liquid chromatographic system consisted of a Pharmacia LKB 2150 pump (Uppsala, Sweden), a Perkin-Elmer ISS-100 autoinjector (Allerød, Denmark), a 206 PHD UV-absorbance detector from Linear (Reno, NV), or a Shimadzu RF 350 fluorescence monitor (Kyoto, Japan). Solvents used were of analytical grade and purchased from Skandinaviska Gentech (Kungsbacka, Sweden).

Determination of Affinity to P-gp by Radioligand-Binding Assay—The affinity of the test compounds to P-gp was investigated using a specific and sensitive radioligand binding assay described previously.[7] The displacement of the radioligand [^{3}H]verapamil from the P-gp-preparation by increasing concentrations of the nonlabeled compound of interest was determined. In short, porated cells of the P-gp-overexpressing Caco-2 cell line were incubated in duplicate with 16 different concentrations of each competitor at 37 °C in HBSS buffered with 10 mM MES at pH 7.0 for 30 min in the presence of ATP. Furthermore an ATP-regenerating system consisting of magnesium chloride (10 mM), creatine phosphate (10 mM), and creatine kinase (100 μg/mL) (19 mM) was present in the incubation mixture. The incubation was stopped by removing the liquid, and the filter membranes were washed twice with 100 μL of ice-cold HBSS buffered with 10 mM MES pH 7.0. The filter membranes were incubated with scintillation fluid for 12–16 h, and total radioactivity was determined by liquid scintillation counting.

Transport Experiments in Caco-2 Cell Monolayers—Transport experiments were performed with vinblastine at donor concentrations of 0.1, 1, 10, and 100 μM, with talinolol at 500 μM, and with quinidine at 0.25, 2.5, 25, and 250 μM. Furthermore transport experiments were carried out on atenolol (100 μM), metoprolol (100 μM), pafenolol (1000 μM), vincristine (0.1 μM), and verapamil (0.001 μM). Furthermore, for vinblastine (0.1 μM), vincristine (0.2 μM), talinolol (250 μM), and quinidine (25 μM), transport experiments in the presence of 0.5 mM verapamil were conducted for validation of the passive flux model under exclusion of P-gp-mediated transport. Transepithelial resistance of the vinblastine-induced Caco-2 monolayers (typically around 2500 Ω·

cm^2, for details see ref 6) was monitored prior to and after each transport experiment for verification of the integrity of the cell layer.

Transport experiments were conducted in HBSS buffered with 10 mM MES to pH 6.5 at 37 °C in correspondence to the experimental conditions of the radioligand-binding experiments. Each compound was added to the apical (A) or basolateral (B) compartment, and samples were taken from the corresponding acceptor compartment at predefined times. For vinblastine and vincristine, samples were taken every 30 min for 2.5 h from the acceptor compartments, for talinolol, metoprolol, atenolol, and pafenolol every 15 min for 1 h, and for verapamil and quinidine, samples were taken every 10 min for 1 h. To quantitate the flux across the monolayer, [^{3}H]vinblastine, [^{3}H]vincristine, [^{3}H]metoprolol, [^{3}H]verapamil, and [^{3}H]atenolol were determined by liquid scintillation counting, and talinolol, pafenolol, and quinidine were analyzed using HPLC methods.

Efflux Experiments—The apparent permeabilities of the apical and basolateral membranes of the vinblastine-induced Caco-2 cells were determined in monolayers grown on Transwell filters. The monolayers were loaded (30 min, 37 °C) with a solution of the drug at a concentration of interest in HBSS buffered with 10 mM MES, in the presence of 0.5 mM verapamil, for competitive inhibition of P-gp. When verapamil was studied, 0.5 mM of rhodamine 123 (Molecular Probes, Leiden, Netherlands) was used for competitive inhibition. The monolayers were washed gently with drug-free, ice-cold buffer of the same composition as used for loading of the cells. Efflux over the apical and basolateral membrane was started by placing the drug-loaded monolayer into a fresh six-well plate containing drug-free, prewarmed (37 °C) loading buffer (including verapamil or rhodamine 123) and adding the same buffer to the apical chamber of the Transwell. Samples were taken from the apical and basolateral compartments at 10, 20, and 30 min except for verapamil where samples were taken at 5.0, 7.5, 10.0, 12.5, and 15.0 min.

HPLC Methods—Validation and quality assurance was performed according to international recommendations.[9]

Talinolol and quinidine were determined as described previously.[6] Talinolol was analyzed using a chiral stationary phase (LiChrospher 100 Chiraspher NT, 250 × 4 mm i.d., Merck, Darmstadt, Germany) with ethanol:triethylamine (1000:0.5 [v:v]) and UV-absorbance detection at 245 nm after liquid−liquid extraction into dichlormethane:2-propanol (95:5 [v:v]) and reconstitution with methanol (internal standard pindolol). The method for the quantification of quinidine employed a LiChrospher RP-18 (Merck, Darmstadt, Germany) HPLC analytical column, 150 × 4.6 mm i.d., using methanol:acetonitrile:sulfuric acid (350:100:450 [v:v:v]), containing 10 mM octanesulfonic acid as the mobile phase and fluorescence detection at an excitation wavelength of 350 nm and an emission wavelength of 450 nm.

For the quantification of pafenolol, samples were analyzed by reversed phase HPLC using a LiChrospher RP-18 (Merck, Darmstadt, Germany) stationary phase (150 × 4.6 mm i.d.) and acetonitrile:0.02 M sodium dihydrogen phosphate pH 4.5:triethylamine (400:2000:1.5) as the mobile phase. UV-absorbance at 227 nm was monitored for detection. Pafenolol was determined with a precision and accuracy of 4.1 to 13.4% and −8.2 to 5.4% in the concentration range from 10 to 1000 ng/mL. For details on the analytical validation, see ref 6.

For talinolol, the precision and accuracy in the concentration range of 2.5 to 500 ng/mL per enantiomer was 3.5 to 12.7% and 1.2 to 15.4% ($n = 6$ for each concentration). The analytical method for the determination of quinidine exhibited in the concentration range from 1 to 1000 ng/mL a precision and accuracy of 1.9 to 9.0% and −4.9 to 5.6%.

Data Analysis—*A. Radioligand Binding Assay for P-gp*—A two-affinity model was fitted to the data obtained from competition experiments as described previosly.[6] SigmaPlot 2.01 (SPSS Science Software, Erkrath, Germany) was used for all nonlinear regression analysis.

B. Transport Experiments—The effective permeability (P_{eff}) was determined from the transport data according to

$$P_{eff} = \frac{dC/dt\,V}{AC_D} \tag{1}$$

where dC/dt is the flux across the monolayer, V is the volume of the acceptor chamber (3.0 mL for experiments in the apical to basolateral direction and 1.5 mL for experiments in the reverse direction), A is the apparent surface area of the monolayer used for the transport experiments (4.71 cm^2), and C_D represents the donor concentration of the respective drug. The flux across the monolayer was calculated as the slope of the amount transported vs time.

C. Efflux Experiments—The relationships between the drug efflux and time were adequately described by a monoexponential decay function.[10,11] The apparent permeability, P_{eff}, of the cell membrane was calculated from initial drug flux versus time into the respective compartment and the concentration used for loading of the cell monolayer.[10,11]

Modeling of Transport Experiments Using Efflux Permeabilities and Data from Radioligand Binding Assay—*A. Passive Permeability without P-gp Activity*—For modeling transport experiments of compounds lacking affinity to P-gp (e.g., atenolol), and transport with inhibition of P-gp, the passive drug fluxes for all three compartments depicted in Figure 1 were calculated according to

$$\frac{dM}{dt} = P_{eff,apical/basolateral} A C_{compartment} \tag{2}$$

where $P_{eff,apical/basolateral}$ was the apparent permeability of the apical or basolateral membrane, as determined from efflux experiments, A is the apparent surface area of the monolayer (4.71 cm^2), and $C_{compartment}$ is the concentration of the analyte in the respective compartment, calculated from the amout of drug in the compartment, the compartmental volume (1.5/3.0 cm^3 for the apical/basolateral compartment and 0.0247 cm^3 for the intracellular compartment of a Caco-2 cell monolayer with an area of 4.71 cm^2. The mean cell number of a monolayer amounted to 2.1×10^5 cells per cm^2 and was determined following trypsinization of monolayers grown in Transwells. The cell volume of 25 pL per Caco-2 cell was calculated on the geometrical dimensions of an ashlar with a basal square area of 4.8×10^{-6} cm^2 and a height of of 30 μm). The time interval used for numerical integration was 2−6 s. The concentration in the acceptor compartment was predicted for the various sampling times, and the apparent permeability of the substrate across the Caco-2 monolayer was calculated.

B. Transport Experiments Including Secretion by P-gp—For the transport experiments performed in the presence of functional P-gp, the carrier-mediated secretion of the drug from the cellular compartment was calculated according to

$$\text{carrier-mediated flux} = A_{max}\left(\frac{(1 - F_h)CC}{K_{i_1} + CC} + \frac{F_h CC}{K_{i_2} + CC}\right)t \tag{3}$$

where the maximum capacity of the P-gp pump, A_{max} [mol/s], is calculated from

$$A_{max} = N_{P-gp} A \tag{4}$$

N_{P-gp} is the number of P-gp molecules per cell, as determined by RBA-saturation experiments in P-gp-overexpressing Caco-2 cells as 800000 binding sites per cell,[6] and A is the average ATP-turn over per second (25 s^{-1}).[12] F_h is the fraction of high-affinity binding sites for the respective compound, K_{i_1} and K_{i_2} are the respective equilibrium dissociation constants ("affinity constants") to P-gp, both determined from competition experiments by radioligand-binding assay, CC is the intracellular concentration of the drug, and t is the interval of numerical integration (2−6 s). All simulations were performed using S-PLUS 3.3 (MathSoft, Seattle, WA).

Results

Permeability across Caco-2 Monolayer—*A. Passive Permeation without Involvement of P-gp*—In this first step, the diffusional transport, i.e., transport for nonsubstrates of P-gp or for P-gp substrates in the presence of 0.5 mM verapamil, was determined from the permeability of the apical and basolateral membranes in efflux experiments. The fluxes across the membranes were calculated from the passive permeabilities of the single membranes given in Table 1.

Table 1—Parameters Used for Predicting the Permeability in Caco-2 Monolayers of the Respective Compound. Passive Permeability (P_{apical} and $P_{basolateral}$) of the Apical and Basolateral Membrane of Caco-2 Monolayers as Determined by Efflux Experiments with Inhibition of P-gp, As Well As Affinity Constants (K_i) to P-gp and Fraction of High Affinity Binding Sites (f_H), As Determined by Radioligand Binding Assay

	passive permeability		affinity data		
compound	$P_{apical} \times 10^6$[cm/s]	$P_{basolateral} \times 10^6$ [cm/s]	K_{i_1} [μM]	K_{i_2} [μM]	f_H
atenolol	0.57	0.69	–	–	–
talinolol	1.3	3.6	72	1570	0.20
metoprolol	43	45	200	1750	0.46
pafenolol	0.70	1.3	5.5	3200	0.20
quinidine	75	96	2.6	225	0.21
verapamil	519	330	0.30	3.6	0.42
vinblastine	18	33	0.15	107	0.34
vincristine	0.33	0.29	0.50	150	0.20

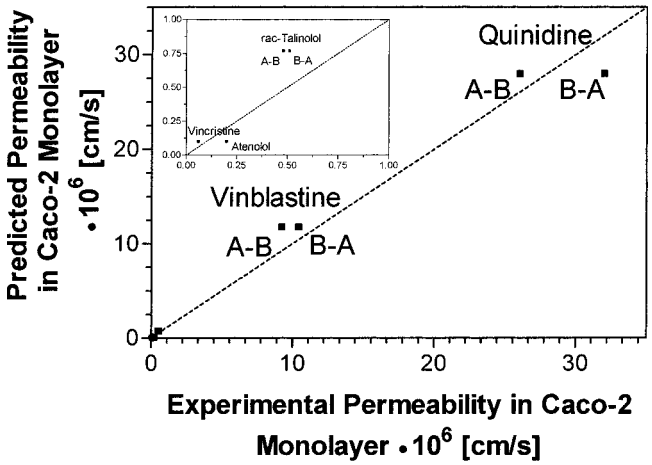

Figure 3—Correlation of experimentally obtained and predicted permeabilities in Caco-2 monolayers for nonsubstrate (atenolol, $C_D = 100$ μM) and different P-gp substrates under inhibition of P-gp (vinblastine, $C_D = 0.1$ μM, vincristine, $C_D = 0.2$ μM, talinolol, $C_D = 250$ μM, quinidine, $C_D = 25$ μM) to evaluate the validity of the passive-flux model used. The hatched line represents the line of identity.

The obtained apparent permeability coefficients were compared with those experimentally determined in transport experiments with Caco-2 monolayers. The results reveal a good correlation between experimental and predicted data, as shown in Figure 3. Thus the passive-flux model was considered an adequate basis for advancing to the next step, the carrier-mediated secretion.

B. Transport Experiments with Functional P-gp in Caco-2 Monolayers—Secretory flux mediated by P-gp was introduced into the permeability model by adding a two-affinity, Michaelis–Menten-type transport process. The values of the affinity constants and the relative proportions of high and low affinity binding sites determined from the radioligand-binding assay are listed in Table 1. The effect of the intracellular drug concentration on the flux mediated by the P-gp pump is shown for verapamil, vinblastine, quinidine, and talinolol in Figure 8. According to these results, the "working range" of P-gp, compared to a classical, single-affinity Michaelis–Menten process is greatly enhanced by the two-affinity mechanism.

The predictive model turned out to satisfactorily describe the permeability of the monolayer for a number of different solutes and permeation conditions, such as various concentrations and permeation directions.

Figures 4 and 5 show the correlations between the observed and predicted results in transport experiments on vinblastine and quinidine. The experiments were performed at four different concentrations covering a 1000-fold difference for both, apical to basolateral and the reverse direction across the P-gp overexpressing Caco-2 monolayers.

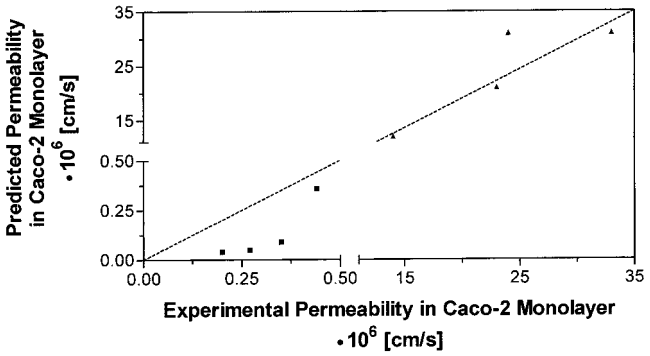

Figure 4—Correlation of experimentally obtained and predicted permeabilities in Caco-2 monolayers for vinblastine in A–B (■) and B–A (▲) direction.

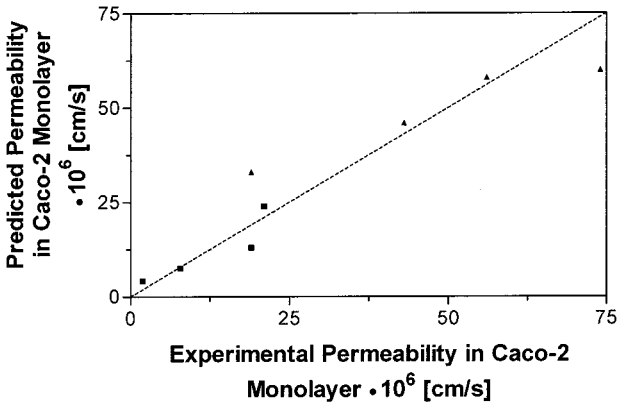

Figure 5—Correlation of experimentally obtained and predicted permeabilities in Caco-2 monolayers for quinidine in A–B (■) and B–A (▲) direction.

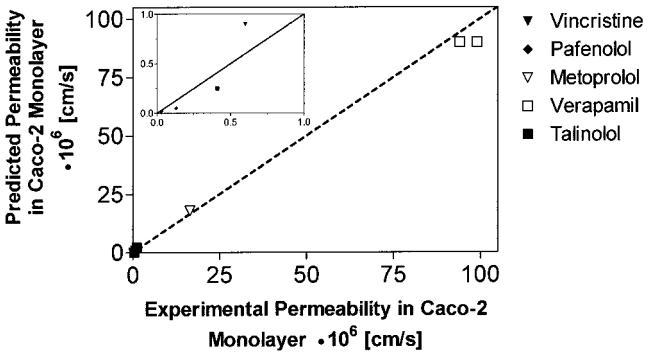

Figure 6—Correlation of experimentally obtained and predicted permeabilities in Caco-2 monolayers for verapamil, vincristine, metoprolol, talinolol, and pafenolol.

Similar results were obtained for various other lipophilic and hydrophilic compounds including examples with both high and low affinity to P-gp, Figure 6.

Dependence of Epithelial Permeability on Apical Drug Concentration—The results of simulations of the transport in the absorptive direction (A–B) in Caco-2 monolayers for four P-gp substrates with varying passive permeabilities and affinities to P-gp at different donor concentrations are given in Figure 7. The dashed line represents the permeability coefficient determined in the absence of P-gp-mediated secretion, in accordance with the fact, that for a diffusive transport process, the permeability is independent of the concentration of the permeating species.

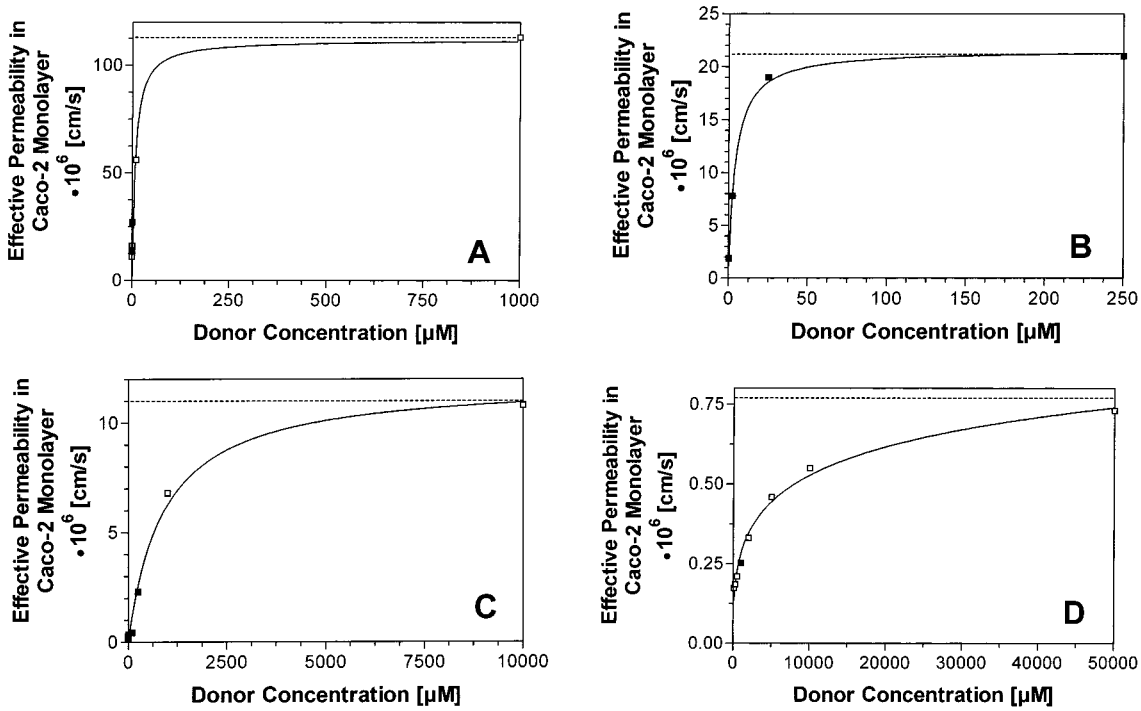

Figure 7—Simulated (□) and experimentally determined (■) effective permeabilities in Caco-2 monolayers (A–B direction) of verapamil (A), quinidine (B), vinblastine (C), and talinolol (D) at different donor concentrations, as well as passive permeability in absence of P-gp (----). The line is drawn according to the Michaelis–Menten equation.

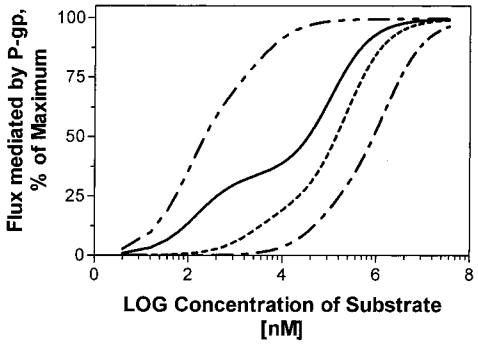

Figure 8—Secretory capacity of P-gp for verapamil (-•••-), vinblastine (—), quinidine (----) and talinolol (-•-•-). Percentage of maximum secretion rate as a function of the respective substrate concentration.

Depending on the drug's affinity to P-gp and its passive membrane permeability, different permeability versus initial donor concentration profiles can be observed:

Verapamil—This drug exhibits very high passive permeability of the cell membrane and high affinity to P-gp (Table 1). This results in a pseudolinear concentration-independent permeability of the Caco-2 cell monolayer. Only at very low donor concentrations, the effect of P-gp is visible, resulting in a systematic trend toward lower permeability values.

Vinblastine and Quinidine—Both compounds are characterized by moderate-to-high passive permeability and moderate-to-high affinity to P-gp, resulting in a strong influence of P-gp on the permeability in the medium and low drug concentration range. For vinblastine this resulted in permeability values comparable to the paracellular flux of small molecules, e.g., mannitol, in Caco-2 monolayers.

Talinolol—This compound possesses moderate-to-low passive permeability and moderate-to-low affinity to P-gp. This results in a clearly visible dependence of P_{eff} on the apical drug concentration over a wide concentration range. Accordingly, the permeability approached that of paracellular flux in the lower concentration range.

Discussion

The results presented here were obtained using the same P-gp-overexpressing cell line for the transport experiments that has also been used for the binding studies. This cell line has been demonstrated to selectively overexpress P-gp and to exhibit expression of other cation transport systems only to a negligible extent. The permeabilites of various P-gp substrates determined in this system were accurately predicted by a model employing the passive drug flux across the apical and basolateral membranes and the P-gp-mediated flux. In the case of vinblastine an overestimation of the influence of P-gp by the model, especially in the low permeability range was obvious. The reason for this might be that only a part of the total P-gp identified in the binding assay is functional, and, e.g., intracellular P-gp may well contribute to substrate binding but not to its transport.[13] Another explanation could be that the model described here does not include paracellular permeation, which might become relevant at the very low permeability range.

The apparent permeability vs donor concentration profiles presented here allow an assessment of the possible compromising influence of P-glycoprotein on the membrane permeability of a drug. The four compounds for which the transport model was applied, verapamil, quinidine, vinblastine, and talinolol, show distinct differences in the quantitative contribution of P-gp-related secretion to the overall membrane permeability. For example, it can be stated that the membrane permeability of verapamil is hardly affected despite the high affinity of verapamil to P-gp. On the other hand, talinolol exhibits a strong influence of P-gp-mediated transport on the permeability over a wide concentration range, despite the fact that it has much lower affinity to P-gp than verapamil.

It can be concluded from the present findings that the passive permeability of a compound in the absence of P-gp-mediated transport equals the maximum possible permeability. Affinity to P-gp determines the shape and concentration range of the observed negative deviation from this

maximum permeability. In addition, this is governed by the intracellular concentration of the compound, being a function of its diffusive permeability of the apical and basolateral membrane.

Assuming 0.25 to 0.5 L of liquid available within the GI tract for dissolution of a perorally administered drug and the dose, an estimate of the local concentration range of a drug in the intestine can be guessed in order to apply the in vitro data to the in vivo situation. For talinolol, nonlinearity in absorption was detected following peroral dosing of four different doses spread over a 16-fold range (25−400 mg of the racemate) in humans.[14] Due to the absence of metabolic degradation, this effect was attributed to saturable intestinal secretion, most probably P-gp. These observations are well in accordance with the results presented here, thus demonstrating the in vivo relevance of this simulation approach. Furthermore, for verapamil, almost complete absorption has been found following p.o. administration of different therapeutic doses.[15,16] This is also in accordance with the predictions of the model presented here. For vinblastine, the bioavailability after peroral administration is negligible at therapeutic doses of 3.5 mg/m^2 body surface in adults, a fact that can also be derived from the P_{eff} vs donor concentration plots provided here.

The findings in this communication can thus be taken as an extension of the hypothesis by Hunter and Hirst[17] with respect to the influence of ATP-dependent efflux on the permeability of physiological barriers. The new findings reveal that relevant deviations from the maximum permeability by simple diffusion requires both affinity to P-glycoprotein as well as appropriate physicochemical properties of the permeating species to reach intracellular drug concentrations in the "working range" of the secretory carrier. Thus the approach chosen here reveals that affinity to P-gp may not necessarily compromise the absorption of a compound, even for a high affinity ligand, as, e.g., shown for verapamil.

In conclusion, high permeability drugs have a much decreased chance that their intestinal permeability is limited by P-glycoprotein activity, whereas low permeability drugs, irrespective of their affinity to P-gp, have a much greater chance of undergoing permability restriction mediated by P-gp at therapeutically applied peroral doses.

Accepted for publication July 21, 1999.

Abstract □ This paper examines the effect of water content, water activity, and glass transition temperature (T_g) on the deamidation of an asparagine-containing hexapeptide (VYPNGA; Asn-hexapeptide) in lyophilized poly(vinyl alcohol) (PVA) and poly(vinyl pyrrolidone) (PVP) at 50 °C. The rate of Asn-hexapeptide deamidation increases with increasing water content or water activity and, hence, decreasing T_g. The rate of deamidation is more sensitive to changes in these parameters in PVA than in PVP. Deamidation is clearly evident in the glassy state in both formulations. In the glassy state, the peptide is more stable in PVA than in PVP formulations but is less stable in the rubbery state. No single variable (water content, water activity, or T_g) could account for the variation in deamidation rates in PVA and PVP formulations. Deamidation rates were correlated with the degree of plasticization by water (distance of T_g from the dry intrinsic glass transition temperature); coincident curves for the two polymers were obtained with this correlation. Deamidation in PVA and PVP was closely correlated with the extent of water-induced plasticization experienced by the formulation relative to its glass transition at 50 °C, suggesting that the physical state of formulations could be used to predict chemical stability.

Introduction

Many proteins are formulated with polymers to protect against degradation during storage and/or processing or to provide a matrix for controlled release. Moisture content, polymer composition, and temperature can affect the stability of solid protein formulations by influencing the rates of chemical degradation reactions, such as asparagine deamidation.[1−4] Hydration of these solid formulations can easily occur during processing, storage, or after in vivo implantation. However, although the importance of polymer selection and moisture content is recognized, a complete mechanistic understanding of their effects on the chemical stability of proteins has not been developed. This manuscript addresses this mechanistic issue by examining the deamidation of a model hexapeptide (Val-Tyr-Pro-Asn-Gly-Ala, Asn-hexapeptide) in lyophilized poly(vinyl alcohol) (PVA) and poly(vinylpyrrolidone) (PVP) matrixes at various hydration levels at a constant temperature of 50 °C.

Water can affect the chemical stability of solid protein formulations in at least three ways: (1) as a solvent, (2) as a reactant in a reaction such as hydrolysis, and/or (3) as a plasticizer.[1,5] Water as a plasticizer of amorphous solids induces a physical transition from a brittle, dynamically constrained glassy state to a more mobile, less viscous, rubbery state at some temperature T_g, the glass transition temperature.[1] Because many reactions require sufficient mobility of the reactants to proceed, an increase in mobility with water content could promote chemical reactivity.[1,6,7] The decrease in T_g with increasing water content is often cited as an important factor in protein degradation in solids.[1,2,4,8] The effect of water as a plasticizer may be qualitatively described by changes in T_g produced by a given amount of water. The effect of water as a solvent or reactant should be related to its concentration (water content) or chemical potential (water activity). We report here the effects of water on the stability of the Asn-hexapeptide in solid formulations as a function of water content, water activity, and T_g.

Poly(Vinyl Alcohol) (PVA)	Poly(Vinyl Pyrrolidone) (PVP)
2 Molecular Weights	2 Molecular Weights
PVA 103 - 20,000	K12 - 4,000
PVA 125 - 125,000	K17 - 10,000

Scheme 1—Structures of poly(vinyl alcohol) (PVA) and poly(vinyl pyrrolidone) (PVP).

Deamidation at asparagine residues is one of the most prevalent chemical instabilities in proteins and peptides. The Asn-hexapeptide was selected as a model compound because its deamidation kinetics and mechanisms have been well characterized in solution.[9,10] This degree of mechanistic understanding makes the Asn-hexapeptide ideally suited for a study of the effect of water on reaction kinetics and mechanisms in solid polymer matrixes. PVP and PVA were selected as model polymers because they are commonly used pharmaceutical excipients with a simple chemical structure. Both polymers are linear, amorphous, polar, and hydrophilic (Scheme 1). Each consists of a vinyl backbone with pendant functional group (*N*-pyrrolidone for PVP and hydroxyl for PVA) at a 1,3-separation.

This paper examines the effect of water on Asn-hexapeptide deamidation in PVA and PVP at 50 °C. The relationships between water content, water activity, and T_g in these two polymer formulations will first be determined to characterize the effect of water on these polymer matrixes. Then the relationship between deamidation rates and residual moisture will be explored by correlating deamidation rates with formulation water content, water activity,

and T_g. The impact of polymer composition on chemical stability is addressed by comparing these correlations in PVA and in PVP.

Experimental Section

Materials—L-Val-L-Tyr-L-Pro-L-Asn-Gly-L-Ala (Asn-hexapeptide) was synthesized by Dr. Madhup Dhaon (Abbott Laboratories, North Chicago, IL). The buffers and salts used in this study, together with organic solvents used in the HPLC mobile phase, were purchased from Mallinckrodt Chemical, Inc. (Paris, Kentucky). The two types of PVA, under the trade names of Airvol 103 and 125 [average MW 20 000 and 125 000], were obtained from Air Products and Chemicals, Inc. (Lehigh Valley, PA). The two types of PVP, under the trade names of Kollidon K12 and K17 [MW 4000 and 10 000], were obtained from BASF Corporation (Parsippany, NJ). Trifluoroacetic acid (TFA) was obtained from Pierce (Rockford, IL). Deionized and distilled water was used throughout.

Preparation of PVA and PVP Formulations—Prior to use in formulations, the polymers were dissolved in water and dialyzed. Spectra/Pro molecular weight cutoff (MWCO) cellulose membranes from Spectrum Medical Industries (Houston, TX) were used to remove low molecular weight impurities. Membranes of MWCO 1000 and 3500 were used for PVP K12 and PVP K17, respectively. PVA 103 and PVA 125 were dialyzed using 10 000 and 50 000 MWCO membranes, respectively. After dialysis, the polymers were lyophilized in a VirTis Unitop 600SL Freeze-Dryer (Gardner, NY).

The polymers were then mixed with 0.01 M potassium phosphate buffer (pH 6.8) to yield 5% w/w polymer solutions. The PVP dissolved readily in buffer. The PVA mixtures were heated at 120 °C for 25 min to dissolve the polymers and then allowed to cool to 25 °C. The Asn-hexapeptide, first dissolved in a small amount of buffer, was added to the polymer solutions to produce a peptide concentration of 1.0−1.5 mg/mL (1.5−2.5 mM), as verified by HPLC. The pH of the resulting solution was measured with a Corning pH/ion Analyzer 350 with a Corning Semi-micro Combination Electrode (Corning, NY) and, if needed, was adjusted to pH 6.8 with NaOH.

The polymer and peptide solutions were placed into individual syringes fitted with 21-gauge needles. The solutions were then dispensed in a dropwise manner into liquid nitrogen to form individual frozen pellets ~2 mm in diameter. The frozen pellets were placed in a FTS Dura-Stop MicroProcessor Freeze-Dryer (FTS Systems, Inc., Stone Ridge, NY) with the shelves precooled to −40 °C. The chamber vacuum was set at 150 mTorr. The shelf temperature was ramped in 10 °C intervals every 3−4 h up to −5 °C. Afterward, shelf temperature was increased in 10 °C intervals every 6−8 h. The final drying was conducted at 25 °C for 17 h. After lyophilization, the resulting white spherical pellets were transferred into containers in a PlasLabs Dry Box (Lansing, MI), which was purged with dry nitrogen, and placed in a desiccator containing $CaSO_4$. The peptide loads for PVP and PVA were 0.017 ± 0.0006 and 0.024 ± 0.001 g/g solid, respectively, based on the maximum amount released. To determine peptide load, both PVA and PVP formulations were immersed in water. The PVP formulations dissolved completely, whereas the PVA pellets released >95% of their theoretical load after 4−8 h. The final composition of the dry formulation (in w/w) was ~2% peptide, 2% buffer, and 96% polymer, with a residual moisture content of <1%.

Characterization of Water Sorption Behavior—Sorption isotherms relating formulation water content to relative humidity (RH, water activity) at 50 °C were generated using a Controlled Atmosphere Microbalance (CAM), which monitored the sample mass at a specified relative humidity. The CAM was built at Pharmacia & Upjohn, Inc., as previously described.[11] The CAM consisted of a Cahn microbalance within an enclosed glass chamber, a nitrogen gas saturator assembly, water baths, and digital interfaces. Data were collected on a 486 PC computer and stored in a Microsoft Excel spreadsheet. Each CAM run was conducted on 5−10 mg of sample over a range of 0 to 85% RH at 5% RH step increases. When equilibrium was achieved, the system would step the chamber humidity to the next level. The criterion for equilibrium was defined as no more than a 0.5 μg change in sample mass over a 20-min interval. Water sorption was rapid, with 95% of the equilibrium mass reached within 20 min. The CAM took, on average, 2−3 h to achieve equilibrium at 5% RH intervals. Water desorption of the PVP and PVA formulations showed little or no hysteresis (data not shown), evidence that equilibrium water content was reached.

Two points on each isotherm were verified independently by thermogravimetric analysis (TGA). Samples from each formulation were stored at two RHs. The water contents were then determined with a DuPont 2050 TGA with a 2200 Data Analysis System from TA Instruments (Newcastle, DE). The water content of each sample was defined as the weight loss during heating from 25 to 120 °C at a heating rate of 10 °C/min.

The water sorption data obtained by the CAM were fitted to the Guggenheim−Anderson−deBoer (GAB) equation (eq 1), which describes the sorption of water by heterogeneous sorbents or solids.[1]

$$W = \frac{W_m C_g K_{GAB}(\rho/\rho_o)}{[1 - K_{GAB}(\rho/\rho_o)][1 - K_{GAB}(\rho/\rho_o) + C_g K_{GAB}(\rho/\rho_o)]} \quad (1)$$

In eq 1, W is the mass (mg) of water vapor adsorbed per mg of dry solid at (ρ/ρ_o), (ρ/ρ_o) is the relative vapor pressure, W_m is generally regarded as the amount of water vapor necessary to saturate the heterogeneous active sorption sites, and C_g and K_{GAB} are dimensionless constants that are related to the thermodynamic parameters for sorption of strongly and weakly interacting water.[12−14] The GAB equation (eq 1) was used because it provides the ability to relate vapor pressure and water content of the systems under investigation. Alternatively, material science-based descriptions for water sorption isotherms of amorphous solids may be more thermodynamically and physically relevant for these systems.[15] However, these alternative models are not necessary to empirically describe the relationship between vapor pressure and water content. All curve fitting of data was carried out with SigmaPlot Version 3.0 (Jandel Corporation, San Rafael, CA).

The relative water vapor pressure (ρ/ρ_o) or humidity was taken to be equal to the activity of water in the systems studied. These systems were assumed to be in equilibrium because the formulations were stored in a closed system (glass chamber) at constant temperature (50 °C) and pressure during the study.

Characterization of Formulation Glass Transition Temperature—A Thermal Analyst Instruments 2920 DSC outfitted with a TA 2200 Data Analysis System (Newcastle, DE) was used to determine T_g values. The DSC was calibrated with indium. A modulated temperature ramping program was used in which the sample temperature was increased at 2 °C/min with a modulation of ±1 °C/min. The DSC was cooled with a liquid nitrogen cooling apparatus. After storage at 50 °C under various RHs for 4 days, ~3−5 mg of each sample was sealed in aluminum DSC pans obtained from TA Instruments (Newcastle, DE). The T_g was defined as the midpoint of the glass transition. The T_g measurements for each formulation at each RH were made in triplicate.

The T_g data were fitted to the Gordon−Taylor equation (eq 2) for two miscible components:

$$T_g = \frac{w_1 T_{g_1} + K_{GT} w_2 T_{g_2}}{w_1 + K_{GT} w_2} \quad (2)$$

where T_g is the glass transition temperature of the mixture, w_1 and w_2 are the weight fractions of the individual components, T_{g1} and T_{g2} are the intrinsic T_gs of each component, and K_{GT} is a constant that can be considered to be a ratio of the free volumes of the two components.[16,17] The T_g for water was set at the estimated value of 135 K.[17]

Stability Study—For the stability study, the solid formulations were transferred to 2-mL glass lyophilization vials, with each vial containing ~5 mg of pellets. The vials were placed in several closed controlled RH chambers, which were maintained at various specified RHs (11−75% RH) using saturated salt solutions.[18] The solid formulations were allowed to equilibrate in chambers at 20 °C for 12 h. Afterward, samples from various RHs chambers were removed and analyzed for Asn-hexapeptide and its degradation products. No degradation products were observed after this initial equilibration period. The samples were then transferred to chambers with similar RHs in a 50 °C room for the stability study. Saturated solutions of LiCl, $MgCl_2$, $Mg(NO_3)_2$, KI, and NaCl were

used to maintain RHs of 11, 30, 45, 64, and 75%, respectively, at 50 °C. $CaSO_4$ was used as the desiccant for the 0% RH condition. Samples were prepared in triplicate. Peptide composition was assayed by HPLC after various storage times to determine degradation kinetics and product distribution. The duration of the study was 6 months.

Peptide Analysis—Analyses of Asn-hexapeptide and its degradation products were performed by reversed-phase HPLC according to an established method.[10] The system consisted of a Varian VISTA 5500 liquid chromatography system with a Varian UV200 detector and a Varian Series 600 Data System (Walnut Creek, CA). Peptide separation was performed with an Alltech Econosphere C18, 5 μm, 250 × 4.6 mm analytical column (Deerfield, IL) in conjunction with a Applied Biosystems Brownlee Spheri-5, C-18, 5 μm, 30 × 4.6 mm guard column (San Jose, CA). A Perkin-Elmer ISS-100 Autoinjector (Norwalk, CT) was used to deliver 50-μL sample injections. An isocratic elution method was used at a flow rate of 0.8 mL/min. The mobile phase consisted of 6% (v/v) acetonitrile and 0.1% (v/v) TFA in 40 mM ammonium acetate at a pH of 4.4, which was adjusted using 1 N HCl. An ultraviolet (UV) detection wavelength of 218 nm was used to detect Asn-hexapeptide and its degradation products, which were identified via co-injection with known standards.

Kinetic Measurements—After a specified time interval, triplicate samples of each formulation at each RH were removed for peptide analysis. A 0.5-mL aliquot of deionized water was added to each vial. The PVP formulations dissolved readily in water. However, PVA was not soluble in water without heating. Therefore, the PVA pellets were immersed in water at 4 °C for 6 h and were shaken periodically. Less than 0.5% peptide decomposition occurred during this extraction ($t_{1/2}$ = 1150 h). More than 90% of the peptide was released in the first 2 h, with >95% released after 6 h. The pH of the resulting solution was ~6.8. The content of Asn-hexapeptide in the resultant solution was assayed by the HPLC method already described.

The observed rate constant (k_{obs}) for the disappearance of Asn-hexapeptide was determined from the slope of the plot of ln(% peptide remaining) versus time. This calculation was based on the pseudo-first-order degradation kinetics previously described for this peptide in solution[10] and solid[8] states according to the following relationship:

$$\ln\frac{A}{A_o} = -k_{obs}t \qquad (3)$$

where A is the amount of peptide at time t, and A_o is the initial peptide concentration. Analysis of kinetic data was handled with Excel Version 5.0 (Microsoft Corporation, Redmond, WA).

Results

Physical Characterization of Formulations—*Physical Appearance*—PVP and PVA formulations stored under desiccated or dry conditions were white, smooth, spherical pellets. The texture for the dry PVP formulation (water content < 0.004 g/g wet solid) was powdery, whereas dry PVA (water content < 0.003 g/g wet solid) had a fibrous, Styrofoam-like texture. As the RH increased, both PVP and PVA pellets decreased in diameter. At lower RHs (11% RH), this decrease in pellet size was the most noticeable change in PVP and PVA. At intermediate RHs (30−45% RH), the PVP pellets were dome shaped and sticky and had a yellowish, melted appearance, whereas the PVA pellets took on a wrinkled appearance and were less foamy in texture. At high RH (65−75% RH), the PVP pellets had become an opaque, viscous fluid, which coated the bottom of the vial. The PVA pellets had collapsed into a hard sphere with a wrinkled surface.

Water Sorption Isotherms—Researchers have reported that residual water in solid formulations can compromise drug stability.[1,19] Therefore, characterizing the hydration behavior of these polymers is important. The water sorption isotherms, which relate formulation water content to relative water vapor pressure or humidity, are shown in Figure 1 for PVA and PVP at 50 °C. The water content of both polymers increases with increasing RH. PVP and PVA formulations have different water sorption behaviors, with PVP being more hygroscopic than PVA. Thus, water activity is greater in PVA than in PVP at a given water content.

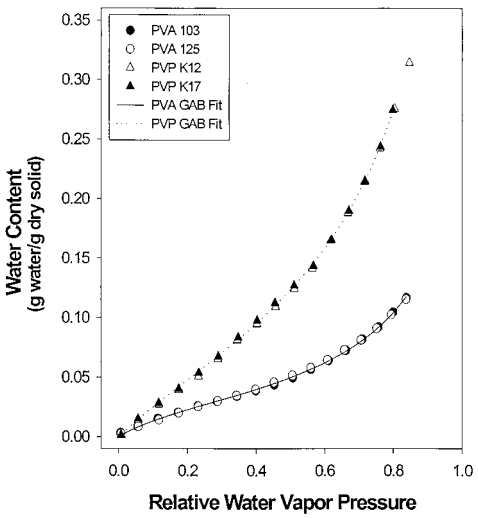

Figure 1—Water sorption isotherms for PVA and PVP formulations at 50 °C. The curved lines are nonlinear least-squares fits of the sorption data to the GAB equation (eq 1).

Table 1—Parameter Values and Standard Errors Derived from Fitting the Water Sorption Data at 50 °C to the GAB Equation (eq 1) for PVA and PVP Formulations

formulation	W_m (g H_2O/g dry solid)	C_g	K_{GAB}
PVA 103	0.0350 ± 0.0010	5.54 ± 0.42	0.861 ± 0.008
PVA 125	0.0378 ± 0.0007	5.00 ± 0.20	0.835 ± 0.006
PVP K12	0.111 ± 0.003	2.61 ± 0.11	0.825 ± 0.007
PVP K17	0.101 ± 0.003	3.13 ± 0.17	0.849 ± 0.009

The curved lines in Figure 1 represent the nonlinear least-squares fit of the water sorption data to the GAB equation (eq 1). The fitted parameter values of the GAB equation are shown in Table 1. Polymer molecular weight did not appear to significantly affect water sorption behavior for either PVA or PVP at 50 °C. The W_m value for PVP was ~3 times greater than for PVA, which is consistent with the greater affinity of PVP for water. The GAB equation, together with these fitted values, was used to relate water content and water activity in the analysis of stability data.

Formulation T_g as a Function of Water Content—Water in amorphous polymers can act as a plasticizer, increasing both the segmental mobility of the polymer chains and the flexional and translational mobility of incoporated low molecular weight solutes.[20] This increased mobility of the peptide in water-plasticized PVA and PVP systems may contribute to reactivity. One way to monitor the plasticizing effect of water is to measure the T_g. Figure 2 shows the effect of water content on formulation T_g. As water content increased, the T_g of PVA and PVP formulations decreased, indicating that water acts to plasticize both polymers. The dry PVP T_g was 80° greater than that of PVA (Table 2). At similar water contents, the PVP T_g was greater than the PVA T_g. Formulations with T_gs above the experimental temperature (T_{exp}= 323 K or 50 °C) were considered to be glassy, whereas those with T_gs of <323 K were assumed to be in the rubbery state.

The solid (PVA 103) and dashed (PVP K17) curves in Figure 2 represent the nonlinear least-squares fits of the

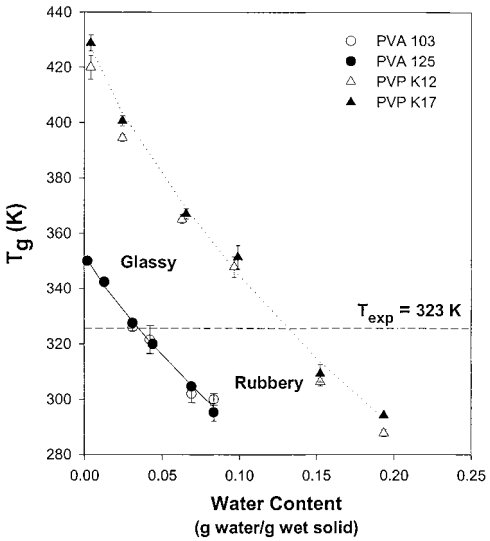

Figure 2—Glass transition temperature (T_g) as a function of water content. The curved lines are nonlinear least-squares fits of the sorption data to the Gordon–Taylor equation (eq 2). The labels "Glassy" and "Rubbery" indicate the physical state of the polymer matrix at the experimental temperature, T_{exp} (dashed line). Matrixes with $T_g > T_{exp}$ are glassy at T_{exp}; matrixes with $T_g < T_{exp}$ are rubbery at T_{exp}. Error bars represent standard deviations ($n = 3$).

Table 2—Glass Transition Data for PVA and PVP[a]

formulation	intrinsic T_g (K)[b]	fitted K_{GT} value	W_g (g H_2O/g wet solid)[c]	A_g[d]
PVA 103	346.3 ± 3.5	0.276 ± 0.04	0.0383	0.40
PVA 125	347.0 ± 1.1	0.266 ± 0.09	0.0384	0.40
PVP K12	421.1 ± 3.8	0.265 ± 0.08	0.127	0.58
PVP K17	429.4 ± 4.4	0.281 ± 0.09	0.135	0.60

[a] The K_{GT} values are from data fitted to the Gordon–Taylor equation (eq 2), and the T_g for water was assumed to be 135 K. [b] T_g value for "dry" formulations (water content < 0.004 g/g dry solid). [c] Amount of water required to reduce T_g to the experimental temperature (323 K). [d] Water activity corresponding to the W_g value.

data to the Gordon−Taylor equation (eq 2). The observed depression of T_g by an increase in water content was well described by the equation, suggesting that the mixing behavior of water with PVA and PVP was ideal.[17] The fitted K_{GT} values (Table 2), which can be considered to be the ratio of free volumes of water and polymer, were similar to the estimated K_{GT} values of 0.29 (PVA) and 0.25 (PVP). The K_{GT} values were estimated based on T_g and density values given for water, PVP, and PVA in the cited references.[17,21]

From the Gordon−Taylor equation (eq 2), the amount of water (W_g) required to induce the glass transition (i.e., to bring T_g into equality with T_{exp}) was calculated for PVA and PVP. The W_g values and the corresponding water activities at T_g (A_g) are listed in Table 2. Three times more water was required to induce the glass transition at 50 °C in PVP than in PVA, in part because of the greater dry T_g of PVP. Correspondingly, the water activity at the glass transition ($T_g = T_{exp}$) was higher in PVP than PVA. Initially, the same amount of water had a greater plasticizing effect on PVP. We will correlate formulation T_g with deamidation rates to evaluate the potential for a relationship between chemical instability and formulation viscosity.

Polymer molecular weight did not significantly affect the T_g values for either PVA or PVP. In general, T_g values are expected to increase with increasing polymer molecular weight up to a limiting or "persistent" T_g value, although both decreases in T_g with molecular weight and molecular-weight-independent T_g values have also been observed.[22]

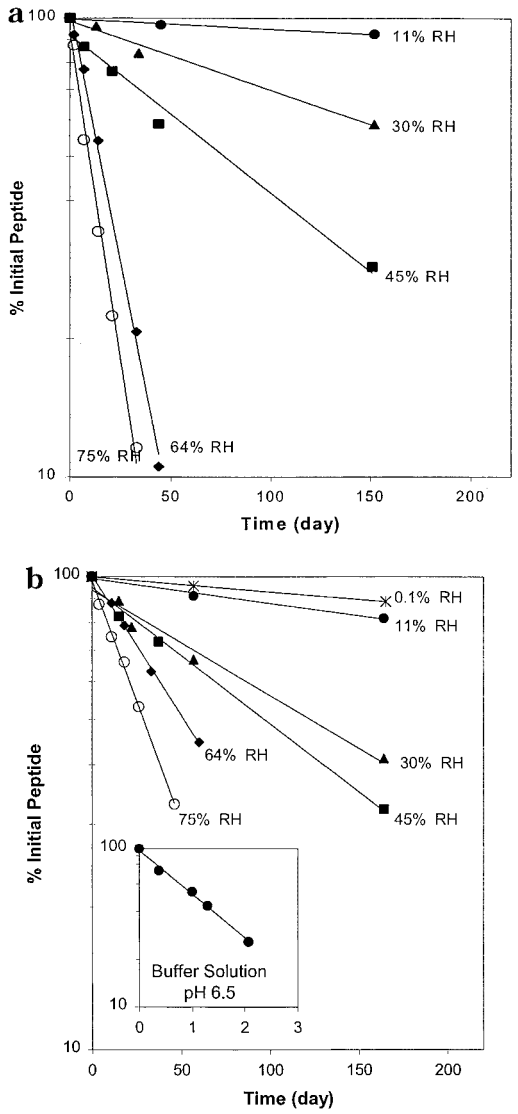

Figure 3—Asn-hexapeptide degradation profiles at various RHs at 50 °C for (a) PVA (Airvol 103) and (b) PVP (Kollidon K12) formulations ($n = 3$). The insert in Figure 3b shows the disappearance of the Asn-hexapeptide in polymer-free phosphate buffer, pH 6.8.

The lack of molecular weight dependence observed here may be due to the narrow range of molecular weights studied (particularly for PVP), to the removal of low molecular weight components during extensive dialysis prior to use, or to unusual intrinsic T_g behavior of the polymers. For our purposes, this result effectively removes polymer molecular weight from the list of independent variables that can be manipulated to control T_g.

Degradation Products—The major degradation products of Asn-hexapeptide deamidation were the isoAsp-hexapeptide (isoAsp), the Asp-hexapeptide (Asp), and the cyclic imide hexapeptide (Asu). Although isoAsp and Asp are commonly observed in solution-state deamidation at neutral pH, the cyclic imide is usually not observed because it is rapidly hydrolyzed to produce the isoAsp and Asp hexapeptides.[9,10] The dominance of isoAsp and Asu suggests that formation of the cyclic imide is the major route of Asn-hexapeptide deamidation in these polymer formulations.[9,10] Oliyai et al. have noted that Asn-hexapeptide deamidation in solid sugar formulations also occurs through a degradation pathway similar to that in solution.[8]

Deamidation Kinetics—Figures 3a and 3b show representative time-dependent disappearances of Asn-hexapeptide in PVA and PVP at different RHs. The disappearance

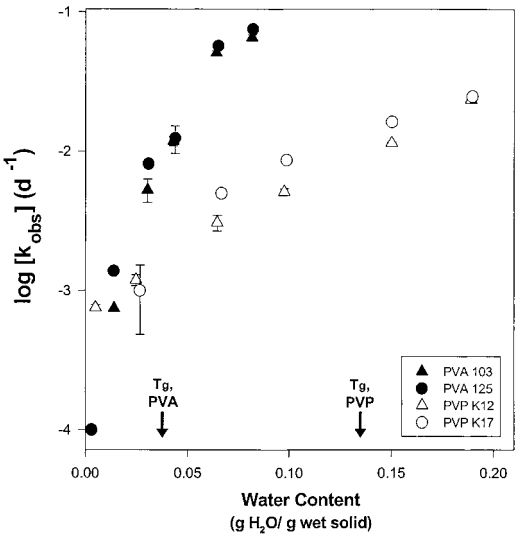

Figure 4—Effect of water content on the observed rate constant of Asn-hexapeptide deamidation (k_{obs}) in PVP and PVA at 50 °C. Error bars represent standard deviations ($n = 3$). The approximate water contents needed to lower the T_g of the PVA and PVP formulations to the experimental temperature are noted with arrows labeled "Tg, PVA" and "Tg, PVP", respectively.

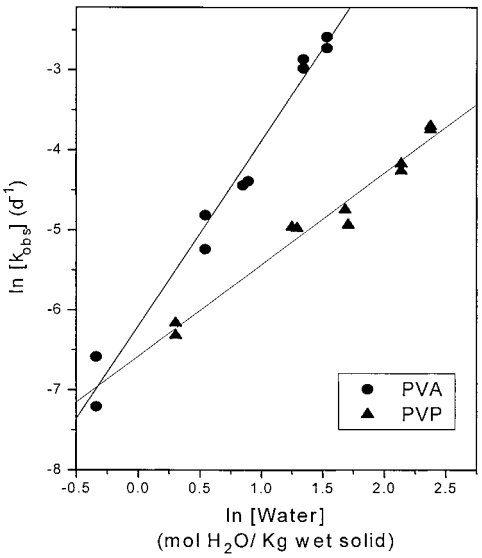

Figure 5—Plot showing the apparent dependence of deamidation rates on water content. Error bars represent standard deviations ($n = 3$).

of Asn-hexapeptide was observed to follow pseudo-first-order kinetics in peptide content at all RHs studied. Deamidation of this peptide in solution is known to exhibit pseudo-first-order kinetics.[9,10] The reaction order in peptide content appears to be similar in the solution and in these solid polymer formulations. As the RH increased, the rate of peptide degradation also increased. The observed rate constants (k_{obs}) were obtained from the slopes of the plots of ln [%Asn-hexapeptide remaining] versus time. Subsequent discussion of Asn-hexapeptide deamidation rates will employ the observed pseudo-first-order degradation rate constant.

Correlation with Water Content—The effect of formulation water content on the deamidation rate of Asn-hexapeptide is shown in Figure 4. At higher water contents ($\cong$ 10% w/w, or 0.10 g H_2O/g wet solid), the rate in PVA is nearly an order of magnitude faster than in PVP. As the water content decreases from 10% to ~2% (w/w), the deamidation rates in the two polymers become nearly equal. At very low water content (<2% w/w), the rate in PVA appears to be approximately an order of magnitude slower than in PVP, but this observation should be regarded as tentative given the limited data in this region. Polymer molecular weight had no apparent effect on peptide reactivity in either polymer. The results are consistent with those of Oliyai et al., who observed an increase in the rate of cyclic imide formation with increasing moisture level in lyophilized sugar formulations.[8]

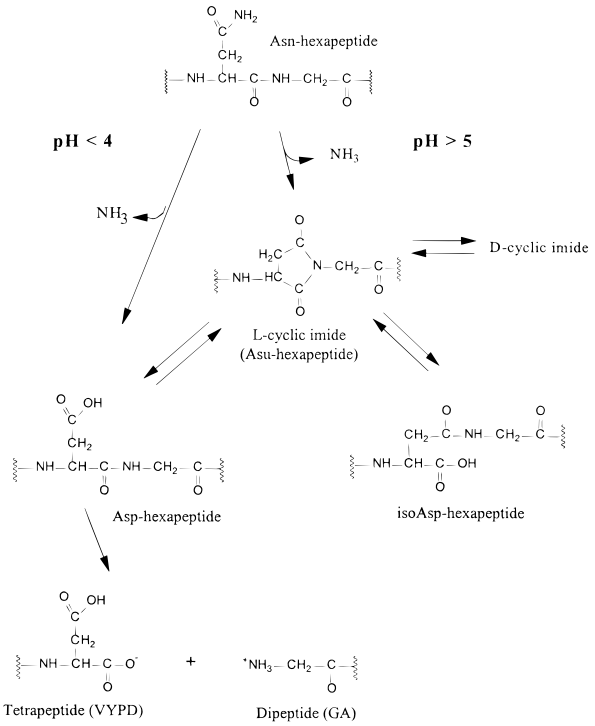
Peptide reactivity in PVA appeared to be more sensitive to increases in water content than in PVP at water contents >5%. An increase in water content of 0.083 g/g wet solid in the PVA formulation increased the observed deamidation rate constant by almost 3 orders of magnitude [$(1.0 \pm 0.05) \times 10^{-4}$ to $(7.5 \pm 0.4) \times 10^{-2}$ day^{-1}]. In contrast, the deamidation rate in PVP increased by only 1 order of magnitude over a wider range of water contents. Figure 5 shows that there is an apparent first-order dependence of the rate of Asn-hexapeptide deamidation on water content in PVP (slope = 1.15 ± 0.10), but an apparent second-order dependence on water content in PVA (slope = 2.31 ± 0.12), according to the following relationship:

$$k_{obs} = k\,[\text{water content}]^n \qquad (4)$$

where k is a constant and n is the order of the reaction with respect to water content in mol water/kg wet solid. The difference in reaction order between PVP (first order) and PVA (second order) is indicative of differences in reaction mechanism or environmental response, or both, in the two media. Further study will be required to establish the molecular origins of the difference because changes in water content can cause both mechanistic and environmental effects. For example, water may serve as a reactant or catalyst in the conversion of a reactant state to a transition state (a mechanistic effect) or may act as a plasticizer in affecting the ease of molecular motion in the medium (an environmental effect). Even a consideration of mechanistic effects alone is less straightforward than it might appear initially. If the reaction in polymeric media proceeds by the mechanism established in the solution state (Scheme 2), the initial cyclization step will not involve water stoichiometrically, whereas the hydrolysis step in ring opening of the cyclic imide will stoichiometrically require one molecule of water per molecule of cyclic imide. This conclusion might suggest that the higher order in water content observed in PVA is associated with rate-determining ring opening, whereas the lower order observed in PVP is indicative of rate-determining cyclization. However, catalytic involvement of unknown numbers of water molecules in either step of the solid-state reaction would render such a conclusion incorrect.

Correlation with Water Activity—The amount of water present is not always representative of the amount of water available for reaction; chemical potential or water activity may be a better indicator of its possible role as a reactant. In this study, the formulations were assumed to be in equilibrium within the closed RH chambers at constant temperature and pressure. Therefore, it is reasonable to assume that the relative water vapor pressure in the chambers is equal to the formulation water activity. Figure 1 shows that PVA and PVP have different water vapor sorption behavior and thus have different water activities when water content is similar.

Figure 6 correlates the rate of Asn-hexapeptide deamidation in PVA and PVP with water activity or RH. The rate of Asn-hexapeptide deamidation increases with increases in water activity (A_w). Reactivity may be better described by water activity (Figure 6) than by water content (Figure 4) in these systems because the differences between the PVA and PVP curves are reduced in Figure



Scheme 2—Solution state degradation pathways of Asn-hexapeptide (adapted from ref 10).

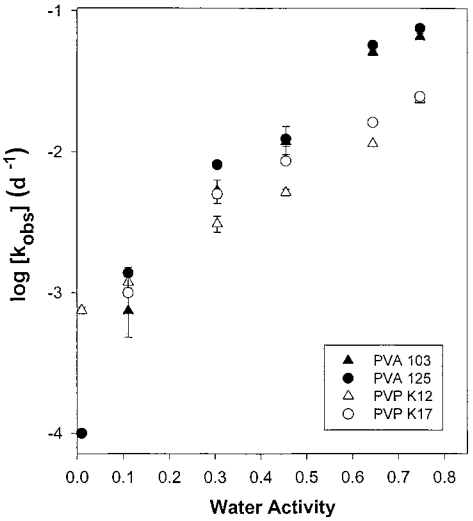


Figure 6—Effect of water activity on the observed rate constant of Asn-hexapeptide deamidation (k_{obs}) in PVP and PVA at 50 °C. Error bars represent standard deviations ($n = 3$).

6. Although the discrepancy in Asn-hexapeptide reactivity between PVA and PVP was less when differences in formulation A_w were taken into account, peptide reactivity at high (>0.6) or low (<0.1) water activity was still markedly different in PVA and PVP. Thus, water activity alone was not adequate to describe peptide reactivity in these different polymer solids, again implying that additional effects of water may be important in these systems.

Correlation with Formulation T_g—The finding that reactivity was not predicted by water content or activity alone suggests that the effect of water on Asn-hexapeptide deamidation in PVA and PVP was not entirely due to its role as a reactant. Another possible role of water is as a plasticizer to facilitate polymer chain mobility and decrease polymer viscosity, along with a decrease in T_g. The T_g was thus taken as a qualitative measure of matrix mobility. If deamidation in the solid state is controlled by reactant mobility, then the degradation rate should be affected by changes in T_g, assuming some degree of coupling between reactant and formulation mobility. It should be noted that because T_g measures a bulk property of the polymer matrix, it is not possible to distinguish the flexional and translational mobilities of the incorporated peptide using T_g.

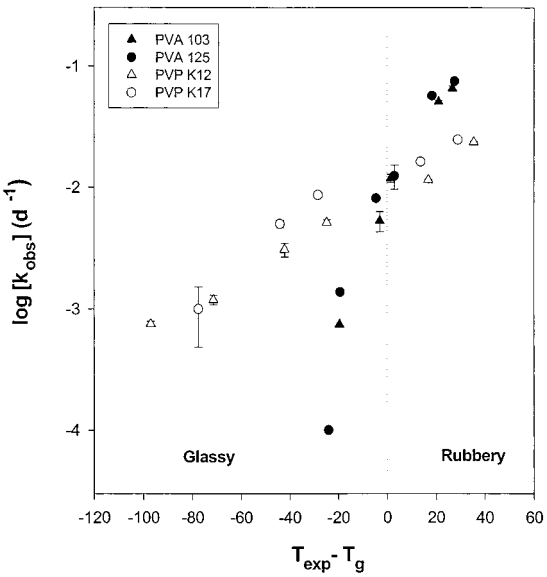

Figure 7—Effect of formulation T_g on the rate of Asn-hexapeptide deamidation in PVA and PVP at 50 °C. Temperatures are in °C. Error bars represent standard deviations ($n = 3$).

Figure 7 correlates the rate of Asn-hexapeptide deamidation to changes in formulation mobility, as expressed by ($T_{exp} - T_g$) based on the Vogel–Tamman–Fulcher and Williams–Landel–Ferry equations.[23–25] The T_{exp} parameter was chosen as the constant reference temperature with T_g as a variable. Negative values on the x axis denote formulations in the glassy state with $T_g > T_{exp}$, whereas positive values represent formulations in the rubbery state with $T_g < T_{exp}$. As the formulation T_g decreased (i.e., as $T_{exp} - T_g$ increased), the rates of deamidation increased in both PVA and PVP. In the glassy state, the rate of Asn-hexapeptide deamidation was greater in PVP than in PVA. However, as the formulations became more rubbery, peptide reactivity in the two polymers was reversed; that is, Asn-hexapeptide deamidation in the rubbery state was more rapid in PVA than in PVP. In going from a glassy to a rubbery state, the deamidation rate in PVA increased by 3 orders of magnitude with a 50 °C decrease in formulation T_g as compared with only 1 order of magnitude increase in PVP over the same range. At the glass transition, the rates of Asn-hexapeptide deamidation were similar in both polymers. The rate of Asn-hexapeptide deamidation seemed to be more sensitive to changes in the T_g of PVA than in PVP. If T_g alone described reactivity in these polymers, the curves for PVA and PVP would be expected to be coincident. That they differ suggests that formulation T_g alone was not adequate in describing Asn-hexapeptide reactivity in the two polymers.

Discussion

The rate of Asn-hexapeptide deamidation increased with increasing water content and water activity and decreasing formulation T_g in PVA and in PVP. However, degradation behavior in the two polymers differed so that chemical reactivity could not be predicted from water content, water activity, or formulation T_g alone. Thus, no single parameter seems to dictate the deamidation rate over the range of water content, water activity, and T_g studied.

Formulation mobility appears to affect the reactivity of the Asn-hexapeptide. All glassy formulations were more stable than rubbery formulations, regardless of water content. This result suggests that limited peptide mobility in the dynamically constrained glassy state may contribute to the greater stability of glassy formulations. This idea is consistent with the likely mechanism of Asn-hexapeptide degradation in these formulations. The degradation product data suggest that the mechanism of deamidation in these polymer solids is similar to that observed in solution. Thus, it is likely that deamidation in these systems proceeds via intramolecular cyclization to form a cyclic imide, a process that requires sufficient peptide mobility to adopt the necessary conformation for cyclization. Local segmental flexibility has been shown to influence the propensity for spontaneous cyclic imide formation from asparagine residues in calmodulin.[26] Yoshioka et al. observed that the γ-globulin aggregation rate was faster in lyophilized PVA than in dextran, although water content was lower in PVA than in dextran (0.098 versus 0.177 g/g of solid).[27] They attributed this lower stability to the lower critical temperature for mobility of PVA and proposed that the greater mobility in PVA accounted for the more rapid aggregation.

Although the less mobile glassy formulations were more stable, chemical reactivity was not negligible in these systems; as shown in Figure 7, deamidation occurred at a measurable rate in glassy matrixes of both PVA and PVP. Hancock et al. have suggested that glassy solids should be expected to experience significant molecular mobility at temperatures up to 50 °C below T_g,[28] which suggests that mobility-dependent reactions may still occur. Notably, the data in Figure 7 demonstrate that the rate of deamidation in glassy PVP matrixes is rapid enough to preclude adequate shelf stability. At an experimental temperature 100 °C below the T_g of the "dry" PVP formulation ($T_{exp} - T_g = -100$ °C, with T_g of the dry formulation = 150 °C), the Asn-hexapeptide was observed to have a half-life of only 2 years, suggesting that significant reactivity may be observed at temperatures far below T_g. Although the dry PVA formulation had a lower T_g (75 °C), the half-life for deamidation was much longer than that observed for the dry PVP formulations (20 versus 2 years). This result suggests that formulation mobility, as measured by T_g, is in itself insufficient to predict deamidation rates in these polymer systems.

An examination of Asn-hexapeptide reactivity and viscosity changes around the glass transition further supports this idea. The transition from a glassy to a rubbery state usually is characterized by a decrease in viscosity of >5 orders of magnitude.[6,24] Around this region ($T_g = T_{exp}$), the rates of deamidation increased by only 3 orders of magnitude in PVA and barely 2 orders of magnitude in PVP. The absence of an increase in rate comparable in magnitude to the decrease in viscosity at the glass transition may suggest incomplete coupling of deamidation rate to matrix mobility.

The inability of T_g alone to predict deamidation rates in PVA and PVP suggests that the level of mobility required for deamidation may be less than the bulk mobility represented by T_g. As already noted, the mechanism of deamidation in these solid polymer systems appears to be similar to that in solution, proceeding via a cyclic imide intermediate. Formation of the cyclic imide requires localized conformational flexibility of the peptide chain, allowing the attack of the backbone NH of the glycine residue on the side-chain amide function of the asparagine. Because T_g measures a bulk property of the system, it may not adequately reflect the localized molecular motions required for deamidation. Thus, although PVA and PVP formulations may have the same T_g, the degree of localized molecular mobility may differ. The characteristic length

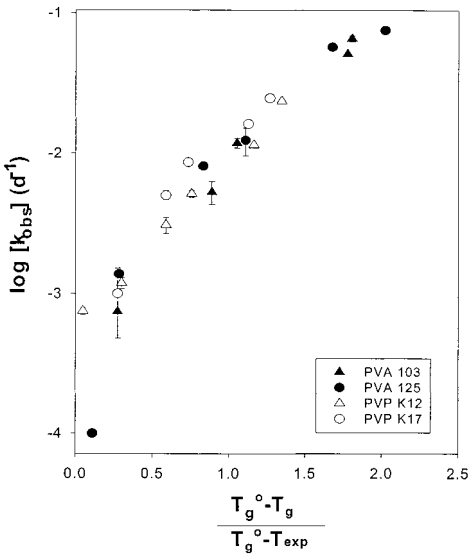

Figure 8—Correlation between deamidation rates and water plasticization in PVA and PVP at 50 °C.

scale for motions associated with the relaxation of the glassy modulus can have different temperature [or water] dependencies and can vary significantly for amorphous polymers.[29] Thus, the discrepancy in deamidation rates in PVA and PVP may be due to differences in polymer properties and structural responses to water, leading to differences in localized molecular mobility changes with increases in water content.

Although mobility affects deamidation, water may affect deamidation also as a solvent and proton-transfer agent. Among the three correlations made between deamidation rates and formulation parameters, water activity appeared to correlate best with Asn-hexapeptide instability in PVA and in PVP. The closer correlation between deamidation rates and water activity in PVA and PVP formulations suggests that some factor related to water activity may be influencing deamidation. In solution, solvent effects have been shown to affect deamidation due to changes in dielectric constant (polarity) and peptide pK_as. Brennan and Clarke have shown that deamidation rates decrease as solvent dielectric constant decreases.[30] Although water contents in these solid systems are low relative to solution, the "solvent" properties of water may still affect chemical reactivity, and changes in deamidation rate may be partially due to "polarity" changes upon hydration. The rate discrepancy in PVA and PVP further suggests that the "solvent" environment may affect deamidation because the PVA and PVP matrixes are serving as the main "solvent" for Asn-hexapeptide.

Water and polymer type both appeared to have an effect on deamidation, indicating that more than one parameter should be required to describe chemical reactivity in these systems. Figure 8 shows the correlation between deamidation rate and the degree of plasticization ($T_g^o - T_g$), normalized for the extent of plasticization required to induce the glass transition at 50 °C ($T_g^o - T_{exp}$). Data for both polymers are described by a single relationship. The expression was derived by making the approximation that the relationship between T_g and water content was linear over the range used in this study (see Figure 2) such that

$$T_g = T_g^o - \alpha W \qquad (5)$$

where α is a constant and W is the weight fraction of water. A similar relationship has been proposed for the more general case of plasticization by any additive.[31] Assuming

that α is constant for each polymer, eq 5 can be expected to hold when $T_g = T_{exp}$ and $W = W_g$ so that

$$\alpha = \frac{T_g^{\circ} - T_{exp}}{W_g} \tag{6}$$

where W_g is the water content needed to induce the glass transition at $T_{exp} = 50$ °C. Substituting this value for α (i.e., the slope) into eq 5 yields:

$$\frac{T_g^{\circ} - T_g}{T_g^{\circ} - T_{exp}} = \frac{W}{W_g} \tag{7}$$

This equation states that the degree of plasticization needed to induce a glass transition is related to water content, the experimental temperature, and the dry intrinsic T_g° of the polymer. A convergence of the deamidation rates in PVA and PVP was also observed when the rate constant (k_{obs}) was plotted against W/W_g. Although this parameter $[(T - T_g)/(T_g^{\circ} - T_{exp})]$ may be useful in correlating reaction rates in other systems, its utility in these studies (Figure 8) may be due to the near linear relationship between T_g and water content observed for PVA and PVP under these experimental conditions (Figure 2).

The results of this study suggest that several factors, including water content and mobility, may affect the chemical reactivity of Asn-hexapeptide in lyophilized polymer formulations. Isolating a single dominant mechanism driving deamidation is difficult because water content, water activity, and T_g are coupled. Future studies will attempt to vary T_g and water content independently with the use of a separate plasticizer to deconvolute their effects on deamidation in the solid state.

Abstract □ The mechanistic role of water in the deamidation of a model asparagine-containing hexapeptide (Val-Tyr-Pro-Asn-Gly-Ala) in lyophilized formulations containing poly(vinylpyrrolidone) (PVP) and glycerol was investigated. Glycerol was used as a plasticizer to vary formulation glass transition temperature (T_g) without significantly changing water content or activity. Increases in moisture and glycerol contents increased the rate of peptide deamidation. This increase was strongly correlated with T_g at constant water content and activity, suggesting that increased matrix mobility facilitates deamidation. In rubbery systems ($T > T_g$), deamidation rates appeared to be independent of water content and activity in formulations with similar T_gs. However, in glassy formulations with similar T_gs, deamidation increased with water content, suggesting a solvent/medium effect of water on reactivity in this regime. An increase in water content also affected the degradation product distribution; less of the cyclic imide intermediate and more of the hydrolytic products, isoAsp- and Asp-hexapeptides, were observed as water content increased. Thus, residual water appears to facilitate deamidation in these solid PVP formulations both by enhancing molecular mobility and by solvent/medium effects, and also participates as a chemical reactant in the subsequent breakdown of the cyclic imide.

Introduction

Many protein and peptide drugs are formulated as lyophilized or freeze-dried products to prolong shelf life.[1−3] Although the "dried" product is usually more stable than the aqueous formulation, chemical degradation reactions such as deamidation and hydrolysis can still occur.[1−3] Residual water in lyophilized protein formulations is known to promote chemical reactivity, leading to loss of biological activity and a shortened shelf life.[2−6] Although the destabilizing effect of water on proteins is widely acknowledged, the exact mechanistic role of water in facilitating chemical reactivity in the solid state is not well understood. This study will examine the mechanistic role of water in the deamidation of the model asparagine-containing hexapeptide Val-Tyr-Pro-Asn-Gly-Ala (Asn-hexapeptide) in lyophilized formulations containing poly(vinylpyrrolidone) (PVP).

Water may affect the solid-state chemical reactivity of polymer-incorporated peptides and proteins through three possible mechanisms: 1) changing the dynamic mobility of the protein or peptide, 2) direct participation as a reactant, or 3) indirect participation as a medium/solvent.[2,7] The mobility mechanism is based on the premise that if chemical reactions require sufficient mobility to proceed, an increase in mobility would result in increased reactivity. In polymer matrixes, water can increase molecular mobility by acting as a plasticizer to increase free volume and decrease viscosity.[8,9] Second, water can increase chemical reactivity directly by acting as a reactant, as in hydrolysis.[2,7] Water may also affect chemical degradation by acting as a medium for the mobilization of reactants or by modifying the reaction environment, as when the effective solvent dielectric or polarity is altered.[2,7]

The plasticizing effect of water on molecular mobility of the matrix may be monitored by measuring the glass transition temperature (T_g), the temperature at which a glassy, brittle, dynamically constrained material becomes rubbery and soft, with increased molecular mobility. Many studies have correlated decreases in T_g with decreases in system viscosity and increases in mobility.[9,10] The Vogel−Tamman−Fulcher (VTF) equation and the Williams−Landel−Ferry (WLF) equation, which is a special case of the VTF, describe the changes in viscosity in terms of $T_{exp} - T_g$ or distance from the glass transition, where T_{exp} is the experimental temperature.[9−12] Thus, we can use T_g as a qualitative measure of the plasticizing effect of water on formulation mobility. Because the effective concentration of a reactant may be expressed in terms of its chemical potential, we can use formulation water activity to measure the role of water as a reactant. Last, water content can probably best describe the medium/solvent effect of water. Thus, we can use water content, water activity, and T_g as indictors of the various mechanistic roles of water.

A technical problem with using these formulation parameters is that they are interdependent; changing water content or water activity will also affect T_g. Unambiguous mechanistic interpretations of the data are therefore difficult to achieve.[13] In a previous study, we demonstrated a dependence of deamidation rate on matrix water content in poly(vinylpyrrolidone) and poly(vinyl alcohol) matrixes, but were unable to distinguish among the more fundamental effects of water as a solvent, reactant, or plasticizer because of this interdependence.[14] To overcome this problem in the present studies, we used glycerol as an additional plasticizer to vary formulation T_g without significantly affecting water content or water activity. We therefore could systematically determine the effect of water activity

10.1021/js9802289 CCC: $18.00
Published on Web 09/01/1999

and content on deamidation kinetics when T_g is constant, as well as the effect of T_g on deamidation under constant water content and activity. Because water content and activity will not vary significantly between formulations, the role of water as a medium cannot be separated from its role as a reactant. In this study, these two roles of water will be combined under the role of solvent effects. Thus, using this strategy, we propose to deconvolute the mechanistic role of water as a plasticizer from its role as a solvent in solid-state deamidation.

Because deamidation is one of the most prevalent chemical degradations found in proteins and peptides,[15,16] we selected the Asn-containing hexapeptide (Val-Tyr-Pro-Asn-Gly-Ala) (Asn-hexapeptide) as the model compound for this study. An advantage of using the Asn-hexapeptide is that its solution-state degradation kinetics and mechanisms are well understood.[16−18] This knowledge will provide a solid mechanistic basis with which we can better interpret the solid-state deamidation kinetic and product distribution data.

In this manuscript, we present our findings on the effect of water on Asn-hexapeptide deamidation in lyophilized PVP formulations. We show that glycerol was successfully used to modify formulation T_g without a significant effect on water content or activity. Then, we correlate the rates of Asn-hexapeptide deamidation with water content/activity and T_g to elucidate the role of water in solid-state deamidation. We also examine the Asn-hexapeptide deamidation product distribution to provide information regarding the mechanism of degradation and the effect of water on product distribution.

Experimental Section

Materials—L-Val-L-Tyr-L-Pro-L-Asn-Gly-L-Ala (Asn-hexapeptide) was synthesized by Dr. Madhup Dhaon (Abbott Laboratories, North Chicago, IL). The buffers and salts used in this study were purchased from Mallinckrodt Chemical, Inc. (Paris, KY). Organic solvents and trifluoroacetic acid were purchased from Fisher Scientific (Fair Lawn, NJ). The poly(vinylpyrrolidone), under the trade name of Kollidon K17 [MW = 10 000], was purchased from BASF Corporation (Parsippany, NJ). Glycerol was obtained from the manufacturing division of Pharmacia & Upjohn, Inc. (Kalamazoo, MI). Deionized and distilled water was used throughout.

Preparation of Formulations—Five formulations were prepared: four solid-state PVP formulations with 0, 10, 20, and 30% glycerol, and a liquid-state formulation in 100% glycerol. The detailed procedure has been described previously.[14] Briefly, the solid PVP formulations were prepared from solutions containing peptide, glycerol, and PVP in phosphate buffer (pH 6.8). The solutions were added in a dropwise manner to liquid nitrogen to form frozen spherical pellets, which were then lyophilized to remove residual moisture. The average peptide load, calculated on the basis of the maximum amount released,[14] was 0.017 g/g dry solid for 100% PVP, 0.022 g/g dry solid for 10% glycerol/PVP, 0.022 g/g dry solid for 20% glycerol/PVP, 0.014 g/g dry solid for 30% glycerol/PVP, and 0.24 g/g glycerol for 100% glycerol, with errors at 5% ($n = 3-5$). The approximate final composition of the formulations was 2% peptide, 2% buffer, and 96% (w/w) PVP and/or glycerol, with a residual water content of <0.1% (w/w).

Characterization of Water Sorption Behavior—Sorption isotherms relating formulation water content to relative humidity (water activity) at 50 °C were generated using a controlled atmosphere microbalance (CAM), according to a method reported previously.[14] As in the previous study, the water sorption data obtained with the CAM were fitted to the Guggenheim−Anderson−deBoer (GAB) equation which describes the sorption of water by heterogeneous sorbents or solids:[2]

$$W = \frac{W_m C_g K_{GAB}(\rho/\rho_o)}{[1 - K_{GAB}(\rho/\rho_o)][1 - K_{GAB}(\rho/\rho_o) + C_g K_{GAB}(\rho/\rho_o)]} \quad (1)$$

where W is the mass (mg) of water vapor adsorbed per mg of dry solid at (ρ/ρ_o), (ρ/ρ_o) is the relative vapor pressure, W_m is generally regarded as the amount of water vapor necessary to saturate the heterogeneous active sorption sites, and C_g and K_{GAB} are dimensionless constants that are related to the thermodynamic measures of sorption for strongly and weakly interacting water.[2,19,20]

Characterization of Formulation Glass Transition Temperature—Glass transition temperatures (T_g) were measured using modulated differential scanning calorimetry (DSC) according to the method described previously.[14] As in that study, the T_g data were fitted to the Gordon−Taylor equation (eq 2), which describes the T_g of two miscible components:

$$T_g = \frac{w_1 T_{g1} + K_{GT} w_2 T_{g2}}{w_1 + K_{GT} w_2} \quad (2)$$

where T_g is the glass transition temperature of the mixture, w_1 and w_2 are the weight fractions of the individual components, T_{g1} and T_{g2} are the intrinsic T_gs of each component, and K_{GT} is a constant of the system describing the true density of the materials and changes in the thermal expansivity.[21,22] In applying the Gordon−Taylor equation, we treated the ternary system PVP/glycerol/water as a binary system, with PVP/glycerol and water as the two components. This simplification is justified because the relative proportions of PVP and glycerol remained unchanged as water content varied in our studies. In fitting the data, we used the experimentally measured values for T_g, w_1 and w_2, and set the T_{g1} value for water to the reported value of 135 K, as in the previous study.[14] Values for T_{g2} (the glass transition temperature of "dry" PVP/glycerol systems) and K_{GT} were determined by regression.

Stability Study—Stability studies were conducted on 4 mg of pellets stored in glass lyophilization vials; details of the method have been reported previously.[14] Before beginning the stability study, the solid Asn-hexapeptide formulations were allowed to equilibrate in chambers at 20 °C for 12 h. After this initial equilibration period, formulations stored at 75% RH were removed and analyzed for Asn-hexapeptide content and integrity prior to beginning the stability study. No significant degradation products were observed. For the stability study, the samples were transferred to controlled relative humidity chambers in a 50 °C room. Samples were prepared in triplicate. Peptide composition was assayed by HPLC after various storage times to determine degradation kinetics and product distribution. At specified time intervals, triplicate samples were removed for peptide analysis, as described previously.[14] Observed rate constants (k_{obs}) for the disappearance of the parent Asn-hexapeptide were determined from the slopes of plots of ln(% peptide remaining) versus time, assuming first-order kinetics as previously observed for this peptide in solution[17] and solid[6,14] states.

Peptide Analysis—The analyses of Asn-hexapeptide and its degradation products were performed by reversed-phase HPLC, using a modification of a method described previously.[14] The HPLC analytical system consisted of a Shimadzu (Shimadzu Corp., California) LC-6A pump, a Shimadzu SPD-6A variable-wavelength UV detector, a Shimadzu CR601 Chromatopac integrator, and a Rheodyne 7161 manual injector outfitted with a 50-μL injection loop. The Asn-hexapeptide and its degradation products were separated on an Alltech Econosphere C-18 reversed-phase column (5 μm resin, 4.6 × 250 mm) by an isocratic method with a mobile phase of 10% (v/v) acetonitrile and 0.1% (v/v) trifluoroacetic acid (TFA) in 40 mM ammonium acetate at a pH of 4.5 and a flow rate of 0.8 mL/min. The detection wavelength was 214 nm. The identification of the degradation products was conducted by co-injection of standards.

Results

Physical Characterization—*Water Sorption Isotherms*—Water sorption isotherms at 50 °C are shown in Figure 1 for PVP formulations with different glycerol contents, and also for liquid glycerol. In all cases, the water content of the formulations increased as relative water vapor pressure increased. The curved lines in Figure 1 represent the nonlinear least-squares fits of the water sorption data to the GAB equation, which adequately described the water

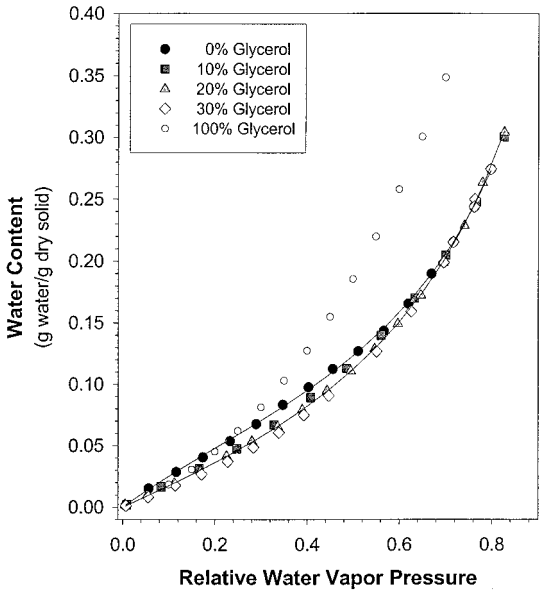

Figure 1—Water sorption isotherms for PVP formulations of various glycerol contents at 50 °C. The curved lines represent nonlinear least-squares fits to the Guggenheim–Anderson–deBoer equation (eq 1) for 0% glycerol–PVP and 20% glycerol–PVP formulations. The 100% glycerol data were taken from the literature.[24]

PVP formulation % glycerol	W_m (g/g dry solid)	C_g	K_{GAB}
0	0.101 ± 0.003	3.13 ± 0.17	0.849 ± 0.009
10	0.129 ± 0.005	1.75 ± 0.09	0.809 ± 0.009
20	0.121 ± 0.004	1.65 ± 0.08	0.833 ± 0.008
30	0.129 ± 0.004	1.29 ± 0.05	0.838 ± 0.007

sorption behavior for all formulations. The calculated parameter values (Table 1) in conjunction with the GAB equation were used to describe formulation water content at specific relative humidities.

Figure 1 and the fitted GAB parameters (Table 1) suggest that the water sorption isotherms of the four solid PVP formulations were similar. At three of the four relative humidities studied (0, 11, and 75%), the presence of glycerol did not significantly affect formulation water sorption behavior, because the formulations (0−30% glycerol) have similar water contents. At 30% RH, the three PVP formulations with glycerol had similar water contents but contained 15% less water than the PVP formulation without glycerol. Thus, the maximum difference in water content is ~15%, and will be observed at the intermediate relative humidity (30% RH) for the PVP formulation without glycerol. The 100% glycerol, which was included as a control (freely mobile system), will also exhibit significantly greater water contents than the other formulations, particularly at 30% RH.

Glass Transition Temperature—The addition of plasticizers can decrease the T_g of amorphous polymers.[23] This plasticizing effect of water is evident in Figure 2. Figure 2a shows a representative DSC thermogram, and Figure 2b shows T_g as a function of water content for the different formulations studied. The curved lines in Figure 2b are the nonlinear least-squares fits of the data to the Gordon−Taylor equation, which appears to adequately describe the depression of formulation T_g by the absorbed water. The fitted parameter values are listed in Table 2. The horizontal dotted line in Figure 2 corresponds to the experimental

20	336.5 ± 2.0	0.164 ± 0.091
30	311.6 ± 1.3	0.153 ± 0.076

[a] The T_g of the "dry" formulation (water content < 0.004 g/g wet solid).

temperature (50 °C). During these stability studies, formulations with T_g > 50 °C will be in the glassy state, whereas those with T_g < 50 °C will be in the rubbery state. All "dry" PVP−glycerol formulations (water content <0.004 g/g dry solid), except for the one containing 30% glycerol, were in the glassy state at 50 °C.

Glycerol also acted as a plasticizer to lower the T_g of PVP. On a weight basis, water was a stronger plasticizer than glycerol. As shown in Figure 2b, an increase in water content from 0 to 20% (w/w) corresponded to a 120 K decrease in T_g, whereas a comparable change in glycerol content depressed the T_g by only 90 K. As the glycerol content increased, the amount of water required to decrease the formulation T_g to the experimental temperature decreased. With no glycerol added, 0.14 g water/g dry solid was needed to lower the PVP formulation T_g to 50 °C. With the addition of 10% (w/w) glycerol to the PVP formulation, less water (0.05 g water/g wet solid) was needed to achieve the same formulation T_g (50 °C).

By using glycerol to vary T_g, we have obtained PVP formulations with similar T_gs but different water contents. These formulations will allow us to study the effect of water content/water activity on deamidation in formulations with similar T_gs. As shown in Figure 2b, we also have generated PVP formulations with similar water contents or activities but significantly different T_gs. These formulations will help determine the effect of T_g on deamidation at constant water activity and water content. From these two sets of formulations, the dominant role of water in peptide deamidation in solid formulations may be inferred.

Physical Appearance—At 50 °C, the physical appearance of the "dry" PVP formulations (water content < 0.4% w/w) changed as the weight percentage of glycerol increased. Most notable was a decrease in pellet size and a change from a brittle to a soft, sticky texture. Formulations without glycerol were white, dry, powdery pellets. PVP pellets with 10% (w/w) glycerol were similar in appearance to the 0% glycerol formulation, except for a decrease in size. PVP pellets with 20% glycerol were approximately one-third the size of the 0% glycerol PVP pellets and had a shiny, opaque surface and a sticky texture. PVP pellets with 30% glycerol had melted into a sticky, viscous, opaque liquid with a yellowish color.

As the relative humidity and water content increased, the pellet size decreased with a concomitant increase in stickiness. At high relative humidity, the 20 and 30% glycerol formulations became viscous liquids. The changes in the physical appearance of the PVP formulations support the T_g data, which indicate that the formulations are undergoing the transition from a glassy state to a rubbery state with increases in water and glycerol content.

Degradation Profiles—Figures 3a and 3b show the disappearance of the Asn-hexapeptide over time for representative PVP−glycerol formulations at different relative humidities. Peptide degradation exhibited a pseudo-first-order dependence on peptide content in all formulations and at all relative humidities studied. This observation is consistent with previous reports of Asn-hexapeptide dea-

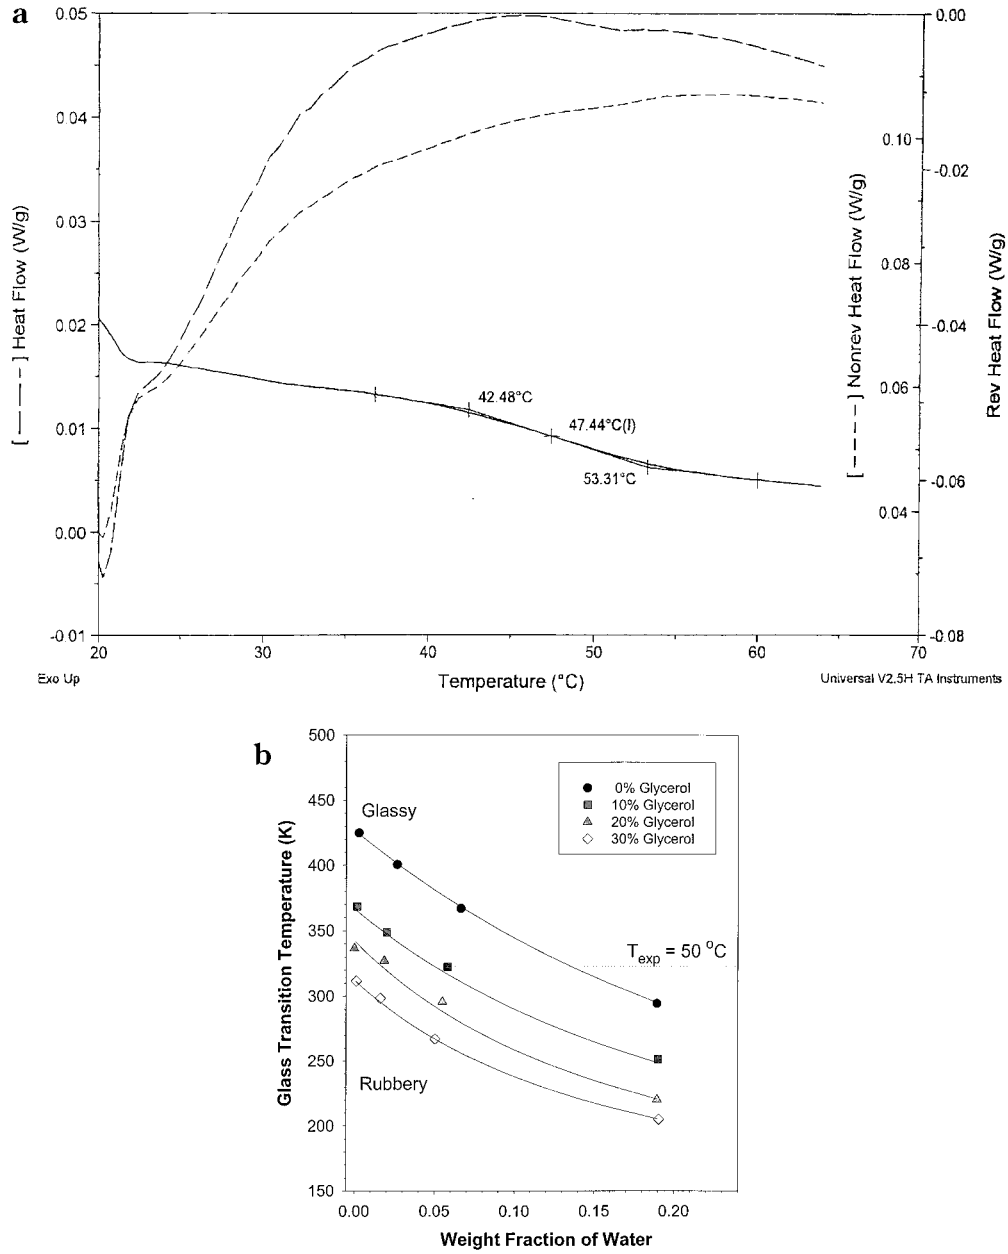

Figure 2—(a) Representative thermogram for a PVP K17 sample (containing 10% glycerol and stored at 30% RH) obtained with a scan rate of 2 °C/min and modulated at ± 1 °C/min. The endothermic T_g at 47.4 °C was calculated using the reversible heat flow curve. (b) Formulation glass transition temperature (T_g) as a function of water content at various glycerol contents ($n = 3$). The dotted line shows the experimental temperature used in the stability studies ($T_{exp} = 50$ °C, 323 K). The curved lines are the nonlinear least-squares fits to the Gordon-Taylor equation (eqn 2).

midation in lyophilized formulations.[6] The reaction order was not affected by glycerol or water. The apparent first-order deamidation rates (k_{obs}) were determined from the slopes of the lines shown in the figure, as described previously.[14]

Deamidation Kinetics—*Effect of Water Content and Activity*—Figure 4 shows the effect of water content on the decomposition of Asn-hexapeptide in lyophilized PVP with different glycerol contents. Because the PVP formulations had similar water sorption behavior (Figure 1), water activity affected deamidation rates in a manner similar to that observed for water content (data not shown). An increase in either water or glycerol content increased the rate of Asn-hexapeptide deamidation (Figure 4). The data suggest that at higher water or glycerol content, increasing the amount of either plasticizer did not affect rate as significantly as at lower levels. Increasing the weight fraction of water from 0 to 1 increased the rate of Asn-hexapeptide deamidation by 3 orders of magnitude in 0% glycerol formulations, by 2 orders of magnitude in PVP formulations with 30% glycerol, and by only 1 order of magnitude in 100% glycerol–0% PVP formulations.

The relatively rapid deamidation in glycerol when little water is present suggests that deamidation may not require water to proceed when the solvent environment allows for sufficient reactant mobility. Deamidation in glycerol was unaffected by increases in water content from <0.006 to 0.09 g/g wet glycerol. In contrast, much greater increases in Asn-hexapeptide reactivity were observed in polymer-containing formulations over the same region.

Effect of Glass Transition Temperature—Water can act as a plasticizer to decrease formulation T_g, with a corresponding decrease in viscosity and increase in molecular mobility.[9] This increase in molecular mobility may be the mechanism by which water promotes deamidation. By correlating deamidation kinetics to formulation T_g at constant water content/activity, we can determine the plasticizing effect of water on deamidation. Figure 5 shows

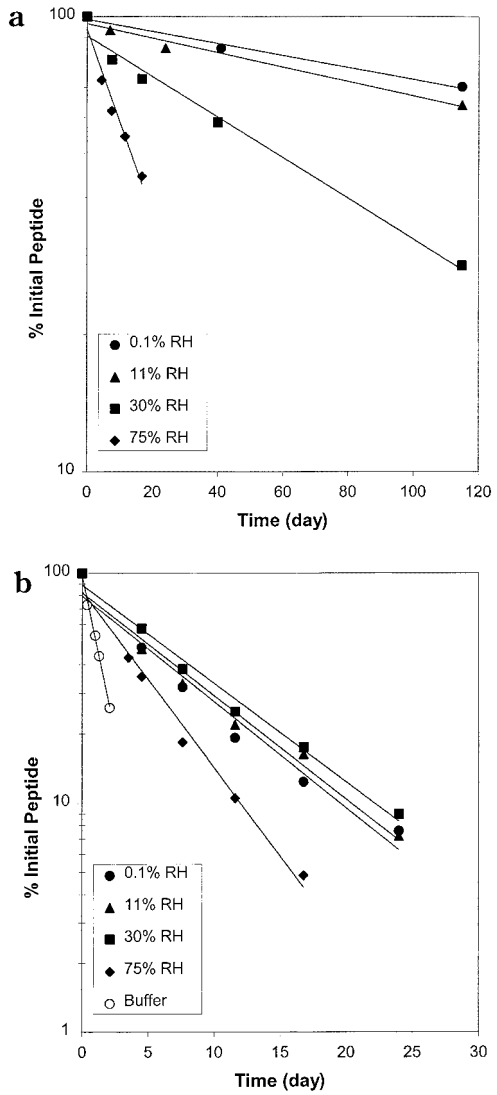

Figure 3—Disappearance of the Asn-hexapeptide as a function of time at 50 °C in (a) 10% glycerol–PVP formulation and (b) 100% glycerol at various relative humidities ($n = 3$).

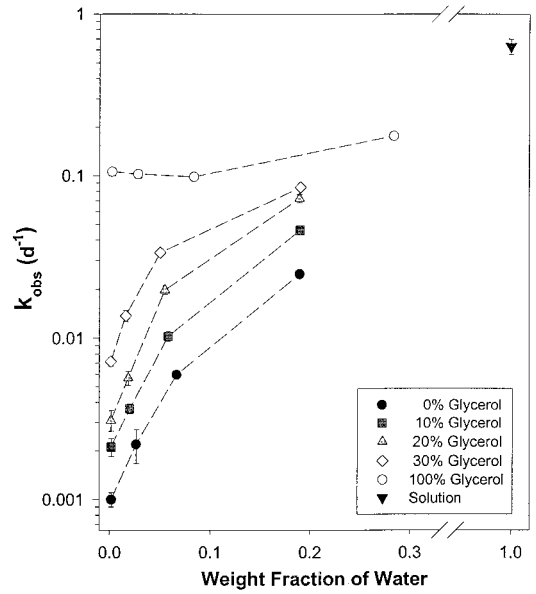

Figure 4—Observed rate constant (k_{obs}) of Asn-hexapeptide degradation at 50 °C as a function of water content in various PVP–glycerol formulations ($n = 3$). Lines have been added to clarify trends and do not represent regression.

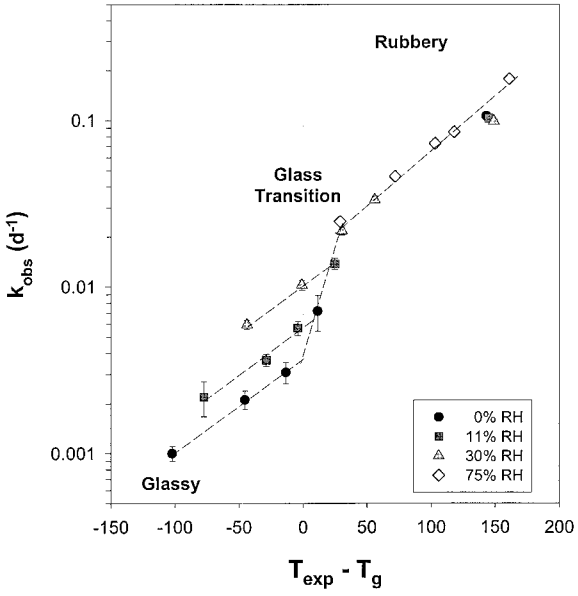

Figure 5—Observed rate constant (k_{obs}) of Asn-hexapeptide degradation as a function of T_g at $T_{exp} = 50$ °C at different relative humidities ($n = 3$). Water content (in g/g wet solid) at 0% RH is <0.004, at 11% RH is 0.02, at 30% RH is 0.06, and at 75% RH is 0.19. At each relative humidity, formulations with increasing ($T_{exp} - T_g$) (i.e., with lower T_g) were generated by adding increasing amounts of glycerol. The dashed lines denote trends in the data and do not represent curve fits to any equation.

the relationship between deamidation kinetics and T_g at different relative humidities for Asn-hexapeptide in 0−30% glycerol−PVP formulations and 100% glycerol.

When water activity was held constant, the rate of deamidation increased with decreasing T_g. For formulations in the rubbery state ($T_{exp} - T_g > 0$), the rate of deamidation appeared to be log linearly related to ($T_{exp} - T_g$), with no observed deviations for formulations with different water activities. This result suggests that the destabilizing effect of water in these formulations may be due to its role as a plasticizer. In the glassy state ($T_{exp} - T_g < 0$), decreases in T_g at constant water activity again resulted in increased deamidation rates. However, increasing water activity or content in formulations with similar T_gs also increased the rate of deamidation, suggesting that the role of water in the glassy state extends beyond that of a plasticizer. These results suggest that water may also facilitate deamidation through its role as a medium or reactant, especially in glassy PVP formulations.

Degradation Products and Their Distribution—In this study, the major degradation products observed for the deamidation of the Asn-hexapeptide in PVP solid formulations were the cyclic imide-hexapeptide (Asu), the isoAsp-hexapeptide (isoAsp), and the Asp-hexapeptide (Asp). In previous studies, these peptides have also been observed to be the products of Asn-hexapeptide deamidation in solution[16,17] and in the solid state.[6] The ratio of isoAsp to Asp was ~3, a value similar to that observed in solution at neutral pH.[16,17]

Figure 6 shows the effect of water on deamidation product distribution for the reaction in 100% glycerol. In this figure, the "% total degradation products" was calculated on the basis of the total area under the chromatographic peaks for the Asn-hexapeptide and its degradation products at each time point. Under low moisture conditions, the dominant degradation product is the cyclic imide-hexapeptide. As water content increases, the product distribution shifts toward increased formation of the isoAsp- and Asp-hexapeptides, with a corresponding de-

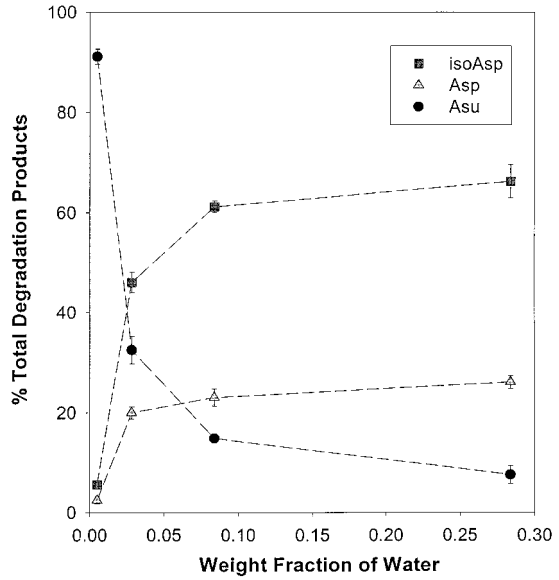

Figure 6—The Asn-hexapeptide degradation product distribution as a function of water content in 100% glycerol after 16 days at 50 °C ($n = 3$). The "% total degradation products" was determined on the basis of the total HPLC peak area at each time point.

crease in the cyclic imide. At higher water contents, isoAsp and Asp are the major degradation products with Asu present in minor quantities. These shifts in product distribution with increasing water content/activity were observed for all formulations (representative plots shown in Figures 7a and 7b, with "% total area" determined as in Figure 6).

When little or no water was present (<0.4% w/w), increasing glycerol content (and therefore decreasing T_g) did not noticeably affect product distribution. However, Figures 6, 7a, and 7b show that formulation mobility may affect the manner in which product distributions shift toward higher levels of isoAsp and Asp, with a reduction in the presence of the cyclic imide as water content increases. For example, at a water content of 0.03 g/g wet solid (water activity = 0.11), the fraction of Asu in the degradation products was lower in PVP formulations with higher glycerol contents. A higher water content was required to obtain the same product distribution in formulations with lower glycerol content and, thus, lower matrix mobility. Because of similar water activities for formulations of similar water content, water activity affected the product distribution (data not shown) in a manner similar to that observed for water content (Figure 6).

Discussion

Residual moisture can decrease the long-term stability of lyophilized protein formulations by promoting chemical degradation reactions such as asparagine deamidation. Numerous mechanistic interpretations for the destabilizing effect of water have been suggested based on relationships between chemical reactivity and formulation parameters such as water content, water activity, and T_g. However, the unambiguous interpretation of experimental results often is difficult because these parameters are interdependent and are affected by temperature.[13,14] To avoid this difficulty, we used glycerol as a plasticizer to change the T_g of the PVP formulation without significantly affecting water content or water activity. In this way, the effects of water content/activity and T_g on the deamidation of the Asn-hexapeptide can be determined independently in solid PVP formulations without a change in temperature.

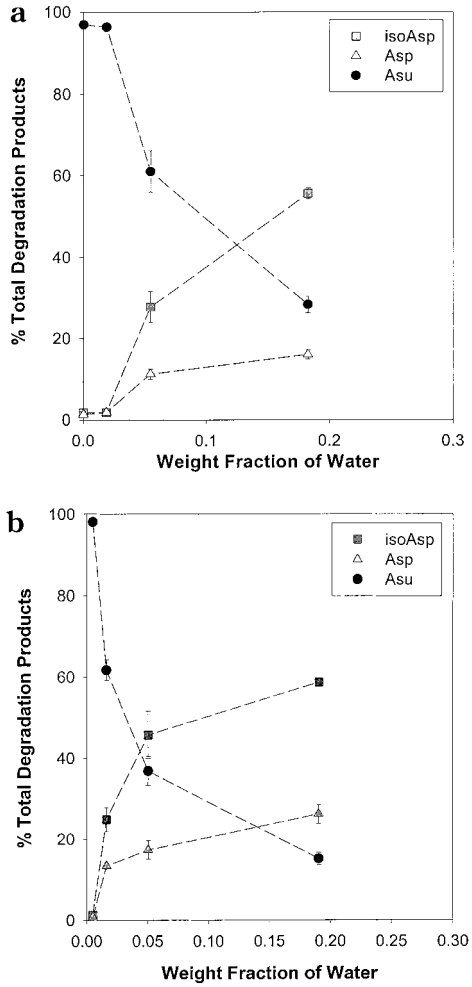

Figure 7—The Asn-hexapeptide degradation product distribution for PVP formulations with (a) 10% and (b) 30% glycerol contents as a function of water content ($n = 3$). The "% total degradation products" was determined on the basis of the total HPLC peak area at each time point.

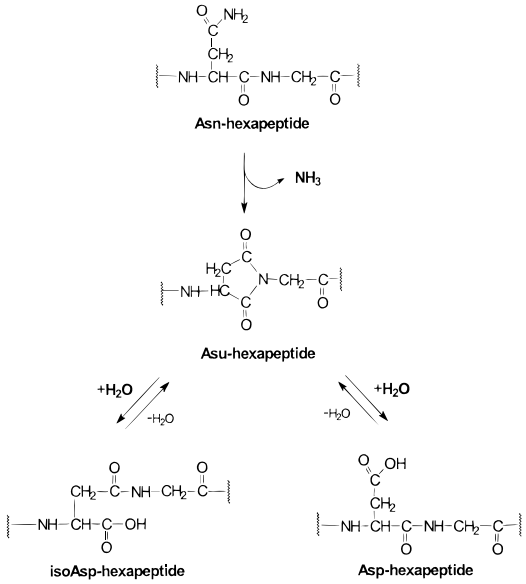
Mechanism of Deamidation—The major degradation products of Asn-hexapeptide deamidation in PVP solid formulations are the cyclic imide hexapeptide (Asu), the isoAsp-hexapeptide (isoAsp), and the Asp-hexapeptide (Asp). These degradation products are identical to those observed for deamidation in solution, suggesting that the mechanism of deamidation in these polymer solids may be similar to that observed in solution. In solution at neutral pH, the deamidation of the Asn-hexapeptide occurs via intramolecular cyclization, which results from the nucleophilic attack of the succeeding peptide nitrogen onto the side-chain carbonyl of the Asn residue to form the cyclic imide (Scheme 1).[17] The cyclic imide hexapeptide is then rapidly hydrolyzed to form the isoAsp- and Asp-hexapeptides.[16,17] The observed ratio of isoAsp to Asp of ~3 in these solid formulations is also similar to the ratio observed for Asn-hexapeptide deamidation in solution and for the hydrolysis of the cyclic imide.[16,17] In solution, isoAsp is formed only from the hydrolysis of Asu.[16] The presence of this product in these solid formulations suggests its formation from Asu hydrolysis here as well. Taken together, these results support the hypothesis that the deamidation of the Asn-hexapeptide in these PVP–glycerol formulations proceeds via intramolecular cyclization to form the cyclic imide intermediate (Scheme 1), a mechanism similar to that observed in solution.

Other researchers have made similar observations. Oliyai et al. observed that Asn-hexapeptide degradation in lyophilized formulations containing either mannitol or



Scheme 1. —Solution-state mechanism for the deamidation of the Asn-hexapeptide at neutral pH (Adapted from Patel et al.[16]).

lactose yielded isoAsp, Asp, and Asu.[6] They concluded that the solid-state deamidation mechanism was similar to that in the solution state. Strickley and Anderson showed that the deamidation of insulin in the solid state was similar to that in the solution state in terms of degradation products, mechanism, and pH−rate profile.[5] The interpretation that the mechanism of Asn-hexapeptide deamidation in these solid systems is via intramolecular cyclization to form a five-membered cyclic imide hexapeptide is consistent with the results of this study and others.

Effect of Water on Deamidation Kinetics—Residual water appears to facilitate deamidation in lyophilized PVP formulations both by enhancing molecular mobility and by medium effects. Figures 4 and 5 show that increased mobility (decreasing T_g) and increased solvation (increased water content/activity) had a destabilizing effect on the Asn-hexapeptide in PVP. When water activity was held constant, the rate of deamidation increased with decreasing T_g, indicating that matrix mobility may be important in determining deamidation kinetics. Notably, water does not appear to act as reactant in the initial loss of the Asn-hexapeptide to form the cyclic imide. The rapid rate of deamidation in 100% glycerol at 0% RH suggests that deamidation can occur when very little water is present (<0.4% w/w). Furthermore, increases in water activity of up to 0.3 in glycerol did not affect the deamidation rate. If water was a reactant, deamidation would not be able to proceed in its absence, and the rate would be expected to vary with water content/activity. Therefore, it is likely that water is not directly affecting deamidation as a reactant. This explanation is also consistent with the deamidation mechanism determined in solution, in which water does not participate directly in the formation of the cyclic imide (Scheme 1).

Many researchers have proposed that increased dynamic mobility in solids leads to increased chemical reactivity.[1,2,7,8] The data in Figure 5 support this hypothesis. That the plasticizing role of water facilitates deamidation in lyophilized PVP formulations by increasing mobility is also consistent with the apparent mechanism of Asn-hexapeptide deamidation. In these polymer formulations, the deamidation of Asn-hexapeptide appears to proceed via intramolecular cyclization to form the cyclic imide hexapeptide. For cyclization to occur, the asparagine side chain and the peptide backbone require sufficient flexibility to assume the correct local conformation. Ota et al. have shown that decreased segmental flexibility decreases the deamidation rate in solution.[24] Because cyclization requires adequate segmental flexibility, deamidation would be expected to be sensitive to changes in formulation molecular mobility.

This explanation is supported by the trends in Figure 5. We observed a sharp increase in deamidation rate with decreasing T_g in the region of the glass transition ($T_g \sim T_{exp}$). This increase in deamidation rate appears to correspond with the sharp decrease in viscosity characteristic of the glass transition. Viscosity can decrease by as much as 4 orders of magnitude at the glass transition, leading to a large increase in matrix mobility.[8,10] The roughly 1 order of magnitude increase in deamidation rate shown in Figure 5 is significantly less than this potential viscosity decrease, which may suggest that deamidation and/or side-chain mobility is not completely coupled to overall matrix viscosity.

Figure 5 shows that the effect of water as a plasticizer and/or solvent on deamidation appears to depend on the physical state of the formulation. In the rubbery state, the strong correlation between reaction rate and T_g, regardless of water activity/content, suggests that water affects deamidation predominantly through its role as a plasticizer. In other words, water or its direct effect on deamidation is not the rate-limiting factor. However, in glassy formulations, water appears to affect deamidation via both mobility and medium/solvent effects. The mobility mechanism is supported by the increase in deamidation rates with decreasing T_g when water activity/content was held constant. In contrast, in formulations with similar T_g, increasing water content/activity increases Asn-hexapeptide reactivity, suggesting that water may also facilitate deamidation in the glassy state through its role as a solvent. If matrix mobility was the only factor dictating Asn-hexapeptide deamidation, then differences in water activity or content would not have affected degradation rates at constant T_g. Alternatively, even in a glassy matrix, the peptide has some degree of mobility. Peptide mobility thus may be influenced by increases in water content in a manner not coupled to matrix mobility.

Interestingly, the relationship between k_{obs} and T_g shown in Figure 5 is linear in both the rubbery and glassy states, with a slightly greater slope in the rubbery region. This relationship is reminiscent of so-called "cooling curves", which show the transition from a liquid to a glassy solid in terms of specific volume (or enthalpy) as a function of temperature, and display families of near parallel curves in the glassy state for materials cooled at different rates.[25] Although this similarity suggests that deamidation rate may be related to matrix specific volume in our studies, this claim must be regarded as speculative on the basis of the current data.

Because of the low amounts present, water technically is not a solvent in these solid systems. However, it is not unreasonable to postulate that water may affect the reaction environment in a manner that facilitates deamidation. The environment to which an asparagine residue is exposed can greatly affect its stability. Studies of deamidation in the solution state reveal that the crucial step for cyclic imide formation is deprotonation of the attacking peptide bond nitrogen to form a charged activated complex in the reaction transition state.[16−18] Brennan and Clarke have shown that deamidation at asparagine residues is markedly reduced in solvents of low dielectric strength because of decreased stability of the anionic peptide bond nitrogen.[26] Deamidation would be expected to be favored in polar environments, which can adequately stabilize the charged transition state during intermolecular cyclization. Although these findings are for the solution

state, water may affect deamidation in glassy formulations by increasing the polarity of the matrix. Water may also facilitate deamidation by serving as a medium for proton transfer during the cyclization process.[5,16]

In addition to having an effect on reactant mobility, matrix mobility may also affect the ability of a solvent to adequately solvate and stabilize charged reaction centers. In the glassy state, the solid polymer solvent may not have sufficient mobility to rearrange itself to "solvate" the charged transition state during Asu formation. Although the polymer may be dynamically constrained, Oksanen and Zografi have shown that water in solid PVP maintains a high degree of mobility relative to the polymer.[27] The more mobile water may be able to facilitate deamidation by "solvating" the charged transition state during Asu formation. In the rubbery state, PVP is more mobile than in the glassy state. With greater mobility, PVP may be more able to solvate and stabilize the development of a charged transition state during deamidation. Thus, matrix mobility may have an impact on chemical reactions beyond influencing reactant mobility.

Because water appears to have a solvent effect on deamidation in these solid systems, glycerol may have had a solvent effect on the reaction rates in addition to a plasticizing effect. We cannot rule out the possibility that the increase in deamidation rates with decreasing T_g (increasing glycerol content) is in part due to a solvent effect (Figure 5).

Effect of Water on Deamidation Product Distribution—Three major degradation products were observed in this study: the cyclic imide hexapeptide (Asu), the isoAsp-hexapeptide (isoAsp), and the Asp-hexapeptide (Asp). In these lyophilized PVP–glycerol systems, the Asn-hexapeptide appears to deamidate through intramolecular cyclization to form Asu, which may degrade to produce isoAsp and Asp. The deamidation product distribution would then depend on Asu formation (deamidation of Asn) and breakdown (hydrolysis to form isoAsp and Asp). In formulations with minimal moisture content (<0.004 g water/g wet solid), Asu is the dominant degradation product with little isoAsp or Asp observed at the sampling time evaluated. As water content increases, the product distribution shifts toward less Asu and greater fractions of isoAsp and Asp. These observations are consistent with the hydrolytic formation of isoAsp and Asp from Asu, as observed in solution (Scheme 1). In solution at neutral pH, Asu undergoes spontaneous hydrolysis to form isoAsp and Asp, where the attack of water or hydroxide ion on the cyclic imide is the rate-limiting step.[16,17,28]

Because the amount of Asu observed depends on the rates of Asn-hexapeptide deamidation and Asu hydrolysis, the decrease in the percentage of Asu among the degradation products with increasing water content suggests that Asu hydrolysis becomes more rapid than Asu formation under these conditions. The shift in product distribution with increasing glycerol content (Figures 6, 7a, and 7b) suggests that mobility may also affect Asu hydrolysis through its role as a plasticizer to increase formulation mobility, although direct evidence for a plasticizing role in this reaction was not obtained in these experiments. These differences in product distribution may be due to differences in the reaction time course. For example, reactions in formulations with higher glycerol contents occur at a faster rate. Therefore, these reactions would be more complete than slower reactions (lower glycerol content) at the time the reactions were sampled.

Conclusion

The mechanistic role of water in the deamidation of an Asn-containing model hexapeptide (Val-Tyr-Pro-Asn-Gly-Ala) in lyophilized formulations containing PVP and glycerol was investigated. Increases in moisture and glycerol contents increased the rate of peptide deamidation. This increase was strongly correlated with T_g at constant water content and activity, suggesting that increased matrix mobility facilitates deamidation. In rubbery systems ($T > T_g$), deamidation rates appeared to be independent of water content and activity in formulations with similar T_gs. However, in glassy formulations with similar T_gs, deamidation increased with water content, suggesting a solvent/medium effect of water on reactivity in this regime. An increase in water content also affected the degradation product distribution; less of the cyclic imide intermediate (Asu) and more of the hydrolytic products, isoAsp and Asp, were observed as water content increased. Under low moisture conditions, the water-catalyzed hydrolysis of the cyclic imide intermediate to produce the isoAsp and Asp is suppressed. Thus, residual water appears to facilitate deamidation in these solid PVP formulations both by enhancing molecular mobility and by solvent/medium effects, and also participates as a chemical reactant in the subsequent breakdown of the cyclic imide.

Accepted for publication July 15, 1999.

Abstract □ The mechanism of organic solvent evaporation during microencapsulation and its role during microsphere hardening has been investigated. Evaporation and encapsulation studies were carried out in a jacketed beaker, filled with aqueous hardening solution, which was maintained at constant temperature and constant stirring rate in the turbulent regime. Evaporation of dissolved methylene chloride (MC), ethyl acetate (EA), and acetonitrile (ACN) was examined by the decline in organic solvent concentration in the hardening bath, which was monitored by gas chromatography. The evaporation from the bath followed first-order kinetics under dilute conditions (e.g., MC < 3 mg/mL), yielding an overall permeability coefficient, *P*. The value of *P* was theoretically related to the Kolmogorov length-scale of turbulence under conditions that favor liquid-side transport control. According to theory, factors that favored liquid-phase control (as opposed to gas-phase control) were those that favored a high Henry's law constant [i.e., elevated temperature near the normal boiling point (bp) of the organic solvent] and properties of the dissolved organic solvent (i.e., low normal bp and low aqueous solubility). These theoretical hypotheses were confirmed by (1) correlating the experimentally determined *P* with process variables raised to the appropriate power according to theory, $r^2 = 0.95$ (i.e., $P \propto$ rotational speed, $\omega^{3/4}$, impeller diameter, $d^{5/4}$, volume of hardening bath, $V^{-1/4}$, and the product of kinematic viscosity and diffusion coefficient, $\nu^{-5/12}D^{2/3}$), and (2) illustrating that at constant temperature, the tendency of the evaporation system to obey liquid-side transport control follows the same order of increasing Henry's law constant (i.e., MC > EA > ACN). To establish the relationship of evaporation with microsphere hardening, the decline in MC concentration was determined in both the continuous and dispersed polymer phases during microencapsulation. By applying a mass balance with respect to MC in the hardening bath, the cumulative hardening profile of the microspheres was accurately predicted from the interpolating functions of the kinetics of MC loss from the bath with and without polymer added. These results have potential use for microsphere formulation, design of encapsulation apparatus, and scale up of microsphere production.

Introduction

The solvent evaporation encapsulation method has been widely used for preparation of microspheres for the controlled release of drugs. During encapsulation, a single oil-in-water (o/w) emulsion is commonly used for un-ionized and lipophilic drugs, and a double w/o/w emulsion is often used for the encapsulation of hydrophilic or ionized compounds, such as proteins and peptides.[1] Despite the widespread use of this technique, encapsulation methodologies are still largely based on trial and error. More quantitative theory and experiments are required to improve our understanding of how the encapsulation conditions affect the final particle characteristics. Such studies also may help to reduce batch-to-batch variation, organic solvent residual content, and scale up difficulties.

The physical chemical events that take place between emulsion formation to eventual microsphere hardening can be separated into several components; such as diffusion of the organic solvent from the embryonic particles into the aqueous hardening bath, evaporation of the solvent, polymer phase separation at the microsphere surface, particle coalescence, and drug loss into the hardening bath. Among these coupled events, the rate of solvent evaporation will directly influence the organic solvent level in the hardening bath, which in turn will influence the chemical potential gradient of the same species across the particle hardening surface, and consequently, the solvent removal rate. It has been shown that the solvent removal rate can have significant effect on the microsphere properties.[1−5] Therefore, the evaporation rate kinetics was selected as a logical place to begin quantitative evaluation of these coupled physical chemical events during microsphere preparation.

The objectives of this paper were (1) to devise a theory to relate process conditions to organic solvent evaporation rate from a stirred aqueous hardening bath, (2) to test such a theory experimentally by measuring solvent evaporation kinetics, and (3) to use the theoretical model to predict the kinetics of microsphere hardening during encapsulation by simultaneously monitoring the kinetics of organic solvent levels in the continuous phase of the hardening bath.

Theoretical Section

Definition of Permeability Coefficients—Consider a system consisting of a stirred jacketed beaker filled with an aqueous hardening bath maintained at constant temperature, as shown in Figure 1A. An overhead mixer rotates an impeller of type shown in Figure 1B at constant rotational speed sufficient to induce turbulent flow [e.g., the impeller Reynolds number (*Re*) >1000 for the system described in Figure 1].[6] *Re* is defined as

$$Re \equiv \frac{\omega d^2}{\nu} \tag{1}$$

where ω, d, and ν are the rotational speed, impeller diameter, and fluid kinematic viscosity, respectively.

When a volatile organic solvent is introduced in the aqueous hardening bath below its aqueous solubility, the solvent dissolves and begins to evaporate. The solvent either is added directly or accumulates during hardening of the polymer microspheres. Let an overall (or total) permeability coefficient (equivalent to overall mass transfer

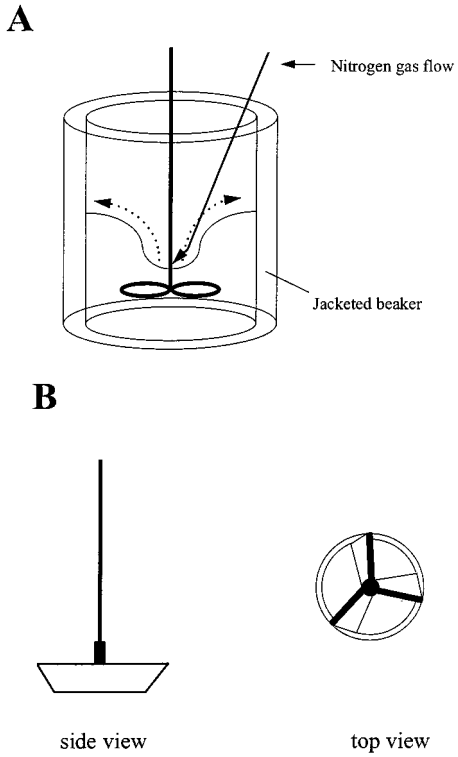

Figure 1—Stirring apparatus used to assess evaporation from the hardening bath. (A) A jacketed beaker was maintained under constant rotational speed and temperature. In some cases, a light flow of N_2 gas was delivered across the air/water interface to disrupt the gas-phase boundary layer. (B) Side and top views of the turbine impeller used to mix the bath.

coefficient) at the air/liquid interface, P, be defined in the usual way from the quotient of mass flux of the evaporating organic solvent, j_s, and the difference in bulk concentration in the bath (continuous phase), C, and some point in space above the bath where the concentration becomes zero; that is

$$P \equiv \frac{j_s}{\Delta C} = \frac{j_s}{C - 0} = \frac{j_s}{C} \tag{2}$$

The P may be separated into contributions of the liquid and gas sides according to eq 3[7]

$$\frac{1}{P} = \frac{1}{P_L} + \frac{1}{H \cdot P_G} \tag{3}$$

where P_L and P_G are the liquid-side and gas-side permeability coefficients, respectively, and H is Henry's law constant.

Organic Solvent Mass Balance in the Hardening Bath—A mass balance with respect to the organic solvent in the continuous phase during hardening of the microspheres yields

$$V\frac{dC}{dt} = R_H - R_E = R_H - PAC \tag{4}$$

where V, R_H, R_E, A, and t are the volume of the fluid, overall rate of organic solvent removal from microspheres (or hardening rate), rate of solvent evaporation, air/water surface area, and time, respectively.

To determine P, let $R_H = 0$ by addition of organic solvent directly (i.e., no microspheres) and the concentration in the solvent bath is monitored. P has been reported to be independent of C,[4,7,8] which results in first-order evaporation kinetics. In this case, integration of eq 4 gives

$$C = C_0\, e^{-P\frac{A}{V}t} \tag{5}$$

where C_0 is the initial organic solvent concentration in the bath. During encapsulation, $R_H > 0$ and integration gives an expression for cumulative mass removed from microspheres, M_H, as follows:

$$M_H \equiv \int_0^t R_H\, dt = V[C(t) - C_0] + A\int_0^t PC\, dt \tag{6}$$

Hence, the cumulative solvent removed may be related to the permeability coefficient and the concentration−time profile in the continuous phase during encapsulation.

Calculation of the Kolmogorov Length-Scale—The size of the characteristic eddy, or Kolmogorov length, δ_K, induced by turbulence originating from the energy input from the impeller, is[9]

$$\delta_K = \left(\frac{\nu^3}{\epsilon}\right)^{1/4} \tag{7}$$

where ϵ is the energy dissipation rate per unit mass of fluid. The Kolmogorov length can be described as the length scale of the smallest eddy at which inertial forces equal viscous forces. In turbulent fluids, large eddies become unstable and cascade into smaller eddies without energy loss until δ_K is reached. At δ_K eddies disappear losing their kinetic energy to thermal energy.

To calculate δ_K, ϵ must be determined. For isotropic turbulence, ϵ is equivalent to the rate of energy loss from the impeller to the fluid, $\dot{Q}$, divided by the mass of fluid (ρV). $\dot{Q}$ is given as[10]

$$\dot{Q} = N_p \rho \omega^3 d^5 \tag{8}$$

where ρ is the density and N_p is the dimensionless power number, which is dependent on the impeller type and thickness, as well as the presence or absence of baffles in the tank.

Thus, in a hardening tank containing a fluid volume, V, by combining eqs 7 and 8, δ_K becomes

$$\delta_K = \left[\frac{\nu^3}{(N_p \rho \omega^3 d^5/\rho V)}\right]^{1/4} = \left[\frac{Vd}{N_p\left(\frac{\omega^3 d^6}{\nu^3}\right)}\right]^{1/4} = \frac{(Vd)^{1/4}}{N_p{}^{1/4} Re^{3/4}} \tag{9}$$

Estimating the Liquid-Side Boundary Layer Thickness, δ_D—The movement of the fluid near an air/liquid interface is somewhat more controversial than near a solid/liquid interface. Near a solid/liquid interface, the turbulence is damped within a viscous sublayer, δ_V, over which the bulk mean velocity is dissipated with the square of position toward the interface.[8] At the interface, the fluid velocity becomes zero in all directions. Near an air/liquid interface, only the velocity component normal to the surface is zero. At a 'clean' interface (i.e., a surface free of contaminants), the vertical mean velocity is dissipated linearly with position toward the interface, and the boundary layer thickness, δ_D ($=D/P_L$), is given as[8]

$$\delta_D \propto \delta_V Re^{*-1/2} Sc^{-1/2} \tag{10}$$

where Re^* is the local Reynolds number, $u_e \cdot \delta_e/\nu$, of approaching eddies (u_e and δ_e are velocity and length scale of the eddy, respectively) to the interface, and Sc is the

Schmidt no. (ν/D), where D is the diffusion coefficient of the volatile species evaporating at the air/liquid interface.

Most surfaces, however, contain contaminants, especially in small-scale laboratory and industrial flows.[8] In this so-called 'dirty' interface category, surface-active substances (e.g., organic solvent molecules and surfactant molecules in the case of encapsulation by solvent evaporation) are present in excess at the surface. The mean vertical velocity component is then dissipated with the square of position (like the solid/gas interface case) and

$$\delta_D \propto \delta_e \cdot Sc^{-1/3} \tag{11}$$

If the characteristic length, δ_e, is assumed to be proportional to the Kolmogorov length-scale, δ_K, then

$$\delta_D \propto \delta_K \cdot Sc^{-1/3} \tag{12}$$

Finally, by assuming a constant impeller type and thickness, and turbulent flow conditions, N_p becomes nearly constant[10] and δ_D may be related to system variables as follows:

$$\delta_D \propto \left(\frac{Vd}{Re^3}\right)^{1/4} Sc^{-1/3} \tag{13}$$

This result also may be given in nondimensional form. The Sherwood number, Sh, is equivalent to Pd/D. Under liquid-side transport control according to the film theory,[7] $P = P_L = D/\delta_D$ and

$$Sh = \frac{d}{\delta_D} \propto Ko \cdot Sc^{1/3} \tag{14}$$

Ko is introduced as the corrected Kolmogorov number as follows:

$$Ko = \left(Re\frac{d}{\sqrt[3]{V}}\right)^{3/4} \tag{15}$$

which is defined as the ratio of the impeller diameter to the Kolmogorov length corrected for $N_p^{1/4}$; that is, $Ko \equiv d/(N_p^{1/4}\delta_K)$.

The relationship in eq 14 can also be written in a manner to test the dependence on individual variables; that is

$$P \propto d^{5/4} V^{-1/4} \omega^{3/4} \nu^{-5/12} D^{2/3} \tag{16}$$

or

$$\delta_D = D/P \propto d^{-5/4} V^{1/4} \omega^{-3/4} \nu^{5/12} D^{1/3} \tag{17}$$

Finally, it is useful to note that the same relationship may be obtained from

$$Sh \propto \left[\frac{d^4(\dot{Q}/V)}{\rho\nu^3}\right]^{1/4} \cdot Sc^{1/3} \tag{18}$$

which has been reported for mass transport at the interface of bubbles or small drops dispersed in a liquid.[7]

Materials and Methods

Chemicals—Methylene chloride (MC) was purchased from Fischer Scientific with gas chromatography (GC) purity of 99.9%. High-performance liquid chromatography (HPLC) grade acetonitrile (ACN), ethyl acetate (EA), and 2-propanol were also obtained from Fisher Scientific. PRA grade chloroform (suitable for pesticide residual analysis) was purchased from Sigma-Aldrich with GC purity of 99.9%. Poly(DL-lactide-*co*-glycolide) (PLGA; 50:50; intrinsic viscosity, 0.65 dL/g in hexafluoro-2-propanol (HFIP) at 30 °C; lot no. 410-27-1A) was obtained from Birmingham Polymers, Inc., and 80% hydrolyzed poly(vinyl alcohol) (PVA; average MW 9000–10 000) was purchased from Aldrich Chemical Company. Triamcinolone acetonide was obtained from Sigma Chemical Company with 99% purity. All chemicals were used as received.

Evaporation of Organic Solvents from Aqueous Solution—Evaporation of organic solvents from aqueous solution was carried out in a jacketed beaker (unbaffled), which was connected with a TYP FS2N water bath (HAAKE Instruments Inc., Saddle Brook, NJ) to maintain constant temperature. Dimensions of the jacketed beaker were 59 mm i.d., 90 mm o.d., and 122 mm height. An overhead stir-tester (G. K. Heller HST 20 series) was purchased from Glas-Col (Terre Haute, IN) and used to maintain a stable rotational speed (100–900 rpm) of an axially mounted turbine impeller (see Figure 1A). Turbine stirrers (45° pitch-blade and ringed, Figure 1B) all had the same thickness (1.2 cm) and were purchased from IKA-WORKS, Inc. (Wilmington, NC; catalog nos. R1311, R1312, and R1313 for stirrers with o.d.'s of 3, 5, and 7 cm, respectively). During the study, a known amount of organic solvent was dissolved in various volumes (150–1000 mL) of double distilled water or 0.3% PVA aqueous solution at a preset temperature and constant rotational speed. Samples were taken at scheduled time intervals and assayed by GC. When examining the large stirrer diameter or large bath volume, a glass cylindrical tank (top open, 166.5 mm i.d., 87.5 mm height) placed directly into the constant temperature bath was used. The constant temperature was confirmed by reading a thermometer inserted directly in the tank.

The volume replacement after each sampling was not carried out for the organic solvent evaporation studies at low temperatures. Control experiments demonstrated that the volume loss due to sampling had little influence on the determination of permeability coefficient (data not shown). However, at relatively high temperatures (T > 40 °C), the volume loss due to evaporation of water became noticeable. Under such conditions, manual water replacement was completed at 10-min intervals at a rate roughly equal to the evaporation rate so that total volume of the bath was kept nearly constant.

Organic Solvent Analysis by Gas Chromatography—Sample analysis was performed on a Varian series 3700 GC with a 5% Carbowax 20M 80/120 Carbopack B-AW analytical column (Supelco). The GC conditions for determination of MC, EA, and ACN in aqueous samples were as follows: N_2 and H_2 carrier gas flow rate, 30 mL/min; air flow rate, 300 mL/min; column oven temperature, 100 °C; and injector and flame ionization detector temperatures, 200 °C. For organic samples where MC was extracted by chloroform, a programmed column temperature gradient with the following settings was used: initial temperature of 100 °C for 2 min, followed by a temperature gradient of 80 °C/min, then a final temperature of 200 °C for 4 min.

Disruption of Gas-Phase Boundary Layer by Blowing N_2 (g) over the Gas/Liquid Interface—The evaporation experiments with nitrogen flow were carried out under identical conditions as the typical evaporation experiments, except that compressed nitrogen gas at room temperature was blown over the liquid/gas interface from a metal ferrule at a fixed gauge pressure (~28 psig; Figure 1A). The distal part of the metal ferrule was deformed to blow directly toward the center of the stirrer shaft to avoid violent disturbance to the surface of the evaporating solution. In this configuration, the gas was presumably forced from the bottom of the vortex outward along the surface of the liquid.

Encapsulation of Triamcinolone Acetonide by the Solvent Evaporation Method—The solvent evaporation encapsulation process was carried out by dissolving 2 × 800 mg of PLGA 50/50 and 2 × 40 mg of triamcinolone acetonide in 2 × 4 mL of MC in two 18 × 150-mm Pyrex glass tubes. A 1% (w/w) PVA aqueous solution (4 mL) was added to each tube, and the system was mixed for 20 s at the highest speed setting on a Vortex Genie 2 (Scientific Industries Inc., Bohemia, NY). The emulsion produced in both tubes was poured into a jacketed beaker (Figure 1A) that contained 142 mL of 0.3% PVA solution (30 °C), and the resulting mixture was stirred at 600 rpm. Samples drawn at specified times were assayed for organic solvent content. After 4 h of agitation, microspheres were collected, centrifuged, washed with double distilled water three times, freeze-dried for 2 days, and stored desiccated in microcentrifuge tubes at 4 °C.

Determination of MC Levels in Dispersed and Continuous Phases during Encapsulation—For MC evaporation without encapsulation, 1-mL aliquots were drawn from the hardening bath at each time point and stored at 4 °C in 1.9-mL Fisherbrand glass vials with a plastic screw cap fitted with a Teflon insert until GC analysis. A 50 μL aliquot of internal standard solution was added to each sample and mixed by vortex.

For determination of MC levels during encapsulation, samples were taken at each scheduled time point, which lasted <1 min/sample. A 0.3% PVA aqueous solution (2 mL) was replenished after each sampling procedure. For determining the MC content of the aqueous continuous phase, 1.4 mL of aqueous dispersion was withdrawn with a 5-mL polypropylene syringe and filtered through a 0.22-μm hydrophilic poly(tetrafluoroethylene) (PTFE) Millex filter unit (SE2M035J5, Millipore Corp.). Triplicate 200-μL aliquots from the filtered solution were mixed with 800 μL of pure water and 50 μL of internal standard and were subjected to GC analysis. Solvent concentrations were calculated by using a standard curve constructed with a filtered 0.3% PVA solution that contained known solvent concentrations processed by the same procedure.

For determination of MC in microspheres, the amount of MC in the dispersion was subtracted from the MC in the continuous phase. To accomplish this, triplicate 0.2-mL aliquots were taken directly from the stirred aqueous dispersion and placed in glass vials containing 0.5 mL of chloroform to prevent fast evaporation of MC. The glass vials were capped immediately. Samples were later mixed by vortex for 5 s and stored overnight at 4 °C to extract MC into chloroform before the GC analysis. The calculation of concentration of MC in the sample was based on the standard curve constructed by equilibrating a series of known amounts of MC in 0.5 mL of chloroform with 0.2 mL of 0.3% PVA aqueous solution, as in the sample preparation case. An impurity in the purchased PRA grade chloroform was used as the internal standard after appropriate validation to correct for variability in injection volume. This compound was stable in chloroform and its polarity was similar to that of MC.

The MC content in the hardening polymer phase (w/w MC/PLGA ratio) during the hardening period was calculated with eq 27, which is described in the *Data Analysis* section. The MC loss during pouring was determined gravimetrically after pouring the emulsion into a tared capped bottle.

Determination of MC Solubility in 0.3% PVA Aqueous Solution—A 5-mL aliquot of MC was added to 10 mL of 0.3% PVA (aq) in 20-mL scintillation vials and mixed. Samples were put on a type 50800 Thermolyne shaker (Bamstead/Thermolyne Corp., Dubugue, IA) under mild agitation in a Precision Economic Incubator (Precision Scientific, Chicago, IL) set at 30 ± 0.5 °C. Samples were taken out every 8 h and vigorously agitated. After 2 days, 200-μL aliquots were removed from the aqueous layer and mixed with 800 μL of pure water and 50 μL of internal standard, and then assayed by GC. Solubility of MC at 30 °C was determined to be 22.6 ± 0.7 mg/mL (mean ± SD, $n = 6$).

Data Analysis—*Calculation of the Surface Area*—Surface area, A, used to determine P was estimated manually for each stirring condition. First, a line was drawn around the outer wall of the stirred beaker, which traced the contour of the air/water surface during the evaporation experiments. After the experiment, a piece of paper was inserted vertically into the beaker and a second line was obtained by projecting the first contour line on the paper. The surface area was calculated by integrating the strips, which were generated by rotating the projected line (which had been segmentally divided) about its center axis.[11]

Determination of Permeability Coefficient P—Below ~3 mg/mL (for MC), the slope of ln C versus t line was constant, and eq 5 is thus satisfied. The value of P was determined from $P = k'V/A$, where k' is the least squares slope of ln C versus t data. The r^2 was invariably >0.99.

Estimation of Diffusion Coefficient and Kinematic Viscosity in the Hardening Bath—The diffusion coefficients for various organic solvents in the aqueous hardening bath under different temperatures were estimated by the Wilke–Chang equation:[12]

$$D = \frac{7.4 \times 10^{-8}(\Phi M_B)^{1/2} T}{\eta_B V_A^{0.6}} \tag{19}$$

where D is the mutual diffusion coefficient of organic solvent at very low concentrations in the aqueous solvent (cm^2/s), M_B is the molecular weight of water, T is the temperature (K), η_B is the viscosity of water (cp), V_A is the molar volume of organic solvent at its normal boiling temperature (cm^3/mol), and Φ is the association factor (2.6 for water). Values of V_A for EA and ACN were taken from literature,[12] whereas the V_A for MC was calculated from the average of estimation methods by Schroeder and Le Bas.[12]

$$\ln \eta_B = k_1 + k_2/T + k_3 T + k_4 T^2 \tag{20}$$

where $k_1 = -0.02471$, $k_2 = 4209$, $k_3 = 0.04527$, and $k_4 = -0.00003376$.

The kinematic viscosity was determined from the ratio of η_B with eq 20 and ρ, which was obtained from literature.[10]

Prediction of Hardening Profile from Microspheres During Encapsulation—According to eq 6, the cumulative organic solvent removed from microspheres, M_H, can be expressed as a function of V, A, C, P, and t. Because V, A, and C can be determined directly during the encapsulation experiment and P can be obtained from pure evaporation experiments carried out under the same conditions as during encapsulation, the hardening profile [i.e., $M_H(t)$ versus t] can be predicted without direct measurement.[13]

However, most encapsulation protocols result in values of C in the range where P is dependent on C. The origin of this dependence is largely determined by the contribution of the derivative of ln(activity coefficient) with respect to ln C.[7] The value of $P(C)$ was determined from a series of pure evaporation experiments ($C_0 \cong C_S$) under the encapsulation conditions of interest (i.e., $V = 150$ mL, $d = 3$ cm, $T = 30$ °C, and $\omega = 600$ rpm). According to eq 4, when $R_H = 0$,

$$V\frac{dC}{dt} = -P(C)\cdot AC \tag{21}$$

which may also be written as

$$P(C) = -\frac{V}{A}\frac{d \ln C}{dt} \tag{22}$$

An n^{th}-order polynomial interpolating function, $p_n(\ln C)$, was fit to the t versus ln C data obtained during evaporation. The $P(C)$ was then determined from the derivative of the $p_n(\ln C)$ with respect to ln C. The interpolating function is

$$t = a_n(\ln C)^n + \ldots + a_1(\ln C)^1 + a_0 = p_n(\ln C) \tag{23}$$

The derivative, d ln C/dt, may be determined from eq 23 by using the chain rule

$$\frac{d(\ln C)}{dt} = \frac{1}{na_n(\ln C)^{n-1} + \ldots + a_1} = \frac{1}{\dfrac{d[p_n(\ln C)]}{d(\ln C)}} = \frac{1}{p_n'(\ln C)} \tag{24}$$

From eqs 22 and 24, $P(C)$ becomes

$$P(C) = -\frac{V}{A}\frac{1}{p_n'(\ln C)} \tag{25}$$

Over the entire concentration range where encapsulation occurs, eq 6 may be rewritten as follows, accounting for concentration-dependent $P(C)$:

$$M_H(t) = \int_0^t R_H dt = V[C(t) - C_0] - V\int_0^t \frac{1}{p_n'(\ln C)} C dt = V\left[q_n(t) - \int_0^t \frac{q_m(t)}{p_n'[\ln q_m(t)]} dt\right] \tag{26}$$

where $C_0 = 0$, and $q_m(t)$ is an mth order polynomial interpolating function for C versus t during encapsulation. From eq 26, the hardening profile M_H was determined numerically by the Runge–Kutta method[14] on a spread sheet (time step size = 0.1 min).

Calculation of Cumulative Amount of MC Removed, M_H, during Encapsulation—The MC content in the dispersed polymer phase was calculated on the basis of the difference of MC in the total aqueous dispersion and in the continuous phase, as follows:

$$C_{DP}(t)(w/w) = \frac{[C_T(t)/\Psi(t) - C(t)]V}{M_P} \quad (27)$$

where C_T, M_P, and Ψ, are the measured MC content in the aqueous dispersion, the overall mass of PLGA in the dispersed system, and the ratio of the volume of the continuous phase to the volume of the entire aqueous dispersion, respectively. The value of Ψ ranged from 0.95 to 1.0 in the experiment and was approximated by

$$\Psi(t) \cong 1 - \frac{C_T(t) - C(t)}{C_T(0)} \quad (28)$$

where $C_T(0)$ is the initial MC content in the aqueous dispersion.

The cumulative amount of MC removed during hardening (or the cumulative hardening profile), M_H, was then calculated according to the following equation:

$$M_H = V[C_{DP}{}^0 - C_{DP}(t)] \quad (29)$$

where $C_{DP}{}^0$ was estimated by the starting weight ratio of the MC to the polymer just before the emulsion was formed and then corrected by the loss of MC into the air during pouring. This loss was determined to be 4.0 ± 0.6% (mean ± SD, $n = 5$).

Results

Organic Solvent Evaporation Kinetics—The kinetics of evaporation in the hardening bath was observed to be first-order under dilute conditions ($C < 3$ mg/mL), as shown for MC evaporation in Figure 2. Also shown in the figure is that increasing either rotational speed or temperature resulted in a faster loss of solvent from the bath (i.e., an increased evaporation rate). The slope of the first-order plots of the type in Figure 2 and the determined air/water surface area (see Experimental Section) allowed the calculation of the P.

Correlation of *P* with Process Variables—To test the correlation in eq 16, four variables were varied independently during the evaporation of MC: temperature (T), liquid volume (V), rotational speed (ω), and diameter of the overhead stirrer (d). Among these variables, V, ω, and d directly appear in the theoretical relationship for P in eq 16. The T influences both kinematic viscosity of water (ν) and the diffusion coefficient of organic solvent in the water (D). The results are shown in Figure 3.

Good linearity between P and process variables, which were raised to their appropriate power according to eq 16, was observed for ω, V, and d under tested conditions. The value of ω was varied from 100 to 900 rpm, that of V from 150 to 1000 mL, and that of d from 3 to 7 cm. The correlation between P and $\nu^{-5/12}D^{2/3}$ [i.e., $f(T)$], however, was not as successful at first glance. A significant deviation from linearity was observed at 5 °C.

Because P_{exp} became nonlinear with respect to the product, $\nu^{-5/12}D^{2/3}$ at the low T, a partial gas-phase control was postulated. According to this postulate, the plotted data from Figure 3 obtained at $T \geq 25$ °C were combined to form a master curve, yielding a proportionality constant a, according to eq 16. Excellent agreement was observed ($r^2 = 0.95$), as shown in Figure 4. This high correlation strongly validates eq 16 for the prediction of P for MC at $T \geq 25$ °C.

Contribution of the Gas-Phase Unstirred Layer to the Overall Mass Transport Resistance—To understand the deviation from eq 16 by the MC data at low T in Figure 3 and to understand the rate-limiting step for mass transport during organic solvent evaporation, the evaporation of two additional solvents, EA and ACN, were studied. In addition, a light flow of nitrogen gas across the air/water interface was included in the experimental procedure to disturb any unstirred layer in the gas phase. It was assumed that by blowing the N_2 (g) over the surface of the liquid, the unstirred layer in the gas phase would be mixed, shifting the rate-determination step (transport control step) to the liquid side. It was also assumed that the light flow of gas would have little effect on the boundary layer in the liquid phase because the N_2 gas flow did not have a direct impact on the gas/liquid interface; that is, the liquid surface contour was not significantly distorted.

Because T appeared to play a role in the transport control of MC in Figure 3, the temperature was varied with and without N_2 flow during the evaporation of the three solvents. As shown in Figure 5, the flow of N_2 gas increased the P in all cases. However, in the two experiments

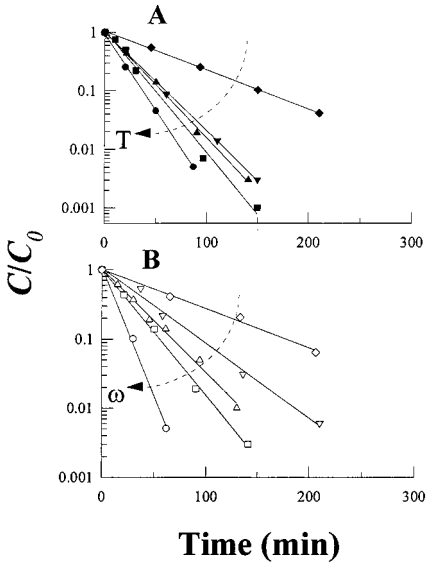

Figure 2—Loss of MC in the hardening bath follows first-order kinetics under dilute condtions. (A) Temperature was varied from 5 (◆), to 25 (▲), to 30 (▼), to 35 (■) and to 40 (●) °C while maintaining ω, V, and d at 600 rpm, 150 mL, and 3 cm, respectively. (B) Rotational speed was varied from 100 (◇), to 300 (▽), to 450 (△), 600 (□), and 900 (○) rpm, while maintaining T, V, and d at 30 °C, 150 mL, and 3 cm, respectively.

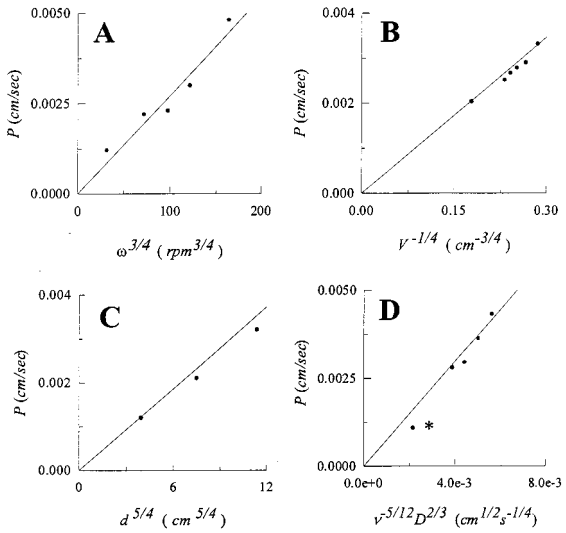

Figure 3—Correlation of process variables with permeability coefficient P. The measured P was correlated with (A) $\omega^{3/4}$ at constant T, V, and d; (B) $V^{-1/4}$ at constant ω, T, and d; (C) $d^{5/4}$ at constant ω, T, and V; and (D) $\nu^{-5/12}D^{2/3}$ (variation of T) at constant ω, ν, and d. The theoretical lines were produced from the master curve in Figure 4. Constant conditions were $T = 30$ °C (303 K), $\omega = 600$ rpm, $V = 150$ mL, and $d = 3$ cm. * The evaporation mechanism at the lowest temperature ($T = 278$ K) was governed by both the gas and liquid phases (see Figure 5).

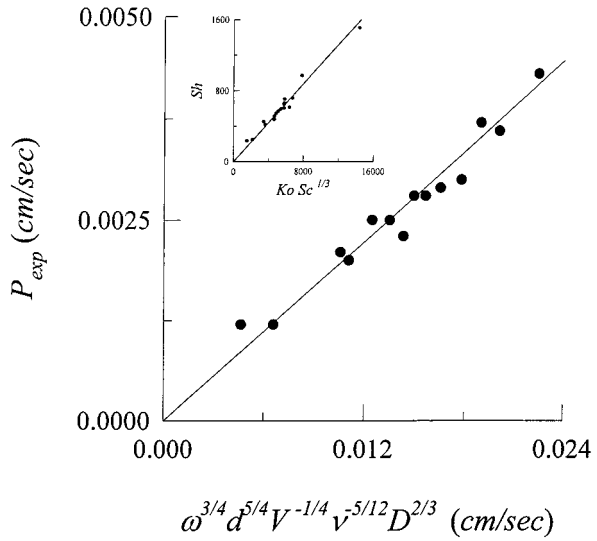

Figure 4—Generation of master curve for evaporation under turbulent flow conditions and liquid-side transport control. The *P* was correlated with the product ($\omega^{3/4}d^{5/4}V^{-1/4}\nu^{-5/12}D^{2/3}$), $r^2 = 0.95$. The data were obtained from evaporation of MC at $T \geq 25$ °C (liquid-side transport control, see Figure 5). The proportionality constant, *a*, was 0.18. Insert: The master curve in dimensionless form: *Sh* is correlated with $Ko \cdot Sc^{1/3}$ ($r^2 = 0.97$) for the same data set.

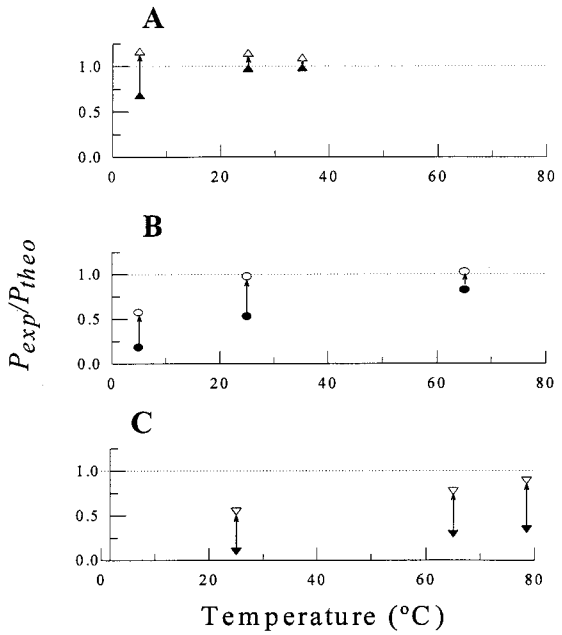

Figure 5—The influence of the gas-phase resistance to solvent evaporation. The gas-phase boundary layer was either unaltered (closed symbols) or disrupted by light N_2(g) flow over the air–water surface (open symbols). The ratio of experimental permeability to that calculated from the master curve obtained in Figure 4 (i.e., P_{exp}/P_{theo}) was determined for (A) methylene chloride, (B) ethyl acetate, and (C) acetonitrile.

included in the master curve (Figure 4; i.e., MC at 25 and 35 °C), the increase was not substantial (<15%). This result indicated that the gas phase had negligible resistance to the transport of MC under these conditions, which is consistent with the assumptions used to arrive at eq 16. In contrast, as *T* was decreased to 5 °C, the presence of N_2 (g) raised the value of P_{exp} near the value expected by liquid-side control as determined with eq 16. This large difference in P_{exp} induced by N_2 flow justifies the exclusion of the 5 °C data in Figure 4.

EA and ACN were selected for evaluation because their Henry's law constants, *H*, favor gas-phase control relative to MC. Because P_L or P_G should not strongly depend on the type of solvent, *H* was used as an indicator of the gas to obey liquid-side transport control at a given temperature according to eq 3. In Table 1, the relative trend of the values of *H* for various solvents at constant *T* is given. Because MC has a low bp (and a high saturated vapor pressure, p^v) and a low solubility in water (C_s), *H* ($\sim p^v/C_s$) must be a relatively high value. Because EA has a higher bp (therefore a lower p^v) and a higher C_s than MC, it must have a lower *H* (i.e., *H* = medium). Finally, because ACN has an equivalent bp to EA but is completely miscible with water, the *H* for ACN must be even lower (i.e., *H* = low). Therefore, it is expected that the trend favoring liquid-side transport control is MC > EA > ACN.

Table 1—Properties of Organic Solvents Examined for Evaporation[a]

organic solvent	bp (°C)[b]	p^v	C_s (w/w)	H ($\sim p^v/C_s$)	observed transport control at 25 °C[f]
MC	40	high	2.0%[c]	high	liquid
EA	77	med	6.92%[d]	med	mixed (gas/liq)
ACN	82	med	miscible[d]	low[e]	gas

[a] Abbreviations: bp normal boiling point; p^v, saturated vapor pressure; C_s, aqueous solubility; *H*, Henry's law constant. [b] Values were taken from ref 15. [c] Values at 25 °C were taken from ref 16. [d] Values at 25 °C were taken from ref 15. [e] $H \sim p^v/C_s$ only applicable to EA and MC. ACN is completely miscible with H_2O resulting in a very low *H*. [f] See Table 2.

As shown in Figures 5B and 5C, as *T* was increased, $P_{exp,\ w/o\ N_2(g)}$ for EA and ACN approached both the $P_{exp,\ w/N_2\ (g)}$ and the P_{theo}, as was the trend for MC just described. Also as expected, the resistance in the gas phase was steadily more difficult to overcome as *H* was decreased (following the trend MC < EA < ACN), indicating the gas-phase resistance increases as *H* decreases. At 25 °C the transport control was in the liquid phase for MC, in both liquid/gas phases for EA, and in the gas phase for ACN (Table 1). These data are consistent with (1) the validity of the correlation in eq 16 to predict *P* under liquid-side transport control conditions, and (2) the presence of significant gas-phase resistance when *H* becomes too low.

Independence of δ_D on *T*—The theoretical boundary layer thickness in the liquid phase varied from ~30 to 170 μm, as shown in Table 2 (which also summarizes the evaporation data). The range of δ_D values determined from theory are consistent with typical values quoted from the literature.[7] A particularly notable trend was the independence of δ_D on *T*. In Table 2, for protocol #1−5, $\delta_D \sim 45\ \mu$m for a temperature range of 5−40 °C. This theoretical result was also confirmed experimentally as indicated by the equivalence of $P_{exp,w/N_2\ gas}$ and P_{theo} for this data set.[25]

Determination of Concentration-Dependent Permeability Coefficient—To make practical use of the evaporation treatment described here, the evaporation was related to the formulation of the microspheres; that is, microsphere hardening kinetics. To illustrate this relationship, the permeability coefficient in the concentration-dependent regime was acquired under the same conditions used during the encapsulation (vide infra). To obtain a reliable permeability coefficient $P(C)$ for the calculation, multiple pure evaporation experiments were performed (three of them from pure water and one of them from 0.3% PVA aqueous solution[17]). After fitting each group of data with a 4th-order polynomial (see eq 11), the data were normalized by plotting ln *C* versus ($t - a_0$), as shown in Figure 6A. This normalization was necessary because MC is so volatile that it is very difficult to start at an exact

[a] $P_{theo} \equiv a\,\omega^{3/4} d^{5/4} V^{-1/4} \nu^{-5/12} D^{2/3}$ (where a is the regression constant), according to linear regression of master curve in Figure 4. [b] Transport governed by liquid-side (liq), gas-side (gas), or a combination (gas/liq). [c] Blowing of N_2(g) over the air/liquid surface was also performed for this protocol; value of P_{exp} for blowing experiment is given in parentheses. [d] The large glass vessel instead of the jacketed beaker was used to perform the evaporation study.

concentration at a precise designated time. Also shown in the figure, the second-, third-, fourth-, and sixth-order polynomial fit (according to eq 23) for the same group of data all interpolated the data extremely well. To select the optional $p_n(\ln C)$, the slope of each polynomial was compared with the slope of the data as C approaches C_s, as shown in Figure 6B. Among $n = 2$, 3, 4, and 6, the optional fit according to this criterion was between $n = 3$ an 4, so $p_3(\ln C)$ was selected for future use.

Predicting Microsphere Hardening Kinetics—To test the ability to predict the hardening profile, a drug soluble in MC, triamcinolone acetonide, was encapsulated in PLGA microspheres under standard conditions of encapsulation. These data are shown in Figure 7. The normalized MC concentration in the continuous phase (i.e., C/C_s) became essentially saturated ($C^* \sim 1$) for the first 40 min, and then declined sharply until negligible solvent remained by 200 min. The normalized MC concentration in the dispersed phase (i.e., C_{DP}/C_{DP}^0) declined exponentially over this time interval until the particles were dry.

Also shown in Figure 7 is the 6th-order interpolating function of $C(t)$, $q_6(t)$. From $q_6(t)$ and $p_3'(\ln q_6(t))$, the hardening profile $M_H(t)$ was predicted and displayed in Figure 8. The theoretical M_H matched very closely with the experimental value determined from the C_{DP} versus t data shown in Figure 7. Thus, both the concentration-dependent $P(C)$ determined without encapsulation and the experimental procedure to detect C and C_{DP} have been validated.

Distribution of Organic Solvent during Encapsulation—The distribution of MC during encapsulation of triamcinolone acetonide is depicted in Figure 9. Note again, over the first 40 min, the concentration of MC in the continuous phase was nearly saturated. It is important to note that hardening still occurred over this time interval, despite this elevated bath concentration, at a rate very similar to the evaporation rate.[18] Thus, the hardening rate during this interval was limited by evaporation. After this period, the hardening rate declined and the MC amount in the continuous phase began to fall below saturation. The

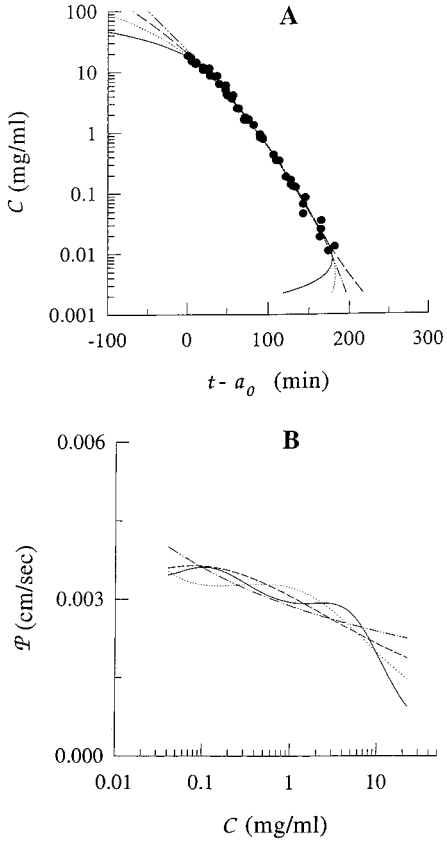

Figure 6—(A) Determination of the interpolating n^{th} order polynomial function to describe the permeability coefficient. The 2nd (–•••–), 3rd (– –), 4th (••••), and 6th (—)-order polynomial functions, $p_n(\ln C)$, were fitted according to eq 21 for the normalized evaporation data ($n = 4$). (B) The dependence of P on C (log-scale), as determined from the derivative of the n^{th} order polynomial interpolating functions with respect to ln C according to eq 25.

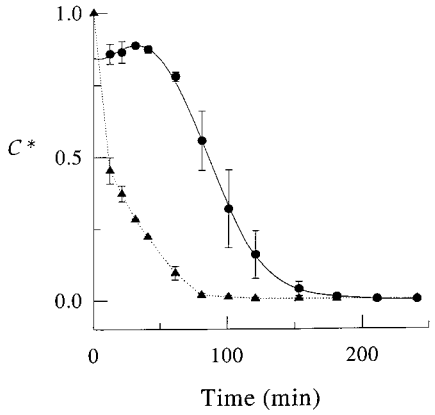

Figure 7—The concentration decline of MC during microencapsulation of triamcinolone acetonide by the solvent evaporation method. The concentration in dispersed (▲) and continuous phases (●) were normalized by the initial MC concentration in the polymer C_{DP}^0 (i.e., $C^* = C_{DP}/C_{DP}^0$) and by the solubility of MC in 0.3% PVA aqueous solution (i.e., $C^* = C/C_s$), respectively. The plotted data are mean ± SD ($n = 2$). (—) is a sixth-order polynomial fit, $q_6(t)$, and (·····) connects data points.

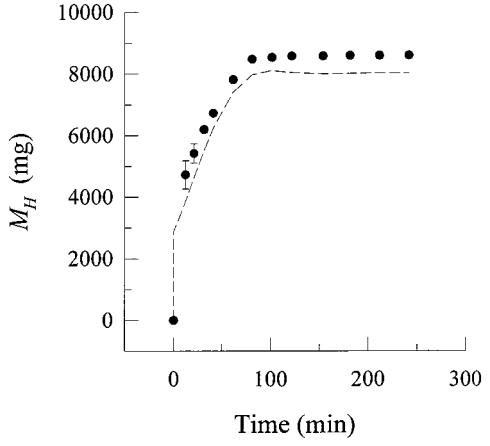

Figure 8—Predicting the hardening profile during microencapsulation of triamcinolone acetonide from $q_6(t)$ and $p_3'(\ln q_6(t))$. The microsphere hardening profile was measured (●) and predicted (– – –). The plotted data are mean ± SD ($n = 2$).

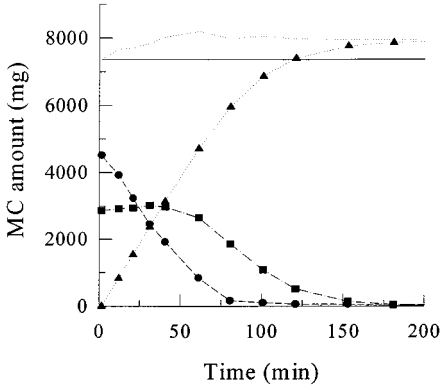

Figure 9—The distribution of MC during microencapsulation of triamcinolone acetonide. The mass of MC was determined in the dispersed phase (●), the continuous phase (■), and the surroundings (evaporated) (▲) during the hardening of the microspheres. The overall mass recovered from the calculation (·····) showed good agreement with the initial MC in the hardening bath (—).

sum of MC mass from experimentally determined C, C_{DP}, and the theoretical loss of MC to surroundings ($\int R_E dt$) accounted for 104−110% of the mass during the entire encapsulation experiment.

For completeness, microspheres thus formed were observed to be spherical under the microscope and had a size distribution of 44 ± 18 (mean ± SD, $n = 100$) by light microscopic size determination. The triamcinolone acetonide loading was 3.9 ± 0.2% (mean ± SD, $n = 6$) as determined by HPLC after dissolution of the polymer in acetonitrile.[19] Control studies also revealed that the controlled-release function of these microspheres was intact; that is, release was slow and continuous for >30 days.

Discussion

Identification of Process Variables that Control Solvent Evaporation—The most efficient method to change the evaporation rate was to adjust ω, d, or T. The effect of V was very weak (−1/4 power dependence). As indicated by the similarity of P_{exp} and P_{theo} in Table 2 (usually <15% error when under liquid phase transport control), the relationship in eq 16 is well validated. This result suggests the potential to accurately affect the hardening rate of microspheres by manipulating the continuous phase concentration, C, during encapsulation. Specific applications of eq 16 will be pursued in a future paper.

Rate-Limiting Step for Mass Transport during Evaporation—As shown in the *Theoretical Section*, the resistance to mass transport in an evaporation system originates from two major sources: the diffusion layers in the liquid and gas phases. Because these two resistance are in series, if one resistance is much greater than the second, the greater of the two will largely determine the overall resistance. If the unstirred layer is relatively thin in the gas phase (or resistance is very small) compared with the liquid phase, the overall mass transport barrier will reside in the liquid phase. Under these conditions, the P of the evaporation system can be predicted by eq 16 with reasonable accuracy (Table 2). If the resistance in the gas phase is not too large to be reduced effectively by N_2 gas flow, the P may still be predicted by eq 16 with acceptable accuracy, as evidenced by the data for MC at 5 °C and for EA at 25 °C (Figure 5).

The analysis in Figure 5 confirms the hypothesis that the Henry's law constant and temperature are the predominant indicators of whether a specific organic solvent evaporates according to gas- or liquid-side transport control. Dissolved gases, such as O_2, with extremely high values of H will always be liquid-side transport limited,[20] and solvents such as ACN that are highly soluble in water with lower vapor pressure (i.e., low H) will be expected to be gas-side transport limited. A particularly notable result was that MC at room temperature is liquid-side transport limited, whereas EA, a frequently used alternative in encapsulation, has a significant resistance in the gas phase at this temperature. This result suggests that blowing N_2 (g), as performed here and elsewhere,[21] may be appropriate for the use of EA at room temperature.

Physical Description of Solvent Evaporation from the Hardening Bath—It was demonstrated that under the most common encapsulation conditions (i.e., MC evaporation at room temperature in turbulent flow), the evaporation largely falls under liquid-phase transport control. Two important concepts underlie the mass transport in the liquid-phase boundary layer. The first concept is turbulence. The nature of the turbulence induced by the impeller controls the size and speed of the smallest eddies that approach the evaporating surface. The eddy of size $\sim\delta_K$ is formed by an energy cascade, which begins with large eddies that are unstable and break up into steadily smaller liquid "packages" of chaotic movement. At the scale where local $Re \sim 1$, the fluid elements lose their kinetic energy to thermal energy. Because δ_K is only dependent on the

kinematic viscosity and the total energy per unit mass (or volume) of fluid according to the assumption of isotropic turbulence, the evaporation rate is somewhat independent of bath geometry after correction for the surface area at the air/water interface. There is, however, a small dependence of P on bath volume because more fluid means more fluid mass available to dissipate the turbulent energy. This dependence as well as the dependence of P on $d^{5/4}$, have obvious scaling implications.

The second concept is the velocity distribution in the viscous sublayer and how it is affected by the approaching eddy to the free air/water surface. The velocity distribution affects the relationship between the diffusion layer thickness and viscous sublayer thickness (by either $Sc^{-1/2}$ or $Sc^{-1/3}$). Because organic solvents are surface active,[22] we must have the equivalent of the 'dirty' surface case, which is similar hydrodynamically to the liquid/solid interface. This hypothesis was confirmed by the validity of eq 16, which would not have been so if a "clean" surface was assumed. The parabolic velocity distribution in the sublayer leads to the well-known variation of δ_D with $Sc^{-1/3}$.[23]

The Role of Solvent Evaporation on Microsphere Hardening during Microencapsulation—Because the microsphere hardening profile was successfully predicted with $P(C)$ and C without directly measuring C_{DP}, it is theoretically possible in the future to continuously monitor the microsphere hardening kinetics by simply measuring C during encapsulation provided that the $P(C)$ is known. It is also reasonable to envision on-line systems to monitor the continuous-phase organic solvent concentration during encapsulation. Because the microsphere hardening kinetics may directly affect the final microsphere quality, the monitored results could potentially be used as quality control criteria for microsphere production.

It is important to note, however, that it is expected that the evaporation will only play a dominant role in the microsphere hardening kinetics if two conditions are satisfied: (1) the extraction capacity of the continuous phase has been saturated; and (2) the diffusion rate of organic solvents from the dispersed phase (DP) to the continuous phase (CP) is fast compared with the solvent evaporation kinetics. The first condition is determined by the organic solvent solubility in continuous aqueous phase and the initial DP/CP volume ratio. The second prerequisite, however, will be much more complicated and influenced by several factors, including the initial organic solvent extraction rate, polymer MW and concentration, and temperature of encapsulation.[24] All these factors are directly related to the microsphere hardening conditions and remain to be investigated in the future.

In closing, the mechanism of evaporation during solvent evaporation encapsulation processes has been elucidated, confirmed experimentally, and used to predict microsphere hardening kinetics. These results have potential use for formulation, design of encapsulation apparatus, and scaling-up of microsphere production.

Nomenclature

A = surface area of air−water interface, cm^2
C = organic solvent concentration in the continuous phase of the bath, mg/mL
C_0 = initial organic solvent concentration in the continuous phase of the bath, mg/mL
C_{DP} = MC content in the dispersed polymer phase, mg/mg PLGA
C_{DP}^0 = initial MC content in the dispersed polymer phase, mg/mg PLGA
C_S = solubility of organic solvent in the continuous phase of the bath, mg/mL
C_T = MC content in the entire aqueous dispersion, mg/mL
C^* = normalized MC content in continuous phase ($C^* = C/C_s$) or in dispersed phase (DP; $C^* = C_{DP}/C_{DP}^0$), unitless
D = diffusion coefficient of the organic solvent in the continuous phase of the bath, cm^2/s
d = impeller diameter, cm
H = Henry's law constant, atm·mL/mg
j_s = organic solvent flux at the air/liquid interface, mg/(cm^2·s)
Ko = corrected Kolmogorov number, $d/(\delta_K \cdot N_p^{1/4})$, unitless
M_B = molecular weight of aqueous solvent in the bath, g/mol
M_H = cumulative mass removed from microspheres, mg
M_P = mass of PLGA in the dispersed aqueous system, mg
N_P = power number, unitless
P = overall permeability coefficient, cm/s
P_G = permeability coefficient in the gas phase, mg/(atm·cm^2·s)
P_L = permeability coefficient in the liquid phase, cm/s
p_n = n^{th}-order polynomial interpolating function for t versus ln C during evaporation, min
$\dot{Q}$ = rate of energy loss from the impeller to the fluid, g·cm^2/s^3
q_m = mth-order polynomial interpolating function for C vs t during encapsulation, mg/mL
R_E = organic solvent evaporation rate, mg/min
R_H = overall rate of organic solvent removal from microspheres (i.e., hardening rate), mg/min
Re = impeller Reynolds number, $\omega\, d^2/\nu$, unitless
Re^* = local Reynolds number, $u_e\delta_e/\nu$, unitless
Sc = Schmidt number, ν/D, unitless
Sh = Sherwood number, Pd/D, unitless
T = temperature, K
t = time, min or s
u_e = velocity of the eddies approaching air−water interface, μm/s
V = volume of fluid in the hardening tank, mL
V_A = molar volume of organic solvent at its boiling temperature, cm^3/mol
δ_e = length scale of the eddies approaching air−water interface, μm
δ_D = diffusion sublayer thickness, μm
δ_K = Kolmogorov length scale, μm
δ_V = viscous sublayer thickness, μm
ϵ = energy dissipation rate per unit mass fluid, cm^2/s^3
ν = kinematic viscosity, cm^2/s
η_B = viscosity of aqueous solution in hardening bath, cp
ω = rotational speed of overhead stirrer, rev/s or rpm
Φ = association factor (for prediction of D), unitless
Ψ = ratio of the volume of the continuous phase to the volume of the entire aqueous dispersion, unitless
ρ = density of aqueous solution in hardening bath, mg/mL

Abstract ☐ The concept of correlating pharmacokinetic parameters with body weight from different animal species has become a useful tool in drug development. The allometric approach is based on the power function, where the body weight of the species is plotted against the pharmacokinetic parameter(s) of interest. Clearance, volume of distribution, and elimination half-life are the three most frequently extrapolated pharmacokinetic parameters. Over the years, many approaches have been suggested to improve the prediction of these pharmacokinetic parameters in humans from animal data. A literature review indicates that there are different degrees of success with different methods for different drugs. Overall, though interspecies scaling requires refinement and better understanding, the approach has lot of potential during the drug development process.

Introduction

To develop a new therapeutic compound, relevant pharmacological and toxicological studies are initially conducted in small laboratory animals such as mice, rats, rabbits, dogs, or monkeys. These initial studies are helpful in screening the potential therapeutic compounds in the process of drug development. This extrapolation, termed as interspecies scaling, may be helpful in the selection of a suitable dose for first-time administration to humans.

Interspecies scaling is based on the assumption that there are anatomical, physiological, and biochemical similarities between animals.[1,2] Two approaches are generally used for interspecies pharmacokinetic scaling: (i) physiological-based models, and the (ii) allometric method. Though physiological models provide a mechanistic-based evaluation of drug disposition, these models are complex. Many investigators[3−6] have used physiological-based models to predict pharmacokinetic parameters of drugs. Since physiological models are costly, mathematically complex, and time-consuming for their use in drug discovery, and development remains limited.

The anatomical, physiological, and biochemical similarities between animal species can be generalized and expressed mathematically by the allometric equations and have been discussed in detail by Boxenbaum.[7,8] Though the allometric approach is empirical, it is less complicated and easy to use than the physiologically based models. Therefore, this review will only focus on the basic principles, application, and issues of the allometric scaling in pharmacokinetics.

The allometric approach is based on the power function, as the body weight from several species is plotted against the pharmacokinetic parameter of interest. The power function is written as follows:

$$Y = aW^b \tag{1}$$

where Y is the parameter of interest, W is the body weight, and a and b are the coefficient and exponent of the allometric equation, respectively. The log transformation of eq 1 is represented as follows:

$$\log Y = \log a + b \log W \tag{2}$$

where $\log a$ is the y-intercept, and b is the slope.

Clearance (CL), volume of distribution (V), and elimination half-life ($t_{1/2}$) are the three most important pharmacokinetic parameters. In the forthcoming sections different allometric approaches to predict these pharmacokinetic parameters from animals to man will be discussed.

Clearance

Both in drug discovery and drug development, clearance is the focus of attention. During drug discovery or the screening process, clearance is important since drugs which are eliminated quickly may have a low bioavailability and may not be suitable for further investigation. Clearance can also play an important role for the selection of the first-time dosing in humans (as inverse of clearance indicates the total exposure (AUC) of a drug). Therefore, over the years, a lot of attention has been focused in order to improve the performance of allometry to predict clearance.

A glance on the literature indicates that clearance cannot be predicted only using the simple allometry (body weight vs clearance).[9,10] Over the years, many different approaches have been suggested to address this issue. Some of the approaches are (i) to predict clearance on the basis of species weight and maximum life-span potential (MLP),[7] (ii) the use of a two-term power equation[11] based on brain weight and body weight to predict intrinsic clearance of drugs, (iii) use of the product of CL × brain weight,[9,10] and (iv) the normalization of in vivo clearance by in vitro clearance versus body weight.[12−14] Unfortunately, these approaches are used indiscriminately without identifying the suitability of a given approach.

In a study, Mahmood and Balian[9] showed that CL × MLP or CL × brain weight estimates the clearance of some antiepileptic drugs more accurately than the simple allometric approach (CL vs body weight). But it is also important to know under what circumstances the simple allometric equation, CL × MLP or CL × brain weight is most suitable. Mahmood and Balian[10] proposed the selection of one of the methods based on the exponents of the simple allometry. The authors demonstrated that there are specific conditions under which only one of the three methods can be used for reasonably accurate prediction (a maximum of 30% error) of clearance: (i) if the exponent of the simple allometry lies between 0.55 and 0.70, simple allometry will predict clearance more accurately than CL × MLP or CL × brain weight; (ii) if the exponent of the simple allometry lies between 0.71 and 1.0, the CL × MLP approach will predict clearance better compared to simple allometry or CL × brain weight; and (iii) if the exponent of the simple allometry is ≥1.0, the product of CL × brain weight is a suitable approach to predict clearance in humans compared to the other two methods. If the exponent of the simple allometry is greater than 1.3, it is possible that the prediction of clearance from animals to man may not be accurate even using the approach of CL × brain weight, and if the exponent of simple allometry is below 0.55, the predicted clearance may be substantially lower than the observed clearance. However, this "rule of exponents" is not rigid, and caution should be applied when the exponents are on the borderline (i.e., 0.69 vs 0.71).

The exponents of allometry have no physiological meaning. As the exponents of the simple allometry get larger, the predicted clearance will be comparatively higher than the observed clearance. Furthermore, the normalization of clearance by MLP or brain weight is a mathematical manipulation which may not be associated with any physiological relevance. The predicted clearance values will be in order of simple allometry > MLP × CL > brain weight × CL. The exponents of a given drug are not universal and will depend on the species used in the allometric scaling. This has been shown for theophylline and antipyrine following iv administration,[10] though this will be true for any given drug.

The concept of using a fixed exponent of 0.75 for the prediction of clearance does not seem to be appropriate. From the data published by Mahmood and Balian,[10] it can be seen that the exponents of allometry range from 0.35 to 1.39. The mean of the exponents is 0.78, which is close to 0.75, but given the wide range of exponents it is obvious that using a fixed exponent of 0.75 will produce serious errors in the prediction of clearance. However, it should be noted that the use of a fixed exponent may be helpful when pharmacokinetic data from only one species are available. This approach may provide a rough estimate of clearance.

Incorporation of in Vitro Data in in Vivo Clearance—Over the years, a lot of interest in using in vitro data in allometric scaling has been developed, and a comprehensive review article has been published by Houston[12] on this topic. Recently, Lave et al.[13] attempted to predict hepatic clearance of 10 extensively metabolized drugs in man by incorporating in vitro data into allometric scaling. The authors concluded that integrating the in vitro data with the allometric approach improved the prediction of clearance in humans as compared to the approach of the simple allometry or the product of clearance and brain weight. In their comparison between simple allometry or the product of clearance and brain weight with the in vitro approach, Lave et al. assumed that clearance of all drugs can be either predicted by simple allometry or by the product of clearance and brain weight. Since this assumption is incorrect, Lave's data[13] were reanalyzed by Mahmood[15] and the results indicated that the normalization of clearance by MLP (as required based on the exponents) could have produced the same results as observed by the in vitro approach. Furthermore, based on the exponents of the simple allometry, it was found that the product of clearance and brain weight was not a suitable approach for the prediction of clearance for these drugs.

In a separate study, Obach et al.[14] used different methods for the prediction of clearance and concluded that the in vitro approach was the best method for the prediction of clearance. In their comparison, the authors also assumed that clearance for all drugs can be predicted by only one method. A comparison between the in vitro approach and the allometry using the "rule of exponents" as suggested by Mahmood and Balian would have provided information whether the in vitro approach is really better than the empirical allometric approach.

There are obvious limitations of the in vitro approach. A definitive disadvantage of the in vitro approach is that one requires to measure the in vitro clearance in at least three species which may be time-consuming. This approach is inappropriate for drugs which are excreted renally as well as for those drugs which are partly metabolized and partly excreted renally.

Extensive work will be needed in this direction before one can clearly establish the advantage and accuracy of the in vitro approach in predicting clearance of drugs over other existing methods. However, it should be kept in mind that the in vitro approach in allometric scaling is one of the many suggested approaches which are attempts to improve the prediction of clearance and should be used as deemed necessary.

Role of Protein Binding in the Prediction of Clearance—Considerable variability in plasma protein binding of drugs have been observed among animal species, resulting in variable distribution and elimination of drugs in different species. The unbound intrinsic clearance of antipyrine,[11] phenytoin,[8] clonazepam,[8] caffeine,[16] and cy-

Table 1—Observed and Total Predicted Clearance (mL/min) of Several Drugs with or without Considering Protein Binding

drug	observed total CL	predicted total CL	predicted total CL
diazepam	26	861	817
tamsulosin	48	814	102
GV150526	5–7	320	5
cyclosporin	273	716	611
quinidine	330	1452	2423

[a] Obtained by multiplying the predicted unbound clearance in humans by free fraction of drug in human plasma. For example, the predicted unbound clearance of tamsulosin in humans was 10218 mL/min and fu was 0.01. Therefore, the predicted total clearance in humans was 10218*0.01 = 102 mL/min.

closporine[17] has been reported in the literature. It is also widely believed that unbound clearance can be predicted with more accuracy than total clearance.[14] However, a systematic study, which compares whether unbound clearance can be predicted better than total clearance, is lacking. Mahmood[18] compared the total and unbound clearance of a wide variety of drugs to determine whether unbound clearance of a drug can be predicted more accurately than total clearance, and if there is any real advantage of predicting unbound clearance. The results of the study indicated that unbound clearance cannot be predicted any better than total clearance. There are drugs whose unbound clearance can be predicted better than total clearance or vice versa. For example, using simple allometry, predicted total clearance of diazepam,[19] tamsulosin,[20] GV 150526,[21] cyclosporin,[17] and quinidine[38–40] was 861, 814, 320, 716, and 1452 mL/min, respectively (Table 1). When the predicted unbound clearance in humans was multiplied by the respective free fraction of drug in human plasma, the predicted total clearances for tamsulosin and GV 150526 were vastly improved, whereas no improvement was observed for diazepam, cyclosporin, and quinidine (Table 1). It is clear from this analysis that protein binding may or may not be helpful for the improved prediction of clearance. At this time it is not possible to determine a priori for which drug unbound or total clearance can be predicted better.

In a separate study, Obach et al.[14] predicted clearance with or without taking protein binding into account. Based on average-fold error (1.91 without protein binding and 1.79 with protein binding), a slightly improved prediction of unbound clearance was noted, though for all practical purposes this difference may not be of any significance.

Prediction of Clearance for Renally Secreted Drugs—Allometry is not always successful in predicting pharmacokinetic parameters. A recent example is the failure of the allometric approach for the prediction of total clearance of renally secreted drugs.[22] Interspecies scaling of drugs for the prediction of clearance may be complicated due to the differences in the mechanism of excretion of drugs in different species. Using 10 renally secreted drugs, it was shown by Mahmood[22] that it is likely that the predicted total and renal clearances for renally secreted drugs may be lower in humans than the observed clearances. The prediction of renal clearance was improved by normalizing the renal clearance by a "correction factor" for animals who exhibited renal secretion. The "correction factor" was obtained by the following equation:

$$\frac{(\text{glomerular filtration rate} \times \text{kidney blood flow})}{(\text{body weight} \times \text{kidney weight})} \quad (3)$$

Though the proposed approach for the prediction of renal clearance for renally secreted drugs worked fairly well on the tested drugs, more work will be needed to validate the approach. Furthermore, a method which can improve the prediction of total clearance for renally secreted drugs requires investigation.

Volume of Distribution—Like clearance, volume of distribution is also an important pharmacokinetic parameter. Volume of distribution of the central compartment (V_c) can play an important role in establishing the safety or toxicity for first-time dosing in humans. Since an administered dose is always known, the predicted V_c can be used to calculate plasma concentration of a drug at time zero (C_0) following intravenous administration. This initial plasma concentration may be an index of safety or toxicity. Furthermore, V_c can also be used to predict half-life, if clearance is known ($t_{1/2} = 0.693V_c/\text{CL}$).

There is a good correlation between body weight and V_c among species. Generally the exponents of volume pivots around 1.0, which indicates that body weight and volume are directly proportional. However, in practice this may not be the case for all drugs; for example, exponents of 0.81, 0.86, 0.58, and 0.76 were observed for topiramate,[9] diazepam,[9] diazepoxide,[23] and ciprofloxacin,[24] respectively. Overall, volume of distribution can be predicted in humans from animals with reasonable accuracy.

Obach et al.[14] used four different methods to predict volume of distribution at steady state (V_{ss}), and on the basis of their geometric mean prediction accuracy they concluded that V_{ss} can be predicted better when protein binding is taken into account.

In the literature one can find that V_{ss} and V_β or V_{area} are also predicted. It has been shown by Mahmood[24] that V_c can be predicted with more accuracy than V_{ss} and V_β. In fact V_{ss} and V_β are of no real significance for the first time dosing in humans and can be estimated from human data.

The concept of a fixed exponent for volume may be acceptable, as in the majority of cases the exponents of volume revolve around 1. Therefore, the use of a fixed exponent of 1 may not produce as much error in predicted volume as clearance and half-life.

Elimination Half-Life—Elimination half-life is difficult to predict across species. Conceptually, it is difficult to establish a relationship between body weight and half-life. In practice, indeed a poor correlation between $t_{1/2}$ and body weight across the species has been found. This poor correlation may be due to the fact that $t_{1/2}$ is not directly related to the physiological function of the body, rather it is a hybrid parameter. Therefore, this poor correlation results in a poor prediction of half-life. To improve the prediction of half-life, some indirect approaches have been suggested by different investigators.

Bachmann,[25] Mahmood and Balian,[9] and Obach et al.[14] used the equation ($t_{1/2} = 0.693V_c/\text{CL}$) to predict the half-lives of many drugs. Though this approach predicted the half-life with reasonable accuracy, to obtain a reasonable prediction of half-life both CL and V_c must be predicted with reasonable accuracy. Another indirect approach was suggested by Mahmood.[24] In this approach, mean residence time (MRT) was predicted, and then predicted MRT was used to predict half-life in humans using the equation ($t_{1/2}$ = MRT/1.44). The results of his study indicated that MRT can be predicted in humans with a fair degree of accuracy from animal data. The predicted half-life from MRT was also reasonably accurate.

Like clearance, the concept of fixed exponent may not be applicable for half-life. From the published work of Mahmood,[24] it can be seen that the exponenmts of half-life varies from −0.066 to 0.547, but the average is 0.19. Therefore, a fixed exponent of 0.25 for the prediction of half-life may also produce serious errors in the prediction of half-life.

Physiological Time or Pharmacokinetic Time Scale—Besides predicting pharmacokinetic parameters, attempts were also made by several investigators to predict plasma concentrations in humans from animal data. The initiative in this direction was taken by Dedrick et al.,[2] and Boxenbaum[7,8] further refined the concept of Dedrick's approach.

In chronological time, heart beat and respiratory rates decrease as the size of the animals increases. On the other hand, on a physiological time scale, all mammals have the same number of heart beats and breaths in their lifetime. The physiological time can be defined as the time required to complete a species independent physiological event. Thus, smaller animals have faster physiological processes and shorter life span. The concept of pharmacokinetic time scale originates from the concept of physiological time which was first described by Brody.[26]

Dedrick et al.[27] were the first to use the concept of physiological time to describe methotrexate disposition in five mammalian species following intravenous administration. They transformed the chronological time to physiological time using the following equation:

$$Y\text{-axis} = \frac{\text{concentration}}{(\text{dose}/W)} \quad (4)$$

$$X\text{-axis} = \frac{\text{time}}{W^{0.25}} \quad (5)$$

where W is the body weight.

By transforming the chronological time to physiological time, the plasma concentrations of methotrexate were superimposable in all species. The authors termed this transformation as "equivalent time". Later, Boxenbaum[7,8] introduced two new units of pharmacokinetic time, kallynochrons and apolysichrons. Kallynochrons and apolysichrons are transformed time units termed as elementry Dedrick plot and complex Dedrick plot, respectively. Boxenbaum also incorporated the concept of MLP in physiological time and termed this new time unit as "dienetichrons".

Though many investigators[28–30] have used the concept of physiological time in their allometric analysis, a direct comparison of allometric approaches with physiological time has not been systematically evaluated. Recently Mahmood and Yuan[31] compared the predicted values of clearance, volume of distribution, and elimination half-life of ethosuximide, cyclosporine, and ciprofloxacine by allometry with physiological time using equivalent time, kallynochron, apolysichron, and dienetichrons. The results of this study indicated that there is no specific advantage of using physiological time over the allometric approach. Almost similar predictions in pharmacokinetic parameters were obtained from both methods. The equivalent time approach based on the assumption that the exponent of half-life is 0.25 was not found to be suitable for the prediction of plasma concentrations or pharmacokinetic parameters. This may be due to the fact that the exponent of elimination half-life of drugs is not always 0.25. Due to the small sample size used in this study, it is difficult to conclude whether the physiological time approach in predicting pharmacokinetic parameters is as good/better as allometric approaches. One advantage of pharmacokinetic time scale approach is that it provides some information about the plasma concentrations of a given drug, though it is not known to what extent the predicted concentrations are reliable?

Prediction of Pharmacokinetic Parameters Using Pharmacokinetic Constants—Swabb and Bonner[32] and Mordenti[33] predicted the plasma concentrations of aztreonam and ceftizoxime, respectively, using an allometric relationship on pharmacokinetic constants (A, B, a, and β). Though the authors successfully used this approach for the prediction of CL, V_c, and $t_{1/2}$, a systematic study of suitability of this approach for prediction of pharmacokinetic parameters was lacking. Mahmood[34] compared the pharmacokinetic parameters of six drugs predicted by pharmacokinetic constants and by the conventional allometric approach.

The following equation representing a two-compartment model following intravenous administration was used to generate plasma concentrations in man from the pharmacokinetic constants predicted from animals.

$$C = Ae^{-\alpha t} + Be-\beta t \quad (6)$$

where A and B are the intercepts on Y-axis of plasma concentration versus time plot. a and β are the rate constants for the distribution and elimination phase, respectively.

Pharmacokinetic constants (A, B, a, and b) were plotted as a function of body weight as described in eq 1. The allometric equation thus generated was used to predict pharmacokinetic constants in man. For the prediction of plasma concentrations in man, the predicted pharmacokinetic constants were used.

The results of the study indicated an inconsistent correlation between body weight and A, B, or a. For some drugs, a good correlation was obtained, whereas a poor correlation was noted for other drugs. Though the prediction of A and B was occasionally reasonable, the predicted a values were manyfold higher or lower than the observed values. Overall it was found that the use of pharmacokinetic constants to predict pharmacokinetic parameters does not necessarily provide an improvement over the conventional allometric approach. Like the pharmacokinetic time scale approach, the pharmacokinetic constant method may provide some information about plasma concentrations of a drug, but the accuracy of the method for the prediction of plasma concentrations in man may not be reliable.

Conclusion

The most important objective of allometric scaling is to select a safe and tolerable dose for the first time administration to humans. Therefore, in recent years, interspecies scaling of pharmacokinetic parameters has drawn enormous attention. Interspecies scaling is not without shortcomings and failures, and over the years, many approaches have been suggested to improve the predictive performance of allometric scaling. These approaches are not perfect, but they may be of considerable importance to understand and refine the concept of allometric scaling. There is no right or wrong approach in interspecies scaling.

There may be anatomical similarities among species, but there are external factors which will affect the allometric scaling. Experimental design, species, analytical errors, and physicochemical properties of drugs such as renal secretion or biliary excretion may have impact on allometric extrapolation. There are drugs such as diazepam,[19] warfarin,[25] valproic acid,[35] tamsulosin,[20] and GV150526[21] whose predicted clearance are manyfold higher than the observed clearance and may be considered as drugs which exhibit vertical allometry. The role and importance of vertical allometry in allometric scaling is unclear. It is also difficult to identify a priori when a drug will exhibit vertical allometry. Extensive work will be needed to classify drugs as vertical allometry and to find a solution to improve the prediction of clearance for such drugs.

There were also attempts to identify the suitability of a particular species for the prediction of clearance in humans. Campbell[36] concluded that the prediction of clearance in humans was best predicted when data from rhesus or cynomolgus monkey were used with the incorporation of MLP. The rat was the next best species for the prediction of human clearance whereas dog appeared to be a poor predictor of clearance in humans. The number of species can also affect the predictive performance of allometry. Mahmood and Balian[37] have shown that three or more species are needed for a reliable prediction of clearance in humans. They also showed that volume of distribution of a compound is predicted equally well using data from two species or more. Therefore, all these methods should be used with caution and proper understanding of allometric scaling.

Besides success, there are numerous failures in interspecies scaling. Such failed studies should also be published so that further investigation can be conducted to find the underlying reasons for failure. Such investigations will be helpful to improve the predictive performance of allometric scaling.

Abstract □ Solubility enhancement has broad implications in parenteral formulation design. A simple mathematical model has been developed to describe the combined effect of cosolvency and complexation on nonpolar drug solubilization. The total drug solubility is determined by the summation of three drug species present in the solution: free drug [D], drug–ligand binary complex [DL], and drug–ligand–cosolvent ternary complex [DLC]. The proposed model established the dependencies of these three species upon the intrinsic drug solubility, $[D_u]$, the cosolvent solubilizing power, σ, the binary and ternary intrinsic complexation constants, K_b^{int} and K_t^{int}, and the cosolvent destabilizing powers for the binary and the ternary complexes, ρ_b and ρ_t. A nonpolar solute, Fluasterone, is used to evaluate the newly generated equation. The model explains the decline in drug solubility produced by low cosolvent concentrations as well as the increase in the solubility produced by high cosolvent concentrations that are observed at all cyclodextrin concentrations.

Introduction

Solubility enhancement has broad implications in parenteral formulation design. This is especially true for poorly water-soluble drugs, as it is often necessary to deliver the desired dose in a specified volume of aqueous liquid. Over the years a variety of solubilization techniques have been studied and widely used including pH adjustment, cosolvent addition, surfactant addition, and cyclodextrin addition.[1−5]

Among these techniques, cosolvent and cyclodextrin addition are highly effective for nonpolar solutes. As a water-miscible or partially miscible organic solvent, the cosolvent reduces strong water−water interactions and thereby reduces the ability of water to squeeze out nonpolar solute.[2] Cosolvency is often considered at early stages due to its huge solubilization potential. Because of their safety, cosolvents are employed in approximately 10% of FDA approved parenteral products.[3] Cyclodextrins are cyclic oligomers of dextrose or its derivatives joined by α-1,4-linkages. They increase drug solubility by forming an inclusion complex with the nonpolar region of the drug molecule (guest) being inserted into the cavity of the cyclodextrin molecule (host).[3−6] Such a drug−ligand complex has a rigid structure and a definite stoichiometry, usually one-to-one at low ligand concentrations.[4−6] It is of note, however, that there exist clinical limitations to these aforementioned methods.[2,3] For example, high concentrations of cosolvent have high viscosity and high tonicity, and phlebitis can result from precipitation of the solubilized drug upon iv injection.[7,8] In fact, ethanol in concentrations greater than 10% may well produce significant pain.[7,8] Some cyclodextrins have been reported to have significant renal toxicity.[3,8,9]

Recently, the combined use of cosolvency and complexation has drawn particular interest.[10−14] Zung et al. observed synergistic effects of cosolvency and complexation in solubilizing pyrene by using a series of alcohols.[14] The complexation constants of both pyrene/β-cyclodextrin and pyrene/γ-cyclodextrin were found to be much greater in the presence of an alcohol than in pure water. It was suggested that the cosolvent act as a space-regulating molecule so that the drug molecule can better fit into the cyclodextrin cavity. In other studies, it was found that the presence of cosolvents decreases the formation of drug−ligand complex. Pitha et al. reported that the complexation constant of testosterone with hydroxy propyl-β-cyclodextrin (HPβCD) is 10 000-fold lower in 80% ethanol than in water.[11] They reasoned that the cosolvent may act by competing with the drug for entry into the cyclodextrin cavity or by reducing the solvent polarity. A similar antagonistic cosolvent effect was observed for ibuprofen in a HPβCD−propylene glycol−water system.[10]

Given the fact that both cosolvency and complexation have been well studied and understood, it is of interest to explore the mechanisms of the combined effect of the two techniques on nonpolar drug solubilization and to explore the dynamics among the solute, cosolvent, and the cyclodextrin. The knowledge gained in this study may shed light for possible synergistic effect out of this combined technique and be useful in future parenteral formulation design.

This paper aims at constructing a simple mathematical model to explain the combined effect of cosolvency and complexation on nonpolar drug solubilization. The model will be evaluated by using Fluasterone as nonpolar solute, ethanol (EtOH) as cosolvent, and hydroxy propyl-β-cyclodextrin (HPβCD) as complexing ligand. Fluasterone (16α-fluoro-5-androsten-17-one) is a structural analogue of dehydroepiandosterone that is being developed for cancer chemoprevention.[12]

Theoretical Background

Assumptions—The proposed model is based upon the following assumption: the complex formed is either a drug−ligand (cyclodextrin) binary complex or a drug−

Fluasterone

ligand–cosolvent ternary complex with the stoichiometries assumed as 1:1 and 1:1:1, respectively.

Basics—For a given complexant solution there is an equilibrium between the free drug and the drug–ligand binary complex. When a cosolvent is introduced into the solution, it not only changes the concentration of the free drug [D] and the binary complex [DL], but it also may be involved in the formation of a drug-bearing ternary species, DLC.[14–16] In the presence of a binary 1:1 complex and a ternary 1:1:1 complex, the total solubility of the drug [D^{tot}] is:

$$[D^{tot}] = [D] + [DL] + [DLC] \quad (1)$$

Free Drug—The concentration of free (i.e., uncomplexed) drug [D] is related to intrinsic drug solubility [D_u] and cosolvent concentration [C] by:[2,8,17]

$$[D] = [D_u] \times 10^{\sigma[C]} \quad (2)$$

where σ is the cosolvent solubilizing power. The value of σ depends on the polarity of both the solute and the solvent.[2,8] Here it is assumed that complexation ligand has a negligible effect on the solubilizing power. Similar assumptions have been made in some other studies.[2,8] Equation 2 indicates that the logarithm of solubility in a mixed solvent increases linearly with cosolvent composition, i.e., an increase in [C] will produce an exponential increase in [D]. It has been validated on hundreds of nonpolar solutes in ethanol, propylene glycol, and other cosolvents.[2,8,17]

Binary Complex—The concentration of drug–ligand binary complex [DL] is related to the concentration of free drug [D], the total concentration of ligand [L], and the apparent binary complexation constant, K_b^{app}, by:[18]

$$[DL] = K_b^{app}[D][L] \quad (3)$$

in which K_b^{app} is a function of cosolvent concentration.[11,18,20] The apparent complexation constant, K_b^{app}, in a cosolvent–water solution is empirically related to the cosolvent concentration and the intrinsic complexation constant K_b^{int}, i.e., the complexation constant in water, by:

$$K_b^{app} = K_b^{int} \times 10^{-\rho_b[C]} \quad (4)$$

where ρ_b is the destabilizing power of the cosolvent for the binary complex. The value of ρ_b depends on the polarity deference between the solute and the cosolvent, the steric factors between the solute and the complexing ligand. By incorporating eqs 2 and 4 into eq 3, the binary complex can be expressed as:

$$[DL] = K_b^{int} \times 10^{-\rho_b[C]}[D_u] \times 10^{\sigma[C]}[L] = [D_u][L]K_b^{int} \times 10^{(\sigma - \rho_b)[C]} \quad (5)$$

which shows that [DL] is linearly dependent upon the ligand concentration and exponentially dependent upon the cosolvent concentration. If $\sigma > \rho_b$, an increase in [C] will give rise to an exponential increase in [DL]. If $\sigma < \rho_b$, an increase in [C] will give rise to an exponential decrease in [DL]. If $\sigma = \rho_b$, [C] will have no effect upon [DL].

Ternary Complex—The concentration of the 1:1:1 ternary complex [DLC] is related to the free drug concentration [D], the ligand concentration [L], the cosolvent concentration [C], and apparent ternary complexation constant, K_t^{app}, by:

$$[DLC] = K_t^{app}[D][L][C] \quad (6)$$

By analogy to eq 4, K_t^{app} is related to the cosolvent concentration and the intrinsic ternary complexation constant, K_t^{int}, by:

$$K_t^{app} = K_t^{int} \times 10^{-\rho_t[C]} \quad (7)$$

where ρ_t is the cosolvent destabilizing power for the ternary complex. The value of ρ_t depends on the polarity deference between the solute and the cosolvent, the steric factors between the solute and the complexing ligand. Note that K_t^{app} approaches K_t^{int} as the cosolvent concentration approaches zero. The concentration of the ternary complex can be expressed by inserting eqs 2 and 7 into eq 6. This gives:

$$[DLC] = K_t^{int} \times 10^{-\rho_t[C]}[D_u] \times 10^{\sigma[C]}[L][C] = [D_u][L][C]K_t^{int} \times 10^{(\sigma - \rho_t)[C]} \quad (8)$$

which indicates that [DLC] has a linear dependency upon the ligand concentration and a complex dependency upon the cosolvent concentration. If $\sigma > \rho_t$, an increase in [C] will produce an increase in [DLC]. If $\sigma < \rho_t$, an increase in [C] will increase [DLC] only when $[C] > 10^{(\sigma - \rho_t)[C]}$; when $[C] < 10^{(\sigma - \rho_t)[C]}$, an increase in [C] will decrease [DLC]. If $\alpha = \rho_t$, an increase in [C] will increase [DLC] linearly.

Total Solubility—In the presence of both cosolvent and complexant the drug's total solubility is determined by the summation of three solution components: free drug [D], drug–ligand binary complex [DL], and drug–ligand–cosolvent ternary complex [DLC]. Inserting eqs 2, 5, and 8 into eq 1 gives:

$$[D^{tot}] = [D_u] \times 10^{\sigma[C]} + [D_u]K_b^{int} \times 10^{(\sigma - \rho_b)[C]}[L] + [D_u]K_t^{int} \times 10^{(\sigma - \rho_t)[C]}[L][C] \quad (9)$$

where the total solubility is related to the parameters: [D_u], K_b^{int}, K_t^{int}, σ, ρ_b, and ρ_t, which have been described in the preceding sections. In the following sections, the combined effect of cosolvent and complexation on drug solubilization described by eq 9 is confirmed by solubilization of a very nonpolar compound, Fluasterone, in a water–EtOH–HPβCD system.

Methods

Solubility Determination—Fluasterone was added to vials containing certain percentages of both hydroxy propyl-β-cyclodextrin (HPβCD) and ethanol (EtOH). HPβCD concentration ranges from 0 to 20% and ethanol concentration ranges from 0 to 75% were investigated. The sample vials were rotated using an end-over-end mechanical rotator at 20 rpm (Glas-Col Laboratory Rotator, Terre Haute, IN) at 25 °C for 6 days (preliminary data indicate that Fluasterone is stable for 50 days under these conditions). Samples with drug crystals present were considered to have reached their equilibrium solubility and were removed from the rotator, passed through a 0.45-μm filter, and analyzed by HPLC. All samples were prepared in duplicate.

HPLC Analysis of Fluasterone—A Pinnacle octylamine column (150 cm × 4.6 mm, Restek, Bellefonte, PA) was used with a mobile phase composed of 75% acetonitrile in water. The flow rate was controlled at 1.1 mL/min (125 Solvent Module, Beckman,

Fullerton, CA). The column effluent was monitored at a wavelength of 220 nm (168 detector, Beckman, Fullerton, CA). The retention time of a 100 μL sample was 6.3 min. The evaluation of the assay was made by using Fluasterone standard solutions at concentrations ranging from 0.001 to 0.1 mg/mL, intraday and interday, coupled with different solubilizing agents. The relative standard deviation was 1.05%. None of the solubilizing agents interfere with the assay.

Results and Discussion

Solubilization by Ethanol Alone—The intrinsic solubility [D_u] of Fluasterone was determined to be 0.045 μg/mL (0.000155 mM). Figure 1 shows the dependency of the drug's total solubility [D^{tot}] upon ethanol concentration [C]. The exponential solubility increase is described by eq 2, with a cosolvent solubilizing power (σ) of 0.3401.

Solubilization by HPβCD Alone—The aqueous solubility of Fluasterone increases linearly with HPβCD concentration [L] up to 20% as shown by the open circles in Figure 2. Incorporating the slope into eq 3 indicates the formation of a 1:1 reversible drug−ligand complex with an intrinsic complexation constant (K_b^{int}) of 1.80×10^5 M^{-1}.

Solubilization by Combined Use of Ethanol and HPβCD—Figure 2 shows that at every HPβCD concentration investigated the Fluasterone solubility is slightly higher in the presence of 0.2% ethanol (open squares in Figure 2) than in pure water. An ethanol concentration of 0.2% is not enough to function as a cosolvent to affect drug complexation.[14−16,21] Nevertheless, it produces a consistent increase in drug solubility. This suggests that ethanol must increase Fluasterone solubility by some other mechanism, such as the formation of a complex that contains drug, ligand, and cosolvent. Equation 9 shows that the formation of a ternary complex would be responsible for the increased Fluasterone solubility in the HPβCD solutions containing 0.2% EtOH. Here, as in other studies,[15,16] it is assumed that the ternary species responsible for the increased drug solubility is a 1:1:1 complex. Extrapolation of K_t^{app} ($= K_t^{int} \times 10^{-\rho_t[C]}$) to zero cosolvent concentration by eq 9 gives a K_t^{int} of 1.42×10^4 M^{-1}.

The solubility of Fluasterone increases linearly with HPβCD concentration at all ethanol concentrations. It is interesting to note that the slope of the solubilization curve varies with ethanol concentrations [C]. The slope decreases when [C] increases from 0.2% to 25.06% as shown in Figure 2, but increases when [C] increases from 25.06% to 75.19% as shown in Figure 3. This can be seen more clearly from cross sections of the data of Figures 2 and 3 at equal HPβCD concentrations that are shown in Figure 4. The figure also indicates a minimum total drug concentration at about 25% ethanol. Nearly 60 total solubility [D^{tot}] data points from Figure 4 and known values of [D_u], σ, K_b, K_t, [L], and [C] were used to calculate ρ_b and ρ_t by means of nonlinear regression analysis. Their values were found to be 0.515 and 0.340, respectively. As the cosolvent concentration increases, the magnitude of ρ_b[C] and ρ_t[C] increases, resulting in a greater destabilizing power for both the binary and ternary complexes. This is because the increased cosolvent concentration reduces solvent polarity so that nonpolar molecules are more likely to stay out of the cyclodextrin cavity.

The concentration of binary drug−ligand complex [DL] is proportional to the product of the apparent complexation

Table 1—Estimation of Solubilization Parameters

parameter	symbol	value
intrinsic binary complexation constant	K_b^{int} (M^{-1})	1.80×10^5
intrinsic ternary complexation constant	K_t^{int} (M^{-1})	1.42×10^4
cosolvent solubilizing power	σ	3.40×10^{-1}
cosolvent destabilizing power on binary complex	ρ_b	5.15×10^{-1}
cosolvent destabilizing power on ternary complex	ρ_t	3.40×10^{-1}

constant and the concentration of the free drug, i.e., K_b^{app}-[D], which equals $[D_u]K_b^{int} \times 10^{(\sigma - \rho_b)[C]}$. An increase in the cosolvent concentration simultaneously produces an exponential increase in [D] ($= [D_u] \times 10^{\sigma[C]}$) and an exponential decrease in K_b^{app} ($= K_b^{int} \times 10^{-\rho_b[C]}$). As a result, [DL] is dependent upon the difference between the solubilizing power (σ) and the destabilizing power (ρ_b) of the cosolvent for [DL]. Since $\sigma = 0.340$ and $\rho_b = 0.515$, this difference is negative. An increase in [C] leads to an exponential decrease in [DL], and the concentration of the binary complex becomes negligible when [C] reaches 50%.

The concentration of the ternary complex depends on the cosolvent concentration [C] and the difference between the cosolvent solubilizing power (σ) and the cosolvent destabilizing power (ρ_t) for the ternary complex. Nonlinear regression analysis of the solubility data indicates that the difference between σ and ρ_t for Fluasterone is negligible (see Table 1). Consequently, the exponential term in eq 8 is constant and an increase in ethanol concentration produces a linear increase in the ternary complex concentration [DLC].

With the values of $[D_u]$, K_b^{int}, K_t^{int}, ρ_b, and ρ_t given in the table, we can calculate [D], [DL], [DLC], and $[D^{tot}]$ at any given combination of EtOH and HPβCD concentration by using eqs 2, 5, 8, and 9, respectively. Figure 5a shows the calculated values of [D], [DL], [DLC], and $[D^{tot}]$ at 20% HPβCD under different EtOH concentrations. Both the exponential increase and the exponential decrease can be seen more directly as straight lines on the semilogarithmic scale of Figure 5b. The figure also shows that the calculated $[D^{tot}]$ decreases initially and approaches a minimum where [C] is approximately at 25%. Such a decrease is due to the fact that the decrease in [DL] outweighs the increase in [D] and [DLC] resulting from the addition of ethanol. After 25%, $[D^{tot}]$ starts to increase due to the increase in both [D] and [DLC]. Note that [DLC] is greater than [DL] even though K_b^{int} is approximately 10-fold greater than K_t^{int}. This finding is consistent with testosterone studies[11] in which [DL] was diminished in a solution containing HPβCD and 60% ethanol. However, the solid produced by evaporating the aqueous solvent contained a small amount of ethanol. Since a 1:1:1 testosterone–HPβCD–ethanol complex would contain only 2.7% ethanol, this observation might be explained by the existence of the ternary complex [DLC], such as described above.

Validation of the Proposed Model—Calculated total drug solubilities (solid lines) using eq 9 are compared in Figure 6 with the experimental solubility data (symbols) at different concentrations of HPβCD. The strong agreement between the predicted and the observed solubility data supports the validity of the proposed model. Note that as the cyclodextrin concentration approaches zero, the total solubility approaches the log-linear relationship commonly observed in a simple cosolvent–water system.

Conclusion

An equation is developed to describe the combined effect of ethanol and HPβCD upon Fluasterone solubility. The equation is validated with respect to the intrinsic drug solubility, $[D_u]$, the cosolvent solubilizing power, σ, the binary and ternary intrinsic complexation constants, K_b^{int} and K_t^{int}, and the cosolvent destabilizing powers for the binary and the ternary complexes, ρ_b and ρ_t. This equation can be used to explain the linear dependence of nonpolar solute solubility upon cyclodextrin concentration that is observed at all ethanol concentrations. It also can be used to describe the decline in the solubility produced by low cosolvent concentrations as well as the increase in the solubility produced by high cosolvent concentrations that are observed at all cyclodextrin concentrations. Thus it provides a theoretical background for understanding the dynamics of the combined cosolvent–complexant technique in the solubilization of nonpolar drugs.

Optimization of Folate-Conjugated Liposomal Vectors for Folate Receptor-Mediated Gene Therapy

JOSEPH A. REDDY,[†] DAVID DEAN,[‡] MICHAEL D. KENNEDY,[†] AND PHILIP S. LOW*,[†]

Contribution from *Department of Chemistry, 1393 Brown Building, Purdue University, West Lafayette, Indiana 47907-1393 and Department of Microbiology and Immunology, College of Medicine, Medical Sciences Building, University of South Alabama, Mobile, Alabama 36688.*

Received May 29, 1999. Accepted for publication August 23, 1999.

Abstract □ A folate-targeted transfection complex that is internalized by certain cancer cells and displays several properties reminiscent of enveloped viruses has been developed. These liposomal vectors are comprised of a polycation-condensed DNA plasmid associated with a mixture of neutral and anionic lipids supplemented with folate–poly(ethylene glycol)–dioleylphosphatidylethanolamine for tumor cell-specific targeting. *N*-Citraconyl-dioleylphosphatidylethanolamine is also included for pH-dependent release of endosome-entrapped DNA into the cytoplasm, and a novel plasmid containing a 366-bp segment from SV40 DNA has been employed to facilitate transport of the plasmid into the nucleus. Because formation of the DNA core is an important step in the assembly of liposomal vectors, considerable effort was devoted to comparing the transfection efficiencies of various DNA condensing agents. It was found that complexation of plasmid DNA with high molecular weight polymers such as acylated-polylysine and cationic dendrimers leads to higher folate-mediated transfection efficiency than DNA complexed with unmodified polylysine. In contrast, compaction of plasmid DNA with small cationic molecules such as spermine, spermidine, or gramicidin S yields only weakly active folate-targeted liposomal vectors. Compared to analogous liposomal vector preparations lacking an optimally compacted DNA core, a cell-specific targeting ligand, a caged fusogenic lipid, and a nucleotide sequence that facilitates nuclear uptake, these modified liposomal vectors display greatly improved transfection efficiencies and target cell specificity.

Introduction

Gene therapy constitutes an attractive strategy for the treatment of a variety of human genetic disorders.[1−5] Although viral gene therapy can report the greatest successes in animal and human trials to date,[6−10] liposomal vectors have stimulated increased attention due to their low immunogenicity, lack of potential infectivity, and ease of assembly from chemically defined components.[11] Unfortunately, liposomal vectors also suffer from their own set of disadvantages, including generally low efficiencies of transfection and elevated toxicities toward normal cells.[9,12] Work on liposomal vectors has consequently focused on developing formulations that improve transfection efficiency without compromising host cell viability.[13,14]

One reasonable approach for addressing the deficiencies of liposomal vectors has been to identify the features of viral vectors that render them efficient vehicles for gene transfer and then mimic these features in synthetic liposomal constructs. Based on information available to date, the desirable characteristics of the more promising viral vectors would seem to include (i) their ability to efficiently compact and package the genetic material, (ii) their expression of a surface-exposed ligand for stable attachment and endocytosis/delivery of the condensed DNA into the target cell, (iii) their means of releasing their nucleic acid from the endosome into the target cell's cytoplasm, and (iv) their mechanisms for enhancing transport of their genome into the host cell's nucleus. It can be speculated that future liposomal gene therapy vectors will incorporate components that mimic many of these desirable viral functions. Indeed, some progress has already been made toward achievement of these objectives.[2,14−20]

Probably the greatest advance in optimizing liposomal vectors has stemmed from development of cationic liposomes that not only promote DNA compaction and avid cell association, but also enhance delivery of the genetic cargo into the cell's cytoplasm.[21−24] Associated with these desirable features, however, is a significant loss of cell-specific targetability, since strongly cationic complexes indiscriminately bind most cell surfaces and thereby render any ligand-specific interactions largely meaningless. While such generic cell surface affinity can be prevented by eliminating excess cationic charge, the resulting neutral DNA−lipid particles are generally poorly fusogenic, even when delivered into target cells by receptor-mediated endocytosis. Clearly, modification of cationic liposomes for cell specific targeting involves more than simple attachment of a high affinity ligand to the liposome surface.

Our laboratory has been interested in the use of folic acid as a targeting ligand to deliver attached therapeutic and imaging agents to cancer cells that overexpress the receptor for folic acid.[25−31] Because folate-linked cargo's of diameters <150 nm are efficiently bound and internalized by folate receptor (FR)-expressing cells, it seemed reasonable to explore the possibility of using folic acid to facilitate liposomal vector delivery to FR-enriched cells. In this paper we describe our efforts at integrating several desirable features of viral vectors into folate-targeted liposomal vectors. While several excellent publications describing the use of folic acid to deliver genes into cancer cells have already appeared,[29,32−34] a more comprehensive attempt to optimize components that might mimic desirable viral characteristics has not been reported.

Materials and Methods

Materials—All commercially available lipids were purchased from Avanti Polar lipids (Alabaster, AL). Citraconic anhydride, 2,6-lutidine, folic acid, poly-L-lysine hydrobromide (MW ∼ 25.6 kDa), myristoyl chloride, palmitic acid *N*-hydroxysuccinimidyl ester (NHS), oleic acid-NHS, and gramicidin S were purchased from Sigma Chemical Co. (St. Louis, MO). Spermine, spermidine, and chitosan (medium MW, 200−800 cps) were from Aldrich (Milwaukee, WI). Cationic dendrimers were obtained from Dendritech Inc. (Midland, MI) and Aldrich (St. Louis, MO). [^{3}H]-

Cholesteryl hexadecyl ester and $Na^{125}I$ were purchased from DuPont. Folate deficient modified Eagle's medium (FDMEM) and other additives were purchased from Life Technologies, Inc. and fetal calf serum was from HyClone Labs (Logan, UT). β-galactosidase assay kits were purchased from Promega (Madison, WI). BCA protein assay reagents were from Pierce (Rockford, IL).

Plasmid Preparation—A 366 bp HindIII−KpnI fragment of SV40 DNA containing the origin and promoter region (SV40 nts 5171 to 294) was amplified by polymerase chain reaction and cloned into the TA cloning vector (Invitrogen, San Diego CA) to create plasmid pTA-DTS. Subsequently, a 384 bp HindIII−SalI fragment was isolated from pTA-DTS and inserted into the corresponding sites of pCMVβgal (Clontech, Palo Alto, CA), downstream of the lacZ gene. Protein-free preparations of plasmids pCMVlacZ and pDTSlacZ were purified following alkaline lysis using Qiagen megaprep columns.

Synthesis of Fatty Acylated Polylysine—Acylated polylysine was synthesized by reaction of polylysine (M_r ~25 700) with activated fatty acids at a fatty acid/lysine ratio of 1:5. Myristoyl chloride, palmitic acid-NHS, or oleic acid-NHS (0.077 mmol) in 1 mL of dry DMF was added to 15 mg of polylysine in 500 μL of dry DMSO, and the mixture was allowed to react for 24 h at room temperature. The solution was then added to a large excess of diethyl ether to precipitate the derivatized polylysine,[35] and the polymer was purified by dialysis against deionized water. The resulting polymer was quantified by trypan blue assay[36] using unmodified polylysine as the standard.

Preparation of Liposome Formulations—*N*-Citraconyl-dioleylphosphatidylethanolamine (C-DOPE) is a caged form of dioleylphosphatidylethanolamine (DOPE) that resists hexagonal phase formation and consequent liposome fusion until the citraconyl moiety is released by acidification at pHs < 6.[37,38] Assuming such low pHs are only experienced following endocytosis by target cells, incorporation of C-DOPE into liposomal vectors should allow acquisition of fusogenic properties only following uptake by transfected cells.

C-DOPE was synthesized by reacting DOPE with citraconic anhydride, and the resulting caged fusogenic lipid was purified as described earlier.[37,38] Liposomes were prepared by mixing chloroform solutions of DOPE, cholesterol, C-DOPE, and folate−poly(ethylene glycol)−dioleylphosphatidylethanolamine (FA-PEG-DOPE, a derivative of dioleylphosphatidylethanolamine linked covalently to folic acid via a poly(ethylene glycol) spacer[28]) or poly-(ethylene glycol)−dioleylphosphatidylethanolamine (PEG-DOPE, the nontargeted control for FA-PEG-DOPE) followed by removal of the chloroform under vacuum to produce a dry lipid film. Hydration of the lipid was then achieved by addition of 1.0 mL of sterile 20 mM HEPES buffer, pH 8.0, followed by vortexing for 1 min and bath sonication to obtain a clear emulsion. The total lipid content in these liposome formulations was ~5 mg/mL.

Preparation of Transfection Competent Complexes—Polylysine, acylated-polylysine, dendrimers, gramicidin S (stock solutions of 10 mg/mL in dimethyl sulfoxide), spermine, spermidine, and chitosan (stock solutions of 10 mg/mL in aqueous 1% acetic acid solution) were diluted to 1 mg/mL in sterile deionized water and stored at 4 °C until use. Polycation−DNA complexes were then generated by vortexing equal volumes (100 μL) of the appropriate polycation solution with 40 μg/mL pCMVlacZ plasmid DNA in serum free medium for 1 min, followed by incubation at room temperature for at least 15 min. Ratios of nucleic acid to polycation charge were estimated from the electrostatic charge present on each component.[32,39−43] The resulting polycation−DNA complexes (200 μL) were then combined with 200 μL of 0.24 mg/mL liposomes suspended in serum free medium by gentle vortexing. The hydrodynamic diameter of the complex was determined by dynamic light scattering (Coulter N4plus Submicron Particle Sizer, Miami, FL).

Cell Culture and Transfection of Cells with Liposomal Vectors—KB cells, a human nasopharyngeal cancer cell that expresses elevated levels of folate receptor were cultured in folate deficient Dulbecco's modified Eagles medium (FDMEM) containing 10% heat-inactivated fetal calf serum (FCS), penicillin (50 units/ml), streptomycin (50 μg/mL), 2 mM L-glutamine, and nonessential amino acids at 37 °C in a 5% CO_2 humidified atmosphere. In a typical experiment, cells were seeded 48 h before transfection in 24-well plates at 15% to 20% confluence. Immediately prior to transfection, the cells were washed with 0.5 mL of serum free FDMEM and then incubated for 4h at 37 °C with DNA/liposome complexes in 400 μL of serum free FDMEM. After incubation, the medium containing any free DNA/liposome complexes was replaced with vector-free medium (FDMEM) containing 10% fetal calf serum. Thirty-six hours after transfection, cells were analyzed for β-galactosidase expression, as described by others.[44]

Evaluation of Liposome Complexation with Condensed DNA—Plasmid DNA was labeled with ^{125}I using the published method of Prensky.[45] Labeled DNA was then separated from free iodine by gel filtration chromatography on a Sephadex G-25 column in 50 mM HEPES (pH 8.0) buffer. A discontinuous sucrose gradient containing layers of 3 mL, 5 mL, and 5 mL of 0%, 20%, and 40% sucrose dissolved in deionized water, respectively, was then constructed. Samples comprised of ^{125}I-labeled DNA/polycation complexes and/or ^{3}H-labeled anionic liposomes were layered on top of the gradient and centrifuged at 24 000 rpm (100 000*g*) in a Beckmann SW28 ultracentrifuge rotor for 45 min. One milliliter fractions were collected sequentially from the top to the bottom of the gradient and analyzed for lipid and DNA content by scintillation and gamma counting, respectively.

Results

In agreement with observations of others,[46−48] we have found that cationic lipid formulations cannot be readily targeted to receptor-bearing cells using cell-specific ligands such as folic acid (data not shown). We, therefore, undertook to integrate features into neutral liposomes that might facilitate uptake and delivery of encapsulated DNA into the nucleus. From previous studies, it was noted that C-DOPE, a caged form of DOPE that converts to the natural fusogenic lipid (i.e., DOPE) upon exposure to acidic pH, could enable pH-dependent release of encapsulated DNA from endosomal compartments.[38] However, because these earlier lipid formulations contained large amounts of unmodified DOPE, they were found to be unstable during storage and hence not viable for eventual clinical applications. Although addition of 40% cholesterol was observed to render these formulations stable for at least a month, the added sterol was simultaneously found to compromise the fusogenicity of the lipid complexes. We, therefore, undertook to reevaluate various lipid formulations for a combination that might be both stable and targetable, yet capable of facilitating efficient transfection of FR-expressing cells. We have used 0.1 mol % FA-PEG-DOPE as the targeting ligand in all such formulations, because we have previously found that this percentage was optimal for targeting vectors to cells expressing folate receptors and since cells lacking such receptors are not detectably transfected by such formulations.[38] Figure 1 shows that lipid envelopes of the composition DOPE/C-DOPE/cholesterol/FA-PEG-DOPE (45.9:10:40:0.1 mol %) are highly efficient in transfecting KB cells with a polylysine-compacted pCMVβgal vector. Importantly, when the FA-PEG-DOPE liposomes are replaced with nontargeted liposomes (FA-PEG-DOPE replaced with PEG-DOPE), the β-galactosidase expression decreases to background levels, indicating the above formulation facilitates ligand selective cell association. Further, when DOPS is substituted for C-DOPE in the targeted formulations, no transfection is observed, demonstrating that the caged lipid's pH dependent fusogenicity rather than its negative charge enables gene expression. Finally, when the optimal formulation is compared with unstable liposomes of the composition DOPE/C-DOPE/FA-PEG-DOPE (97:3:0.1 mol %), the cholesterol-stabilized liposomes are seen to exhibit only 15 to 20% lower transfection activity (data not shown). Since the nonstabilized formulations lose all transfection activity during 3 days of storage, formulations containing 40% cholesterol were employed in all remaining experiments.

Inclusion of C-DOPE in the lipid mixture was found to benefit the vector formulation by a second mechanism.

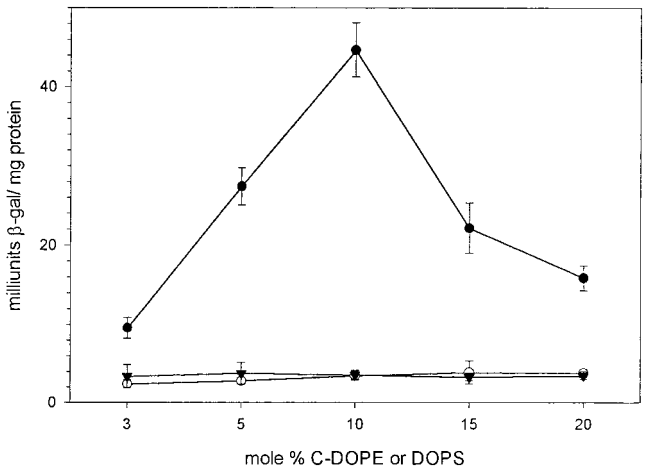

Figure 1—Optimization of C-DOPE content for maximum transfection activity. Liposomal vectors were prepared by mixing pCMVlacZ:polylysine (1:0.75 w/w) complexes with liposomes consisting of 40% cholesterol, 0.1% FA-PEG-DOPE (●,▼) or PEG-DOPE (○), plus the indicated mole % of C-DOPE (●,○) or DOPS (▼). DOPE was then added to raise the lipid total to 100%. Folate receptor bearing KB cells were transfected as described in the Methods section. Assay results are expressed as milliunits of β-galactosidase per mg cell protein. Data are presented as means ± SD where $n = 6$ from two independent experiments. Mean values were compared using one-way analysis of variance (ANOVA) followed by the Student–Newman–Keuls Multiple Comparisons Test (Sigmastat). Significance was set at $p < 0.05$. *P* values for comparison of βgal expression with FA-PEG-DOPE liposomes containing the indicated mole % of C-DOPE are 3% versus 5% < 0.001, 5% versus 10% < 0.001, 10% versus 15% = 0.003 and for 15% versus 20% = 0.002.

Because of its double negative charge at neutral pH, C-DOPE incorporation endowed the derived liposome with a strongly anionic character. Thus, upon mixing with cationic DNA/polycation complexes, a particle spontaneously formed that had a neutral to slightly negative charge (data not shown). In contrast to positively charged particles, this neutral to slightly anionic particle could be readily targeted by attachment of a cell-specific ligand (i.e. folic acid). Thus, the C-DOPE assisted in vector assembly, vector targeting, and pH-dependent vector release into the target cell's cytoplasm.

Since physical characteristics of liposomal vectors can make an important contribution to the transfection efficacy, we measured the sizes of the DNA/polylysine/liposome complexes. All vectors tested were found to have diameters of 170 ± 40 nM, and no statistical variance between the many preparations of control and C-DOPE vectors was detected. We also did not notice any trend in the size of the vectors as C-DOPE content was varied. This is probably because the primary step of DNA condensation is always performed with the same amount of polylysine, and the added C-DOPE containing liposomes simply conform to the size of this particle. Hence, we conclude that a variation in size is not the basis for the differences in transfection efficiency observed at different C-DOPE concentrations.

Effect of Incorporating a DNA Targeting Sequence into the Plasmid—Since most vectors employed for eukaryotic gene therapy must enter the nucleus to function, we next explored whether facilitated nuclear import of the plasmid DNA would enhance the efficiency of gene expression. For this purpose, a novel plasmid (pDTSβgal) was constructed (Figure 2), which is identical to the commercial plasmid (pCMVβgal) except for insertion of a 366 bp SV40 nuclear targeting sequence downstream of the *lacZ* gene and polyadenylation signal. To evaluate the possible contribution of this nuclear targeting sequence, pDTSβgal was compared with the parent pCMVβgal for expression of β-galactosidase in transfected cells. Figure 3 shows that a 1.5−2-fold increase in β-galactosidase activity was measured when pDTSβgal plasmid was substituted for pCMV-βgal in each of the three formulations tested. This nuclear-directed plasmid was therefore employed in the remainder of the studies reported here.

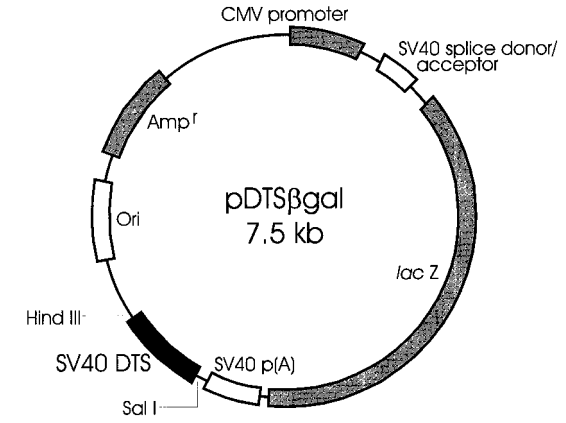

Figure 2—Map of pDTSβgal plasmid. A 384 bp HindIII–SalI fragment (SV40DTS) containing the origin and promoter region (SV40 nts 5171 to 294) from SV40 DNA was inserted into the corresponding sites of pCMVβgal, downstream of the lacZ gene, to facilitate plasmid entry into the nucleus. A cytomegalovirus immediate early gene promoter/enhancer was employed to drive expression of the reporter gene, β-galactosidase (lac Z). SV40 p(A), SV40 polyadenylation signal; Amp^r, β-lactamase gene.

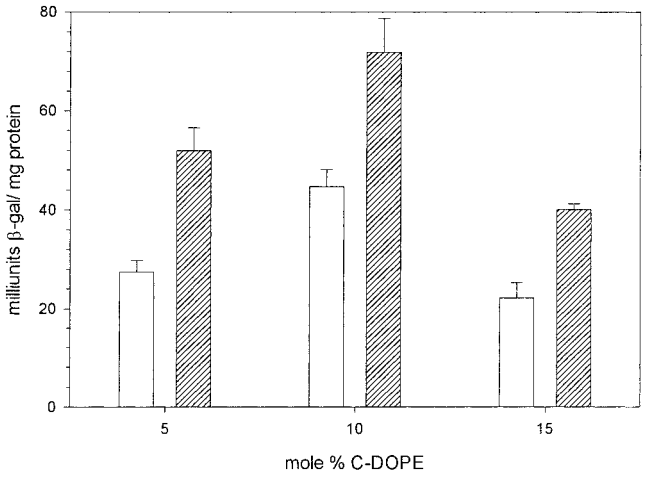

Figure 3—Effect on transfection efficiency of inserting a 366 bp SV40 nuclear targeting sequence into the pCMVlacZ plasmid. Transfection particles were prepared by mixing 4 μg of control plasmid, pCMVβgal (open bar) or 4 μg of plasmid containing a nuclear targeting sequence, pDTSβgal (slashed bar) with 3 μg polylysine, and then incubating the derived complexes with liposomes consisting of 40% cholesterol, 0.1 mol % FA-PEG-DOPE plus the indicated mole % of C-DOPE. Unmodified DOPE was added to bring the total lipid content to 100%. Transfection of KB cells was then assayed as described in the Methods section. Data are expressed as means ± SD where $n = 6$. *P* values comparing βgal expression with pCMVβgal and pDTSβgal are < 0.001 in all three cases.

Identification of Optimal DNA Compacting Polymers—Although a variety of cationic polymers have been exploited as DNA condensing agents, the resulting complexes are thought to differ in degree of compaction, compatibility with different lipid formulations, resistance to cellular nucleases, and extent of DNA unloading following entry into a cell's interior. Since ligand-mediated endocytic pathways might differ considerably from cationic lipid-promoted uptake pathways, it seemed advisable to reevaluate various DNA compaction methods for use with ligand-targeted liposomal vectors.

A panel of polycations including spermine, spermidine, gramicidin S, polyamidoamine dendrimer, polylysine, and chitosan were therefore examined for their abilities to

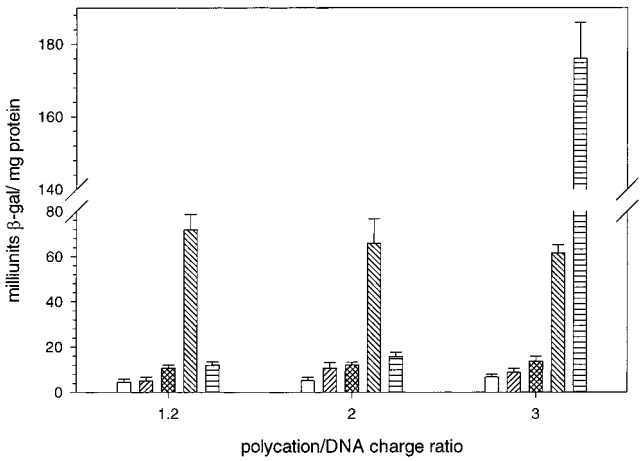

Figure 4—Effect of various oligo- and polycations on the transfection ability of folate-targeted liposomes. Polycation/DNA complexes at the indicated charge ratios were prepared by mixing pDTSlacZ with spermine (open bar), spermidine (left slashed bar), gramicidin S (double slashed bar), polylysine (right slashed bar), or 68 Å polyamidoamine cationic dendrimers (horizontal slashed bar). FA-PEG-liposomes were then prepared and transfection efficiencies compared, as described in the Methods section. The lipid composition of the complexes was 10 mol % C-DOPE, 49.9 mol % DOPE, 40% cholesterol, 0.1 mol % FA-PEG-DOPE. The polycation/DNA charge ratio refers to the charge ratio of the complex before addition of the anionic liposomes. Data are expressed as means ± SD where $n = 6$.

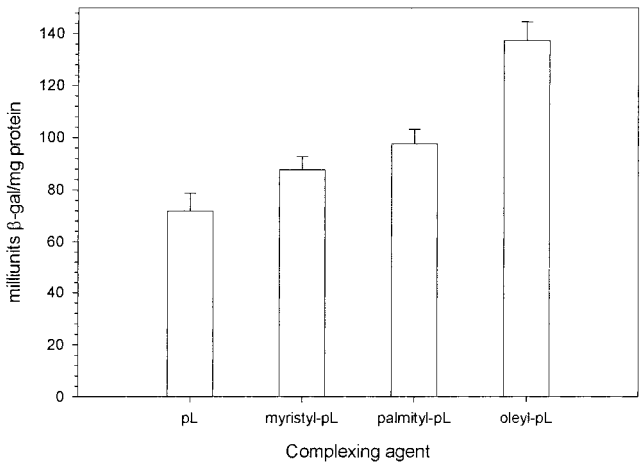

Figure 5—Effect of polylysine acylation on transfection efficiency. pDTSlacZ plasmid was mixed with polylysine (pL) or polylysine derivatized with the indicated acyl chains (see Methods) at a ± charge ratio of 1.2/1. The resulting complexes were then incubated with FA-PEG-liposomes and tested for transfection efficiency on KB cells. The lipid composition of the FA-PEG-liposomes was 10 mol % C-DOPE, 49.9 mol % DOPE, 40 mol % cholesterol, 0.1 mol % FA-PEG-DOPE. Data are expressed as means ± SD where $n = 3$. *P* values for comparison of βgal containing the indicated type of polylysine are pL versus myristyl-pL = 0.032, myristyl-pL versus palmityl-pL = 0.086 and for palmityl-pL versus oleyl-pL = 0.002.

facilitate folate-targeted gene expression. Charge ratios (±) of 1.2/1, 2/1, and 3/1 were chosen so that upon further complexation with anionic lipid mixtures the vectors would remain anionic, neutral, or even slightly cationic to ensure low levels of nontargeted gene transfection. As seen in Figure 4, only the high molecular weight polylysine and polyamidoamine dendritic polymers were highly active. Oligocations such as spermine, spermidine, and gramicidin S, in contrast, yielded low transfection efficiencies at the charge ratios tested. It was also noted that transfections with chitosan-condensed DNA (data not shown) resulted in high mortality, eliminating this complex from further consideration. However, the near absence of toxicity of the polylysine and dendritic polymers qualified them for further exploration, as described below.

Further Examination of Polylysine-Derived DNA Condensing Agents—Encouraged by the potential displayed by polylysine, and motivated by a recent report that partially acylated isoforms of the polycation might enable still better transfection efficiencies,[35] we undertook to compare various acylated polylysines in our folate-targeted KB cell transfection assay. Acylated polylysines were synthesized by N-alkylation of polylysine at a fatty acid-to-lysine ratio of 1:5 under anhydrous coupling conditions. Following purification[35] and determination of residual charge,[36] pDTSβgal plasmid DNA was successively complexed with acylated-polylysine and then DOPE/C-DOPE/cholesterol/FA-PEG-DOPE (45.9:10:40:0.1 mol %) liposomes. As shown in Figure 5, folate-targeted vectors with acylated polylysines showed higher transfection activities (~1.3 to 2-fold) than vectors with nonacylated polylysine. Furthermore, oleic acid-derivatized polylysine displayed higher transfection efficiency than either palmitic acid- or myristic acid-conjugated polylysine.

Optimization of Dendrimer/DNA Complexes for Transfection—To determine the optimal charge ratio of dendrimer/DNA complexes for ligand-targeted gene therapy, KB cells were transfected with dendrimer-compacted DNA (generation 6; 68 Å diameter) complexed with either FA-PEG-DOPE- or PEG-DOPE-containing liposomes. β-Galactosidase expression was then measured as a function of dendrimer/DNA charge ratio, which ranged from 1.2:1 to

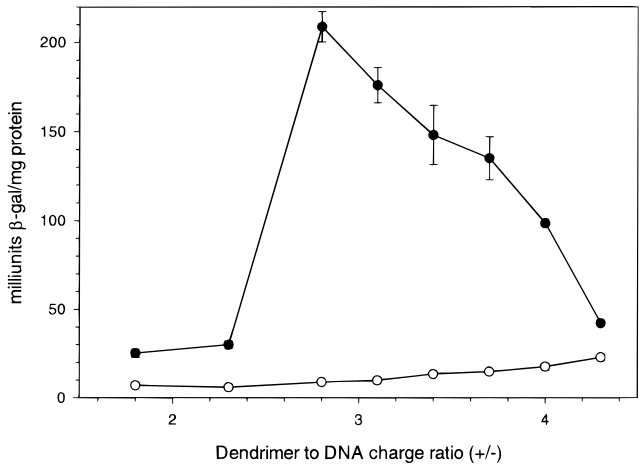

Figure 6—Effect of dendrimer/DNA charge ratio on folate-targeted liposomal vector transfection of KB cells. Complexes were prepared by mixing dendrimer/pDTSlacZ complexes at increasing charge ratios with C-DOPE liposomes consisting of 10 mol % C-DOPE, 49.9 mol % DOPE, 40% cholesterol, and 0.1 mol % FA-PEG-DOPE (●) or PEG-DOPE (○). Transfection competency was then analyzed in KB cells, as described in the Methods. The dendrimer to DNA charge ratio refers to the charge ratio of the complex before addition of the anionic liposomes. Data are expressed as means ± SD where $n = 6$.

4.5:1. As seen in Figure 6, the maximum level of β-galactosidase expression was observed at a charge ratio of 2.8:1, while at none of the examined charge ratios were nontargeted liposomes effective agents for gene delivery. A charge ratio of 2.8:1 was, therefore, used in all further dendrimer-based studies.

The heterogeneous nature of most DNA−polycation complexes makes it difficult to determine which of the diversity of complexes in any suspension is most effective in mediating transfection.[49] In contrast, dendrimers with their uniform shapes and sizes allow quantitative analysis of the influence of vector size on the efficiency of gene transfer. As shown in Figure 7, an increase in transfection efficiency was observed with increasing dendrimer size from 40 to 68 Å, followed by a decrease in activity at 84 Å. Interestingly, expression of β-galactosidase with the optimum (68 Å) dendrimer complexes was 2.5- to 3-fold higher

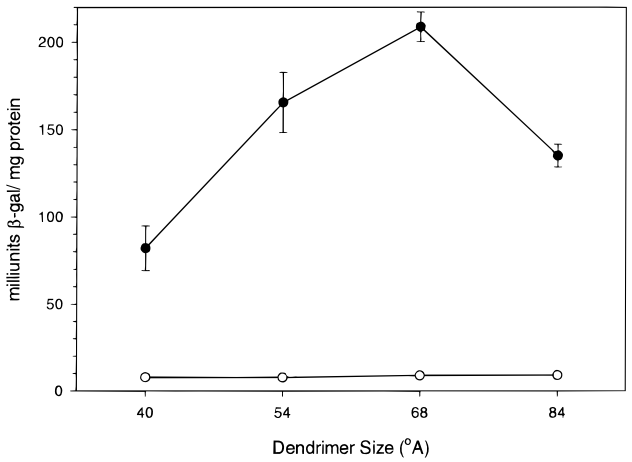

Figure 7—Influence of dendrimer size on gene transfer efficiency. pDTSlacZ plasmid vectors were formulated with dendrimers of the indicated sizes at the optimal dendrimer/DNA charge ratio of 2.8:1. The resulting complexes were then mixed with FA-PEG-liposomes (●) or PEG-liposomes (○) and tested for transfection efficiency on KB cells, as described in Figure 6. Data are expressed as means ± SD where $n = 3$.

than that seen with polylysine complexes (compare with Figure 3). As before, negligible levels of β-galactosidase expression were observed when FA-PEG-DOPE was replaced with equimolar PEG-DOPE in the lipid fraction of all dendrimer complexes tested.

Analysis of the Interaction of Polycation/DNA Complexes with Anionic Liposomes—With any ligand-targeted gene therapy formulation, it is important to determine the fraction of ligand-derivatized empty liposomes that might compete with DNA containing liposomes for cell surface receptors. For this purpose, oleyl-polylysine/DNA or cationic dendrimer (68 Å)/DNA complexes were prepared at their optimal DNA:polycation ratios, and the complexes were incubated with anionic liposomes comprised of DOPE/C-DOPE/cholesterol/FA-PEG-DOPE. The resulting folate-tethered liposomal vectors were then fractionated on a 0%/20%/40% discontinuous sucrose gradient and fractions were analyzed for their DNA and lipid contents. As noted in Figure 8 and elsewhere,[32,39] free DNA and free liposomes remained on top of the gradient, while unprotected polycation/DNA complexes migrated to the bottom (Figure 8A). In contrast, fully assembled polycation/DNA/liposome complexes were of intermediate density and sedimented as a broad band in the middle of the gradient (Figures 8B and 8C). Quantitative evaluation of the distribution of lipid and DNA radiolabels in these gradients revealed that the majority of the DNA complexes were associated with liposomes, and very few empty liposomes remained in the preparations to compete with the DNA-containing liposomes for folate receptors.

Discussion

We have shown that the transfection efficiency of folate-targeted, cholesterol-stabilized liposomal vectors can be significantly enhanced by (i) use of a pH-sensitive fusogenic lipid, (ii) incorporation of a nuclear localization sequence into the encapsulated plasmid, and (iii) selection of the optimal composition, size and charge density of the compacting polycation. Indeed, when compared to polylysine-compacted conventional plasmids, associated with folate-targeted, but pH-insensitive (lacking C-DOPE), liposomes, an increase in gene expression of more than 100-fold is observed. While further improvements in each of these features may be necessary before a clinically useful vector can be assembled, the above exploratory study constitutes

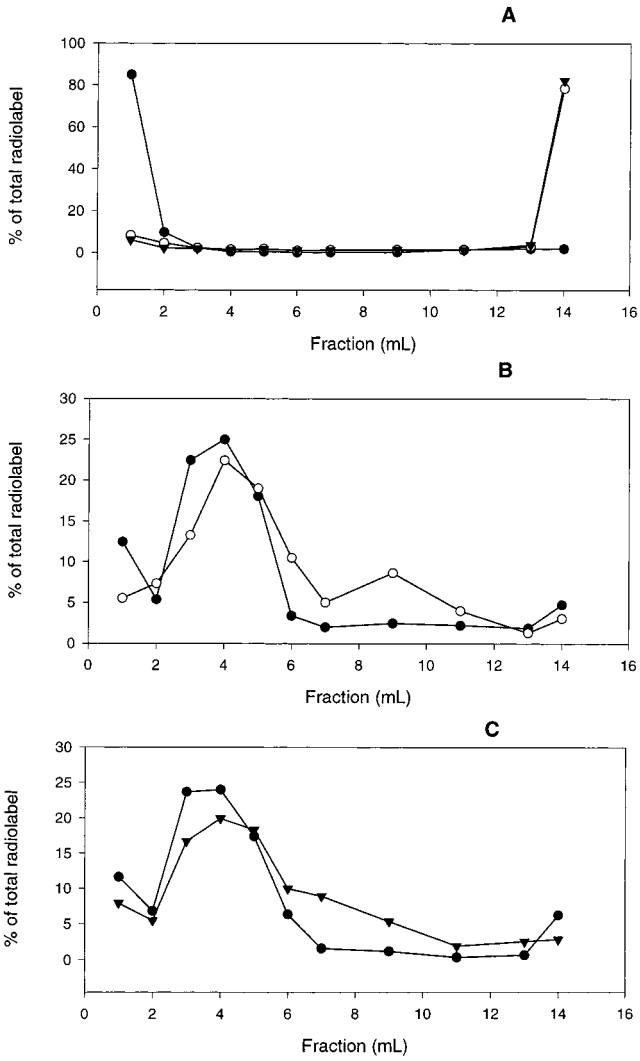

Figure 8—Analysis of polycation–DNA–liposome interactions using sucrose density gradient ultracentrifugation. (A) Oleyl-polylysine/DNA (○) or dendrimer/DNA (▼) complexes containing ^{125}I-labeled DNA (20 μg), and free liposomes containing ^{3}H-labeled lipids (240 μg) (●) were separately fractionated on a 0/20/40% (3/5/5 mL) discontinuous sucrose gradient at 100 000*g* for 45 min. One milliliter fractions were collected starting from the top of each gradient and counted for ^{125}I and ^{3}H radioactivity. After incubating the liposomes with either oleyl-polylysine/DNA (B) or dendrimer/DNA (C) particles, as described in the text, the assembled liposomal vectors were fractionated using the same gradient and counted for radioactivity. The oleyl-polylysine/DNA and the dendrimer/DNA complexes are seen to sediment to the bottom of the gradient, while the anionic liposomes and free DNA remain at the top. Mixed complexes sediment to an intermediate position in the gradient. Data are expressed as means ± SD where $n = 3$.

at least a first step toward development of a liposomal vector that mimics the desirable traits of many viral vectors.

One of the most critical limitations of standard neutral liposomal vectors appears to be their inability to dock with and enter mammalian cells.[50] Cationic liposomes obviously do not share this problem, but they are encumbered with their own set of limitations.[14] Although the advantages of ligand-mediated cell association and internalization were not emphasized in this report, it should be noted that the nontargeted vectors were generally 50 to 100-fold less effective than their folate-targeted counterparts. This differential would suggest that ligand-mediated cell association and uptake is a viral feature that should be mimicked in liposomal vectors whenever possible.

A second characteristic that contributes measurably to the usefulness of viral vectors involves their ability to

promote gene transfer across a target cell's plasma/endosomal membrane into the cell's cytoplasm. In the liposomal vector described here, this capability is accomplished in two steps. First, the cell's natural folate receptor-mediated endocytosis pathway is exploited to carry the therapeutic vector into the target cell's endosome, and then both the citriconylated and unmodified DOPE combine to facilitate escape of the DNA from the endosome into the cytoplasm. According to this strategy, the vector's full fusogenic potential is not realized until the citraconyl group of the C-DOPE is hydrolyzed at low pH. Because the required acidic conditions are not encountered prior to entry into endosomes, incorporation of C-DOPE limits vector unloading prior to intracellular uptake. With the optimized combination of C-DOPE and DOPE employed here, an increase in gene expression over vectors lacking C-DOPE of 40- to 70-fold was observed. Excess C-DOPE presumably reduced transfection efficiency, either because too much C-DOPE had to be hydrolyzed to enable fusion, or because the excess lipid assembled into folate-targeted but plasmid-free liposomes that competed with the plasmid-containing liposomes for cell surface receptors.

Probably the easiest viral trait to mimic in liposomal vector formulations lies in the ability of the viral genome to promote its own nuclear import. Because the DNA sequences involved in this process are located within the origin of replication and promoter regions, the likely mechanism for nuclear import involves binding of specific cellular proteins and their facilitation of genome transfer across the nuclear membrane.[51] While the enhancement accompanying inclusion of this viral sequence into our plasmid vector was only ~2-fold (Figure 3), the benefit to vectors targeted to less actively dividing cells could be considerably greater.[52] Thus, DNA transit across the nuclear membrane only becomes rate-limiting when the nuclear membrane remains intact over long intervals. In rapidly dividing cells such as those used in our study, this membrane is dismantled each time the cell enters M phase.

Viral capsids are able to condense their nucleic acids to a size that can be efficiently packaged and internalized by target cells. Synthetic polycations have been traditionally employed to achieve the same objective with liposomal vectors.[20,53] Indeed, for folate-targeted neutral liposomes, both polylysine and polyamidoamine dendrimers were judged to be acceptable mediators of DNA compaction (Figure 4). Further, when polylysine was partially derivatized with fatty acyl chains of varying length, an additional increase in transfection efficiency was observed. This enhancement in expression activity could conceivably be due to a decrease in electrostatic interaction between the acylated polylysine and DNA, thereby allowing the internalized plasmid to dissociate from the polylysine and enter the nucleus more easily.[35,54] Alternatively, the lipophilicity of the acylated polylysine could enhance association of the DNA/polylysine complex with the anionic liposomes or improve the stability of the folate-targeted vectors. We suggest that incorporation of acylated polycationic condensing agents warrants further examination in any quest for an optimal liposomal vector.

In contrast to the substituted and unmodified polylysines, simple oligocations such as spermine, spermidine, and the cyclic amphipathic peptide, gramicidin S, were only weakly active. Although spermine, spermidine,[40] and gramicidin S[41] are known to condense DNA and facilitate transfection, the spermine/DNA complexes are unfortunately not stable at physiological ionic strength.[39,55] This inherent instability may be responsible for the overall weak transfection activity of these targeted liposomal formulations.

The complex of plasmid DNA and cationic dendrimers was found to display the highest targeted gene expression activity of any formulation tested. Unlike the polycations of low molecular weight, cationic dendrimers have a higher surface charge density and are consequently capable of forming DNA complexes that are stable at a variety of pHs and salt concentrations.[56] With these dendrimers, transfection efficiency was found to depend on the number and size of dendrimers in each complex, with the highest expression obtained using the 68 Å dendrimer at a ± charge ratio prior to liposome addition of 2.8/1. Although stable DNA complexes could be formed at charge ratios greater than 5:1, these complexes were invariably ineffective, even though such vectors had been previously shown to be optimal in the absence of complexation with anionic lipid.[57] Why the more strongly charged complexes were less efficient in our hands is not clear, but an excess of noncomplexed dendrimer could have competed for association with the folate-linked anionic liposomes, thereby reducing the total number of dendrimer/DNA/liposome complexes capable of folate receptor binding on the cell surface.

Conclusions

Although neutral liposomal vectors generally exhibit lower transfection efficiencies than cationic liposomal vectors, they simultaneously display several advantages not shared by their cationic counterparts. Thus, vectors with low surface charge density can be readily targeted to specific cell types, commonly exhibit little or no nonspecific cytotoxicity,[20] and display reduced tendency to activate complement,[58] in contrast to most cationic liposomal vectors.[58] With the development of novel components/strategies to facilitate (i) DNA compaction, (ii) cell surface association and entry, (iii) endosome unloading, and (iv) intranuclear delivery, the prospects for improving the transfection efficiency of neutral liposomal vectors is increasingly bright.

Received May 24, 1999. Accepted for publication August 26, 1999.

Abstract □ This study examined the absorption and disposition of clomipramine in rats after sublingual (5 and 50 mg/kg), oral (50 mg/kg), and iv (5 mg/kg) administration. The mean oral bioavailability of clomipramine was 24.8% and 29.7%, respectively, in conscious rats and in rats anesthetized with ketamine/xylazine (30/3 mg/kg). When given sublingually in isotonic saline at a dose of 50 mg/kg, clomipramine was rapidly absorbed, and the mean absolute bioavailability (36.2%) was increased over oral dosing. The mean AUC values of clomipramine were 2258 ± 1762 ng·h/mL and 1891 ± 867 ng·h/mL after oral administration to conscious and anesthetized rats, respectively, and 3303 ± 1576 ng·h/mL after sublingual administration to anesthetized rats. Sublingual administration (5 mg/kg doses) of clomipramine formulated with a permeation enhancer, 2-hydroxypropyl β-cyclodextrin, further increased the sublingual bioavailability to 57.1%. The sublingual route may be an alternative route of administration of clomipramine, providing enhanced bioavailability.

Introduction

Clomipramine is a tricyclic antidepressant widely used for the treatment of depression in a number of countries in Western Europe and Canada. In the United States, it has only recently been approved for the treatment of obsessions and compulsions in patients with obsessive-compulsive disorder.[1] Beneficial effects of clomipramine have also been reported in patients with phobia, panic disorder, chronic pain, premature ejaculation, enuresis, and anorexia nervosa.[2] Despite the widespread use of clomipramine for more than a decade, its pharmacokinetics are less well documented than those of other tricyclic antidepressants.[3,4] There are a few reports on the oral absorption of clomipramine in humans in which the oral bioavailability is approximately 50%.[5−7] To our knowledge, no information is available on the bioavailability of clomipramine after sublingual or buccal administration in humans or laboratory animals. Of the antidepressant drugs available at present, only imipramine has been indirectly shown to be efficiently absorbed across the oral mucosa in humans.[8]

The aim of this study was to determine the extent of absorption of clomipramine in rats after sublingual administration. Clomipramine given sublingually as a solution in isotonic saline was rapidly absorbed and its sublingual bioavailability was increased over oral dosing. The sublingual bioavailability of clomipramine was further enhanced when given with hydroxypropyl β-cyclodextrin as a permeation enhancer.

Experimental Section

Chemicals—Clomipramine hydrochloride, imipramine hydrochloride, ketamine, xylazine, and triethylamine were purchased from Sigma Chemical Co. (St. Louis, MO). Methocel MC (methyl cellulose) and 2-hydroxypropyl β-cyclodextrin were obtained from Fluka Chemie AG (Buchs, Switzerland). Sodium hydroxide and phosphoric acid were purchased from Samchun Chemical Co. (Pyungtaek, Korea) and Yakuri Chemical Co. (Osaka, Japan), respectively. Acetonitrile and methanol (all HPLC grades) were obtained from Fisher Scientific (Fair Lawn, NJ) and hexane (HPLC grade) from Mallinckrodt (Paris, KY). Mannitol and heparin were obtained from Choongwae Pharma Co. (Seoul, Korea).

Animals and Surgical Preparation—Male Sprague Dawley rats (7−8 weeks, 240−300 g) were purchased from Jaeil Animals Co. (Ansung, Korea). The rats were placed in plastic rat cages and housed in a temperature-controlled (23 ± 2 °C) animal facility with light/dark cycle of 12/12 h and relative humidity of 50 ± 10%. The animals had free access to standard rat diet (DaeJong Co., Seoul, Korea) and water throughout the study. After at least one week of acclimatization, the rats were anesthetized with im injection of ketamine and xylazine (90/10 mg/kg) and cannulated with PE tubing (0.58 mm i.d. and 0.96 mm o.d., Natume Co., Tokyo, Japan) in the right jugular vein. In animals used in the iv injection study, the right femoral vein was also cannulated with PE tubing. After surgery, at least 2 days of recovery were allowed prior to drug administration.

Intravenous Injection Study—Clomipramine dissolved in isotonic saline (3 mg/mL) was administered iv in rats via the femoral vein at 5 mg/kg doses (n = 4). Serial blood samples of approximately 0.3 mL were collected from the jugular vein at 0, 5, 15, 30, and 45 min and 1, 1.5, 2, 4, 8, 12, and 24 h after drug injection. Equal volumes of drug-free heparinized saline were injected after each sampling. Serum samples were harvested by centrifugation at 2500 rpm for 10 min and were kept at −70 °C until drug analysis.

Oral Dosing—Clomipramine dissolved in isotonic saline was administered po at 50 mg/kg doses in rats (n = 4). A second group of rats (n = 4) was also given clomipramine orally (50 mg/kg) followed by induction of light anesthesia with ketamine/xylazine (30/3 mg/kg). The animals gained consciousness within 10−30 min. Serial blood samples of approximately 0.3 mL were collected from the jugular vein as described above. Equal volumes of drug-free saline were injected after each sampling. Serum samples were harvested by centrifugation at 2500 rpm for 10 min and were kept at −70 °C until drug analysis.

Sublingual Administration—Clomipramine dissolved in isotonic saline (50 mg/kg doses) was applied to the sublingual mucosa of rats (n = 4) under light ketamine/xylazine (30/3 mg/kg) anesthesia. The volume of the drug solution administered was approximately 30 μL applied with an autopipet. Prior to application, the buccal and subligual areas were blotted dry with cotton swabs, and the animals were kept face downward until recovery from anesthesia. The animals gained consciousness within 10−30 min after induction of anesthesia. Separately, clomipramine (5 mg/kg doses) formulated with 2-hydroxypropyl β-cyclodextrin (100 mg/mL), mannitol (50 mg/mL), and Methocel M. C. (20 mg/mL) in isotonic saline was applied to the sublingual mucosa of rats (n = 4) as described above. Serial blood samples of approximately 0.3 mL were collected from the jugular vein at 0, 5, 15, 30, and 45 min and 1, 1.5, 2, 4, 8, 12, and 24 h after application.

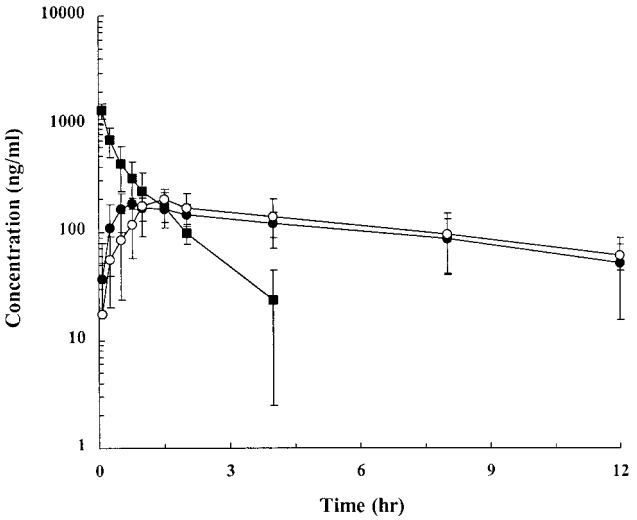

Figure 1—Mean serum concentration vs time curves of clomipramine after iv administration (5 mg/kg doses) to conscious rats (■) and after oral administration (50 mg/kg doses) to conscious (●) and anesthetized (○) rats ($n = 4$ each).

Equal volumes of drug-free saline were injected after each sampling. Serum samples were harvested by centrifugation at 2500 rpm for 10 min and were kept at −70 °C until drug analysis.

Drug Analysis—Drug analysis was performed on a HPLC system consisting of a Gynkoteck Model M480G pump, a Model UVD 340 photodiode array detector and a Model Gina 50 autosampler (Germering, Germany), a degasser (Lab-Quatec Co., Tokyo, Japan), and a Chromeleon Data System integration software (Softran GmbH, Germering, Germany). Chromatographic separations were achieved using a HAISIL HL RP C_{18} analytical column (4.6 mm i.d. × 250 mm, 5 μm) and a guard column (3.2 mm i.d. × 20 mm, 5 μm) (Higgins Analytical Inc., Mountain View, CA). The mobile phase consisted of acetonitrile:0.1% triethylamine in deionized water (50/50, v/v). The mobile phase was adjusted to pH 3.5 by phosphoric acid, passed through a 0.2 μm membrane filter, and degassed prior to use. Clomipramine was extracted by a single liquid−liquid extraction with hexane. Briefly, to an aliquot (100 μL) of the rat serum were added 100 μL of the internal standard solution (imipramine 200 ng/mL) and 100 μL of 5.0 M NaOH, and the mixture was vortexed for 10 s. The mixture was then extracted with 2 mL of hexane on a vortex mixer for 60 s and centrifuged at 2500 rpm for 3 min. The resulting supernatant was transferred into a fresh tube and dried at 35 °C under nitrogen gas. The residue was then reconstituted with 100 μL of the mobile phase on a vortex mixer for 30 s. The reconstituted solution was centrifuged at 2500 rpm for 60 s, and a portion (40 μL) was injected onto the chromatograph. The flow rate of the mobile phase was 1.0 mL/min at ambient temperature, and the effluent was monitored at 253 nm. Clomipramine and imipramine were well-resolved, with retention times of 3.8 and 5.0 min, respectively. Standard curves were linear over the concentration range of 10−1000 ng/mL, with a typical correlation coefficient of $r = 0.9998$. The intra- and interday assay coefficients of variation were <3.2% and <4.7%, respectively, for clomipramine and imipramine over the concentration range studied ($n = 5$ each).

Data Analysis—Serum clomipramine concentration vs time data were analyzed by a compartmental method for the iv injection study and by a noncompartmental method for the oral and sublingual studies. The nonlinear least squares regression program WinNonlin (Scientific Consulting Inc., Cary, NC) was used in the analysis. Statistical differences in pharmacokinetic parameters between conscious and anesthetized rats and between different doses were tested by the unpaired Student t-test. The significance level was set at $p < 0.05$.

Results and Discussion

Figure 1 shows the serum concentration vs time curves of clomipramine in rats obtained after iv injection (5 mg/kg doses) and oral administration (50 mg/kg doses). Following iv injection, the disposition of clomipramine was described by a biexponential curve, with a mean distribution and terminal elimination half-life of 7.8 ± 4.2 min and 63.0 ± 15.6 min, respectively. The elimination half-life of clomipramine in rats was much shorter than in humans (mean range, 24−39 h), primarily due to a higher systemic clearance and lower V_{ss} (96.6 ± 27.3 mL/min/kg and 6.1 ± 1.3 L/kg, respectively) (Table 1) compared to those in humans (10.8 mL/min/kg and 7−20 L/kg, respectively).[5,7,9,10] Clomipramine was administered orally at 50 mg/kg doses so that the maximum serum drug concentrations were within an acceptable therapeutic range of 150−450 ng/mL.[3] Upon oral administration in conscious rats, clomipramine was rapidly absorbed (Figure 1), with an average t_{max} of 0.8 ± 0.2 h and C_{max} of 209.4 ± 44.1 ng/mL (Table 2). The mean C_{max} found in this study (209.4 ng/mL) was higher than those reported after administration of 90 mg/kg po doses (162 ng/mL) or 15 mg/kg i.p. doses (144 ng/mL).[11,12] The oral bioavailability of clomipramine was 24.8% in conscious rats and 29.7% in rats anesthetized with ketamine/xylazine (30/3 mg/kg). There was no significant difference in AUC between the conscious and anesthetized rats (2258 ± 1762 ng·h/mL vs. 1891 ± 867 ng·h/mL). The C_{max} values between the two groups of animals were comparable, although the rate of absorption was lower in the anesthetized rats (Table 2). Therefore, it is unlikely that the light anesthesia induced by ketamine/xylazine (30/3 mg/kg) caused any significant alterations in the extent of drug absorption and elimination. The terminal elimination half-life was prolonged after oral administration (9.2 ± 7.8 h) as compared with iv injection (1.1 ± 0.3 h), suggesting that the drug elimination was rate-limited by the absorption process. These increased elimination half-lives are similar to the half-life of 6 h reported previously in rats after i.p injection.[12] The oral bioavailability of clomipramine in the rat was lower than that found in humans (approximately 50%).[5,6]

When the drug was given sublingually at 50 mg/kg doses, higher C_{max} (414.5 ± 47.0 ng/mL) and AUC (3303 ± 1576 ng·h/mL) were observed compared to those obtained after oral administration (Figure 2). Also, the absolute bioavailability of clomipramine after sublingual administration (36.2%) was higher than after oral administration. Clomipramine is known to be extensively metabolized by the liver in rats and humans via demethylation and hydroxylation.[13,14] Since the rats used in the sublingual study were lightly anesthetized to facilitate drug administration, it may be argued that the increased bioavailability was due to reduced hepatic metabolism caused by anesthesia. However, given no differences in AUC, C_{max} and $t_{1/2,\lambda z}$ between conscious and anesthetized rats after oral administration, it is unlikely that the increased sublingual bioavailability was caused by induction of anesthesia.

Cl/*F* (mL/min/kg)	522.1 ± 284.3	500.7 ± 178.4	289.3 ± 116.8	170.6 ± 44.7
F (%)[b]	24.8	29.7	36.2	57.1

[a] Significantly different from anesthetized rats ($p < 0.05$). [b] $F = (AUC_{sublingual} \cdot dose_{iv}) \cdot 100/(AUC_{iv} \cdot dose_{sublingual})$.

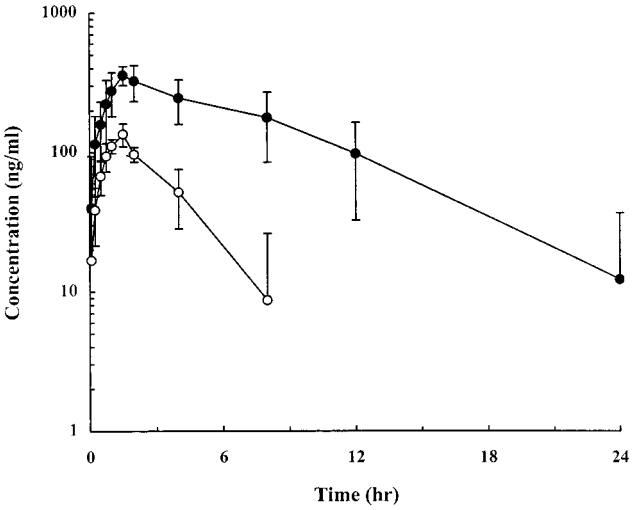

Figure 2—Mean serum concentration vs time curves of clomipramine after sublingual administration to rats with (5 mg/kg, ○) and without (50 mg/kg doses, ●) permeation enhancer ($n = 4$ each).

To further improve the sublingual bioavailability, clomipramine was formulated with a permeation enhancer, 2-hydroxypropyl β-cyclodextrin together with methyl cellulose and mannitol. After administration of this sublingual formulation in rats (5 mg/kg dose), C_{max} and AUC were higher by 3.3- and 1.6-fold, respectively, on a dose-normalized basis, than without permeation enhancer. Whether these increases were caused by the presence of the absorption enhancer, or were a result of a dose-dependent absorption, is unclear at present, although all the C_{max} values obtained in our study were within an acceptable therapeutic range. The terminal elimination half-life (2.2 ± 1.3 h) was shorter than found after oral and sublingual administration of 50 mg/kg doses but was still longer than found after iv injection. Therefore, at 5 mg/kg sublingual doses, the absorption process across the sublingual mucosa still seemed to have governed the elimination of clomipramine from the body. Nonetheless, the bioavailability of clomipramine was significantly increased (57.1%) for the sublingual formulation containing the permeation enhancer, and its relative bioavailability was increased to >192% over oral administration.

In conclusion, the pharmacokinetics of clomipramine showed multicompartment characteristics in rats. The oral bioavailability of clomipramine was low after administration of 50 mg/kg doses in rats. However, when given sublingually, clomipramine was well absorbed and its bioavailability was significantly increased over oral dosing. The sublingual route may be an alternative route of administration for clomipramine, providing enhanced bioavailability.

Abstract □ Human apolipoprotein A-1 was formulated in "Immune Stimulating Complexes" (ISCOMs). The structure of the protein in ISCOMs was examined directly using several biophysical techniques including Fourier transform infrared (FTIR) spectroscopy, near UV circular dichroism (CD), and fluorescence spectroscopy. Amide I FTIR data indicate that human apolipoprotein A-1 displays a slightly increased α-helical content after its incorporation into ISCOMs. Near UV CD and tryptophan fluorescence data suggest that association with ISCOMs results in the tryptophan residues of the protein experiencing a relatively hydrophobic environment, motional restriction, and local electrostatic interactions. These observations are consistent with an increased order in the protein structure upon incorporation in ISCOMs. In addition, biomolecular interaction analysis (BIA), based on surface plasmon resonance (SPR) measurements, suggests that the binding affinity of human apolipoprotein A-1 to a monoclonal anti-human apolipoprotein A-1 antibody is moderately decreased (by 20%) after its incorporation into ISCOMs. This study demonstrates that these biophysical techniques can be used to noninvasively monitor integrity of or changes in secondary and tertiary structure of proteins within the ISCOM particles without the need for protein extraction.

Introduction

Monitoring the structure of a protein following its formulation is crucial to the development of a successful formulation. Unfolding or changes in protein structure during formulation may result in loss of the desired biological efficacy. Although a large number of protein and peptide drugs have been formulated in delivery systems, monitoring structural changes after incorporation in these systems remains a challenging task. Most existing techniques require extraction of protein from the delivery systems with an organic solvent or a strong detergent.[1] These harsh extraction methods can be damaging to the secondary and tertiary structures of a protein and, therefore, prevent meaningful examination of any structural perturbations that may have occurred during formulation.[1]

In this study, several noninvasive spectroscopic techniques, including Fourier transform infrared (FTIR), near UV circular dichroism (CD), and fluorescence, were employed to directly examine the structure of a formulated protein. FTIR spectroscopy is a powerful tool for studying protein secondary structure, and it can be applied to samples in different physical states.[2] This technique has recently been applied to directly examine the integrity of recombinant human growth hormone[1,4] (rhGh), bovine serum albumin[3] (BSA), and chicken egg-white lysozyme[3] in poly(lactic-*co*-glycolic acid) (PLGA) microspheres, and in PLGA films.[4] Near UV CD spectroscopy is widely used for monitoring changes in the environments of aromatic amino acids that may result from changes in the protein's tertiary structure.[5] Changes in tryptophan fluorescence spectra usually reflect changes in the local environment of tryptophan residues, which may result either from a global change or a subtle local perturbation in the tertiary structure of a protein.[6] All of these spectroscopic techniques provide direct structural information using intrinsic chromophores or fluorophores of a protein, provided that any background interference from formulation excipients or delivery vehicles is minimal or can be corrected for.

Biomolecular interaction analysis (BIA) is a functional assay that monitors biological interactions at the molecular level. It uses an optical phenomenon called surface plasmon resonance (SPR) and a continuous flow system to monitor biomolecular interactions in real time.[7] Typically, one biomolecule is immobilized on the sensor surface, while a solution containing other biomolecules flows continuously over the sensor surface. As molecules from the solution bind to the immobilized biomolecule, a signal is registered in the form of a sensorgram which is based on the change of refractive index that results from this binding.[7] Real time monitoring of intermolecular interactions in the form of sensorgrams provides kinetic information such as association rate constants and dissociation rate constants as well as equilibrium binding constants.[7]

Human apolipoprotein A-1 was used in this study as a model protein and was incorporated into immune stimulating complexes (ISCOMs), a nanoparticulate delivery system made of a phospholipid, cholesterol, and Quil A.[8] Human apolipoprotein A-1 protein is the major protein component of high-density lipoprotein (HDL) particles. It has a molecular weight of 28 kDa, and its known protein sequence is composed of 243 amino acid residues including four tryptophan residues.[9] In the solution form, it is loosely folded with a high degree of exposure of its nonpolar groups to solvent.[10] Upon interaction with lipids, it undergoes subtle rearrangements in its tertiary structure to accommodate the more nonpolar environment of lipids.[10]

In the study reported here, FTIR, near UV CD and fluorescence spectra of human apolipoprotein A-1 in solution and in ISCOMs were compared. Binding of human apolipoprotein A-1 in ISCOMs to a specific monoclonal anti-human apolipoprotein A-1 antibody was studied using BIAcore (Biacore, Inc.) and compared to binding of the free protein in solution to the same antibody. The data indicate that human apolipoprotein A-1 undergoes subtle changes in secondary and tertiary structures when incorporated into ISCOMs. Furthermore, incorporation in ISCOMs also resulted in a modest alteration in its binding affinity for the anti-human apolipoprotein A-1 antibody. These results are consistent with the reported ability of human apolipoprotein A-1 to change its structure to accommodate lipophilic environments.[10] Our findings suggest that these

biophysical techniques can indeed be used to monitor protein structure in ISCOMs without the need for protein extraction.

Experimental Methods

ISCOMs Formation—ISCOMs were formed according to previously published method[11] with slight modifications. Briefly, 10 mg of L-α-phosphatidylcholine dipalmitoyl (Sigma) and 10 mg of cholesterol (Sigma) were dissolved in 1 mL of 20% decanoyl-*N*-methylglucamide (Mega-10, Sigma) in phosphate-buffered saline (PBS, pH 7.4). A 100 μL amount of the lipid mixture was mixed with 200 μL of 20 mg/mL Quil A (Superfos Biosector) and 600 μL of 2 mg/mL human apolipoprotein A-1 in PBS (Calbiochem). When preparing protein-free ISCOMs, PBS alone was used. The final volume was made up to 1 mL with PBS. The mixture was dialyzed against PBS over 48 h to remove the detergent. ISCOMs were formed upon detergent removal.

Sucrose Gradient Ultracentrifugation—Human apolipoprotein A-1 incorporated into ISCOMs was separated from unincorporated protein by ultracentrifugation at 200 000*g* for 18 h at 10 °C through a 10−50% discontinuous sucrose gradient. The gradient was then fractionated into volumes of 1 mL. The fractions were tested for the presence of protein with a colorimetric Lowry assay kit from BioRad, and for the presence of cholesterol with a colorimetric total cholesterol assay kit obtained from Sigma. Fractions containing both protein as well as cholesterol were pooled and washed with PBS to remove sucrose. Final protein concentration in each sample was determined by SDS−PAGE densitometry.

Dynamic Light Scattering—Hydrodynamic size distribution of the ISCOMs was determined using a dynamic light scattering (DLS) apparatus (Model 4700, Malvern Instrument) using the 488 nm line of a 5 W argon ion laser and a detection angle of 90°. The autocorrelation functions obtained from scattering measurements were fitted using the nonnegative least square (NNLS) algorithm to yield the size distribution of the ISCOMs.[12]

Transmission Electron Microscopy—Transmission electron microscopy (TEM) was used to examine the morphology of ISCOMs. Samples were stained with 2% uranyl acetate and examined under a JEOL JEM 1010 microscope.

Fourier Transform Infrared (FTIR) Spectroscopy—FTIR spectra were recorded at 25 °C with a resolution of 4 cm^{-1} on a BOMEM MB-104 FTIR spectrometer (BOMEM, Inc.), continuously purged with nitrogen and equipped with a DTGS detector. For each spectrum, 400 scans were accumulated in the single beam mode. Samples were placed in a sample cell with two CaF_2 windows separated by a 6 μm spacer. Human apolipoprotein A-1 and its ISCOM formulation were concentrated to 5 mg/mL using a 10 000 MWCO ultrafiltration device (Millipore). Proper blank spectra (PBS buffer for protein in solution and protein-free ISCOMs for protein in ISCOMs) and water vapor components were subtracted from the protein spectra using the BOMEM-PROTA (BOMEM, Inc.) software. Second derivatives of the spectra were calculated for peak identification. Secondary structure of the protein was analyzed using factor analysis[13] with the BOMEM-PROTA database[14] (BOMEM, Inc.).

Near UV Circular Dichroism (CD)—Near UV CD (in the wavelength range of 250−350 nm) spectra were obtained using a Jasco J-715 spectropolarimeter. Samples at a protein concentration of 0.3 mg/mL were placed in a rectangular quartz cell of 0.1 or 1 cm path length. The cell holder was maintained at a temperature of 25 °C. A bandwidth of 2 nm and a scan speed of 20 nm/min were used for each spectrum. For each sample, four spectral scans were averaged. Proper background spectra (PBS or protein-free ISCOMs) were recorded and subtracted to obtain background-corrected protein spectra.

Fluorescence Spectroscopy—Steady-state fluorescence spectra were recorded using a Perkin-Elmer LS50B fluorometer. Samples were excited at 295 nm, and tryptophan fluorescence was monitored between 305 and 400 nm using excitation and emission slits of 5 nm. Blank spectra (PBS or protein-free ISCOMs) were subtracted to obtain background-corrected tryptophan fluorescence spectra. Spectra were then corrected for wavelength-dependent monochromator and photomultiplier tube responses.

Biomolecular Interaction Analysis (BIA)—Binding interactions between human apolipoprotein A-1 (in solution or in ISCOMs) and a specific antibody were determined using a BIAcore 3000 biosensor system (Biacore, Inc.). Rabbit anti-mouse antibody (Biacore, Inc.) was immobilized on a research grade CM5 sensor chip in 10 mM sodium acetate, pH 4.5, using the amine-coupling kit (Biacore, Inc.). Mouse monoclonal anti-human apolipoprotein A-1 antibody (Calbiochem) was captured at a concentration of 10 μg/mL. Human apolipoprotein A-1 in solution or in ISCOMs was diluted in HEPES buffer for kinetic binding study. The samples were allowed to flow over the captured antibody for binding. Dissociation of the protein from the antibody was achieved by continuously flowing HEPES buffer over the sensor chip. All measurements were carried out at 25 °C using a flow rate of 20 μL/min. The sensor chip surfaces were regenerated with 20 μL of 10 mM glycine/HCl, pH 2, after each measurement.

The resulting sensorgram data were fitted with the 1:1 Langmuir binding model[7,15] using the BIAevaluation 3.0 software (Biacore, Inc.), yielding values for association and dissociation rate constants (k_a and k_d, respectively). Binding affinities of the antibody for human apolipoprotein A-1 in solution and in ISCOMs were expressed as dissociation constants K_D, where $K_D = k_d/k_a$.

Results and Discussion

ISCOMs Characterization—*A. Size*—TEM indicated that human apolipoprotein A-1 ISCOMs had the characteristic cagelike appearance[8] (Figure 1A). DLS measurement showed that the ISCOMs had a *z*-average hydrodynamic diameter of 50 nm with a narrow unimodal size

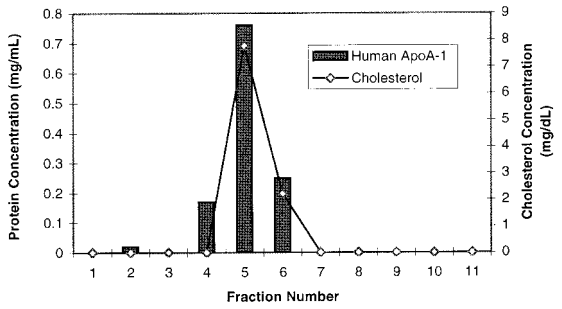

Figure 2—Sucrose gradient centrifugation of human apolipoprotein A-1 in ISCOMs. The gradient was fractionated into 1 mL fractions and each fraction was analyzed for the presence of cholesterol and protein.

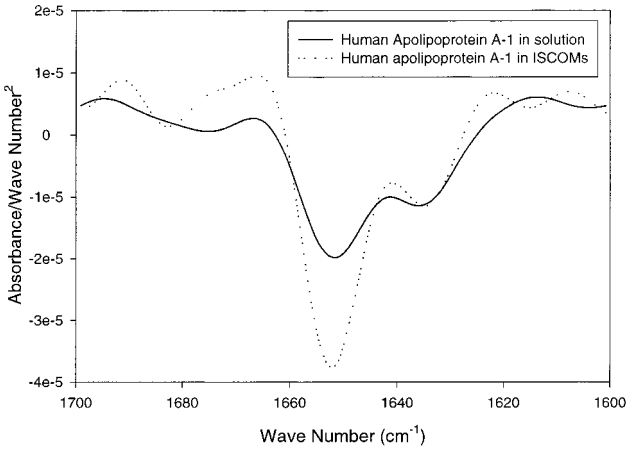

Figure 3—Amide I region of second derivative FTIR spectra of human apolipoprotein A-1 in solution and in ISCOMs. Proper blank spectra have been subtracted as described in the text.

distributions (polydispersity index = 0.08) (Figure 1B). This particle size is consistent with the size estimated from the TEM image shown in Figure 1A.

B. Protein Incorporation—The percentage of human apolipoprotein A-1 incorporated into the ISCOMs was determined using sucrose gradient ultracentrifugation. The ISCOMs showed up as a narrow band on the gradient after ultracentrifugation. Fractionation of the gradient indicated that close to 90% of the protein was associated with cholesterol after ultracentrifugation. Since cholesterol is an essential component of ISCOMs, the data suggested that approximately 90% of the total protein added was incorporated into the ISCOMs (Figure 2).

Direct Estimation of Protein Secondary Structure in ISCOMs by FTIR Spectroscopy—Protein-free ISCOMs gave minimal spectral interference in the region of interest, i.e., the amide I region (1600−1700 cm^{-1}). Figure 3 shows the amide I region of the second derivative FTIR spectra of human apolipoprotein A-1 in solution and in ISCOMs. Human apolipoprotein A-1 is known to contain a high percentage of α-helices.[9,16] This was clearly reflected in the prominent absorption band observed at 1656 cm^{-1} for human apolipoprotein A-1 in solution (Figure 3). The presence of some β-sheets was also seen from the band at 1634 cm^{-1}. The assignments of these amide I IR bands to defined secondary structures are based on a previously published report.[17] For the protein formulated in ISCOMs, an increase in absorption intensity was observed for the 1656 cm^{-1} absorption band. This observation is consistent with previously published findings that human apolipoprotein A-1 displays increased amount of α-helices when it is in HDL particles and bound to lipids, as compared to being in a lipid-free solution environment.[9,16]

	helix (%)	sheet (%)	bend and turn (%)	coil (%)
apolipoprotein A-1 in solution	44 ± 5	16 ± 2	17 ± 2	23 ± 3
apolipoprotein A-1 in ISCOMs	56 ± 5	10 ± 2	15 ± 2	20 ± 2

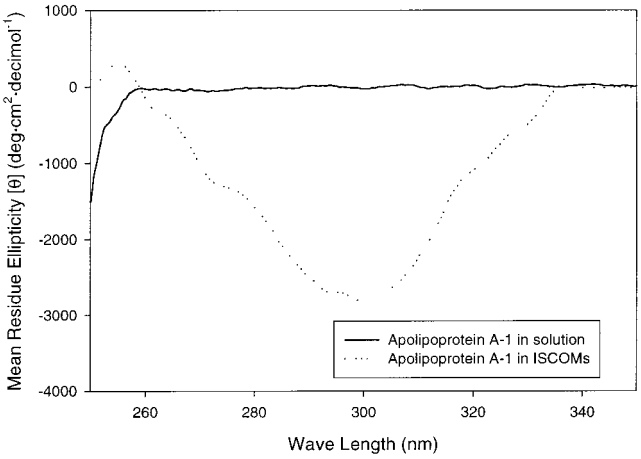

Figure 4—Near UV CD spectra of human apolipoprotein A-1 in solution and human apolipoprotein A-1 in ISCOMs. Proper blank spectra have been subtracted as described in the text.

Factor analysis was used to generate quantitative information on protein secondary structure from the IR absorption spectra.[13,14] This method predicts the secondary structure of an unknown protein using the (BOMEM-PROTA database of proteins with known crystal structures.[13,14] The results for human apolipoprotein A-1 in solution and in ISCOMs obtained from factor analysis are shown in Table 1. These values represent averages of results from three independently measured spectra. A modest increase in the amount of α-helices and a slight decrease in the amount of β-sheets were observed after apolipoprotein A-1 was incorporated into ISCOMs. These estimates are in qualitative agreement with the second derivative spectra in Figure 3.

It should be noted that far UV CD spectroscopy could not be used reliably to estimate secondary structure content of the protein in ISCOMs due to large interferences from the lipids and Quil A in ISCOMs.

Near UV Circular Dichroism—Near UV CD spectra for human apolipoprotein A-1 in solution and human apolipoprotein A-1 in ISCOMs are shown in Figure 4. When free in solution, human apolipoprotein A-1 did not show any near UV CD signal at the concentration of 0.3 mg/mL used, at either 0.1 or 1 cm optical path length, suggesting motional freedom of its aromatic side-chains. When incorporated into ISCOMs, human apolipoprotein A-1 displayed a broad CD signal with the spectral maximum at 300 nm and a shoulder at 295 nm. This indicates that the tryptophan residues experience motional restriction when the protein is in ISCOMs. It should be noted that apolipoprotein A-1 contains four tryptophan residues, and the individual contribution of each to the near UV CD or fluorescence spectrum (below) may or may not be equal. These data, therefore, reflect the environment of one or more, but not necessarily of all, of the tryptophans in the protein.

Fluorescence Spectroscopy—Figure 5 shows the tryptophan fluorescence spectra for human apolipoprotein A-1 in solution and in ISCOMs. The observed fluorescence maximum at 345 nm suggests that, on the average,

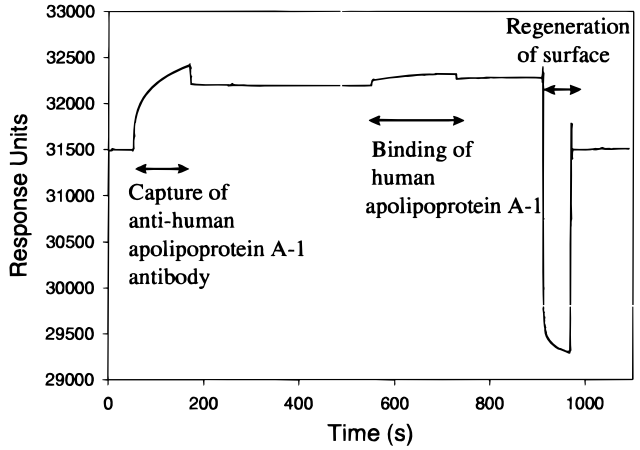

Figure 6—Sensorgram illustrating capture of a monoclonal anti-human apolipoprotein A-1 antibody, binding of human apolipoprotein A-1, and surface regeneration steps in kinetic analysis.

tryptophan residues in the free protein are partially exposed to water. This is consistent with previously published data suggesting that, in solution, human apolipoprotein A-1 has a high degree of exposed nonpolar groups.[10] After incorporation into ISCOMs, a blue-shift of the fluorescence maximum to 335 nm was seen, suggesting that ISCOMs provide a more hydrophobic environment for the tryptophan residues, possibly via interaction with the phospholipid or cholesterol in the ISCOMs. The quenching of fluorescence observed upon incorporation of the protein in ISCOMs may be a result of electrostatic interactions with the lipids or Quil A, which are in close proximity to the contributing tryptophan(s). Alternatively, the protein in ISCOMs may experience sterically allowed neighboring group interactions.

Biomolecular Interaction Analysis (BIA)—The sensorgram in Figure 6 illustrates the BIA data collection process. A mouse monoclonal anti-human apolipoprotein A-1 antibody was immobilized onto the sensor chip surface through binding to the rabbit anti-mouse antibody covalently bound to the chip surface. Human apolipoprotein A-1 in solution or in ISCOMs was then flowed over the chip surface and allowed to bind to the anti-human apolipoprotein A-1 antibody. Finally, the chip surface was regenerated before the next cycle would begin.

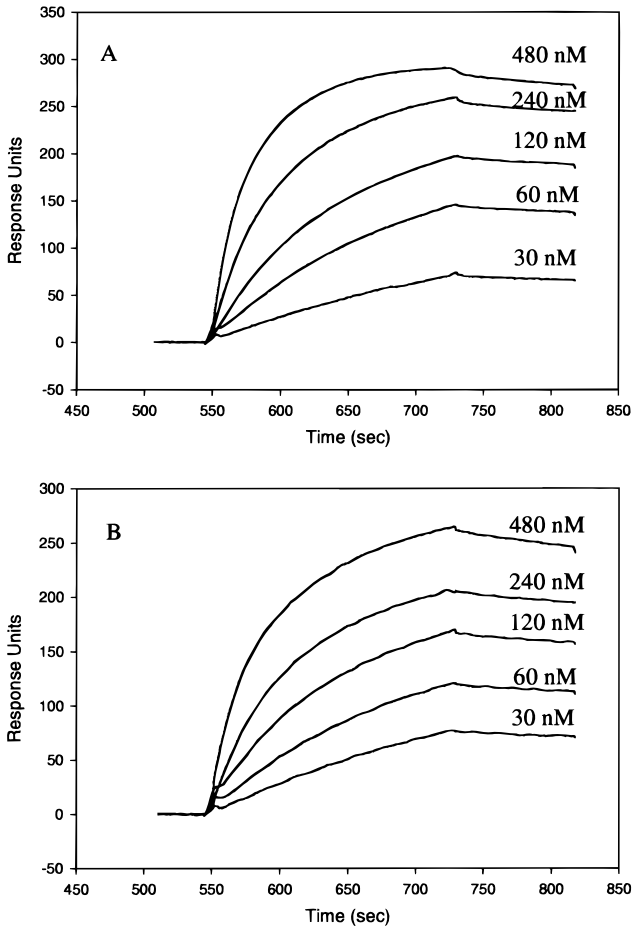

Figure 7—Effects of varying concentrations of human apolipoprotein A-1 on its binding kinetics to immobilized monoclonal antibody. (A) Human apolipoprotein A-1 in solution. (B) Human apolipoprotein A-1 in ISCOMs.

Table 2—Affinity and Rate Constants for Human Apolipoprotein A-1 in Solution and Human Apolipoprotein A-1 in ISCOMs. A Total of Three Measurements Were Made and the Results Are Presented as Mean ± sd

	$k_a \times 10^4$ ($M^{-1}s^{-1}$)	$k_d \times 10^{-4}$ (s^{-1})	K_D (nM)
human apolipoprotein A-1 in solution	11.5 ± 0.1	6.3 ± 0.1	5.7 ± 0.1
human apolipoprotein A-1 in ISCOMs	7.3 ± 0.1	4.8 ± 0.1	6.6 ± 0.1

(Figure 7A) and for human apolipoprotein A-1 in ISCOMs (Figure 7B). Five different protein concentrations were tested in each case. It can be seen that as the protein concentration was increased (either in the case of protein in solution or that of protein in ISCOMs), binding response increased correspondingly. When protein-free ISCOMs were tested, no response was seen (data not shown).

The sensorgram data in Figure 7 were fitted using the BIAevaluation 1:1 Langmuir binding model[7,15] to yield binding affinity and rate constants. A total of three evaluations were made for each sample, and the mean results are summarized in Table 2. After incorporation into ISCOMs, human apolipoprotein A-1 showed a 1.6-fold and a 1.3-fold decrease in k_a and k_d, respectively, for the monoclonal antibody. This translated to a 1.2-fold decrease in the binding affinity (or a 1.2-fold increase in K_D) for this interaction upon incorporation of the protein in ISCOMs. It is not known whether this slightly decreased antibody

affinity is the result of reduced accessibility of the antibody to ISCOM-associated protein compared to the free protein in solution.

Conclusion

FTIR spectroscopy suggests that human apolipoprotein A-1 experiences small changes in its secondary structure content upon incorporation in ISCOMs. Tryptophan fluorescence and near UV CD data indicate the protein's tryptophan residues, on the average, experience a more hydrophobic and motionally restrictive environment in ISCOMs compared to that in aqueous solution. BIA results suggest that the binding affinity of the protein to a monoclonal antibody is slightly reduced upon incorporation into ISCOMs. Results from these measurements suggest that the protein largely maintains its folded structure in ISCOMs, with its side chains engaged in local interactions with components of the ISCOM matrix. We conclude that a combination of biophysical techniques, such as those employed here, can provide complementary information on the secondary and tertiary structures of a protein formulated in ISCOMs. For other delivery systems, problems of interference will need to be carefully evaluated for each technique.

Received May 12, 1999. Accepted for publication August 11, 1999.

Abstract □ Substance P (SP) was degraded by synaptic membranes of rat spinal cord. Cleavage products were separated by reversed phase high performance liquid chromatography and identified by amino acid composition analyses. Major products of SP were phenylalanine, SP(1–4), SP(1–6), SP(1–7), SP(10–11), and SP(8–9). Both the degradation of SP and the accumulation of the major cleavage products were strongly inhibited by a metal chelator, *o*-phenanthroline, and also by specific inhibitors of endopeptidase-24.11, thiorphan, and phosphoramidon. Thus, endopeptidase-24.11 plays a major role in SP degradation in the rat spinal cord. N-Terminal fragments, SP(1–7) and SP(1–4), detected after incubation with spinal synaptic membranes were examined in vivo for antagonism against the scratching, biting, and licking response induced by intrathecal (IT) injection of SP (3.0 nmol) in rats. When IT coadministered with SP, SP(1–7) and SP(1–4) produced a significant inhibition of behavioral response to SP with ED_{50} of 135.0 pmol and 6.2 nmol, respectively. These results suggest that the degradation of SP in the spinal cord is not only responsible for inactivation of parent peptide, but may also lead to the formation of N-terminal SP-fragments which are shown to display a novel physiological function.

Introduction

Substance P (SP) is an undecapeptide which is widely distributed in the central nervous system and peripheral tissues.[1] This peptide is thought to function as a neurotransmitter or neuromodulator after secretion into synapse.[2,3] A member of tachykinins, SP is the endogenous ligand for the tachykinin NK_1 receptor, while neurokinin A and neurokinin B are endogenous ligands for NK_2 and NK_3 receptors, respectively.[4,5]

SP is believed to play an important role as an excitatory peptide in the spinal cord. Recently, two groups have reported that mice in which the preprotachykinin A gene was disrupted showed reduced responses to pain stimuli. Zimmer et al.[6] indicated that knockout mice which cannot produce SP and neurokinin A display no significant pain responses following hindpaw formalin injection. In addition, the animals have an increased pain threshold in the hot-plate test. Cao et al.[7] also reported that nociceptive response evoked by a hindpaw injection of capsaicin, an intensely noxious chemical stimulus that directly activated C-fibers, was significantly reduced in the knockout mice. They also found decreased nociceptive response of the knockout mice in the model of acute visceral pain by using the procedure of the acetic acid- and $MgSO_4$-induced writhing assay.

The physiological action of SP is probably terminated by a membrane-bound protease capable of degrading SP in the synaptic region, by analogy with membrane-bound acetylcholinesterase functioning in acetylcholine degradation in the synapse. Several membrane-bound neuropeptidases, endopeptidase-24.11,[8−10] SP-degrading enzyme from human brain,[11] SP-degrading endopeptidase from rat brain,[12] post-proline dipeptidyl-aminopeptidase,[13] and angiotensin-converting enzyme,[10,14−16] have been reported to be involved in the degradation of SP. SP is degraded into N- and C-terminal fragments by endogenous neuropeptidase. However, the physiological function of these neuropeptidases from a membrane fraction of rat spinal cord has still remained obscure. It has been reported that some of C-terminal SP-fragments exert actions within the central nervous system similar to those observed with SP, whereas N-terminal fragments have opposite or antagonizing effects on SP action.[17]

In our previous study,[18] SP(1−7) and SP(1−8) in the low picomole range antagonize the scratching, biting, and licking response induced by IT co-administration of SP in mice. In this study, we examined the degradation of SP by synaptic membranes of rat spinal cord. Additional in vivo experiments were performed to investigate the antagonizing effect of N-terminal SP-metabolites, SP(1−7) and SP-(1−4), on the characteristic behavioral response elicited by IT administration of SP in the rat.

Experimental Section

Animals—Male Wistar rats (Shizuoka Laboratory Center, Japan), weighing 250−300 g at the time of surgery, served as subjects. Animals were housed in a temperature (22 ± 24 °C)- and humidity (60−70%)-controlled room illuminated on a 12-h light and 12-h dark cycle. Food (Clea Japan, Inc., Osaka, Japan) and water were provided ad libitum throughout the course of the study.

Peptides and Chemicals—The commercial drugs used were: SP, phosphoramidon, chymostatin, leupeptin (Peptide Institute, Inc., Osaka, Japan), SP (1−4), SP(1−7), SP(1−9), SP(2−11), SP-(3−11), SP(4−11), SP(5−11), SP(8−11), SP(9−11), SP(6−11), SP-(7−11), *p*-chloromercuribenzenesulfonic acid (PCMBS), thiorphan (Sigma Chemical Co., St. Louis, MO), constant boiling hydrochloric acid (Pierce Chemical Co., Rockford, IL), captopril and phenylmethyl sulfonyl fluoride (PMSF) (Nacalai tesque, INC, Kyoto, Japan). Z-321 was obtained through courtesy of Zeria Pharmaceutical Co., Ltd., Saitama, Japan.

Preparation of Synaptic Membranes from Rat Spinal Cord—Rat spinal cord was washed with 10 mM Tris-HCl (pH 7.5)

containing 155 mM NaCl, suspended in a 10-fold volume of 10% (w/w) sucrose, and homogenized with a Teflon homogenizer. The homogenate was centrifuged at 800*g* for 20 min and then at 9000*g* for 20 min. The second pellet was suspended in about a 5-fold volume of 5 mM Tris-HCI (pH 8. 1). Then the suspension was incubated at 0 °C for 30 min for lysis of the pellet and subjected to discontinuous sucrose density gradient centrifugation according to the method of Jones and Matus.[19] Particle materials present at the interface between the layer containing 28.5% sucrose and that containing 34% sucrose were taken, diluted with 5 mM Tris-HCI (pH 8.1), and centrifuged at 100 000*g* for 1 h. The resulting pellet was suspended in 10 mM [2-[4-(2-hydroxyethyl)1-piperazinyl]ethanesulfonic acid (HEPES)−NaOH (pH 7.5) containing 155 mM NaCl and stored at −80 °C. Protein was determined by the method of Bradford[20] using bovine serum albumin (Bio-Rad) as a standard.

Degradation of Substance P by Synaptic Membranes of Rat Spinal Cord—The degradation of SP by synaptic membranes of rat spinal cord was carried out at 37 °C in a mixture (0.1 mL) containing of 10 mM HEPES−NaOH (pH 7.4), 80 mM NaCl, 2.5 mM KCl, 2 mM $MgCl_2$, 1 mM $CaCl_2$, 50 μM SP, and 50 μg protein of the membrane. The reaction was terminated by heating at 100 °C for 10 min. The reaction mixture was centrifuged, filtered through a membrane filter (Cosmonice Filter; pore size, 450 nm), and subjected to high performance liquid chromatography (HPLC) on a reversed phase column (4.6 × 150 mm) of SYMMETRYC18 (Waters) which had previously been equilibrated with l % (v/v) acetonitrile in 0.05% (v/v) trifluoroacetic acid (TFA). Elution was carried out at room temperature with a 32 min linear gradient of 1−65% acetonitrile in 0.05% TFA at a flow rate of 1 mL/min. The peptide fragments eluted were detected by monitoring the absorbance at 210 nm.

Identification of Substance P Fragments—The cleavage products separated by HPLC were lyophilized and hydrolyzed with 6 M hydrochloric acid containing 0.1% mercaptoethanol at 150 °C for 1 h. Their amino acid compositions were determined as phenylthiocarbamoyl amino acid derivatives by the reversed phase HPLC.[21]

Intrathecal Injection—To permit application of peptides directly into the spinal subarachnoid space, rats were anesthetized with pentobarbital sodium (50 mg/kg, ip) and chronically implanted with IT catheters.[22,23] Briefly, this involved inserting a length of polyethylene tubing (PE-10) following laminectomy between L3 and L4 and careful placing the catheter tip in the subarachnoid space of L5 and L6. The rats were allowed to recover over 7 days following implantation of the catheter. The catheter was filled with sterile artificial cerebrospinal fluid (CSF) containing (in g/L) NaCl 7.4, KCl 0.19, $MgCl_2$ 0.19, $CaCl_2$ 0.14. Peptides used in the experiments were administered in volumes of 10 μL followed by 15 μL of artificial CSF to ensure that peptides reached the spinal cord. SP(1−7) or SP(1−4) was mixed and coadministered IT with SP such that all doses were delivered in a total volume of 10 μL followed by 15 μL of artificial CSF to flush the catheter.

Behavioral Observation—One hour prior to IT injection, animals were adapted to an individual plastic cage (34 × 30 × 17 cm) which also served as the observation chamber. Immediately following IT injection of SP, each rat was replaced into the transparent cage, and behavioral testing was begun. The total respose time(s) of behaviors was measured for 5 min beginning immediately after IT injection of SP. These behaviors included hindlimb scratching directed toward the flank, biting, or licking of the hindpaw. All these different behaviors were pooled as a single value for each animal. Studies on the behavioral experiments were performed with the approval of the Ethics Committee of Animal Experiment in Tohoku Pharmaceutical University.

Calculations of ED_{50} and Data Analysis—Statistical analyses of the results were performed using the Dunnett's test for multiple comparisons, after analysis of variance (ANOVA). Differences were considered to be significant if $P < 0.05$. All values are expressed as means ±SEM.

Results

Degradation of SP by Synaptic Membranes of Rat Spinal Cord—Degradation of SP by synaptic membranes of rat spinal cord was analyzed by HPLC (Figure 1). About

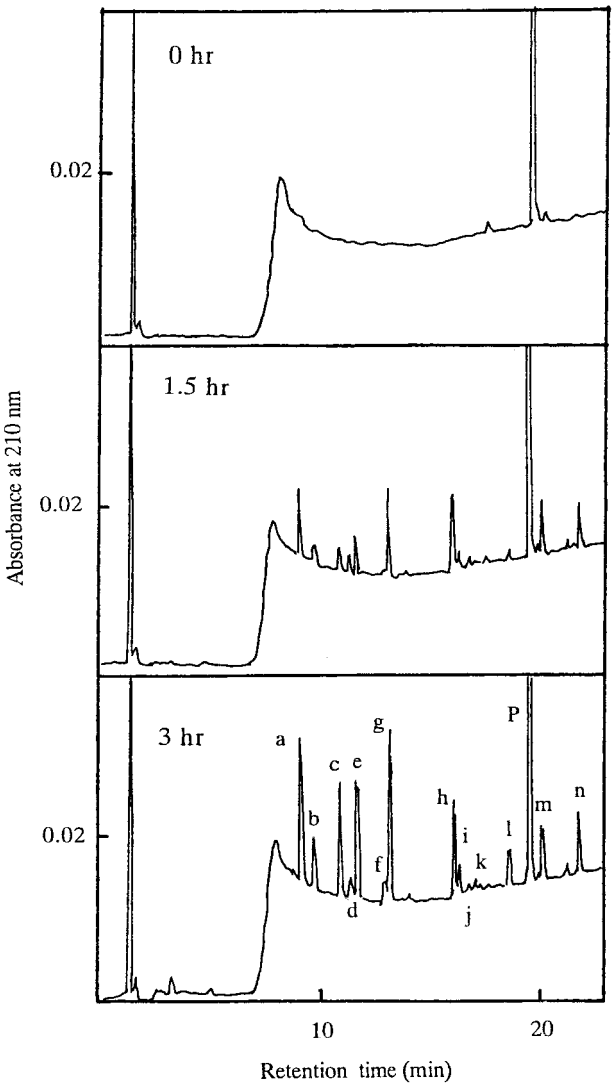

Figure 1—Degradation of substance P by synaptic membranes of rat spinal cord. The reaction mixture (0.5 mL, pH 7.5) containing 150 μg of the membrane preparation was incubated 37 °C for 0, 1.5, and 3.0 h. After heating at 100 °C for 5 min, 30 μL aliquots of the mixture were analyzed by HPLC on a reversed-phase column (4.6 × 150 mm) of SYMMETRYC18, which had been equilibrated with 1% acetonitrile in 0.05% trifluoroacetic acid. Elution was carried out at the room temperature with a 32-min linear gradient of 1–65% acetonitrile in 0.05% trifluoroacetic acid at a flow rate of 1 mL/min. The absorbance at 210 nm was monitored.

14 peaks were separated and named alphabetically from a to n according to the increasing order of their retention times. When only the membrane was incubated in the absence of SP or only SP was incubated, newly formed peaks were not detected at all. The position of peak P was identical to that of the substrate, SP, and the area of this peak decreased as a function of time (i.e., 15% and 32% of SP were degraded 1.5 h and 3 h after incubation, respectively), whereas those of other peaks increased. The results of analyses of amino acid compositions for the cleavage products separated by HPLC allowed their assignment (Table 1). Fragments b, c, g, h, l, m, and n were assignable as SP(1−4), free phenylalanine, SP(1−7), SP(1−9), SP(8−11), SP(3−11), and SP(5−11), respectively, by comparing their retention times in HPLC. The yield of peaks (a to n) was calculated on the basis of SP degraded by using procedure of quantitative amino acid composition analysis. Thus, N-terminal SP-fragments, SP(1−4), SP(1−6), SP(1−7), and SP(1−9), were found as major products in addition to free phenylalanine, SP(8−9), and SP(10−11).

Table 1–Amino Acid Composition of Fragments of SP[a] Produced through the Action of Synaptic Membranes of Rat Spinal Cord

peak	amino acid (mol %)								fragment identified	yield[b] (%)

[a] The sequence, Arg-Pro-Lys-Pro-Gln-Gln-Phe-Phe-Gly-Leu-MetNH_2. [b] Yield was determined on the basis of SP degraded. [c] The extent of degradation of SP was 68%. n.d., not determined.

Table 2–Effect of Protease Inhibitors on the Degradation of SP by Synaptic Membranes of Rat Spinal Cord[a]

inhibitor	concentration (mM)	inhibition (%)
o-phenanthroline	1.0	94
phosphoramidon	0.1	78
thiorphan	0.1	80
PCMBS	1.0	18
PMSF	1.0	24
captopril	0.1	0
bestatin	0.1	0
leupeptin	0.1	0
chymostatin	0.1	28
Z-321	0.1	3

[a] The activity was measured on the basis of the disappearance of SP, as detected by HPLC with isocratic elution.

Next, we examined the effects of various protease inhibitors on the degradation of SP by synaptic membranes of rat spinal cord. First, the inhibitory effects on the initial cleavage rate of SP were analyzed by measuring the effects on decrease of the HPLC peak for SP (peak P). The result was shown in Table 2. A metal chelator, *o*-phenanthroline and specific inhibitors for endopeptidase-24.11, phosphoramidon and thiorphan, inhibited SP degradation by synaptic membranes. Other inhibitors, including an angiotensin-converting enzyme inhibitor (captopril), a prolylendopeptidase inhibitor (Z-321),[24] an aminopeptidase inhibitor (bestatin), and inhibitors (PCMBS, PMSF, leupeptin, and chymostatin) for serine and cysteine proteases, had little inhibitory effects on SP degradation.

Second, the inhibitory effects on the generation of cleavage products of SP separated by HPLC were analyzed (Figure 2). The generation of all of the peaks including major peaks of N-terminal SP-fragments was strongly inhibited by the addition of thiorphan. Phosphoramidon and *o*-phenanthroline also showed strong inhibition, while other inhibitors exerted little inhibitory effect on the generation of almost all of the peaks (data not shown).

Effect of SP(1−7) and SP(1−4) on SP-Induced Behavioral Response—IT injections of SP (3.0 nmol) produced an immediate behavioral syndrome characterized by reciprocal hindlimb scratching, caudally directed biting, and licking. The intensity of the behavior peaked at 0−5 min, declined gradually at 5−10 min, and was no longer apparent at 15 min postinjection. In subsequent experiments, therefore, the animals were observed for 10 min following IT administration. In the in vivo experiments, N-terminal SP-fragments were tested for antagonism against the behavioral response induced by IT administration of SP. When coadministered IT with SP, SP(1−7) at doses of 40−400 pmol reduced the SP-induced behavioral response consisting of scratching, biting, and licking in a dose-dependent way (Figure 3). The SP-induced response was also dose-dependently decreased by IT coadministration of SP(1−4) (0.6−38.4 nmol) (Figure 3). The ED_{50} for SP(1−7) and SP(1−4) was 135.0 pmol and 6.2 nmol against SP, respectively. SP(1−7) and SP(1−4) in the dose-range tested did not produce SP-like behavioral response or any other motor disturbance.

Discussion

Although a number of laboratories have demonstrated that SP is extracellularly hydrolyzed by cell-surface endopeptidase, within the central nervous system,[8−16] the concurrent monitoring of SP and its metabolic fragments by synaptic membranes of rat spinal cord have not yet been explored. It is extremely of importance to note metabolic routes of SP in the spinal cord, since spinal dorsal horn is regarded as an important site for the processing of information related to the transmission and/or modulation of sensory signals including pain. The present findings show that SP was readily cleaved into SP(1−7) as a major product when incubated with synaptic membranes of rat spinal cord. Other N-terminal SP-fragments were also found, including SP(1−4), SP(1−6), and SP(1−9). It is, therefore, likely that the C-terminal SP-fragments released through the initial cleavage of SP may be susceptible readily to the action of neuropeptidases, since recoveries of C-terminal fragments were low compared with those of N-terminal fragments. These results are in accordance with our previous data that SP(1−7) is the main metabolite after endogenous cleavage of SP; in the dorsal spinal cord of rats the levels of SP(1−7) were about 20% those of SP, though in most of areas of the CNS the concentrations of SP(1−7) were about 10% those of SP.[25,26] Both the degradation of SP and the accumulation of the major cleavage products were strongly inhibited by a metal chelator, *o*-phenanthroline, and also by specific inhibitors of endopeptidase-24.11, thiorphan and phosphoramidon. Formation of the fragment SP(1−4) was also inhibited by the addition of thiorphan and phosphoramidon to the reaction medium. Since fragment SP(1−4) has not been reported to be formed directly by the action of endopeptidase-24.11 on SP, it may arise from the action of some other protease on the initial cleavage products formed by endopeptidase-24.11. Other peptide fragments were those formed by the cleavage between the Gln^6-Phe^7, Phe^7-Phe^8, Gly^9-Leu^{10} bonds of SP, all of which have been reported to be the sites of cleavage by endopeptidase-24.11 obtained from various synaptic membranes of pig caudate,[8] pig kidney,[9] human kidney,[10] rat substantia nigra,[27] glioma C6 cells,[28] and glial cells cultured from rat fetal brain.[29] In our previous report,[30] we have examined the effect of protease inhibitors on the scratching, biting, and licking response elicited by IT injection of SP in mice. Phosphoramidon simultaneously injected with SP remarkably enhanced and prolonged SP-induced behavioral response in a dose-dependent manner. SP-induced behavioral response was not enhanced by bestatin, an aminopeptidase inhibitor, and captopril, an angiotensin-converting enzyme inhibitor. Taking account of these behavioral observations, the present results suggest that thiorphan-sensitive metalloendopeptidse, probably endopeptidase-24.11, would play a critical role in the initial stage of cleavage of SP by synaptic membranes of rat spinal cord.

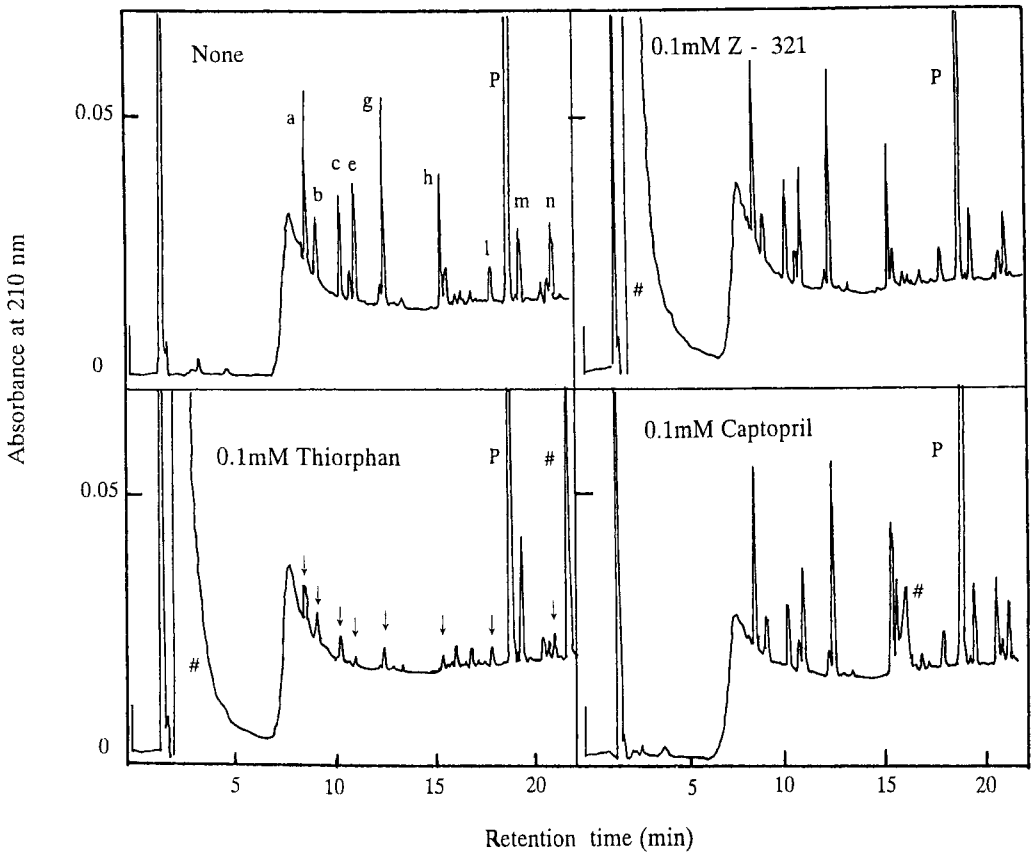

Figure 2—Effect of protease inhibitors on the degradation of substance P by synaptic membranes of rat spinal cord. The reaction mixture (0.5 mL, pH 7.5) containing 50 μg of the membrane preparation was incubated 37 °C for 6 h in the absence or the presence of 0.1 mM thiorpan, 0.1 mM Z-321, or 0.1 mM captopril. After heating at 100 °C for 5 min to stop the reaction, 20 μL aliquots of the sample were analyzed by HPLC as in Figure 1. # indicates the peak derived from the inhibitor added.

There are some reports related to SP degradation in rat spinal cord. Mauborgne et al.[31] have previously examined the effect of peptidase inhibitors on SP-like immunoreactive materials released by K^+-induced depolarization from slices of the rat spinal cord. They indicated that bacitracin was the most potent agent to protect SP-like immunoreactive materials from degradation, and captopril and thiorphan also protected it from degradation. Suzuki et al.[32] have reported the effects of peptidase inhibitors on the enzymatic degradation of SP by synaptic membranes of neonatal rat spinal cord. While they did not analyze and characterize the cleavage products of SP, they have presented that thiorphan, actinonin for an aminopeptidase N inhibitor, and captopril inhibited SP degradation. The inhibition potency of each peptidase inhibitor was lower than that of the mixture. They have also reported in electrophysiological studies that the magnitude of SP-evoked depolarization of a lumbar ventral root in the isolated spinal cord preparation was increased by a mixture of peptidase inhibitors, consisting of actinonin for an aminopeptidase N inhibitor, arphamenine B for an aminopeptidase B inhibitor, bestatin for an aminopeptidase B and M inhibitor, captopril, and thiorphan. These results are inconsistent with our results. Although the reason for this discrepancy remains unknown, in all cases, however, susceptibilities of SP degradation to thiorphan are consistent with each other. Recent biochemical data show that two enzymes with SP-degrading activity from the membrane bound fraction of the rat spinal cord are separated,[33] one enzyme exhibited similarity to endopeptidase-24.11, while the other resembled a substance P converting endopeptidase which has been identified and purified from human cerebrospinal fluid. Accordingly, SP(1−7), SP(1−8), SP(8−11), and SP(9−11) were detected after incubation with both enzyme. The former enzyme preparation also gave SP(1−6) as a major product. It is still unknown whether these enzymes play critical roles in SP degradation in rat spinal cord synapses.

Thus, SP is enzymatically cleaved into several C-terminal and N-terminal fragments, which have biological activity in the CNS sensory system. Some of C-terminal fragments, injected IT into mice, elicit scratching, biting, and licking response similar to that observed with SP, whereas N-terminal fragments have antagonizing effects on SP-induced behavioral response.[34] In addition, central actions of N-terminal fragments have previously been found to produce effects opposite to those of C-terminal fragments in mice. For example, the N-terminal heptapeptide inhibited grooming and increased rearing, whereas the C-terminal hexapeptide had the opposite effect.[17,35] Studies with microinjection into the substantia nigra demonstrate that SP induces dopamine release in the ipsilateral striatum and produces contralateral rotation in a dose-dependent manner.[36] In addition, intranigrally injected SP(1−7) produces an antagonistic action on the SP-induced response. In agreement with these previous findings, SP(1−7), injected into conscious rats produced a dose-dependent antagonizing effect on SP-induced behavioral response. Similar effects were obtained by coadministration of SP-(1−4), though SP(1−4) is approximately 45 times less potent than SP(1−7) in antagonizing the response to SP. These results are in line with our recent data in mice (unpublished data) that SP(1−7) is much more potent than SP(1−4) as assayed by the spinally mediated SP response. Taken together, our biochemical and pharmacological results suggest that endogenously formed SP(1−7) may be a main modulator of SP actions in the rat spinal cord.

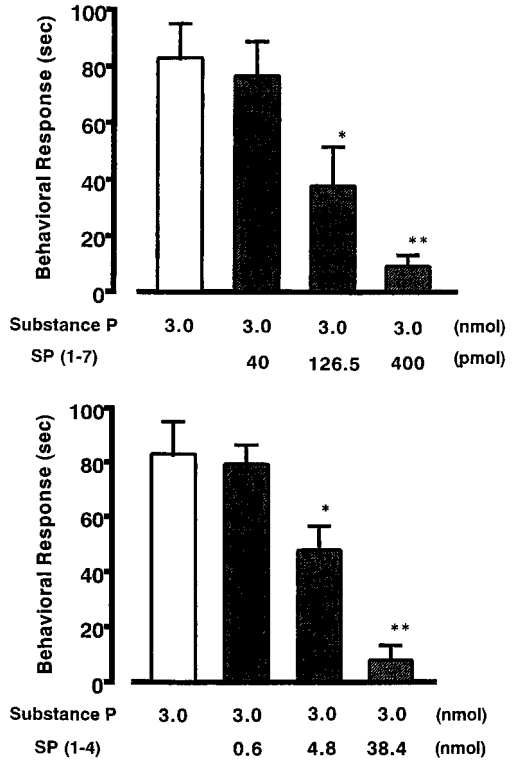

Figure 3—The effectiveness of substance P(1–7) (upper panel) and substance P(1–4) (lower panel) in antagonizing the scratching, biting, and licking behavior induced by substance P in rats. Substance P (3.0 nmol) was coadministered intrathecally with substance P(1–7) or substance P(1–4). The duration of the behavioral response induced by substance P was determined over a 10 min period starting immediately after intrathecal injection. The data are given as means ±SEM of six rats in each group. $^{**}P < 0.01$, $^{*}P < 0.05$ when compared to substance P alone.

Mechanism of spinal actions of N-terminal SP-fragments is still unclear. In the present study, there was no significant difference of potency in the antagonizing effect of SP(1−7) on SP-induced behavioral response between rats and mice, when comparing the ED_{50} value of SP(1−7) (135.0 pmol) against SP (3.0 nmol) in rats with that of SP(1−7) (2.9 pmol) against SP (100 pmol) in mice.[34] These data suggest that SP(1−7) may inhibit binding of [^{3}H]-SP(1−7) to rat and mouse spinal cord membranes with similar potency.[37] It is noteworthy that similar phenomena are seen in affinities of CP-96,345 for tachykinin NK_1 receptor; the nonpeptide tachykinin NK_1 receptor antagonist, CP-96,345, was much less active at NK_1 receptors in rat and mouse than the other mammalian species including human, whereas there was no significant difference in affinity of CP-96,345 for NK_1 receptors between rat and mouse.[38,39]

It is of interest to note that the antagonistic effect of SP-(1−7) on SP-induced behavioral response in mice was inhibited by naloxone, an opioid receptor antagonist, and [D-Pro^2, D-Phe^9] SP(1−7), an inhibitor of [^{3}H]-SP(1−7) binding, but not by selective antagonists of μ-, δ-, and κ-opioid receptors.[40] One could speculate that a physiological action of SP(1−7) in the spinal cord may not be mediated by an action at a typical opioid receptor but by an action at SP(1−7) binding site or its own receptor.

In conclusion, the degradation of SP by endopeptidase-24.11 in the spinal cord is not only responsible for inactivation of SP, but may also lead to the formation of N-terminal fragments which are shown to display a novel physiological function as a result of a shift to receptor specificity.

Abstract □ Picotamide is an antiplatelet agent given by mouth as monohydrate (PICOW) (Plactidil) in thrombo-embolic disorders. This study deals with physical characterization of PICOW recrystallized from various solvents and the respective dehydration products using X-ray powder diffractometry (XRD), infrared spectroscopy (IR), and thermal analytical techniques (differential scanning calorimetry, DSC; thermogravimetric analysis, TGA; simultaneous TGA/DSC; hot stage microscopy, HSM). Monophasic and biphasic DSC and TGA profiles of water loss were recorded under open conditions for PICOW samples which showed the same monoclinic crystal structure. Biphasic profiles became monophasic for gently ground samples which were, however, structurally identical to the intact samples. Morphological factors, the various degree of "perfection" of the PICOW crystal lattice, and/or cluster aggregation of PICOW crystals were assumed to be responsible for the differing dehydration patterns. Polymorphism in anhydrous picotamide, i.e., nucleation of crystal forms A, mp 135.5 ± 0.4 °C, and B, mp 152.9 ± 0.3 °C after dehydration of PICOW, was detected by DSC and HSM. The dehydration product of PICOW under isothermal conditions (115 °C, 20 mmHg), PICOA, was mainly composed of the lower melting polymorph A (fusion enthalpy 74.4 ± 2.2 J g^{-1}), which gradually reverted to the starting hydrate by storing in an ambient atmosphere. Dissolution tests of PICOW and PICOA in water at 37 °C as both powders and compressed disks reflected to some extent the higher solubility of the metastable form (by 24% at 37 °C) in terms of both higher dissolution efficiency and percent of active ingredient dissolved (by 28%) and intrinsic dissolution rate (by 32%).

Introduction

Picotamide (4-methoxy-*N*,*N*′-bis(3-pyridinylmethyl)-1,3-benzenedicarboxamide, Figure 1) is an antiplatelet agent sharing a dual anti-thromboxane activity (i.e., inhibition of thromboxane A2 synthase and thromboxane A2 receptor antagonism) which in the second half of the 1990s has been widely studied from the pharmacological and clinical point of views mainly in Italy.[1] Picotamide is given by mouth in thrombo-embolic disorders as monohydrate (PICOW), the active ingredient present in commercial dosage forms (Plactidil). The crystal structure of PICOW has been determined since 1986,[2] but the solid-state properties of this drug[3] and some of its binary systems with pharmaceutical excipients[4,5] have been investigated only recently.

Although all picotamide samples recrystallized by precipitation from various solvents showed the same physicochemical properties as PICOW, different DSC dehydration profiles and dehydration products were obtained depending on the recrystallizing solvent of the tested PICOW sample.[3] The same anhydrous crystal form, hereafter reported as PICOA, was however obtained by dehydration under isothermal conditions (115 °C, 20 mmHg) of PICOW, whatever the recrystallization solvent of the sample.

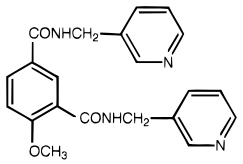

Figure 1—Molecular structure of picotamide.

The thermodynamic differences between a drug hydrate and its anhydrous counterpart necessitate detailed studies on their phase stability. The change in thermodynamic activity of the drug due to hydration/dehydration alters pharmaceutically important properties such as physical and chemical stability, as well as solubility and dissolution rate.[6–8] The effect of mechanical treatments, i.e., grinding, also deserve attention in this respect,[9] particularly because of the possible dependence of the dehydration mechanism on the particle size.[10,11]

The present study deals with the physical characterization of PICOW and PICOA by X-ray powder diffractometry (XRD), mid- and near-infrared (IR) spectroscopy, differential scanning calorimetry (DSC), thermogravimetric analysis (TGA), simultaneous TGA-DSC, and hot-stage microscopy (HSM). Thermal dehydration of intact and ground samples of PICOW from different recrystallization solvents and rehydration of PICOA under controlled conditions of relative humidity (RH) and temperature were investigated. The aqueous solubilities of PICOW and PICOA as a function of temperature (20−45 °C), as well as their dissolution rates in water at 37 °C as both powders and compressed disks, were also determined.

Experimental Section

Materials—Commercially available PICOW (Manetti & Roberts, Firenze, Italy) was used. The product was recrystallized from water−ethanol 8:1 (v/v) and subsequently dried in a desiccator over P_2O_5 at room temperature (see Table 1). PICOA was prepared by drying PICOW from water−ethanol 8:1 (v/v) under reduced pressure (over P_2O_5 in a drying pistol, 20 mmHg) in a hot air oven at 115 °C for 1 h and storing over P_2O_5 in a desiccator (see Table 1). Solvents of analytical reagent grade and bi-distilled water were used.

Preparation of PICOW Samples—Recrystallized samples were prepared by precipitation of PICOW from different recrystallization solvents following the procedures described in ref 3. Ground samples were prepared by manually grinding 500 mg of

material with pestle and mortar. Rehydrated samples were prepared by storing PICOA (≈2 g samples spread on Petri dishes) in a desiccator at room temperature (22 °C) kept at a relative humidity (RH) of 45% or ≈100% by equilibrating over a saturated solution of KNO_2 or pure water, respectively. Samples (5−10 mg) were taken out at appropriate intervals and checked for water content by DSC and TGA (see below).

X-ray Diffractometry (XRD)—Powder X-ray diffraction patterns were taken at ambient temperature and atmosphere with a computer-controlled Philips PW 1800/10 apparatus equipped with a specific PC-APD software. Wavelengths: Cu $K_{\alpha,1} = 1.54060$ Å, Cu $K_{\alpha,2} = 1.54439$ Å. Scan range: 2−50° 2θ. Scan speed: 0.02° 2θ s^{-1}. Monochromator: graphite crystal.

Infrared (IR) Spectroscopy—Mid-IR (400−4000 cm^{-1}) spectra were recorded by the Nujol mull method using a double beam Perkin-Elmer 983 IR spectrophotometer. Near-IR (4500−10000 cm^{-1}) spectra (NIR) were recorded directly on powder samples (75−150 μm sieve granulometric fraction) by using an optical head linked to the NIR reflectance analyzer (Infraprover II Technicon Model No. 450 RP) by optical fibers.

Karl Fischer Titrimetry (KFT)—The amount of water in the PICOW samples was determined with a Mettler DL40GP Memo titrator apparatus. Samples (80−90 mg) were quickly transferred to the titration vessel containing anhydrous methanol and titrated using Hydranal Composite 5 (Riedel-de Haen, Milano, Italy).

Differential Scanning Calorimetry (DSC)—Temperature and enthalpy values were measured with a METTLER STAR^e system equipped with a DSC821^e Module on 3−5 mg (Mettler M3 Microbalance) samples in uncovered aluminum pans under static air. An uncovered empty pan was used as reference. The heating rate was 5 K min^{-1} over the 30−180 °C temperature range.

Thermogravimetric Analysis (TGA)—Mass losses were recorded with a Mettler TA 4000 apparatus equipped with a TG 50 cell at the heating rate of 5 K min^{-1} on 7−10 mg samples in open alumina crucibles in the 30−180 °C temperature range under static air.

Simultaneous TGA-DSC—Simultaneous recording of mass loss and enthalpy change was carried out with a METTLER STAR^e system equipped with a TGA/SDTA851^e Module and calibrated with indium on 2.5−3.5 mg samples in a platinum crucible under nitrogen gas flow (150 mL min^{-1}). The heating rate was 10 K min^{-1} over the 40−200 °C temperature range.

Hot-Stage Microscopy (HSM)—Microscopic observation of the thermal events was carried out under a Reichert polarized light microscope equipped with a Mettler FP82HT/FP80 system at a heating rate of 10 K min^{-1} which was reduced to 5 K min^{-1} in the regions of the DSC peaks. Images were transferred via a Panasonic WV-CP100E CCTV camera to a Panasonic WC-CH110A video monitor.

Solubility Measurements—Excess amounts (50 mg) of PICOW or PICOA powder (75−150 μm sieve granulometric fraction) were added to 30 mL of nonbuffered water (pH ≈ 6) in sealed 50 mL glass containers, which were electromagnetically stirred at a constant temperature (20, 25, 32, 37, 45 °C ± 0.2 °C). At suitable time intervals aliquots were withdrawn, filtered (pore size 0.45 μm), suitably diluted with water, and spectrophotometrically assayed for drug concentration at $\lambda = 254.4$ nm (Perkin-Elmer 552S Spectrophotometer). Residual solid material was identified

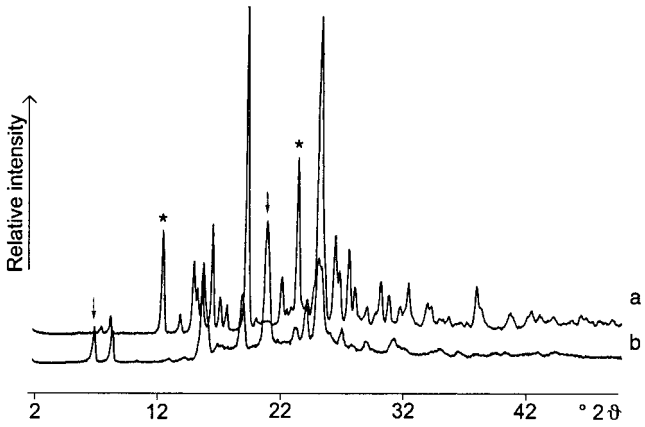

Figure 2—XRD patterns of (a) picotamide monohydrate (PICOW) from water–ethanol 8:1 (v/v) and (b) anhydrous picotamide (PICOA). Characteristic diffraction peaks of PICOW at 12.6° and 23.6° (2θ) (stars) and of PICO A at 7.1° and 21.2° (2θ) (arrows) are indicated.

postequilibrium by DSC and IR analysis. Plateau values of dissolved concentration of the metastable PICOA form, before declining toward the corresponding plateau value of the stable PICOW form, were assumed as the equilibrium solubility. Tests were performed in triplicate and averaged.

Dissolution Tests—Dispersed amount experiments were performed in nonbuffered water (pH ≈ 6) at 37 ± 0.2 °C by adding 45 mg of PICOW or PICOA powder (75−150 μm sieve granulometric fraction) to 75 mL of water in a 150 mL beaker (nonsink conditions). A glass three-blade propeller (19 mm diameter) was immersed in the beaker 25 mm from the bottom and rotated at 100 ± 1 rpm. In the rotating disk method, tablets (1.3 cm in diameter) were prepared by compressing 300 mg of powders using a Perkin-Elmer hydraulic press for KBr disks for IR spectroscopy, at a force of 1.5 t cm^{-2} for 10 min which yielded tablets with a surface area of 1.33 cm^2 which would not disintegrate during the test. No lubricant was used. No detectable PICOW dehydration or PICOA hydration associated with compression was found in the disks by IR, DSC, and TGA analysis of powder samples taken by gently scratching the disk surface with a blade. The tablets were inserted into a stainless steel holder, so that only one face was exposed to the dissolution medium. The holder was then connected to a stirring motor, centrally immersed in a 150 mL beaker containing 100 mL of nonbuffered water (pH ≈ 6) at 37 ± 0.2 °C and rotated at 100 ± 1 rpm. In both methods, suitable aliquots were withdrawn with a filter-syringe (pore size 0.45 μm) at the specified times and assayed for drug content as in Solubility Measurements. A correction was calculated for the cumulative dilution caused by replacement of the sample with equal volume of original medium. Each test was repeated four times (coefficient of variation, CV < 3% and < 7% for dispersed amount and rotating disk experiments, respectively).

Results and Discussion

Physicochemical Properties of the Solid Phases—PICOW and PICOA (see Table 1 for elemental analysis and water stoichiometry) were characterized with data from XRD, IR, conventional and simultaneous DSC and TGA, and HSM. The XRD pattern of PICOW corresponding to the theoretical powder pattern assessed from crystal structure data[3] was obtained using a ground sample (Figure 2). Actually, using an intact sample, a strong enhancement of the diffracted intensities of some peaks probably due to preferred orientation effects[12] was observed.[3] A distinctly different XRD pattern was recorded for PICOA, which shows characteristic reflections at 7.1° and 21.2° (2θ) which are useful for identification purposes and an apparent lower crystallinity than that of the parent hydrate.

The IR spectra of PICOW and PICOA are presented in Figure 3. In the O−H stretching region of PICOW, crystal-

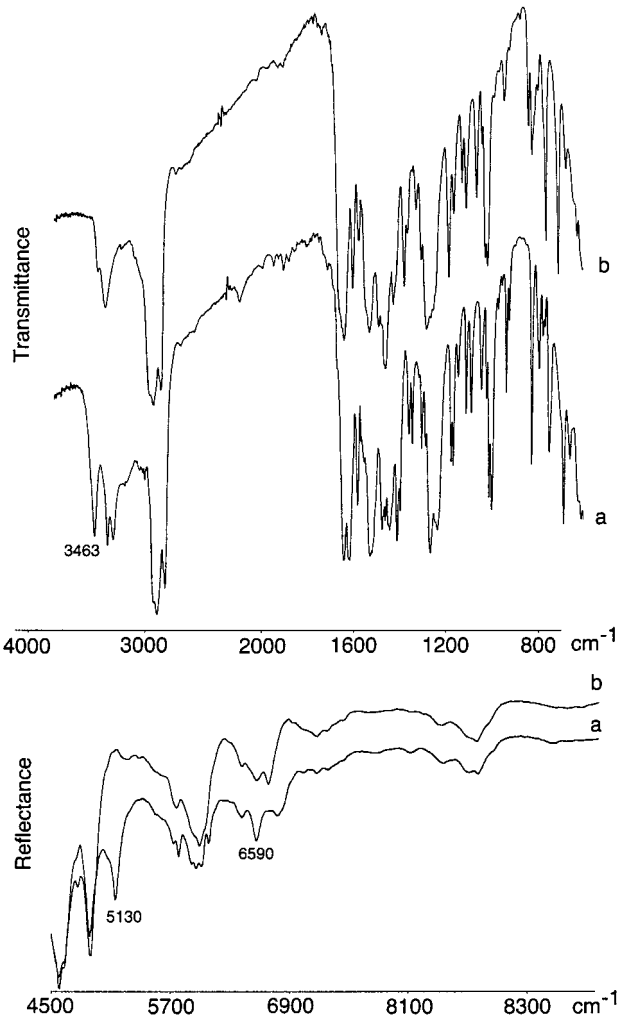

Figure 3—IR spectra of (a) picotamide monohydrate (PICOW) from water–ethanol 8:1 (v/v) and (b) anhydrous picotamide (PICOA) in the 4000–700 and 4500–9900 cm^{-1} range. Characteristic absorption bands of water at 3463 cm^{-1}, 5130 cm^{-1}, and 6590 cm^{-1} are indicated.

line water shows a sharp high-frequency (3463 cm^{-1}) absorption band[13] which suggests the presence of "tightly bound" water in the crystal lattice.[14] The number and strength of hydrogen bonds involving the water molecules regularly arranged through the crystal[2] confirm this hypothesis. Other differences at the level of the 3354−3304 (assignable to the N−H amide stretching) and 1658−1632 cm^{-1} (assignable to the amide carbonyl group) doublets in the anhydrous and hydrated structures can be attributed to the absence and presence of lattice water within the hydrogen bond patterns. The NIR absorption bands at 5130 and 6590 cm^{-1} are also characteristic of crystalline water[15,16] and permit discrimination between the anhydrous and hydrated picotamide forms.

The thermal behavior of PICOW obtained by recrystallization from water−ethanol 8:1 (v/v), ethyl acetate, or benzene and of PICOA is depicted in Figures 4−6. The negative DSC peak for endotherms between 60 and 130 °C (enthalpy change 189 ± 5 J g^{-1}) of the intact PICOW sample from water−ethanol 8:1 (v/v) (Figure 4a) was reflected by the negative derivative TGA peak for mass loss over the same temperature range (Figure 5a). The relevant mass loss of 4.84 ± 0.21% (w/w) was confirmed by simultaneous TGA/DSC (Figure 6) and corresponded to a monohydrate stoichiometry (see Table 1). Moderate grinding did not substantially alter the water content and the dehydration enthalpy of the sample, whereas it decreased (by 3−4

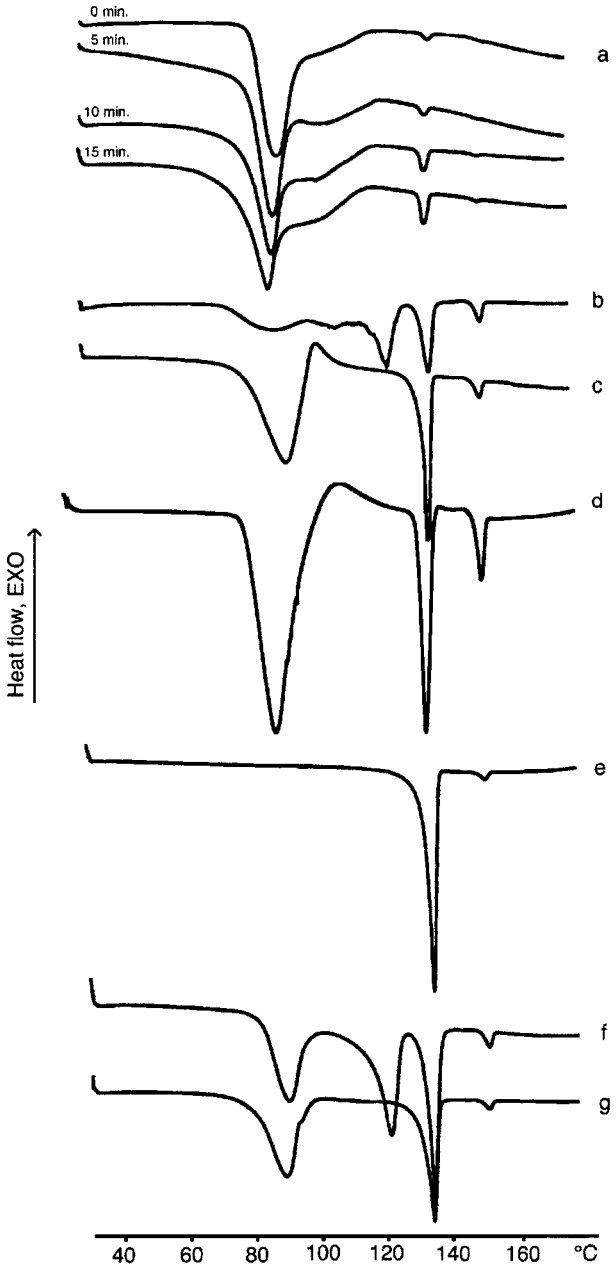

Figure 4—DSC curves of picotamide monohydrate (PICOW) and anhydrous picotamide (PICOA). Key: (a) PICOW from water–ethanol 8:1 (v/v) (grinding time on the curves); (b) PICOW from ethyl acetate, intact sample; (c) PICOW from ethyl acetate, ground sample; (d) PICOW from benzene, intact sample; (e) PICOA by isothermal dehydration (115 °C, 20 mmHg) of an intact sample of PICOW from water-ethanol 8:1 (v/v); (f) PICOW by rehydration of PICOA in an ambient atmosphere (RH ≈ 45%), intact sample; (g) PICOW by rehydration of PICOA at RH ≈ 45%, ground sample.

°C) the onset and peak temperatures of the DSC dehydration endotherm (see Figure 4a) possibly by reducing the particle size and changing the surface feature of the crystals.[17] A parallel increase in the enthalpy change of the small endothermal effect at ≈136 °C was evident. This effect was attributable to melting of the anhydrous crystal form A of picotamide (see later).

A thermal behavior similar to that depicted in Figures 4a and 5a was recorded for PICOW samples recrystallized from water, methanol, ethanol, and *n*-propanol.[3] Different DSC and TGA profiles in both the dehydration and post-dehydration stages were instead observed for PICOW recrystallized from ethyl acetate (Figures 4b and 5b) and from benzene (Figures 4d and 5d). The distinct crystal-

Key: (a) PICOW from water–ethanol 8:1 (v/v), intact sample; (b) PICOW from ethyl acetate, intact sample; (c) PICOW from ethyl acetate, ground sample; (d) PICOW from benzene, intact sample; (e) PICOA by isothermal dehydration (115 °C, 20 mmHg) of (a); (f) PICOW by rehydration of PICOA in an ambient atmosphere (RH ≈ 45%), intact sample; (g) PICOW by rehydration of PICOA at RH ≈ 45%, ground sample.

lization of the lower-melting crystal form A (mp 135.5 ± 0.4 °C, fusion enthalpy 62 ± 10 J g^{-1}; $n = 8$) and the higher-melting crystal form B (mp 152.9 ± 0.3 °C, fusion enthalpy 14 ± 3 J g^{-1}; $n = 8$) of anydrous picotamide can be seen by the small exothermal effects at 115 °C and 138 °C in the sample recrystallized from benzene (Figure 4d).

The sequence of thermal events in Figure 4d was confirmed by HSM. Upon heating at 10 K min^{-1} from 25 to 100 °C and then reducing the heating rate to 5 K min^{-1} on a microscope stage, water evolution started at 110 °C and the newly formed small prismatic crystals melted at 136 °C. Upon further heating very few needle crystals were formed, which then melted at 153 °C.

XRD patterns of all recrystallized picotamide samples matched the theoretical XRD pattern of the monohydrate,[2,3] indicating that no difference existed in the fundamental

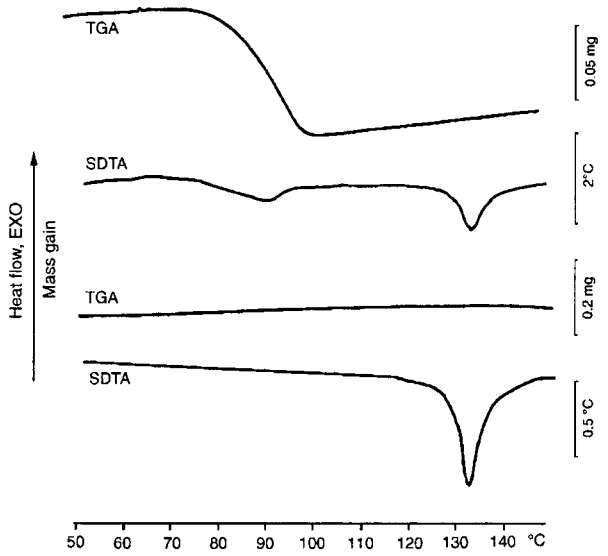

Figure 6—Simultaneous TGA-DSC curves over the 50–150 °C temperature range of picotamide monohydrate (PICOW) from water–ethanol 8:1 (v/v) (upper curves) and anhydrous picotamide (PICOA) (lower curves).

crystal lattice of the PICOW samples examined.[18] IR spectra also show that these samples were structurally identical. Therefore, the biphasic DSC dehydration profile recorded for the intact sample from ethyl acetate (Figure 4b) and reflected by the dTGA curve (Figure 5b) can be attributed to different crystal size and shape or various degrees of "perfection" of a common lattice structure of the tested samples.[19,20] Implications of the morphology of a pharmaceutical solid on the bulk properties of the material have been reported for furosemide,[21] nitrofurantoin,[22] and diclofenac/*N*-(2-hydroxyethyl)pyrrolidine salt.[23] Surface characteristics, adsorbed or occluded impurities and crystal defects which prevent the perfect alignment of molecules in the crystal lattice as well as nuclei of anhydrous polymorphs formed, may also affect the kinetics of solid-state transitions,[23] in particular dehydration. Actually, a highly strained or stressed lattice structure loses water more easily than a regular one. Cluster aggregation of PICOW crystals grown in ethyl acetate solution may also be responsible for the observed thermal behavior. Samples from ethyl acetate, which had been gently ground to ensure homogeneity of the polycrystalline material with no apparent alteration of the XRD pattern of the intact samples, showed indeed a monophasic dehydration pattern in both DSC (Figure 4c) and dTGA (Figure 5c) curves.

As can be seen in Figures 4e and 5e, the product of isothermal dehydration at 115 °C and 20 mmHg of PICOW from water−ethanol 8:1 (v/v) was almost totally composed of the lower-melting crystal form A, with enthalpy of fusion 74.4 ± 2.2 J g^{-1} ($n = 7$). Simultaneous TGA/DSC confirmed that no mass loss was associated with the endothermal effect at ≈136 °C (Figure 6). By storing at a RH of 45% or ≈100% and room temperature (22 °C), PICOA transformed to PICOW, as confirmed by DSC, TGA, and IR spectroscopy. Transformation to monohydrate was rather fast (within 48 h) at ≈100% RH and rather slow (within 3 months) at 45% RH. PICOW samples obtained by rehydration of PICOA in an ambient atmosphere (RH ≈ 45%) show biphasic dehydration patterns similar to those recorded for intact PICOW samples recrystallized from ethyl acetate (see Figures 4b and 5b). The couple of DSC endotherms centered at 91 °C (dehydration enthalpy 56.2 J g^{-1}) and 122 °C (dehydration enthalpy 60.4 J g^{-1}) in Figure 4f was reflected by a two-step TGA mass loss of 1.9% (w/w) and 2.5% (w/w) in Figure 5f. Thermal analysis of gently ground samples of rehydrated PICOA showed that

the split DSC endotherms and dTGA peaks gathered in a single thermal effect with an associated enthalpy change (121.5 J g^{-1}) and mass loss (4.9% (w/w)) nearly equal to the sum of those of the single effects (Figures 4g and 5g). The monophasic dehydration pattern of ground samples, which show the same XRD pattern (i.e., structural arrangement) as the intact ones, confirms that external factors such as morphology, surface characteristics, cluster aggregation, etc., are responsible for the observed thermal behavior.

Solubility and Dissolution Properties of the Solid Phases—The equilibrium solubilities of PICOW and PICOA in water as a function of temperature are given in Table 2. The solubility of the stable hydrated form was calculated from the plateau value of dissolved concentration at each temperature. The maximum concentrations of dissolved PICOA at each temperature also gave plateau values, which were maintained for about 1 h (at 45 °C) to about 4 h (at 20 °C) before declining toward the corresponding equilibrium solubility values of PICOW due to phase transition. A crystalline anhydrous to hydrate phase change has been reported for theophylline, which is rapidly transformed to monohydrate in contact with water where simultaneous dissolution and hydrate formation occurs.[24,25] At 45 °C the solubility level of PICOW (i.e., complete transformation of the metastable phase, as confirmed by DSC and IR analysis of the residual solid material) was reached in >4 h. This behavior suggested that the maximum dissolved concentration of PICOA can be assumed as its equilibrium solubility.[26] The metastable to stable solubility ratios of 1.1−1.8 over the range of temperatures tested (Table 2) were typical of anhydrous−hydrate drug systems[27] and confirmed this hypothesis. By plotting the solubility data according to the van't Hoff equation,[26] a good linearity was observed (Figure 7). The least squares linear regression gave a slope of $(-4.90 \pm 0.16) \times 10^3$, an intercept of 21.2 ± 0.5 and a coefficient of determination of 0.997 for the stable PICOW form, and a slope of $(-3.0 \pm 0.2) \times 10^3$, an intercept of 15.4 ± 0.6 and a coefficient of determination of 0.988 for the metastable PICOA form. The transition temperature at which PICOW and PICOA have equal solubilities, free energies, and stabilities was 50 ± 6 °C.

Table 3—Dissolution Efficiency (DE),[a] Percent of Active Ingredient Dissolved (DP),[b] and Intrinsic Dissolution Rate Constants (IDR)[c] of Picotamide Monohydrate (PICOW) from Water–Ethanol 8:1 (v/v) and Anhydrous Picotamide (PICOA) in Water at 37 °C (standard deviations in parentheses refer to last decimal digit).[d]

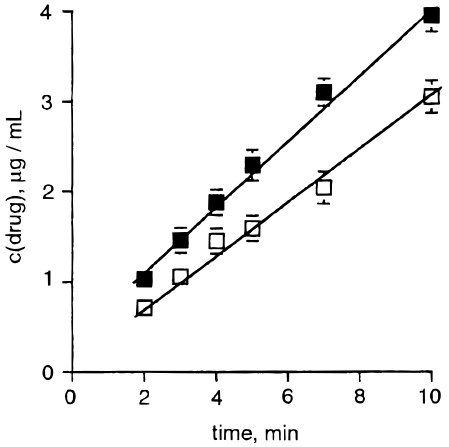

Figure 9—Intrinsic dissolution rates in water at 37 °C of picotamide monohydrate (PICOW) from water-ethanol 8:1 (v/v) (□) and anhydrous picotamide (PICOA) (■). Error bars indicate standard deviation ($n = 4$).

times, in accordance with the solubility data (Table 3 and Figure 8). The metastable to stable dissolution efficiency ratios and percent of drug dissolved ratios (≈1.3 at each time point) reflect to some extent the metastable to stable solubility ratio (1.24 at 37 °C). The higher thermodynamic activity and lower crystallinity (see Figure 2) of PICOA probably concur to its higher dissolution efficiency (by 28%) compared to PICOW. The dissolution rate data in water at 37 °C using nondisintegrating disks of PICOA or PICOW were in agreement with those obtained from powder samples (Table 3 and Figure 9). The metastable anhydrous form shows a better performance also in terms of intrinsic dissolution rate, which results higher than that of the stable hydrated form by 32%.

Conclusions

PICOW, the most stable picotamide form in water and organic solvent as well as under ambient atmosphere, is the raw material of choice for the preparation of commercial tablets (Plactidil). The dehydration of PICOW under open DSC and TGA conditions follows a monophasic or biphasic pattern, depending on the history of the sample (recrystallization solvent, rehydration conditions, intact or ground specimen, etc.). Morphological factors, various degrees of "perfection" of a common lattice structure, and/or cluster aggregation may be responsible for the distinct thermal behavior of the same hydrate phase and for the nature of the dehydration products (amorphous or polymorphic crystal forms A and B).

Total or partial dehydration of PICOW can occur in pharmaceutical processes where aqueous wetting and drying are involved. The subsequent in situ rehydration of PICOA, which depends on numerous factors (temperature, water vapor pressure, excipients in the formulation, etc.), is also possible. The careful characterization of the solid state is necessary so that the behavior of the material can be predictable and reproducible.

PICOA, the metastable picotamide anhydrous form, due to its physical stability in an ambient atmosphere and compatibility with pharmaceutical excipients, could be a promising modification to improve the dissolution rate of the active principle in solid dosage forms because of its higher solubility reached in water before recrystallizing to the less soluble hydrate. A study of possible implications on bioavailability will be the subject of future work.

Accepted for publication September 9, 1999.

Abstract □ In this work a new approach for in situ interactions between drug and electrolyte(s) is devised to control the release of highly water soluble drugs from oral hydrophilic monolithic systems. The model drug diltiazem hydrochloride (water solubility in excess of 50% at 25 °C), in conjunction with specific electrolytes, was principally employed in the design of swellable tablet formulations comprised of hydrophilic polymers such as hydroxypropylmethlcellulose (HPMC) or poly(ethylene oxide) (PEO). Electrolytes such as sodium bicarbonate or pentasodium tripolyphosphate were used to modulate intragel pH dynamics, swelling kinetics, and gel properties. Through in situ ionic interactions (an intragel matrix system composed of different chemical species that promote competition for water of hydration), a compositionally heterogeneous structure referred to as a "metamorphic scaffold" was established. It is shown that this latter structure results in the inhibition of drug dissolution, induction of a differential swelling rate, and attainment of "matrix stiffening" and axially provides a uniform gel layer. Presence of such phases in matrix structure and its influence on swelling dynamics enabled control of diltiazem hydrochloride release in a zero-order manner in different pH environments over a 24-h period. From kinetic analysis using the power law expressions [$M_t/M_\infty = k_1 t^n$, $M_t/M_\infty = k_1 t^n + k_2 t^{2n}$] and Hopfenberg model [$M_t/M_\infty = 1 - (1 - k_1 t)^n$], it became apparent that the dynamics of matrix relaxation and controlled erosion were major factors involved in the release mechanism, while the composite rate constant k_1 (in Hopfenberg model) decreased by approximately 2-fold in the presence of electrolyte(s). These findings indicated that the dynamics of swelling and gel formation in the presence of ionizable species within hydrophilic matrices provide an attractive alternative for zero-order drug delivery from a simple monolithic system.

Introduction

Controlled release drug delivery systems have received much attention in the past two decades with numerous technologically sophisticated products on the marketplace. Such advancements have come about by the simultaneous convergence of many factors, including the discovery of novel polymers, formulation optimization, better understanding of physiological and pathological constraints, prohibitive cost of developing new drug entities, and the introduction of biopharmaceutics in drug product design. The major benefits of these products lie in the optimization of drug input rate into the systemic circulation in order to achieve an appropriate pharmacodynamic response. This in turn should add to product safety and reduce the extent and incidence of major adverse drug reactions due to a more strict control of blood levels. Furthermore, with less frequent dosing, it is speculated that this should improve patient compliance and possibly maximize drug product efficacy in therapeutics.

Recently numerous hydrophilic polymers have been investigated and are currently used in the design of complex controlled release systems.[1−4] In many cases the formulator depends on the inherent rate-controlling mechanisms of the polymer to provide constant rate drug delivery. Among desirable features, the polymer should possess inherent physicochemical characteristics which provide for the attainment of high gel-state viscosity upon swelling, ability to maintain constant gel layer integrity over a prolonged period of time and hence low erosion rate, and complete dissolution of polymer upon exhaustion of drug release. Alternatively, a programmed system is sought for which swelling and erosion are the key factors in controlling drug liberation. The ideal polymer would permit these processes to operate synchronously, i.e., affording a balance between the principal processes of swelling, erosion, and dissolution. Among the most widely used polymers, such as the nonionic hydroxypropylmethylcellulose (HPMC), hydroxypropylcellulose (HPC), poly(ethylene oxide) (PEO) types, the cationic chitosan types, and anionic alginate types, the attainment of high gel-state viscosity, maintenance of constant gel layer, or synchronous erosion−dissolution in a monolithic sense for linear drug release over a prolonged period of time is not easily achievable and still remains a challenge. Since the various dynamic phases in the rate processes of polymer relaxation, disentanglement, and/or erosion during dissolution are manifested in a nonconstant manner, realization of zero-order drug release from such monolithic devices is difficult.

This limitation of hydrophilic polymers may be circumvented through modification of the physical and chemical infrastructure of the polymeric gel system. In the present work a reliable process has been established for inducing in situ reactions between pharmaceutically acceptable electrolytes/acids and drug which influences the intragel swelling dynamics and relative physical integrity of the swollen matrix structure. Furthermore, this may produce heterogeneous domains within the swollen gel boundary referred to as "metamorphic scaffold" in this work (see Figure 1).

In the past, alkaline compounds or buffers have been included in solid oral formulations of several acidic drugs that undergo dissolution rate-limited absorption.[5−11] The same principle of addition of buffers, osmotically active agents, surfactants, or combinations thereof has also been utilized to control the swelling of hydrophilic polymers with different coating and inclusion techniques.[12] However, no specific strategy has been employed to apply the same principle to design a simple, directly compressible, monolithic, controlled-release system with provision of zero-order kinetics. In general, the application of buffers and ionizable

compounds in dosage form design has essentially been limited to the minimization of localized gastrointestinal tract adverse effects and the pH-solubility dependency of poorly soluble compounds.[5,6,13,14]

The aim of this work was to provide and expand on a means to design, formulate, and develop a novel oral monolithic, controlled-release tablet dosage form for drugs of various solubility that may be tailored to provide zero-order or quasi-steady-state drug release over a 24-h period.[15] The model drug employed in this work was diltiazem hydrochloride, which has a water solubility in excess of 50% at 25 °C. The rationale behind the mechanisms and dynamics of electrolyte-induced matrix stiffening and modulation of intragel pH changes for the provision of controlled drug release will be elucidated.

Experimental Section

Materials—Hydroxypropylmethylcellulose (HPMC K4M, Dow Chemical Company, Midland, MI) and poly(ethylene oxide) (PEO 4 million molecular weight, Union Carbide, CT) were employed in tablet production. Diltiazem hydrochloride (Seloc AG, Switzerland) was use as a model compound. The following electrolytes/acids used were of analytical grade: sodium bicarbonate (Ruger Chemical Co., NJ), potassium bicarbonate, magnesium carbonate (Fischer Scientific Co., NJ), calcium carbonate (E.M. Science, NJ), dibasic sodium phosphate as the 12-hydrate crystal (J. T. Baker Inc., NJ), sodium carbonate, pentasodium tripolyphosphate, sodium deoxycholate from parent 7-deoxycholic acid, maleic acid, adipic acid, and L-(+)-tartaric acid (Sigma Chemical Co., St. Louis, MO).

Methods—*Preparation of Tablets*—A typical monolithic formulation consisted of polymer, drug, and electrolyte. The ratio of drug:polymer was always maintained at the 1:2 level (i.e., 100 mg:200 mg), while the electrolyte content was varied. For example, a single tablet would be composed of 200 mg of HPMC K4M or PEO 4M, 0−100 mg of electrolyte, and 100 mg of drug. Pure and drug-loaded compacts of polymer were used as control indicators. The powder mixture was blended in a V-blender for 15 min prior to compression at 4000 lbs in an 11.5 mm diameter die using the Carver Press (Model C, Fred S. Carver, IN) and flat-faced punch. To minimize processing variables, all tablets were produced under identical conditions.

Drug Release and Matrix Erosion Studies—Dissolution studies on each formulation were performed in a calibrated six station dissolution test apparatus (VK 7000, Vankel Industries Inc., Edison, NJ) using the USP 23 Apparatus 2 in USP-recommended buffers (pH 1.5, 2.6, 4.1, 5.4, 6, 6.4, 6.8; 900 mL, 37 ± 0.5 °C, 50 rpm). All studies were conducted in triplicate ($N = 3$) using an automated sampling procedure. Drug release was analyzed by ultraviolet spectroscopy (HP Diode Array) at 238 nm.

The erosion properties for the above-described HPMC and PEO tablets were studied in pH 1.5 using Apparatus 2 in order to simulate actual dissolution conditions. At predetermined time intervals, tablets were removed, dried to constant weight under vacuum at 40 °C, and thereafter weighed.

Diltiazem Free Base Formation—Diltiazem hydrochloride (1.5 g) was solubilized in deionized water (10 mL) and transferred to a separatory flask. This solution was alkalinized with sodium bicarbonate (0.5 g) to precipitate the drug as the free base. The free base was extracted with ether (20 mL) and recrystallized on a rotavap (Rotavapo-R, Buchi) at 35 °C over a period of 30 min. The solvent residue was completely removed by drying under vacuum over a further 30-min period through an acetone−dry ice reservoir maintained at −178 °C.

Intragel pH Measurements—Transitions in the intragel pH (i.e., within the tablet gel matrix) were monitored with aid of a flat surface polymer combination electrode having a 5 mm contact area (Accumet, Fischer Scientific). The electrode, attached to a pH meter (Accumet pH meter 25, Fischer Scientific), was used for pH measurements of gel at the periphery and within the swollen matrix in both the axial and radial planes at predetermined time intervals on tablet formulations exposed to dissolution medium pH 1.5. Various inwardly depths were exposed for pH measurements by excisions with a scalpel. Furthermore, a continuous pH measurement of the external matrix interface was performed by having the perforated guard and the flat surface of the pH electrode in constant contact with the tablet during a dissolution study in buffer medium pH 1.5. pH titration methods were also adopted on plain HPMC solutions with and without drug to evaluate the influence of electrolyte content on concurrent pH changes and interaction with drug.

Sample Treatment and Force−Displacement Profiling by Textural Analysis—Textural analysis was performed on different tablet formulations in order to determine the electrolyte-related effects on structural alteration of the gelled scaffold and swelling dynamics. One planar base as well as the entire lateral surface of each tablet was sealed off with an organic coating consisting of 20 g of Eudragit PO in a mixture of 50 mL of acetone and 50 mL of 2-propranol. This coating rendered these surfaces impermeable to penetration by buffer medium. These steps ensured (i) prevention of interfacial deformation of core/gel structure during probe advancement, and (ii) confinement of swelling in the axial direction. When radial measurements were undertaken, both planar surfaces of the tablet were coated. Triplicate samples were then placed in dissolution vessels containing 900 mL of buffer medium pH 1.5 at 37 °C during separate tests. The paddle speed was set at 50 rpm to simulate the actual tablet dissolution process. At

predetermined time intervals individual tablets were removed and subjected to textural analysis in a similar manner described in recently published work.[16]

In summary, the Texture Analyzer instrument (TA XT2*i*, Stable Micro Systems, England) which has the ability to capture stress–strain profiles with a high degree of accuracy was used. Data were captured at a rate of 200 pps via the Texture Expert for Windows software, Version 1.20. A flat-tipped steel probe, 2 mm in diameter, was connected to a force transducer within the analyzer that measured the force of resistance encountered by the probe during advancement into the sample. During a typical test, the probe was advanced at a predetermined velocity into the sample in accordance with the following parameters: Pretest speed = 1 mm/s, test speed and post-test speeds = 0.2 mm/s, maximum compression force = 40 N, and an auto trigger using 0.5*g* as the trigger force.

Furthermore, the influence of stepwise pH changes on matrix structure was also evaluated in Apparatus 2 by periodically moving the tablets into different pH environments (i.e., pH 1.5, 3, 5.4, 6, 6.4, 6.8) and then evaluating their textural properties.

Data Treatment for Analysis of Release Kinetics and Deconvolution of Texture Profiles—To precisely determine the nature of release mechanism in the presence and absence of electrolyte, application of kinetic modeling for analysis of release profiles is necessary. Such analysis was performed on formulations comprised of HPMC K4M in the absence and presence of 100 mg of sodium bicarbonate. The kinetics of drug release (buffer medium pH 1.5) were analyzed using WinNonlin, Version 1.0 (SCI Software). In all least squares analyses, the Gaussian-Newton (Levenberg–Hartley) approach was adopted. The power law expression (eq 1) and its geometry-independent form (eq 2) were considered for data analysis.[17–20] In addition, the Hopfenberg model, a geometry-dependent equation (eq 3), was also employed for determination of release kinetics[21] (see below).

With reference to textural analysis, the predetermined maximum compression force of 40 N was established over a series of tests, such that after deconvolution of raw data, based on computed gradient changes within the matrix, distinct matrix phase transitions could be identified. By running Texture Expert macros, triplicate data from each experimental formulation was used in the calculation of time-related parameters associated with the diffusion layer, peripheral gel phase, swollen infiltrated gel phase, and glassy swelling fronts. These include changes in force, phase thickness, swelling gradients in axial and radial planes (determined from up-curving force–displacement changes), and associated resistance to probe penetration. The rationale behind the establishment of the above-mentioned phases will be discussed.

Results and Discussion

Drug Release Potential as a Function of Electrolyte Content and Release Kinetics—By incorporation of sodium bicarbonate into hydrophilic monolithic tablet matrices, it was possible to progressively reduce the release rate of diltiazem hydrochloride (water solubility in excess of 50% at 25 °C) over a 24-h period. Distinct evidence of this phenomenon is provided with application of a typical nonionic hydrophilic polymeric material such as poly(ethylene oxide), 4 million molecular weight (PEO 4M) (Figure 2a). With an increase in electrolyte concentrations (from 0 to 100 mg), the release rate of diltiazem hydrochloride tended to slow, indicating greater inhibition in release in comparison to the control formulation (i.e., in the absence of electrolyte). This electrolyte-induced, controlled release phenomenon was also observed with other polymeric materials such as HPMC, chitosan, and sodium alginate. To further illustrate the utility of the electrolyte effect typical release profiles for HPMC K4M-based matrix and diltiazem hydrochloride is provided (Figure 2b). The distinctive feature in the case of HPMC formulations is that an increase in the linearity of the release profiles was evident as the electrolyte content increased from 10 mg to 100 mg, with corresponding correlation coefficients of 0.7499 to 0.9836 (Figure 2b). Based upon this latter

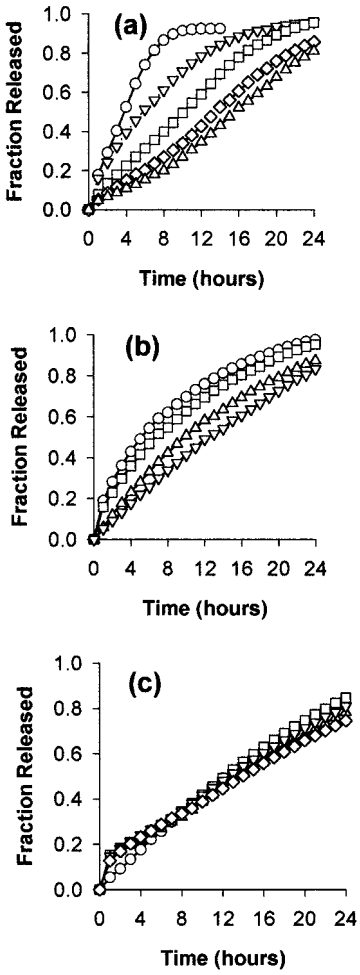

Figure 2—(a) Release of diltiazem hydrochloride from PEO 4 million formulations containing different quantities of sodium bicarbonate in buffer medium pH 1.5: 0 mg (○), 10 mg (▽), 50 mg (□), 75 mg (◇), 100 mg (△). (b) Release of diltiazem hydrochloride from HPMC K4M formulations containing different quantities of sodium bicarbonate in buffer medium pH 1.5: 0 mg (○), 10 mg (□), 50 mg (△), 100 mg (▽). (c) Influence of different bulk pH media on the release of diltiazem hydrochloride (100 mg) from formulation containing 100 mg of sodium bicarbonate: pH 1.5 (○), pH 5.4 (□), pH 6 (△), pH 6.4 (▽), pH 6.8 (◇).

observation, all other testing procedures were conducted on the HPMC-based matrices. In addition, HPMC has good compactibility behavior and is widely used within the pharmaceutical industry. Under the given experimental conditions, the formulation containing 100 mg of sodium bicarbonate was considered optimal. On exposure of this electrolyte-containing HPMC formulation to different pH environments, a minimal burst effect (<10% of total dose) and linear drug release for up to 24 h was achieved (see Figure 2c). It is apparent that the delivery system has potential to function in a relatively pH-independent manner and is able to control the release of a highly soluble drug such as diltiazem hydrochloride (solubility >50% in water at 25 °C).

As an initial test to confirm that the process of electrolyte inclusion within the swelling matrix was not purely a catalyst for free base formation but was also involved in fundamental structural changes in gel boundary, the hydrochloride form of diltiazem was converted into its free base and incorporated into a HPMC-based tablet dosage form in the presence of acidic and basic electrolytes and thereafter evaluated its drug release potential in pH 1.5 and 6.8 buffer media (Figure 3a,b). As expected from pH-solubility theory, the free base displayed a higher solubility

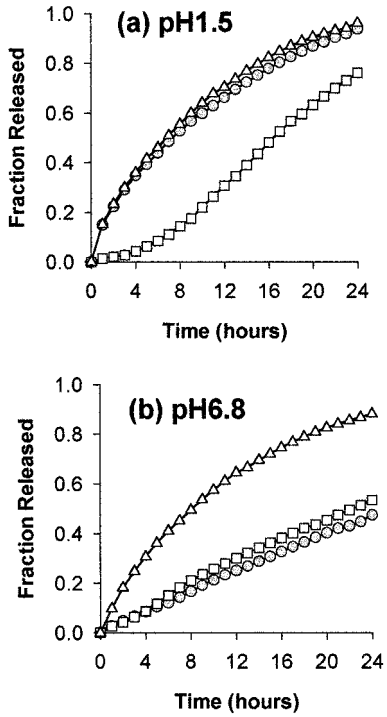

Figure 3—(a) Release of diltiazem free base in pH 1.5 from HPMC-based control (i.e., no electrolyte) and formulations containing sodium bicarbonate (100 mg) or tartaric acid (100 mg): control (gray ○), sodium bicarbonate (□), tartaric acid (△). (b) Release of diltiazem free base in pH 6.8 from control (i.e., no electrolyte) and formulations containing sodium bicarbonate (100 mg) or tartaric acid (100 mg): control (gray ○), sodium bicarbonate (□), tartaric acid (△).

in strongly acidic media (Figure 3a) as opposed to higher pH or weakly acidic media (Figure 3b). However, the overall release profile in this case was significantly different from that of the hydrochloride form shown in Figure 2c. The incorporation of tartaric acid in the free base-containing formulation did not alter drug release in acidic environment such as pH 1.5 (Figure 3a), but release was enhanced at higher pH values such as pH 6.8 (Figure 3b). It appears that the presence of sodium bicarbonate was crucial in controlling the release process (see Figure 3a). Even though the profiles for free base and free base mixed with sodium bicarbonate are comparable in pH 6.8, the extent of release is not acceptable (only 45−50% of drug is released in 24 h, Figure 3b). Therefore it is postulated that the incorporation of electrolyte into the tablet might essentially inhibit the dissolution of diltiazem hydrochloride through intragel pH-control and subsequent induction of textural variations in the swollen matrix. On substitution of sodium bicarbonate by other electrolyte types (e.g., sodium carbonate, calcium carbonate, magnesium carbonate, potassium bicarbonate, pentasodium tripolyphosphate, sodium phosphate (dibasic), or sodium deoxycholate), it appears that electrolyte solubility and formation of a buffer threshold within the matrix plays an essential role in effective interaction with drug and textural changes as shown in Figure 4 and Table 1 (based on extent of constant drug release and corresponding correlation coefficients).

Detailed consideration will be given to the rationale of these postulated mechanisms in following sections.

In general, drug release from simple swellable systems may be described by the power law expression:[17]

$$M_t/M_\infty = k_1 t^n \qquad (1)$$

where M_t and M_∞ are the amounts of drug released at time

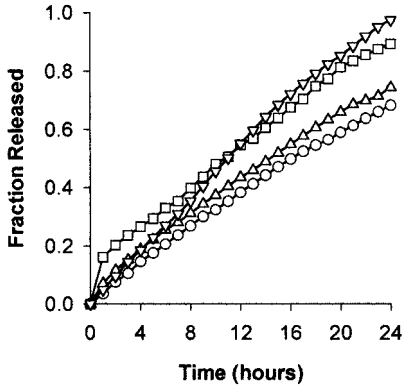

Figure 4—The influence of different electrolytes (100 mg) on the release of diltiazem hydrochloride–HPMC matrices in buffer media pH 1.5 using magnesium carbonate (○), potassium bicarbonate (▽), pentasodium tripolyphosphate (□), sodium carbonate (△).

t and the overall amount released respectively, k_1 is a release constant, and n is a release exponent indicative of the release mechanism. Classically, $n = 0.5$, $0.5 < n < 1$, or $n = 1$ for a slab, is indicative of Fickian release, anomalous transport, or Case II transport kinetics, respectively. However, the n values may change with the matrix geometry. Particularly in the case of a cylinder (as considered in this work), zero-order release is indicated by an n-value of 0.89, instead of 1.

Irrespective of dosage form geometry, various authors[18−20] have reported on the evaluation of contributions provided by Fickian diffusion and matrix relaxation/dissolution through the use of the following equation:

$$M_t/M_\infty = k_1 t^n + k_2 t^{2n} \qquad (2)$$

where k_1 is the Fickian kinetic constant and k_2 is the relaxational/erosion rate constant.

Additionally, release from systems with surface erosion and varying geometries also have been analyzed by Hopfenberg,[21] where a model applicable to a slab, cylinder, or sphere showing heterogeneous erosion is proposed (eq 3):

$$M_t/M_\infty = 1 - (1 - k_1 t)^n \qquad (3)$$

In this equation, k_1 is equal to $k_0/C_0 r_0$, k_0 is the erosion rate constant, C_0 is the uniform initial concentration of drug in the matrix, and r_0 is the initial radius for a sphere or cylinder or the half-thickness for a slab. In eq 3 the n values are as follows: $n = 1$ for a slab, $n = 2$ for a cylinder, and $n = 3$ for a sphere. The model assumes that time-dependent diffusional resistances internal or external to the eroding matrix do not influence the release kinetics. Furthermore, the contribution of the secondary surfaces to the release process is not considered, as discussed by Katzhendler and co-workers.[22]

From model fitting, it was observed that the simple power law expression (eq 1) provided an n-value of 0.837 for the electrolyte-containing formulation, confirming the closeness to attainment of ideal zero order drug release. The control formulation (i.e., without electrolyte) produced an n-value of 0.466, indicating a Fickian release mechanism. However, on the basis of the application of the geometry-independent expression (eq 2), it becomes apparent that through separation of the release constant into Fickian and relaxational components, matrix relaxation is predominant both in the presence and absence of electrolytes (without electrolyte $k_1 = 1.8 \times 10^{-5}$, $k_2 = 0.232$; with electrolyte $k_1 = 1.2 \times 10^{-5}$, $k_2 = 0.059$). Using an n-value of 2 in the Hopfenberg model (eq 3) produces a k_1 of 0.045

Table 1—Physicochemical Properties and Influence of Various Electrolytes on Drug Release

[a] Source of solubility data and pK_a values are shown as superscripts. All data reported at 25 °C except for sodium deoxycholate (15 °C), tartaric acid (20 °C), and adipic acid (20 °C). Due to the practically insoluble nature of calcium carbonate and magnesium carbonate in water, the solubility products (K_{sp}) are reported at 25 °C. [b] Measured using approach described in Methods section ($N = 3$, SD < 0.1). [c] Each of maleic acid and tartaric acid were used in combination with sodium carbonate to develop a system with pH-independent release. [d] The phase at which constant release is initiated is in part also an indication of the degree of reactivity of the electrolyte within the matrix and reflects an existence of a pH threshold value for the attainment of constant release. [e] Intercept set to zero.

in the absence of electrolyte while 0.024 in the presence of electrolyte. As k_1 incorporates the erosion rate constant k_0, it is evident that through drug–electrolyte interaction and related mechanisms of textural stiffening, the electrolyte-containing formulation experiences a 2-fold reduction in matrix erosion. On the basis of erosion studies (data not provided here), it became apparent that control formulations (i.e., without electrolyte) demonstrated a linear decrease in matrix weight. In this case 49.19% and 96.27% weight reduction was observed after 16 h for HPMC and PEO, respectively. However, in the case of the electrolyte-containing formulations, matrix weight reduction followed square root of time kinetics with 67.04% and 61.93% weight reduction observed at equivalent time (16 h) for both HPMC and PEO.

Determination of Intragel pH Changes in Swellable Matrices and Drug–Polymer Solutions—Specific physicochemical data extracted from the literature and experimentally determined values with respect to solubility, acid–base dissociation, solution pH, and intragel pH-control by the above-mentioned electrolytes and some acids to be evaluated are presented in Table 1.

pH measurements in the axial and radial planes were performed on swollen tablet formulations with and without sodium bicarbonate. Typically from axial plane pH measurements on control formulations (i.e., without sodium bicarbonate) at different depths, it became evident that the internal matrix essentially maintained a pH value that was the same as that of the surrounding dissolution medium (pH ≈ 1.5). This may be regarded as the baseline pH as shown in Figure 5a (broken line). On the other hand, the formulation containing sodium bicarbonate had the ability to maintain a relatively constant pH level >8 within the swollen matrix at similar depths to that of the control (Figure 5a). In the axial plane, the pH tended to stabilize at a depth of 5 mm. The constant pH value seen in the case of control on the gel surface interface in contact with the flat end of the pH electrode may be attributed to the predominance of the dissolution medium at this interface. Diltiazem hydrochloride has been reported to possess pH-independent solubility when studied with respect to buffer solutions.[27] In addition, when the solubility study was undertaken in our lab using USP-recommended buffers in the range from pH 1.5–10, no significant differences in drug solubility were observed. This may be due to the fact that the ionic strength of the electrolytes in the buffer systems has not reached the required threshold to induce marked changes in diltiazem hydrochloride solubility. Such levels of ionic strength might be achievable within a restricted gel structure. Hence, the ionic strength achieved with sodium bicarbonate within the swollen matrix tablet might be sufficiently high to produce this intragel pH effect on drug solubility.

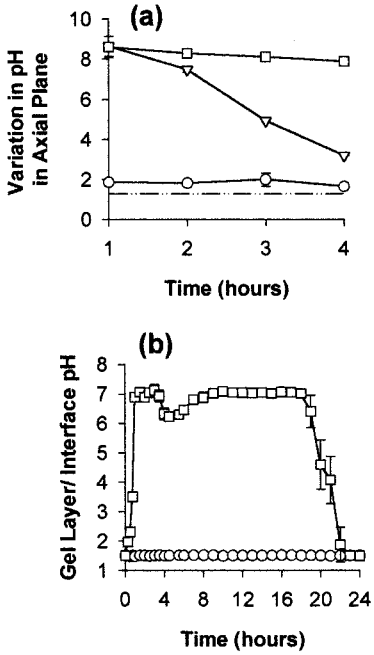

Figure 5—(a) Relationship between time and pH variation obtained by examination of swollen HPMC matrixes with and without sodium bicarbonate (100 mg), after exposure to buffer medium pH 1.5 for different time periods: Axial depth measurements: 0 mm, i.e., surface (○), 2 mm (▽), 5 mm (□). (b) Illustration of time–pH profile for diltiazem hydrochloride–HPMC K4M tablet formulations without (○) and with (□) sodium bicarbonate (100 mg) attached to the pH electrode during a typical dissolution study in buffer medium pH 1.5.

From the investigation on simultaneous transitions in intragel pH and drug release (i.e., tablet attached to electrode), it was found that approximately after 1 h, a maximum surface/gel layer pH of ≈7 was attained in the formulation containing sodium bicarbonate, as opposed to the control tablet formulation which essentially maintained a pH value equivalent to the dissolution medium (Figure 5b). This constant intragel pH was maintained for up to ≈20 h, upon which a rapid decrease in pH was noted possibly due to the exhaustion of sodium bicarbonate and dominance of the penetrated dissolution medium to the matrix core.

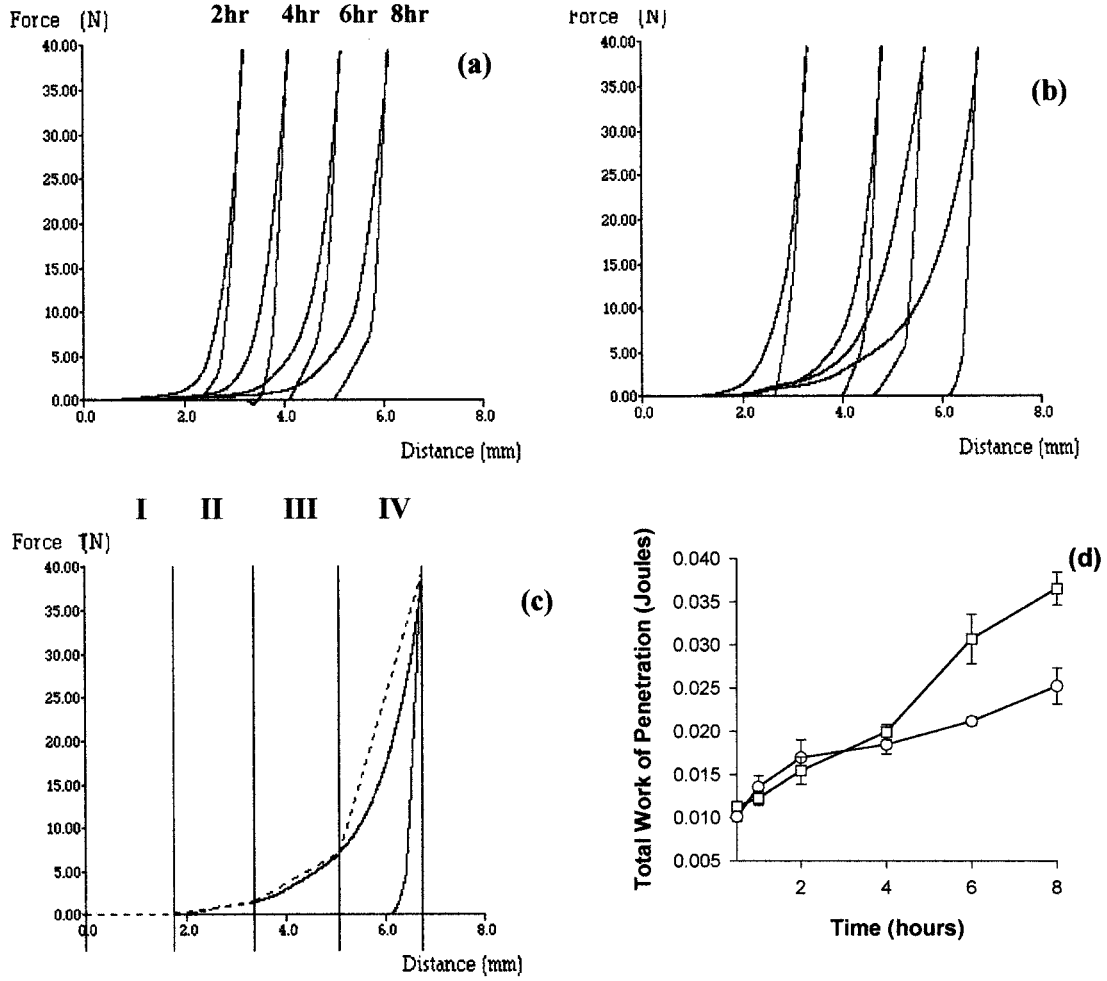

Figure 6—(a) Force–displacement (F–D) profiles for drug-loaded, control HPMC K4M compacts exposed for different time periods to buffer medium pH 1.5. (b) Similar profiles for electrolyte-containing formulation. (c) Details of typical F-D profile for electrolyte containing formulation after 8 h of exposure to buffer medium pH 1.5: (I) water-saturated diffusion front; (II) peripheral gel layer; (III) swollen infiltrated layer; and (IV) glassy swelling front. (d) Profiles depicting compositional heterogeneity within the polymer matrix as manifested through total work of probe penetration.

Through pH-titration studies in the presence and absence of drug-loaded polymeric solutions, it was established that drug−electrolyte interaction is effectively initiated at pH ≈ 6.4. This phenomenon may be used to develop a rationale on which constant release of diltiazem hydrochloride from the swollen gel system might be attainable. Table 1 effectively demonstrates that all electrolytes used in this study are able to maintain a basic pH in solution. However, this does not exclusively apply within the polymeric gel system (i.e., variable water availability), as some electrolytes appear to have a poor buffer threshold when confronted by the acidic penetrant (buffer medium pH 1.5) and hence are unable to maintain basicity, e.g., calcium carbonate (practically water-insoluble, pH-drop from 9.561 to 5.674), sodium phosphate (pH-drop from 9.072 to 1.530), and sodium deoxycholate (pH-drop from 7.979 to 1.448). The other electrolytes such as sodium bicarbonate, sodium carbonate, magnesium carbonate (practically water-insoluble), potassium bicarbonate, and pentasodium tripolyphosphate are able to maintain an intragel pH in excess of ≈6.4, a threshold above which drug−electrolyte interaction is likely to occur. Through this intragel pH-control, significant drug−electrolyte interaction was anticipated, which may lead to variable textural properties in the gel structure and suppression of drug release. Knowing that the pK_a of diltiazem hydrochloride is 7.7,[28] the degree of ionization and hence solubility will be affected in this pH threshold. Such effects may also affect the degree of polymer relaxation and swelling leading to formation of the putative metamorphic scaffold (see Figure 1).

Evaluation of Gel Strength and Time-Dependent Phase Transitions—To measure any transitions in gel matrix structure and alteration in swelling behavior in the presence of electrolytes, textural analysis was undertaken. By application of the texture analyzer instrument, it was possible to obtain the compressive force−displacement profiles for monolithic tablets containing (i) HPMC and drug, and (ii) HPMC, drug, and interacting electrolyte (such as sodium bicarbonate).

Figure 6a illustrates typical force−displacement profiles for compacts comprised of HPMC and drug (e.g., controls) exposed to buffer medium (pH 1.5) up to an 8-h period. The common feature presented in these profiles is a sharp, smooth, up-curving region followed by a rapid decline associated with the probe retraction. The overall features of these profiles reflect the formation of a relatively uniform gel boundary in different stages of hydration. On inclusion of sodium bicarbonate (100 mg) within the matrix system and measuring the profile under identical conditions, there are systematic increases in swelling as well as up-curving force after the initial 2 h of the experiment. Values computed for the maximum increase in matrix swelling (using the control as reference) corresponding to 0.5, 1, 2, 4, 6, and 8 h of exposure to buffer media are typically represented by −4.79%, −25.99%, −4.55%, 6.11%, 5.55%, and 5.34% (negative % indicates the value by which

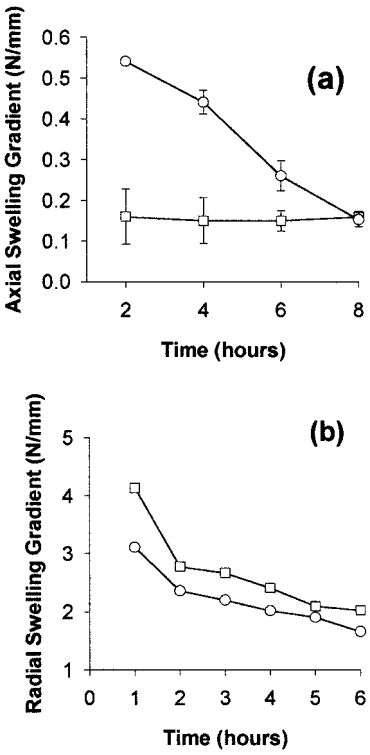

Figure 7—(a) Depiction of the attainment of constant average gradients of axial swelling for diltiazem hydrochloride–HPMC K4M formulations containing 100 mg of sodium bicarbonate (□) and control formulations, i.e., without electrolyte (○) in buffer medium pH 1.5. (b) Changes in the average gradients of radial swelling for HPMC-based formulations containing 100 mg of sodium bicarbonate (□) and control, i.e., without electrolyte (○) in buffer medium pH 1.5.

swelling of the electrolyte-containing formulation is lower than that of the control). In addition, the presence of increased resistance to probe penetration, as seen in the nonlinear rise in the initial stages of force–displacement in Figure 6b, reflects the more heterogeneous nature of the electrolyte-containing matrix. On the basis of the trend that was observed in force–displacement in both controls and in the presence of electrolyte, it was possible to identify and classify four distinct transition phases/regions (see Figure 1 and Figure 6c), namely:

- Phase I: Water saturated diffusion front;
- Phase II: Peripheral gel layer where initial interaction between sodium bicarbonate (or other electrolyte) and diltiazem hydrochloride is observed;
- Phase III: Swollen infiltrated layer where the electrolyte-induced effects are fully manifested; and
- Phase IV: Glassy swelling front.

The sharp increase in the total work associated with probe penetration (Figure 6d) in the case of the electrolyte-containing formulation is indicative of two phenomena, namely higher matrix swelling and greater resistance of the swollen structure to probe penetration, reflecting the heterogeneous structure induced through electrolyte interactions. This is contrasted by the uniform and linear trend in the work changes associated with the control formulation. Further work on this aspect is presently underway.

Differential Swelling Characterization of Matrices—As shown in Figure 7a, the constant peripheral gel phase observed to the depth of 1.5 mm through measurement of the axial gradient developed during matrix swelling of formulations containing sodium bicarbonate in buffer medium pH 1.5 essentially indicates the formation of a constant gel layer thickness, a phenomenon not seen in the absence of electrolyte.

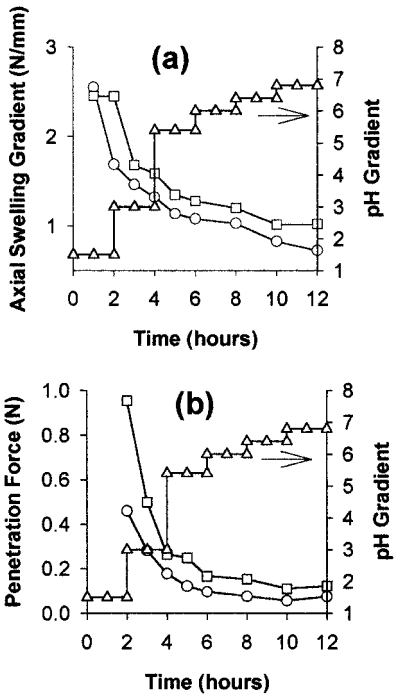

Figure 8—Influence of stepwise pH variation on (a) average gradients of axial swelling, and (b) penetration force in the axial plane for diltiazem hydrochloride–HPMC K4M formulations without (○) and with (□) 100 mg sodium bicarbonate. pH variation follows the order of 1.5, 3, 5.4, 6, 6.4, and 6.8 with both formulations being exposed for 2 h in each environment.

One of the important aspects revealed in this work is that the degree of swelling in the axial direction appears to be greater than that in the radial plane (i.e., for both controls and electrolyte-containing formulations). Apart from actual measurements, this was also apparent from the fact that the lower resistance to penetration in the axial plane (Figure 7a) as opposed to the radial plane (Figure 7b) is indicative of greater matrix infiltration and hence more swollen gel network in the axial plane. For example, from actual measurements on the electrolyte-containing formulation, it was shown that axial expansion occurred up to ≈5.75 mm in 6 h as opposed to ≈2.35 mm in the radial plane during the same time period. This swelling differential represents the nonuniform gel structure, and it is apparent that gel formation is relatively more rigid diametrically (Figure 7b).

Additional investigation conducted under different pH conditions demonstrated the sensitive nature of the electrolyte-containing gel matrix in terms of swelling gradients (determined from up-curving F–D profiles) and resistance to probe penetration (Figure 8a). From Figure 8a it can be seen that in spite of the lack of formation of a constant and uniform peripheral gel layer during stepwise pH changes, it may still be possible to attain constant drug release in these various pH environments (see Figure 2c). It has been postulated that attainment of zero-order drug release in these different pH environments may be attributed to associated textural changes in the swollen matrix, namely, an increase in the stiffness of the gelled structure induced through drug–electrolyte interactions as opposed to formulations without electrolyte (Figure 8b).

Release Modulation and Mechanisms—On the basis of the above data supporting electrolyte-induced compositional heterogeneity in intragel pH-control and proposed metamorphic scaffold structure, the following mechanisms may prevail during the period of drug release in a controlled, constant manner.

As the penetrant enters the periphery of the tablet, there is a rapid electrolyte–water interaction with significant

chemical reactivity through electrolyte solubilization and subsequent events that may lead to both initial suppression and later enhancement of polymer swelling. During this infiltration process, chemical species likely to be present within the gelled boundaries include sodium bicarbonate, sodium chloride formed via the interaction between the former electrolyte and hydrochloride species of the drug, ionized diltiazem, and possibly existence and formation of a free drug base. Diltiazem hydrochloride has a pK_a of 7.7,[28] and since the measured intragel pH is >7 but <pK_a, it is expected that drug species would not entirely exist in a precipitated base form. However, limited formation of the base form of drug may precipitate within the polymeric matrix and may result in hindrance of the relaxation process. Employing a modified concept of Schott,[29] the passive and actively formed electrolyte species within the gelled polymeric HPMC matrix would compete for water species at the outset and hence bind part of the water of the gelling polymer in order to become hydrated. This initial competition for water of hydration "dehydrates" the polymer molecules, leading to suppression of initial swelling, as seen up to 2 h where the formulation containing 100 mg of sodium bicarbonate is maximally inhibited in the range of ≈4−25% in overall swelling when compared to control tablet. However, once sufficient water has been attracted by electrolyte species into the polymer matrix the solubilized species will diffuse out, creating a capillary network for more water penetration after which an enhancement of swelling in comparison to controls is observed. Such possible alterations in physical polymeric configuration are manifested as a textural effect shown by the increased resistance to probe penetration resulting in "matrix stiffening" (see Figures 6d and 7b). The degree of matrix stiffening consistently decreases toward the center of the matrix core in a time-dependent manner over a long period (e.g., 24 h). Through these mechanisms and dynamics of intragel changes, it seems possible to inhibit drug dissolution and enhance polymer swelling to an extent, both of which would significantly contribute to achieving zero-order kinetics. This inhibition in dissolution may also be a time-dependent phenomenon, since as more penetrant enters the gel matrix layer-by-layer (i.e., sequentially), the electrolyte(s) content and their byproducts (such as sodium chloride) are diluted and any drug base may revert to its hydrochloride form and is subsequently released. An additional parameter that requires a more in-depth analysis is the influence of osmotic pressure and its impact on both swelling dynamics and diffusion mechanism.

Electrolyte Effects for Establishment of pH-Independent System—In an attempt to develop a pH-independent system, the sodium bicarbonate was replaced by sodium carbonate since it displays a less vigorous and delayed effervescent reaction in the presence of acidic electrolytes (Figure 9). Furthermore, to counteract the strong interaction between drug and sodium carbonate in higher pH environments, an opposing electrolyte was added to the system, namely maleic acid. Maleic acid essentially served to reduce the intragel pH at higher external pH conditions. PEO 4 million molecular weight was selected as the polymer for its ability to display greater free volume changes than HPMC, hence ensuring drug release in less acidic pH environments. Adipic and tartaric acids were also evaluated, but did not prove successful in providing comparable release in acidic and basic media. This may be due to the relatively lower and higher solubility of each acid within the gel system (see Table 1) and the dynamic structural changes during polymer infiltration and associated swelling conditions.

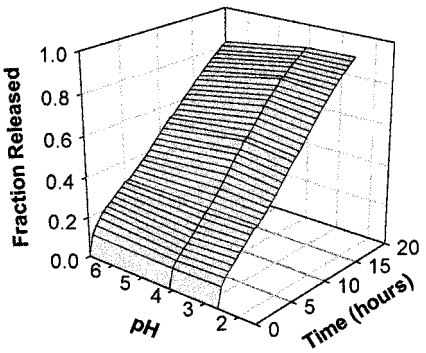

Figure 9—Release plot for diltiazem hydrochloride from a designed pH-independent system containing 100 mg of sodium carbonate and 50 mg of maleic acid in buffer media pH 1.5, 4, and 6.8.

Conclusions

This work has provided a novel simple approach to formulate an oral, swellable, monolithic, controlled-release delivery system designed for delivery of highly soluble, ionizable drugs over a long time period. An important feature of this system is the potential for generating constant drug release, a trend highly desirable for many pharmaceutical agents such as cardiovasculars, antiasthmatics, antihistamines, and narrow therapeutic index drugs. Through careful selection of electrolyte(s) and drug, an *in situ chemical interaction* within the gelled structure may be induced for the alteration of matrix-swelling dynamics and inhibition of drug dissolution. On the basis of textural analysis, peripheral axial front synchronization and greater radial matrix stiffening was observed to occur. This directional discrepancy in operating swelling mechanisms may be related to the fact that the degree of axial expansion of HPMC compacts was greater than radial expansion. In addition, the presence of electrolyte in the formulation clearly contributed to the formation of a more heterogeneous gel structure referred to as "metamorphic scaffold" in this work. The delivery system was also shown to be versatile in that it was neither electrolyte- nor polymer-limited, and specific formulation design can lead to release that is independent of variation in pH.

Accepted for publication August 20, 1999.

Abstract □ The purpose of this study was to determine the plasma lipoprotein (LP) distribution of amphotericin B (AmpB) and amphotericin B lipid complex [ABLC; Abelcet composed of dimyristoyl phosphatidylcholine (DMPC) and dimyristoyl phosphatidylglycerol (DMPG)] and define the relationship between LP lipid concentration and composition and the distribution of AmpB and ABLC in human plasma with varying total and lipoprotein cholesterol and triglycerides. AmpB and ABLC at a concentration of 20 μg amphotericin B/mL were incubated in plasma obtained from different human subjects ($n = 7$) for 60 min at 37 °C. Following these incubations plasma samples were separated into their high-density lipoprotein (HDL), triglyceride-rich lipoprotein (TRL; which contains very low-density lipoproteins and chylomicrons), low-density lipoprotein (LDL), and lipoprotein-deficient (LPDP) fractions by density-gradient ultracentrifugation (UC) and each fraction was assayed for AmpB using high-pressure liquid chromatography (HPLC). The HDL fraction was further separated into its HDL_3 and HDL_2 subclasses by UC and assayed for AmpB using HPLC. Separation of HDL into its subclasses was confirmed by gel electrophoresis. To assess the influence of modified lipoprotein concentrations and lipid composition on the plasma distribution of AmpB and ABLC, these compounds were incubated in plasmas from human subjects with varying total and lipoprotein lipid concentrations. In addition, to demonstrate that alterations in HDL lipid composition influence the plasma distribution of ABLC, ABLC (20 μg amphotericin B/mL) was incubated in plasma pretreated with dithionitrobenzoate (DTNB, a compound which inhibits lecithin:cholesterol acyltransferase conversion of HDL_3 free cholesterol to esterified cholesterol) 18 h prior to the experiment or in untreated plasma for 60 min at 37 °C. Total plasma and lipoprotein cholesterol (TC), free cholesterol (fC), esterified cholesterol (CE), triglyceride (TG), phospholipid (PL), and protein (TP) concentrations in each human sample were determined by enzymatic assays. When AmpB was incubated in human plasmas of varying lipid concentrations, the majority of the drug was recovered in the LPDP fraction. However, the majority of AmpB was recovered in the HDL_3 fraction following the incubation of ABLC. Differences in lipid coat content (fC and PL) carried by HDL influenced the distribution of ABLC within plasma of different human subjects. These findings were confirmed by the DTNB treatment experiments. These findings suggest that the association of AmpB with DMPC and DMPG to form drug–lipid complexes modifies the plasma distribution of the AmpB. In addition, the distribution of ABLC among plasma lipoproteins of different human subjects is defined by the HDL lipid coat content and is possibly an important consideration when evaluating the pharmacokinetics, toxicity, and activity of these compounds following administration to humans with differing plasma lipid concentrations.

Introduction

Amphotericin B (AmpB) remains one of the most effective and widely used agents in the treatment of systemic fungal infections including *Candida albicans* and *Histoplasma capsulatum*.[1] The clinical use of AmpB has been limited by dose-dependent nephrotoxicity, which may result in as much as a 60% reduction in the glomerular filtration rate.[1,2] The fungal cytotoxicity of AmpB is related to its amphiphilic structure, which facilitates binding to cell membrane sterols, thereby disrupting membrane integrity, and to its preferential binding to ergosterol in fungal membranes versus cholesterol in mammalian membranes.[3,4] However, when AmpB is formulated into a amphotericin B lipid complex (ABLC) it has been shown to be well-tolerated in doses up to 5 mg/kg of AmpB/kg of body weight and has been effective in patients that failed to respond to conventional AmpB therapy.[5,6]

Plasma lipoproteins are macromolecules of lipid and protein that transport polar and nonpolar lipids through the vascular and extravascular body fluids.[7−9] However, it is well-known that plasma lipoprotein profiles vary considerably between different animal species.[7,8] In addition, disease states can significantly influence plasma lipoprotein profiles, possibly resulting in altered therapeutic outcomes. Current research has shown that lipoprotein association of drug compounds can significantly influence not only the pharmacological and pharmacokinetics of the drug but also the relative toxicity.[7,8]

There is growing evidence that suggests increases in serum cholesterol concentrations increase the renal toxicity of AmpB. Koldin and co-workers demonstrated elevated AmpB-induced nephrotoxicity when AmpB bound to low-density lipoproteins (LDL) was administered to hypercholesterolemic rabbit's compared to AmpB alone.[10] Recent work by our lab suggests that increases in cholesterol, specifically LDL cholesterol levels, modify the disposition and renal toxicity of AmpB alone when administered to hypercholesterolemic rabbits.[11] However, the pharmacokinetics and renal toxicity of ABLC were independent of elevations in total and LDL cholesterol levels.[11] Lopez-Berestein et al. observed that when AmpB was administered to patients with leukemia who exhibited lower serum cholesterol concentrations, AmpB-induced renal toxicity was decreased.[12] Chabot and co-workers observed no measurable renal toxicity when AmpB was administered to cancer patients who exhibited hypocholesterolemia.[13] We have further reported that patients with a higher percentage of AmpB recovered within the serum LDL fraction are more susceptible to AmpB-induced kidney toxicity.[14]

A number of recent studies have suggested that increases in the association of AmpB with serum LDL enhanced the

Published on Web 09/28/1999

ability of AmpB to damage cells. Verlut-Doi et al. demonstrated that internalization of AmpB into Chinese hamster ovary cells in the presence of serum occurred by endocytosis.[15] Kreiger further reported that the cellular uptake of AmpB was a result of LDL-receptor mediated endocytosis.[16] We have reported that LDL-bound AmpB was as toxic to kidney cells as unbound AmpB.[17] However, HDL-bound AmpB was less toxic to these cells than either unbound or LDL-bound AmpB.[17] Furthermore, when the number of LDL receptors expressed on these cells were reduced, LDL-bound AmpB was less toxic to these cells than unbound AmpB,[17] suggesting that LDL receptors may play an important role in promoting the renal toxic affects of AmpB. Taken together, these studies[11,17] suggest an alternative hypothesis on how the ABLC formulation may decrease AmpB-induced renal toxicity than simply maintaining drug in the circulation in a complexed form effectively reducing the free concentration available to exert toxicity and/or by the rapid removal of the lipid complex from the circulation, thus reducing kidney tissue exposure.[5,6]

Our laboratory has recently observed that when ABLC was incubated in human plasma for 5−120 min at 37 °C, the majority of drug was recovered in the HDL fraction.[8] These findings are similar to what was observed with liposomal nystatin and annamycin.[8] A rationale for these results may be related to the similar lipid composition of these formulations [i.e., they all contain dimyristoyl phosphatidylcholine (DMPC) and dimyristoyl phosphatidylglycerol (DMPG)]. We have further observed that the DMPG component of these lipid-based formulations predominantly distributes into HDL because of its interaction with the protein components of HDL (apolipoproteins AI and AII).[8] Since ABLC is composed of the same phospholipids as liposomal nystatin and annamycin, the increased distribution of AmpB into the HDL fraction when formulated into these lipid complexes may also be a result of the attraction of DMPG for apolipoproteins AI and AII.[8,18] This rationale is further substantiated by recent findings which demonstrated that as the amount of HDL protein decreased, the percent of nystatin recovered within the HDL fraction proportionally decreased following the incubation of liposomal nystatin.[19]

The studies presented in this paper determine the plasma lipoprotein distribution of AmpB and ABLC following incubation in plasma from different human subjects with varying total and lipoprotein lipid concentrations and address the role of lipoprotein lipid and protein content on the distribution of AmpB to plasma lipoproteins.

Materials and Methods

Chemicals, Lipids, and Plasma—AmpB formulated as a micelle clear liquid (Fungizone; Bristol Myers Squibb, Princeton, NJ) and as a lipid complex, i.e., amphotericin B lipid complex (ABLC; Abelcet; The Liposome Company Inc., Princeton, NJ), were purchased from Vancouver General Hospital, Department of Pharmaceutical Sciences. The British Columbia Red Cross provided human plasma from seven different human volunteers not known to have preexisting hyperlipidemia. Organic solvents (methanol, etc.) were purchased from Fisher Canada. Ultracentrifugation supplies (i.e., centrifuge tubes, density gradient solutions) were purchased from Beckman Canada. Lipid and protein analysis kits were purchased from Sigma Chemical (St. Louis, MO). Free cholesterol and phospholipid analysis kits were purchased from Boehringer Mannheim (Germany).

Heterogeneity of Human Plasma Lipoprotein Profiles—Blood collected from healthy human volunteers (Screened by British Columbia Red Cross) was placed in drug-free glass test tubes, which contained 0.05M EDTA and centrifuged using a tabletop centrifuge for 10 min at 2,000 rpm; plasma was stored at −20 °C until used in the study.

Lipoprotein Separation—*Lipoprotein Separation by Step-Gradient Ultracentrifugation*—For the separation of lipoprotein plasma components by step-gradient ultracentrifugation, sodium bromide density solutions were carefully layered on top of the plasma samples in order of highest to lowest density. The density of the plasma samples was initially altered such that it had the greatest density of all layers in the gradient. The samples were ultracentrifuged overnight, and separation of the lipoprotein fractions was accomplished in a single spin. Each distinct layer was removed and separated for further analysis.

(i) Treatment of Plasma with AmpB or ABLC—To an ultraclear centrifuge tube (Beckman Instruments, Inc., Palo Alto, CA) was added 2.88 or 3 mL of human plasma for sample ($n = 3$ for AmpB and $n = 3$ for ABLC) or standard curve ($n = 6$) purposes, respectively. The contents of all tubes were prewarmed to 37 °C. To the samples tubes was added either 12 μL of an AmpB solution (5 mg/mL) or 12 μL of an ABLC suspension (5 mg/mL). The final concentration of AmpB in human plasma for both AmpB and ABLC formulations was 20 μg/mL. Immediately after the addition of AmpB or ABLC, the samples were returned to 37 °C and incubated for 60 min, whereupon they were removed and cooled on ice for 30 min.

(ii) Separation of Lipoprotein Constituent—Briefly, solutions of all densities (density [δ] = 1.006, 1.063, and 1.21 g/mL) were stored at 4 °C prior to the layering of the gradient. To the previously cooled plasma used for standard curves and the plasma samples was added 1.02 g of accurately weighted sodium bromide (0.34 g of sodium bromide per 1.0 mL of plasma) in order to modify the density of the plasma to approximately 1.25 g/mL.[19] Once the sodium bromide had dissolved into the plasma, 2.8 mL of the highest density sodium bromide ($\delta = 1.21$ g/mL) was carefully layered on top of the plasma. By using the same volume of 2.8 mL, the next highest sodium bromide solution ($\delta = 1.063$ g/mL) was layered on top of the sample, followed by 2.8 mL of the lowest density solution ($\delta = 1.006$ g/mL). The ultracentrifuge tubes were balanced, placed into individual titanium buckets, and capped. The buckets were placed into their respective positions on a SW 41 Ti swinging bucket rotor (Beckman Instruments, Inc.) and centrifuged at 40 000 rpm for 18 h at a temperature of 15 °C in a Beckman L8−80M Ultracentrifuge (Beckman Instruments, Inc.) Upon completion of the run, the ultracentrifuge tubes were carefully removed from the titanium buckets. Each tube showed four visibly distinct regions represented by the triglyceride rich lipoprotein (TRL, which includes very low-density lipoproteins and chylomicrons), LDL, HDL, and lipoprotein-deficient plasma (LPDP) fractions. Subsequently, each of the layers was removed with a Pasteur pipet from the top to the bottom layer, respectively, and the volume of each of the fractions was measured. Fractions removed for standard curve purposes were pooled together. All sample and pooled standard curve fractions were transferred to clean test tubes, covered, and stored at 4 °C until further analysis.

(iii) Control—LPDP was used as the control medium. The LPDP was acquired by the technique of step-gradient ultracentrifugation as described above. The LPDP was dialyzed (molecular weight cutoff 1000) against a 0.9% sodium chloride solution for 24 h at a temperature of 4 °C and was then used as the control medium for the incubation of AmpB or ABLC. Preparation of the samples with AmpB or ABLC as well as separation of the constituents was carried out by techniques identical to those described above for step-gradient ultracentrifugation. After ultracentrifugation, the removal of each "lipoprotein" fraction was estimated by comparison to previously separated lipoprotein fractions (i.e., removal of the layer from where TRL would normally reside was based on previous separation of actual plasma in which the layers were visible). The removal of the nonlipoprotein fractions in the control medium was estimated as being close to the placement of their separated lipoprotein counterparts in plasma.

HDL_2/HDL_3 Separation by Step-Gradient Ultracentrifugation—Plasma was separated into its TRL/LDL, HDL_2, HDL_3, and LPDP fractions by an ultracentrifugation method modified from the published methods of Groot et al.[20]

(i) Treatment of Plasma with AmpB or ABLC—To an ultraclear centrifuge tube (Beckman Instruments, Inc., Palo Alto, CA) was added 1.64 or 1.7 mL of human plasma for sample ($n = 3$ for AmpB and $n = 3$ for ABLC) or standard curve ($n = 6$) purposes, respectively. The contents of all tubes were prewarmed to 37 °C. To the samples tubes was added either 6.4 μL of an AmpB solution (5 mg/mL) or 6.4 μL of an ABLC suspension (5 mg/mL). The final

concentration of AmpB in human plasma for both AmpB and ABLC formulations was 20 μg/mL. Immediately after the addition of AmpB or ABLC, the samples were returned to 37 °C and incubated for 60 min, whereupon they were removed and cooled on ice for 30 min.

(ii) Separation of Lipoprotein Constituent—Briefly, solutions of all densities (δ = 1.00, 1.19, and 1.25 g/mL) were stored at 4 °C prior to the layering of the gradient. To the previously cooled plasma used for standard curves and the plasma samples was added 0.936 g of accurately weighed sodium bromide in order to modify the density of the plasma to approximately 1.40 g/mL.[20] Once the sodium bromide had dissolved into the plasma, 1.70 mL of the highest density sodium bromide (δ = 1.25 g/mL) was carefully layered on top of the plasma. By using the volume of 6.4 mL, the next highest sodium bromide solution (δ = 1.19 g/mL) was layered on top of the sample, followed by 1.70 mL of the lowest-density solution (δ = 1.00 g/mL). The ultracentrifuge tubes were balanced, placed into individual titanium buckets, and capped. The buckets were placed into their respective positions on a SW 41 Ti swinging bucket rotor (Beckman Instruments, Inc.) and centrifuged at 40 000 rpm for 21 h at a temperature of 15 °C in a Beckman L8-80M Ultracentrifuge (Beckman Instruments, Inc.) Upon completion of the run, the ultracentrifuge tubes were carefully removed from the titanium buckets. Each of the layers was removed from the top to the bottom layer with the following volumes; TRL/LDL, 0.5 mL; HDL_2, 2.4 mL; HDL_3, 4.8 mL; and LPDP/bottom, 4.3 mL. Fractions removed for standard curve purposes were pooled together. All sample and pooled standard curve fractions were transferred to clean test tubes, covered, and stored at 4 °C until further analysis.

(iii) Control—LPDP was used as the control medium. The LPDP was acquired by the technique of step-gradient ultracentrifugation as described above for HDL_2/HDL_3. The LPDP was dialyzed as previously described and then used as the control medium for the incubation of AmpB or ABLC. Preparation of the samples with AmpB or ABLC as well as separation of the constituents was carried out by techniques identical to those described above for HDL_2/HDL_3 step-gradient ultracentrifugation.

HDL_2/HDL_3 Separation by Gel Electrophoresis—Polyacrylamide gradient gels with a linear gradient of 4−30% of acrylamide were used in the separation of HDL_2 and HDL_3 as previously described.[21] The electrophoresis buffer contained TRIS base (90 mM), boric acid (80 mM), EDTA (3 mM), and sodium azide (3 mM) at pH 8.35. The gradient gels were preconditioned in electrophoresis buffer for 20 min at 125 V and 10° C in an electrophoresis chamber. Ten microliters of a sample containing HDL and sucrose (40%) and bromphenyl blue (0.05%) was applied to the gel for 20 min at 15 V, 30 min at 70 V, and then 24 h at 125 V at 10 °C. Calibration protein standards containing 2.5 μg of thyroglobulin, ferritin, catalase, lactate dehydrogenase, and bovine serum albumin were applied concurrently to other wells of the gel. Following electrophoresis, gels were stained for 1.5 h with Coomassie G-250 (0.04%) in methanol and acetic acid. The gels were than destained in 10% acetic acid and 30% methanol until the background was clear.

AmpB Quantification—AmpB was extracted from each lipoprotein and lipoprotein-deficient fraction by a liquid−liquid extraction method previously described.[22] Immediately prior to analysis, the residue was reconstituted with methanol and injected onto a high-pressure liquid chromatography (HPLC) column. The drug level was analyzed against external calibration curves by HPLC.

TRL, LDL, and LPDP Standard Curve Preparation—To a series of test tubes labeled 0, 0.039, 0.078, 0.156, 0.3125, 0.626, 1.25, 2.5, 5, 10 μg/mL was added 0.5 mL of pooled standard curve fraction, and to a test tube labeled 20 μg/mL was added 0.96 mL of the same pooled fraction. A 4 μL aliquot of either an AmpB solution (5 mg/mL) or an ABLC suspension (5 mg/mL) was then added to the test tube labeled 20 μg/mL, and the test tube was vortexed for 10 s. From the 20 μg/mL test tube, a 0.5 mL aliquot of this mixture was subsequently transferred to the test tube labeled 10 μg/mL. This procedure of serial dilution was carried out for the remaining tubes used for the standard curve.

(i) HDL Standard Curve Preparation—The procedure for the preparation of a HDL standard curve is the same as described above with one minor adjustment. To all tubes in the standard curve was added 1.0 mL of pooled standard curve fraction. To the tube labeled 20 μg/mL was added 1.92 mL of pooled standard curve fraction. An 8 μL aliquot of either an AmpB solution (5 mg/mL) or an ABLC suspension (5 mg/mL) was then added to the test tube labeled 20 μg/mL, and the procedure was carried out as described above.

(ii) Determination of AmpB Content within the Separated Lipoprotein Fraction: TRL and LDL—To an appropriately labeled test tube was added a 0.5 mL aliquot of sample. To these sample tubes as well as the tubes used for the standard curve was added 3 mL of dichloromethane. The mixture was vortexed for 10 s, and all samples were dried under a steady stream of nitrogen at ambient temperature. Once the sample was dried, the AmpB was extracted from the residue with a single methanol wash. Extraction efficiency was determined to be greater than 90% (data not shown). Briefly, a 3.0 mL aliquot of methanol was added to the residue, and the mixture was vortexed for 20 s before being completely dried under a steady stream of nitrogen at ambient temperature. Immediately prior to analysis, the residue was reconstituted with 0.5 mL of methanol and was injected onto the column.

(iii) Determination of AmpB Content within the Separated Lipoprotein Fraction: HDL—To an appropriately labeled test tube was added a 1.0 mL aliquot of sample. The procedure described above was then followed until the last step, when the residue was reconstituted with 0.250 mL of methanol prior to injection onto the column.

(iv) Determination of AmpB Content within the Separated Lipoprotein Fraction: LPDP—To an appropriately labeled test tube was added a 0.5 mL aliquot of sample. To these sample tubes as well as the tubes used for the standard curve was added 3 mL of dichloromethane. The mixture was vortexed for 10s, and all samples were dried under a steady stream of nitrogen at ambient temperature. Once the sample was dried, the AmpB was extracted from the residue with a series of methanol washes. Briefly, a 3.0 mL aliquot of methanol was added to the residue and the mixture was vortexed for 20 s. All test tubes were then centrifuged at 1200*g* for 2 min at 15 °C. The supernatant was transferred to a clean test tube, and the procedure was repeated an additional two times with 2.0 mL of methanol. The supernatant from each of the three extraction steps was pooled with the previous supernatant to provide a final volume of approximately 7 mL of methanol. This pooled methanol was then dried to completion under a steady stream of nitrogen at ambient temperature. Immediately prior to analysis, the residue was reconstituted with 0.5 mL of methanol and was injected onto the column.

HPLC Apparatus—The HPLC system consisted of a Waters 600 Controller interfaced to a Waters 717_{plus} autosampler and a Waters 486 tunable absorbency detector. The detector was set at an UV absorbency wavelength of 405 nm and an absorbency sensitivity of 0.05 absorbency units-full scale. All results were recorded on a Waters 746 Data Module Integrator (Waters Corp., Milford, MA). Samples (100 μL volume) were injected onto a Zorbax SB-C18 column (4.6 × 150 mm; 5 μm particle size), prefitted with a Zorbax Reliance SB-C18 guard column (4.6 × 12.5 mm; 5 μm particle size) (Rockland Technologies, Inc.). Chromatographic separation was carried out at ambient temperature. The mobile phase employed an isocratic flow and consisted of sodium acetate (10 mM) with acetonitrile (70/30 v/v) at a flow rate of 1.5 mL/min. The sensitivity of this assay was 50 ng/mL with an intraday CV of 5−8% (data not shown).

Lipid and Protein Content Analysis of Lipoprotein and Lipoprotein-Deficient Plasma Fractions—Total plasma and lipoprotein triglycerides, cholesterol (free and cholesteryl ester), phospholipids (phosphatidylcholine), and protein concentrations of the human plasma were determined by enzymatic assays purchased from Sigma Diagnostics (St. Louis, MO) and Boehringer Mannheim (Laval, QUE, Canada).

Experimental Design—To assess the distribution of AmpB and ABLC within human plasma, AmpB and ABLC at 20 μg of drug/mL of plasma were incubated in human plasma obtained from seven different human subjects for 60 min at 37 °C. Following incubation, the plasma samples were placed on ice to prevent redistribution of drug within the plasma samples as previously described.[19,22] The plasma was then partitioned into its lipoprotein and lipoprotein-deficient plasma fractions: TRL, consisting of VLDL and chylomicrons; LDL, consisting of intermediate-density lipoproteins and LDLs; HDL, consisting of all subclasses of HDL; and LPDP, consisting of albumin and α-1-glycoprotein by step-gradient ultracentrifugation. Each lipoprotein fraction was analyzed for cholesterol (total, esterified, and unesterified), triglyc-

eride, phospholipids, protein, and AmpB concentration. Since the majority of AmpB was not recovered in the HDL fraction following the incubation of free AmpB in plasma (Table 2), all additional experiments pertaining to HDL were done with only ABLC.

To determine which subfractions of HDL AmpB is recovered from, AmpB (as a negative control) and ABLC at 20 μg of drug/mL of plasma were incubated in human plasma for 60 min at 37 °C. Following incubation the plasma was separated into its HDL_2 and HDL_3 fractions by ultracentrifugation and each fraction was assayed for AmpB by HPLC. Separation of HDL into its different subfractions was confirmed by gel electrophoresis (Figure 1).

To further assess the influence of HDL lipid composition and structure on the plasma distribution of ABLC, ABLC at 20 μg of drug/mL of plasma was incubated in human plasma pretreated for 18 h with a lecithin:cholesterol acyltransferase (LCAT) inhibitor, dithionitrobenzoate (DTNB; 15 mM), as previously described[24] for 60 min at 37 °C. Following incubation the plasma was separated into its TRL, LDL, HDL, and LPDP fractions by ultracentrifugation and each fraction was assayed for AmpB by HPLC (Figure 2). DTNB is a sulfhydryl inhibitor that prevents the esterification of cholesterol to cholesteryl ester,[23] resulting in an elevation of HDL_3 coat lipid concentrations (fC + PL) (Table 6). In a second DTNB treatment experiment following the incubation of ABLC in plasma, the plasma was separated into its HDL_2 and HDL_3 fractions by ultracentrifugation and each fraction was assayed for AmpB by HPLC (Table 6).

Data and Statistical Analysis—Correlation coefficients between the amount of AmpB recovered within the TRL, HDL, and LDL plasma fractions and the amount of fC, CE, TC, TG, and TP within these fractions and plasma lipoprotein composition were determined using Pearson's Test (Tables 3 and 4). Differences in plasma distribution of AmpB and ABLC following incubation in plasmas obtained from different human subjects with varying lipid concentrations were determined by two-way analysis of variance without repeated measures (INSTAT; Human Systems Dynamics). Critical differences were assessed by Newman–Keuls and Tukey post hoc tests. A difference was considered significant if the probability of chance explaining the results was reduced to less than 5% ($p < 0.05$). All data were expressed as a mean ± standard deviation.

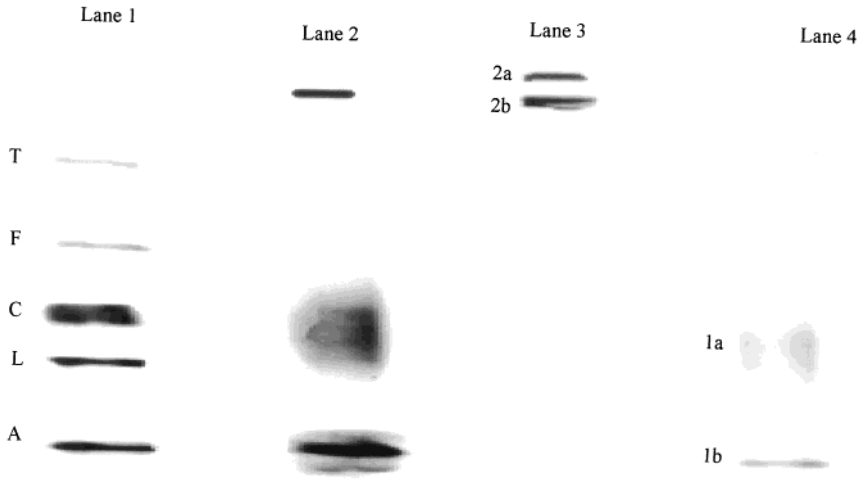

Figure 1—Human plasma samples run on the HDL gel formats. Lane 1 contains the standards: T, thyroglobulin; F, ferritin; C, catalase; L, lactate dehydrogenase; A, bovine serum albumin. Lane 2 is total HDL (including both HDL_3 and HDL_2) separated by ultracentrifugation. Lane 3 is HDL_2 separated by ultracentrifugation, 2a-HDL_{2b}, and 2b-HDL_{2a}. Lane 4 is HDL_3 separated by ultracentrifugation, 1a-HDL_{3a}, and 1b-HDL_{3b}. Lipoproteins and proteins in the standards were stained with Coomassie Brilliant Blue as described in the text (methods section).

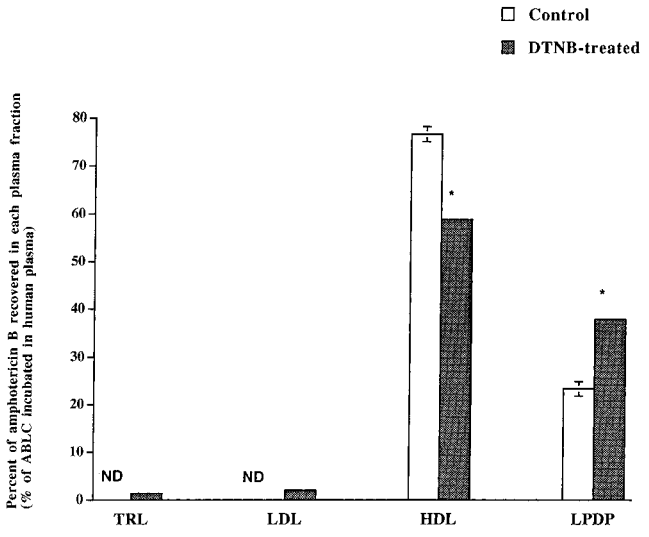

Figure 2—Distribution of amphotericin B lipid complex (ABLC) (20 μg of AmpB/mL of plasma) following incubation within human plasma that has been treated with DTNB (15 mM). ABLC was incubated in plasma pretreated with DTNB 18 h prior to the experiment or in untreated plasma (control) for 60 min at 37 °C. Following incubation the plasma was separated into its triglyceride-rich lipoprotein (TRL), low-density lipoprotein (LDL), high-density lipoprotein (HDL), and lipoprotein-deficient plasma (LPDP) fractions by ultracentrifugation and assayed for AmpB by HPLC. $N = 3$; data are expressed as mean ± standard deviation. *$p < 0.05$ vs control.

Table 4—Correlational Analysis Comparing Amount of AmpB Recovered to Lipid and Protein Contents and Compositions of the Separated Lipoprotein and Lipoprotein-Deficient Plasma Fractions Following the Incubation of AmpB (20 μg/mL) for 60 min at 37 °C in Plasmas from Seven Different Human Subjects[a]

[a] Calculations are based on the Pearson correlation coefficient values with significance. Abbreviations: AmpB, amphotericin B; TRL, triglyceride-rich lipoproteins (which includes very low-density lipoproteins and chylomicrons); LDL, low-density lipoproteins; HDL, high-density lipoproteins; LPDP, lipoprotein-deficient plasma (which includes α-1-glycoprotein and albumin); TC, total cholesterol; CE, cholesteryl ester; fC, free cholesterol; TG, total triglycerides; PL, phospholipid; TP, total protein. [b] NA, not applicable; analysis was not performed due to a lack of sufficient data. [c] $P < 0.05$.

Results

Distribution of Amphotericin B (AmpB) and Amphotericin B Lipid Complex (ABLC) following Incubation in Plasma from Human Subjects with Varying Lipid Concentrations—Table 1 reports differences in total plasma and lipoprotein cholesterol (esterified and unesterified), triglyceride, and protein concentrations that were observed for the seven different patient samples measured.

Table 2 reports the human plasma lipoprotein and lipoprotein-deficient fraction distribution of AmpB and ABLC in seven different plasma samples following incubation at 37 °C for 60 min. For plasma incubated with AmpB, 0.5%−12.2% of the original AmpB concentration incubated was recovered in the TRL fraction, 1.3%−5.7% was recovered in the LDL fraction, 1.6%−12.3% was recovered in the HDL fraction, and 66.8%−89.8% was recovered in the LPDP fraction. For plasma incubated with ABLC, nondetectable levels to 0.9% of the original AmpB concentration incubated was recovered in the TRL fraction, nondetectable levels to 2.0% was recovered in the LDL fraction, 50.0%−89.7% was recovered in the HDL fraction, and 2.7%−42.6% was recovered in the LPDP fraction. Similar findings were observed following the incubation of AmpB and ABLC at 1, 5, and 10 μg AmpB/mL of plasma (data not shown).

When AmpB and ABLC were incubated in the LPDP fraction, the majority of the drug (>92%) was recovered in the density fraction from 1.21 to 1.25 g/mL, suggesting that the distribution of AmpB and ABLC is not a function of formulation density (data not shown).

When correlations between the amount of AmpB recovered within the TRL, LDL, HDL, and LPDP fractions following ABLC incubation and the amount of TC, CE, fC,

Table 5—Chemical Composition by Dry Weight of Plasma HDL_2 and HDL_3 and Amphotericin B Concentrations Recovered in HDL_2 and HDL_3 following the Incubation of Amphotericin B or Amphotericin B Lipid Complex (20 μg/mL) in Human Plasma for 60 min at 37 °C

	(13)	(9.4)	(0.6)
DTNB-treated	39	18.4	8.6*
	(6)	(5.3)	(0.6)

[a] Data are presented as mean ± standard deviation (n = 6 replicates). *$P < 0.05$ vs control. Abbreviations: ABLC, amphotericin B lipid complex; AmpB, amphotericin B. HDL, high-density lipoproteins; TC, total cholesterol; CE, esterified cholesterol; PL, phospholipid. [a]percent of the original ABLC concentration incubated in human plasma.

TG, PL, TP, core lipid content, and coat lipid content within these fractions were calculated for all seven patient plasma samples, only one statistically significant relationship was observed. As HDL coat lipid content (fC + PL) increased, the amount of AmpB recovered in this fraction proportionally decreased (Table 3).

When correlations between AmpB amount recovered in each lipoprotein and lipoprotein-deficient fraction and lipoprotein composition were determined following AmpB incubation, only one statistically significant relationship was observed. As the HDL TG:TC ratio increased, the amount of AmpB recovered in HDL proportionally increased (Table 4).

Amphotericin B (AmpB) and Amphotericin B Lipid Complex (ABLC) Distribution within Plasma HDL_2 and HDL_3 Subfractions—Table 5 shows the human plasma HDL_2 and HDL_3 distribution of AmpB and ABLC in plasma. The distribution of AmpB and ABLC in the HDL_2 and HDL_3 and LPDP fractions of plasma incubated at 37 °C for 60 min showed the following differences. For plasma incubated with AmpB and separated into HDL_2 and HDL_3 subfractions, only 6.8% of the total drug incubated was recovered from the HDL_3 fraction, with the remaining drug being found within the LPDP fraction (Table 5). For plasma incubated with ABLC and separated into HDL_2 and HDL_3 subfractions, >95% of the initial concentration of the drug incubated was recovered from the HDL_3 fraction, with the remaining drug located within the LPDP fraction (data not shown).

When ABLC was incubated in plasma pretreated with DTNB for 18 h, the percentage of AmpB recovered in the HDL fraction was significantly decreased and the percentage recovered in the LPDP fraction was significantly increased compared to controls (Figure 2). Furthermore, the percentage of AmpB recovered in the HDL_3 and HDL_2 fractions was significantly decreased compared to the HDL_3 and HDL_2 fractions in untreated control plasma (Table 6).

Discussion

We have previously observed that AmpB predominantly associates with HDL in human serum when AmpB is incorporated into a lipid complex containing DMPC and DMPG.[16] When annamycin (Ann), an anticancer anthracycline analogue, and Nys were incorporated into liposomes with the same phospholipid composition, the majority of Ann and Nys was recovered in the HDL fraction.[8,18,22] Since HDL and LDL are not found in an equimolar ratio in human plasma but at LDL cholesterol/HDL cholesterol ratios varying from 4:1 to 6:1,[7] these data suggest that a mechanism(s) besides random probability or mass lipoprotein cholesterol levels must drive these drug–liposome complexes toward HDL rather than LDL. One such mechanism appears to be related to liposome composition. We have observed that the DMPG component of ABLC predominantly distributes into HDL because of its interaction with the protein components (apolipoproteins AI and AII) of HDL.[7,19]

In this study, consistent with our previous findings,[7,19] differences in AmpB lipoprotein distribution were observed following the incubation of free AmpB or ABLC in human plasma (Table 2). In particular, independent of plasma lipoprotein lipid and protein concentration, the majority of AmpB was recovered in the LPDP fraction (which contains albumin and α-1-glycoprotein) following the incubation of free AmpB (Table 2). However, the majority of AmpB was recovered in the HDL fraction following the incubation of ABLC (Table 2).

Previous studies with AmpB have suggested that an alteration in plasma lipid concentrations modify this drug's pharmacological behavior. Chavanet and co-workers have demonstrated that an increase in plasma triglyceride concentration led to a reduction in AmpB toxicity in rats.[24] These findings suggested that triglycerides, or their main vehicle in serum, chylomicrons, and VLDL, were involved in the protective effect against AmpB toxicity. Souza and co-workers have further shown that a triglyceride-rich emulsion that behaves in vivo in rats as chylomicrons was able to reduce the in vivo and in vitro toxicity of AmpB.[25] Our laboratory has recently shown enhanced AmpB-induced kidney toxicity within patients who exhibited elevated serum LDL cholesterol concentrations.[14]

In the present study, we have observed differences in the plasma distribution of AmpB when ABLC was incubated in plasmas from seven different human subjects (Table 2). It appears that these differences can be attributed to differences in the lipoprotein lipid and protein concentration profile of the plasmas (Table 1). In particular, increases in HDL coat lipid content (which contains free cholesterol and phospholipid) resulted in less AmpB recovered in this fraction following the incubation of ABLC (Table 3). However, increases in the TG:TP ratio within HDL resulted in more AmpB recovered in this fraction following the incubation of free AmpB (Table 4). These findings suggest that the AmpB lipoprotein distribution following the incubation of free AmpB is regulated by

different plasma HDL components (triglycerides and cholesterol) than following the incubation of ABLC, which appears to be regulated by HDL coat lipid content (free cholesterol and phospholipids).

We further observed that the majority of the AmpB recovered in the HDL fraction following the incubation of ABLC was found in the HDL_3 fraction following experiments in two different human plasmas (Tables 5 and 6). In addition, when the HDL_3 coat lipid content (fC + PL) was artificially elevated by DTNB, the percentage of AmpB recovered in this fraction was significantly decreased compared to controls following the incubation of ABLC (Table 6 and Figure 2). These findings suggest that the compositional and structural differences of HDL_3 as compared to HDL_2 may play an important role in determining the plasma distribution of the drug. In particular, since HDL_3 has a lower percentage by weight coat lipid content (free cholesterol and phospholipids) than does HDL_2[26] (Table 5), the lower percentage of AmpB recovered in the HDL fraction as HDL coat lipid content increased (Table 3) may be a function of the percentage of HDL_3 particles within the HDL fraction. This is supported by our observation that increases in the HDL_3/HDL_2 particle ratio in plasmas from different subjects resulted in a greater percentage of AmpB recovered in the HDL fraction ($r > 0.70$; $P = 0.05$) following the incubation of ABLC (data not shown). Taken together, these findings suggest that HDL coat lipid content (specifically HDL_3) may be an important factor in determining which lipoprotein AmpB associates following the incubation of ABLC.

In conclusion, we have determined that the plasma distribution of AmpB is altered when incorporated into a lipid complex composed of DMPC and DMPG. Furthermore, not only does the relative levels of individual lipoproteins but also the HDL coat lipid content defines the distribution of AmpB among plasma lipoproteins of different human subjects and may be an important consideration when predicting and/or evaluating the pharmacokinetics and toxicity of these compounds following administration to patients with varying lipid profiles.

Abstract □ Trialkylammonium acetoxymethyl esters of dexanabinol were synthesized and evaluated as water-soluble prodrugs. Syntheses were performed by conventional methods; solubility in water and stability in buffers and human plasma were determined by HPLC, and in vivo tissue distribution studies were performed in a rat model. Most of the new derivatives were soluble in water (~50 mg/mL). They were relatively stable in water, while rapidly hydrolyzed in human plasma. Distribution studies indicated that peak concentrations of drug both in blood (30 μg/mL) and brain (2 μg/mL) were rapidly (5 min) achieved after iv administration of a selected prodrug to rats. The blood concentration decreased faster than brain levels which were detectable even after 24 h. Some of the examined esters could be further developed as water soluble prodrugs of dexanabinol.

Introduction

Dexanabinol (HU-211), [(6a*S-trans*)-6,6-dimethyl-3-(1,1-dimethylheptyl)-1-hydroxy-6a,7,10,10a-tetrahydro-6*H*-dibenzo[*b*,*d*]pyran-9-methanol] (**1**), a synthetic, nonpsychotropic cannabinoid,[1] is a noncompetitive *N*-methyl-D-aspartate (NMDA) receptor antagonist[2] and an effective radical scavenger.[3] The compound is currently in clinical trials as a neuroprotective agent with potential use in the treatment of brain damage associated with stroke, head trauma, and cardiac arrest.[4−6]

An obstacle in the development of dexanabinol as a single-dose neuroprotective agent, considering the intravenous route as the best way of administration, is its very poor solubility in water, which makes formulation in aqueous compositions extremely difficult. The large dimethylheptyl side-chain and potential formation of stable, lipophilic molecular aggregates, such as dimers, mediated by strong hydrogen bonding[7] account for this behavior.

Cosolvent systems containing cremophor EL used in vivo and in phase I and II clinical trials are associated with allergic-type side effects and, accordingly, not unanimously accepted. Other technologies for solubilization of dexanabinol in aqueous compositions, including water-soluble prodrug approaches, have been investigated.

Various polar combinations or combinations bearing permanent charges were synthesized for dexanabinol as esters at either the allylic hydroxyl or phenolic functionalities. They included glycinate and N-substituted glycinates,[8,9] esters of amino acids containing tertiary or quaternary heterocyclic nitrogen,[10] and hemiesters of dicarboxylic acids[8] and phosphates;[11] more than 30 combinations were used in a preliminary screening process in which solubility in water and stability in water and plasma (rat and human) were determined. The results demonstrated that only trialkylammonium glycinate salts possessed properties required by prodrugs: solubility and stability in water and rapid hydrolysis in human plasma.

The in-depth investigation of trialkylammonium moiety containing glycinates, targeting identification of a prodrug of practical use for dexanabinol, has been considered in this work. Syntheses, solubility, and stability determinations, in vivo tissue distribution in a rat model and preliminary formulation experiments of a selected prodrug, are presented herein.[12]

Materials and Methods

Synthesis—Conventional procedures were used for the synthesis of the novel derivatives. Melting points are uncorrected and were determined on an Electro-thermal melting point apparatus (Fisher Scientific). Elemental microcombustion analyses were performed by Atlantic Microlabs, Inc., Atlanta, GA. Proton (^{1}H) and carbon (^{13}C) nuclear magnetic resonance spectra (NMR) were recorded on a Varian XL-300 spectrometer. Samples were dissolved in an appropriated deuterated solvent, and chemical shifts were reported as parts per million (δ) relative to tetramethylsilane (0.00) which served as an internal standard. Coupling constants (J) are reported in hertz. The progress of various reactions were followed by thin-layer chromatography (TLC). TLC was performed on EM Reagents DC aluminum foil plates coated to a thickness of 0.2 mm with silica gel (60 mesh). All solvents and chemicals were of reagent grade. Dexanabinol was synthesized in-house.

(6a*S-trans*)-9-(Chloroacetoxymethyl)-6,6-dimethyl-3-(1,1-dimethylheptyl)-1-hydroxy-6a,7,10,10a-tetrahydro-6*H*-dibenzo[*b*,*d*]pyran—A solution of dexanabinol (4.93 g, 12.7 mmol) and chloroacetic anhydride (2.05 g, 12.0 mmol) in chloroform (20 mL) was stored under argon in a dark room at 22 °C for 4 days. The reaction mixture was poured onto crushed ice (100 g), neutralized with 5% aqueous $NaHCO_3$, and extracted with chloroform (200 mL). The extract was washed with 5% aqueous $NaHCO_3$ (100 mL) and dried over anhydrous $MgSO_4$. The solvent was evaporated, and the residue was purified by column chromatography (silica gel, hexanes:diethyl ether, 9:11) to give 4.73 g (80%) of the product as a sticky oil of 98% purity (HPLC). Anal. Calcd for $C_{27}H_{39}ClO_4$: C, 70.03; H, 8.49; Cl, 7.66. Found: C, 70.28, H, 8.56; Cl, 7.46.

[(6a*S-trans*)-6,6-Dimethyl-3-(1,1-dimethylheptyl)-1-hydroxy-9-(trimethylammonioacetoxymethyl)-6a,7,10,10a-tetrahydro-6*H*-dibenzo[*b*,*d*]pyran] Chloride (**2**)—Anhydrous trimethylamine (0.65 g, 11.0 mmol) was added via a needle to a solution of (chloroacetyl)dexanabinol (1.90 g, 4.1 mmol) in anhydrous toluene (30 mL) and stirred under argon in a flask with a septum at 40 °C for 3 days. The precipitate was filtered, washed with toluene (20 mL), and dried in a vacuum oven (0.5 Torr, 60 °C, 4 h) to give

2.05 g (96%) of product of 98% purity (HPLC); mp 212 °C. Anal. Calcd for $C_{30}H_{48}ClNO_4$: C, 69.01; H, 9.27, Cl, 6.79; N, 2.68. Found: C, 68.93; H, 9.26; Cl, 6.82; N, 2.69.

(6a*S-trans*)-9-(Bromoacetoxymethyl)-6,6-dimethyl-3-(1,1-dimethylheptyl)-1-hydroxy-6a,7,10,10a-tetrahydro-6*H*-dibenzo[*b,d*]pyran—A modified previously described procedure[9] was used, starting from dexanabinol (3.40 g, 8.8 mmol) and bromoacetic anhydride (3.43 g, 13.2 mmol) in anhydrous toluene (20 mL). After stirring 20 h at 22 °C, ethyl ether (20 mL) and 5% aqueous $NaHCO_3$ were added, and the mixture was stirred vigorously for 30 min. The organic phase was dried on $MgSO_4$, the solvent evaporated, and the resulting oil dried in a vacuum oven (0.5 Torr, 80 °C, 6 h). No column chromatography was required, the purity of compound (4.08 g, 91%) being 98% (HPLC peak area). Anal. Calcd for $C_{27}H_{39}BrO_4$: C, 63.90; H, 7.75; Br, 15.74. Found: C, 63.79; H, 7.80; Br, 15.68.

[(6a*S-trans*)-6,6-Dimethyl-3-(1,1-dimethylheptyl)-1-hydroxy-9-(trimethylammonioacetoxymethyl)-6a,7,10,10a-tetrahydro-6*H*-dibenzo[*b,d*]pyran] Bromide (**3**) (reported earlier[9])—A solution of (bromoacetyl)dexanabinol (1.10 g, 2.2 mmol) and anhydrous trimethylamine (0.25 g, 4.3 mmol) in hexanes (20 mL) was kept at − 5 °C for 3 days. The resulting precipitate was filtered, rinsed with hexanes, and dried in a vacuum oven (0.5 Torr, 70 °C, 4 h) to give 1.10 g (90%) of product with 98.6% purity (HPLC); mp 215 °C. Anal. Calcd for $C_{30}H_{48}BrNO_4$: C, 63.59; H, 8.54; N,2.47; Br, 14.01. Found: C, 63.75; H, 8.62; N, 2.45; Br, 14.08.

[(6a*S-trans*)-6,6-Dimethyl-3-(1,1-dimethylheptyl)-1-hydroxy-9-(triethylammonioacetoxymethyl)-6a,7,10,10a-tetrahydro-6*H*-dibenzo[*b,d*]pyran] Bromide (**4**) (reported earlier[9])—A solution of (bromoacetyl)dexanabinol (1.00 g, 1.97 mmol) and triethylamine (0.35 mL, 2.50 mmol) in hexanes (10 mL) was stored under argon in a dark room at 22 °C for 3 days. The deposited crystalline material was separated by decantation, washed with hexanes, and dissolved in hot tetrahydrofuran (1.7 mL). The solution was diluted with diethyl ether (10 mL), filtered through a sintered glass funnel, and stirred at 22 °C for 2 days. The obtained precipitate was filtered, washed with diethyl ether, and dried in a vacuum oven (0.5 Torr, 50 °C, 24 h) to give 404 mg (34%) of product of 98% purity (HLPC); mp 127 °C. Anal. Calcd for $C_{33}H_{54}BrNO_4$: C, 65.11; H, 8.94; Br, 13.13; N, 2.30. Found: C, 65.23; H, 8.80; Br, 13.42, N, 2.42.

[(6a*S-trans*)-6,6-Dimethyl-3-(1,1-dimethylheptyl)-1-hydroxy-9-(*N,N*-dimethyl-*N*-ethylammonioacetoxymethyl)-6a,7,10,-10a-tetrahydro-6*H*-dibenzo[*b,d*]pyran] Bromide (**5**)—A solution of (bromoacetyl)dexanabinol (622 mg, 1.23 mmol) and *N,N*-dimethylethylamine (0.162 mL, 1.50 mmol) in anhydrous diethyl ether (10 mL) was stored under argon at − 5 °C for 4 days. The obtained precipitate was separated by filtration, rinsed with diethyl ether, and dried in a vacuum oven (0.5 Torr, 60 °C, 4 h) to give 0.69 g (97%) of product of 98.6 purity (HPLC); mp 134 °C. Anal. Calcd for $C_{31}H_{50}BrNO_4$: C, 64.12; H, 8.68; Br, 13.76; N, 2.41. Found: C, 63.87; H, 8.69; Br, 13.99; N, 2.37.

[(6a*S-trans*)-6,6-Dimethyl-3-(1,1-dimethylheptyl)-1-hydroxy-9-(*N*-methyl-*N,N*-diethylammonioacetoxymethyl)-6a,7,10,-10a-tetrahydro-6*H*-dibenzo[*b,d*]pyran] Bromide (**6**)—A solution of (bromoacetyl)dexanabinol (622 mg, 1.23 mmol) and *N,N*-diethylmethylamine (0.182 mL, 1.50 mmol) in anhydrous ether (10 mL) was stored at 22 °C for 1 week and then at − 15 °C for an additional week. The resulting precipitate was filtered, rinsed with diethyl ether, and dried in a vacuum oven (0.5 Torr, 50 °C, 2 h) to give 424 mg (59%) product of 91.9% (HPLC) purity; mp 134 °C. Anal. Solubility—The solubility of the novel derivatives in deionized water (pH 5.6−5.7; determined with a Ionalyzer7 model 501, Orion Research pH meter) was determined by preparation of saturated solutions at 21 °C (sonication for 60 min), filtration of the undissolved material, and determination of the concentration of the resulting solutions by HPLC. Calibration solutions of 0.1, 0.25, 0.50, and 1.00 mg/g concentrations were prepared. The four-point calibration had correlation of 0.99991. Average results of three determinations are reported.

Stability—The stability in aqueous buffers and human plasma of selected prodrugs was determined.

Sample Preparation and Incubation Conditions for Stability in Buffers—Stock solutions were prepared by dissolving prodrugs in water (pH 6.1) at concentrations of 50 mg/mL. Work solutions were prepared by diluting stock solutions with buffers of various pHs to final concentrations of 5 mg/mL. Samples were then incubated at 21 °C. Aqueous samples were analyzed by HPLC at various time points (pHs were determined each time both at the beginning and at the end point of determinations and proved to be unchanged). For HPLC determinations 100 μL of work solutions were diluted with 900 μL water to concentration of 0.5 mg/mL. Buffers used were: pH 7.4, Dulbeko's phosphate saline buffer (2.00 g/L KCl; 2.00 g/L KH_2PO_4; 8.00 g/L NaCl; 1.78 g/L Na_2HPO_4); pH 9, 0.05 M solution of tris(hydroxymethyl)aminomethane 5.47 g/L; pH 1.2 (simulated gastric fluid): 1 g of NaCl, 1.6 g of pepsin, 3.5 mL of HCl dissolved in 500 mL solution (according to USP XXII); pH 5.5: 0.1 N citric acid (6.4 g/L) (pH, 2.2) adjusted with 1 N NaOH; pH: 3.0 was prepared from 0.05 M K_2HPO_4 (pH 8.95) by adjusting pH with 0.1 N HCl. Aliquots were analyzed by HPLC, and concentrations of dexanabinol resulting from hydrolysis were determined. Hydrolysis followed first- order kinetics, and half-lives of compounds were calculated by plotting time versus the natural logarithm of peak area. Average values for three experiments were reported.

Sample Preparation and Incubation Conditions for Stability in Blood—Stock solutions were prepared at concentrations of 30 mg prodrug/mL in pH 7.4 buffer (0.05 M, $\mu = 0.15$). Work solutions were obtained by diluting stock solution with freshly collected blood to give 3 mg/mL or 200 μg/mL concentrations. Samples were incubated at 37 °C, and HPLC determinations were performed at various time points by extracting 100 μL samples with acetonitrile (900 μL for higher concentration and 400 μL for the lower concentration), followed by vortexing and immediate centrifugation and analysis.

Assay Method—High performance liquid chromatography (HPLC) (reversed-phase) was used for quantitative determinations. The HPLC consisted of a Spectra-Physics SP 8810 precision isocratic pump, Spectra-Physics SP 4290 system 2 integrator, Spectra-Physics SP 8880 autos ampler, Kratos Spectroflow 757 UV absorbance detector, and a Hewlett-Packard-HP3365, series II, version 3.33 Chemstation. The chromatographic conditions: HPLC columns, Alltima C8, 5 μm, 250 × 4.6 cm; mobile phase: acetonitrile: buffer (5 mL acetic acid and 5 mL triethylamine/L), 75:25 (v/v); flow rate: 1.0 mL/min; UV detection: 230 nm; volume of injection: 10 μL.

In Vivo Tissue Distribution Studies—The tissue distribution of a selected prodrug (**2**) was determined in a rat model. Male Sprague−Dawley rats (250−300 g body weight) were injected via tail vein with an aqueous (deionized water) solution of prodrug at 6.75 mg/kg body weight dose (250 g rats received ~200 μL of solution obtained by dissolving 25 mg prodrug in 3 mL water, the final pH being ~5). Animals were sacrificed by decapitation at 5, 15, 30, 60, 120, 240, 480, and 1440 min, and blood and brain tissues were collected. Three rats were used per time point. The research adhered to the "Principles of Laboratory Animal Care" (NIH publication no. 85-23, revised in 1985).

Sample Preparation—Plasma was obtained from trunk blood by centrifugation (1500 rpm). Brain was removed and rinsed with ice-cold saline. Samples were kept frozen until extraction. Acetonitrile (4 mL) was added to plasma (1 mL) followed by addition of the internal standard, a deuterated dexanabinol, synthesized in-house[13] (0.1 μg dexanabinol-d_5 in DMSO). Brain was weighed and homogenized in 2 mL of deionized water, and then acetonitrile (4 mL) was added, followed by the addition of the internal standard (0.5 μg/g brain). Multistep liquid−liquid extraction was then applied (both for plasma and brain homogenate). After the protein precipitation by acetonitrile, the supernatants were removed and concentrated to ~1 mL. A solution of NaOH (2 N, 2 mL) was added, followed by extraction with hexane/ethyl acetate (9/1, v/v) (4 mL). The organic phase was separated and washed with 0.1 N aqueous HCl solution (4 mL), and the solvent was evaporated under a

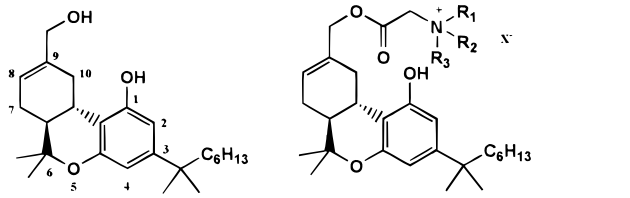

Figure 1—Structures of dexanabinol (**1**) and its prodrugs.

stream of nitrogen gas. Sample reconstitution was done in the HPLC mobile phase (100 μL). Average recovery for **1** was 55–60%.

Analytical Method—LC/MS methods were developed for determination of concentrations of **1** in plasma and brain. HPLC separation was done on a Supelco (Bellefonte, PA) LC–CN (cyanopropylsilica) 3.3 cm × 4.6 mm i.d. analytical column, protected with a Supelguard LC–CN (2 cm × 4.0 mm i.d.) cartridge. The mobile phase was 45% methanol and 55% aqueous acetic acid (1% v/v) at 1.0 mL/min flow rate. The solvent delivery system consisted of a Kratos (Manchester, UK) Spectroflow 400 isocratic pump. A Finnigan MAT (San Jose, CA) LCQ[7] ion-trap mass spectrometer with the manufacturer's APCI source was used. Injection volume was 5 μL. Retention time for analyte and internal standard was 2.70 min. Selected-ion monitoring (SIM) of the protonated molecules *m/z* 387.40 and 392.33 were used for the analyte and internal standard, respectively.

Quantitation was based on calibration by tissue spiked with known amount of analyte (0.1, 10, and 150 μg/mL plasma and 0.1, 1.0, and 5.0 μg/g brain) and the ratio of the area under the peak for the analyte ion (*m/z* 387.40, 1-amu window) to the area under the curve for the ion of the internal standard (*m/z* 392.33, 1-amu window) was used for regression to concentration (linear fitting, with quadratic weighing for concentration).

Results and Discussion

The investigated prodrugs are summarized in Figure 1. The synthetic procedures included acylation of dexanabinol (**1**) with chloroacetic or bromoacetic anhydride, followed by reaction of the resulting haloacetyl dexanabinol with appropriate tertiary amines. The allylic hydroxyl group is chemically more reactive than the sterically hindered and more rigid phenolic group. Accordingly, the acylation was quite specific, resulting in allylic esters without formation of any side products. The bromoacetate of dexanabinol reacted rapidly with trimethylamine, even at low temperature (−5 °C), affording high purity product with good yield. Consecutive substitution of methyl groups with ethyl groups led to slower reactions, lower yields, and products with lower melting points; the isolation of triethylammonium derivative, which proved to be quite lipophilic and soluble in common organic solvents, was difficult. However, this trend was surprisingly reverted to some degree in the case of derivatives containing higher alkyl groups, such as the tripropylammonium derivative.

To determine the influence of the counterion on the solubility of the quaternary derivatives, the chloride of the trimethylammonium acetate was also synthesized.

Attempts to use a similar procedure for the synthesis of trialkylammonium propionate derivatives of dexanabinol failed, because the reaction of bromopropionyl ester with tertiary amines gave predominantly dehydrobromination (elimination of hydrogen bromide) with formation of the acrylic ester, rather than the quaternization. While the dimethylamino derivative could be obtained from acrylate, by reaction with dimethylamine, its quaternization with methyl iodide was not possible since the resulting trimethylammonium derivative easily eliminated hydrogen iodide with formation of the acrylate.[14]

Table 1—Stability (half-lives) of Prodrugs in Buffers[a]

	half-lives ($t_{1/2}$) (days, mean ± SEM) at various pH

3	NA	NA	11.96 ± 0.8	3.64 ± 0.4
4	140.3 ± 5	51.30 ± 0.6	27.68 ± 0.9	11.94 ± 0.6
5	NA	NA	14.80 ± 1	10.30 ± 0.8
6	NA	NA	19.90 ± 0.7	10.45 ± 0.9

[a] SEM = standard error means. NA = data not available.

Prodrugs of practical use should have adequate solubility and sufficient stability in water to allow for formulation and storage. On the other hand, they should rapidly convert to the active parent drug within the body, particularly in blood since the administration is performed intravenously.

Solubility studies indicated that all of the investigated prodrugs were soluble in water. The determined solubilities were around 50 mg/mL (53.4, 52.2, 47.5, 47.0 mg/mL for **3**, **2**, **6**, **4**, respectively) except for compound **5** which proved to be less soluble (5 mg/mL) (no data are available for **7**). This spectacular increase in the solubility of the esters, as compared to dexanabinol which is insoluble in water, is a result of two factors: (1) the ionic character of the molecule induced by the permanently charged ammonium moiety, and (2) the prohibition of formation of strong dimers by double hydrogen bonding. It is difficult to explain some anomalies in solubilities in the examined series. While derivatives **2** and **3** were expected to have the best solubility due to smaller, less lipophilic alkyl groups linked to the quaternary nitrogen, the much lower solubility of **5** compared to **4** and **6** is unusual. The counterion, Cl^- or Br^- in **2** and **3**, respectively, does not have much influence, the two otherwise similar esters having almost the same solubility in water.

The esters were relatively stable in aqueous buffers. In each case, the stability was higher at the pH of distilled water (5.5), as compared to physiological pH (7.4) (Table 1).

Stability of selected prodrugs was determined at other pHs as well. At basic pH (9.0), the tested prodrugs were rapidly hydrolyzed (half-lives could not be calculated due to the fast rate of hydrolysis), while at strongly acidic pH (such as at 1.2, the pH of the stomach fluid) their stability increased considerably.

The results indicate that esters of **1** can be easily dissolved in water (buffered or unbuffered), but since the resulting solutions are not stable enough to allow for long time storage, they should be stored in the form of lyophilized powders and reconstituted a short time before their use.

Stability of **2** and **4** in human whole blood and plasma was determined at body temperature (37 °C). At concentration of 200 μg/mL, half-lives were 102 and 114 min (whole blood) and 47 and 90 min (plasma) for **2** and **4**, respectively. At lower concentration, which better reflects the real situation (doses used in clinical trials are in the range of ~100–300 mg dexanabinol/person), **2** hydrolyzed even faster, $t_{1/2}$ in plasma being 26.3 min at 50 μg/mL and very short at 20 μg/mL (70% of prodrug hydrolyzed at time point zero). This difference indicates saturation at higher concentration. As demonstrated during preliminary studies,[8,9] glycinate esters containing quaternary ammonium moieties are substrates for blood esterases and as a result are readily hydrolyzed. There are numerous esters containing

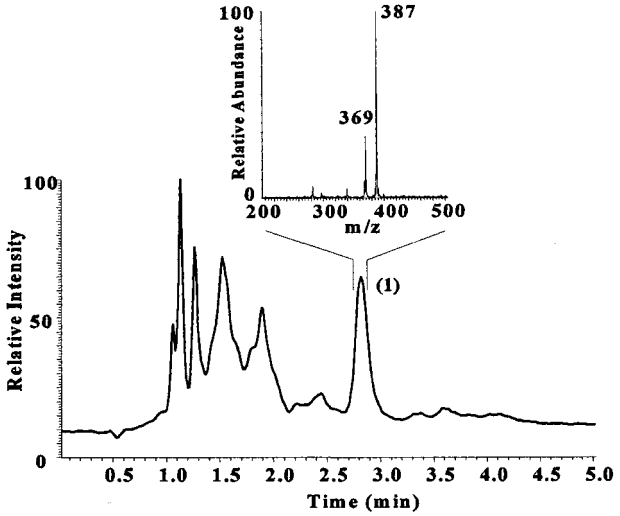

Figure 2—Representative LC-MS total-ion current (TIC) chromatogram of an extract of plasma spiked with 1.5 μg/mL dexanabinol (**1**). Inset: atmospheric pressure chemical ionization (APCI) mass spectrum of the peak indicated.

quaternary ammonium groups which are good substrates for enzymes which possess an anionic site. That includes obviously acetylcholine which is hydrolyzed by acetylcholinesterase present in postsynaptic membranes and also in plasma. Cholinesterases from plasma (pseudocholinesterases) are less specific than those from brain and they, or related esterases, might have a role in the hydrolysis of dexanabinol esters. These results indicate that the quaternary ammonium moiety containing esters can be used as prodrugs since they rapidly release the active **1** after their intravenous administration.

In vivo tissue distribution studies were performed in a rodent model. A selected prodrug (**2**) was administered intravenously to groups of rats, animals were sacrificed at various time points, and blood and brain concentrations of **1** were determined. These studies also addressed analytical method development for LC-MS, which offered an improvement over the gas chromatographic separation developed for compounds with similar structures, where sample derivatization was needed.[15] The HPLC assay developed during this study has benefits over similar methods using alkyl silica bonded phases, because the endogenous lipids extracted from the tissue elute before the analyte upon using cyanopropylsilica bonded phase. The short (3.3-cm), 3-μm particle-size column afforded reduced analysis time (5 min), compared to the 15-cm or 25-cm (5 μm) columns employed previously. A representative total-ion current chromatogram and the APCI mass spectrum of **1** are shown in Figure 2.

The in vivo distribution results are presented in Table 2 and in Figure 3. In agreement with the in vitro experiments performed in rodent blood,[9] a rapid hydrolysis of the prodrug was noticed. At 5 min following the administration, plasma levels of ~30 μg/mL were obtained. At the same time point, brain concentrations of dexanabinol reached a peak concentration of 2 μg/g as well. As the blood concentration of dexanabinol decreased following a typical two-compartment pharmacokinetic model, brain concentrations also became lower. However, the brain/blood concentration ratio increased from 0.07% at 5 and 15 min to 0.13, 0.35, 0.65, 2.48, 2.68, and 3.90 at 30, 60, 120, 240, 480, and 1440 min, respectively. Apparently, the lipophilic compound was retained by the brain tissues, while eliminated from blood. Even after 24 h, detectable levels of dexanabinol were identified in brain. It is important that peak concentrations of drug can be obtained rapidly (5 min) after administration, since the faster the neuroprotectant agent reaches the

[a] Area under the curve = 14.51 μg mL^{-1} h, clearance = 0.345 L kg^{-1} h^{-1}, mean residence time = 8.0 h. Two-compartment pharmacokinetic model[16] for plasma concentration of 1, $c = Ae^{-\alpha t} + Be^{-\beta t}$: A = 33.7 μg/mL, B = 0.392 μg/mL, α = 0.066 min^{-1}, β = 0.0011 min^{-1} (nonlinear curve fitting by Scientist for Windows, Version 2.0, MicroMath, Inc., Salt Lake City, UT). k_{el} = 0.0393 min^{-1}, k_{12} = 0.0259 min^{-1}, k_{21} = 0.0019 min^{-1}, volume of the central compartment = 0.147 L kg^{-1}; apparent volume, steady state = 2.201 L kg^{-1}.

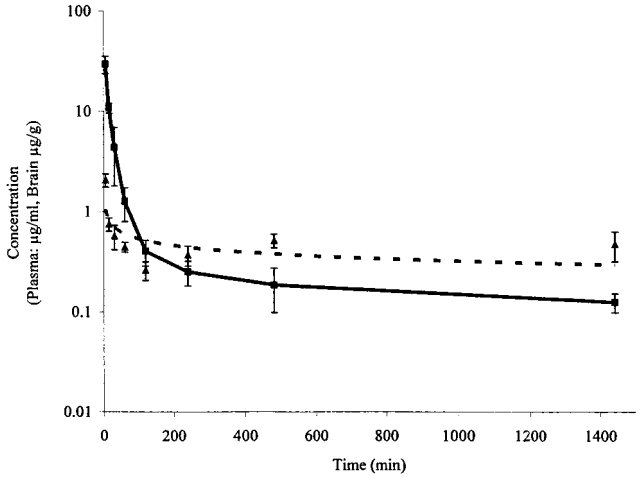

Figure 3—Concentration versus time profile of dexanabinol (**1**) in rat plasma (■, solid line) and brain (▲, dashed line) after iv administration of 6.75 mg/kg of prodrug **2**.

target, the more effective it is. It has to be mentioned that distribution results generated in rodent model might be different in humans, since esterases in mice and rats are much more active than in more evolved mammals. However, the in vitro experiments indicated that the selected combinations are good substrates for human blood esterases as well. It is then safe to affirm that the presented distribution study can be extrapolated to humans. Table 2 also contains some important pharmacokinetic parameters, calculated from the concentration−time profiles, including area under the curve, clearance, mean residence time, etc.

No control experiments, using **1** dissolved in a cosolvent system were performed. Such a study, in which **1** (5 mg/kg) was administered to rats in a cremophor/ethanol vehicle,[17] has been available for comparison and indicated a different tissue distribution profile. For example, the blood levels of dexanabinol were lower (maximum 4.5 μg/mL) and brain concentrations higher (maximum 10 μg/g) as compared to the results of the present study. The comparison of data might be misleading due to a variety of differences induced by solvents, including effects on the permeability of the blood−brain barrier.

Preliminary formulation studies were performed for selected prodrugs. Compounds **2** and **3** were dissolved in pure water (concentrations of ~50 mg/mL), and the resulting solutions were filtered through S&S Nylon-66 mem-

brane (45 μm pore size) and then freeze-dried in a Labconco freeze-dryer, model 77500, equipped with a Sargent-Welch vacuum pump, at a vacuum of 10 mmHg and temperature of − 50 °C for 6 h. The resulting powder was stored in dry conditions in dark, closed containers. The compound was analyzed by HPLC following the lyophilization and at a 1 month interval for 3 months; no degradation was registered, the purity being constantly 98%.

Conclusions

Several quaternary nitrogen-containing glycinate esters of dexanabinol were synthesized and investigated. Most of these combinations possess the required properties to be used as water-soluble prodrugs; they are soluble and fairly stable in water, but rapidly hydrolyze in human blood. In vivo distribution studies performed in a rat model indicated the brain uptake of **1**, when administered intravenously in the form of a prodrug, as a result of the rapid hydrolysis of the water-soluble ester. The prodrugs should be formulated as freeze-dried powders and reconstituted in water prior to their use. Prodrugs might present an advantageous alternative to the currently used formulations of dexanabinol.

Dodecylphosphocholine-Mediated Enhancement of Paracellular Permeability and Cytotoxicity in Caco-2 Cell Monolayers

DONG-ZHOU LIU,† EDWARD L. LECLUYSE, AND DHIREN R. THAKKER*

Contribution from *Division of Drug Delivery and Disposition, School of Pharmacy, The University of North Carolina at Chapel Hill, Chapel Hill, North Carolina 27599-7360.*

Received March 27, 1999. Accepted for publication August 26, 1999.

Abstract □ The intestinal epithelium is a significant barrier for oral absorption of hydrophilic drugs because they cannot easily traverse the lipid bilayer of the cell membrane and their passage through the intercellular space (paracellular transport) is restricted by the tight junctions. In this report we show that dodecylphosphocholine (DPC) can improve the paracellular permeability of hydrophilic compounds across Caco-2 cell monolayers by modulating the tight junctions. The results show that the alkyl chain as well as the zwitterionic head group of DPC are required for its activity. DPC appears to act by modulating the permeability of tight junctions as evidenced by the fact that treatment of Caco-2 cell monolayers by this agent results in a decreased transepithelial electrical resistance (TEER), increased permeability of paracellular markers (e.g., mannitol) with no change in the permeability of the transcellular marker testosterone, and redistribution of the tight junction-associated protein ZO-1. The effect of DPC on Caco-2 cells (e.g., decrease in TEER) is reversible, and is not caused by gross cytotoxicity (as indicated by the MTT test) or by nonspecific disruption of the cell membrane (as indicated by only slight nuclear staining due to the nonpermeable DNA-specific dye propidium iodide). We propose in the present study a parameter, potency index, that allows comparison of various enhancers of paracellular transport in relation to their cytotoxicity. The potency index is a ratio between the IC_{50} value (concentration at which 50% inhibition of control mitochondrial dehydrogenase activity occurs in the MTT test) and the EC_{50} value (concentration at which TEER drops to 50% of its control (untreated) value). By this parameter, DPC is significantly safer than the commonly used absorption enhancer palmitoyl carnitine (PC), which has the potency index of ~1 (i.e., no separation between effective and toxic concentration).

Introduction

The intestinal epithelium represents a major barrier to absorption of orally administered drugs and nutrients into systemic circulation. The translocation of drug molecules across the intestinal epithelium occurs by passive diffusion via transcellular or paracellular route, or through carrier-mediated active or facilitated transport. The intercellular space of the intestinal epithelium restricts the passage of molecules because of the presence of junctional complexes (tight junctions, intermediate junctions, and desmosomes).[1,2] Hence, the intestinal epithelium is a significant barrier for hydrophilic molecules because they cannot easily traverse the lipid bilayer of the cell membrane, and their passage through the intercellular space is restricted by the tight junctions, i.e., zonula occludens (ZO).

Numerous classes of compounds with diverse chemical properties, including detergents, surfactants, bile salts, Ca^{2+} chelating agents, fatty acids, phospholipids etc., have been reported to enhance the intestinal absorption of not only small drug molecules but also relatively large polypeptides drugs.[3−19] Many of these enhancers act as detergents/surfactants and increase the transcellular transport of drugs by disrupting the structure of the lipid bilayer and rendering the cell membrane more permeable and/or by increasing the solubility of insoluble drugs. Others act as Ca^{2+} chelators, and improve the paracellular transport of hydrophilic drug molecules by disrupting the tight junctions after the removal of extracellular Ca^{2+} from the medium. Several phospholipid-like agents, many of which are lysophosphatidylcholines,[8−12] medium chain fatty acids,[16−18] and acyl carnitines (e.g., palmitoyl carnitine),[3,5,13−15] appear to increase the paracellular permeability of hydrophilic compounds by mechanism(s) other than Ca^{2+} chelation. Although the exact mechanism(s) of action for many of these agents is yet to be determined, at least one mechanism by which they appear to exert their effect on the tight junctions is via upregulation of intracellular Ca^{2+}.[16−18]

A major concern regarding the use of these agents to enhance intestinal absorption is their postulated linkage to the epithelial damage and toxicity associated with the compromised mucosal function and morphology.[6,7] While these compounds are extensively used as absorption/transport enhancers, it is difficult to assess their relative potency and toxicity because of limited data available on concentration vs effect and also because of the use of different agents in different model systems. For example, palmitoyl carnitine (PC) has been used as a transport enhancer at a concentration range of 0.1−0.4 mM[14,15] in Caco-2 cell culture model. In our hands, PC was effective as transport enhancer in Caco-2 cell culture model at concentrations above 0.4 mM (cf., Figures 2, 5).

Our preliminary results have shown that dodecylphosphocholine (DPC), which lacks the glycerol moiety present in lysophoshatidylcholines, enhances the transport of hydrophilic compounds across Caco-2 cell monolayers by modulating the tight junctions (and perhaps other junctional complexes).[20] These results suggest that the activity of LGPC and other lysophosphatidylcholines[9] as enhancers of paracellular permeability is due to the presence of alkyl chain and a zwitterionic group and not due to the glycerol functionality. DPC contains these structural features in the simplest possible configuration. Hence, in this paper we report a systematic evaluation of DPC as an enhancer of paracellular transport of hydrophilic compounds across Caco-2 cell monolayers. Furthermore, we have compared DPC with several absorption enhancers in order to determine its potency as a paracellular transport enhancer and its cytotoxicity relative to the potency and cytotoxicity of other well-established absorption enhancers. While several

reports of the use of Caco-2 cells to evaluate toxicity of absorption enhancers have appeared recently,[20−24] we propose in the present study a parameter, potency index, that allows comparison of various paracellular transport enhancers in relation to their cytotoxicity.

Materials and Methods

Reagents—Caco-2 cells were purchased from American Type Culture Collection (Rockville, MD). Eagle's Minimum Essential Medium (EMEM), 0.25% trypsin/0.02% ethylenediamine−tetraacetic acid−sodium salt (EDTA-4Na), goat serum, and fetal bovine serum (FBS) were obtained from Gibco (Grand Island, NY). Nonessential amino acids (NEAA), Hank's balanced salt solution (HBSS), 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium (MTT), palmitoyl-DL-carnitine chloride (PC), sodium caprate (CA), sodium dodecyl sulfate (SDS), palmitic acid (PA), dodecyltrimethylammonium chloride (DTAC), phosphorylcholine (pC), and DL-carnitine hydrochloride were purchased from either Sigma (St. Louis, MO) or Aldrich (Milwaukee, WI). Dodecylphosphocholine (DPC), 1-myristoyl-*sn*-glycero-3-phosphate sodium (MGP), 1-lauroyl-*sn*-glycero-3-phosphocholine (LGPC) were purchased from Avanti Polar Lipids (Alabaster, AL). *N*-(2-Hydroxyethyl)piperazine-*N*′-2-ethanesulfonic acid (HEPES) and penicillin /streptomycin were obtained through the Tissue Culture Facility (UNC at Chapel Hill, NC). Transwell plates and inserts (12 wells/plate, 3.0 μm pore and 1.0 cm^2 area, polycarbonate) were purchased from Corning-Costar (Cambridge, MA). [^{3}H]Mannitol, [^{3}H]-PEG-900, [^{3}H]-PEG-3500, and [^{14}C]testosterone were obtained from DuPont NEN (Boston, MA). Lucifer Yellow (LY) and propidium iodide were obtained from Molecular Probes (Eugene, OR).

Antibodies—Rabbit polyclonal antibody against ZO-1 was purchased from Zymed Laboratory, Inc. (San Francisco, CA). Fluorescein isothiocyanate (FTIC)-labeled Goat anti-Rabbit IgG antibodies were purchased from Sigma (St. Louis, MO).

Caco-2 Cell Culture—Caco-2 cells were maintained in EMEM, containing 10% fetal bovine serum, 1% l-glutamine, 1% NEAA, and antibiotics (100 U/mL of penicillin and 100 μg/mL of streptomycin) in 75 cm^2 culture flasks. The cultures were kept at 37 °C in an atmosphere of 5% CO_2, 95% air, and 90% relative humidity. Cells were passaged after 95% confluency and were seeded with a density of 1.2×10^5 cells/mL onto porous polycarbonate filter membranes with a pore size of 3.0 μm and a surface area of 1.0 cm^2. Cells of passage number 40−55 were used throughout. Media were changed every 2 days after seeding until late confluence (21−23 days). Just before the experiments, the culture medium was replaced with transport buffer (HBSS contained 25 mM HEPES and glucose) and incubated for 1 h at 37 °C.

Preparation of Enhancer Solution—All the compounds being evaluated as transport enhancers were dissolved in a HBSS that contained 25 mM HEPES at pH 7.4. The stock solutions (50 mM) of the test compounds were obtained by dissolving them in HBSS-buffer/ethanol (60:40, v/v) and were stored at −20 °C. Just before the experiments, the enhancer solutions were thawed and diluted to the appropriate concentrations by HBSS buffer and sonicated for 5 min in an ice bath.

Critical Micelle Concentration (CMC)—The CMC of all tested enhancers was determined by measurement of surface tension as a function of concentration of enhancers in HBSS (contained 25 mM glucose and 25 mM HEPES) buffer at room temperature. For this study, a Kruss K10T digital tensionmeter (Hamburg, Germany) was used.

Cell Viability Assay—The cell viability was measured by the MTT test[25] as performed for evaluation of the cytotoxic effects of absorption enhancers to Caco-2 cells.[26] Approximately 3×10^3 cells (in 100 μL of cell culture medium) were seeded into the wells in a 96-well tissue culture plate (Corning-Costar, Cambridge, MA). The cells were then cultured under the same condition as the monolayer preparation for 72−96 h before use. Just prior to the start of each experiment, the medium was removed from the wells, and 100 μL of the enhancer solution in HBSS was added to each well. After exactly 20 min, 20 μL of a 5 mg/mL MTT solution was added to each well, and the cells were incubated for another 90 min. Then 100 μL of 5% SDS in 0.02 M HCl/isobutanol (1:1, v/v) solution was added to stop the reaction and solubilize the reaction products. The absorption was measured at 590 nm with a multiwell scanning spectrophotometer (Bio-Rad, Hercules, CA).

Transepithelial Electrical Resistance (TEER)—The monolayers were treated on the apical side with the absorption enhancers at various concentrations dissolved in 0.5 mL of HBSS. The volume of HBSS on the basolateral side was 1.5 mL. Measurements of the effects of these enhancers on TEER across Caco-2 monolayers were performed using an EVOM Epithelial Tissue Voltohmmeter (World Precision Instruments, Sarasota, FL) at room temperature and 37 °C. The resistance due to the cell monolayers was determined in the presence or absence of the enhancers after subtracting the contribution of the blank filter and the HBSS. The control TEER values were in the range of 500−600 Ω·cm^2.

Cytoplasmic Membrane Permeability—The DNA-intercalating dye, propidium iodide, was used to discern cells with damaged membranes. Caco-2 cells (5.0×10^4 cells/mL) were seeded on to glass coverslips. After 5 days, the completely confluent cell monolayers were used for propidium iodide staining. After expo-

sure by DPC at 0.75 mM, 1.0 mM, and 1.25 mM, the monolayers were rinsed twice with PBS and then incubated with propidium iodide (30 μg/mL PBS) for 3 min. After rinsing twice with PBS, the cells were fixed for 10 min in 3.7% formaldehyde in PBS on ice and then rinsed four more times in PBS. In a separate experiment, the same DPC-exposed monolayer samples, after rinsing with PBS, were incubated in cell culture medium for 8 h and then stained by propidium iodide. Experiments excluding the enhancer were run as controls. The preparations were mounted on glass slides in a 1:1 solution of PBS and glycerol and examined under a fluorescence microscope.

Immunohistochemistry—Caco-2 cell monolayers were prepared as described under "Cell Culture" for transport experiments, and those with TEER values 600−800 O·cm^2 were used for the immunohistochemistry study. The cell monolayers were first treated with 0.75 mM DPC for 20 min. Then the monolayer was washed twice after removal of DPC-containing medium. The cells were fixed in 3.7% paraformaldehyde, rinsed in 1x PBS and permeabilized using 0.25% Triton X-100. After further rinsing, the cell monlayer was blocked with PBS containing 10% FCS, 10% goat serum, and 0.2% Tween 20. The primary antibody (rabbit polyclonal antibody against ZO-1), diluted in PBS containing 10% FCS/10% goat serum/0.2% Tween 20, was applied to the cell monolayers and incubated for 2 h. After several washes with 1x PBS/0.2% Tween 20, the monolayer was blocked again and then incubated for another 2 h with the FITC-labeled goat anti-rabbit IgG antibody that was diluted in PBS containing 10% FCS/10% goat serum/0.2% Tween 20. After rinsing in PBS, the filter was cut out, mounted in glass slides, and examined using Zeiss confocal microscope fitted with 60× objective. ZO-1 staining excluding DPC was run as a control. The final images were stored digitally and transferred to Adobe Photoshop for graphical representation.

Transport Experiments—Transport studies were performed at room temperature on filter-grown Caco-2 monolayers with [^{3}H]-labeled mannitol (80 μM, 0.5 μCi/mL), [PEG-900 (100 μM, 0.5 μCi/mL) and PEG-3500 (100 μM, 0.5 μCi/mL), [^{14}C]testosterone (100 μM, 0.1 μCi/mL), or LY (100 μM). The enhancer solution in HBSS (0.5 mL) was added to the apical side of the cells and 1.5 mL of HBSS was added to the basolateral side. After treatment for 20 min, the enhancer solutions were discarded, and the monolayers were washed once with fresh HBSS. Then 0.5 mL of HBSS solution containing one of the compounds was applied to the apical side. Transport rates were determined by measuring the radioactivity/fluorescence associated with the transported compounds present in the BL side at 20-min intervals. The amount of radioactivity was measured by liquid scintillation counting in a PACKARD 1600 TR analyzer (Downers Grove, IL). Transported LY was quantitated with Perkin-Elmer LS50B Luminescence Spectrometer (Beaconsfield, Buckinghamshire, England).

Data Analysis—All transport experiments were carried out under sink conditions, such that the concentration of the compounds in the receiver compartment was always less than 10% of the concentration in the donor compartment. TEER was measured prior to each experiment to ensure the confluency of the cell monolayer. The apparent permeability coefficient was calculated using the following equation:

$$P_{app} = (dQ/dt)\cdot(1/A)\cdot(1/C_o)$$

where dQ/dt (mol transported/sec) is the flux of the marker compound across Caco-2 cell monolayer, A (cm^2) represents the diffusional area of the inserts, and C_o (M) denotes the initial concentration of marker compound in the donor compartment. All measurements and transports were in triplicate and expressed as mean ± SD values.

Results

Comparative Effect of DPC, PC, and LGPC on TEER and Mannitol Transport Across Caco-2 Cell Monolayers—Because both TEER and mannitol permeability across Caco-2 cells are indicators of tight junction integrity of the cell monolayer, relative effect of compounds on these two indicators reflects their relative ability to modulate tight junctions. PC[15] and lysophosphosphatidylcholines[9] (e.g., LGPC) have been reported as absorption enhancers. The structural features that are common to these very different classes of molecules include a several-carbon-long alkyl chain, an anionic functionality (carboxyl or phosphate group), and a cationic functionality (trimethylaminoalkyl group). We have chosen DPC as a model compound to confirm the role of these structural features in affecting the paracellular permeability. This is because DPC contains all three structural moieties in relatively simple configuration (see Figure 1). In a preliminary study,[20] we have reported that DPC, PC, and LGPC (at 0.75 mM) cause a decrease in TEER to less than 10% of the control value and a significant increase in mannitol permeability across Caco-2 cell monolayers. To elucidate the common structural features that may be responsible for the effect of these compounds on tight junctions, we have evaluated the effect of several other compounds that represent only a partial structure of DPC, PC, or LGPC on TEER and mannitol permeability across Caco-2 cell monolayers at the same concentration (0.75 mM) as that used for the above three compounds (Figures 1 and 2). Interestingly, compounds with an 11- to 15-carbon alkyl chain and either an anionic group or a cationic group (e.g., sodium caprate,[27] palmitate,[27] DTAC, or MGP) did not show any effect on TEER or mannitol transport at the concentration used. Similarly, compounds containing the zwitterionic functionality without the alkyl chains (e.g., carnitine or phosphorylcholine) did not cause any change in TEER or permeability of mannitol. These findings are in agreement with previous findings that the structural components of PC, i.e., carnitine chloride and palmitic acid, had no effect on the transport of paracellular markers across Caco-2 cell monolayers.[15] While DPC, LGPC, and PC appear different structurally, they all contain an alkyl chain and a zwitterionic functionality. All three compounds are quite effective at causing a decrease in TEER and an increase in mannitol permeability across Caco-2 cells. Thus, it is reasonable to conclude that the glycerol functionality of LGPC is not necessary for the activity, and that the minimum structural features contributing to the activity of these compounds include a medium to long alkyl chain and a zwitterionic group. While these results do not show that a zwitterionic compound containing a short alkyl chain is not very effective as an enhancer of paracellular permeability, a previous report[9] clearly suggests that such is the case.

Effect of DPC on TEER as a Function of Time and Concentration—The influence of DPC on TEER across Caco-2 monolayer was monitored as a function of time at several concentrations (Figure 3). At room temperature, monolayers treated with up to 0.5 mM DPC showed very little change in TEER with only 0−20% drop for the first 30 min. However, when the concentration of DPC was increased to 0.75 mM, a rapid decrease in TEER (within 3 min) was observed. The drop in TEER as a function of concentration exhibited a sharp inflection between 0.5 mM and 0.75 mM of DPC. Interestingly, the drop in TEER as a function of concentration is more gradual and uniform at 37 °C (data not shown) than at room temperature. To determine whether the effect of DPC on Caco-2 cell monolayers is reversible, apical HBSS containing DPC was replaced with fresh cell culture medium after 30 min of treatment. In all cases, TEER returned to the control value upon removal of DPC when measured after 10 h. This indicates that DPC treatment does not lead to the disruption of the monolayer or cell lysis (see cytotoxicity of tight junction modulators).

The effect of DPC on TEER was much more pronounced when it was applied to the apical side than to the basolateral side of Caco-2 cell monolayers (Figure 3 insert). Furthermore, the decrease in TEER achieved after baso-

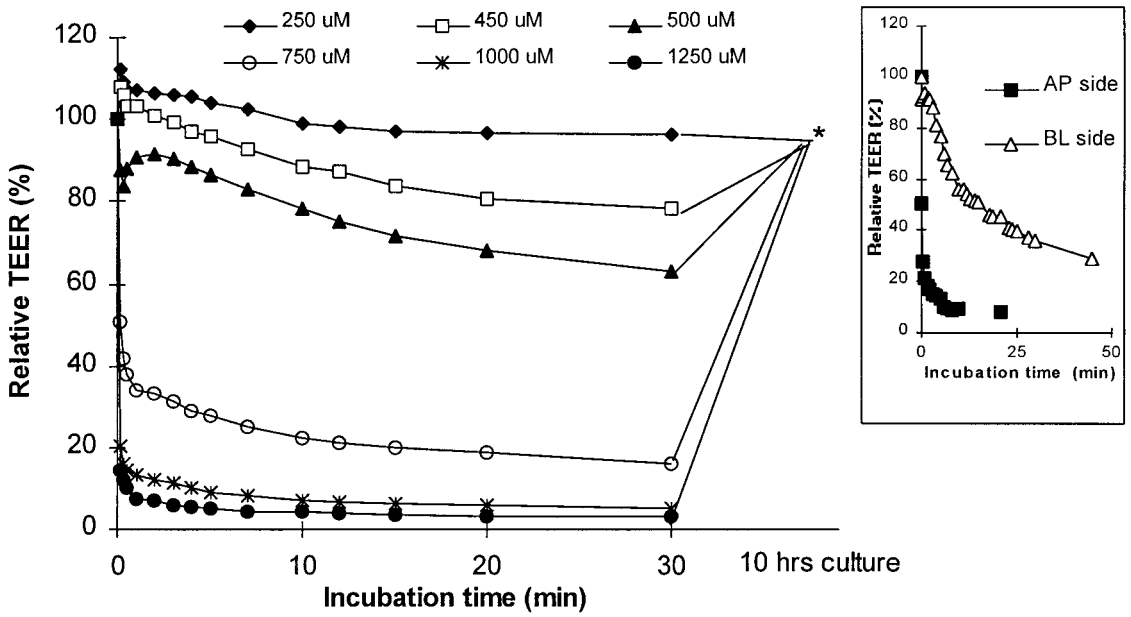

Figure 3—Effect of DPC on TEER (ambient temperature) across Caco-2 cell monolayers as a function of time and DPC concentration. In all cases TEER values returned to the control value when measured 10 h after removal of DPC (after 30 min treatment). The insert displays the effect of 1.0 mM DPC on TEER when it was applied to AP or BL side of the cell monolayers.

lateral application of DPC was much more gradual than that achieved after apical application; in fact, the magnitude of maximum decrease in TEER after basolateral application of DPC never approached that seen with the apical application. We have confirmed that the delayed and decreased effect of DPC when applied on the basolateral side is not due to the polycarbonate membrane, as it does not constitute a significant barrier to the transport of DPC (data not shown). The asymmetry in the effect on TEER suggests that the effect of DPC on TEER or mannitol permeability is not due to its permeation into the cells, followed by an intracellular change. Rather, the effect appears to be due to different interactions with the tight junction components depending on whether DPC is on the apical or the basolateral side. It is also possible that the observed difference in the effect on the decrease in TEER is due to interactions of DPC with cell membrane on the apical versus the basolateral side that lead to different effects on the structure and function of the tight junctions.

Effect of DPC on the Transport of Paracellular Markers—To determine if DPC-induced drop in TEER is accompanied by an increase in the tight junction permeability, we measured transport rates of a few paracellular markers across the Caco-2 cell monolayers. The enhancing effect of DPC pretreatment of the cell monolayers on the transport of hydrophilic paracellular markers was concentration-dependent (Figure 4). At low concentration of DPC (less than 0.5 mM), the permeability of all paracellular molecules was the same as that of the control. In general, DPC-induced decrease in TEER correlated with an increase in transport of the paracellular markers. At 0.75 mM concentration (a nontoxic concentration, see cytotoxicity of tight junction modulators), DPC pretreatment increased the apparent permeability constant (Papp) across Caco-2 cells for mannitol by 12-fold, for LY by 16-fold, and for PEG-900 by 2.2-fold. It caused no significant enhancement in the Papp value for PEG-3500, a large MW paracellular marker. Furthermore, DPC did not affect the transport rate of testosterone, a transcellularly transported marker, indicating that cell membranes were not compromised or disrupted by DPC at 0.75 mM concentration.

The enhancement in permeability of paracellular molecules is treatment-dependent. When DPC was coadministered with the paracellular markers after the initial pretreatment by DPC for 20 min (0.75 mM), further enhancement in the transport rates was observed for these compounds. Especially the transport of PEG-3500, a larger molecular weight marker, could be effectively enhanced with pre- plus cotreatment with DPC (data not shown).

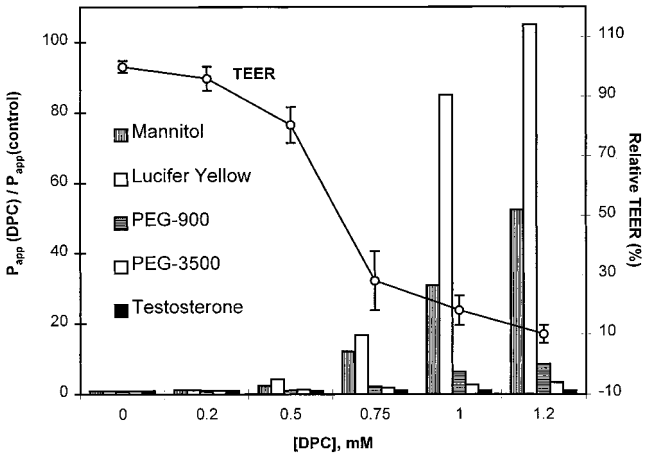

Figure 4—Enhancement of transport of paracellular markers by DPC after 20 min pretreatment. Testosterone was included as control (marker for transcellular transport) to ensure that the cell membrane was not disrupted and that the integrity of the cell monolayer was not compromised. ○: relative TEER (%).

Comparison of Potency of the Tight Junction Modulators—The absorption enhancers are used at different concentrations and in different model systems by different groups. Because of this, it is impossible to establish the concentration at which a given enhancer is effective or to determine (from the literature) relative potencies of different enhancers. Hence, we define the term EC_{50}, the concentration at which an enhancer decreases the TEER of the cell monolayer to 50% of the initial (control) value, and propose that the enhancers should be tested at several concentrations in order to define their effective concentration(s) and their relative potencies. This will allow a more meaningful translation of the results from different groups and comparison of relative potencies of different enhancers. While TEER at a given value may not

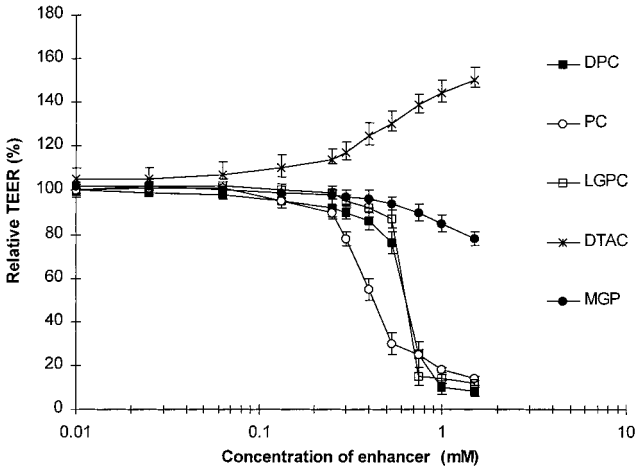

Figure 5—Relationship between concentration of the transport modulators and TEER. The cell monolayers were treated with the compounds for 20 min at ambient temperature. The measurements were made in triplicate and expressed as mean ± SD.

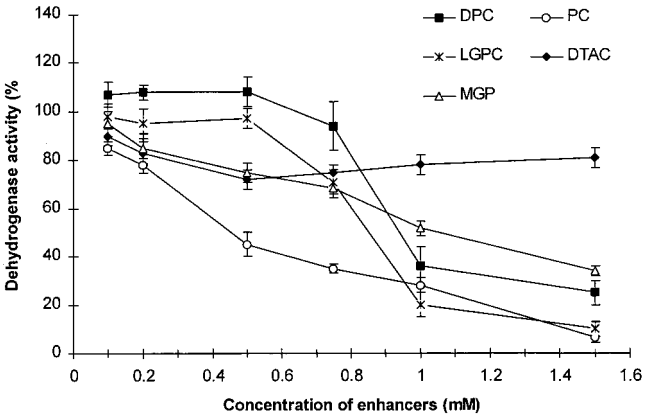

Figure 6—Mitochondrial dehydrogenase activity (MTT) in Caco-2 cells after treatment with transport modulators at various concentrations. All measurements were made in triplicate and expressed as mean ± SD.

be indicative of the paracellular permeability of compounds, the changes in TEER over a range of the enhancer concentrations correspond well with the changes in paracellular permeability.[28] Therefore, the EC_{50} values provide a good indicator of the potency of a given compound in causing an increase in paracellular permeability. Such an approach has been previously used by Anderberg et al.[29] to compare the efficacy of surfactant excipients. The effect of five agents on TEER is compared as a function of concentration in Figure 5. The EC_{50} values for PC (0.42 ± 0.06 mM), LGPC (0.65 ± 0.04 mM), and DPC (0.65 ± 0.05 mM) indicate that DPC and LGPC are equipotent, with PC showing a somewhat higher potency than the other two compounds. Interestingly, the EC_{50} value for DPC increased from 0.65 mM to 0.74 mM when the temperature increased from 20 °C to 37 °C (data not shown). The anionic MGP was significantly less effective as it caused less than 20% drop in TEER at concentration as high as 1.5 mM. The cationic compound DTAC actually caused a concentration-dependent increase in TEER at concentrations above 0.2 mM. Similar increase in TEER by cationic compounds has been observed previously.[30,31]

Cytotoxicity of the Tight Junction Modulators—The reversibility of the effect of DPC on TEER across Caco-2 cell monolayers (Figure 3) suggests that its effect is not secondary to cytotoxicity resulting in disruption of the cell monolayer. To further evaluate the cytotoxicity of these enhancer-related agents toward Caco-2 cells, the viability of the cells was directly measured using the MTT test.[25,26,29] MTT is a tetrazolium salt that is oxidized by mitochondrial dehydrogenases in living cells to give a dark blue formazan product. Damaged or dead cells show reduced or no dehydrogenase activity. Reports of this and other related tests to assess the cytotoxicity of absorption enhancers toward Caco-2 cells have appeared recently.[20–24,26,29] The results depicted in Figure 6 indicate that at 0.1 mM concentration, none of the agents were cytotoxic. However, at higher concentrations (more than 0.2 mM), the toxicity caused by the agents showed significant differences. To quantitatively compare the cytotoxicity of the enhancer-related agents, the IC_{50} values (concentration at which the enhancer produces 50% inhibition of the mitochondrial dehydrogenase activity measured by the MTT method) were determined. DPC (IC_{50} = 0.92 ± 0.03 mM) and LGPC (IC_{50} = 0.84 ± 0.02 mM) were approximately 2-fold less cytotoxic than PC (IC_{50} = 0.45 ± 0.05 mM) toward Caco-2 cells. SDS, used as a positive control, had an IC_{50} value of ~0.2 mM (data not shown). It is interesting to note that for the extensively used absorption enhancer PC there is no separation between its EC_{50} and its IC_{50} value. Both DPC and LGPC are likely to be somewhat better as absorption enhancers than PC, as their IC_{50} values are ~50% greater than their EC_{50} values. It is important to note that the "cytotoxic" effect of DPC (and other agents) reported here may actually be "cytostatic" effect as evidenced by the fact that removal of DPC from the solutions bathing the cell monolayers results in restoration of TEER over several hours.

Effect of DPC on the Apical Cell Membrane Integrity—To ensure that the effect of DPC and related enhancers was predominantly due to modulation of the tight junctions and not due to compromised apical membrane, we have evaluated DPC-induced DNA staining by propidium iodide. This probe fluoresces when it interacts with DNA, but can access DNA only if the cell membrane and the nuclear membrane are compromised, as it does not permeate intact membranes.[32] When Caco-2 cells were treated with different concentrations of DPC prior to propidium iodide staining, fluorescence microscopy showed that the permeability of the cell membrane remained low after 20 min of exposure to 0.75 mM DPC, but increased at 1.0 mM and 1.25 mM DPC exposures (Figure 7). After removal of DPC and incubation in cell culture medium for 8 h, the membrane integrity was restored for 0.75 and 1.0 mM DPC treatment, but not after treatment with 1.25 mM DPC. These results suggest that above 1 mM concentration, DPC causes irreversible damage to the cell membrane and/or the nuclear membrane.

Effect of DPC on ZO-1 Redistribution—ZO-1 is a tight junction-associated protein,[33,34] which is localized on the cytoplasmic surface just beneath the membrane. When Caco-2 cells are treated with a rabbit antibody to ZO-1 (and visualized by treatment with FTIC-labeled goat anti-rabbit IgG antibody), the fluorescence image obtained with a confocal microscope clearly indicates a uniform distribution of ZO-1 at intercellular junctions (Figure 8A). Interestingly, treatment of these cells with DPC (0.75 mM) appears to cause a redistribution of ZO-1 as indicated by discontinuous ZO-1 labeling (Figure 8B). Thus, DPC appears to affect the spatial distribution of ZO-1 in Caco-2 cells by inducing its dissociation from the plasma membrane.

Discussion

To date, numerous compounds have been evaluated and used as absorption enhancers for orally administered drugs.[3–20] These enhancers fall in one of two categories: Ca^{2+} chelators that act by reducing the extracellular Ca^{2+}

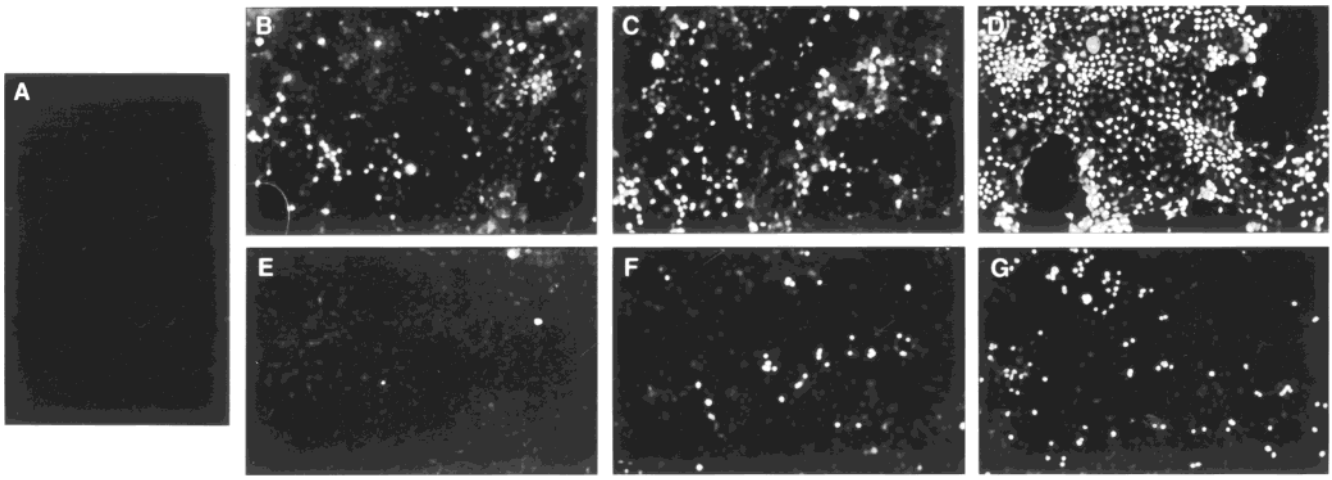

Figure 7—Effect of DPC treatment on the permeability of Caco-2 cells to propidium iodide. Caco-2 cells were treated with propidium iodide; control cells exclude propidium iodide and show no nuclear fluorescence (A). Cells were exposed for 20 min to 0.75 mM (B, E), 1.0 mM (C, F), and 1.5 mM (D, G) DPC. Propidium iodide was applied immediately after DPC treatment (B, C, D) or after DPC was removed and the cells were allowed to recover for 8 h (E, F, G). The frames are photographs of the images obtained by fluorescence microscope using 10x objective.

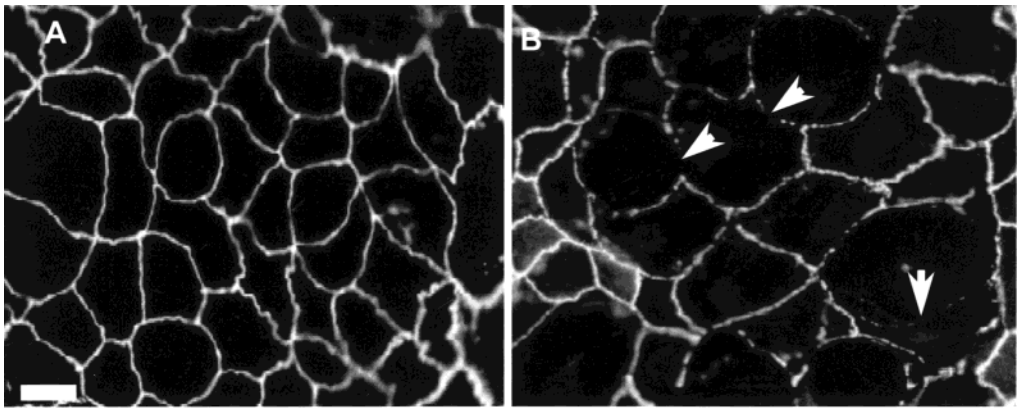

Figure 8—Effect of DPC treatment on the distribution of the tight junction-associated protein ZO-1 in Caco-2 cells. Untreated cells (A) or those treated with 0.75 mM DPC (B) were allowed to react sequentially with ZO-1 antibody and FITC-labeled anti-rabbit IgG as described in the Methods Section, and examined with a fluorescence confocal microscope. Bar = 50 μm.

concentration and thus compromising the integrity of the tight junctions, and detergents/surfactants that may act by causing a perturbation in the lipid bilayer of cell membrane as well as by a variety of intracellular mechanisms.[15–18,22,23] Among the latter class of compounds, PC has been one of the most extensively studied and used absorption enhancers. It appears to function by increasing the intracellular concentration of Ca^{2+} ions; however, the exact mechanism of its action is yet to be understood.[15,17] Also included in the latter class of compounds are phospholipid derivatives such as lysophosphatidylcholines[9,35,36] that appear to increase the permeability of peptides such as human growth hormone and a vassopressin derivative by unknown mechanism(s). These compounds have several features that make them particularly attractive as absorption enhancers. They occur in biological membranes as products of phospholipid metabolism[8,9] and are further metabolized to relatively nontoxic endogenous products. Furthermore, their absorption-promoting effects are spontaneously reversible upon their removal.

In the present study we have demonstrated that DPC, a zwitterionic amphiphile that lacks the glycerol moiety of lysophosphatidylcholine, is equally effective as the lysophosphatidylcholine LGPC in improving the permeability of hydrophilic compounds across Caco-2 cell monolayers. We have further showed that the presence of an (medium to long) alkyl chain and a zwitterionic functionality are essential for its activity. Thus, our studies have defined the minimum structural requirements of the phospholipid derivatives for their activity as absorption enhancers. It is interesting to note that while PC is a member of a different chemical class than phospholipids, its structural features essential for absorption-enhancing activity are quite similar to those for DPC; i.e., presence of an alkyl chain and a zwitterionic functionality (see Figures 1, 2). This is an important finding as the structures of DPC and PC can form the basis of a systematic structure–activity relationship that could lead to a more definitive information regarding the biochemical mechanism underlying their activity as absorption enhancers.

Our studies have shown that DPC, like PC, increases the permeability of the Caco-2 cell monolayers toward hydrophilic compounds predominantly by modulation of the tight junctions and not by disruption of the cell membrane. This was evidenced by a decrease in TEER and an increase in the permeability of paracellular markers (e.g., mannitol, LY, etc.) with no change in the permeability of the transcellular transport marker testosterone. While the cell membrane was rendered somewhat permeable to propidium iodide at high concentration of DPC, it was clear that DPC did not cause extensive damage to the cell membrane at the concentrations that caused significant decease in TEER and an increase in mannitol permeability. Furthermore, our evidence that DPC caused significant redistribution of the tight junction-associated protein ZO-1 (Figure 8) provided confirmation that this compound

increases the permeability of Caco-2 cell monolayers by modulation of the tight junctions.

Our results show that DPC causes a rapid decrease in TEER as has been observed for other agents that act via modulation of tight junctions, such as PC[15] and sodium caprate.[16] The decrease in TEER is more gradual and less extensive when DPC is applied from the basolateral side, suggesting that the effect on the apical side is due to modulation of the tight junctions directly or through perturbation in the apical membrane that is not as accessible from the basolateral side due to the presence of the tight junctions. The decrease in TEER and increase in the permeability of the paracellular markers caused by DPC was concentration dependent, with a sharp inflection occurring (for drop in TEER) between 0.5 and 0.75 mM concentration (Figure 3). The inflection did not correspond to a change in solution properties of DPC; for example, the critical micelle concentration (CMC) for DPC was found to be 0.96 mM. In fact, our results suggested that the effect on TEER was not related to the CMC of these agents, as CMC for PC was more than 1 order of magnitude lower (0.015 mM) than that for DPC despite their somewhat similar potency in causing a decrease in TEER. When the Caco-2 cell monolayers were exposed to DPC, LGPC, and PC at concentrations above CMC for 20 min and then washed, the TEER values rapidly decreased and the transport rates of mannitol were also significantly enhanced compared to the control (data not shown). These results suggest that the monomer and the micelle, at least for these agents, are both active as modulators of the tight junctions.

It has been shown previously[14] that treatment with paracellular enhancers such as EGTA or PC causes a greater enhancement in the permeability of anionic or cationic compounds than of the neutral molecules. Our results confirm this finding in that the permeability of anionic LY was enhanced to a greater extent than that of neutral mannitol by pretreatment of Caco-2 cell monolayers with DPC (Figure 4). As expected, the enhancement in the permeability of the larger neutral molecules (PEG-900 and PEG-3500) is much smaller than that achieved with a smaller neutral molecule like mannitol (Figure 4).

It is important that we are able to compare different absorption enhancers not only in terms of their potency in causing an increased transport of drug molecules, but also in terms of the separation between their potency as enhancers and their potency in causing cellular toxicity. Hence, we propose the use of the parameter PI (potency index) that is a ratio of IC_{50} and EC_{50}, where IC_{50} refers to the concentration that causes a 50% decrease in mitochondrial dehydrogenase activity (an indicator of cytotoxicity in MTT test) and EC_{50} refers to the concentration that causes 50% decrease in TEER with respect to untreated control. We have used TEER as a surrogate for permeability of a paracellular marker because it is an easy measurement and EC_{50} values for TEER relate well to the similar index for permeability of a paracellular marker.[28] While it has been reported frequently that a change in TEER does not parallel a change in the permeability of paracellular markers, when these effects are measured over a concentration range and expressed as relative change they do indeed relate well with each other as has been shown.[28] The potency index for DPC is 1.42; for LGPC, 1.29; for PC, 1.07; for SDS, 1.11; and for MGP, less than 0.22. The larger potency index would mean a better separation between the activity and cytotoxicity of an enhancer, and thus a greater potential for an agent to be useful as an absorption enhancer. DPC possesses better separation between activity (tight junction modulation) and cytotoxicity than all other absorption enhancers evaluated, although less than 2-fold separation is not adequate for safe use of such an agent as an absorption enhancer. Interestingly, for one of the more extensively used agent PC, the potency index is approximately 1, indicative of no separation between toxic and effective concentrations. Clearly, the relationship between such parameters obtained in vitro to the activity and toxicity of such agents in vivo needs be evaluated extensively before the in vitro parameters can be used to compare different enhancers. However, use of such parameters should make the comparison of enhancers more meaningful when they have been evaluated in different groups and in different model systems rather than reporting the activity at one or two arbitrary concentrations. The comparisons of the efficacy of absorption enhancers evaluated by different groups can be made even more meaningful if one of the enhancers is used as a reference compound so that the potencies of the other enhancers can be expressed in relation to the EC_{50} of the reference compound.

Abstract □ The oral route is the preferred route of delivery for a large number of drug molecules. However, the intestinal epithelium presents a formidable barrier for delivery of drugs into systemic circulation. Phospholipids are among compounds that enhance the absorption of drugs across the intestinal epithelium. In this paper, we describe structure–activity relationships for phospholipid derivatives as enhancers of paracellular permeability across Caco-2 cell monolayers. In a series of 2-alkoxy-3-alkylamidopropylphosphocholine derivatives, compounds with a long chain at C-3 (R_3) and short chain at C-2 (R_2) were potent in causing a decrease in transepithelial electrical resistance (TEER) and an increase in mannitol transport, but also showed significant cytotoxicity. Compounds with 9–11 carbons at C-3 and 6–10 carbons at C-2 provided good separation (up to 2.7-fold) between activity and cytotoxicity. Notably, a good correlation ($r^2 = 0.93$) was observed between EC_{50} (TEER) [concentration that caused a drop in TEER to 50% of its control (untreated) value] and $EC_{10\times}$ (mannitol) [concentration that caused 10-fold increase in mannitol transport over the control (untreated) value], confirming that a decrease in TEER is associated with enhanced permeability of the hydrophilic compounds across Caco-2 cell monolayers. Compounds with *medium to long carbon chains* at C-2 and C-3, *and* the total carbons in the alkyl chains > 20, showed poor activity and no cytotoxicity.

Introduction

The oral route is the preferred route of delivery for a large number of drug molecules. However, the intestinal epithelium presents a formidable barrier for delivery of many drugs into systemic circulation. Lipophilic drug molecules can cross this barrier by diffusion through the cell membranes, whereas small hydrophilic compounds diffuse through the intercellular space via the paracellular route. Some drugs can act as substrates for the carrier proteins present in the intestinal epithelium (e.g., amino acid, di/tripeptide, glucose, etc.), and are absorbed by a carrier-mediated active transport process. For those hydrophilic drugs that are likely to traverse the intestinal epithelium via the paracellular route, the intestinal barrier is particularly formidable because of the presence of the tight junctions that severely restrict the free passage of solutes through the paracellular space.[1,2] Hence, development of absorption enhancers that can improve the absorption of hydrophilic molecules via the paracellular route is an active area of research in many laboratories. To date, a large number of absorption enhancers with diverse chemical structures have been identified. These include bile salts, medium chain fatty acids, phospholipids, acyl carnitines, Ca^{2+} chelators, surfactants, and detergents.[3−23]

Among many compounds that can enhance the intestinal absorption of hydrophilic drug molecules, phospholipid-like agents with medium length fatty acid chains are of special interest, because they are ubiquitous in living organisms and are found in the membranes and membranous organelles of all living matter.[7] In two separate studies, formulations containing dodecanoylphoshatidylcholine achieved ~8−13% bioavailability (with respect to the iv bolus dose) of insulin after intranasal administration to healthy volunteers.[8,9] Lysophosphatidylcholine, containing a mixture of palmitoyl and stearoyl side chains, significantly increased the nasal absorption of human growth hormone in rats, rabbits, and sheep.[10] Palmitoyllysophosphatidylcholine[11] as well as its analogues[12] increased the permeability of poorly permeable vasopressin analogues across Caco-2 cell monolayers by almost 2 orders of magnitude. The increase in the permeability was achieved at concentrations of the enhancer that did not perturb the membrane significantly (trypan blue exclusion).[12] Lysophoshatidic acid caused a decrease in transepithelial electrical resistance (TEER) and an increase in sucrose flux across cultured brain capillary endothelial cells.[13] Our recent studies have shown that dodecylphosphocholine (DPC) can cause an increase in the permeability of hydrophilic compounds and a decrease in TEER across Caco-2 cell monolayers by modulation of the tight junctions.[14]

Very little information is available regarding the mechanism by which the phospholipid derivatives are able to enhance the absorption of drug molecules or the structural requirements for their activity. In vitro studies[11−14] suggest that these agents increase the paracellular permeability of compounds by modulation of the tight junctions. Studies with the brain endothelial capillary cells[13] suggest that such agents may alter the permeability of the tight junctions by intracellular mechanisms such as tyrosine phosphorylation of proteins at focal contact, recruitment of focal adhesion components, and activation of yet undefined signaling pathways. Our studies have shown that DPC displaces some of the tight junction (zonula occludens)-associated protein ZO-1 at a concentration that causes a decrease in TEER and an increase in paracellular perme-

ability across Caco-2 cells.[14] Our studies with DPC[14] have further suggested that the presence of a medium (or long) alkyl chain and a zwitterionic headgroup are essential for the activity of phospholipid-like agents as enhancers of paracellular permeability across Caco-2 cell monolayers. Similar requirements (i.e., alkyl chain and zwitterionic headgroup) for enhancement of paracellular permeability by structurally unrelated acyl carnitines[14,15] suggest the possibility of an emerging structure−activity relationship for enhancement of paracellular permeability across intestinal epithelium by modulation of tight junctions.

In this paper, we describe a more definitive and detailed study to delineate the structure−activity relationship for phospholipid-like agents as enhancers of paracellular permeability across Caco-2 cell monolayers. An excellent group of compounds for such a structure−activity relationship study is a series of 2-alkoxy-3-amidopropylphosphocholine derivatives[22] with varying lengths of alkyl chains at C-2 and C-3 positions. As proposed in our previous study,[14,23] we have applied the concept of potency index in developing the structure−activity relationship. Embedded in the potency index are two parameters—one reflecting the potency of the compounds as modulators of the tight junctions, i.e., transepithelial electrical resistance (TEER), and the other reflecting their potency in causing cytotoxicity by indiscriminate damage to the cell membrane (MTT test). We report here one of the first attempts to delineate the relationship between phospholipid structure and enhancement of paracellular permeability in relation to the cytotoxicity of this class of compounds.

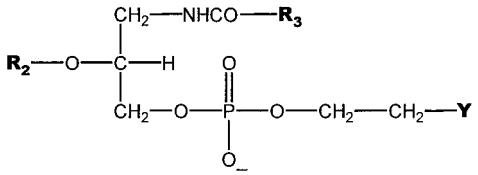
Materials and Methods

Materials—Caco-2 cells were purchased from American Type Culture Collection (Rockville, MD). Eagle's Minimum Essential Medium (EMEM), 0.25% trypsin/0.02% ethylenediaminetetraacetic acid−tetrasodium salt (EDTA-4Na), and fetal bovine serum (FBS) were obtained from Gibco (Grand Island, NY). Nonessential amino acids (NEAA), Hank's balanced salt solution (HBSS), antibiotic antimycotic solution, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), palmitoyl-DL-carnitine chloride, sodium dodecyl sulfate (SDS), DPC, 1-myristoyl-sn-glycero-3-phosphate sodium (MGP), 1-lauroyl-sn-glycero-3-phosphocholine (LGPC), 3-amino-1,2-propanediol, acyl chlorides, triphenylmethyl chloride, 60% sodium hydride (in oil), alkyl halides, *p*-toluenesulfonic acid monohydrate, and aqueous (40%) trimethylamine were purchased from either Sigma (St. Louis, MO) or Aldrich (Milwaukee, WI). *N*-(2-hydroxyethyl)piperazine-*N*′-2-ethanesulfonic acid (HEPES) was obtained through Tissue Culture Facilities (UNC at Chapel Hill, NC). Transwell plates and inserts (12 wells/plate, 3.0 μm pore and 1.0 cm^2 area, polycarbonate) were purchased from Corning-Costar (Cambridge, MA). [^{3}H]Mannitol was obtained from DuPont NEN (Boston, MA).

Caco-2 Cell Culture—Caco-2 cells were grown in EMEM containing 10% FBS, 1% l-glutamine, 1% NEAA and antibiotics (100 U/mL of penicillin, 100 μg/mL of streptomycin, and 0.25 μg/mL of amphotericin B) in 75 cm^2 culture flasks. The cultures were kept at 37 °C in an atmosphere of 5% CO_2, 95% air, and 90% relative humidity. Cells were passaged after 95% confluency and were seeded with a density of 1.0×10^5 cells/mL on to porous polycarbonate filter membranes with a pore size of 3.0 μm and a surface area of 1.0 cm^2. Cells of passage number 45−55 were used in all the studies. Media were changed every 2 days after seeding until late confluence (20−22 days). Just before the experiments, the culture medium was replaced with HBSS transport buffer (HTB) that contained 1x HBSS, 25 mM HEPES, and 25 mM glucose at pH 7.4 and incubated for 1 h at 37 °C. The cell monolayers with TEER values in the range of 600−800 Ω·cm^2 were used for the experiments.

General Chemical Methods—Compounds **1**−**12** (Table 1) were synthesized as described previously.[24,25] Briefly, 3-amino-1,2-propanediol was reacted with various acyl chlorides to give the corresponding (alkylamido)propanediols. The primary hydroxyl group was selectively protected as the trityl ether with triphenylmethyl chloride in pyridine. Reaction of the secondary hydroxyl with sodium hydride and various alkyl halides gave the C2 alkyl ether. Deprotection of the primary hydroxyl group with *p*-toluenesulfonic acid in CH_2Cl_2/MeOH gave the 3-alkylamido-2-alkoxy-1-propanol. The phosphocholine was formed in two steps: (1) reaction with 2-bromoethyl dichlorophosphate and (2) amination with aqueous trimethylamine in $CHCl_3$/*i*-PrOH/DMF. Confirmation of chemical structure and determination of purity of the compounds have been reported.[26,27]

Table 1—Structures of 2-Alkoxy-3-alkylamidopropylphosphocholines



group	enhancers	R_3	R_2	Y
I	**1**	$C_{17}H_{35}$	CH_3	$N(CH_3)_3$

	11	C_9H_{19}	$C_{12}H_{25}$	$N(CH_3)_3$
	12	$C_{11}H_{23}$	$C_{12}H_{25}$	$N(CH_3)_3$

The stock solutions of phospholipids (80 mM) were obtained by dissolving them in HBSS/ethanol (20:80, v/v) and were stored at −20 °C. Just before the experiments, the phospholipid solutions were thawed and diluted to the appropriate concentrations with HTB (final ethanol concentrated up to 2% v/v) and sonicated for 5 min in an ice bath.

Cytotoxicity Assay—The cell viability was measured by the MTT assay.[26,27] Approximately 3.0×10^3 Caco-2 cells (in 100 μL of cell culture medium) were seeded into each of the wells in a 96-well tissue culture plate (Corning-Costar, Cambridge, MA). The cells were then cultured under the same condition (see Caco-2 Cell Culture) for 96 h, and the culture medium was changed once. Just prior to the start of each experiment, the medium was removed from the wells, and 100 μL of the compound solution in HTB was added to each well. After 20 min, 20 μL of a 5 mg/mL MTT solution was added to each well, and the cells were incubated for another 90 min. Then 100 μL of 10% SDS in 0.02 M HCl/isobutanol (1:1, v/v) solution was added to stop the reaction. The cells without the treatment of any compound were harvested as above and were used as controls. Absorbance was measured at 590 nm (indicative of the formation of the formazan product by mitochondrial dehydrogenase of the viable cells) using a multiwell scanning spectrophotometer (Bio-Rad, Hercules, CA). IC_{50} represented the concentration of the phospholipid derivatives that caused 50% cell death as measured by the mitochondrial dehydrogenase activity.

EC_{50} (TEER) Determination—To measure the effect of the phospholipids on the TEER values of Caco-2 cell monolayers, the test compounds, dissolved in 0.5 mL of HTB at various concentrations, were applied to the apical side. The monolayers were treated for 20 min at room temperature and the TEER measured using an Epithelial Tissue Voltohmmeter (EVOM, World Precision Instruments, Sarasota, FL) and calculated as Ω·cm^2 by multiplying it with the surface area of the monolayer (1.0 cm^2). The resistance due to the cell monolayers was determined after subtracting the contribution of the blank filter and HTB. From the data, EC_{50} for TEER, the concentration at which the phospholipid decreases the TEER of cell monolayer by 50% of the control (untreated) value, was calculated.

Transport Experiments—All transport studies were performed at room temperature on filter-grown Caco-2 monolayers. The transport experiments were carried out under sink conditions such that the concentration of the transported compound in the

receiver compartment was less than 10% of its initial concentration in the donor compartment. Permeability coefficients (P_{app}) were calculated using the following equation:

$$P_{app} = (dQ/dt)\ (1/A)\ (1/C_o)$$

where dQ/dt (mol transported/s) is the flux of the marker compound across the Caco-2 cell monolayer, A (cm^2) represents the diffusional area of the inserts, and C_o (M) denotes the initial concentration of marker compound in the donor compartment. All measurements were in triplicate and expressed as mean ± SD values.

Transport without the Tight Junction Barrier—To evaluate the maximum transport rate of mannitol without the functional barrier of epithelial tight junctions, EDTA was used to open up the tight junction completely.[28] A solution of EDTA at concentration range of 0.001 mM to 15 mM was prepared using HTB without Ca^{2+}/Mg^{2+}. The solution was applied to the apical and basolateral sides of cell monolayer for 30 min. Then the solution was removed, and the cells were washed once with HTB without Ca^{2+}/Mg^{2+}. [^{3}H]-Mannitol (0.5 mL of 0.1 mM, 0.25 μCi) was added to the apical compartment, and the transport rate was determined by measuring the radioactivity (PACKARD 1600 TR liquid scintillation counter, Downers Grove, IL) appearing in the basolateral compartment as a function of time.

Absorption Enhancement—To calculate the compound concentration at which the permeability of mannitol is increased by 10-fold [$EC_{10\times}$ (mannitol)], the compound solution at concentration range of 0.05 to 5.0 mM in HTB (0.5 mL) was added to the apical side of the cells. HTB (1.5 mL) was added to the basolateral side. After treatment for 20 min, the lipid solution was removed and the monolayer was washed once with fresh HTB. Following the measurement of the TEER, 0.5 mL of HTB solution containing 0.1 mM [^{3}H]mannitol (0.25 μCi) was applied to the apical side. Samples from the basolateral side were taken at 10, 20, 40, and 60 min. Transport rates were determined by measuring the radioactivity in the basolateral side by liquid scintillation counter.

Results

Previous studies with two structurally distinct compounds, i.e., DPC and PC, have shown that the minimum structural requirements to cause a decrease in TEER and a corresponding increase in paracellular permeability across Caco-2 cells are (i) the presence of a medium to long alkyl chain and (ii) a zwitterionic group.[14,15] The same structural features may also confer a similar activity to phospholipid derivatives.[7−12,14] Here we report the effect of varying the length of alkyl chains at C-2 and C-3 positions of phospholipid derivatives on TEER, paracellular permeability across Caco-2 cell monolayers, and cytotoxicity to these cells.

Effect of Synthetic Phospholipid Derivatives on TEER and Paracellular (mannitol) Permeability across Caco-2 Cells—The chemical structures of the 2-alkoxy-3-alkylamidopropylphosphocholines studied are shown in Table 1. The effect of these compounds on TEER across Caco-2 cell monolayers was determined by exposing the cells to various concentrations of these agents on the apical side for 20 min prior to the measurement of TEER. The time of exposure was determined based on our studies with DPC which showed that maximal effect on TEER was achieved in 20 min.[14] Under these conditions, the mannitol permeability across Caco-2 cell monolayers was also determined. The typical TEER−concentration profiles as well as mannitol permeability−concentration profiles observed are shown in Figure 1. Based on the TEER/mannitol permeability−concentration profiles, the synthetic ether phospholipids were classified into three groups. Compounds in group I (**1**−**4**, Table 1) caused a precipitous drop in TEER and a steep rise in mannitol permeability with concentration (e.g., compound **2**, Figure 1A). These compounds are

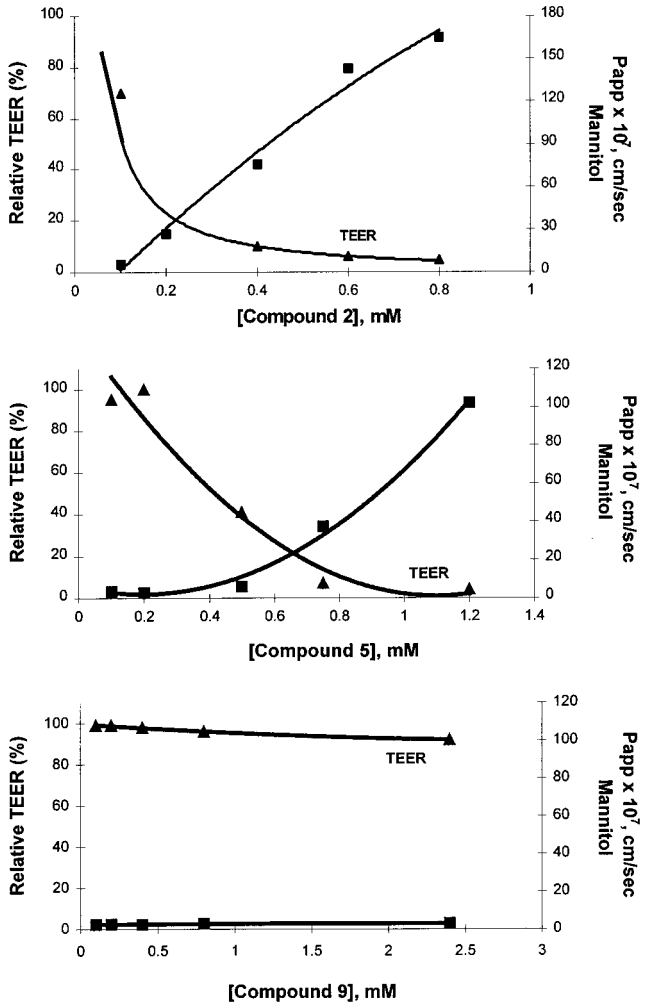

Figure 1—Effect of concentration on TEER and mannitol permeability for 2-alkoxy-3-alkylamidopropylphosphocholines. A, compound **2**; B, compound **5**; C, compound **9**. ■, mannitol permeability; ◆, TEER. Compounds were applied to the apical side of the monolayers for 20 min at room temperature.

characterized by a short alkyl chain (1−2 carbons) as the R_2 substituent and a long alkyl chain (16−19 carbons) as the R_3 substituent. In contrast, compounds in group II (**5**−**8**, Table 1) caused a more gradual decrease in TEER and increase in mannitol permeability with concentration (e.g., compound **5**, Figure 1B). These compounds contain medium length alkyl chains as the R_2 (6−10 carbons) and R_3 (9−11 carbons) substituents, with the total carbons in both the alkyl chains < 20. Compounds in group III (**9**−**12**, Table 1) had little or no effect on TEER or mannitol permeability over the concentration range examined (e.g., compound **9**, Figure 1C). These compounds contain a medium length alkyl chain as the R_2 substituent (8−12 carbons) and a medium to large alkyl chain as the R_3 substituent (9−17 carbons) with the total number of carbons in both alkyl chains > 20.

For comparison, the effect of EDTA, a known modulator of paracellular permeability via tight junction modulation,[28] on TEER and mannitol permeability is shown in Figure 2. The mannitol permeability reached a plateau at high concentrations of EDTA; no such plateau was reached with 2-alkoxy-3-alkylamidopropylphosphocholines (Figures 1 and 2). The compounds in groups I and II appear to be more potent than EDTA in causing a drop in TEER and an increase in the mannitol permeability across Caco-2 cell monolayers.

Comparison of the Effect of Synthetic Phospholipids on TEER and Mannitol Permeability across

	12	no effect	ND	no effect	–

[a] Values of EC_{50} (TEER), $EC_{10}\times$ (mannitol) and IC_{50} (MTT) are expressed as mM; the numbers in parentheses indicate SD. [b] PI: the ratio of IC_{50}/EC_{50} based on the data from Caco-2 cells. [c] ND: not detectable because of the insolubility of the lipids at higher concentrations.

Caco-2 Cells—To express the effect of these compounds on TEER and paracellular permeability quantitatively, we have defined the terms EC_{50} (TEER)[14] and $EC_{10\times}$ (mannitol).[22] EC_{50} (TEER) is the concentration of an enhancer at which TEER drops to 50% of its control value (untreated cells), and $EC_{10\times}$ (mannitol) is the concentration at which mannitol permeability is increased by 10-fold over the control value (untreated cells). In case of mannitol permeability, the term $EC_{10\times}$ was defined instead of EC_{50} because the plateau in the mannitol permeability was not always easy to obtain (see Figure 1); hence, a percentage of maximal effect could not always be determined. Furthermore, 10-fold increase in mannitol permeability over the control value ($\sim 2.5 \times 10^{-7}$ cm/s) represented 50% of the maximal mannitol permeability (25×10^{-7} cm/s) obtained by opening up the tight junctions with EDTA (Figure 2). The EC_{50} (TEER) and $EC_{10\times}$ (mannitol) for the synthetic phospholipids are shown in Table 2. By both these parameters, the compounds in group I were the most potent phospholipid derivatives tested, the compounds in group II showed moderate potency, and those in group III were weakly active or inactive.

The relationship between the EC_{50} (TEER) and the EC_{10x} (mannitol) is shown in Figure 3. Clearly, an excellent correlation exists between the EC_{10x} (mannitol) values and the EC_{50} (TEER) values. Hence, EC_{50} (TEER) can serve as a reliable index of the potency of the compounds as enhancers of paracellular permeability if the data on mannitol permeability are not available.

Interestingly, at their EC_{50} concentrations, the changes in TEER and mannitol transport caused by group II compounds were reversible. After removal of the compounds and recovery of the cells in complete cell culture medium (10% fetal calf serum, 1% NEAA in EMEM) for 2 h, the decreased TEER and the enhanced mannitol transport returned to their initial values (approximately 85–95% TEER recovery and 90–95% recovery of mannitol permeability). However, on similar treatment of the cell monolayers with group I compounds, the TEER and mannitol transport values did not recover, indicating that tight junction integrity cannot be restored after exposure of the cells to group I compounds.

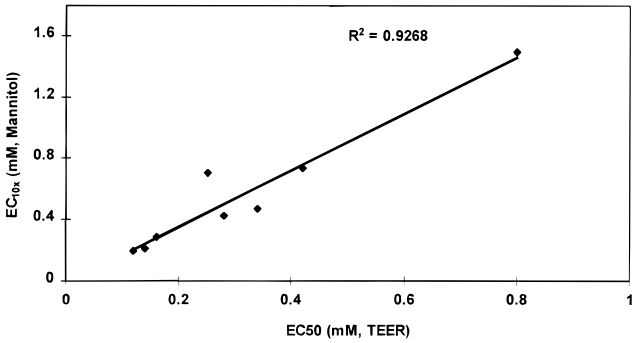

Figure 3—Relationship between EC_{50} (TEER) and EC_{10x} (mannitol) for 2-alkoxy-3-alkylamidopropylphosphocholines. EC_{50} (TEER) and EC_{10x} (mannitol) have been defined in Materials and Methods.

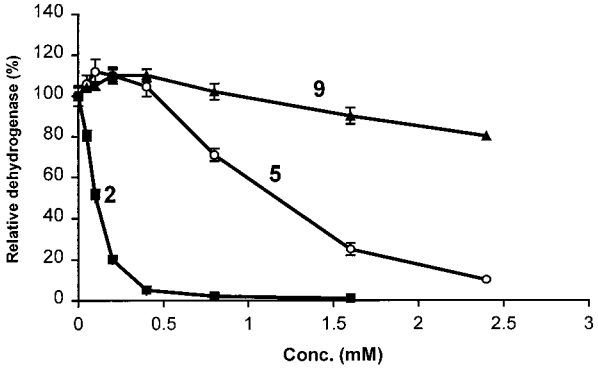

Figure 4—Relationship between concentration and mitochondrial dehydrogenase activity (MTT) for 2-alkoxy-3-alkylamidopropylphosphocholines that are typical of three groups of compounds within this series. All measurements were in triplicate and expressed as mean ± SD.

Cytotoxicity of the Synthetic Phospholipids—To evaluate cytotoxicity of the synthetic phospholipids toward Caco-2 cells, the viability of the cells was evaluated using the MTT method.[26,27] MTT is a tetrazolium salt that is cleaved by mitochondrial dehydrogenase in living cells to give a dark blue formazan product. Damaged or dead cells show reduced or no mitochondrial dehydrogenase activity. Cytotoxicity of compounds **2**, **5**, and **9**, representing the compounds in groups I, II, and III, respectively, as a function of their concentration is shown in Figure 4. The toxicity of these compounds is expressed as IC_{50}, which is defined as the concentration at which the compounds caused 50% decrease in mitochondrial dehydrogenase activity in the MTT test. The IC_{50} values of all the compounds tested are given in Table 2. Among the three compounds shown in Figure 4, compound **2** was most cytotoxic ($IC_{50} = 0.11$ mM), compound **5** showed moderate cytotoxicity (IC50 = 1.1 mM), and compound **9** did not show any toxicity even at the highest concentration (2.5 mM) tested. The cytotoxicity of compounds **2**, **5**, and **9** was representative of the cytotoxicity exhibited by compounds in their respective groups.

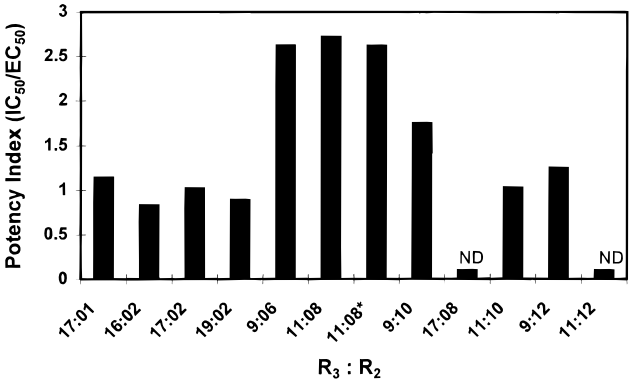

Figure 5—Relationship between R2 and R3 substituents in 2-alkoxy-3-alkylamidopropylphosphocholines and the potency index, PI [IC_{50}/EC_{50}(TEER)]. The compounds are in numerical order (**1** to **12**) from left to right. *The trimethylammonium group is separated from the phosphate group by a three-carbon chain instead of a two-carbon chain

Discussion

A decrease in TEER and an increase in mannitol permeability across Caco-2 cell monolayers caused by 2-alkoxy-3-alkylamidopropylphosphocholines suggest that this class of compounds has the potential to act as absorption enhancers. Their effect on TEER and mannitol permeability suggests that they are acting via modulation of the tight junctions; however, the evidence is entirely circumstantial. In a previous study,[14] we had presented evidence that a long alkyl chain and a zwitterionic functionality are essential for the activity of such compounds as modulators of paracellular permeability. In the present study, we have examined a limited structure−activity relationship (2-alkoxy-3-alkylamidopropylphosphocholines) that provides more insights on the effect of branching of the alkyl chain on the activity (as enhancers of paracellular permeability) and toxicity of phospholipid derivatives. The branching is not achieved with branched alkyl chains, but rather by introducing an ether functionality at C-2 and an amido functionality at C-3 of a propylphosphocholine.

Surprisingly, introduction of a small alkyl group at the C-2 position (R_2) significantly enhanced the potency of phospholipids in causing a decrease in TEER and an increase in mannitol permeability across Caco-2 cell monolayers. For example, the EC_{50} (TEER) value of compound **2** (0.12 mM) was 3.5- to 5-fold lower than the previously reported values for PC (0.42 mM), DPC (0.65 mM), or LGPC (0.65 mM). Unfortunately, this structural feature also caused the phosphocholine derivatives to be more potent cytotoxic agents. Thus the IC_{50} value for compounds **2** (0.11 mM) is much lower than that for PC (0.45 mM), DPC (0.92 mM), and LGPC (0.84 mM).[14] Increasing the length of C-2 alkyl chain to 6−8 carbon atoms while simultaneously decreasing the length of C-3 alkyl chain caused a decrease in the potency of the compounds as modulators of the paracellular permeability with a concurrent decrease in cytotoxicity. Finally, further increase in the length of the C-2 or C-3 alkyl chains rendered the compound inactive.

In developing a structure−activity relationship for paracellular permeation enhancers, the potency of these agents must be addressed in relation to their cytotoxicity. Hence, we have defined the term potency index (PI), which is a ratio of the IC_{50} (MTT) value of a compound to its EC_{50} (TEER) value.[14,22] For the synthetic phospholipid derivatives, the PI values are listed in Table 2 and plotted in Figure 5. Clearly, for all compounds having a short alkyl chain at C-2 (group I), the PI value is ∼1; i.e., the concentration at which they can exhibit enhancement in paracellular permeability is very similar to the concentration at which they are cytotoxic. In contrast, the compounds in group II, with medium length alkyl chains at C-2 and C-3 (total carbons < 20), have PI values in the range of 1.75−2.72 and achieve the best separation of activity as paracellular permeation enhancer and cytotoxicity among all the compounds tested including those tested in our previous study.[14] This PI range is significantly greater than that for the extensively investigated enhancer PC (PI ≅ 1). Compounds **6** and **7** exhibit comparable PI values despite the fact that their cationic and anionic centers are separated by two and three carbons, respectively. Thus a small change in the distance between the cationic and the anionic centers does not lead to any change in activity or toxicity. Some compounds in group III (medium to long alkyl chains at C-2 and C-3 *and* total carbons > 20) have PI values of approximately 1, whereas others are too inactive to determine either the EC_{50} or the IC_{50} value.

In conclusion, with this limited series of compounds, we have been able to demonstrate that the structure−activity (modulation of paracellular permeability) relationship for synthetic phospholipid derivatives is distinct from the structure−toxicity relationship. Interestingly, the separation of activity and toxicity is most pronounced (>2.5-fold) for moderately active compounds, while the activity and the toxicity appear to converge among the more potent compounds. Hence, further assessment of the structure−activity relationships should focus on phospholipid derivatives with medium-size alkyl substituents at C-2 and C-3. The relationship between relative position and distance of the anionic and cationic centers and the activity/toxicity should be further explored.

Abstract □ The aqueous interaction of the sodium salt of ibuprofen with the cellulose ethers ethyl hydroxyethyl cellulose, EHEC, and hydroxypropyl methyl cellulose, HPMC, has been investigated in the concentration range 0–500 mM ibuprofen and 0.1–1% (w/w) polymer, by cloud point, capillary viscometry, equilibrium dialysis, and fluorescence probe techniques. Ibuprofen forms micelles in pure water, with the critical micelle concentration, cmc, at 180 mM. A combination of time-resolved and static fluorescence quenching shows that micelle-like ibuprofen aggregates are formed in the solution. The average aggregation number of pure ibuprofen micelles in water is about 40. In the presence of EHEC or HPMC the aggregation numbers decrease. The interaction of ibuprofen with cellulose ethers is similar to the normally accepted model for polymer–surfactant interaction, although more complex. Ibuprofen adsorbs to the polymer in the form of mixed polymer–drug micelles, noncooperatively up to cmc and cooperatively when cmc is passed. The interaction starts below 50 mM ibuprofen as monitored by the fluorescent probes pyrene and 1,3-di(1-pyrenyl)-propane, P3P, with a maximum in microviscosity below cmc, corresponding to polymer-dense mixed micelles. The study illustrates the importance of a precise apprehension of the aggregation behavior as a background for transport studies in drug–polymer systems.

Introduction

Amphiphilic molecules are characterized by the presence of both polar and nonpolar regions of the same molecule. This dual nature is responsible for the surface activity of these substances leading to accumulation at hydrophobic interfaces and formation of aggregates. Many types of drug molecules, such as antihistamines, antidepressants, tranquilizers, local anesthetics, and nonsteroidal antiinflammatory drugs (NSAIDs) are known to be amphiphilic in character and to form ordinary micelles or micelle-like associations[1] above a critical concentration value. Although the self-association of surface active drugs usually occurs at concentrations well above average therapeutic levels, the local concentration can reach, under certain circumstances, high values, for instance when the drug is instantaneously released from a tablet or accumulated at a membrane.

Cellulose derivatives play an important role in many technical applications and especially in the pharmaceutical field[2,3] where they have several uses such as to regulate the rheology of a system and to control the release of the drug. These polymers have an amphiphilic structure with mixed hydrophilic/hydrophobic segments, thus leading to an apparent surface activity the magnitude of which depends on type and degree of substitution.[4]

The interaction between polymers and surfactants in aqueous solution has attracted great interest during the last 20−30 years, and the topic has recently been reviewed.[5] As a prerequisite for a better understanding of polymer−drug interaction there has in this laboratory been a specific focus on the interaction of nonionic cellulose derivatives and the common anionic surfactant sodium dodecyl sulfate, SDS, in dilute aqueous solutions.[6−8] It has been shown that the surfactant forms interaction complexes with the polymer in a cooperative manner, giving rise to formation of a three-dimensional polymer network where mixed micelles of surfactant and polymer act as connecting tie points.

Since a surface active drug can form micelles by itself or bind hydrophobically to membranes, proteins, or other biological macromolecules as well as associate with hydrophobic excipients present in pharmaceutical formulations, all these types of associations may affect the release of the drug and alter the therapeutic effect.

The present paper deals with the general problem of the aqueous association of surface active drugs and polymers. The sodium salt of ibuprofen is an NSAID which is surface active[9] and was chosen as model substance, due to its, contrary to normal surfactants, high critical micelle concentration (180 mM) and hence a wider molar concentration interval of interest for the buildup of the interaction. Previous studies of NSAIDs have reported on dissolution properties,[10−12] solubility behavior,[13] release,[14] and other thermodynamic properties[12,15] of the drugs. In this work we have studied the association behavior in aqueous solutions between ibuprofen and two nonionic cellulose derivatives ethyl hydroxyethyl cellulose, EHEC, and hydroxypropyl methyl cellulose, HPMC. These two cellulose ethers are well-characterized materials[16] and represent polymers of different hydrophobicity. Both macroscopic and microscopic system properties are presented. The results will furthermore be discussed and compared in close relation to previous knowledge about the features of the corresponding polymer/SDS complexes.

Materials

The ethyl hydroxyethyl cellulose (EHEC) fraction CST-103, $DS_{ethyl} = 1.5$, $MS_{ethylene\ oxide} = 0.7$, was obtained from Akzo Nobel AB, Stenungssund, Sweden. The hydroxypropyl methyl cellulose (HPMC) fraction Methocel E4MCR was obtained from Pharmacia and Upjohn, Stockholm, Sweden. The sodium salt of ibuprofen (α-methyl-4-[isobutyl]phenylacetic acid), 9-methylanthracene, 98% (9-MA), and tris(2,2′-bipyridyl)ruthenium(II) chloride ($Ru(bipy)_3^{2+}$) were bought from Sigma-Aldrich Chemie, Steinheim, Germany, and used as supplied. Pyrene (+98%), Janssen Chimica, Geel, Belgium, was recrystallized twice from absolute ethanol prior to use. 1,3-Bis-(1-pyrenyl)propane (P3P) was bought from Molecular Probes, Eugene, OR, and used as supplied. Analytical grade NaCl was obtained from Merck, Darmstadt, Germany. The standard

procedure for producing an EHEC or HPMC stock solution is presented elsewhere.[6] After preparation, the stock solutions were rinsed from low molecular weight material and salts using a Spectra/Por tube dialysis membrane, Spectrum Medical Ind., Houston, TX, with molecular weight cut off at 12 000−14 000. Dialysis was performed against Milli Q water (Millipore) during 1 week, and then the stock solutions were centrifugated at 20 000 rpm. The polymer concentrations of these stock solutions were determined gravimetrically by drying samples to constant weight at 105 °C. All polymer/ibuprofen solutions were prepared using Milli Q water as solvent. The pH of all solutions containing ibuprofen was close to 7.0. The pK_a of the corresponding acid of ibuprofen is about 4.6. It is thus taken that the sodium salt of ibuprofen is quantitatively ionized. To achieve appropriate concentrations of the very hydrophobic substances P3P and 9-MA, these substances were dissolved in absolute acetone of which aliquots were dissolved in the solutions to be measured by fluorescence.

Experimental Section

Cloud Point—The cloud point of polymer/ibuprofen solutions was determined visually in glass tubes and taken as the temperature when the last visible sign of clouding in the solution disappeared upon cooling.

Capillary Viscometry—The viscosity measurements were performed in ordinary Ostwald viscometers with a water flow time of approximately 100 s at 20 °C. The samples were thermostated in a Lauda CD 20 water bath for 15 min prior to measurements. Corrections for capillary and end effects were considered unnecessary.

Equilibrium Dialysis—The equilibrium dialysis experiments were performed in order to determine the adsorption isotherm of ibuprofen onto the cellulose ethers. The dialysis cell used consists of two compartments of 2 mL volume each, separated by a dialysis membrane (Spectra/Por with a M_w-cutoff of 12 000−14 000) according to the principle developed by Fischman and Eirich.[17] The polymer solution was placed on one side of the dialysis membrane, and a water solution on the other side, both sides with equal ibuprofen concentrations at the start. The cells were maintained at 20 °C for one week, and the ibuprofen concentrations on both sides of the membrane were determined spectrofotometrically at 273 nm ($\epsilon = 256.5\ M^{-1}\ cm^{-1}$). Kinetic studies showed that 6 days were needed to reach equilibrium. Since the ternary system EHEC (CST-103)/ibuprofen/water shows phase separation at 20 °C in the ibuprofen concentration range ≈120−200 mM, cf., Figure 1, dialysis experiments on this system were also performed at 10 °C in order to confirm the adsorption isotherm to be correct. The equilibrium ibuprofen concentration not bound to the polymer ($[ibu]_{eq}$), the amount of ibuprofen bound to the polymer (y, in mmol/g polymer), and the total ibuprofen concentration ($[ibu]_{tot}$) can then be calculated. Since the system studied is salt-free, a correction for the Donnan effect has been made as described previously.[6] The mass balance equation then becomes

$$[ibu]_{tot} = [ibu]_{eq} + c_p y \quad (1)$$

where c_p is the polymer concentration in grams per liter. This methodology has been utilized in several recent investigations of interactions in aqueous mixtures of the surfactant sodium dodecyl sulfate and nonionic cellulose ethers.[6,7,18−22]

Steady-State Fluorescence Measurements—All steady-state fluorescence measurements were performed at room temperature on a SPEX Fluorolog 2 model FL1T2 spectrometer operated in the "s" mode with 1.88 nm excitation and 0.85 nm emission bandwiths. All fluorescence measurements including time-resolved were run in duplicates, and the error was ±5% or less. The fluorescent probe concentrations were about 10^{-6} M. The concentration of the quencher 9-MA was ≤ 10^{-4} M.

Emission spectra were recorded for pyrene excitation at $\lambda = 334$ nm. The first (I_1, $\lambda = 374$ nm) to third (I_3, $\lambda = 388$ nm) emission intensity peak height ratio (I_1/I_3, the micropolarity index) of the vibrational emission spectrum of pyrene is a qualitative measure of the micropolarity at the probe solubilization site.[23] The micropolarity index is at most 2.0 in pure water and 1.0 in hydrophobic solvents such as toluene. It has been shown[23] that I_1/I_3 suddenly drops when the critical micelle concentration (cmc) is passed since pyrene quantitatively distributes to the more hydrophobic micellar phase if present. Micropolarity measurements with pyrene have been utilized in several papers from this laboratory on ternary surfactant/cellulose ether/water systems.[7,8,22,24]

P3P consists of two pyrene molecules connected by a propane chain, making this fluorescent probe capable of forming intramolecular excimers. Emission spectra were recorded between $\lambda = 350$ nm and $\lambda = 500$ nm for P3P excitation at $\lambda = 348$ nm. The extent of intramolecular excimer formation of P3P is dependent on the local friction of the probe imposed by its surroundings.[25] Hence, the monomer (I_M, $\lambda = 377$ nm) to excimer (I_E, $\lambda = 485$ nm) emission intensity peak ratio, I_M/I_E, is a qualitative index of the microviscosity at the probe solubilization site. P3P have been used in this laboratory to measure the microviscosity in polymer−surfactant systems,[8,24,26] and the method has been validated by NMR relaxation measurements.[27]

Time-Resolved Fluorescence Measurements—Time-resolved fluorescence measurements were recorded on a Photon Technology International model C-72 apparatus, equipped with a pulsed GL 3300 nitrogen laser/GL 320 dye laser as light source. Time-resolved fluorescence quenching, TRFQ, was used here in combination with steady-state fluorescence quenching, SSFQ, to measure the average aggregation number, the average number of ibuprofen monomers per aggregate or micelle, in aqueous solution. $Ru(bipy)_3^{2+}$ was used as probe and 9-MA as quencher. The fluorescence decay or steady-state luminescence of $Ru(bipy)_3^{2+}$ was recorded at $\lambda = 625$ nm for excitation at $\lambda = 450$ nm. In TRFQ experiments the decay was recorded up to 1000 ns. The concentration of 9-MA was determined spectrofotometrically at $\lambda = 388$ nm. Fluorescence decay curves were recorded for each sample both in the presence and absence of quencher. The lifetime of $Ru(bipy)_3^{2+}$ in solutions without quencher, τ_0, was determined by fitting the decay to a single-exponential function. Suggested by Infelta et al.[28] and proved by Tachiya,[29] the time evolution of the quenched fluorescence decay signal $F(t)$ from an ensemble of probe molecules situated in small monodisperse micelles can be expressed by

$$F(t) = A_1 \exp[-A_2 t + A_3\{\exp(-A_4 t) - 1\}] \quad (2)$$

If the probe and quencher can be considered as stationary within the micelle during the time of activation−deactivation, and a Poisson distribution of the quencher among the micelles is assumed, the parameters A_i in eq 2 take the simple forms

$$A_1 = F(0) \quad (2.1)$$

$$A_2 = 1/\tau_0 \quad (2.2)$$

$$A_3 = \langle n \rangle \quad (2.3)$$

$$A_4 = k_q \quad (2.4)$$

where k_q is the quenching rate constant, $F(0)$ the decay intensity signal at time zero, and $\langle n \rangle$ the average number of quencher molecules per micelle. Since the quencher concentration, [Q], is known, the average aggregation number, N, can be calculated by

putting

$$N = \langle n \rangle ([\text{ibu}]_{\text{tot}} - \text{cmc})/[\text{Q}] \quad (3)$$

where $[\text{ibu}]_{\text{tot}} - \text{cmc}$ represents the molar concentration of ibuprofen monomers constituting the aggregates, taken that all ibuprofen exceeding cmc are incorporated in micelles. In SSFQ the micellar concentration in the solution, denoted [micelles], is obtained from the relationship[30]

$$\ln(I^{\circ}/I) = [\text{Q}]/[\text{micelles}] \quad (4)$$

where I° and I are the steady-state luminescence in absence and presence of quencher, respectively. The mean aggregation number is then simply calculated by putting

$$N = ([\text{ibu}]_{\text{tot}} - \text{cmc})/[\text{micelles}] \quad (5)$$

SSFQ works well if there is no migration between probe and quencher and if the quenching is efficient. This is the case if an efficient probe-quencher pair is employed that distributes quantitatively to the micelles, and if the aggregation numbers to be determined are small, ≤ 120.[31] TRFQ showed no sign of migration between probe and quencher for any of the solutions investigated, as the semilogarithmic decay curves with and without added quencher at longer times were parallel, that is, equations 2:1−4 are valid. The quenching rate constant was in all cases larger than 3×10^7 s^{-1}. The use of TRFQ thus monitors the presence of micelle-shaped clusters, or aggregates of finite sizes, which can be considered as zero-dimensional entities as monitored by fluorescence quenching. Since the concentration of micelles in the solutions is high—up to 10 mM—compared to the highest quencher concentration that can be used practically, which is $\leq 5 \times 10^{-4}$ M, the effect of added quencher is quite small. Therefore the aggregation numbers presented here were finally determined by SSFQ since fitting a quenched decay time curve by global analysis only with very low $\langle n \rangle$ available gives a higher error than using steady-state luminescence, which has a very high signal-to-noise ratio.

Results and Discussion

A characteristic feature of nonionic cellulose ether/water systems is the existence of reversible phase separation including a lower critical solubility temperature, LCST, also denoted cloud point, CP, above which the solution becomes "cloudy". At the CP the polymer precipitates out of solution as a consequence of equal chemical potentials between two phases, one richer in polymer, of solute and solvent, respectively.[32] Thus CP provides a simple and powerful tool for qualitative characterization of the polymer thermodynamics in systems with LCST behavior and their interactions with low molecular amphiphiles. A more hydrophobic cellulose ether will have a lower CP than a more hydrophilic one. The EHEC fraction CST-103 in this study is more hydrophobic than the HPMC fraction as can be seen in Figure 1, where CP is plotted as a function of the ibuprofen concentration. The CP values for the binary 0.1% EHEC/water and 0.1% HPMC/water systems are 29 and 45 °C, respectively. When ibuprofen is added, the systems diverge even more. The CP of HPMC increases with increasing ibuprofen concentration, slowly at first, and with an increasing positive derivative in the ibuprofen concentration range 150−200 mM. The EHEC fraction on the other hand has an unaffected CP up to 80 mM ibuprofen and then passes through a minimum at 150 mM whereafter CP increases steeply. Both polymers thus interact with ibuprofen which at higher drug concentrations markedly increases the solubility of the polymers. The reason for this is the formation of a micellar ibuprofen phase into which the polymers solubilize their hydrophobic parts. Similar CP curves have been reported for these cellulose ethers in the presence of sodium dodecyl sulfate, SDS.[20,33] From these CP data a rough estimate of cmc of ibuprofen in the presence of the polymer fractions can be made; its value is found to be about 150−200 mM for both EHEC and HPMC. The minimum in CP observed for the EHEC/ibuprofen system is most likely a salting-out effect due to a combination of a quite hydrophobic polymer and the considerable ionic strength from >100 mM of the sodium salt of ibuprofen, resulting in conformational changes of the polymer. The salting-out effect is further illustrated by the addition of NaCl (not shown in figure) which lowers CP over the whole drug concentration span for both polymers. An interesting effect is the difference in derivatives of the CP curves between the polymer concentrations, at higher drug concentrations. For both polymers, the derivative is higher at 0.1% polymer than at 0.5% polymer. This is a composition-dependent effect as it takes more ibuprofen to increase CP by one degree by solubilization, if more polymer is present in the solution.

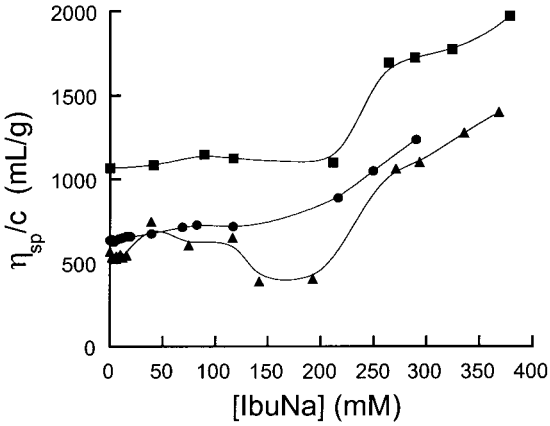

Figure 2—The reduced viscosity, η_{sp}/c, for the EHEC/ibuprofen-system as a function of the ibuprofen concentration, [IbuNa], for ▲ 0.1%, ● 0.2% and ■ 0.5% EHEC at 20 °C.

Capillary viscometry is another experimentally simple but very powerful method to explore semidilute polymer systems since aggregation phenomena most often affect the hydrodynamic flow properties, especially in polymer−amphiphile systems.[5] The EHEC/SDS/water system, for example, shows a maximum in the reduced viscosity close to the onset of polymer−surfactant interaction with respect to the surfactant concentration, for certain compositions, due to network formation.[6] The reduced viscosity for the EHEC/ibuprofen/water system is shown in Figure 2. The system HPMC/ibuprofen/water follows the same trends although the effects with this more hydrophilic polymer are smaller. Not shown in the figure but important to note is that the relative viscosity of the binary ibuprofen/water system is close to 1 for the whole concentration range investigated. The formation of pure ibuprofen micelles, as expected, was thus not measurable by capillary viscometry. No data are shown between approximately 100 and 200 mM ibuprofen because of the phase separation, cf. Figure 1. For the polymer concentrations shown in Figure 2, the reduced viscosity increases at higher drug concentrations above cmc. This evidence for EHEC−ibuprofen interaction is most likely an effect of the extension in space of the polymer chains, i.e., an increase in hydrodynamic volume, as these solubilize into ibuprofen micelles. For the lowest EHEC concentration, 0.1%, there is a decrease in the reduced viscosity prior to the cmc, which is coupled to the salting-out effect as discussed above. The polymer shrinks in this region of composition, with a notable effect on the reduced viscosity since the polymer concentration is here below the critical overlap concentration, c^*. c^* is the onset of polymer coil−coil entanglement with respect to the polymer concentration. A similar effect, also due to in-

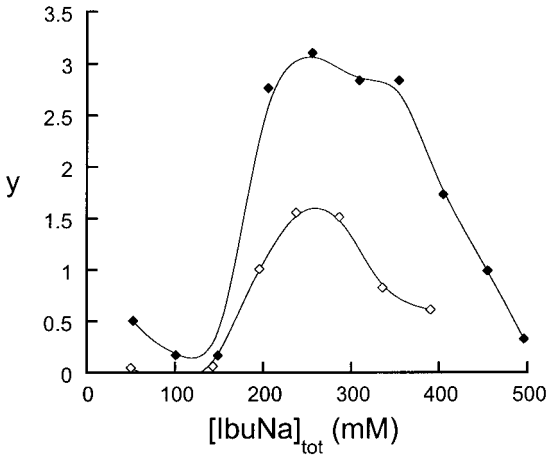

Figure 3—Equilibrium dialysis data for ◆ 1.0% EHEC, and 1.0% ◇ HPMC at 20 °C. y, mmoles of iboprofen bound per gram polymer as a function of the total concentration of ibuprofen, $[IbuNa]_{tot}$.

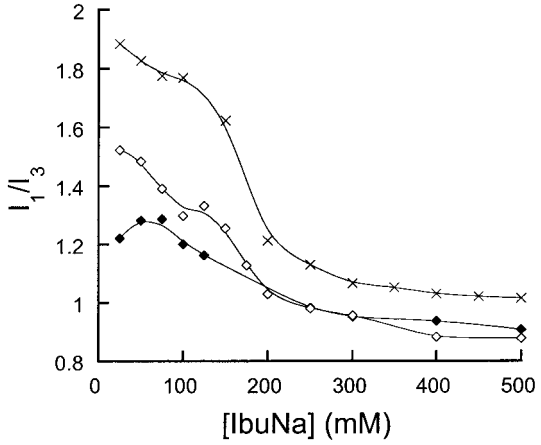

Figure 4—The micropolarity index, I_1/I_3, of pyrene in: × water solutions of ibuprofen, ◆ the ibuprofen/1.0% EHEC/water system, and ◇ the ibuprofen/1.0% HPMC/water system, as functions of the ibuprofen concentration, [IbuNa], at 20 °C.

tramolecular aggregation with respect to EHEC, but most likely not by salting-out, has been reported for the 0.1% EHEC/SDS/water system.[6] The absolute values in reduced viscosity, ≤2000 mL/g for 0.5% EHEC, are low compared to that of the maximum detected for the EHEC/SDS/water system, about 3800 mL/g for 0.3% EHEC,[6] indicating a more flexible network with weaker intermolecular tie points for the present system under study. Only 5 mM of SDS is present at the maximum in reduced viscosity in the EHEC/SDS system, which suggest that the surfactant act as "connector" between hydrophobic sites on the polymer chains. In the case of ibuprofen, more than 200 mM is present at the higher values in reduced viscosity. Furthermore, the values of reduced viscosity for the EHEC/SDS system drop well below 1000 mL/g at higher SDS concentrations, whereas there is an increase in the reduced viscosity for the EHEC/ibuprofen system instead, above 1000 mL/g. One interpretation is that SDS molecules at higher amphiphile concentrations more effectively "dress" the hydrophobic parts of EHEC and hereby the intermolecular ties between the EHEC chains diminish, as compared to ibuprofen which has a lower surface activity and also is a sterically more hindered molecule with its aromatic ring.

The adsorption of ibuprofen to the two polymer fractions was determined by equilibrium dialysis according to the principle employed for the SDS/cellulose ether/water systems previously studied.[6,18−20,22,33] The adsorption isotherm expressed as the number of millimoles of ibuprofen bound per gram of EHEC, *y*, as a function of the ibuprofen concentration, is shown in Figure 3. Significant amounts of ibuprofen bind to EHEC at [IbuNa] ≥ 150 mM. There is a positive second derivative in the adsorption isotherm up to about 180 mM ibuprofen, and then there follows a steep cooperative binding to $y = 3$ at an ibuprofen concentration of just above 200 mM. After this, *y* levels off on a plateau and then decreases again after 350 mM ibuprofen. The adsorption isotherm of HPMC is similar to that of EHEC up to $y = 1.5$ and then decreases. At the maximum in *y*, about 15% at most of the total amount of ibuprofen is EHEC-bound ($c_p y = 30$, cf., eq 1). This is to be compared with the adsorption of SDS onto 1% EHEC which reaches a maximum of $y = 3$ when about 75% of the total amount of SDS present in the solution is adsorbed (unpublished results). There is a major difference between a polymer−surfactant system such as EHEC/SDS and the EHEC/ibuprofen system. The former usually shows an onset of surfactant−polymer aggregation with respect to the surfactant concentration (usually denoted cac, critical aggregation concentration) well below the cmc for the corresponding binary surfactant/water system.[5] The maximum in adsorption is here typically reached before any ordinary micelles are formed in the solution. The EHEC/ibuprofen system, on the other hand, reaches the maximum in *y* at concentrations exceeding the ordinary cmc. This suggests a weaker mechanism of binding in the latter system, in accordance with the argument that the value of cac is a measure of the thermodynamic strength of polymer−amphiphile adsorption, cac being lower for a stronger binding.[5] In short terms, SDS forms micelles onto EHEC polymer chains below the cmc of SDS, whereas ibuprofen first forms micelles into which EHEC distributes. There is, however, significant adsorption of ibuprofen onto EHEC from about 150 mM before free "ordinary" micelles of ibuprofen start to form in the solution, with a cooperative binding as a result. A small significant binding of ibuprofen onto EHEC is also observed below 100 mM ibuprofen. This suggests that premicellar ibuprofen clusters form on the EHEC chains, and the result is consistent with the fluorescence data discussed below. After the maximum, dialysis adsorption isotherms generally show a decrease in *y*, as is the case also for the EHEC/SDS/water system.[20] The reason for this cannot be fully explained, but the membrane dialysis system tends to equilibrate by increasing the concentration of amphiphile on the side of the dialysis membrane having no polymer, as soon as free micelles are present in the solution. Thus, although it is unclear whether the entire decrease in *y* is a true redistribution from bound to free micelles, the dialysis experiments in this higher concentration region monitor a change in interaction between ibuprofen and the cellulose ethers—stronger for EHEC than for HPMC in accord with the higher hydrophobicity of the former.

Fluorescence probe techniques have been utilized in this study to give information on micellar sizes and characteristics. The fine vibrational emission spectrum of pyrene is sensitive to the polarity of the immediate surroundings of the probe,[23] see the Experimental Section. The micropolarity index I_1/I_3 is presented as a function of the ibuprofen concentration in Figure 4. The binary ibuprofen/water system gives values of $I_1/I_3 \approx 1.8$ for low drug concentrations, indicating a polar probe environment close to that of water. At intermediate ibuprofen concentrations there is a steep drop in I_1/I_3 down to ≈1.0 to 1.1 which indicates formation of micelles. These values are comparable to those of pyrene dissolved in most common surfactant micelles.[23] The cmc, as taken at the inflection point of the sigmoidal drop of the curve, is about 180 mM. In the presence of 1%

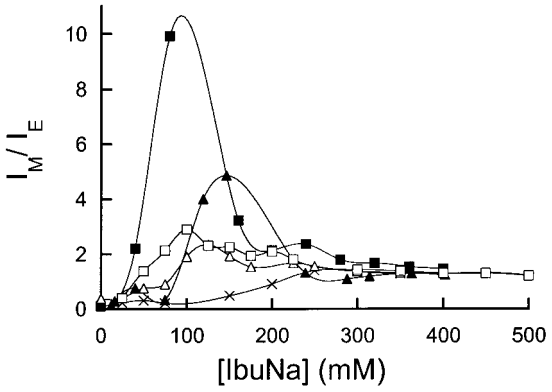

Figure 5—The microviscosity inex I_M/I_E of P3P as a function of the ibuprofen concentration, [IbuNa], at 20 °C. × no polymer present; ▲ 0.1% EHEC; ■ 0.5% EHEC; △ 0.1% HPMC, □ 0.5% HPMC.

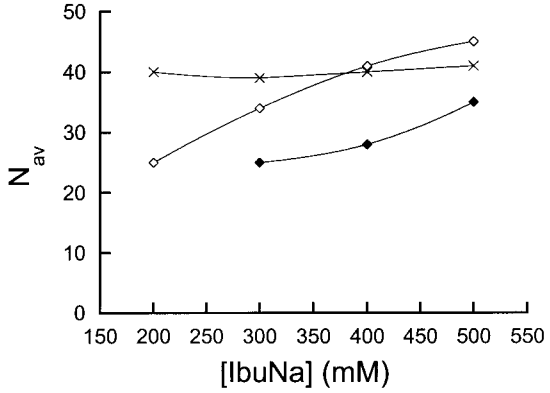

Figure 6—Average aggregation numbers of the total ensemble of ibuprofen micelles formed in solution, N_{av}, as a function of the ibuprofen concentration, [IbuNa], at 20 °C. × no polymer present; ◆ 1.0% EHEC; ◇ 1.0% HPMC.

polymer, the general trend with a drop in I_1/I_3 at cmc remains, but the absolute values are now lower. The HPMC sample gives $I_1/I_3 \approx 1.5$ at 25 mM ibuprofen and levels off at 0.9 at the higher drug concentrations. Hence, 1% HPMC mediates a more hydrophobic environment for the ensemble of pyrene molecules throughout the composition interval (25−500 mM ibuprofen). There is, for this curve, a significant decrease in I_1/I_3 in the ibuprofen concentration range 25−100 mM which can be interpreted as adsorption of ibuprofen onto HPMC in this composition interval. The more hydrophobic sample EHEC, fraction CST-103, gives even lower values of I_1/I_3 at ibuprofen concentrations below cmc than that of HPMC, suggesting that EHEC forms more polymer-dense mixed clusters with less water penetration. Pyrene thus monitors a complex interaction pattern of ibuprofen with both polymer samples starting at low ibuprofen concentrations in the range 25−50 mM.

The onset of polymer−ibuprofen interaction can also be investigated by the fluorescent microviscosity probe P3P. As further outlined in the Experimental Section, the intramolecular monomer-to-excimer emission intensity ratio, I_M/I_E, is a qualitative index of the microviscosity at the site of solubilization of the ensemble of probe molecules.[25] For a set of cellulose ethers of varying hydrophobicity, it was found that the onset of SDS−polymer interaction with respect to the surfactant concentration, here denoted c_1, as monitored by an abrupt increase in I_M/I_E, correlated with a similar abrupt decrease in I_1/I_3 for each polymer sample, as monitored by pyrene.[26] I_M/I_E is presented in Figure 5 as a function of the ibuprofen concentration in the absence as well as presence of polymer. The binary system ibuprofen/water displays an increase in I_M/I_E at cmc from about 0.2 to 1.5, an increase comparable in magnitude to that of SDS (up to about $I_M/I_E = 1$).[8] The reason for ibuprofen micelles being slightly more rigid than SDS micelles as monitored by P3P, might have its origin in the stiff aromatic ibuprofen molecule as compared to the more flexible hydrocarbon tail of SDS. Furthermore, the flat aromatic pyrene entities of P3P might associate to the aromatic ring of ibuprofen, with a decrease in the degrees of freedom for P3P. The ternary EHEC/ibuprofen/water and HPMC/ibuprofen/water systems display qualities similar to the corresponding polymer/SDS/water systems,[26] including a well-developed maximum in I_M/I_E right after c_1 and a lower plateau in I_M/I_E at higher amphiphile concentrations. The maximum in microviscosity corresponds to, as argued earlier,[8] mixed micelles or clusters with a high molar ratio polymer/ibuprofen which effectively hinders the molecular motion and excimer formation of P3P. At higher ibuprofen concentrations, the mixed micelles have a lower molar ratio polymer/ibuprofen—the mixed micelles now resemble free not polymer bound micelles—which increases the molecular mobility of P3P. Also, the fraction of micelles not bound to the polymer at higher ibuprofen concentrations is large, and much larger than in the EHEC/SDS case,[8] which tends to shift the value of I_M/I_E toward that of ordinary free micelles. The numerical value of the maximum of I_M/I_E for the 0.5% EHEC sample is about 10. This is more than three times the maximum value in I_M/I_E observed for the 0.5% HPMC sample, which is about 3. Consequently, as monitored by P3P, EHEC forms more rigid and dense mixed polymer−ibuprofen micelles than HPMC, in the lower ibuprofen concentration regime. This finding is in accord with the higher hydrophobicity of EHEC, and correlates with the values of I_M/I_E for the corresponding polymer/SDS/water systems.[26] P3P, like pyrene, monitors the onset of polymer−drug interaction to be in the range 25−50 mM ibuprofen for both polymer samples. Figure 5 also illustrates that a maximum in microviscosity does not need to be coupled to a maximum in bulk viscosity, cf., Figure 2. The former will definitely affect the transport properties of drug molecules in solution, but might pass undetected by only using conventional rheological methods.

The average aggregation numbers of ibuprofen micelles—the average number of ibuprofen molecules per micelle—were determined by a combination of static and time-resolved fluorescence quenching as described in the Experimental Section. In the model calculation of the aggregation numbers the cmc of ibuprofen is taken to be 180 mM throughout the calculation in accord with the data shown above. This assumption is probably not totally correct as there might be a redistribution of free ibuprofen monomers into micelles above the cmc, but the calculation still gives a good estimate of the micelle sizes and shows the effect of the presence of polymer in the system. As can be seen in Figure 6 where the average aggregation numbers of all micelles present in the system, N_{av}, are plotted as a function of the ibuprofen concentration, N_{av} for the binary system ibuprofen/water remains about 40 in the concentration range investigated. This is in accord with the start−stop process signifying micellization including a certain micelle size distribution for a certain solute, solvent, temperature, and ionic strength.[5] The ibuprofen micelles are comparable in size with many surfactant micelles, e.g., SDS, which have aggregation numbers in the range 60−70 as monitored by the same technique.[5] Turning next to the ternary 1% cellulose ether/ibuprofen/water systems, no aggregation numbers could be determined at 100 mM ibuprofen since not enough quencher could be solubilized in the clusters for accurate determinations. At 200 mM and 300 mM ibuprofen, the total micelle concentrations are significantly higher if 1% HPMC is present in the solutions as compared to the polymer-free case, cf., Table 1. This is

Table 1—Total Micelle Concentrations [micelle] (mM)

[IbuNa] (mM)	no polymer present	1% EHEC	1% HPMC
200	0.49	-	0.79
300	3.11	4.70	3.58
400	5.48	7.82	5.36
500	7.87	9.21	7.11

an indication of polymer-bound micelles which alter the micellar concentrations. The effect is smaller average aggregation numbers including both polymer-bound and free micelles, N_{av}, as presented in Figure 6. At 400 mM and 500 mM ibuprofen, the effect of HPMC on N_{av} diminish, suggesting the total ensemble of micelles at these high drug concentrations to be similar to the binary ibuprofen/water system, in accord with the P3P data of Figure 5. The more hydrophobic polymer sample EHEC CST-103 affects the micellar concentrations and hence N_{av} to an even larger degree, which seems correct as EHEC binds more ibuprofen ($y_{max} = 3$) than HPMC does ($y_{max} = 1.5$) as shown by the dialysis experiments. At higher ibuprofen concentrations, N_{av} for the EHEC/ibuprofen system also strives toward that of the binary system. The aggregation numbers of polymer-bound micelles are hence smaller than free micelles, an observation in line with the corresponding cellulose ether/SDS systems.[7,22] An illustrative example of this is the 300 mM ibuprofen/1% EHEC solution. The EHEC-bound ibuprofen concentration is, with $y = 3$ from Figure 3, 30 mM. This gives, with the cmc = 180 mM, 90 mM of ibuprofen incorporated into free micelles. With a total micelle concentration from Table 1 of 4.70 mM and $N_{av} = 40$ for free micelles, the average aggregation number of polymer-bound micelles becomes 12.

Conclusion

The aggregation behavior of ibuprofen in aqueous solution, with and without addition of interacting polymer, can be well-characterized by a combination of phase equilibrium data, adsorption isotherms, rheology measurements, and fluorescence probe investigations. It is shown that cmc of ibuprofen in pure water is 180 mM, and that above cmc, micelles are formed which resemble ordinary surfactant micelles, as monitored by fluorescence quenching and microviscosity measurements. In the presence of a cellulose ether, adsorption to the polymer occurs below cmc, but the strong cooperative part of the adsorption coincides with the normal cmc, in contrary to the normally accepted model for polymer−surfactant interaction.[5] The more complex interaction pattern of the ibuprofen−cellulose ether system might be mediated by the ionic strength which varies considerably in the investigated ibuprofen concentration interval (0−500 mM) and thus changes the system with changed drug concentration. The present study was undertaken to provide a background for transport studies in drug−polymer systems. Obviously the results obtained indicate that since, for instance, aggregation numbers and microfluidity of the mixed polymer−drug micelles can vary considerably as a function of composition these facts must be taken into account in order to correctly describe the irreversible process of mass transport in drug release from such systems.

Solubility Parameters as Predictors of Miscibility in Solid Dispersions

DAVID J. GREENHALGH,[†] ADRIAN C. WILLIAMS,*[,†] PETER TIMMINS,[‡] AND PETER YORK[†]

Contribution from *Drug Delivery Group, Postgraduate Studies in Pharmaceutical Technology, the School of Pharmacy, University of Bradford, BD7 1DP, U.K., and Bristol-Myers Squibb, Pharmaceutical Research Institute, Moreton, Merseyside, L46 1QW, U.K..*

Received March 18, 1999. Accepted for publication July 30, 1999.

Abstract □ This paper reports interactions and possible incompatibilities in solid dispersions of hydrophobic drugs with hydrophilic carriers, with solubility parameters employed as a means of interpreting results. Systems containing ibuprofen (IB) and xylitol (XYL) in varying proportions and systems of IB with other sugars and a sugar polymer were produced using solvent evaporation and fusion methods. Additionally, bridging agents were employed with IB/XYL systems to facilitate the production of a solid dispersion. Results show that IB formed no interactions with any of the sugar carriers but interacted with all the bridging agents studied. The bridging agents were immiscible with XYL in the liquid state. Results of other reported drug/carrier systems and those from the systems studied in this paper were interpreted using Hildebrand solubility parameters. A trend between differences in drug/carrier solubility parameters and immiscibility was identified with incompatibilities evidence when large solubility parameter differences exist between drug and carrier. It was concluded that Hildebrand parameters give an indication of possible incompatibilities between drugs and carriers in solid dispersions, but that the use of partial solubility parameters may provide a more accurate prediction of interactions in and between materials and could provide more accurate indications of potential incompatibilities.

Introduction

Solid dispersions have been employed to enhance the dissolution rates of poorly water-soluble drugs, including ethenzamide,[1] nifedipine,[2,3] furosemide,[4] griseofulvin,[5,6] and tolbutamide.[6,7] However, although some amorphous dispersions are currently marketed, few solid dispersions have been developed into commercial products, due to various limitations of these systems, including physical instabilities on storage[8,9] and problems of drug/carrier immiscibility.[10,11] If the drug and the carrier are incompatible, dispersion of the drug into the carrier can be problematic, with irregular crystallization, uniformity problems, and possibly little improvement in drug dissolution rate. With a hydrophobic drug the carrier must be hydrophilic to facilitate fast dissolution of the therapeutic agent into the aqueous medium of the gastrointestinal tract. In this paper solid dispersions of ibuprofen (IB) with various sugars and polymer carriers were investigated. Results were interpreted in terms of solubility parameters, an approach which was extended to literature reports of similar systems in order to probe the applicability of this method for predicting drug/carrier compatibility.

Cohesive energy represents the total attractive forces within a condensed state material and can be defined as the quantity of energy needed to separate the atoms/molecules of a solid or liquid to a distance where the atoms or molecules possess no potential energy, i.e., no interactions occur between atoms or molecules. Further, cohesive energy density (CED) is the cohesive energy per unit volume. The CED for a material can be used to predict its solubility in other materials; if two components have similar values, they are likely to be soluble in each other, since interactions in one component will be similar to those in the other component. Thus, the overall energy needed to facilitate mixing of the constituents will be small, as the energy required to break the interactions within the components will be equally compensated for by the energy released due to interactions between unlike molecules. In addition, CED values can be transformed into Hildebrand solubility parameters (δ), defined as the square root of the CED,

$$\delta = (\mathrm{CED})^{0.5} = (\Delta E_v/V_m)^{0.5} \quad (1)$$

where ΔE_v is the energy of vaporization and V_m the molar volume.

Solubility parameters are widely used to describe the cohesive forces within materials and have been used to describe many physical properties of a material and predict interactions between materials.[12−14] The use of solubility parameters to predict solubility/miscibility is attractive and can be applied to low molecular weight materials and polymers. Solubility parameters can be evaluated by solubility studies of test materials in solvents of known solubility parameter, from refractive index values by using inverse gas chromatography, from heat of vaporization data (not suitable for many polymers), or by calculation using group contribution methods. The group contribution method was used in this paper to calculate Hildebrand solubility parameters, since these data compare well with values obtained by other methods. For example, sulfisomidine has a solubility parameter of 25.7 $MPa^{1/2}$ calculated using Fedors group contribution method and a value of 25.9 $MPa^{1/2}$ by the peak solubility method.[15] Caffeine (anhydrous) gives a solubility parameter of 28.0 $MPa^{1/2}$ using the group contribution method,[16] 28.3 $MPa^{1/2}$ by the peak solubility method,[17] and 29.9 $MPa^{1/2}$ by dissolution calorimetric measurements.[18]

Calculation of the molar vaporization energy of a material (and ultimately its Hildebrand parameter) using the group contribution method involves the summation of molar vaporization enthalpies of structural fragments in the material. The molecular volume of the material is derived from its density and molecular weight (molecular weight/density) or it can be calculated using the volume of the molecular fragment present in the material in an additive fashion similar to the calculation of vaporization energy. This enables the solubility parameter to be calculated using eq 1. An example of the calculation of solubility

parameters using the group contribution method is shown in Figure 1.

A short review of solid dispersion systems reported in the literature has been included in this paper and the Hildebrand solubility parameter has been calculated for the materials used. The aim was to report any incompatibilities between components in the solid dispersions and to use solubility parameters of the drug and carrier as a possible explanation, and subsequently as a predictor, for the incompatibilities. Hildebrand solubility parameters were also calculated for the materials used in this paper.

Experimental Section

Materials—The following materials were used as supplied: Ibuprofen (IB) (APS−Berk Pharmaceuticals, Eastbourne, U.K.), xylitol (XYL), sucrose, xylose, maltose, mannose, sorbitol, dextran 6, 40, 110 (Sigma-Aldrich Co. Ltd., Poole, U.K.), methanol HPLC grade (BDH Laboratory Supplies, Poole, U.K.), poloxamer 188 (Lutrol F68) (BASF plc, Cheadle Hume, U.K.), polysorbate 20, 40, 60, 80, and polyoxyethylene 40 stearate (Croda Oleochemicals, Hull, U.K.).

Preparation of Ibuprofen−Xylitol Dispersions—*Fusion Method*—IB (mp 75 °C) and XYL (mp 93 °C) were mixed at 1:1, 1:3, and 3:1 w/w to give batches of 5 g before heating to 130 °C for 1 h followed by immersion in liquid nitrogen (−196 °C) for 5 min. After solidification, samples were stored at room temperature in desiccators over P_2O_5 for 24 h before grinding and analysis by differential scanning calorimetry (DSC) and X-ray powder diffraction (XRPD).

Solvent Evaporation—Five gram batches of IB:XYL (1:1, 1:3, 3:1, and 1:9 w/w) were dissolved in the minimum volume of methanol at 40 °C. The solvent was removed under vacuum (850 mbar) using a rotary evaporator at 50 °C and 100 rpm. Samples were dried for 24 h under vacuum in a desiccator containing P_2O_5. The coevaporates formed were powders which were used without processing.

Ibuprofen−Xylitol Solubility/Miscibility Studies—Various compositions of finely ground IB and XYL (0.1−16% w/w) to give batches of 5 g were mixed in glass beakers. The mixtures were heated to 90 °C for 30 min and were stirred every 2−3 min. Visual inspections of the mixtures were made before the samples were heated to 120 °C for 30 min, again being stirred every 2−3 min. Further observations of the number of phases were made.

Miscibility Studies of Ibuprofen with other Sugars—Five gram samples of IB were heated in glass beakers to 130 °C. Sucrose (mp 190 °C), xylose (mp 158 °C), maltose (mp 128 °C), mannose (mp 135 °C), and sorbitol (mp 99 °C) were individually mixed with molten IB samples at a level of 1% w/w. The mixtures were stirred every 5 min and were maintained at 130 °C for 1 h. Five gram samples of maltose, sorbitol, and mannose were heated to 140 °C, whereupon 1% w/w IB was added to each sugar melt; the three mixtures were stirred every 5 min and were maintained at 140 °C for 1 h. This was not carried out with sucrose (mp 190 °C) and xylose (mp 158 °C) due to their high melting point and the rapid vaporization of IB above 150 °C, as confirmed by thermogravimetric analysis where a 12.1% weight loss in a sample of IB was noted between 150 °C and 200 °C (heating rate 10 °C/min). Samples were inspected for the presence of phase separation.

Preparation of Ibuprofen-Sugar Coevaporates—A 0.4 g sample of each individual sugar (sucrose, maltose, sorbitol) was dissolved in methanol at 65 °C, whereupon IB (1.6 g) was added and dissolved into the sugar solutions (1:4 w/w, sugar:drug). Solvent was removed on a rotary evaporator at 40 °C under vacuum. The coevaporates formed were transferred to a vacuum oven and evacuated to 850 mbar at room temperature overnight. The dried powders were used as produced. Coevaporates were stored in sealed vials at −18 °C for 24 h before characterization by DSC and XRPD.

Preparation of Ibuprofen−Dextran 40 Dispersion—IB (4.5 g, 90% w/w) and dextran 40 (0.5 g, 10% w/w) were dissolved in the minimum amount of a cosolvent mixture of ethanol:water (1:1 w/w) at 60 °C. The cosolvents were removed by rotary evaporation under vacuum at 50 °C. Samples were dried overnight in a vacuum oven evacuated to 850 mbar at room temperature. Samples were ground to a powder before characterization by DSC and XRPD.

Miscibility Study of Ibuprofen and Dextran 40—IB (5 g) was heated to 120 °C and 1% w/w dextran 40 was added; the melt was maintained at 120 °C for 1 h and was stirred every 5 min. Visual inspection of the melt was made to note if the dextran particles dissolved in the molten IB.

Preparation of Ibuprofen−Xylitol Dispersions incorporating Lutrol F68—Samples of IB:XYL:Lutrol F68 (1:8:1, 1:8.9:0.1, 0.5:9.4:0.1, and 0.5:9.45:0.05) were prepared to give batches of 5 g. The mixtures were heated to 110 °C for 30 min with stirring every 2−3 min before being allowed to cool to room temperature. All three components were molten at 110 °C (Lutrol F68, mp 55 °C). Samples of the melts were withdrawn using a heated Pasteur pipet (110 °C) and placed on a heated glass slide (110 °C) to be viewed under a microscope during cooling.

Miscibility Studies of Lutrol F68 with Ibuprofen and Xylitol—IB (2 g) was heated to 80 °C and XYL (2 g) to 110 °C in glass beakers, whereupon 25% w/w Lutrol F68 was mixed into the melts. Samples were stirred every 10 min and were maintained at their respective temperatures for 2 h before being allowed to cool to room temperature. The experiments were repeated using 10%, 5%, 2%, and 1% w/w Lutrol F68. Visual inspection of all the mixtures was undertaken when the samples were molten.

Miscibility Studies of Other Potential Bridging Agents with Ibuprofen and Xylitol—IB at 80 °C and XYL at 110 °C were individually mixed with other potential bridging agents, i.e., polysorbate 20, 40, 60, 80 and polyoxyethylene 40 stearate at 2% and 98% w/w to give batches of 4 g. Each mixture was heated in glass beakers to make visual assessment of the melts easier. Mixtures were maintained at their respective temperatures for 1 h with stirring every 5 min before being allowed to cool to room temperature. Visual inspection of all the mixtures was undertaken when samples were molten.

Preliminary Studies of the Interaction between Lutrol F68 and Ibuprofen—Various proportions of Lutrol F68 and IB (0−100% w/w) were mixed to give samples which had a total weight of 5 g. Each composition was heated to 90 °C for 30 min with vigorous stirring every 2−3 min before crash-cooling in liquid nitrogen. After cooling, samples were immediately transferred to a desiccator and stored over P_2O_5 for 24 h before characterization. The samples were left intact until analysis but were then ground with a mortar and pestle. All samples were characterized by DSC and XRPD. A 1:3 w/w IB:Lutrol F68 physical mix was also prepared and characterized by DSC and XRPD.

Characterization of Materials and Dispersions—*Visual Inspection*—Molten samples were viewed to assess phase separation. If components are immiscible, distinct boundaries between the constituents are expected, i.e., two liquid layers or possibly globules of one component in the continuous phase of the second component.

Thermal Analysis—Samples and starting materials were analyzed using a Perkin-Elmer Series 7 differential scanning calorimeter. Aluminum pierced and crimped pans were used in all analyses. Melting points, heat of fusion, and glass transition temperatures (T_g) quoted are the mean of three determinations,

unless otherwise stated. Temperature ranges and scan rates for each experiment are given with the results.

X-ray Powder Analysis—Samples were powdered in a mortar and pestle before X-ray analysis. X-ray patterns were obtained using a Siemens D5000 diffractometer (Stuttgart, Germany). Samples were scanned from 2° to 72° 2θ (sampling interval of 0.05°) at 1°/min using Ni-filtered Cu Kα radiation. Operating voltage and current were 40 kV and 30 mA, respectively. Diffractograms of the individual starting materials and solid dispersions were recorded.

Uniformity Study—A Philips PU 8740 UV/VIS Scanning spectrophotometer was used to analyze IB distribution within the 1:9 IB:XYL coevaporate. A calibration curve was constructed using six standard solutions of ibuprofen in methanol (range 2.0−30 μg/mL) analyzed at the λ_{max} of 221 nm. A rectilinear relationship between absorbance and ibuprofen concentration was obtained between 0.08 and 1.0 absorbance (correlation coefficient of 0.9983). XYL and methanol show no interference over the range 90−300 nm. Ten random samples (50 mg) of the unprocessed coevaporate were dissolved, filtered (0.2 μm membrane filter), and diluted with methanol to give a theoretical IB concentration in the range 0−30 μg/mL. Absorbance values for each sample at λ_{max} were converted to IB concentration and to IB concentration per gram of coevaporate using the respective weights of each random sample. The standard deviation and coefficient of variation of the IB content of the samples were used as a measure of homogeneity in the coevaporate.

Solubility Parameters and Review of Literature—Hildebrand parameters were calculated using the molar vaporization energies and molar volume values obtained by Fedors,[19] unless otherwise stated. These values are regarded as being less accurate estimations of cohesive energy[20] but are useful due to the great number of groups considered compared with other data sets. This is important as many drug molecules have complex structures.

The criterion for inclusion of solid dispersion systems in the review was the presentation of phase diagrams in the report of the systems. It was also important that the analysis of the phase diagram was by more than DSC alone, such as thermomicroscopy or capillary tube melting, so that immiscibility in the liquid state could be reported; this would not be detected by DSC analysis. Three systems were reported which did not include a phase diagram, but they were included primarily due to the evidence of liquid/liquid immiscibility by visual inspection. In these cases it was not the degree of immiscibility in the liquid state which was important but the fact that immiscibility had been identified. All the solid dispersion systems reviewed were classified into arbitrary compatibility categories based on their phase diagrams. The categories were from A (highest compatibility) to E (lowest compatibility).

Results and Discussion

Ibuprofen−Xylitol Systems—*Visual Analysis*—Visual inspection of all compositions of the IB:XYL fusion samples and samples from the solubility/miscibility study showed two distinct phases in the molten state. In the solubility/miscibility study, the mixtures at 90 °C showed particles of XYL undissolved in the IB melts at all compositions. Results indicate that the solubility of XYL in molten IB is below 0.1% w/w up to 120 °C.

DSC Studies—DSC scans (25−120 °C at 20 °C/min) of the resolidified IB:XYL fusion samples and coevaporates in Figure 2 show melting endotherms of IB (mp 75−78 °C) and XYL (mp 96−97 °C), in all compositions studied (1:1, 3:1, and 3:1 w/w). No evidence for interactions between drug and carrier is given by the DSC data, supporting the visual inspection of the melts that the drug and carrier are immiscible. The heat of fusion, corrected for dilution within the sample ($\Delta H_{f\,corr}$) and melting onset temperature of IB used in the study and those of IB in the fusion and coevaporate samples are in Table 1.

The onset of melting temperatures (Table 1) is essentially unchanged for IB in the fusion and coevaporate samples with xylitol, as compared with the starting material, again indicating little or no interaction between the drug and carrier. The melting endotherm of XYL in all dispersions with IB remained unchanged in terms of onset and peak melting temperatures compared with XYL alone. The similarity in melting points of the two components after fusion and coevaporation with the data for the starting materials indicates that no major degradation of the components occurred during the preparation procedure. This is also the case with all other systems examined in this work. The variability in $\Delta H_{f\,corr}$ (large standard deviation) shown in both coevaporate and fusion samples for IB is attributed to heterogeneity in the samples arising from the immiscibility.

X-ray Powder Analysis—XRPD diffractograms of fusion and coevaporate samples show both drug and carrier to be present in crystalline form. Peaks characteristic of IB and XYL are shown in all compositions and dispersion types. No shifts in peak positions for IB and XYL were noted, and no new peaks were observed. XRPD analysis of the resolidified fusion and coevaporate samples indicates two separate phases with no change in the crystal structures of IB and XYL. X-ray analysis gave no evidence of any interaction between the two components. Figure 3 shows diffractograms of IB, XYL, and two samples taken from the 1:3 IB:XYL coevaporate; one coevaporate sample shows peaks characteristic of XYL but none of IB, while the second sample from the same coevaporate shows the reverse. The results illustrate that IB and XYL do not

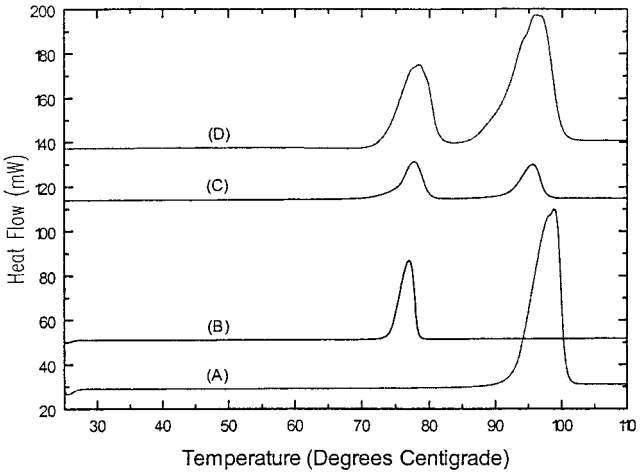

Figure 2—DSC data for xylitol alone (A), ibuprofen alone (B), 1:1 w/w IB:XYL fused sample (C), and 1:1 w/w IB:XYL coevaporate (D).

Table 1—Melting Point and Heat of Fusion of Ibuprofen in Various Solid Dispersions[a]

sample	onset of melting (°C)	melting peak (°C)	$\Delta H_{f\,corr}$ (kJ/mol)
ibuprofen	73.7 ± 0.1	75.4 ± 0.1	25.8 ± 0.2
1:1 w/w IB:XYL fusion sample	73.7 ± 0.7	78.3 ± 0.2	17.0 ± 10.0
1:3 w/w IB:XYL fusion sample	73.4 ± 0.3	76.3 ± 0.6	13.0 ± 8.0
3:1 w/w IB:XYL fusion sample	73.6 ± 0.4	79.0 ± 2.0	14.0 ± 8.0
1:1 w/w IB:XYL coevaporate	73.9 ± 0.9	77.2 ±0.5	27.0 ± 21
1:3 w/w IB:XYL coevaporate	76.0 ± 2.0	78.0 ± 2.0	33.0 ± 49
3:1 w/w IB:XYL coevaporate	74.0 ± 2.0	77.6 ± 0.8	29.5 ± 0.8
4:1 w/w IB:sucrose coevaporate	75.0 ± 2.0	80.0 ± 1.0	25.0 ± 1.0
4:1 w/w IB:maltose coevaporate	74.4 ± 0.7	78.0 ± 1.0	24.7 ± 0.1
4:1 w/w IB:sorbitol coevaporate	74.1 ± 0.4	79.6 ± 0.3	29.1 ± 0.8
9:1 w/w IB:dextran 40 coevaporate	69.7 ± 0.1	74.9 ± 0.2	19.5 ± 0.3

[a] $\Delta H_{f\,corr} = \Delta H_{obs}$ (heat of fusion of ibuprofen in sample)/theoretical % IB in sample × 100. Note: The $\Delta H_{f\,corr}$ for ibuprofen in each sample should be equivalent to the heat of fusion of the ibuprofen starting material, if ibuprofen is unaffected by the presence of excipients and the drug is uniform within the sample.

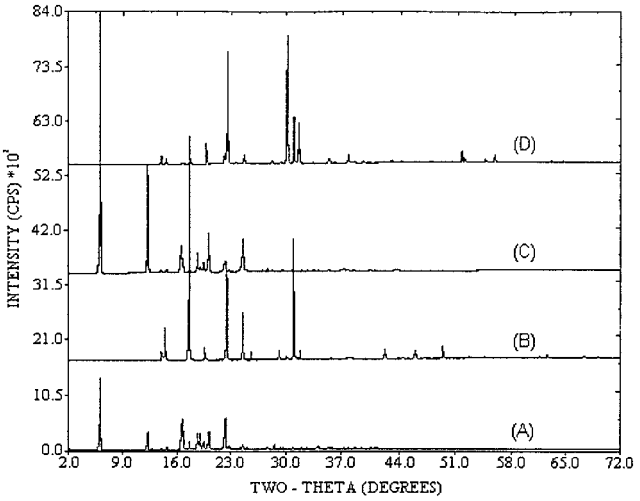

Figure 3—X-ray powder diffractograms: ibuprofen (A), xylitol (B), and IB:XYL 1:3 w/w coevaporate (C and D).

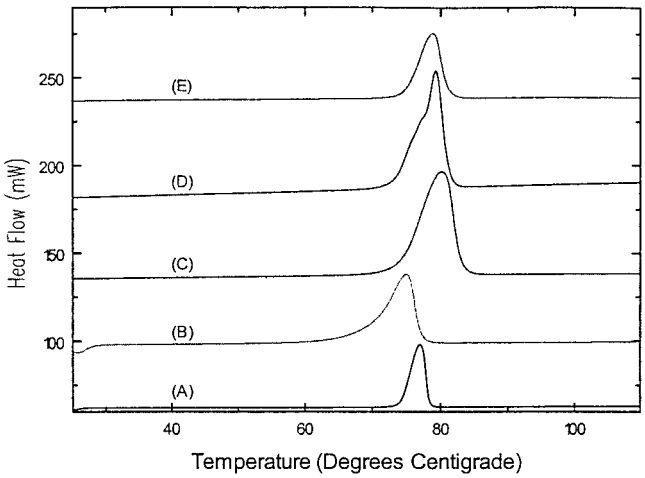

Figure 4—DSC data for ibuprofen alone (A), 1:9 w/w IB:dextran 40 coevaporate (B), 4:1 w/w IB:sorbitol (C), 4:1 w/w IB:sucrose (D), and 4:1 w/w IB:maltose (E).

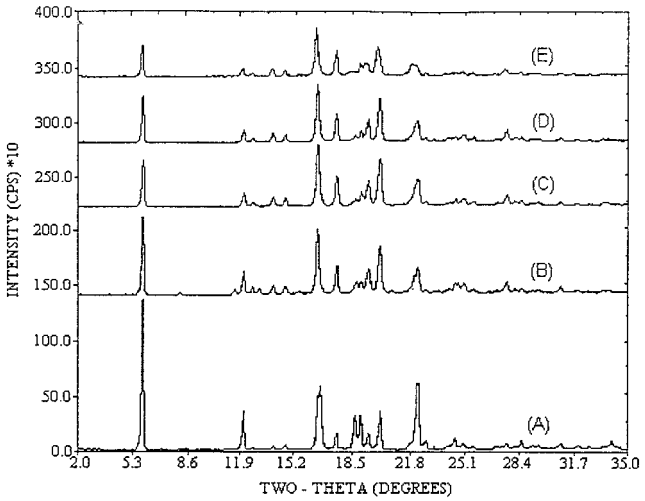

Figure 5—X-ray powder diffractograms: ibuprofen (A), IB:sucrose 4:1 w/w coevaporate (B), IB:sorbitol 1:4 w/w coevaporate (C), IB:maltose 4:1 w/w coevaporate (D), and IB:dextran 40 9:1 w/w coevaporate (E).

cocrystallize in the solvent evaporation samples, suggesting that neither drug nor carrier maintains the supersaturation of the other in solution. This would lead to the two components crystallizing out at different rates, creating isolated domains of drug and sugar.

Uniformity Study of the 1:9 IB:XYL Coevaporate—The ibuprofen content, as determined by UV spectrophotometric analysis of 10 random samples taken from the coevaporate, gave a standard deviation of ±41.9 mg/g, leading to a coefficient of variation of 64%. This shows very poor uniformity in the coevaporate at a scale of scrutiny of 50 mg (sample size). This provides further evidence of the incompatibility between IB and XYL.

Miscibility Studies of Ibuprofen with Other Sugars—*Visual Analysis*— Inspection of molten IB individually mixed with 1% w/w sucrose, xylose, and mannose showed the presence of undissolved sugar particles in all cases. Mixtures of maltose (1% w/w) with ibuprofen and sorbitol (1% w/w) with IB showed globules of sugar in the IB melts. Results show all sugars to have a solubility/miscibility below 1% w/w with ibuprofen at 130 °C. Melts of maltose, sorbitol, and mannose at 140 °C containing 1% w/w IB again show two phases with globules of IB being clearly visible.

Ibuprofen–Sugar Coevaporates—*DSC Analysis*— Coevaporates of IB:sucrose, IB:maltose, IB:sorbitol (all 4:1 w/w) were scanned from −30 to 130°C at 20 °C/min. The melting endotherm of IB was present in all three coevaporates, and the peak temperature of IB in the coevaporate remained unchanged in comparison to the starting material (Table 1). This invariance suggests that there is no disruption of the IB crystal lattice or interaction between the drug and carrier. Table 1 shows the $\Delta H_{f\,corr}$ of IB in the coevaporates to be very different from that of IB starting material. This was attributed to poor distribution of the drug in the coevaporates and correlates with the visual evidence that the sugars studied were immiscible with ibuprofen. Figure 4 shows DSC data for the IB:sugar coevaporates.

Many sugars are reported to form glasses.[21–24] No glass transition was noted over the temperature range from −30 to 130 °C for any of the sugar carriers in the coevaporates. A sample of sorbitol (5 mg) was heated in the DSC to 130 °C and maintained at this temperature for 10 min, whereupon it was cooled at 50 °C/min to −30 °C. The sample was immediately reheated in the DSC to 130 °C at 20 °C/min. A glass transition was observed at −2 °C with an associated endotherm representing the enthalpy of relaxation. Timko and Lordi[25] reported the T_g for sorbitol to be −2 °C. Maltose has been reported to have a T_g at 95 °C[24] and sucrose to have a T_g at 74 °C.[26] It must be borne in mind that glass transition temperatures can vary depending on the heating rate and with the water content of the sample.

The melting endotherms of sorbitol and maltose were not detected in the coevaporates by DSC analysis. The IB:sucrose coevaporate was not heated past the melting point of sucrose due to rapid vaporization of IB above 150 °C. The lack of melting endotherm for the sugar carriers could indicate that the sugars exist as amorphous glasses within the coevaporates. Additionally, no glass transitions were detected, probably due to the relatively low level of sugars present in the coevaporates and resulting from sampling heterogeneity due to segregation of the drug and carriers in the solid dispersions. The absence of melting endotherms for the sugar carriers is probably due to both poor homogeneity in the samples (carrier domains not sampled) and amorphous deposition of the sugars.

X-ray Powder Diffraction Studies—The X-ray diffractograms shown in Figure 5 were taken 24 h after coevaporate production. All three coevaporates produced diffraction patterns which are almost identical to each other and almost identical to that of ibuprofen starting material. The individual hydrophilic carriers cannot be easily detected

in any of the traces. Three samples of each coevaporate were analyzed by XRPD, but only one run is shown, as all the spectra produced for each coevaporate were identical. No increase in the noise level which might indicate the presence of an amorphous sugar can be seen, although the X-ray powder diffractometer may not be able to detect glassy material at a theoretical level of 20%. The XRPD data suggest that sampling and analysis of IB rich regions of the coevaporate has occurred. Segregation of the coevaporate may have occurred due to the separate crystallization of the drug and carrier.

Ibuprofen−Dextran 40 Coevaporates—*DSC Results of the Coevaporate*—Table 1 shows the melting peak temperature of IB in the dextran 40 coevaporate to be similar to the IB starting material, but the corrected heat of fusion ($\Delta H_{f\,corr}$) value is very low. The onset of melting for ibuprofen in the coevaporate is significantly lower (4 °C) compared to that of the IB starting material. The low value of $\Delta H_{f\,corr}$ is likely to be due to poor uniformity of the drug in the coevaporate; miscibility studies of IB and dextran 40 show that the two components form separate phases when mixed. The melting endotherm of IB shown in Figure 4 has a shallow onset slope which starts to rise at approximately 55 °C, this could indicate the presence of residual solvent in the coevaporate. Ibuprofen has a relatively high solubility in ethanol (1−1.5 parts ethanol[27]) and possibly forms a strong association with the solvent.

X-ray Powder Diffraction Studies—All diffractograms of the coevaporate show the crystalline structure of IB (Figure 5). One sample does show a small diffuse pattern in a diffractogram which could indicate the presence of dextran 40. X-ray analysis of dextran 40 shows it to be amorphous with no sharp diffraction peaks. Other samples do not show a significant diffuse pattern characteristic of dextran 40, indicating the absence of the carrier in the samples studied with the possibility of regions of different drug/carrier concentration being present in the coevaporate. The X-ray diffractograms show no interaction between ibuprofen and dextran 40, as no shifts in position of peaks characteristic of ibuprofen occur. No new peaks appear in any of the spectra. The intensity of peaks characteristic of IB in the dextran coevaporate are lower than the peaks in the IB starting material, even after taking into account the dilution factor of dextran 40. This could possibly be due to a decrease in IB particle size in the coevaporate or particle orientation on analysis. Several changes in relative intensities of peaks characteristic of IB are shown between the starting material and the IB−Dextran 40 coevaporate in Figure 5. Changes in crystal habit and preferred orientation of IB may have occurred in the coevaporate. If indeed this has occurred, it is debatable as to whether the presence of dextran 40 is responsible for this change. It is possible that the strong affinity of the solvent ethanol for IB has somehow modified the growth kinetics of different crystal faces on the growing IB crystals. The effect of solvent of crystallization on the morphology of IB has been shown, with needlelike crystals being produced when IB is recrystallized from hexane and more equidimensional crystals being produced when recrystallized from ethanol.[28]

Miscibility Study of Ibuprofen and Dextran 40—Inspection of the IB melt at 120 °C containing 1% w/w dextran 40 showed particles of the carbohydrate dispersed in the melt; dextran 40 is not soluble in IB under these conditions.

Ibuprofen−Xylitol Dispersions Incorporating Lutrol F68—*Microscopy*—In all cases the ternary dispersions showed two phases when molten with a dispersion of the lipophilic IB globules in the XYL continuous phase. It was noted that with the binary system of IB and XYL in the molten state, phase separation was quite distinct with two completely separate regions. Vigorous stirring of the melts created globules of one phase dispersed in the continuous phase of the second component. The dispersion was not stable and reverted to separate phases within a matter of seconds on discontinuation of stirring. The incorporation of Lutrol F68 caused visible "macroglobules" of IB in the XYL continuous phase. The dispersion of globules was relatively stable in comparison to the binary system of IB: XYL, as discontinuation of stirring did not result in complete phase separation of IB and XYL. Results suggest that the addition of Lutrol F68 has lowered the interfacial tension between IB and XYL. Microscopy highlighted the two phases and showed separate crystallization of the phases, with xylitol crystallizing first in all sample compositions. The IB phase crystallized 2−3 h after the crystallization of XYL.

DSC Analysis—Many of the samples taken from the resolidified mixtures of various ratios of drug:carrier: bridging agent only showed the melting endotherm of XYL (onset, 92 ± 1 °C, $n = 5$) when analyzed by DSC (10−110 °C at 5 °C/min). The possibility that IB and Lutrol F68 were amorphous in the dispersion was disproved with subsequent XRPD experiments and by preliminary interaction studies. The absence of melting endotherms for Lutrol F68 and especially for IB was attributed to the phase separation and heterogeneity observed by microscopy. A sample of the 1:1:8 IB:Lutrol F68:XYL dispersion showed a melting endotherm of 44 °C (onset, 39 °C), which did not correspond to the melting points of any of the components; melting onset of Lutrol F68 is 52.0 ± 0.5 °C (Figure 5). This suggested an interaction between components in the sample. This was further investigated by studying dispersions of Lutrol F68 with IB produced by the fusion method.

X-ray Powder Analysis—Diffractograms of all resolidified ternary mixtures showed heterogeneity in the samples with two phases present. Peaks characteristic of IB and XYL were identified. The absence of any shifts in peak positions or the presence of new peaks indicated no change in the crystal structures of IB or XYL in any of the dispersions. XRPD did not detect any peaks characteristic of Lutrol F68 in any of the samples.

Miscibility Studies—*Lutrol F68 with IB and XYL*—Inspection indicated that at least 25% w/w Lutrol F68 dissolved in IB at 80 °C, whereas a 1% w/w Lutrol F68 in xylitol mix showed a fine dispersion of Lutrol F68 at 110 °C.

Polysorbate 20, 40, 60, 80 and Polyoxyethylene 40 Stearate with IB and XYL—Inspection of the melts (80 °C) showed IB to be miscible with all of the bridging agents at 2% and 98% w/w, while XYL showed two phases with every bridging agent at the 2% and 98% w/w levels (110 °C).

Preliminary Interaction Studies of Ibuprofen and Lutrol F68—The resolidified IB:Lutrol F68 samples were analyzed by DSC from 0 to 120 °C at 5 °C/min. A binary phase diagram produced from the DSC curves of the dispersions showed the system to be a simple eutectic with a eutectic composition between 65 and 70% w/w Lutrol F68 (approximate mole ratio 20:1, IB:Lutrol F68) and a eutectic melting point of 37 ± 2 °C (onset temperature). This eutectic behavior between IB and Lutrol F68 has been documented previously.[29] Figure 6 shows DSC data on the physical mix and fusion samples of the IB:Lutrol F68 system. It can be seen that both the physical mix and fusion sample have a melting endotherm at approximately 37 °C. It appears that eutectic formation can occur by simply mixing. Three samples of the 1:3 w/w (slight excess of Lutrol F68) physical mix were analyzed by DSC and all show the same single melting endotherm at 39.6 ± 0.3 °C (onset temperature).

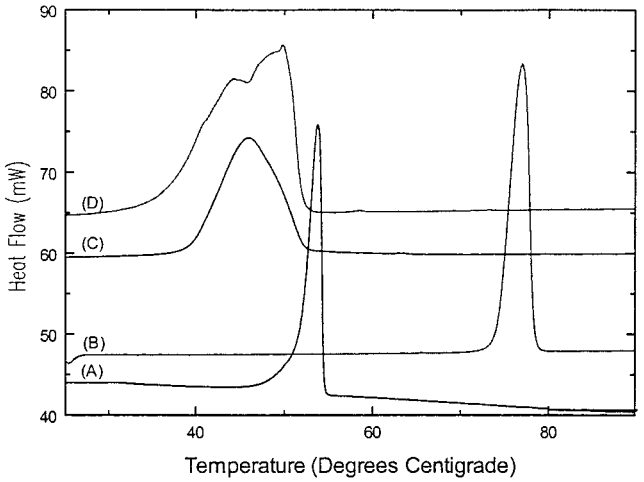

Figure 6—DSC analysis of Lutrol F68 alone (A), ibuprofen alone (B), 1:3 w/w IB:Lutrol F68 physical mixture (C), and 1:3 w/w IB:Lutrol F68 fused sample (D).

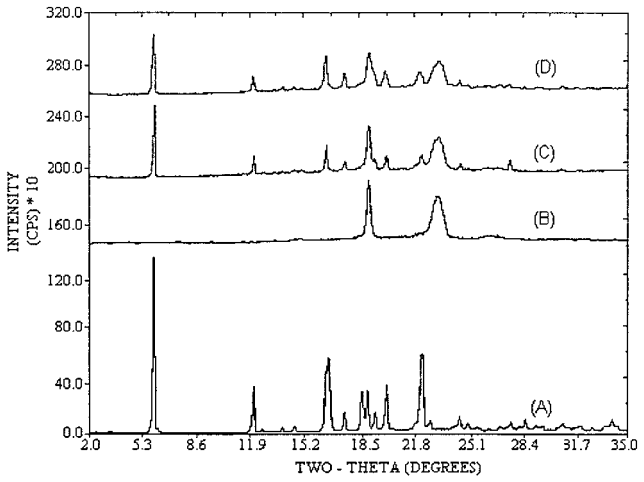

Figure 7—X-ray powder diffractograms: ibuprofen (A), Lutrol F68 (B), IB: Lutrol F68 1:3 w/w ground mixture (C), and IB:Lutrol F68 1:3 w/w fusion sample (D).

XRPD Analysis—Diffractograms of the IB:Lutrol F68 solid dispersions indicate IB to be crystalline and Lutrol F68 to be semicrystalline. Figure 7 shows traces of IB, Lutrol F68, a 1:3 w/w IB–Lutrol F68 physical mix, and fusion sample at 25 °C. Peaks characteristic of IB and Lutrol F68 can be seen in both the physical mix and fusion sample. The diffractograms of the physical mix and fusion samples in Figure 7 show that fusion of the components does not cause interactions between the drug and carrier on a bulk scale at 25 °C; crystal surface interactions may occur undetected by XRPD. Little change in crystallinity occurs on fusing the drug and carrier, as illustrated by the similar peak intensities in the traces of the physical mix and fusion sample (Figure 7). Further analysis of XRPD data from the binary system shows no shifts in peak position for IB or Lutrol F68, suggesting no changes in their bulk crystal structures. No evidence for solid solution formation between 10 and 90% w/w Lutrol F68 was found.

Solubility Parameters—Table 3 gives a list of drug/carrier systems which have been used in this and other selected studies in an attempt to produce solid dispersions of poorly water-soluble drugs. A brief description of each system, the solubility parameters of the components, and the difference in solubility parameters of the two materials are given in an attempt to identify a link between immiscibility problems and differences in the solubility parameter. The systems have been categorized in terms of miscibility, using the classification system in Table 2.

Several of the drug/carrier systems in Table 3 show a strong link between differences in solubility parameter and incompatibility. IB, tolbutamide, and nifedipine show interactions with carriers that possess similar solubility parameters (differences ranging from 1.6 to 7.0 $MPa^{1/2}$) and immiscibility problems with carriers where the difference in solubility parameter is above 10 $MPa^{1/2}$ (differences ranging from 10.8 to 18.0 $MPa^{1/2}$). The systems in Table 3 have been classified into arbitrary groups. Category B contains several different types of phase diagram, but these cannot be differentiated further by studying $\Delta\delta$. For example, 70% w/w of phenobarbital dissolves in citric acid at its melting point and $\Delta\delta$ is 4.3 $MPa^{1/2}$. Within the same category naproxen shows negligible solubility in PEG 4000 at its melting point but $\Delta\delta$ is only 3.5 $MPa^{1/2}$. From the data in Table 3 it is difficult to predict what type of phase diagram will result with drug/carrier systems where the $\Delta\delta$ is below 7.5 $MPa^{1/2}$. However, Table 3 does show a general trend in that systems with a $\Delta\delta$ ranging from 1.6 to 7.5 $MPa^{1/2}$ show complete miscibility when molten; systems with a $\Delta\delta$ from 7.4 to 15.0 $MPa^{1/2}$ show some sign of immiscibility in the liquid state, and systems with a $\Delta\delta$ above 15.9 exhibit total immiscibility over the entire composition range. The lack of a clear link between the type of phase diagram and $\Delta\delta$ where $\Delta\delta$ is relatively small (i.e. systems in category B) may relate to the accuracy of the solubility parameters quoted, especially with polymer carriers. It is also considered that Fedors' values of group contributions are less accurate than other data sets.[20] Further, Hildebrand parameters do not detail types of interactions in materials, unlike Hansen partial solubility parameters, which give the relative strengths of the dispersion forces, polar forces, and hydrogen bonding forces present in the material. If Hansen parameters were compared between drug and carrier, clearer links between partial solubility parameters and degree of miscibility may be established. The lack of a clear relationship between phase diagrams and $\Delta\delta$ may also relate to the fact that materials may exhibit two or more solubility parameters in an effort to adapt to their environment,[39] which is not accounted for with Hildebrand parameters. This can occur with materials that possess functional groups capable of hydrogen bonding; this "chameleonic effect" has been reported with sulfamethyoxypyridazine in solvents of vary-

Table 2—Classification of Miscibility

category	type of phase diagram
A	Both components completely miscible at all compositions in the liquid state. Large degree of solid/solid solubility (above 5% w/w). Complex formation.
B	Both components completely miscible at all compositions in the liquid state. Eutectic systems (immeasurable solid solution formation), where there is substantial solubility of one component in the second component at its melting point. Systems where there is a melting point depression of only the highest melting point component but negligible solubility of this material in the second component at its melting point.
C	Both components completely miscible at all compositions in the liquid state. Limited or no solubility of component A in B or B in A below melting point of either component.
D	Some degree of immiscibility when both components are in the liquid state.
E	Complete immiscibility at all proportions when both components are molten.

Table 3—Solubility Parameters and Classification of Solid Dispersions in Terms of Miscibility

drug/carrier system (category)	description	δ (MPa)$^{1/2}$	$\Delta\delta$[a]	ref
ibuprofen/PVP (A)	IB forms a 1:1 drug:polymer complex in the solid state (XRPD and DSC studies).	20.9/22.5[b]	1.6	Najib et al.[30]
chlorthalidone/urea (B)	Forms a eutectic system. Eutectic composition contained 35% w/w chlorthalidone.	32.6/38.5	5.9	Bloch et al.[31]
diazepam/PEG 4000 (B)	Forms a eutectic system. Eutectic composition contained 17% w/w diazepam.	27.4/19.9[c]	7.5	Anastasiadou et al.[32]
famotidine/xylitol (B)	Forms a eutectic system. Eutectic composition contained ca. 2.4% w/w famotidine.	29.6/37.1	7.5	Mummaneni and Vasavada[33]
flurbiprofen/PEG 400 and 6000 (B)	Forms a eutectic system by physical mixing, coevaporation, and comelting. Eutectic composition contained 35% w/w flurbiprofen with PEG 4000 and 33% w/w with PEG 6000.	23.7/19.9,[c] 23.7/19.8[c]	3.8, 3.9	Lacoulonche et al.[34]
griseofulvin/PEG 2000 (B)	Melting point depression of drug (liquidus curve), but not of PEG (solidus curve). Negligible solubility of drug in PEG at its mp. Liquidus curve meets solidus curve at 0% drug and mp of PEG. The rising liquidus curve with increasing amount of drug analogous to the solubility of the drug in molten PEG at various temperatures.	23.9/20.1[c]	3.8	Kaur et al.[35]
griseofulvin/polyoxyethylene 40 stearate (POES) (B)	Melting point depression of drug (liquidus curve), but not of POES (solidus curve). Negligible solubility of drug in POES at its mp. Liquidus curve meets solidus curve at 0% drug and mp of POES. The rising liquidus curve with increasing amount of drug analogous to the solubility of the drug in molten POES at various temperatures.	23.9/19.8[c]	4.1	Kaur et al.[35]
ibuprofen/Lutrol F68 (B)	Forms a eutectic system. Eutectic composition contained 30–35% w/w ibuprofen.	20.9/19.0[d]	1.9	Reported in this paper. Hawley et al.[29]
naproxen/PEG 4000 and 6000 (B)	Melting point depression of drug (liquidus curve), but not of PEG (solidus curve). Negligible solubility of drug in PEG at its mp. Liquidus curve meets solidus curve at 0% drug and mp of PEG. The rising liquidus curve with increasing amount of drug analogous to the solubility of the drug in molten PEG at various temperatures.	23.4/19.9, 23.4/19.8	3.5, 3.6	Mura et al.[36]
nifedipine/ethylurea ETU (B)	Melting point depression of drug (liquidus curve), but not of ETU (solidus curve). Negligible solubility of drug in ETU at its mp. Liquidus curve meets solidus curve at 0% drug and mp of ETU. The rising liquidus curve with increasing amount of drug analogous to the solubility of the drug in molten ETU at various temperatures	24.8/28.9	4.1	Suzuki and Sunada[3]
nifedipine/nicotinamide (B)	Forms a eutectic system. Eutectic composition contained 25% w/w nifedipine.	24.8/31.8	7.0	Suzuki and Sunada[3]
nifedipine/PEG 6000 (B)	Melting point depression of drug (liquidus curve) but not of PEG (solidus curve). Negligible solubility of drug in PEG at its mp. Liquidus curve meets solidus curve at 0% drug and mp of PEG. The rising liquidus curve with increasing amount of drug analogous to the solubility of the drug in molten PEG at various temperatures.	24.8/19.8[c]	5.0	Suzuki and Sunada[3]
phenobarbital/citric acid (B)	60–70% w/w phenobarbital is soluble in citric acid at its melting point. All mixtures show a single homogeneous phase when molten.	29.5/33.8	4.3	Timko and Lordi[37]
tolbutamide/PEG 2000 (B)	Melting point depression of drug (liquidus curve) but not of PEG (solidus curve). Negligible solubility of drug in PEG at its mp. Liquidus curve meets solidus curve at 0% drug and mp of PEG. The rising liquidus curve with increasing amount of drug analogous to the solubility of the drug in molten PEG.	23.2[e]/20.1[c]	3.1	Kaur et al.[35]
tolbutamide/polyoxyethylene 40 stearate (B)	10% w/w tolbutamide dissolves in POES at its melting point; liquidus curve (drug melting) meets solidus curve (POES melting) at 10% w/w tolbutamide and mp of POES. The rising liquidus curve with increasing amount of drug analogous to the solubility of the drug in molten POES at various temperatures. No mp depression of POES at any composition.	23.2[e]/19.8[c]	3.4	Kaur et al.[35]
acetaminophen/dextrose (D)	Liquid immiscibility over large composition range in phase diagram. Visual inspection of melts shows two phases. Two T_gs representing glass solution of carrier in drug in midrange of phase diagram, corresponds to two phases when both components are molten. Single T_g at low and high % drug; single phase when drug and carrier are molten.	30.8/43.1	12.3	Timko and Lordi[25]
acetaminophen/sorbitol (D)	Liquid immiscibility over large composition range in phase diagram. Visual inspection of melts shows two phases. Two T_gs representing glass solution of drug in carrier and glass solution of drug in carrier and glass solution of carrier in drug in midrange of phase diagram; corresponds to two phases when both components are molten. Single T_g at low and high % drug, single phase when drug and carrier are molten.	30.8/38.2	7.4	Timko and Lordi[25]
nifedipine/erythritol[f] (D)	At 25% w/w nifedipine, two liquid phases identified when components are molten.	24.8/35.6	10.8	Suzuki and Sunada[3]
nifedipine/urea[f] (D)	At 25% w/w nifedipine, two liquid phases identified when components are molten.	24.8/38.5	13.7	Suzuki and Sunada[3]
nifedipine/xylitol[f] (D)	At 25% w/w nifedipine, two liquid phases identified when components are molten.	24.8/37.1	12.3	Suzuki and Sunada[3]
phenobarbital/sorbitol (D)	Liquid immiscibility over large composition range in phase diagram. Visual inspection of melts shows two phases. Two T_gs representing glass solution of drug in carrier and glass solution of carrier in drug in midrange of phase diagram; corresponds to two phases when both components are molten. Single T_g at low and high % drug; single phase when drug and carrier are molten.	29.5/38.2	8.7	Timko and Lordi[25]
tolbutamide/mannitol (D)	Eutectic formation. Eutectic composition contained 94% w/w tolbutamide. Formation of two liquid phases at 40 and 80% w/w mannitol above melting point of mannitol.	23.2[e]/38.2	15.0	El-Banna et al.[11]
hexobarbital/dextrose (F)	Liquid/liquid immiscibility over complete composition range. Visual inspection of melts. Two T_gs representing pure drug and pure carrier were present over entire composition range.	27.2/43.1	15.9	Timko and Lordi[25]
ibuprofen/maltose (F)	Immiscible when both components are molten at 1% and 99% w/w; visual inspection of melts.	20.9/38.9	18.0	reported in this paper

Table 3 (Continued)

drug/carrier system (category)	description	δ (MPa)$^{1/2}$	$\Delta\delta^a$	ref
ibuprofen/sorbitol (F)	Immiscible when both components are molten at 1% and 99% w/w, visual inspection of melts.	20.9/38.2	17.3	reported in this paper
ibuprofen/xylitol (F)	Immiscible when both components are molten at 25% w/w, 50% w/w, 75% w/w and 99.9% w/w, ibuprofen	20.9/37.1	16.2	reported in this paper

[a] $\Delta\delta$ is difference in solubility parameters between drug and carrier. [b] The molar group contributions to polymer cohesive energies compiled by Van Krevelen and Hoftyzer[38] were used. These tables contain no value for the amide group in the molecule, so Fedors' value[19] for the group was used. [c] The Hildebrand solubility parameter was calculated using entire molecule. Group molar attraction constants of Van Krevelen and Hoftyzer[38] were used. [d] The Hildebrand solubility parameter for Lutrol (polyoxyethylene–polyoxypropylene–polyoxyethylene block copolymer) was calculated using molar group contributions to polymer cohesive energies compiled by Van Krevelen and Hoftyzer.[38] [e] A value for the contribution of the $-SO_2-$ group to the molar vaporization energy of the molecule was obtained from Martin et al.[15] Values for the other groups within the molecule were obtained from tables compiled by Fedors.[19] [f] Drug/carrier systems could belong to category E as the degree of immiscibility in the liquid state is not known.

ing polarity, with the drug showing solubility maxima in solvents with Hildebrand solubility parameters of 30.9 MPa$^{1/2}$ (lower solubility peak) and 20.9 MPa$^{1/2}$ (higher solubility peak). The Hildebrand solubility parameter of sulfamethoxypyridazine was calculated at 25.0 MPa$^{1/2}$ using Fedors' group contribution method.[39] Benzoic acid also shows a solubility parameter of 26.9 MPa$^{1/2}$ in highly polar solvents and 23.1 MPa$^{1/2}$ in less polar mixtures;[39] the calculated value was 24.4 MPa$^{1/2}$. Many of the drugs in Table 3 possess several polar and hydrogen bonding groups within the molecule and are probably capable of interacting with different materials in a number of different ways. The donor−acceptor capacity of hydrogen-bonding groups in drug and carrier must be considered to maximize interaction between the two materials. One further consideration when using solubility parameters is that δ may modify with temperature. It is possible that different materials will have solubility parameters which change to varying degrees with a change in temperature; these differences may become significant at high temperatures and may play a role in high melting point drug/carrier systems, for example, phenobarbital (mp 174−178 °C) and citric acid (mp 152−156 °C). Crystallinity can also have an effect on solubility parameters, as was shown by Egawa et al.,[40] where amorphous cefalexin was shown to have higher partial solubility parameters compared to a crystalline sample.

However, despite the limitations of the approach, solubility parameters may provide a simple and generic capability for rational selection of carriers in the preparation of solid dispersions. From the data generated in the present study, miscibility was shown between ibuprofen and Lutrol F68, where solubility parameters differed only by 1.9 and where a eutectic system was formed. Similarly, from the literature, ibuprofen/PVP systems where $\Delta\delta$ is only 1.6 were also completely miscible.[30] In contrast, our data have also demonstrated immiscibility where solubility parameters are markedly different; ibuprofen with maltose, sorbitol, and xylitol did not form solid dispersions and $\Delta\delta$ values were 18.0, 17.3, and 16.2, respectively. These data thus appear to support the validity of using solubility parameter differences as a tool for judicial selection of carrier components. Subsequent analysis and further refinement of this approach would need to address other factors such as crystallization inhibition by the excipient.

Conclusion

Ibuprofen has been shown to be incompatible with many sugar carriers when attempting to form solid dispersions. The coevaporate and fusion samples of ibuprofen with xylitol and the other sugar carriers show a decreased uniformity of the drug in the carrier compared to simple mixing. Both coevaporates and fusion samples must be powdered and blended to get a homogeneous dispersion. The mixing of ibuprofen with noninteracting sugar carriers may increase the drug's dissolution rate to a small extent, but overall it is probable that a drug and carrier combination where interactions between components occur will show a faster dissolution rate of the hydrophobic drug in aqueous medium. The use of bridging agents to facilitate dispersion of ibuprofen into xylitol did not prove successful, since none of the bridging agents mixed with xylitol. All bridging agents were miscible with ibuprofen.

This paper has highlighted a trend in terms of increasing degrees of immiscibility with increasing difference in solubility parameter between drug and carrier. The use of Hildebrand solubility parameters to predict compatibility has been reported by Suzuki and Sunada[41] and was found useful for selecting a suitable polymer as a component of combined carriers in solid dispersions of nifedipine. The Hildebrand solubility parameters used in this paper are relatively quick to calculate using group contribution methods and have the advantage that data for different structural groups are readily available, enabling calculation of solubility parameters for many complex drug molecules. However, it has been highlighted that the use of Hildebrand parameters in predicting accurately the phase diagram and specific level of interaction between drugs and carriers is limited. Several reasons for the observed anomalies have been discussed, including the fact that Hildebrand parameters give the overall cohesive energy in the materials but less information on the relative strengths of the various types of forces present (dispersion, polar, and hydrogen bonding). On this basis improved predictive qualities can be obtained using the Hansen partial solubility parameters (δ_d, δ_p, and δ_h). One practical problem of calculating Hansen parameters using group contribution methods is the limited data available on structural groups, thus causing difficulties for complex drug molecules. A database of partial solubility parameters for carriers and the determination of the contribution to partial solubility parameters of more structural groups found in drug molecules may enable prediction of compatible carriers which form strong associations with the drug, resulting in anticipating solid dispersion systems with fast drug dissolution rates.

Abstract □ Cromolyn sodium (CS, disodium cromoglycate) is an antiasthmatic and antiallergenic drug. The solid-state behavior of CS is still not completely understood. CS forms nonstoichiometric hydrates and sorbs and liberates water in a continuous manner, although with hysteresis. The reported continuous changes in crystal lattice parameters of CS, which are associated with the changes in water stoichiometry, renders CS physically variable, which may complicate formulation and processing. In addition, controversies still remain as to whether CS exists as different stoichiometric hydrates, mainly because of its variable powder X-ray diffraction (PXRD) patterns (Cox, J. S. G. et al. *J. Pharm. Sci.* **1971**, *60*, 1458–65), which indicates a variable crystal structure. The objectives of this study are (a) to understand this unusual water uptake in the light of the molecular and crystal structures of CS, (b) to understand the relationship between the crystal structure and the PXRD patterns using Rietveld analysis, and (c) to investigate whether CS exists as different stoichiometric hydrates. The crystal structure of CS containing 6.44 molecules of water per molecule of CS was determined at 295 and 173 K. The packing arrangements in these structures (space group *P*1) are similar to those in a previous report, in which the water stoichiometry is 5 to 6, but the bond lengths, bond angles, and lattice parameters are different, reflecting the different water stoichiometries. In the crystal structure solved at 295 K, the position of only one of the two sodium ions could be determined. In the crystal structure solved at 173 K, the previously undetermined sodium ion is disordered over three sites, while four of eight water positions are partially occupied. The 2-hydroxypropane chain that links the two cyclic moieties of CS was found to be flexible, perhaps allowing the CS crystal to accommodate variable amounts of water. The lack of a fixed coordination site for the second sodium ion may contribute to the disorder of the water molecules. The nonstoichiometric water content of CS is mainly attributed to the water molecules that are associated with the two unoccupied sodium sites. From the PXRD patterns of CS powder, equilibrated at various relative humidities, the various lattice parameters, including previously unreported α, β, and γ values, were calculated using Rietveld analysis. The peak shifts in these PXRD patterns are quantitatively explained by slight changes in the unit cell parameters. The recently described solid forms of CS were prepared and were found to correspond to the original crystalline CS, described by Cox et al. (1971), but with contamination by the known M mesophase in various proportions. The present results support a variable crystal structure and not the existence of different stoichiometric hydrates of CS.

Introduction

Background—Cromolyn sodium (CS, the disodium salt of 1,3-bis(2-carboxychromon-5-yloxy)-2-hydroxypropane, also known as disodium cromoglycate, Figure 1), was introduced as an antiasthmatic and antiallergenic drug in 1967.[1] Despite a history of more than 30 years, the solid-state behavior of CS is still not completely understood.

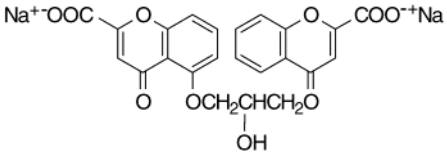

Figure 1—Molecular structure of cromolyn sodium.

In 1971, Cox et al.[2] reported that CS exists as two liquid crystalline phases (M and N) and a crystalline hydrate phase that sorbs and liberates water continuously and reversibly (although with a hysteresis loop) to give an infinite series of nonstoichiometric hydrates with a limiting composition of about 9 molecules of water per molecule of CS. The nonstoichiometric hydrate is physically unstable, in the sense that its composition changes readily as a function of the environmental relative humidity (RH). This potential for change may complicate formulation and processing. Understanding the reasons why cromolyn sodium forms nonstoichiometric hydrates, from the perspective of molecular and crystal structures, may help future preformulation and formulation of nonstoichiometric hydrates.

No polymorph of the crystalline hydrate phase was found by Cox et al.[2] The PXRD pattern of this phase was observed to change considerably with the surrounding RH, which the authors attributed to lattice expansion upon water sorption. In the same work, the lattice parameters, *a*, *b*, and *c*, of CS, were successfully calculated for RH values from 0 to 88%. However, only the changes in these lattice parameters *a*, *b*, and *c* were used to account for the shift in the PXRD peak positions. These changes alone could neither account for the peaks at small 2θ angle that correspond to *d*-spacings much larger than *a*, *b*, or *c*, nor for the observed appearance and disappearance of some PXRD peaks, because all six parameters, *a*, *b*, *c*, α, β, and γ, are actually influential. Further study is therefore needed to understand how the properties of the crystalline hydrate phase of CS change in response to the surrounding RH and to explain fully the changes in the PXRD patterns in the light of the molecular and crystal structures.

The crystal structure of cromolyn sodium with 5 or 6 water molecules per CS molecule was partially solved at room temperature by Hamodrakas et al. in 1973.[3] Unfortunately, the three-dimensional coordinates of the crystal structure were not reported or registered in any structural database. Hamodrakas et al.[3] located the positions of only one sodium ion and two water molecules and found that the other sodium ion and water molecules were disordered. Therefore, to further understand the crystal structure and to correlate it with the physical properties, redetermination of the crystal structure is necessary.

The detailed analysis of the two liquid crystalline phases, M and N, of CS, was provided by Hartshorne and Woo-

[a] The setting of the unit cell follows Hamodrakas et al.,[3] who interchanged *b* and *c* of Cox et al.[2] [b] Number of moles of water associated with 1 mol of cromolyn sodium in sorption (lower number) and desorption (higher number) from Cox et al.[2] [c] Profile residual: $R_p = \sum|y_i(o) - y_i(c)|/\sum y_i(o) \times 100\%$, where $y_i(o)$ is the observed signal and $y_i(c)$ is the calculated signal. [d] The weighted profile residual. $R_{wp} = [\sum w_i[y_i(o) - y_i(c)]^2/\sum w_i[y_i(o)]^2]^{0.5} \times 100\%$, where $y_i(o)$ is the observed signal and $y_i(c)$ is the calculated signal.

dard.[4] Their X-ray diffraction study showed that the M phase has one intense sharp peak and two faint but sharp peaks at 2.4° to 6.0° 2θ, and a broad peak at 25.5° to 26.0° 2θ. The positions of the sharp peaks were reported to vary with the water composition, while the position of the broad peak remained invariant. This X-ray diffraction study also showed that the N phase, which exists at high water compositions, gives only the broad line at 25.5 to 26.0° 2θ. The CS crystalline hydrate phase readily converts to the M liquid crystalline phase and does so reversibly under certain circumstances.[4] The conversion from the M to the N liquid crystalline phase is also rapid and reversible.[4] Mesophase N is a nematic liquid crystal, whereas M is a "middle" phase in which the molecules are arranged as rods of indefinite length, parallel to the optic axis, and with the molecular planes oriented at 90°, on average, to the axes of the rods.[4]

In 1996 and 1997, Oguchi et al.[5,6] reported two new crystalline forms of CS, termed forms B and C, and applied designation form A to the original crystalline form of CS reported by Cox et al.[2] Oguchi et al.[5,6] reported differences between these forms of CS in their powder X-ray diffraction (PXRD) patterns, moisture sorption diagrams, and differential scanning calorimetric (DSC) traces. However, doubts remain as to whether B and C are truly new crystalline forms of CS. First of all, the hysteresis in water sorption and desorption of B and C is still not well explained. Second, the sharp diffraction peaks at small 2θ angles correspond to the sharp diffraction peaks of large *d*-spacings for the M liquid crystalline phase.[4] Other differences in the PXRD patterns may be attributed to the lattice expansion caused by the uptake of nonstoichiometric water, as reported by Cox et al.[2] On the other hand, the moisture sorption diagrams of B and C show stepwise water uptake, which is a characteristic of stoichiometric hydrates. Therefore, further investigations are needed to prove or to disprove the existence of the new crystalline forms of CS. In view of these conflicting interpretations, this report seeks to clarify the solid-state behavior of CS hydrates. Because the exact nature of the reported new forms A, B, and C is not clear, they are termed materials A, B, and C in this report.

Hypotheses To Be Tested—(1) Contamination of solid cromolyn sodium hydrate phases by liquid crystalline phases can occur under certain conditions, which will complicate the PXRD patterns, the moisture sorption isotherms, and the thermal analytical data. (2) The unusual nonstoichiometric water uptake of CS can be explained in light of its particular molecular and solid-state structures.

Specific Aims of the Work—(1) To redetermine the crystal structure of CS and to locate the second sodium ion and all the water molecules, and hence (2) to explain why cromolyn sodium forms nonstoichiometric hydrates and sorbs and liberates water continuously, (3) to understand the influence of relative humidity on the PXRD patterns of CS crystalline hydrate, and (4) to investigate whether CS exists as different stoichiometric crystalline hydrates.

Experimental Section

Materials—Cromolyn sodium, in the form of hydrated white crystalline powder, was a gift from Fisons, plc, Pharmaceutical Division (now Astra Charnwood and Rhône-Poulenc Rorer, Loughborough, UK). The glass capillaries, 0.5 and 1.0 mm in diameter and 0.01 mm in thickness, used to house single crystals for structure determination and small crystallites for obtaining PXRD patterns of CS at various defined RH values, were purchased from the Charles Supper Company (Natick, MA). The silicon powder, 60 mesh, used as a peak position reference for the PXRD experiments, was obtained from Aldrich Chemical Co. (Milwaukee, WI). Methanol was obtained from Fisher Scientific (Fair Lawn, NJ). Water was deionized and glass distilled in-house.

The single crystal used for the structural determination was crystallized from a slightly supersaturated solution of CS in water + methanol mixtures (v:v = 10:9, water activity = 0.76).[7] The elemental analysis of the crystals was carried out to ascertain their sodium stoichiometry.

Elemental Analysis—The prepared single crystals were dried at 170 °C for 30 min prior to elemental analysis by Quantitative Technology (Whitehouse, NJ). The carbon and hydrogen weight percentages were calculated from the evolved carbon dioxide and water vapor upon combustion. The sodium weight percentage was determined from atomic absorption.

Preparation of the Reported Crystalline Materials of Cromolyn Sodium—The three reported[5] materials of CS were prepared here by the methods outlined[5,6] for further characterization. Material A, the original CS crystal form reported by Cox et al.,[2] was crystallized from ethanol + water mixture (v:v = 4:7, water activity = 0.88).[7] Material B was crystallized by slow diffusion of *n*-hexane + 2-propanol (v:v = 1:1) into a 10% w/v aqueous solution of CS. Material C was crystallized from ethanol + water mixture (v:v = 6:9, water activity = 0.87).[7]

Optical Microscopy—Crystals of materials A, B, and C were observed under a video-enhanced microscope (Nikon Optiphot-Pol, Tokyo, Japan) equipped with the Metamorph Imaging System software (Universal Imaging Co., West Chester, PA).

Powder X-ray Diffraction (PXRD)—The PXRD patterns of materials A, B, and C were determined under ambient condition using a powder X-ray diffractometer (D-5005, Siemens, Munich, Germany) with Cu Kα radiation at 40 mA and 45 kV. The sample was packed in a quartz holder and scanned at room temperature (23 °C) at a step size of 0.05° with a counting time of 1 s per step.

The PXRD patterns of the original CS powder[2] were determined after equilibration at defined RH values. For this purpose the CS powder was sealed in glass capillaries together with saturated salt solutions (Table 1) of known relative humidity values[8,9] and allowed to equilibrate at 23 °C for more than one week. After equilibration, the PXRD patterns were obtained using a microdiffractometer (Bruker AXS, Siemens, Munich, Germany), equipped with an area detector (HI−STAR, Siemens, Munich, Germany) and a data analysis software (General Area Detector Diffraction System, GADDS, Siemens, Munich, Germany). Cu Kα radiation at 40 mA and 45 kV was used. The diffraction data were collected

Table 2—Isotropic Temperature Factors and Occupancies of the Sodium Ions and Oxygen Atoms in the Water Molecules in the Cromolyn Sodium Structure Solved at 173 K

O(17)	0.0623	0.439
O(18)	0.7954	1
O(19)	0.1773	1

[a] The occupancies of Na(2), Na(3), and Na(4) add up to 1. The occupancies of O(12)–O(19) add up to 6.44.

for 3000 s in a frame of 30° 2θ and a resolution of 0.02° 2θ. The sample was spun at 1 cycle per 5 s to minimize the effect of preferred orientation. At a given RH value, the same PXRD pattern was obtained when the original CS crystals were recrystallized from methanol + water mixtures (v:v = 2:1, water activity = 0.60)[7] and gently ground in an agate mortar.

Crystal Structure Determination and Refinement—An elongated crystal of CS, 0.40 × 0.20 × 0.05 mm, was covered with a thin layer of heavy oil to prevent moisture exchange with the environment, was attached to a glass fiber with epoxy resin, and was mounted on a goniometer (SMART system, Siemens, Munich, Germany) for data collection at 173 and 295 K. A cryogenic nitrogen stream was used to obtain the low temperature, 173 K. To determine the crystal structure of CS with low water content, a crystal was equilibrated at 23 °C and at 0, 11.6, or 21.6% RH for more than one month in a sealed glass capillary 0.5 mm in diameter,[10] which was then mounted on the diffractometer. An initial set of cell constants and an orientation matrix were calculated from reflections collected from three sets of 20 frames which were oriented such that the orthogonal wedges of reciprocal space were surveyed. This procedure produced orientation matrixes determined from 54 reflections. Final cell constants were calculated from a set of 3593 strong reflections of the actual data collection.

The data collection technique used was hemisphere collection. A randomly oriented reciprocal space was surveyed to the extent of 1.3 hemispheres to a resolution of 0.84 Å. Three major swaths of frames were collected with 0.30° steps in ω. Because the lattice is triclinic, some additional sets of frames were collected to provide a more accurate absorption correction.

A successful direct-methods solution (SHELX-V5.0, Siemens Industrial Automation, Inc., Madison, WI) was calculated and revealed most non-hydrogen atoms from the E-map. Several full-matrix least squares/difference Fourier cycles were performed which located the remainder of the non-hydrogen atoms. All non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms were placed in ideal positions and refined as riding atoms with individual (or group, if appropriate) isotropic displacement parameters.

Lattice Parameter Determination—The unit cell parameters of the original CS crystal form equilibrated at various RH values were refined using a Rietveld module (DBWS, Cerius 2, San Diego, CA), which interfaces with the DBWS[11] program for Rietveld refinement. Because CS gives complex diffraction patterns with severe peak overlap, it is difficult to index and to measure accurately the positions of each diffraction peak, as required for conventional unit cell parameter least squares refinements. The Rietveld method, which obtains a global least-squares fit between the calculated and the observed powder patterns, is a well-accepted method for refining accurate unit cell parameters.[12] The crystal structure of the original CS crystal form, solved at 295 K, was used as the starting trial structure. The diffraction intensities, peak shape (modeled by pseudo-Voigt profile shape function), systematic instrumental error in powder pattern measurement, and the unit cell parameters were refined.

Calculation of Theoretical Powder X-ray Patterns—The theoretical PXRD pattern of a given structure was calculated from the crystal structure using suitable software (Diffraction Simulation Module, Cerius2, San Diego, CA).

Table 3—Crystallographic Data, Data Collection, Solution and Refinement Parameters for the Crystal Structure of Cromolyn Sodium Prepared from Methanol + Water Mixtures (v:v = 9:10, water activity = 0.76) and Solved at 173 K

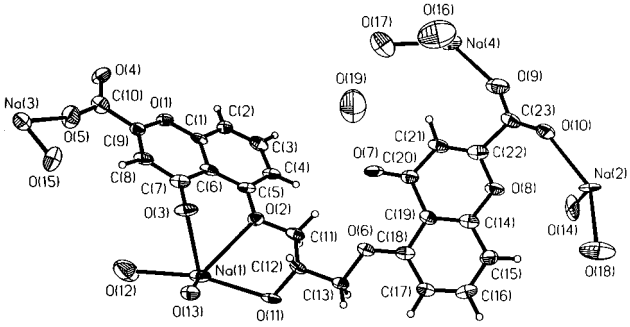

Figure 2—Thermal ellipsoid diagram, showing the atomic labeling scheme, of cromolyn sodium crystallized from methanol + water mixtures (v:v = 9:10, water activity = 0.76) and solved at 173 K.

Results and Discussion

Crystal Structure of the Original Crystalline Phase of Cromolyn Sodium—The CS structure was initially determined at 295 K and is similar to the structure previously reported.[3] The space group was determined as *P*1, a chiral space group, even though the molecule itself

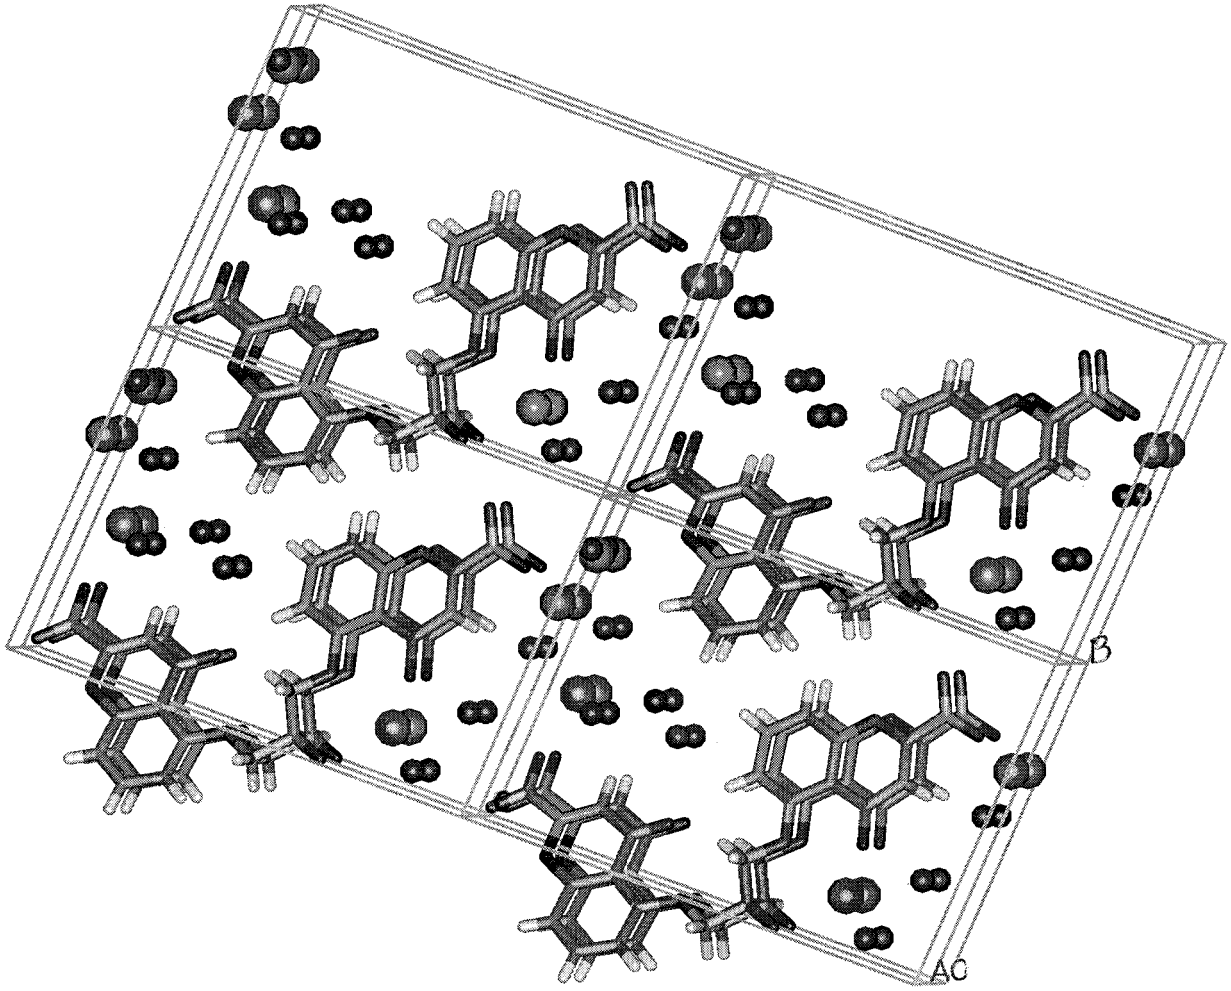

Figure 3—Crystal packing diagram, looking down the *a*-axis and showing 2*2*2 unit cells, for cromolyn sodium crystallized from methanol + water mixtures (v:v = 9:10, water activity = 0.76) and solved at 173 K. The smaller balls represent the oxygen atoms of the water molecules that have been located crystallographically, while the larger balls represent the located sodium ions.

is achiral. Examination of the molecular structure shows that the carbon atom bonded to the hydroxyl group can act as a chiral center in the crystal because the two cyclic moieties attached to this carbon are inequivalent in three-dimensional space. The CS crystallized as a racemic conglomerate of the two packing enantiomers. The structure solved at 173 K was a mirror image of the structure solved at 295 K and of that reported in the literature. Inversion was necessary for direct visual comparison of the three structures. The structures solved at 295 and 173 K were essentially identical. The intramolecular bond lengths and bond angles differed by less than 0.04 Å or 2°.

The structure was determined at 173 K in an attempt to locate all the water molecules and sodium ions. The smaller thermal motions at the lower temperature allowed better refinements of the water and sodium positions. The sodium positions are differentiated from the water positions by their coordination environment and smaller displacements (Table 2). Table 3 shows the crystallographic data and refinement parameters. Figure 2 is the thermal ellipsoid diagram with the atomic labeling scheme, while Figure 3 displays the crystal packing of 2*2*2 unit cells. Both Figures 2 and 3 show the ordered sodium ions, Na(1), and the disordered sodium ions, Na(2), Na(3), and Na(4), at 173 K, discussed in the next paragraph. Table 4 compares the intramolecular bond lengths and angles of the structure solved at 173 K with those of the structures solved at 295 K. Table 5 gives the sodium coordination distances in the structure solved at 173 K.

For the structure solved at 173 K, one sodium cation, Na(1), is tightly held in coordination with five neutral oxygen atoms of one ketone, one alcohol, and one ether group and two water molecules (Figure 4a). The second sodium ion is disordered over three partially occupied sites, Na(2), Na(3), and Na(4), in a maze of Na−O contacts (Figure 4b, c, and d, respectively). Four out of eight water positions are partially occupied. The occupancies of the sodium ions and water molecules are provided in Table 2. The three disordered sodium positions, Na(2), Na(3), and Na(4), all appear to have inferior coordination when compared to Na(1). All three disordered sodium positions have at least one water oxygen that must be displaced, due to unrealistically short contacts, if they are to occupy these sites. These contacts are Na(2)/O(14), Na(3)/O(15), and Na(4)/O(16). A restraint was used to force the sum occupancy of the three partially occupied sodium positions to unity. The occupancies of the unrealistic oxygen contacts were forced to have residual occupancy with respect to the sodium sites. Finally, O(17) appears to be partially occupied and not paired with a specific sodium ion. The total count of water molecules was 6.44 per cromoglycate anion.

Elemental analysis was deemed necessary because only one sodium ion could be located. Elemental analysis, in duplicate, afforded as follows: C 53.11, 52.97; H 2.91, 3.02; Na 8.32, 8.39%. These results agree well with those calculated from the molecular formula of cromolyn sodium: C 53.92; H 2.75; Na 8.97%. The observed differences between the experimental and the calculated weight per-

[a] The atom parentheses are omitted for clarity.

centages were ascribed to residual moisture, which the samples may have sorbed from the ambient environment during transfer from the drying oven to the analyzer. Nevertheless, these results indicate that the sodium stoichiometry of the prepared single crystals is indeed two (not one) sodium cation per cromoglycate anion, in accordance with the requirement of charge balance. Thus, one of the sodium ions, and some of the associated water molecules, are disordered in the CS crystal structure, explaining why the location of the sodium ion cannot be refined.

In the packing diagram (Figure 3), large sodium and water channels, which occupy approximately 50% of the cell volume, can be observed parallel to the *a*-axis and perpendicular to the plane of cromoglycate anions. The presence of relatively large sodium and water channels allows easy passage of water molecules with minimum energy expenditure and minimum disruption to the packing arrangements.

The entire structure of CS, equilibrated at 295 K and at RH values of 0, 11.4, and 21.6%, could not be solved by single crystal X-ray diffraction, suggesting significant reductions in crystallinity and emphasizing that the water molecules are structural elements necessary for holding together the crystal structure. On reducing the RH, both the water content and the crystallinity decreased gradually, suggesting that the transition between the crystalline form A and the amorphous form cannot be precisely defined.

Comparison of the Unit Cell Parameters of Cromolyn Sodium Structures with Different Water Contents—The lattice parameters, expressed as a function of RH and water content (Table 1), were derived from the PXRD patterns (Figure 5) using the Rietveld method. Figure 6 compares the observed PXRD pattern with that calculated after Rietveld refinement.

As the RH in the environment decreased, the unit cell parameters, *a*, *b*, *c*, α, and the volume, *V*, also decreased

Table 5—Sodium Coordination Distances of the Cromolyn Sodium Structure Solved at 173 K. The Structure Corresponds to 6.44 Water Molecules per Cromoglycate Anion

[a] These atoms are shown in Figure 4a–d. The atom parentheses are omitted for clarity. [b] (0,0,0) refers to the original unit cell. The digit 1 indicates forward transition by one unit cell. The digit –1 indicates backward transition by one unit cell. [c] This sodium ion–oxygen distance is unreasonably small, so the water molecule will be displaced when the sodium ion occupies this position.

(Table 1). The general trend of the unit cell dimensions as a function of RH is consistent with Cox et al.,[2] but the cell lengths differed slightly (<1%). The α angle was approximately 90° at RH ≤ 58.5%, but was approximately 92.5° at RH ≥ 75.4%. The β and γ angles were found to be relatively constant, at approximately 97.5° and 94.5°, respectively, over the entire RH values examined. At 0% RH, CS is mainly amorphous, as indicated by the broad amorphous halo, with only four distinguishable PXRD peaks for the (001), (010), (01−1), and (011) planes (Figure 5). From the 2θ values of these four peaks and with the assumption that the values of the lattice parameters, a, β and γ, at 6.5% RH are approximately equal to those at 0% RH, the lattice parameters b, c, and α of the CS structure at 0% RH were estimated (Table 1).

Molecular Conformation of the Cromolyn Anion—The structure of cromolyn sodium reported by Hamodrakas et al.[3] contains 5 to 6 (~5.5) water molecules per cromoglycate anion, while that solved here contains 6.44 water molecules per cromoglycate anion. Comparison between two structures can provide insight into the influence of water content on the molecular conformation of the cromolyn anion.

The two structures show similarities in packing arrangements and in most intramolecular bond lengths and bond angles. The major differences occur in the torsional angles of the two carboxylate groups and in the torsional and bond angles of the 2-hydroxypropane linking chain. The part of the 2-hydroxypropane chain that is coordinated to Na(1) is more rigid than the part that is not (Figure 7a). The largest changes in bond angle occur in C(12)−C(13)−O(6) and C(13)−O(6)−C(18), and are approximately 6° and 5°, respectively. As the water content increases from ~5.5 to 6.44, the two carboxylate groups rotate away from each other (Figure 7a), while the angle formed by the planes of

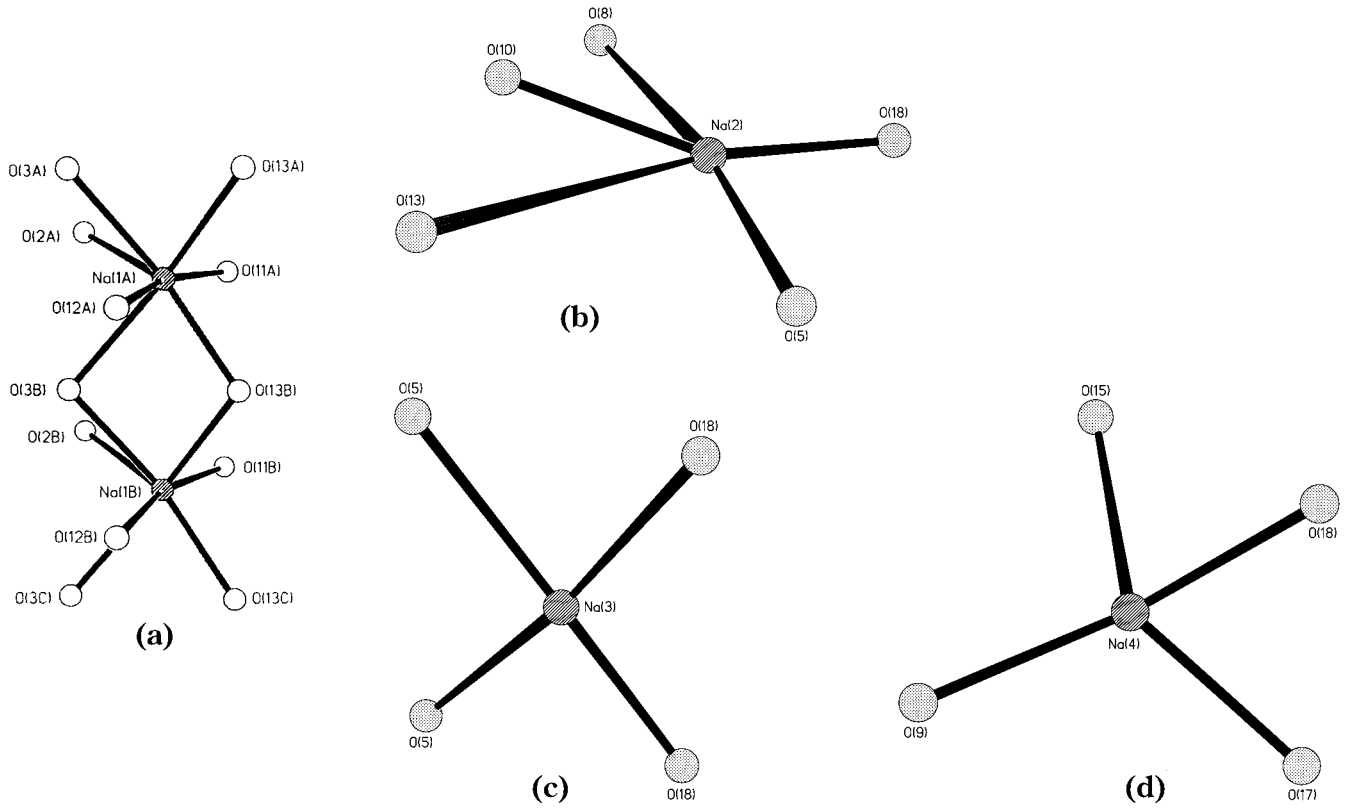

Figure 4—Coordination environment of: (a) the first (ordered) sodium ion, Na(1), shown in two neighboring unit cells (A and B); and the second (disordered) sodium ion at the three partially occupied sites, (b) Na(2), (c) Na(3), and (d) Na(4). The striped circles represent the sodium sites. The open circles represent the oxygen atoms coordinated to Na(1). The dotted (gray) circles represent the oxygen atoms coordinated to Na(2), Na(3), or Na(4).

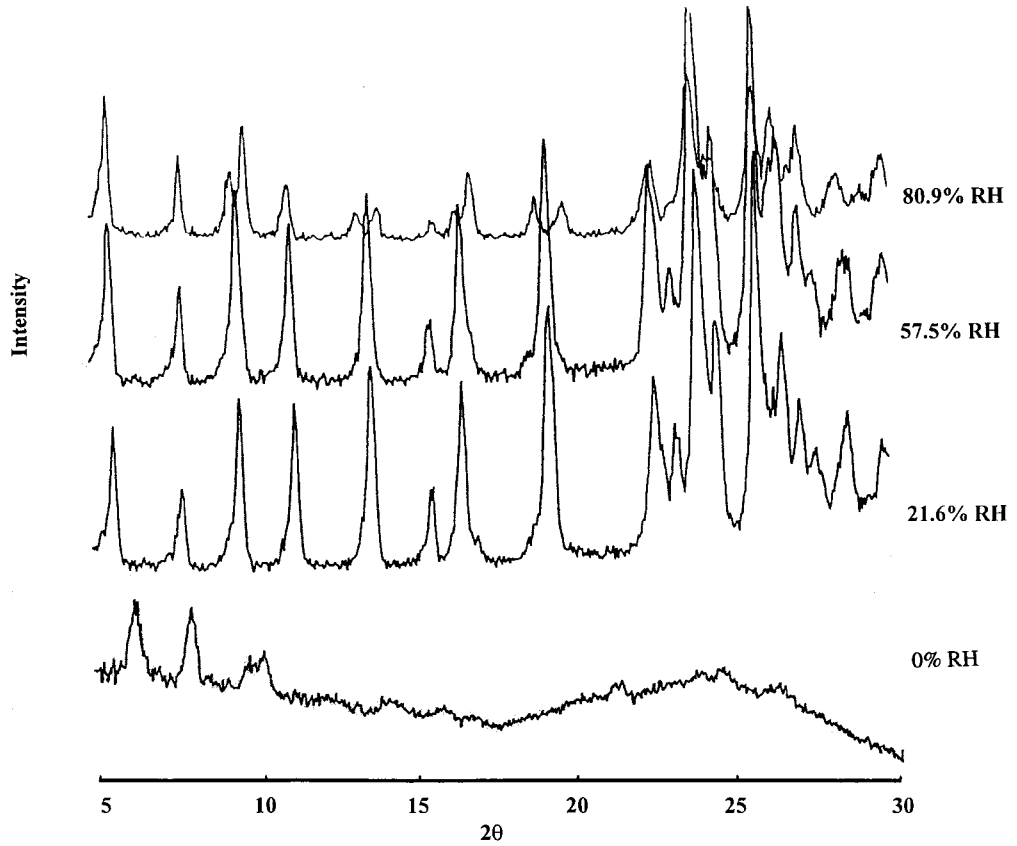

Figure 5—Powder X-ray diffraction patterns of cromolyn sodium crystallites equilibrated at four relative humidities: 80.9, 57.5, 21.6, and 0% at 23 °C.

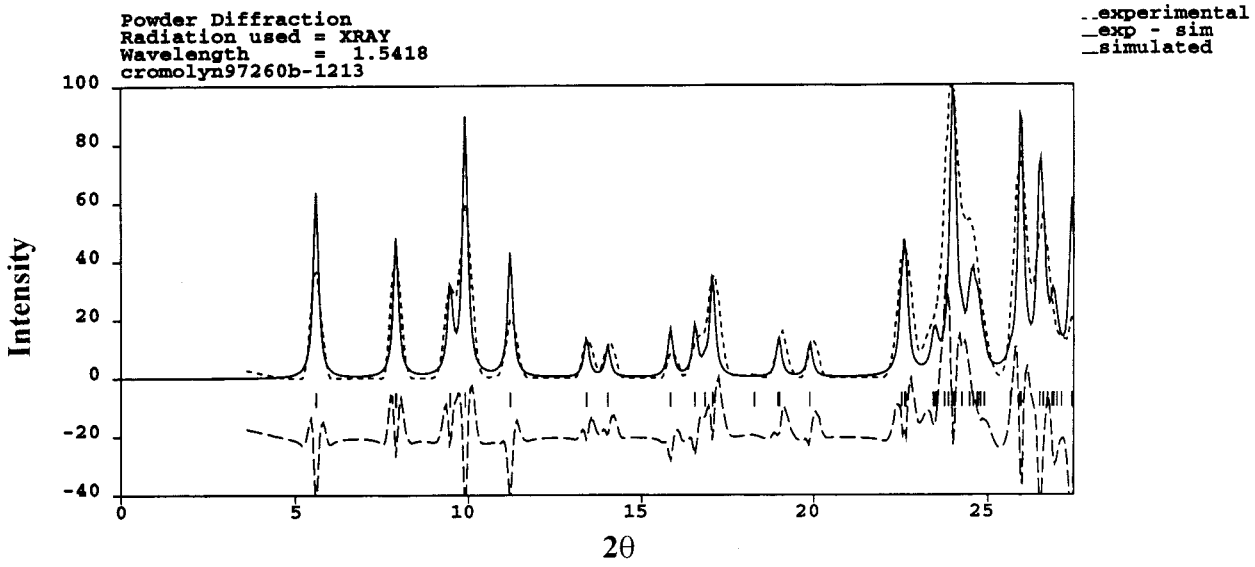

Figure 6—Powder X-ray diffraction patterns of cromolyn sodium: observed after equilibration at 80.9% relative humidity at 23 °C (top dashed line); calculated from the Rietveld-refined crystal structure at 173 K (top full line); difference between the calculated and the observed patterns (bottom dashed line). The vertical sticks mark the positions of the calculated diffraction peaks.

the two cyclic moieties decreases (Figure 7b) to form a larger water channel and stronger hydrophobic interactions between the cromoglycate anions in the *a* and *b* crystallographic directions. Because the carboxylate groups are coordinated to the second sodium ion, Na(2), Na(3), and Na(4), the change in torsional angles, C(8)−C(9)−C(10)−O(5) and C(21)−C(22)−C(23)−O(9), most likely reflect the change in its relative position.

In symmetrical molecules containing two planar moieties, such as CS or biphenyl,[13] the question arises whether the planar groups are in the same plane. For biphenyl in the crystalline state, Bushing[13] found that, above the transition temperature, the molecules have an average coplanar conformation, whereas below the transition temperature one phenyl ring is twisted relative to the other by as much as 10° at 22 K. While the two phenyl rings in biphenyl are linked by a covalent bond, the two cyclic moieties in CS are linked by a flexible 2-hydroxypropane chain, as discussed above. In the solution state, the cyclic moieties of CS are coplanar and the molecule (divalent anion) is symmetric. However, CS crystallizes in the space group, *P*1, corresponding to a complete lack of symmetry.

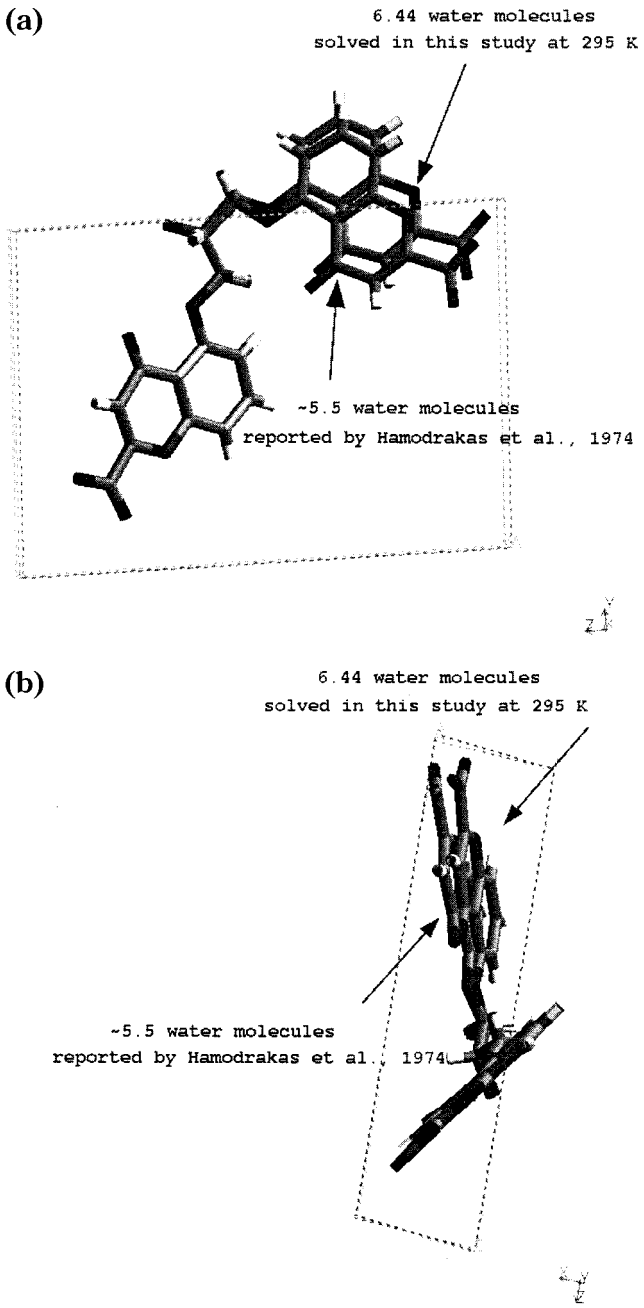

Figure 7—Overlay of the unit cells of the following two cromolyn sodium structures solved at 295 K: the structure with ~5.5 molecules of water per molecule of cromolyn sodium (reported by Hamodrakas et al., 1974);[3] the structure with 6.44 molecules of water per molecule of cromolyn sodium (solved in the present study); looking down (a) the *a*-axis and (b) the *b*-axis. The sodium ions and water molecules are omitted.

Moreover, the crystal contains a channel parallel to the short *a*-axis in which the disordered array of sodium ions and water molecules is found. It is possible that the crystal might achieve an ordered state with a certain water content at a certain temperature. However, this behavior has not been observed and would require further study.

Water Uptake of Cromolyn Sodium and Its Relationship to Structural Features—The high affinity for water and the reversible water sorption–desorption behavior of CS (Cox et al.,[2] also summarized in Table 1) can be understood from its molecular and crystal structures.

The hygroscopicity of CS is due to its ionic nature and the various polar functional groups: carboxylate, carbonyl, ether, and hydroxyl. The large sodium and water channels

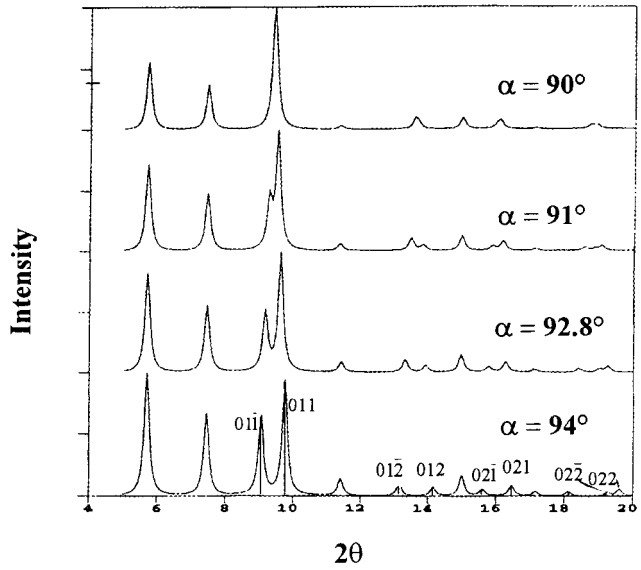

Figure 8—Theoretical powder X-ray diffraction patterns calculated by varying the α angle of the crystal structure of cromolyn sodium crystallized from methanol + water mixtures (v:v = 9:10, water activity = 0.76) and solved at 295 K.

along the *a*-axis, seen from the crystal packing diagram (Figure 3), allow easy passage of water molecules with little energy expenditure and minimal disruption to the crystal packing. This feature may explain the reversible water uptake of CS. Several factors contribute to the continuous and nonstoichiometric uptake of water by CS. First and foremost, the flexible 2-hydroxypropane chain linking the two cyclic moieties can relax readily to accommodate continuous lattice expansion caused by the continuous uptake of water. Second, the disordered sodium ion and the variable size of the large water channel cause the water to be disordered and allow for variable nonstoichiometric water contents that depend on the occupancies of the second sodium ion and the size of the water channel.

Powder X-ray Diffraction Pattern of Cromolyn Sodium as a Function of Relative Humidity—As stated above, the crystal structure of CS equilibrated at RH < 22% could not be solved by single-crystal X-ray diffraction, suggesting significant reductions in crystallinity. As the immediate environmental RH decreases, the PXRD pattern of CS (Figure 5) shows peak shifts toward smaller *d*-spacing (larger 2θ). Some PXRD peaks disappear and some appear as the RH changes. These appearances and disappearances can be explained by the change in the α angle of the crystal structure. The α angle is approximately 92.5° at RH ≥ 75.4% and is approximately 90° at RH ≤ 58.5%. As the α angle changed from 92.5° to 90°, the (100) and (004) peaks separated and the following pairs of peaks merged: (01−1) and (011); (01−2) and (012); (02−1) and (021); (02−2) and (022) (Figure 8).

Studies of the Different Crystalline Forms of Cromolyn Sodium Previously Reported[5,6]—The crystalline materials A, B, and C, prepared here following the procedures outlined by Oguchi et al.,[5,6] are all elongated transparent slabs (Figure 9); their PXRD patterns (Figure 10) correspond to those of the original crystal form of CS reported by Cox et al.,[2] with the exception of a diffraction peak below 5° 2θ, attributed to the formation of M liquid crystalline phase.[4] Close examination of the PXRD patterns of materials A, B, and C reported by Oguchi et al.,[5,6] reveals peaks corresponding to the M liquid crystalline phase.[4] Excluding the peaks corresponding to the liquid crystalline phase, the PXRD pattern of material A is identical to that of the original crystal form of CS equilibrated at RH ≤ 58%.

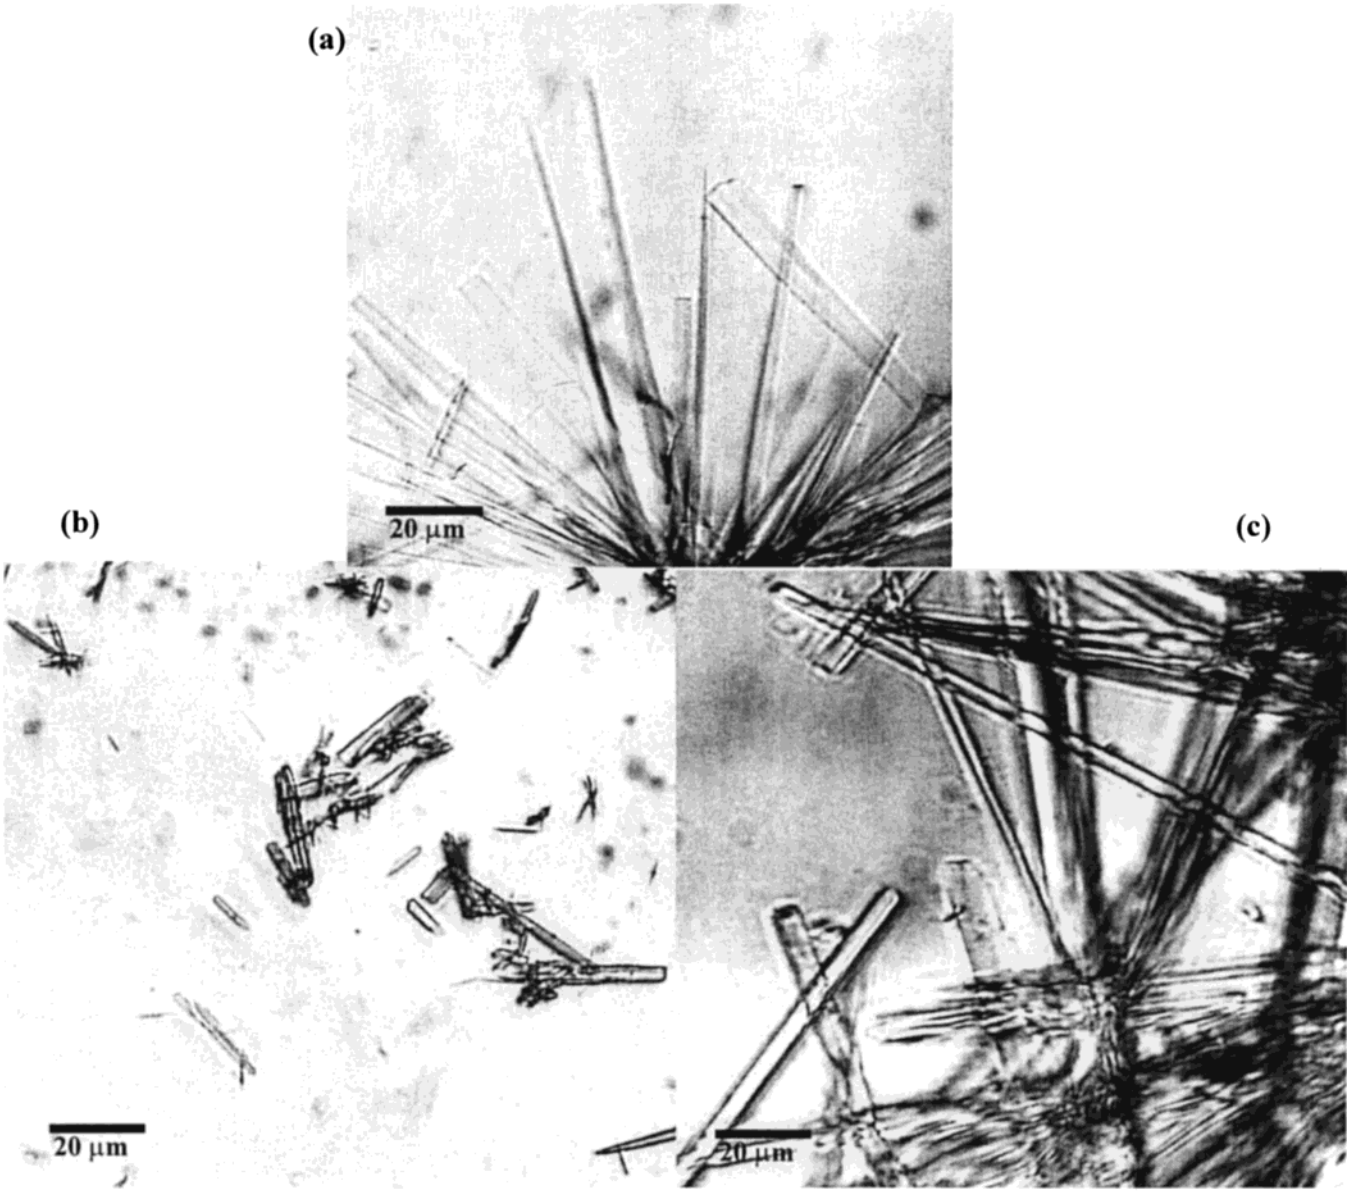

Figure 9—Photomicrographs of (a) material A, (b) material B, and (c) material C, prepared in our laboratory, according to procedures described by Oguchi et al.,[5–6] and submerged in silicone oil.

Similarly, the PXRD pattern of material B can be superimposed on the PXRD pattern of the original crystal form of CS equilibrated at RH ≥ 75.4%, with the exception of some small shoulder peaks, which can be attributed to fluctuations in the lattice parameters.[2] The sharp diffraction peaks in the PXRD pattern of material C can also be superimposed on the PXRD pattern of the original crystal form of CS equilibrated at RH ≥ 75.4%. When damp freshly harvested materials A, B, and C were observed under the polarized microscope, the crystals changed to a birefringent gel within 5 min. PXRD analysis showed that this gel is the M mesophase of CS.[4] The preferential evaporation of the alkanol used to prepare materials A, B, and C increased the water concentration and caused the observed formation of the M mesophase. These results indicate that materials A, B, and C are the original crystalline hydrate form[2,3] of CS contaminated by varying proportions of M, and hence explain the moisture sorption diagrams and the DSC curves of Oguchi et al.[5,6] The reported[6] DSC curve of material C appears identical to that of the M mesophase in the present work. The steps observed in the reported[5,6] moisture sorption diagrams are probably a reflection of the

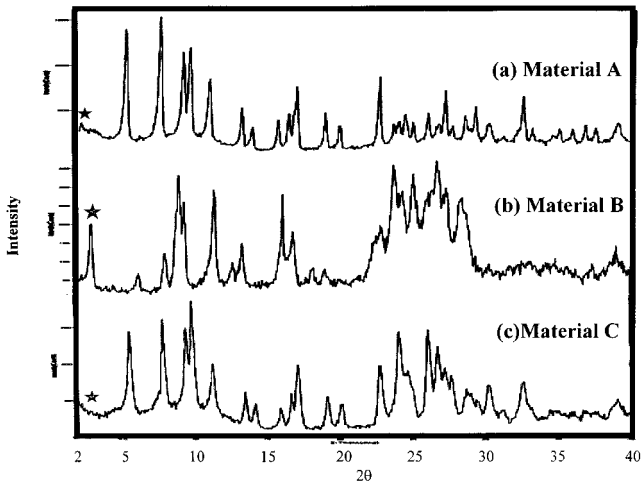

Figure 10—Powder X-ray diffraction patterns of (a) material A, (b) material B, and (c) material C prepared in our laboratory, according to the procedures described by Oguchi et al.[5,6]

reduction in the number of degrees of freedom caused by contamination with the liquid crystalline phase, M, in accordance with Gibbs phase rule and are not evidence for the formation of stoichiometric hydrates.

Conclusions

1. The "new forms" of CS reported by Oguchi et al.[5,6] have been prepared, characterized, and shown to be contaminated by the liquid crystalline phase, M, which complicated the PXRD pattern, moisture sorption, and the thermal analytical data.

2. Only one crystalline hydrate form of CS is observed, is nonstoichiometric, and corresponds to that reported by Cox et al.[2]

3. The crystal structure of CS with 6.44 water molecules per cromoglycate anion has been solved at 295 and 173 K. At 0% RH, loss of crystallinity accompanies loss of water, suggesting that the water molecules are necessary for holding together the crystalline structure. The second sodium ion of the CS occupies three partial crystallographic sites.

4. The solved crystal structure of CS is compared with that of Hamodrakas et al.,[3] which contains 5 to 6 water molecules per cromoglycate anion. The CS crystal structure is found to be flexible. The bond and torsional angles in the 2-hydroxypropane linking chain can change the relative orientations of the two cyclic moieties to accommodate lattice expansion or contraction resulting from water adsorption and desorption. The torsional angles of the two carboxylate groups can also change with changing water content.

5. The high water affinity and reversible water sorption−desorption of CS can be explained in terms of its molecular and crystal structure. The ionic nature and the polar groups of CS explain its hygroscopicity. The reversible and nonstoichiometric water sorption and desorption can be explained by the presence of large water channels, the flexible 2-hydroxypropane linking chain, and the disordered second sodium ion and the surrounding water molecules.

Abstract □ A diffusion model for the percutaneous absorption of a solute through the skin is developed for the specific case of a constant donor concentration with a finite removal rate from the receptor due to either perfusion rate or sampling. The model has been developed to include a viable epidermal resistance and a donor–stratum corneum interfacial resistance. Numerical inversion of the Laplace domain solutions were used for simulations of solute flux and cumulative amount absorbed and to model specific examples of percutaneous absorption. Limits of the Laplace domain solutions were used to define the steady-state flux, lag time, and receptor concentration. Steady-state approximations obtained from the solutions were used to relate the steady-state flux and the effective permeability coefficient to the viable epidermis resistance, a donor–stratum corneum interfacial resistance, receptor removal rate, and partitioning between the receptor and donor phases. The lag time was shown to be dependent on these parameters and on the volume of the receptor phase. It is concluded that curvilinear cumulative amount and flux–time profiles are dependent on the processes affecting percutaneous absorption, the shapes of the profiles reflecting the processes most determining transport.

Introduction

The interpretation of percutaneous absorption kinetics is highly dependent on the assumed mathematical model representation of transport across the epidermis. This information is then commonly applied to (1) optimize topical formulations, (2) develop transdermal delivery systems, (3) provide risk assessment for skin contaminants, and (4) predict the effect of physiological processes (such as changes in dermal blood flow) on the rate of percutaneous penetration.[1] A number of mathematical models have been used to describe percutaneous absorption kinetics.[2] Most percutaneous absorption kinetic models describe the time dependency of the cumulative amount of solute penetrating the epidermis into a sink receptor phase.[2] The models derived recognize constant and depleting donor concentrations and the resistance of the viable epidermis. When a constant donor concentration exists, the cumulative amount of solute penetrating the epidermis under steady-state conditions ($Q_{ss}(t)$) is linearly related to the exposure time t:

$$Q_{ss}(t) = J_{ss}A(t - \text{lag}) \quad (1)$$

where J_{ss} is the steady-state flux, lag is the lag time, and A is the area of application. The steady-state flux of solutes through the epidermis can be expressed in terms of an apparent permeability coefficient k'_p, and the difference in vehicle (C_{d0}) and receptor compartment ($C_{r\,ss}$) concentrations:[1−4]

$$J_{ss} = k'_p(C_{d0} - C_{r\,ss}) \quad (2)$$

A number of studies have shown that k'_p is defined by the resistances of both the stratum corneum and viable epidermis.[4−7] $C_{r\,ss}$ is defined by k'_p, A, C_{d0}, and the rate of removal of solute from the receptor compartment, designated as a clearance Cl_r:[8]

$$C_{r\,ss} = \frac{k'_pAC_{d0}}{Cl_r + k'_pA} \quad (3)$$

It is apparent that an increased Cl_r will reduce $C_{r\,ss}$ (eq 3) and, accordingly, increase J_{ss} (eq 2). A number of studies have shown that an increase in perfusion flow rate can increase percutaneous absorption.[9−11] In addition, a number of studies have shown that percutaneous absorption of lipophilic solutes is highly dependent on the nature of the receptor fluid and that certain receptor fluids underestimate *in vivo* absorption.[12−19]

We are not aware of mathematical expressions describing the curvilinear $Q(t)$ versus time profiles associated with nonsink conditions using a diffusion model for epidermal transport. Guy and Hadgraft[20] have given a theoretical expression for the diffusion-controlled release of a solute from a slab into a nonsink receptor. Curvilinear $Q(t)$ versus time profiles also occur when there is depletion in the donor phase associated with the application of a finite donor.[2] Parry et al.[21] presented an expression for the accumulation of solute in the receptor compartment with time when there was no clearance of solute from the receptor. Guy and Hadgraft[22] reported a pharmacokinetic model in which the influx into the membrane was assumed to be an exponential decline in vehicle concentration and the efflux from the membrane was defined by a first-order rate constant.

In this paper, we derive diffusion equations for the cumulative amount of solute penetrating through the epidermis from a constant donor concentration into a finite receptor volume with a finite removal clearance. Given the potential contribution of the viable epidermis and unstirred water layers as a resistance to transport into the dermis or receptor,[1−7] we have included this effect in our derivations. We have also included the complementary contribution of the vehicle−stratum corneum resistance, as this is relevant to transdermal patch delivery with delivery being controlled in part by a membrane or adhesive patch component. The Laplace expressions for cumulative amount−time and flux−time relationships are then used to define steady-state flux and lag times. These expressions were also used to characterize the effects of changing various determinants on the profiles described by the relationships and to explain experimental data. Given that

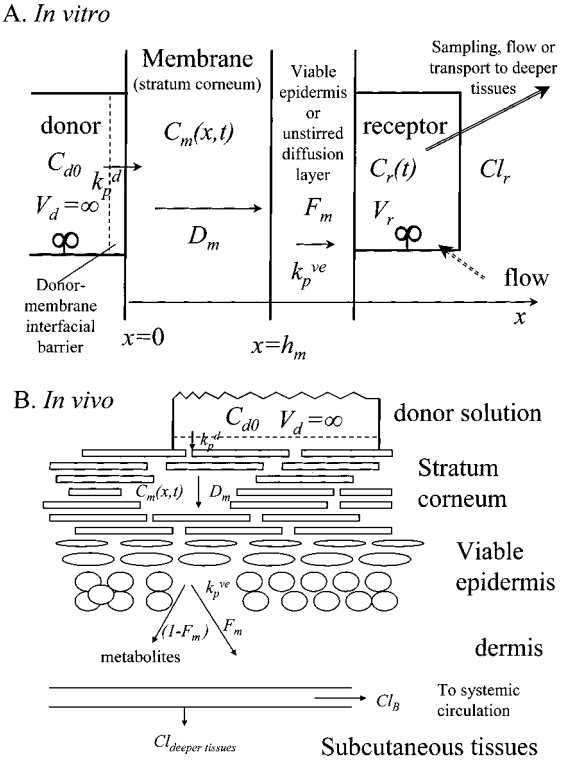

Figure 1—Schematic diagram of the model. (A) *In vitro* and (B) *in vivo* (see text for explanations of symbols).

many receptor fluids yield percutaneous absorption fluxes *in vitro* considerably lower than for *in vivo* with highly lipophilic compounds,[23] we have also considered the estimation of the apparent permeability coefficient from the apparent solubility of the solutes in a given receptor fluid.

Theory

Figure 1 shows a schematic diagram of the model used in this work. Both donor and receptor phases are represented as a well stirred compartments. The transport of solute through the stratum corneum, referred to in this section as the membrane, is described by the diffusion equation:

$$\frac{\partial C_m}{\partial t} = D_m \frac{\partial^2 C_m}{\partial x^2} \tag{4}$$

where $C_m(x,t)$ is the concentration of solute in the membrane at distance x at time t, and D_m is the diffusion coefficient. We assume there is no solute initially present in the membrane. The initial condition is therefore:

$$C_m(x,0) = 0 \tag{5}$$

The boundary conditions at the donor surface ($x = 0$) are defined by the partitioning of the solute between donor phase and membrane:

$$C_m(0,t) = K_m C_{d0} \tag{6}$$

where C_{d0} is the concentration in the donor phase, K_m is the partition coefficient between the membrane and donor ($K_m = C_m^{ss}/C_d^{ss}$ at the equilibrium between the membrane and donor).

Donor Surface Boundary Conditions—When an interfacial barrier exists adjacent to the membrane in the donor phase, boundary condition 6 becomes:

$$-D_m \frac{\partial C_m}{\partial x}|_{x=0} = k_p^d \left(C_{d0} - \frac{C_m}{K_m} \right) \tag{7}$$

where k_p^d is permeability coefficient through this barrier. In the specific case when this barrier is an unstirred diffusion layer in the donor phase, $k_p^d = D_{dl}/h_{dl}$, where D_{dl} and h_{dl} are diffusion coefficient and thickness of the layer.

Receptor Surface Boundary Conditions—The boundary conditions at the receptor surface ($x = h_m$, h_m is effective thickness of the membrane) are:

$$-D_m \frac{\partial C_m}{\partial x}|_{x=h_m} = k_p^{ve} \left(\frac{C_m}{K_m} - \frac{C_r}{K_r} \right) \tag{8}$$

$$V_r \frac{dC_r}{dt} = -AD_m \frac{\partial C_m}{\partial x}|_{x=h_m} - Cl_r C_r \tag{9}$$

where Cl_r is the removal rate (mL/min) of solution containing solute from the receptor phase, V_r is the volume of the receptor, K_r is the partition coefficient between the receptor and donor ($K_r = C_r^{ss}/C_d^{ss}$ at the equilibrium between the receptor and donor), A is the area of application, and C_r is the concentration in the receptor. In eq 8, k_p^{ve} is the permeability coefficient of solute due to a barrier between the membrane and receptor. In the specific case of the viable epidermis or an unstirred aqueous diffusion layer being the barrier, $k_p^{ve} = K_{ve}D_{ve}/h_{ve}$ where h_{ve} is the thickness of the viable epidermis/layer, D_{ve} is the diffusion coefficient in the viable epidermis/layer, and K_{ve} is the partition coefficient between the viable epidermis/layer and donor ($K_{ve} = C_{ve}^{ss}/C_d^{ss}$ at the equilibrium between the viable epidermis/layer and the donor). It is also noted that k_p' (eq 2) can be expressed in terms of k_p^{sc} and k_p^{ve} by[3–8] $1/k_p' = 1/k_p^{sc} + 1/k_p^{ve}$, where k_p^{sc} is the stratum corneum permeability coefficient. We have limited this analysis to pseudo-steady-state permeability coefficients k_p^{ve} and k_p^d for transport in the viable epidermis and unstirred receptor/donor diffusion layers, as representation of transport by the diffusion equation unnecessarily increases the complexity of the solutions, given that the lag time in the viable epidermis and unstirred diffusion layers is normally very small. While Cl_r *in vitro* is defined by either sampling rate or flow rate, Cl_r *in vivo* is defined by the sum of removal by blood flow and clearance by transport into deeper tissues below the application site.[3]

Laplace Domain Solution—We now consider the Laplace domain solution of eq 4 with boundary conditions 6–9. The Laplace transform of eq 4 with initial condition 5 is:

$$s\hat{C}_m = D_m \frac{d^2\hat{C}_m}{dx^2} \tag{10}$$

where hat over function (ˆ) denotes the Laplace transform.

The Laplace transforms of boundary condition expressions 6–9 are:

$$-D_m \frac{d\hat{C}_m}{dx}|_{x=0} = k_p^d \left(\frac{C_{d0}}{s} - \frac{\hat{C}_m}{K_m} \right) \tag{11}$$

$$-D_m \frac{d\hat{C}_m}{dx}|_{x=h_m} = k_p^{ve} \left(\frac{\hat{C}_r}{K_r} \right) \tag{12}$$

$$V_r s\hat{C}_r = -AD_m \frac{d\hat{C}_m}{dx}|_{x=h_m} - Cl_r \hat{C}_r \tag{13}$$

The general solution to eq 10 is

$$\hat{C}_m(x,s) = A_1 \sinh\left(\sqrt{st_d}\frac{x}{h_m}\right) + B_1 \cosh\left(\sqrt{st_d}\frac{x}{h_m}\right) \quad (14)$$

where A_1 and B_1 are constants independent of x to be determined by the boundary conditions, and t_d is the parameter with the dimension of time:

$$t_d = \frac{h_m^2}{D_m} \quad (15)$$

Substitution of $\hat{C}_m(x,s)$ in the form of eq 14 to boundary condition 11 yields for B_1:

$$B_1 = \frac{C_{d0}K_m}{s} + \frac{\sqrt{st_d}}{\kappa_d}A_1, \quad (16)$$

where dimensionless parameter κ_d is the relative permeability of the diffusion layer in the donor:

$$\kappa_d = \frac{k_p^d}{k_p^{sc}} \quad (17)$$

and k_p^{sc} is the permeability coefficient of membrane:

$$k_p^{sc} = \frac{K_m D_m}{h_m} \quad (18)$$

Solving boundary conditions 12 and 13 for A_1 with $\hat{C}_m(x,s)$ in the form of eq 14 and with B_1 determined in eq 16 yields expression for A_1:

$$A_1 = -\frac{C_{d0}K_m}{s}\frac{g_2(s)}{g_1(s) + \frac{\sqrt{st_d}}{\kappa_d}g_2(s)} \quad (19)$$

where functions $g_1(s)$ and $g_2(s)$ are:

$$g_1(s) = 1 + \frac{\kappa_{ve}}{Cl_{rN} + V_{rN}st_d} + \frac{\kappa_{ve}}{\sqrt{st_d}}\tanh\sqrt{st_d} \quad (20)$$

$$g_2(s) = \left(1 + \frac{\kappa_{ve}}{Cl_{rN} + V_{rN}st_d}\right)\tanh\sqrt{st_d} + \frac{\kappa_{ve}}{\sqrt{st_d}} \quad (21)$$

and dimensionless parameters κ_{ve}, Cl_{rN}, and V_{rN} are defined as:

$$\kappa_{ve} = \frac{k_p^{ve}}{k_p^{sc}} \quad (22)$$

$$Cl_{rN} = \frac{Cl_r K_r}{k_p^{sc}A} \quad (23)$$

$$V_{rN} = \frac{V_r K_r}{V_m K_m} \quad (24)$$

We note that the kinetic interpretations of parameters introduced here are as follows: t_d is of the order of magnitude of the diffusion time through membrane; κ_{ve} is a measure of the relative resistance of membrane ($1/k_p^{sc}$) to the resistance of the viable epidermis/aqueous layer ($1/k_p^{ve}$); Cl_{rN} is a measure of the magnitude of the removal rate from the receptor phase (Cl_r) relative to transport through the membrane ($k_p^{sc}A$); V_{rN} is the ratio of the amount of drug in the receptor phase and membrane ($C_rV_r/[C_mV_m]$) assuming equilibrium exists between phases.

Substitution of A_1 from 19 and B_1 from 16 to eq 14 yields the equation for the concentration in the membrane:

$$\hat{C}_m(x,s) = \frac{C_{d0}K_m}{s}\frac{g_1(s)\cosh\left(\sqrt{st_d}\frac{x}{h_m}\right) - g_2(s)\sinh\left(\sqrt{st_d}\frac{x}{h_m}\right)}{g_1(s) + \frac{\sqrt{st_d}}{\kappa_d}g_2(s)} \quad (25)$$

Flux of Solute—The flux of solute into the receptor phase is given by:

$$\hat{J}(s) = -D_m\frac{d\hat{C}_m}{dx}|_{x=h_m}. \quad (26)$$

Hence, from eqs 25 and 26:

$$\hat{J}(s) = \frac{k_p^{sc}C_{d0}}{s}\left[\left(\frac{1}{Cl_{rN} + V_{rN}st_d} + \frac{1}{\kappa_{ve}} + \frac{1}{\kappa_d}\right)\cosh\sqrt{st_d} + \left(\frac{1}{\sqrt{st_d}} + \frac{\sqrt{st_d}}{\kappa_d}\left[\frac{1}{\kappa_{ve}} + \frac{1}{Cl_{rN} + V_{rN}st_d}\right]\right)\sinh\sqrt{st_d}\right]^{-1} \quad (27)$$

Amount of Solute Absorbed—The cumulative amount of solute absorbed $Q(t)$ over time t into the receptor can be derived from the flux–time relationship for a solute:

$$Q(t) = \int_0^t AJ(t')dt' \quad (28)$$

Or in the Laplace domain:

$$\hat{Q}(s) = \frac{A\hat{J}(s)}{s} \quad (29)$$

Hence, from eqs 27 and 29:

$$\hat{Q}(s) = \frac{k_p^{sc}AC_{d0}}{s^2}\left[\left(\frac{1}{Cl_{rN} + V_{rN}st_d} + \frac{1}{\kappa_{ve}} + \frac{1}{\kappa_d}\right)\cosh\sqrt{st_d} + \left(\frac{1}{\sqrt{st_d}} + \frac{\sqrt{st_d}}{\kappa_d}\left[\frac{1}{\kappa_{ve}} + \frac{1}{Cl_{rN} + V_{rN}st_d}\right]\right)\sinh\sqrt{st_d}\right]^{-1} \quad (30)$$

Receptor Phase Concentration—Combining eqs 26 and 13 yields

$$V_r s\hat{C}_r = A\hat{J}(s) - Cl_r\hat{C}_r \quad (31)$$

Rearrangement yields the receptor concentration $\hat{C}_r(s)$:

$$\hat{C}_r(s) = \frac{A\hat{J}(s)}{V_r s + Cl_r} \quad (32)$$

Simulations and Data Analysis

Simulations in this section have been performed by numerical inversion of functions from the Laplace domain to the time domain using the program SCIENTIST (Micro-Math Scientific software). Numerical inversion of the Laplace domain solutions were used in these simulations for simplicity. The inversion of $\hat{Q}(s)$ to the time domain for arbitrary t is only possible in a form of an infinite sum of residues of function $e^{st}\hat{Q}(s)$ at its singularities and involves solving bulky transcendental equations. A solution in this form

was felt to be of limited value as reliable numerical inversion techniques are now available.[24]

Experimental data illustrating the effect of receptor composition (aqueous solutions containing Volpo N 20 or bovine serum albumin) and sampling times on the penetration of octyl salicylate as a 10% solution in liquid paraffin through 20 μm high density polyethylene membrane were produced by our group.[18,25] In addition, solubilities of octyl salicylate determined in Volpo N 20 6% (9.73 ± 0.21 mg/mL) and 4% bovine serum albumin (0.24 ± 0.01 mg/mL)[18,25] were used for data interpretation.

Results

The present model shows that, under conditions of constant donor concentration, the cumulative amount absorbed $Q(t)$, the flux $J(t)$ and the receptor phase concentration $C_r(t)$ can be expressed in Laplace domain by eqs 30, 27, and 32, respectively. These values have been expressed in terms of six parameters reflecting both intrinsic and extrinsic determinants of the resulting time profiles. The two usual intrinsic variables are the stratum corneum permeability coefficient (k_p^{sc}) and the diffusion time through the stratum corneum (t_d). The extrinsic variables are κ_d, κ_{ve}, Cl_{rN}, and V_{rN}. These variables are determined by receptor (dermal) clearance, receptor (dermal) volume (assuming it is effectively well-mixed), receptor phase composition (affinity for solute), viable epidermal (aqueous diffusion layer) resistance, and the vehicle–membrane interfacial resistance. We now consider the effects of each of these determinants on $Q(t)$, $J(t)$ and $C_r(t)$ versus t profiles. Later we express equations 30, 27 and 32 as steady state approximations and consider the explicit effects of each determinant.

Receptor (Dermal) Clearance—The effect of receptor (dermal) clearance on $Q(t)$ versus t profiles is defined by Cl_{rN}, which expresses Cl_rK_r relative to $k_p^{sc}A$ (eq 23). Figure 2a shows normalized plots of $Q/(k_p^{sc}AC_{d0}t_d)$ versus t/t_d for a specific case where both the relative viable epidermis resistance (κ_{ve}) and relative receptor volume (V_{rN}) equal 0.5, and there is no donor–stratum corneum interfacial resistance ($\kappa_d \rightarrow \infty$). It is apparent that as Cl_{rN} decreases, corresponding to a reduction in sampling rate, the cumulative amount absorbed decreases in a curvilinear manner. However, at long times, an apparent steady-state flux is reached. Figure 2b shows that decreasing the receptor clearance results in a lower steady-state flux (slope of relationship), a longer time to reach steady state, and, in this case, a negative lag time (lag_2). Figure 2c and Figure 2b show that the flux is reduced and receptor phase concentration increased by decreasing the receptor clearance.

Receptor (Dermal) Volume—Figure 3a shows that the volume of the receptor phase, as represented by $V_{rN}(= V_rK_r/[V_mK_m])$, eq 24 also affects the cumulative amount–time profiles. This analysis assumes that this volume is effectively well-mixed. The curvilinear profiles are less pronounced as V_{rN} increases. When $V_{rN} \rightarrow \infty$, the profile is equivalent to that for infinite sampling. It is apparent from Figure 3a that reducing the receptor volume results in the same steady-state flux when a finite receptor volume exists, as distinct from the much higher steady-state flux with sink conditions as defined by $V_{rN} \rightarrow \infty$. Figure 3a also shows that decreasing V_{rN} decreases the time to reach steady state. Consistent with this observations, V_{rN} affects the time for $C_r(t)$ to reach steady state, but not the actual $C_{r\,ss}$, when a finite volume exists.

Receptor Solution Composition—The receptor solution composition will determine the partition coefficient of the solute between the stratum corneum and receptor solution K_r and, in turn, $Cl_{rN}(= Cl_rK_r/(k_p^{sc}A)$, eq 23) and

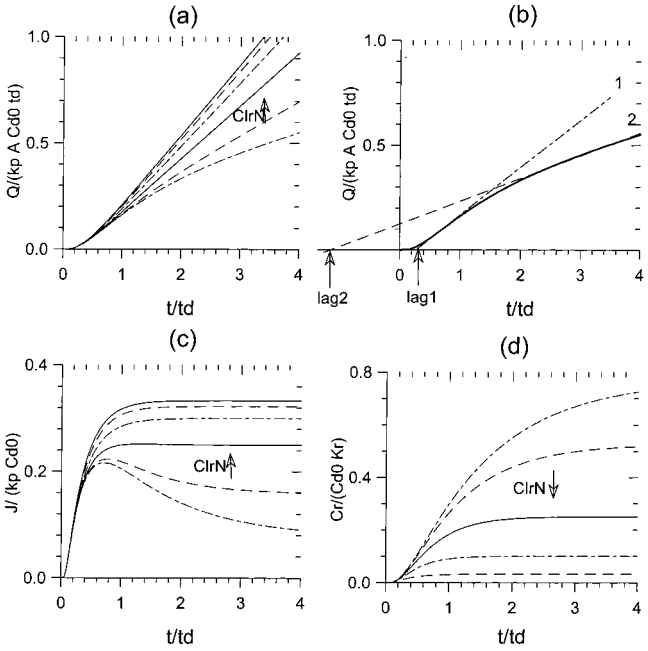

Figure 2—(a) Normalized cumulative amount absorbed versus normalized time profiles for $\kappa_{ve} = V_{rN} = 0.5$ and $\kappa_d = \infty$ based on eq 30 (κ_{ve} represents ratio of resistance of membrane, $1/k_p^{sc}$, to the resistance of the viable epidermis/aqueous layer, $1/k_p^{ve}$, κ_d represents ratio of resistance of membrane, $1/k_p^{sc}$, to the resistance of the vehicle–stratum corneum interface, $1/k_p^d$, whereas V_{rN} defines ratio of receptor–membrane effective distribution volumes). The curves on each graph represent Cl_{rN} values of 0.1, 0.3, 1, 3, 10, and ∞, with arrows indicating the increase of Cl_{rN} (Cl_{rN} defines relative rate of receptor clearance to permeability through membrane). (b) The curve corresponding to $Cl_{rN} = 0.1$ from part a (solid line) is presented together with its steady-state (dashed line) and quasi-steady-state (dash-dotted line) extrapolations. Intercepts of extrapolations with x axis define negative (lag2) and positive (lag1) lag times for the steady and quasi steady states. (c) Normalized flux versus normalized time (t/t_d). (d) Normalized receptor concentration versus normalized time.

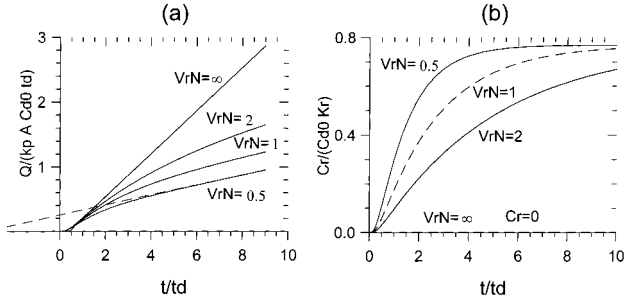

Figure 3—(a) Normalized cumulative amount absorbed versus normalized time profiles for different receptor phase volumes (varying V_{rN}) with $\kappa_{ve} = 0.5$, $Cl_{rN} = 0.1$, and $\kappa_d = \infty$. On each graph, curves represent V_{rN} values of 0.5, 1.0, 2.0, and ∞, respectively, starting from lower curve (see Figure 2 for simplistic description of κ_{ve}, V_{rN}, and Cl_{rN}). (b) Corresponding receptor concentrations C_r normalized for donor concentration C_{d0}.

$V_{rN}(= V_rK_r/(V_mK_m)$, eq 24). Figure 4a shows that as K_r decreases, the cumulative amount absorbed also decreases. It is apparent that reduced K_r is associated with a lower steady-state flux. Given that K_r is also defined by the solubility in the receptor divided by that in the donor when Henry's law applies, similar profiles can be shown for a given vehicle or donor phase when the receptor composition is characterized by the solubility of the solute in the receptor phase.

Figure 4b shows that a decreased K_r (and receptor phase solubility for solute) leads to a decreased C_r but does not greatly affect the time to reach $C_{r\,ss}$. It is evident in Figure 4c that experimental data, in which the Volpo N20 con-

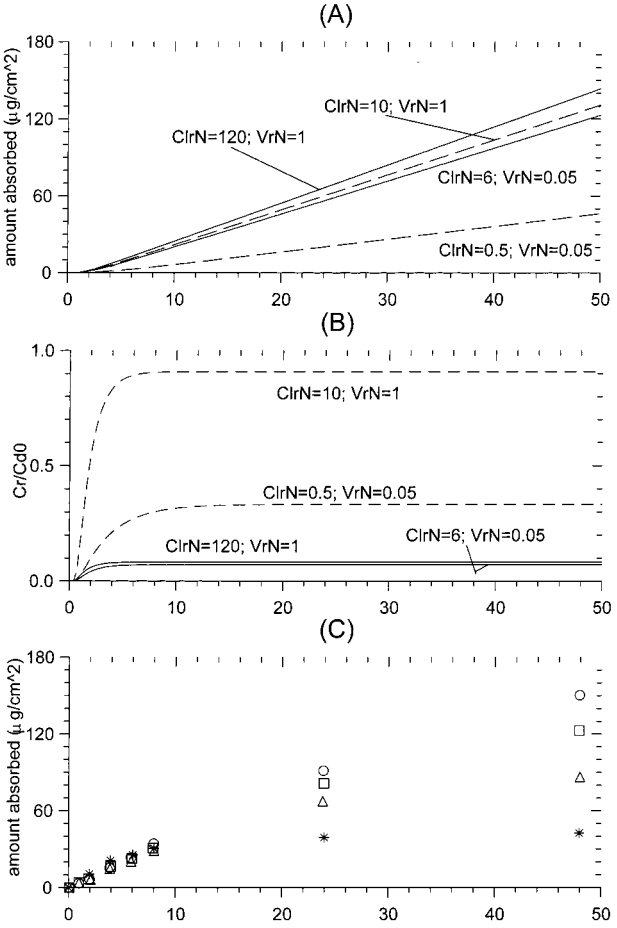

Figure 4—Effect of sampling times, sampling rate, and receptor composition on the amount absorbed versus time plots. A: Simulations with eq 48 of a rapid sampling rate (solid lines, $Cl_{rN} = 12K_r$, and $V_{rN} = 0.1K_r$) and slower sampling rate (dashed lines, $Cl_{rN} = K_r$, and $V_{rN} = 0.1K_r$) for two different partition coefficients K_r (0.5, 10) and $t_d = 10$h; B: corresponding receptor concentration C_r normalized for donor concentration C_{d0}; C: experimental data for 10% octyl salicylate in liquid paraffin (v-v) applied to 20 μm high density polyethylene membranes[18,25] with different receptor fluids and a high sampling rate for the first eight hours. (○), (□), (△), and (*) represent 10% of Volpo-N 20, 6% of Volpo-N 20, 3% of Volpo-N 20, and 4% of bovine serum albumin (BSA) in the receptor phase, respectively.

centration in the receptor phase was reduced, is consistent with lower penetration for receptor phase in which the solute is less soluble. An even lower penetration is observed for the BSA receptor phase in which octyl salicylate is 1/40 the solubility in 6% Volpo N20. Figure 4c also shows that the effects of receptor phase variability on penetration is diminished as the receptor sampling rate is increased.

Contribution of Viable Epidermis (aqueous diffusion layer)—Figures 5a and 5b show plots of normalized cumulative amount penetrating versus time when the resistance of the viable epidermis is 1/10th and 10×, respectively, that of the stratum corneum. It is apparent that as the relative resistance of the viable epidermis or aqueous diffusion layer increases, the steady-state flux is reduced and the lag time increased. Further, the significant effect of receptor clearance observed when there is a relatively low viable epidermal resistance effectively disappears when the relative resistance is high.

Contribution of Vehicle–Stratum Corneum Interfacial Resistance—An effect, similar to that when viable epidermis is significant, applies when the relative resistance of the vehicle–stratum corneum interface is high. Figure 5c and Figure 5d show that when this resistance becomes high, the steady-state flux is reduced, lag time is

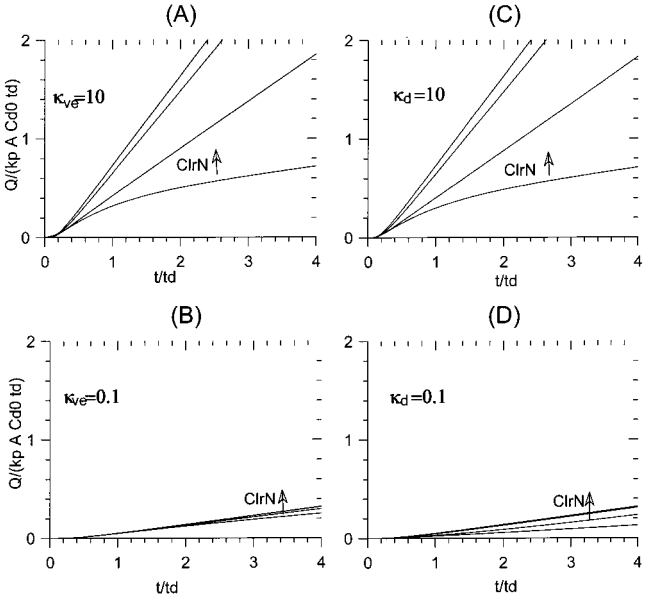

Figure 5—(a,b) Effect of epidermal resistance as described by κ_{ve} (k_p^{ve}/k_p^{sc}) on normalized amount absorbed versus normalized time profiles for $V_{rN} = 0.5$ and $\kappa_d = \infty$; (c,d) Effect of vehicle–stratum corneum resistance as described by κ_d (k_p^{d}/k_p^{sc}) on normalized amount absorbed versus normalized time profiles for $V_{rN} = 0.5$ and $\kappa_{ve} = \infty$. The curves on each graph represent Cl_{rN} values of 0.1, 1, 10, and ∞ starting from the lower curve, respectively.

increased, and removal clearance effects are less pronounced. The receptor (dermal) concentration (not shown) is also decreased.

Steady-State Approximations—It is apparent in Figures 2–5 that a steady-state regime is approached at long times ($t \gg t_d$) by $Q(t)$, $J(t)$, and $C_r(t)$. For ($t \gg t_d$), the resulting $Q_{ss}(t)$, J_{ss}, and $C_{r\,ss}$ are defined by the singularity at $s = 0$. Hence, for $Q_{ss}(t)$:

$$Q_{ss}(t) \approx k_p^{sc} A C_{d0} \left(t \lim_{s \to 0} q(s) + \lim_{s \to 0} \frac{dq(s)}{ds} \right) \qquad (33)$$

where

$$q(s) = \left[\left(\frac{1}{Cl_{rN} + V_{rN} s t_d} + \frac{1}{\kappa_{ve}} + \frac{1}{\kappa_d} \right) \cosh \sqrt{s t_d} + \left(\frac{1}{\sqrt{s t_d}} + \frac{\sqrt{s t_d}}{\kappa_d} \left[\frac{1}{\kappa_{ve}} + \frac{1}{Cl_{rN} + V_{rN} s t_d} \right] \right) \sinh \sqrt{s t_d} \right]^{-1} \qquad (34)$$

Writing eq 33 in an identical form to that described in equation 1 yields expressions for the steady-state flux, J_{ss}, and lag time, lag, given by:

$$J_{ss} = C_{d0} k_p^{sc} \left[1 + \frac{1}{\kappa_{ve}} + \frac{1}{\kappa_d} + \frac{1}{Cl_{rN}} \right]^{-1} \qquad (35)$$

$$\text{lag} = \frac{t_d}{6} \left(1 + \frac{2(Cl_{rN}^2 \kappa_d + \kappa_{ve} Cl_{rN} \kappa_d + \kappa_{ve} Cl_{rN}^2) + 6(Cl_{rN}^2 + \kappa_{ve} Cl_{rN} - \kappa_{ve} V_{rN} \kappa_d)}{Cl_{rN}(Cl_{rN} \kappa_d + \kappa_{ve} \kappa_d + Cl_{rN} \kappa_{ve} + Cl_{rN} \kappa_{ve} \kappa_d)} \right) \qquad (36)$$

The corresponding expression for $C_{r\,ss}$ is

$$C_{r\,ss} = \frac{A C_{d0} k_p^{sc}}{Cl_r} \left[1 + \frac{1}{\kappa_{ve}} + \frac{1}{\kappa_d} + \frac{1}{Cl_{rN}} \right]^{-1} \qquad (37)$$

In the absence of a significant viable epidermis and donor diffusion layer resistance and when sink conditions apply, the steady-state flux due to transport across the stratum corneum J_{ss}^{sc} is given by $C_{d0}k_p^{sc}$. Hence, if the steady-state flux J_{ss} is defined for given values of κ_d, Cl_{rN}, and κ_{ve}, J_{ss}^{sc} can be estimated from J_{ss}, Cl_{rN}, κ_d, and κ_{ve} using eq 35. It is to be noted, that when infinite sink conditions apply, $Cl_r \rightarrow \infty$ so that $Cl_{rN} \rightarrow \infty$, noting $\kappa_{ve} = k_p^{ve}/k_p^{sc}$, $\kappa_d = k_p^d/k_p^{sc}$ (eqs 22, 17) and $J_{ss}^{sc} = C_{d0}k_p^{sc}$, the steady-state flux can be rearranged into the form:

$$J_{ss} = C_{d0}\left(\frac{1}{k_p^{sc}} + \frac{1}{k_p^{ve}} + \frac{1}{k_p^d}\right)^{-1} = C_{d0}k_p' \qquad (38)$$

where k_p' is the apparent permeability coefficient defined in eq 2 and C_{d0} is the donor concentration.

The determinants of J_{ss} under nonsink conditions can be better understood by equating the definition for J_{ss} defined in eqs 2 and 35:

$$J_{ss} = k_p'(C_{d0} - C_{r\,ss}) = C_{d0}k_p^{sc}\left[1 + \frac{1}{\kappa_{ve}} + \frac{1}{\kappa_d} + \frac{1}{Cl_{rN}}\right]^{-1} \qquad (39)$$

Hence, after some rearrangement

$$k_p'\left(1 - \frac{C_{r\,ss}}{C_{d0}}\right) = \left(\frac{1}{k_p^{sc}} + \frac{1}{k_p^{ve}} + \frac{1}{k_p^d} + \frac{1}{k_p^r}\right)^{-1} \qquad (40)$$

where $k_p^r(=Cl_rK_r/A)$ is an "effective" removal permeability coefficient for the receptor. Equation 39 could therefore be expressed as:

$$J_{ss} = C_{d0}\left(\frac{1}{k_p^{sc}} + \frac{1}{k_p^{ve}} + \frac{1}{k_p^d} + \frac{1}{k_p^r}\right)^{-1} = k_p''C_{d0} \qquad (41)$$

Hence, the "effective" permeability coefficient recognizing nonsink condition k_p'' reflects not only the stratum corneum and viable epidermis permeability coefficients, but also the "effective" removal permeability coefficient and donor interface resistance.

Using eq 32 with $s = 0$ and $\hat{J}(0) = J_{ss}$ the steady state concentration in the receptor phase can be defined as:

$$C_{r\,ss} = \frac{C_{d0}A}{Cl_r}\left(\frac{1}{k_p^{sc}} + \frac{1}{k_p^{ve}} + \frac{1}{k_p^d} + \frac{1}{k_p^r}\right)^{-1} \qquad (42)$$

The removal clearance is of particular importance in determining the steady state concentration in the receptor phase $C_{r\,ss}$. Noting eq 41, eq 42 can be expressed as

$$C_{r\,ss} = \frac{C_{d0}Ak_p''}{Cl_r} \qquad (43)$$

Thus, even if the removal permeability coefficient $k_p^r(=Cl_rK_r/A)$ is not rate limiting in epidermal transport, it may be a significant determinant of local tissue concentrations.

The removal permeability coefficient k_p^r or Cl_{rN} is also a major determinant of whether lag time is positive or negative. Rearranging eq 36 yields:

$$\text{lag} = \frac{t_d}{6}\left[1 + \frac{2\left(\frac{1}{\kappa_{ve}} + \frac{1}{Cl_{rN}} + \frac{1}{\kappa_d}\right) + 6\left(\frac{1}{\kappa_{ve}\kappa_d} + \frac{1}{\kappa_d Cl_{rN}} - \frac{V_{rN}}{Cl_{rN}^2}\right)}{\frac{1}{\kappa_{ve}} + \frac{1}{Cl_{rN}} + \frac{1}{\kappa_d} + 1}\right] \qquad (44)$$

It is apparent that lag time will approach $t_d/6$ when κ_{ve}, Cl_{rN}, and κ_d are infinitely large. Further, the potential to have a negative lag time, as shown in Figures 2b and 3a will only occur when Cl_{rN} is small and the receptor volume is relatively large, so that the term in square brackets in eq 44 becomes negative.

In summary the data shown in Figures 2−5 arise from the explicit effects of the vehicle−stratum corneum, stratum corneum, viable epidermal, and "effective" removal permeability constants on k_p'' and, hence, J_{ss}. J_{ss} will be largely defined by whichever permeability constant is smallest. The lag time will be determined not only by these variables but also by receptor volume. Finally, $C_{r\,ss}$ is dependent on the relative magnitudes of $C_{d0}Ak_p''$ and Cl_r (eq 43).

Discussion

The present work has evolved from our overview of mathematical models in percutaneous absorption[2] and the realization that receptor clearance effects had been only examined to a limited extent. A major impetus for the present study was the apparent inconsistency in the results obtained for the penetration of sunscreens through excised human skin and polyethylene membranes *in vitro*.[18,25,26] It was not until we experimented with different receptor compartments as shown in Figure 4c and confirmed that no receptor depletion had occurred that we become aware of the dominant role of composition and sampling or flow rate on the absorption of the lipophilic solutes. Interestingly, the most commonly used receptor fluid remains pH 7.4 phosphate-buffered saline.[27] It has been suggested that $C_r(t)$ should not exceed 10% of its saturation solubility,[28] as a consequence a greater variety of receptor phases ranging from 25% (v/v) aqueous ethanol, 50% aqueous methanol, various albumin solutions, and various surfactant solutions[27] may be necessary when the water solubility is less than 10 μg/mL.[29] However, this principle is compromised by effects of solubilizers, particularly on the stratum corneum.[27]

The choice of a suitable receptor solution can also be compromised by a need to maintain skin viability.[19] Macpherson et al.[30] have reported that the pesticide aldrin is absorbed through skin into ethanol−water but not aqueous receptor fluids. However, skin viability was not supported by an ethanol−water system. It may therefore be difficult to find a suitable receptor solution providing both *in vivo* equivalent "sink" conditions and viability. In this instance, it may be preferable to estimate k_p^r from Cl_r and K_r and substitute into eq 41 to find k_p', i.e., $1/k_p' = 1/k_p'' - 1/k_p^r$. It should be noted that a flow through *in vitro* system will facilitate both skin viability[31] and consistency in Cl_r over time.

Numerical inversion of Laplace transforms defined by eqs 27 to 32 have been used in this work. The validity of such an approach has been studied by many authors including Purves[32] who showed that numerical inversion of the Laplace transform for the two compartment dispersion model described by Roberts et al.[33] was identical to

the analytical solution given by them. A better understanding of the behavior of a system is often achieved by an examination of the limits of the Laplace solution and the resulting analytical solutions. Such an approach has been described by Guy and Hadgraft[20,22] for other models in percutaneous absorption.

In this work we have reported the steady-state flux and lag time which can be defined from Laplace expressions as $s \rightarrow 0$. The resulting expressions show the interrelationship between receptor phase solubility, receptor phase volume, and sampling rate on *in vitro* absorption kinetics, thus allowing an estimation of k_p' when $C_{r\,ss}$ becomes significant. These relationships are also important in quantitatively interpreting the effects of perfusate flow rate on percutaneous absorption[9−11] and the reported underestimated *in vivo* absorption provided by a number of *in vitro* studies on lipophilic solutes.[12−19]

This model is also directly applicable to *in vivo* studies in both humans and animals. The expression given allows the combined affects of epidermal transport kinetics and changing blood flow on *in vivo* absorption to be understood as codeterminants of plasma concentration−time profiles after topical application. This effect is most explicitly apparent in the expressions for the steady-state flux and lag times. Cooper[34] considered some pharmacokinetics of solutes into a single compartmental model after topical application. Similar, but more complex expressions, can be developed when the present model is combined with the disposition of drugs in the body. The *in vivo* pharmacokinetics are probably best described in terms of the Laplace transform of plasma concentration $\hat{C}_p(s)$, or another biological concentration effect being expressed as a potentially complex function of parameters describing both the absorption through skin and disposition kinetics in the systemic circulation. As discussed by Roberts *et al*.[2] for a case when plasma concentration does not affect the absorption kinetics (infinite sink condition), $\hat{C}_p(s)$ can be expressed as a product of the input into the systemic circulation $\hat{J}(s)$ and disposition in the body Cl(*s*) ie $\hat{C}_p(s) = \hat{J}(s)\mathrm{Cl}(s)$. The solution for $C_p(t)$ is then most readily obtained by numerical inversion of the resulting Laplace transform $\hat{C}_p(s)$. The steady-state plasma concentration in this case is simply J_{ss}/CL, where CL is the clearance of solute from the body.

Equation 41 is an extension of expressions given by Scheuplein and Blank[35] and Robinson.[36] Scheuplein and Blank[35] expressed k_p^r in terms of the skin blood flow in the upper 200 μm of the dermis. They suggested that the removal permeability coefficient was large in comparison to the stratum corneum permeability coefficient, except possibly for small lipid-soluble molecules like octanol and permeant gases. In reality, the removal permeability coefficient *in vivo* is defined by both clearance into perfusing blood and transport into deeper tissues.[37] The latter process, however, normally contributes only 10−30% to the overall removal clearance ($k_p^r A/K_r$). Benowitz et al.[38] suggested vasoconstriction of dermal blood vessels by intravenously administered nicotine as a cause for a slowing of nicotine transdermal absorption.

Importantly, eq 43 shows that even if the removal permeability coefficient $k_p^r (= \mathrm{Cl}_r K_r/A)$ is not rate limiting in epidermal transport, it may be a significant determinant of local tissue concentrations. Increased local tissue concentrations have been observed when the local blood flow has been decreased in perfused skin preparations.[39,40] A reduction of effective blood flow by vasoconstriction[41] also leads to higher local tissue concentrations. A reduced form of eq 43 corresponding to the case of $K_r = 1$, k_p^{ve}, and k_p^d not being rate limiting has been used to explain structure−permeability absorption relationships:[1]

$$C_{r\,ss} = \frac{C_{d0} A k_p^{sc}}{\mathrm{Cl}_r(1 + 1/\mathrm{Cl}_{rN})} = \frac{C_{d0} A k_p^{sc}}{\mathrm{Cl}_r + k_p^{sc} A/K_r} \tag{45}$$

Roberts[1] has suggested that $\mathrm{Cl}_r \ll k_p^{sc} A/K_r$ for phenols so that their viable epidermal concentrations reflect those applied as aqueous solutions. In contrast, for steroids $\mathrm{Cl}_r \gg k_p^{sc} A/K_r$, and low concentrations will be found in the viable epidermis. The resulting expression for $\mathrm{Cl}_r \gg k_p^{sc} A/K_r$ is:

$$C_{r\,ss} = \frac{C_{d0} A k_p^{sc}}{\mathrm{Cl}_r} \tag{46}$$

Equation 46 is now in the same form as the classical steady-state plasma concentration expression associated with a constant input rate ($C_{d0} A k_p^{sc}$) and clearance from the body.[3]

Removal rate *in vitro* and *in vivo* is a major determinant of the apparent lag time. When k_p^{ve} and k_p^d are very large, lag reduces to:

$$\mathrm{lag} = \frac{t_d}{6}\left(1 + \frac{2\mathrm{Cl}_{rN} - 6V_{rN}}{\mathrm{Cl}_{rN}(1 + \mathrm{Cl}_{rN})}\right) \tag{47}$$

Thus a negative lag is predicted when $V_{rN} > (\mathrm{Cl}_{rN} + 3)\,\mathrm{Cl}_{rN}/6$. The remaining complexity of this expression and the difficulty in estimating lag times accurately from experimental data provides some justification in recommending that lag time values be interpreted with caution. In particular, it should be noted that short or negative lag times may be associated with a long time to reach steady state. We therefore consider an approximate estimate of this time when only Cl_{rN} is rate limiting. When κ_{ve}, $\kappa_d \rightarrow \infty$, the expression for $\hat{Q}(s)$ reduces to:[2]

$$\hat{Q}(s) = \frac{k_p^{sc} A C_{d0}}{s^2} \frac{\sqrt{st_d}}{\dfrac{\sqrt{st_d}}{\mathrm{Cl}_{rN} + V_{rN} st_d}\cosh\sqrt{st_d} + \sinh\sqrt{st_d}} \tag{48}$$

Inverting this equation to time domain yields:

$$Q(t) = Q_{ss}(t) + k_p^{sc} A C_{d0} t_d \sum_{n=1}^{n=\infty} \frac{\exp(-\gamma_n^2/t_d)}{\gamma^4{}_n \dfrac{d}{dx} f(x)|_{x=-\gamma_n{}^2}} \tag{49}$$

where $Q_{ss}(t)$ is defined in eq 1,

$$f(x) = \frac{1}{\mathrm{Cl}_{rN} + V_{rN} x}\cosh\sqrt{x} + \frac{\sinh\sqrt{x}}{\sqrt{x}} \tag{50}$$

and γ_n are roots of equation:

$$\tan\gamma = \frac{\gamma}{V_{rN}\gamma^2 - \mathrm{Cl}_{rN}} \tag{51}$$

If time to steady state t_{ss} is defined as the time for $Q(t) - Q_{ss}(t)$ to become less than $[Q(0) - Q_{ss}(0)]/e$, then t_{ss} can be written as:

$$t_{ss} \approx \frac{t_d}{\gamma_1^2} \tag{52}$$

where *e* is the base of the natural logarithm and γ_1 is the smallest root of eq 51. When $(\mathrm{Cl}_{rN}/V_{rN})^{1/2} < \pi/2$, it can be

shown that $(Cl_{rN}/V_{rN})^{1/2} < \gamma_1 < \pi/2$, and the upper bound on t_{ss} is therefore $t_d V_{rN}/Cl_{rN}$. Numerical inversion of eq 48 for $Q(t)$ was used to confirm that $t_d V_{rN}/Cl_{rN}$ is a reasonable approximation for t_{ss} for $Cl_{rN} < 3$ and when lag is negative. Hence, whereas lag is short or negative for large V_{rN} and small Cl_{rN}, t_{ss} is normally long.

A number of authors have suggested that the viable epidermis or aqueous diffusion layer may be a transport limitation between the stratum corneum and the receptor phase. This limitation could be due to a desorption process[22,42] or a viable epidermis/aqueous diffusion layer resistance.[4,6,7] In each case, an infinitely rapid sampling rate is implicitly assumed. Figure 5 showed that a dominant viable epidermal resistance will reduce the steady-state flux, increase the lag time, and reduce the effect of sampling clearance. A comparison of Figures 5a and 5b shows that the presence of ether viable epidermis or equivalent transport limitation or a sampling limitation may be discerned by examining the shapes of the profiles. A viable epidermis transport limitation will be defined by a profile which is similar in shape to the traditional profile in the absence of such a limitation but characterized by a lower steady-state flux. In contrast, a sampling limitation is defined by a curvilinear profile with a negative intercept.

The skin first-pass effect may be important in interpreting some percutaneous absorption studies. Hotchkiss[43] has reviewed the vide range of solutes metabolized by skin. As well as metabolism by skin, there may be an incomplete availability of solutes from vehicles. Skin microflora has been shown to metabolize benzoyl peroxide, glyceryl trinitrate, betamethasone-17-valerate, and estradiol.[43] However, the half-lives for metabolism are often long, limiting the affect on absorption kinetics. In contrast, irreversible adsorption (sometimes with chemical reaction) have been observed with solutes such as hair dyes. Indeed, the competing adsorption provided by hair for hair dyes and other solutes[44] would reduce availability further. In the specific case when there is no epidermal resistance and there is a "perfect" receptor sink, the values for J_{ss}, Q_{ss}, and $C_{r\,ss}$ may be reduced to $F_m J_{ss}$, $F_m Q_{ss}$, and $F_m C_{r\,ss}$[3] where $F_m < 1$ is the availability of unmetabolized solute due to metabolism in the epidermis. When the epidermal resistance is finite or there is not a "perfect" receptor sink as well as when metabolism or irreversible binding takes place in the stratum corneum, metabolism will affect both the flux profiles and time lags due to the diffusive processes involved. The appropriate model for this situation is developed in a later paper.

The present analysis has also included a vehicle−stratum corneum interfacial permeability constant. Such a term is particularly relevant to transdermal patch systems where a rate-limiting membrane or adhesive may affect or control the rate of delivery from the patch material. The term is also applicable to solutions in which there is an unstirred layer in the vehicle at the interface or when there is a partitioning limitation in the transfer of solute from the vehicle to the stratum corneum. There has been an assumed flux from a constant donor concentration of solute in the vehicle into the stratum corneum in certain of the percutaneous absorption kinetics models.[22] This assumed flux can also be represented by the vehicle−stratum corneum interfacial permeability constant defined in the present model.

The present model has been limited to a constant well-mixed donor vehicle with various permeability "barriers" determining transport. In practice, diffusion in the vehicle may also determine percutaneous absorption. Guy and Hadgraft[45] have recognized such an effect in their evaluation of the effect of applied vehicle thickness on the percutaneous absorption of solutes. When diffusivity in the vehicle is rate limiting, with permeability "barriers" present, the profiles for $Q(t)$ versus t are described by a burst effect.[46] The shapes of the profiles do not differ greatly from those obtained in this work, assuming a constant donor concentration but with accumulation to steady state in the receptor (dermis). Analysis of donor concentrations on the vehicle−stratum corneum interface before or on completion of a percutaneous absorption study or varying the removal rate from the receptor is therefore required to distinguish these two effects.

Conclusion

This work has shown that the experimental protocol and *in vivo* perfusion conditions can markedly affect percutaneous absorption kinetics. These need to be recognized in undertaking percutaneous absorption studies and their perturbations on the resulting kinetics realized from the shape of the profiles obtained, as discussed in this work. Knowledge of the exact conditions can enable actual permeability coefficients to be estimated from apparent steady-state fluxes. Such calculations are particularly pertinent that nonsink receptor conditions be used to maintain viable skin. A major limitation in assessing the current literature for structure−skin permeability relationships[47,48] is the lack of available experimental information to make the appropriate corrections to reported steady-state permeability constants.

A second outcome of this work is the description of the effects of perfusate flow rate, finite receptor volume, and viable epidermis/aqueous diffusion layer resistance on percutaneous absorption kinetics and dermal concentrations. A necessary limitation in the present work to derive simple Laplace expressions has been the assumption of well-stirred vehicle and receptor phases. A subsequent paper will consider the effects of finite donor volume and epidermal metabolism on percutaneous absorption kinetics.

Accepted for publication August 30, 1999.

Abstract □ The peculiar solubility behavior of propylparaben (propyl ester of 4-hydroxybenzoic acid) in aqueous solution, when tested separately and together with methyl-, ethyl-, and butyl-parabens, has been investigated in detail. The results clearly indicate that the decrease in solubility (≈50% compared to the solubility value of propylparaben alone) is typical of those mixtures containing also ethylparaben, as demonstrated by solubility experiments on binary, ternary, and quaternary mixtures of the parabens. Phase diagrams of all the six binaries show that propylparaben and ethylparaben are the only pair that form almost ideal solid solutions near the melting temperatures. Moreover, phase-solubility analysis shows that propylparaben and ethylparaben, at room temperature, can also form solid solutions whose solubility is related to the composition of the solid phase at equilibrium. To achieve an independent confirmation of the possible solid solution formation that supports the above interpretation of the solubility behavior, the crystal structures of the four parabens have been examined and isostructurality has been found to exist only between ethylparaben and propylparaben. Powder X-ray diffraction has also been performed on ethylparaben, propylparaben, and their solid solutions obtained by recrystallization from water. The progressive shift of distinctive diffraction peaks with phase composition clearly indicates that propylparaben and ethylparaben form substitutional solid solutions. The small value (<1) of the disruption index provides thermodynamic support for substitutional solid solutions based on isostructural crystals.

Introduction

Parabens (esters of 4-hydroxybenzoic acid) are preservatives widely used in cosmetics, food products, and pharmaceutical formulations. Parabens are generally used in combination to take advantage of synergistic effects, are active over a wide pH range, have a broad spectrum of antimicrobial activity, and are most effective against yeasts and molds.[1] The antimicrobial activity of the parabens increases as the chain length of the alkyl moiety is increased; their aqueous solubility, however, decreases, so the sodium salts of the parabens are also frequently used in formulations. An alternative approach to increasing solubility is the use of cyclodextrin complexation. Many reports[2−4] deal with the formation of inclusion compounds with natural and semisynthetic cyclodextrins to increase the aqueous solubility of selected parabens.

Recently[5] the solubilities of four parabens (methyl, ethyl, propyl, and butyl esters) have been measured singly and together in water and in aqueous solutions of 2-hydroxypropyl-β-cyclodextrin. Aqueous solubilities (without 2-hydroxypropyl-β-cyclodextrin) of all parabens were found to agree well with literature values[6,7] when determined separately. Rather surprisingly, however, when the solubilities in water at 25 °C of the four parabens were measured together, the solubility of propylparaben was found to be reduced by approximately 50%, with relatively small increases or decreases (within 10%) for methyl-, ethyl-, and butyl-paraben.

Changes of solubility generally can be attributed to the formation of hydrates, recrystallization of more stable polymorphs, or interaction phenomena in solution as well as in the solid state.[8−11] In the system under investigation, it is intriguing and stimulating that the solubility of only one component (propylparaben) seemed to be significantly affected when tested in the combination of four homologues. The massive decline of propylparaben solubility has hitherto remained unexplained: furthermore no evaluation of the physical nature or chemical composition of the solid phases present at equilibrium has been reported.

Aiming to find a plausible explanation for the unpredictable behavior described above for propylparaben[5] we report here the results of investigations with the same four homologues (methyl- (M), ethyl- (E), propyl- (P), and butyl- (B) paraben). In particular, the solubilities in water of each paraben from the binary, ternary, and quaternary mixtures are measured. The solid phases recovered at equilibrium from solubility experiments are characterized by their thermal behavior, using differential scanning calorimetry (DSC), thermogravimetry (TGA), and hot stage microscopy (HSM), by their composition using high performance liquid chromatography (HPLC), and by their structural properties, using powder X-ray diffractometry (PXRD). The solubility profiles at ambient temperature are also investigated by means of phase solubility analysis as suggested by Higuchi and Connors.[12] Moreover, the phase diagrams of all possible binaries are drawn from DSC measurements and compared with the corresponding calculated ones.

Finally, to complete the physicochemical characterization and to accomplish a comprehensive understanding of the solid state properties of these compounds by relating molecular scale properties and bulk properties, the crystal structures of propylparaben and butylparaben are also determined and critically evaluated together with those of

methyl paraben and ethyl paraben whose crystallographic data have been reported previously.[13,14]

Experimental Section

Materials—Methyl-, ethyl-, propyl-, and butyl-paraben were obtained from Sigma Chemical Company (St. Louis, MO) and were used as received. Organic solvents were of chromatographic grade purity. Double-distilled water was used for solubility experiments and buffer preparation.

Aqueous Solubility—The solubility in water for each paraben, singly or from the binary, ternary, and quaternary mixtures, was determined by equilibrating the liquid phase with a known weight of each component in powdered form at 25.0 ± 0.5 °C with agitation. In all cases, a 5-day period had previously been shown to afford equilibrium. Three independent sets of experiments were performed on single components or their combinations.

Recrystallization from Water—Mixtures containing E and P in molar ratios of 1:1 and 1:2 were recrystallized from water by dissolving 200 mg of the mixture in 200 mL of water at 75 °C and allowing, after filtration, the spontaneous cooling to ambient temperature. The crystalline solid phase which separated at equilibrium was recovered by vacuum filtration: both the filtrate and the solid phase were analyzed for E and P contents by HPLC.

HPLC Analysis—Samples of the solution under examination, appropriately diluted with the mobile phase (methanol/0.04 M ammonium acetate, 55:45, v:v), were analyzed with an HPLC system (LC-10 AS Shimadzu, Japan); detector (UV−vis, SPD-10A Shimadzu) at λ = 256 nm; column (C-18 BondapaK, Waters, Milford, MA) 10 μm, 3.9 × 300 mm; flow rate 0.8 mL min^{-1}. Peak integration was performed with a C-R6A Cromatopac (Shimadzu, Japan). Linearity of response in the 0−20 mg mL^{-1} concentration range was assessed for each compound from plots of peak area against concentration.

Thermal Analyses—Differential scanning calorimetry (DSC) and thermogravimetry (TGA) were performed by means of a Mettler 821e STARe system and a TG50 cell (Mettler Toledo, Switzerland): hot stage microscopy (HSM) was carried out with a HFS 91 Linkam hot stage (Linkam, UK) and a Nikon Labophot microscope (Nikon, Japan).

Experimental phase diagrams of binary systems were constructed by plotting melting temperatures taken from DSC curves versus composition. Solid mixtures of each binary system were prepared by combining appropriate volumes of methanolic solutions with known concentrations of each paraben and slowly evaporating the solvent under reduced pressure. Four to six samples for each mixture were scanned at 10 K min^{-1} from 40 °C to a temperature 10 K above the melting point of the higher melting component under a flux of dry nitrogen (100 mL min^{-1}).

Calculation of the liquidus curves was performed using the Schröder−Van Laar equation[15] in its simplified form:

$$\ln x = \frac{\Delta H_A^f}{R}\left(\frac{1}{T_A^f} - \frac{1}{T^f}\right)$$

where x is the mole fraction of the more abundant component of a mixture whose melting terminates at T^f (in Kelvin), ΔH_A^f (cal mol^{-1}), and T_A^f (also in Kelvin) are the enthalpy of fusion and the melting point of the pure component, respectively, and R is the gas constant, 1.9869 cal mol^{-1} K^{-1}.

Phase Solubility Analyses on Binary Systems—Fixed amounts (approximately twice the quantity necessary for a saturated solution) of the accurately weighed paraben with increasing amounts (up to an excess with respect to its solubility) of the second paraben under investigation were placed in 100 mL flasks, which were then filled to volume with water. After equilibration at constant temperature (25.0 ± 0.5 °C), the suspension was filtered through a 0.22 μm Millipore filter. The filtrate, after appropriate dilution with the mobile phase (described under HPLC analysis), was assayed for each paraben concentration, while the solid residue was examined by thermal analyses (DSC and TGA). The concentrations of both parabens in solution were then plotted against the total amount of the second paraben in the system. The compositions of both the solid and liquid phases at equilibrium for each preparation were thereby precisely determined.

X-ray Crystal Structure Determination—Large transparent prismatic crystals of propylparaben and butylparaben were grown from solution in methanol and cyclohexane, respectively, by slow evaporation of the solvent at ambient temperature and pressure. Crystal densities were measured at 20 °C by flotation in aqueous KI solution. Preliminary unit cell and space group data for each species were obtained from precession photographs taken with Cu Kα-radiation (λ = 1.5418 Å). For the propylparaben crystal, the space group $P2_1/c$ was uniquely determined from the systematic absences, whereas for butylparaben, extinction conditions indicated the space groups Cc or $C2/c$. The latter, chosen on the basis of intensity statistics which indicated a centric distribution, was vindicated by successful structural solution and refinement.

Reflection intensity data were measured at 293(2) K on a Nonius Kappa CCD diffractometer using Mo Kα radiation (λ = 0.71069 Å) and a crystal to detector distance of 35 mm. Both data collections involved 1.0° ϕ-rotations followed by 1.0° ω-rotations and exposure times per frame of 34 s (propylparaben) and 20 s (butylparaben), yielding 21849 and 11601 measured reflection intensities, respectively. Cell refinement and data reduction were performed with programs DENZO16 and maXus17. Both structures were solved by direct methods (program SHELXS8618) which revealed the non-hydrogen atoms of the two independent molecules in the asymmetric unit of the propylparaben crystal and the single molecule in that of the butylparaben crystal. The hydrogen atoms were located in difference electron-density maps; those attached to C were included in idealized positions in a riding model (C−H 0.93−0.97 Å) and the hydroxyl H atoms refined freely. All H atoms were treated isotropically and non-H atoms anisotropically. Full-matrix least-squares refinement on F^2 was performed with program SHELXL9319. The C atoms of the alkyl chain of the butylparaben molecule were found to be disordered, all four occupying two alternative sites each. Final refinement yielded site-occupancy factors of 0.61 and 0.39 for the two arrangements.

Powder X-ray Diffraction (PXRD)—PXRD traces were recorded on a Philips PW1050/25 goniometer with Cu Kα-radiation (λ = 1.5418 Å) produced at 50 kV and 40 mA. The system was calibrated with a silicon standard which yielded peak positions of 28.45 ± 0.01° 2θ before and after each scan. All samples were manually ground, sieved (through a 200 μm screen), and packed successively in the same aluminum sample holder for reproducibility of conditions, taking care also to minimize preferred orientation effects. Full PXRD traces (scan speed 1.0° 2θ min^{-1}, step size 0.1° 2θ, 2θ-range 8−32°) were recorded for pure ethylparaben (E), pure propylparaben (P), and the two solid phases obtained by recrystallization from water of mixtures of E and P of molar compositions 1:1 and 1:2, respectively.

PXRD traces in the narrow 2θ-range 23.0−26.5° were recorded for the same four samples. To optimize the resolution of these traces, each sample was scanned in three passes, accumulating the counts at a scan speed of 0.50° 2θ min^{-1} with a step size of 0.02° 2θ.

Indexing of reflections was achieved using program Lazy Pulverix,[20] with single-crystal X-ray data (unit cell, space group, atomic coordinates, thermal parameters) for E and P as input.

Results and Discussion

Solubility—The solubility data from binary, ternary, and quaternary mixtures are collected in Table 1. It is evident that a decrease of P solubility in water (approximately 50%) can be detected only for mixtures containing also E (bold figures), as shown previously by McDonald et al.[5] for the combination of the four parabens. Furthermore, a decrease (approximately 10%) of E solubility from all mixtures containing P is also seen.

Crystal Structures of Parabens—Table 2 summarizes the available single crystal X-ray data and selected physical properties of the four parabens under discussion. It should be noted that for compounds M, E, and P, the number of molecules per unit cell (Z) exceeds the site multiplicity of the general equivalent positions of the respective space groups, namely 4 for both Cc and $P2_1/c$. Thus, M contains three crystallographically independent molecules in the

asymmetric unit while both E and P contain two. While the occurrence of more than one molecule in the asymmetric unit may suggest an incorrect choice of unit cell and/or space group, we have in these instances confirmed the data listed in Table 2 by preliminary X-ray photography of all three compounds and by successful structural refinements of not only compound P, but also M and E in recent structure redeterminations.[21] Compound B, crystallizing in the space group *C*2/*c*, has Z equal to the number of general equivalent positions and therefore contains only one molecule in the asymmetric unit.

Full details of the crystal and molecular structures of P and B will be published elsewhere.[21] For the purposes of the present study, however, the salient feature evident from a comparison of the space group and unit cell data is that compounds E and P are isostructural and different in crystal structure from either M or B. The term "isostructural" is used here in the sense defined by Kálmán and Párkányi[22] to denote the fact that E and P crystallize in the same space group with very similar unit cell dimensions and with atomic coordinates which are in close correspondence for common atoms.

Details of the common crystal packing mode in the isostructural species E and P, as exemplified by compound P, are illustrated in Figure 1. This figure shows that the two crystallographically independent molecules (A, B) form separate, but structurally analogous, infinite chains by head-to-tail hydrogen bonding involving the OH group as donor and the carbonyl O atom as acceptor. Within a given chain, successive molecules are related by a 2-fold screw axis (2_1) parallel to b, array A being generated by the 2_1 located at x = $^1/_2$, z = $^1/_4$ and array B by the 2_1 at $x = 0$, z = $^1/_4$. The symmetry-independent molecules A and B are nearly coplanar, and the resulting crystal structure, shown in projection in Figure 2, consequently has a distinctive layered nature. The layers lie midway between the (202)

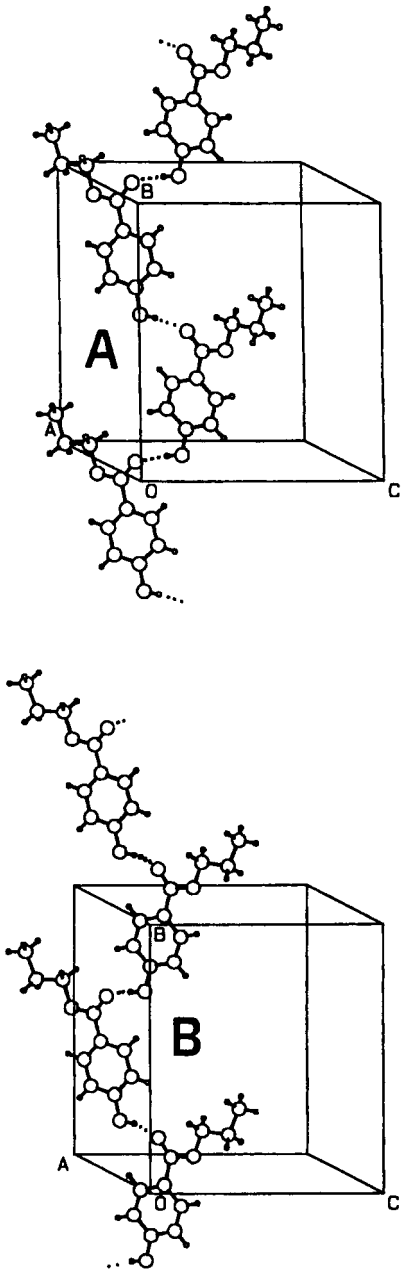

Figure 1—Head-to-tail hydrogen bonding arrays for the two crystallographically independent molecules A and B in propylparaben. Analogous arrays occur in the isostructural species ethylparaben.

crystal planes, thus accounting for the fact that the (202) reflection is predominant in the PXRD patterns of E and P.

A detailed exposition of the variations in molecular structures and packing modes for crystals of M, E, P, and B will be discussed elsewhere.[21] Here, it is relevant to emphasize the isostructurality of E and P (both crystallizing in space group $P2_1/c$) and to contrast their common crystal packing arrangement with the different packing

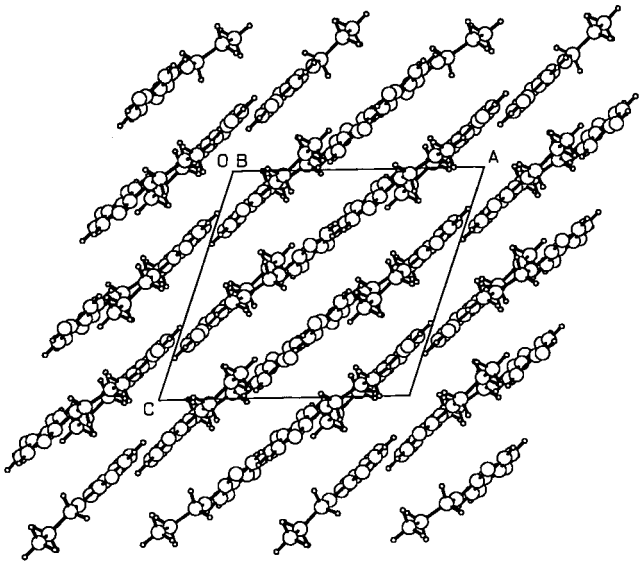

Figure 2—The [010] projection of the propylparaben crystal structure showing the characteristic molecular layers situated midway between the (202) planes.

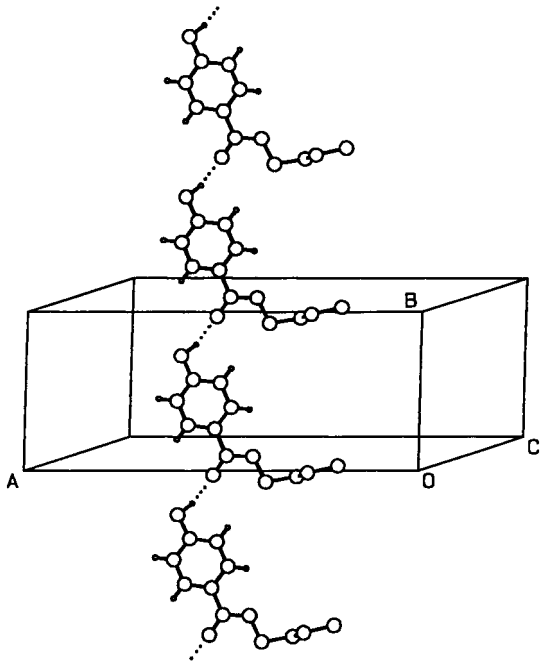

Figure 3—Head-to-tail hydrogen bonding array in the crystal of butylparaben. For clarity only the dominant conformer of the butyl chain is shown and the H atoms are omitted.

modes observed in M (*Cc*) and B (*C*2/*c*). The molecules in all four paraben crystals associate by head-to-tail (O−H···O) hydrogen bonding, leading to infinite chains, as discussed above for E and P. However, successive molecules of the chains in E and P are generated by 2_1-axes, whereas those in B are related by translation only, as shown in Figure 3. The resulting layered structure of B superficially resembles those of E and P, but the layers are distorted due to noncoplanarity of the butyl substituent and the aromatic ring as well as to the observed disorder of the butyl chain. The crystal packing mode in M is unique and complicated, owing to the presence of three symmetry-independent methyl paraben molecules. Alternate molecules in the hydrogen bonded chains have their aromatic ring planes nearly orthogonal to one another, giving rise to a complex packing arrangement[13] devoid of the layers which are characteristic of the crystal structures of E, P, or B.

Cocrystallization, or solid solution formation, is a well-known consequence of isostructurality.[22] For the four parabens involved, the increments in the volume of the asymmetric unit of the crystal through the series M → E → P → B are 31.1, 18.7, and 26.7 Å^3, the smallest of these being a consequence of the isostructurality of E and P. This fact indicates that the molecules of E and P, in these crystal packing arrangements, have a high degree of molecular complementarity; substitution of one molecule for the other during crystallization of physical mixtures should therefore be favored. This conjecture was explored by means of thermal methods of analysis and its validity subsequently confirmed by PXRD measurements.

Thermal Analytical Studies—Thermal data of the pure compounds and their binaries are collected in Tables 3 and 4. There was no evidence of any solvate formation (TGA measurements) for samples recrystallized from water or methanol.

While experimental data for binaries fit the calculated phase diagrams reasonably well for the combinations, M + E, M + P, M + B, E + B, and P + B, the plot of melting point against the mole fraction for the E + P system (Figure 4) shows a large plateau region up to a mole fraction for x(E) value of about 0.6. No eutectic melting was observed at any composition, either in DSC runs or by HSM. It should be noticed that all melted samples readily recrystallized upon cooling; in all cases melting temperatures and heats measured during the second runs were not significantly different from those determined during the first runs.

These results suggest a solid solution behavior that is not far from ideal and that is probably substitutional, indicating a minimal disturbance of the crystal lattice when P molecules are progressively substituted by E, in the x(E) range, 0 to 0.6. The smooth dependence of the melting point of E and P combinations on the mole fraction of either E or P, shown in Figure 4, has a barely perceptible minimum

at x(E) near 0.4, which is close to the unrealized eutectic composition predicted by the Schröder−Van Laar equation in its simplified form (Table 4). This trend in melting point is paralleled by the enthalpies of fusion (ΔH^f, kJ mol^{-1} = 26.4 for pure E, minimum value of 20.5 at 0.436 x(E), 27.5 for pure P) and consequently by the entropies of fusion (ΔS^f, J K^{-1} mol^{-1} = 67.8 for pure E, minimum value of 55.1 at 0.436 x(E), 74.1 for pure P). This behavior corresponds to a continuous series of solid solutions that show minor deviations from ideal behavior toward molecular segregation with weaker interactions between unlike molecules (E + P) than between like molecules (E + E or P + P). (Extreme deviations from ideality toward complete segregation would, of course, correspond to a eutectic system, often with limited miscibility in the solid state at compositions near the pure components).

A measure of the extent of lattice disorder created in the "host" crystal lattice by "guest" molecules in solid solution is provided by a dimensionless "disruption index" (di).[23] The di is evaluated as the negative slope of the plot of the molar entropy of fusion, ΔS^f, of the host (+ guest) against the ideal molar entropy of mixing, ΔS^m, of the host + guest at low mole fractions of the guest (additive or impurity molecules).[23] If the guest simply "dilutes" the host without causing any lattice disruption, both the solid solution and its liquid melt will behave as ideal solutions, so ΔS^f will not be changed by the presence of the guest and therefore the di will be zero. If the guest disrupts the crystal lattice of the host by forming lattice defects or imperfections, additional disorder will be created in the host crystal lattice but not in the liquid melt which is randomly disordered and probably behaves almost ideally, so ΔS^f will decrease significantly and the di will be appreciable. Thus, di measures the extent of disruption of the crystal lattice of the "host" by molecules of the "guest". For solid solution in which P is the host and E is the guest, the di is 0.6, suggesting very little lattice disruption. A similar, but less accurate, value is given by a solid solution in which E is the host and P is the guest. Small values of di less than 1.0 are also given by metallic systems, e.g., for Cd or In as the guest in $InCd_3$ as the host or for $InCd_3$ as the guest in Cd as the host. Evidently, the substitution of Cd atoms for In atoms and vice versa in these metallic systems gives little lattice disruption, presumably because the Cd and In atoms occupy similar volume;[23] they are also neighbors in the periodic table. The isostructurality of E and P (Table 2) readily explains the small value of di. On the other hand, the additional methylene group in the P molecule as compared with E explains the slight tendency toward molecular segregation deduced above from the plots of melting point, enthalpy of fusion, and entropy of fusion against mole fraction of E or P in the solid solution of E + P. By contrast, if the host and guest are different small organic molecules and therefore possess different crystal lattices, the di is appreciable and of the order 5 to 10.[23] If the host and guest are opposite enantiomers, or other closely related isomers, the di is significantly larger, of the order 20, because of the greater disorder (disruption) created by chiral discrimination in ordered structures.[24] If the host is a molecular crystal and the guest is a polymeric surfactant, di can be much larger, of the order 200.[25]

Powder X-ray Diffraction Patterns—The PXRD traces for the pure phases E and P are shown superimposed in Figure 5. Each individual experimental pattern matches the computed pattern calculated from the corresponding single crystal X-ray data, confirming that the forms present are those listed in Table 2. The close similarity of the traces in Figure 5 confirms the isostructurality of E and P that is established above from the single crystal X-ray diffraction data. Furthermore, the peaks in the trace for P occur at slightly lower 2θ-values than the corresponding peaks for E, in accordance with the larger unit cell parameters of P (Table 2).

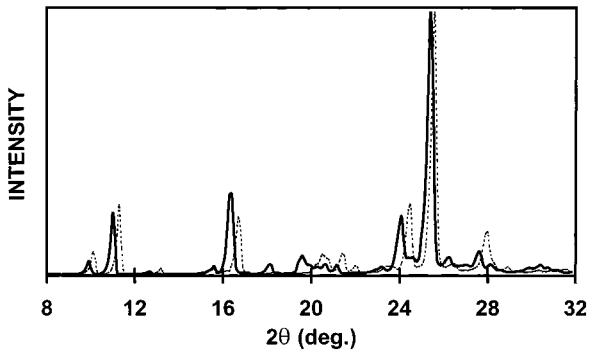

Figure 5—Powder X-ray diffraction patterns of pure propylparaben (solid trace) and pure ethylparaben (dotted trace).

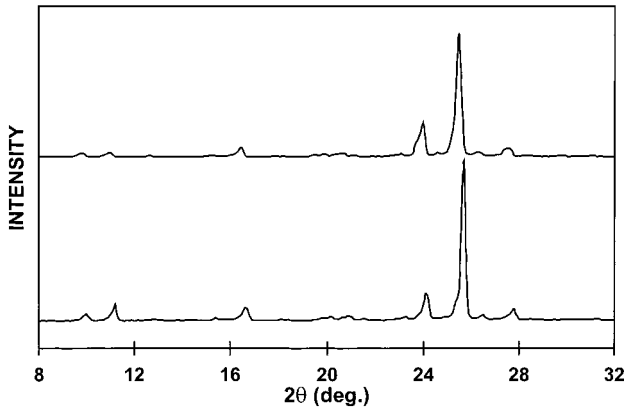

Figure 6—Powder X-ray diffraction patterns of two solid phases obtained by recrystallization of E/P mixtures with P:E molar ratios 2:1 (upper trace) and 1:1 (lower trace).

To validate the partial conclusions suggested by thermal analyses and phase diagrams, the two samples obtained by recrystallization of P + E mixtures from water were subjected to a detailed study. While the original mixtures contained P:E molar ratios of 1:1 and 2:1, HPLC analyses yielded P:E molar ratios of 0.97:1 and 3:1 for the two recrystallized phases, respectively. Figure 6 shows the PXRD traces for these species. The close similarity of these traces to each other, and to those shown for the pure phases (Figure 5), leads to the conclusion that all four phases are isostructural, which strongly supports the notion that the phases obtained by recrystallization of physical mixtures are solid solutions of E and P.

For quantitative confirmation, the narrow 2θ-range 23.0−26.5° was selected, within which two prominent, representative diffraction peaks appeared for all four phases. From simulated patterns of E and P, these peaks were identified as the (310) and (202) reflections, with calculated 2θ-shifts, $\Delta(2\theta)$, of 0.52° and 0.26°, respectively, for the pure components E and P. Figure 7 shows the PXRD traces for E, P, and the two samples indicated as being solid solutions. It is evident from these traces that, as the percentage of P in the sample increases, there is a general shift of corresponding peaks to lower 2θ-values and hence to larger d spacings. This finding is consistent with the expected increase in unit cell volume, which should accompany progressive substitution of ethyl paraben molecules by propyl paraben molecules in the solid state. In support of this conclusion, which is based on the measurement of small angular differences, it is pertinent to note that, for the extreme members of the series of solid solutions, E and P, the experimental $\Delta(2\theta)$ values for the

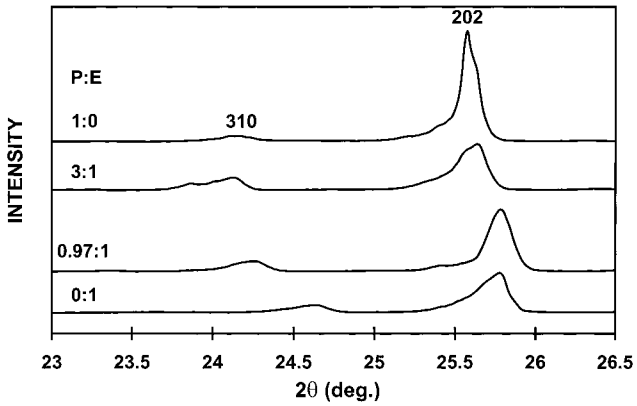

Figure 7—High-resolution powder X-ray diffraction patterns showing shifts of the (310) and (202) peaks as a function of P:E molar ratio in the solid phase.

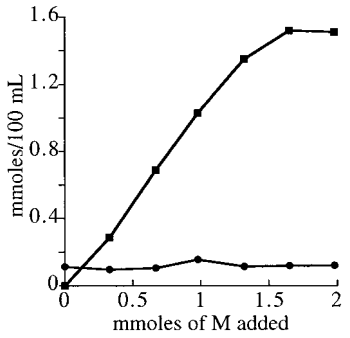

Figure 8—Phase-solubility diagram for the M + B system: ■ methylparaben, ● butylparaben ($n \geq 4$; cv $\leq$ 3%).

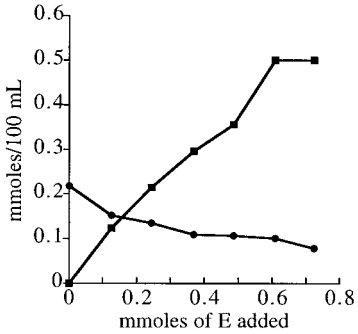

Figure 9—Phase-solubility diagram for the E + P system: ■ ethylparaben, ● propylparaben ($n \geq 4$; cv $\leq$ 3%).

(310) and (202) reflections are ~0.5° and ~0.2°, in close agreement with the calculated values stated above. Because the unit cell involved is monoclinic, with the packing arrangement shown in Figures 1 and 2, progressive substitution of E molecules by P molecules is expected to lead to anisotropic unit cell expansion. From the data in Table 2, we note that the percentage increase in unit cell lengths on proceeding from E to P are 2.4, 4.9, and 1.8% for a, b, and c, respectively. In summary, the combined evidence from single-crystal X-ray diffraction and powder XRD studies confirms that E and P form substitutional solid solutions.

Phase-Solubility Investigations—The phase-solubility diagrams of the M + B and E + P systems are shown in Figures 8 and 9. When methylparaben is progressively added to a saturated solution of butylparaben, the saturation concentration of the latter (i.e., the solubility of B, circles in Figure 8) is not affected. The system becomes invariant (three phases and three components, at constant temperature and pressure) for both M and B, only when two solid phases are in equilibrium with a liquid phase

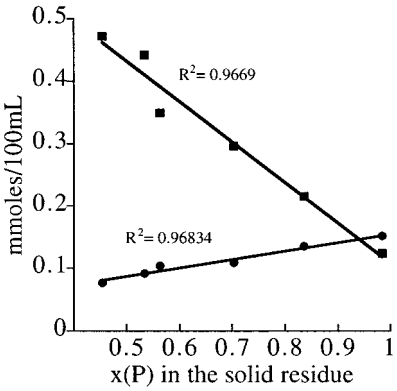

Figure 10—Relationship between composition of the solid phase at equilibrium and composition of the solution for each component: ■ ethylparaben, ● propylparaben. Data derived from phase-solubility analyses.

which is independently saturated by both compounds. Analogous patterns (not reported here) were found for other binaries.

For the E + P system, shown in Figure 9, the addition of increasing amounts of E to suspensions of P in water gives rise to a phase-solubility pattern that is different not only from the example reported above, involving no significant interaction between components, but also from the phase diagram for the formation of a solid stoichiometric complex.[12] In the E + P system, in fact, the concentration of the more abundant compound (P in this example) should remain constant until solid P is completely transformed into the solid solution P + E of lower solubility.

By plotting the data of Figure 9 as concentration of each paraben in the aqueous solution against the mole fraction of P in the solid residue, Figure 10 is obtained. It is evident that the solubilities of each paraben are affected by the presence of the second component. E can therefore be found in the solid-phase just after the first addition to a suspension of P in water, although its solubility is far below that of pure E.

Within the composition range explored and represented (x(P) in the solid residue from 0.985 to 0.45), the solubilities of E and P are clearly linear functions of the solid composition at equilibrium.

Conclusions

The solubility behavior for propylparaben in the mixture of four components has been investigated in detail. As a necessary preliminary step, we simplified the quaternary system by examining all possible binary systems. The results clearly show that this peculiar behavior can be ascribed to the simultaneous presence of ethylparaben and propylparaben, as demonstrated by the individual solubility values for binary, ternary, and quaternary mixtures. Phase diagrams of all binaries show that, among all the systems investigated, P and E are the only pair that form almost ideal solid solutions.

Furthermore, phase-solubility analyses have shown that P and E at room temperature form solid solutions whose solubility is strictly related to the composition of the solid phase at equilibrium.

To obtain independent structural confirmation that solid solution formation explains the solubility behavior, the crystal structures of propylparaben and butylparaben have been solved, and the structural analogies between E and P have been demonstrated. PXRD of E, P, and their putative solid solutions each recrystallized from water show peaks whose 2θ-positions progressively shift as the composition proceeds from that of one pure compound to the other.

While not forgetting that crystallization is an irreversible, nonequilibrium process, the solid with the lowest chemical potential of E or P tends to crystallize out of the solution that contains both E and P. This solid solution contains a lower mole fraction of E and P than does pure E or P, respectively, because it has a lower chemical potential of E or P, respectively, and therefore has a lower solubility with respect to E or P. Therefore, if E is the solid in excess, E will tend to dissolve, whereas if P is the solid in excess, P will tend to dissolve, and the solid solution will crystallize out. The concentration of E or P in equilibrium with this solid solution (the measured apparent solubility) is less than that in equilibrium with pure E or P (the true solubility).

Accepted for publication August 10, 1999.

Abstract □ The present study was conducted to characterize the structural specificity of an anion exchange transporter in intestinal epithelial cells. The transport of carboxylic acids with hydroxyl group(s) at the 2, 3, 4, and/or 5 positions with respect to carboxylate was examined by using Caco-2 cells in the presence of bicarbonate ions on the basolateral side to enhance the activity of the anion-exchange transporter. In the presence of the bicarbonate ion gradient, transport of L-lactic acid consisted of a saturable process and a nonsaturable process as judged from the Eadie–Hofstee plot. The transport of L-lactic acid at 1 μM was reduced by sodium azide, dinitrophenol, and 4,4′-diisothiocyanostilbene-2,2′-disulfonic acid (DIDS). It was also reduced by 2-, 4-, and 5-hydroxycarboxylic acids such as hydroxyacetic acid, 4-hydroxybutyric acid, and 5-hydroxydecanoic acid, but not by 3-hydroxycarboxylic acids such as 3-hydroxypropionic acid and 3-hydroxybutyric acid. Transport of both 2- and 4-hydroxybutyric acids involved saturable and nonsaturable processes, whereas that of 3-hydroxybutyric acid was nonsaturable and was not inhibited by DIDS. These results indicate that 3-hydroxycarboxylic acids might not be substrates for this anion exchange transporter in intestinal epithelial cells, suggesting that the position of hydroxylation is significant for molecular recognition by the transporter.

Introduction

We have demonstrated that at least two types of carrier-mediated transport mechanisms, energized by an inward-directed proton gradient (proton cotransport) and/or an outward-directed bicarbonate gradient (anion-exchange transport), are involved in the intestinal absorption of monocarboxylic acids such as acetic acid, L- and D-lactic acids, nicotinic acid, benzoic acid, and salicylic acid, by means of studies using rabbit and rat jejunal brush-border membrane vesicles (BBMVs), a human carcinoma cell line, Caco-2, and gene products expressed in *Xenopus laevis* oocytes and in mammalian cells.[1−13] These carrier-mediated transport processes are likely to predominate over passive diffusion according to the pH-partition hypothesis[14] in the absorption of various monocarboxylic acids across the intestinal membrane.

Previously, we have demonstrated that pravastatin, a 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitor, and (*R*)-mevalonic acid, an intermediate in terpenoid and cholesterol biosynthesis, are transported across intestinal epithelial cells via a proton-cotransport mechanism. However, these compounds are not transported by an anion-exchange transport mechanism in intestinal BBMVs or in isolated intestinal tissues mounted in Ussing-type chambers.[11] Pravastatin and (*R*)-mevalonic acid have a structural similarity in terms of the hydroxyl groups at the 3 and 5 positions with respect to the carboxylate, so such structural characteristics might determine their transport across the intestinal epithelial cells via the anion-exchange transport mechanism. The present study was intended to characterize the common structure of monocarboxylic acids which is required for transport via the anion-exchange transporter in intestinal epithelial cells, by examining the transcellular transport of substituted monocarboxylic acids, especially those with a hydroxyl group at the 2, 3, 4, or 5 position of the carboxylates.

Materials and Methods

Materials and Cell Culture—Caco-2 cells were obtained from American Type Culture Collection (Rockville, MD) and cultivated as described previously.[9] All cells used in this study were between passages 53 and 108. The cells were grown for 21 to 23 days on a polycarbonate membrane (Transwell: 11.2 mm in diameter and 3.0 μm pore size, effective area of 1 cm^2, Costar, Bedford, MA). L-[^{14}C]Lactic acid (5.55 GBq/mmol), [^{14}C]-2-hydroxybutyric acid (2.04 GBq/mmol), [^{14}C]-3-hydroxybutyric acid (2.05 GBq/mmol), [^{14}C]-4-hydroxybutyric acid (2.04 GBq/mmol), and (*R*)-[^{3}H]mevalonolactone (555 GBq/mmol) were purchased from American Radiolabeled Chemicals Inc. (St. Louis, MO). Mevalonic acid was prepared by hydrolysis of the mevalonolactone according to the method reported previously.[11,15] [^{14}C]Salicylic acid (2.04 GBq/mmol) was obtained from Moravek Biochemicals (Brea, CA). [^{14}C]-Benzoic acid (0.70 GBq/mmol) and [^{3}H]mannitol (1110 GBq/mmol) were purchased from New England Nuclear (Boston, MA). 5-Hydroxydecanoic acid was kindly supplied by Mochida Pharmaceutical Co., Ltd. (Tokyo). All other chemicals were of reagent grade or the highest purity commercially available.

Transcellular Transport Experiments—The conditions of each experiment are described in figure legends or table footnotes. A typical experiment on L-lactic acid transport was performed as follows. For the study of the transcellular transport across Caco-2, the cells grown on a polycarbonate membrane were washed twice with Hank's balanced salt solution (HBSS; 0.952 mM $CaCl_2$, 5.36 mM KCl, 0.441 mM KH_2PO_4, 0.812 mM $MgSO_4$, 136.7 mM NaCl, 0.385 mM Na_2HPO_4, 30 mM D-glucose, and 10 mM HEPES for pH 7.4 or 10 mM MES for pH 6.0), and the osmolarity was adjusted to 315 mOsm/kg.[9] To initiate transport, 1.5 mL of HBSS (pH 7.4, 37 °C) was put on the basolateral side (receiver side), and 0.5 mL of the test solution (pH 6.0 or pH 7.4, 37 °C) containing a radio-labeled compound was loaded on the apical side (donor side) of a cell insert. At 15, 30, 45, and 60 min after that, 0.5-mL

aliquots of the solution were removed from the receiver side and replaced with an equal volume of fresh HBSS. In the case of the bicarbonate-gradient condition, modified HBSS (0.952 mM $CaCl_2$, 5.36 mM KCl, 0.441 mM KH_2PO_4, 0.812 mM $MgSO_4$, 111.7 mM NaCl, 0.385 mM Na_2HPO_4, 25 mM $NaHCO_3$, 30 mM D-glucose, and 10 mM HEPES, pH 7.4 with the osmolarity of 315 mOsm/kg, 37 °C), which contained a suitable amount of bicarbonate ion to maintain the bicarbonate gradient during the experiments, was used on the basolateral side. The amount of the radio-labeled compound transported by cells was estimated by radioactivity measurement and expressed as permeability (μL/mg protein), obtained by dividing the transported amount by the initial concentration in the donor compartment and correcting for the cellular protein amount. Each result represents the mean ±SEM of three experiments using the same cultivation of Caco-2 cells. Radioactivity was determined with a liquid scintillation counter (LS6000TA, Beckman, Fullerton, CA). Cellular protein was measured by the method of Lowry et al.[16] with bovine serum albumin as a standard.

Measurement of Physicochemical Properties—The partition coefficient of each compound between *n*-octanol and HBSS (pH 7.4), log $D_{7.4}$, was determined by means of the flask shaking method.[17] The proton nuclear magnetic resonance (^{1}H NMR; 300 MHz) spectra were obtained in dimethyl sulfoxide-d_6 using tetramethylsilane as an internal standard at room temperature.

Data Analysis—The permeability coefficient (μL/min/mg protein) was determined from the slope of the initial linear portion of the permeability (μL/mg protein) versus time (min) curves by linear regression analysis. A permeability coefficient of 1 μL/min/mg protein corresponded to 15.4×10^{-6} cm/s, since cellular protein averaged 0.922 mg/cm^2. To estimate the kinetic parameters for the saturable transport across Caco-2 monolayers, the transport rate (J) was fitted to one of the following equations, consisting of both saturable and nonsaturable-linear terms, by using a nonlinear least-squares regression analysis program (WinNonlin, SCI, Apex, NC),

$$J = J_{max} \times S/(K_t + S) + k_d \times S \quad (1)$$

or

$$J = J_{max,1} \times S/(K_{t,1} + S) + J_{max,2} \times S/(K_{t,2} + S) + k_d \times S \quad (2)$$

where J_{max} is the maximum transport rate for the carrier-mediated process, S is the concentration of substrate, K_t is the half-saturation concentration (Michaelis constant), subscript integers 1 and 2 indicate saturable processes of high and low affinity, respectively, and k_d is the first-order rate constant. Statistical analysis was performed by using Student's two-tailed t test. A difference between means was considered to be significant when the P-value was less than 0.05.

Results

pH and Bicarbonate Ion Dependence of L-Lactic Acid Transport—Figure 1 shows the time-courses of the permeability of L-[^{14}C]lactic acid and [^{3}H]mannitol from the apical to the basolateral side across a Caco-2 cell monolayer in the presence or absence of a proton or bicarbonate gradient, or both. The permeability of L-[^{14}C]lactic acid increased linearly with time after an initial lag period of a few minutes, as reported previously.[9] In the bicarbonate-free condition, the permeability coefficient of L-[^{14}C]lactic acid at the apical pH of 6.0 was 0.365 ± 0.020 μL/min/mg protein, being significantly higher than that (0.176 ± 0.010 μL/min/mg protein) observed at the apical pH of 7.4. In the presence of 25 mM bicarbonate ions on the basolateral side, the permeation rates of L-[^{14}C]lactic acid at the apical pH values of 6.0 and 7.4 were 1.32 and 1.33 times faster (0.482 ± 0.031 and 0.233 ± 0.010 μL/min/mg protein, respectively) than those observed in the absence of a bicarbonate ion gradient, respectively. Since the permeability coefficients of L-[^{14}C]lactic acid under all conditions examined were significantly higher than that (0.087 ± 0.001 μL/min/mg protein) of [^{3}H]mannitol, which reflects the paracellular permeability, L-lactic acid transport occurred mainly by transcellular permeation rather than through the paracellular pathway.

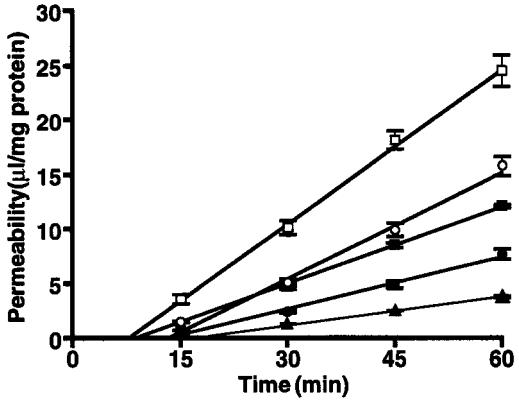

Figure 1—Time-courses of the transport of L-[^{14}C]lactic acid and [^{3}H]mannitol from the apical side to the basolateral side across Caco-2 cell monolayers. Permeability of L-[^{14}C]lactic acid (1 μM) was measured at 37 °C by incubating Caco-2 monolayers in HBSS buffer at an apical pH of 6.0 (□, ○), or 7.4 (●, ■) with a constant basolateral pH of 7.4, in the presence of 0.952 mM $CaCl_2$, 5.36 mM KCl, 0.441 mM KH_2PO_4, 0.812 mM $MgSO_4$, 136.7 mM NaCl, 0.385 mM K_2HPO_4, 25 mM D-glucose and 10 mM HEPES for pH 7.4 or 10 mM MES for pH 6.0 (circles). When bicarbonate-containing HBSS buffer at a basolateral pH of 7.4 was used (squares), 111.7 mM NaCl and 25 mM $NaHCO_3$ were contained instead of 136.7 mM NaCl. [^{3}H]Mannitol (33 nM; ▲) transport was measured at 37 °C in Caco-2 monolayers in HBSS buffer at an apical pH of 7.4 and bicarbonate-containing HBSS buffer at a basolateral pH of 7.4. An aliquot was withdrawn from the basolateral side at each time indicated. Each point represents the mean ± SEM of three experiments using the same culture of Caco-2 cells.

Concentration Dependence of L-Lactic Acid Transport—Figure 2 illustrates the relationship between the initial transport rate of L-[^{14}C]lactic acid and the concentration in the medium (from 1 μM to 20 mM) under the two different conditions, namely at the apical pH values of 6.0 (panel A) and 7.4 (panel B), while the pH on the basolateral side was kept at 7.4 with 25 mM bicarbonate ions. The results indicate that the permeation rate of L-[^{14}C]lactic acid under both conditions involves both saturable and nonsaturable processes, as shown in the inset of Figure 2. When the data at the apical pH of 6.0 were analyzed by means of an Eadie–Hofstee plot, two different types of transport processes were observed, as illustrated in panel A. Kinetic analysis of the concentration-dependent permeation according to eq 2, gave $J_{max,1}$ and $K_{t,1}$ values of 0.098 ± 0.021 nmol/min/mg protein and 0.28 ± 0.10 mM, and $J_{max,2}$ and $K_{t,2}$ values of 1.46 ± 0.20 nmol/min/mg protein and 10.9 ± 2.0 mM, respectively. The k_d value was 0.056 ± 0.043 μL /min/mg protein (mean ± SD). At the apical pH of 7.4, the Eadie–Hofstee plot apparently shows a single saturable process. Kinetic analysis of L-lactic acid transport according to eq 1 gave J_{max}, K_t, and k_d values of 1.03 ± 0.36 nmol/min/mg protein, 8.26 ± 2.80 mM, and 0.056 ± 0.010 μL/min/mg protein, respectively. Accordingly, the transport of L-[^{14}C]lactic acid across Caco-2 cell monolayers seems to be bicarbonate-ion dependent. So, in subsequent experiments, transport studies were performed at apical and basolateral pH values of 7.4 in the presence of 25 mM bicarbonate ions on the basolateral side to magnify the relative activity of anion-exchange transport.

Inhibitory Effect on Monocarboxylate Transport—Table 1 shows the effects of the bicarbonate ion gradient, metabolic inhibitors, and monocarboxylates on the transport of L-[^{14}C]lactic acid, [^{3}H]mevalonic acid, [^{14}C]benzoic acid, [^{14}C]salicylic acid, and [^{3}H]mannitol. DNP (1 mM), an uncoupler of oxidative phosphorylation, sodium azide

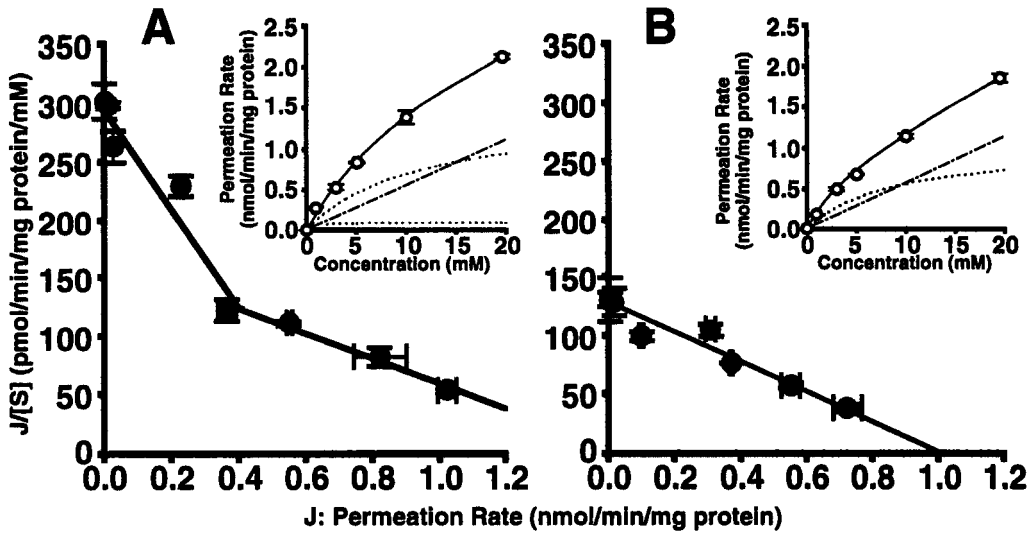

Figure 2—Concentration dependence of L-[^{14}C]lactic acid transport across Caco-2 cell monolayers at an apical pH of 6.0 (panel A) or 7.4 (panel B), at a constant basolateral pH of 7.4 with 25 mM bicarbonate. The concentrations of L-lactic acid used were 1, 10, and 100 μM and 1, 3, 5, 10, and 20 mM, which were adjusted by addition of the nonlabeled compound to L-[^{14}C]lactic acid (1 μM). The incubation conditions were identical to those described in the legend to Figure 1. The broken lines represent the contribution of the saturable (••••) and nonsaturable (–•–) components to the permeation, calculated from the kinetic parameters obtained as described in the results. Each point represents the mean ± SEM of three experiments using the same culture of Caco-2 cells.

Table 1—**Effect of Various Compounds and Condition on Monocarboxylic Acid and Mannitol Transports**[a]

condition	relative permeability (% of control)[b]				
	L-[^{14}C]lactic acid	(*R*)-[^{3}H]mevalonic acid	[^{14}C]benzoic acid	[^{14}C]salicylic acid	[^{3}H]mannitol
control	100.0 ± 3.8	100.0 ± 12.2	100.0 ± 0.7	100.0 ± 5.7	100.0 ± 1.8
bicarbonate free	75.4 ± 4.1*	88.2 ± 1.8	52.9 ± 1.3*	40.4 ± 1.6*	99.8 ± 3.4
+1 mM DNP	43.9 ± 2.2*				106.2 ± 2.9
+10 mM NaN_3	54.5 ± 6.0*				101.2 ± 3.9
+2 mM DIDS	32.4 ± 1.1*	97.4 ± 0.9	45.4 ± 0.5*	41.4 ± 1.9*	98.0 ± 6.4
+10 mM L-lactic acid	45.8 ± 3.2*				
+10 mM (*R*)-mevalonic acid	88.4 ± 5.8	86.8 ± 6.4			
+10 mM (*S*/*R*)-mevalonic acid	104.8 ± 6.0				
+10 mM benzoic acid	42.0 ± 6.1*		59.8 ± 1.3*		
+10 mM salicylic acid	47.6 ± 1.3*			57.9 ± 3.6*	

[a] Note: Transport of L-[^{14}C]lactic acid (1 μM), (*R*)-[^{3}H]mevalonic acid (50 nM), [^{14}C]benzoic acid (10 μM), [^{14}C]salicylic acid (10 μM), and [^{3}H]mannitol (33 nM) were measured at 37 °C for 60 min by incubating Caco-2 cells in HBSS buffer (apical pH 7.4, basolateral pH 7.4 with bicarbonate) in the presence of each inhibitor. The other incubation conditions were the same as described in the legend to Figure 1. [b] Each value represents the mean ± SEM of three experiments using the same cultivation process of Caco-2 cells and is expressed as percentage of the control. *Significantly different from the control value by Student's *t* test ($p < 0.05$).

(10 mM), a respiratory chain inhibitor, and DIDS (2 mM), an anion exchange inhibitor, significantly diminished the transport of L-[^{14}C]lactic acid. Salicylic acid and benzoic acid (10 mM) were inhibitory, whereas neither (*R*)- nor racemic mevalonic acid (10 mM) had any effect on the transport of L-[^{14}C]lactic acid. Moreover, the permeability of [^{3}H]mevalonic acid was not affected by the bicarbonate ion gradient or the addition of DIDS to the transport buffer. Further, mevalonic acid transport was not saturable as shown by the apparent lack of inhibition by unlabeled mevalonic acid. In contrast, the permeability of [^{14}C]salicylic acid and [^{14}C]-benzoic acid was significantly reduced in the absence of the bicarbonate gradient and was inhibited by DIDS and 10 mM of each of these unlabeled compounds in the transport buffer. The transport of [^{3}H]mannitol did not change in the presence of DNP, sodium azide, or DIDS.

Structural Specificity of the Anion-Exchange Transporter—As shown in Table 2, to examine the properties of the anion-exchange transporter responsible for L-lactic acid transfer across Caco-2 cells, the effects of various monocarboxylic acids bearing a hydroxyl group and their derivatives were examined in the presence of a bicarbonate gradient. The permeability of L-[^{14}C]lactic acid was reduced by 2- and 4-hydroxycarboxylic acids (10 mM) such as hydroxyacetic acid, 2-hydroxybutyric acid, and 4-hydroxybutyric acid. It was also reduced by a 5-hydroxycarboxylic acid (10 mM), 5-hydroxydecanoic acid. In contrast, 3-hydroxycarboxylic acids (10 mM), such as 3-hydroxypropionic acid, 3-hydroxybutyric acid, and 3-hydroxy-3-phenylpropionic acid, did not show any significant inhibitory effect on

Table 2—**Inhibitory Effect of Monocarboxylic Acids on L-[^{14}C]Lactic Acid Transport**[a]

inhibitor	relative permeability (% of control)[b]
hydroxyacetic acid	80.3 ± 3.2*
3-hydroxypropionic acid	95.6 ± 2.0
4-hydroxybutyric acid	72.8 ± 3.5*
2-hydroxybutyric acid	59.9 ± 1.6*
3-hydroxybutyric acid	93.8 ± 12.7
3-hydroxy-3-phenylpropionic acid	89.5 ± 3.9
3-methoxypropionic acid	64.7 ± 1.2*
5-hydroxydecanoic acid	58.0 ± 0.6*

[a] Note: Transport of L-[^{14}C]lactic acid (1 μM) was measured at 37 °C for 60 min by incubating Caco-2 cells in HBSS buffer (apical pH 7.4, basolateral pH 7.4 with bicarbonate) in the presence of each inhibitor. The other incubation conditions were the same as described in the legend to Figure 1. [b] Each value represents the mean ± SEM of three experiments using the same cultivation process of Caco-2 cells and is expressed as percentage of the control. *Significantly different from the control value by Student's *t* test ($p < 0.05$).

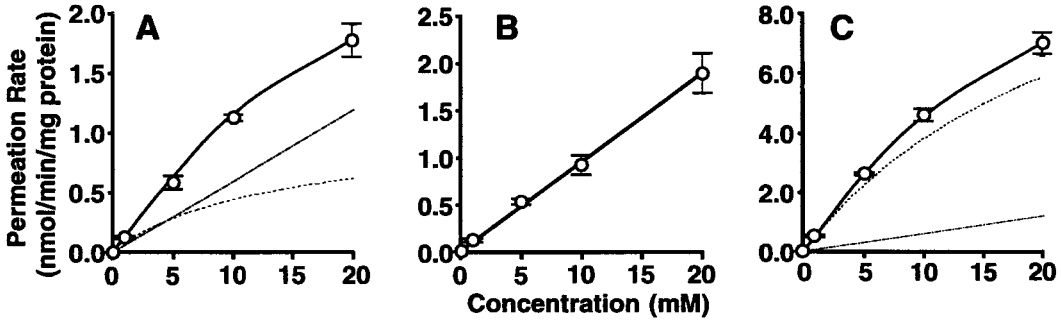

Figure 3—Concentration dependence of the transport of hydroxybutyric acids across Caco-2 cell monolayers. 2-Hydroxybutyric acid (panel A), 3- hydroxybutyric acid (panel B), and 4-hydroxybutyric acid (panel C) were examined. The concentrations of each hydroxybutyric acid (2.5 μM, and 1, 5, 10, and 20 mM) were adjusted by addition of the nonlabeled compound to [^{14}C]hydroxybutyric acid (2.5 μM). The incubation conditions were identical to those described in the legend to Figure 1. The broken lines represent the contribution of the saturable (••••) and nonsaturable (–•–) components to the permeation, calculated from the kinetic parameters obtained as mentioned in the results. Each point represents the mean ± SEM of three experiments using the same culture of Caco-2 cells.

Table 3—Inhibitory Effect of DIDS on [^{14}C]Hydroxybutyric Acids Transport[a]

substrate	permeability coefficient (μL/min/mg protein)[b]	
	control	+2 mM DIDS
[^{14}C]2-hydroxybutyric acid	0.125 ± 0.009	0.084 ± 0.005*
[^{14}C]3-hydroxybutyric acid	0.111 ± 0.008	0.108 ± 0.014
[^{14}C]4-hydroxybutyric acid	0.555 ± 0.032	0.459 ± 0.011*

[a] Note: Transport of [^{14}C]hydroxybutyric acid (2.5 μM) was measured at 37 °C for 60 min by incubating Caco-2 cells in HBSS buffer (apical pH 7.4, basolateral pH 7.4 with bicarbonate) in the presence of each inhibitor. The other incubation conditions were the same as described in the legend to Figure 1. [b] Each value represents the mean ± SEM of three experiments using the same cultivation process of Caco-2 cells. *Significantly different from the control value by Student's *t* test ($p < 0.05$).

the transport of L-[^{14}C]lactic acid, though 10 mM 3-methoxypropionic acid was inhibitory.

Transport Properties of 2-, 3-, and 4-Hydroxybutyric Acids—Figure 3 illustrates the relationship between the initial transport rate of [^{14}C]2-, 3-, and 4-hydroxybutyric acids and the concentration in the medium from 1 μM to 20 mM at the apical pH of 7.4, while the pH on the basolateral side was kept at 7.4 with a 25 mM bicarbonate ion gradient. The results indicate that the permeation of 2- and 4-hydroxybutyric acids involve saturable and nonsaturable processes. Kinetic analysis of the concentration-dependent permeation gave J_{max}, K_t, and k_d values of 2.21 ± 0.22 nmol/min/mg protein, 3.75 ± 0.40 mM, and 0.09 ± 0.01 μL/min/mg protein for 2-hydroxybutyric acid, and 8.44 ± 2.67 nmol/min/mg protein, 23.9 ± 6.41 mM, and 0.12 ± 0.03 μL/min/mg protein for 4-hydroxybutyric acid, respectively. In contrast, the saturable process was not observed for 3-hydroxybutyric acid within the tested concentration range. The first-order rate constant, k_d, was 0.09 ± 0.01 μL/min/mg protein.

Table 3 shows the effects of DIDS on the transport of [^{14}C]-2-, 3-, and 4-hydroxybutyric acids. Permeability of [^{14}C]-2- and 4-hydroxybutyric acids (2.5 μM) in the presence of 2 mM DIDS amounted to 67.1% and 82.6% of the respective control values. The permeability of [^{14}C]-3-hydroxybutyric acid was not affected by DIDS.

Discussion

In the present study, we set out to establish conditions that would maximize the relative activity of anion-exchange transport and to clarify the structural features of substrates required for intestinal transport by examining the transcellular transport of several hydroxy-monocarboxylic acids and their derivatives across monolayers of Caco-2 cells. In the presence of a bicarbonate ion gradient, but not a proton gradient, the concentration dependence of L-lactic acid transport was explained by the participation of a single saturable component, which might be ascribed to the anion-exchange transport mechanism. Under the same conditions, the transport of L-[^{14}C]lactic acid was inhibited by DIDS, which is a typical inhibitor of the anion-exchange transporter. Similar anion antiport activity with bicarbonate was found in the transport of propionic acid and acetic acid.[18,19,3] Previously, we observed enhanced uptake of nicotinic acid when an outward-directed bicarbonate gradient was imposed in isolated jejunal BBMVs.[11] It appears that similar anion-exchange transport mechanisms are involved in the permeation and absorption of monocarboxylic acids in the human intestine.

Mevalonic acid, a 3-hydroxycarboxylic acid, had no effect on the transport of L-[^{14}C]lactic acid in the presence of a bicarbonate ion gradient. In addition, as our previous study using rabbit intestinal BBMVs[11] indicated, the permeation of [^{3}H]mevalonic acid was not affected by the bicarbonate gradient or DIDS. The transport of L-[^{14}C]lactic acid was also inhibited by 2-, 4-, and 5-hydroxycarboxylic acids but not by 3-hydroxycarboxylic acid. These observations suggested that the position of hydroxylation might be an important determinant of monocarboxylate transport by the anion antiport system. Accordingly, we compared the transport of several hydroxycarboxylic acids. The concentration dependence of the 2- and 4-hydroxybutyric acid transport indicated that the permeation involves saturable and nonsaturable processes, whereas that of 3-hydroxybutyric acid was nonsaturable. Since the partition coefficients (as hydrophobic/hydrophilic parameters) of these compounds are almost the same (log $D_{7.4}$ 2-hydroxybutyric acid: −2.35, 3-hydroxybutyric acid: −2.72, 4-hydroxybutyric acid: −2.40), differences in hydrophobicity do not account for the result. It is suggested that 3-hydroxycarboxylic acids might not be substrates for the anion-exchange transporter in intestinal epithelial cells. Interestingly, 3-methoxypropionic acid was shown to have affinity for the anion-exchange transporter, because the transport of L-[^{14}C]lactic acid was inhibited by 3-methoxypropionic acid. This result suggests that a hydrogen bond between the 3-hydroxyl group of carboxylate and the transporter protein might block appropriate interaction with the anion-exchange transporter. It was expected that salicylic acid would not be a substrate for the anion-exchange transporter because it could be regarded as a 3-hydroxycarboxylic acids. However, contrary to expectation, the permeability of [^{14}C]salicylic acid was significantly reduced by the bicarbonate ion-free condition, DIDS, and unlabeled salicylic acid. Within the salicylic acid molecule, there is a relatively stable hydrogen bond conjugated with

the aromatic benzene ring, namely between the 3-hydroxyl group and oxygen of the carboxylic group. This is demonstrated by the ^{1}H NMR signals of the 3-hydroxyl group in salicylic acid and in 3-hydroxybutyric acid (salicylic acid: 11.3 ppm, 3-hydroxybutyric acid: 7.02 ppm). This internal hydrogen bond in salicylic acid might be too strong to allow the blocking interaction with transporter proteins, whereas the relatively "flexible" 3-hydroxyl group in other carboxylic acids can interfere with the proper binding of the substrate to the anion-exchange transporters.

Recently, we demonstrated that the anion exchanger AE2, which is present in several tissues,[20−25] transported organic monocarboxylic acids, when the AE2 gene was transiently overexpressed in HEK 293 cells.[12] So, AE2 might be partially responsible for monocarboxylic acid/anion exchange in the intestine, although more studies are needed on this point.

In conclusion, we have established some of the required structural characteristics for substrates of the anion-exchange transporter using Caco-2 cell monolayers. The observations suggest that an anion antiport system is involved in the intestinal absorption of monocarboxylic acids in parallel with a proton gradient-dependent monocarboxylic acid transporter. Therefore, intestinal absorption of many acidic drugs may proceed, at least in part, via the anion-exchange transporter, rather than by passive diffusion according to the pH-partition hypothesis.

Received January 12, 1999. Accepted for publication July 29, 1999.

Abstract □ The investigation of dissolution failures for erythromycin dihydrate tablet formulation over a 12-month period using a near-infrared spectroscopy technique revealed the role of a desolvated dihydrate in the retardation of dissolution. Near infrared spectroscopy (NIR) indicated a dehydrated dihydrate of erythromycin is produced during formulation and gradually binds with $Mg(OH)_2$. The binding delays the process of dissolution. NIR was used to successfully predict that humidifying the tablets would reverse the binding and increase the dissolution rate.

Introduction

The occurrence of a variety of crystal forms for many pharmaceuticals has been well established and investigated.[1−11] The first recognition of this phenomenon of polymorphism may have been as early as the 18th century.[12] The fact that pharmaceuticals can exist as various polymorphs and/or solvates can be problematic in terms of stability, processing, and solubility since the different crystal forms and solvates of a drug can differ in these physical properties. In fact, the different polymorphs of a compound can be as different in these properties as are individual compounds from each other.

The established analytical techniques used to demonstrate that a compound exists in various crystal forms include X-ray powder diffraction (XRD), differential scanning calorimetry (DSC), solid-state C-13 nuclear magnetic resonance (SS NMR), polarized light microscopy (PLM), and near- and mid-infrared (NIR and IR) spectroscopy.

For several years the pharmaceutical literature reported various crystal forms and hydrates of erythromycin including an anhydrate, a monohydrate, and a dihydrate. In an earlier work[13] we proposed that the crystal form of erythromycin dihydrate as determined by X-ray powder diffraction was unchanged when the water was removed, indicating minimal if any difference in the crystal structure in the presence or absence of water. As a result of readily available channels or tunnels within the crystal lattice,[14] water is readily transported into and out of the crystal lattice depending on the environmental conditions. Pfeiffer et al.[15] has referred to molecules of this kind as pseudopolymorphs, and Stephenson et al.[16] note that the desolvated state or isomorphic desolvate is of higher energy than the solvated form and that there is a driving force to fill the void created when the solvent is removed. In this paper we will present an example of this tendency to fill the void created when the water is removed from erythromycin dihydrate, its resultant effect on tablet behavior, and the use of NIR spectroscopy to investigate the problem.

Experimental Section

Materials—Several formulations of erythromycin dihydrate containing no magnesium hydroxide as well as the primary formulation which contained magnesium hydroxide were investigated. All formulations were manufactured at Abbott Laboratories and used erythromycin dihydrate USP grade. The USP grade erythromycin dihydrate was also manufactured at Abbott Laboratories through a fermentation process followed by a series of aqueous and organic extractions. This material was dried at less than 95 °C. All bulk lots met Abbott specifications.

Microscopy was performed using a Nikon Microphot-FXA polarized light microscope and a Leica Stereo Microscope Model MZAPO. X-ray powder diffraction was performed with a Nicolet I2 X-ray powder diffractometer fitted with a diffracted beam monochromator tuned for copper radiation at 1.54180 Å. All samples were ground to similar particle size immediately prior to X-ray analysis. Thermal gravimetric analysis (TGA) was performed using a TA Instruments Model 2950 TGA module with a Model 3100 Thermal Analyst, at a heating rate of 5 °C/min, and a sample weight of about 15−20 mg. A Nicolet Magna-IR Spectrometer Model 750 bench with a Nicolet SabIR near-infrared (NIR) diffuse reflectance fiber optic probe accessory were used to obtain NIR spectra at a resolution of 8 cm^{-1} with 16 scans. Intact tablets were place directly on the probe tip whereas bulk material was put into a clear glass one dram vial and then placed on the probe tip. The NIR spectrum of a bulk material was an average spectrum of four spectra acquired after manually mixing the sample for about 15 s followed by manual tapping to remove air gaps. Dynamic moisture sorption gravimetry (DMSG) was performed on a VTI Corp. Model MB300G sorption microbalance using vacuum to control the relative humidity (RH). The Automated system controlled the RH and temperature to which the sample was exposed, while continually recording sample weight changes. Sample weights were typically about 5−10 mg. Sorption and desorption isotherms were performed at 25 ± 0.1 °C with 5 ± 1% RH step intervals from 0 to 95% RH. Samples were dried under vacuum for up to 240 min (approximate RH = 0−1% RH) before each experiment. The weight loss observed during the drying period was used to estimate how tightly each sample held water. After the drying period, sorption isotherms started at 5% RH. A weight equilibrium criteria of less than 3 μg weight change over three 7 min periods was used to move to the next RH step. When the equilibrium conditions were achieved for the 95% RH step, the desorption step started. Typical sample run times were between about 24 and 48 h. Dissolution testing of tablets was performed using a single tablet in a dissolution medium of 0.05 M phosphate buffer pH 6.8 ± 0.05 at 60 °C. Quantitation was performed by UV absorbance at 236 nm versus a reference standard of erythromycin dihydrate. Intrinsic dissolution of bulk drug samples was performed at 37 °C with the same dissolution media. Quantitation was accomplished by HPLC versus a reference standard at 205 nm using an octadecylsilyl column at 50 °C and an eluent of 35% acetonitrile/65% 0.06 M phosphate buffer (pH 6.6).

to fail the dissolution specification at the 60 min interval but pass at the 90 min interval. Historically, sporadic tablets of this formulation (lots 3, 6, 13 Table 1) had failed dissolution; however, this lot, which had very good initial dissolution of greater than 99%, released at 60 min failed uniformly at the 12-month time point with an average of 71% released at 60 min. Other lots of this same formulation (lots 1, 18, Table 1) had maintained very high dissolution for periods greater than 12 months. Material which had acceptable dissolution over the 12-month period will be referred to as passing while those with decreased dissolution will be designated as failing. One of these former lots (lot 1, Table 1) was used as a reference for passing tablets. The manufacturing process for erythromycin tablets involves milling and drying, and these factors have historically been shown to affect crystallinity and, as would be expected, water content. Initial work concentrated on these properties as well as examination of the tablet coating.

Results and Discussion

X-ray powder diffraction was performed on the erythromycin dihydrate tablets using computer subtraction of a placebo diffraction pattern to examine the consistency of the crystal form of erythromycin in the tablet. Figure 1 shows two representative diffraction patterns. Pattern A is that of the passing tablet, and pattern B represents a failing tablet. Both tablets give the characteristic spectrum of erythromycin dihydrate; however, resolution differences were observed, which most likely reflect a difference in crystallinity. In addition, significant changes in the relative intensities of the X-ray peaks can be observed between passing and failing lots. As previously reported,[13] crystalline erythromycin can vary in water content over a large range (50−200%) of dihydrate theory without affecting the X-ray pattern. TGA of these samples showed two weight losses, indicating the presence of a small amount of surface water as well as interstitial water. The most highly crystalline lot shows a continuous weight loss approximately equal to the dihydrate stoichiometry of 4.7%. In addition, NIR spectroscopy[17] was used to further evaluate their water content by examining the hydroxyl peak (water combination band) at approximately 1.95 μm, which reflects hydroxyl contributions from erythromycin as well as from water. Table 1 shows a compilation of XRD patterns in terms of resolution, amount of water from TGA weight loss,

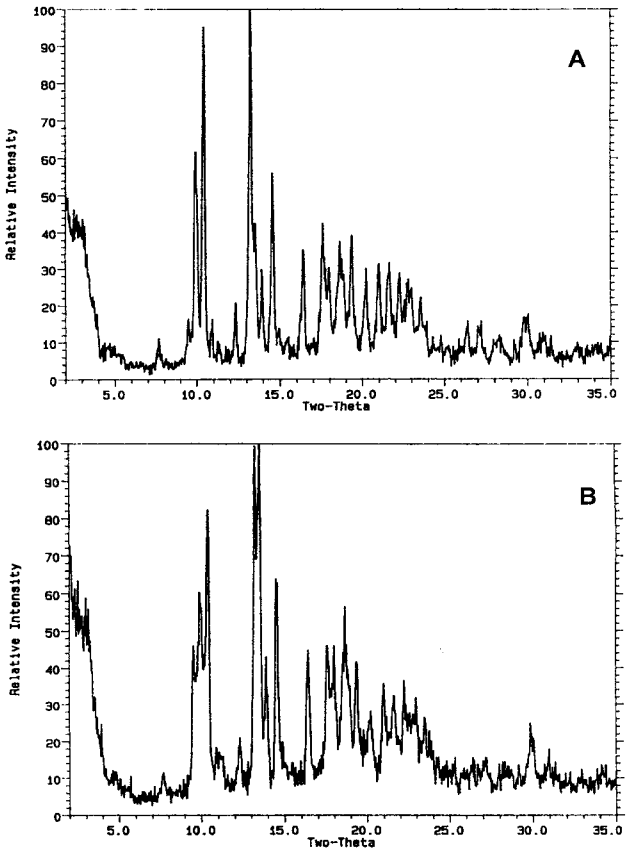

Figure 1—XRD of passing and failing Erythromycin tablet lots. (A) Passing tablets. (B) Failing tablets.

and the relative amount of hydroxyl content by NIR. The data indicate that the samples with low water content relative to the theoretical dihydrate stoichiometry also show broader, less-resolved peaks in the X-ray pattern. The NIR hydroxyl content also follows the same trend, i.e., lower hydroxyl content corresponds to broader X-ray peaks. Samples with less than 3.3% weight loss up to 136 °C show the lowest crystallinity and hydroxyl content compared to lot 1 which is the stoichiometric dihydrate. NIR spectroscopy was used in the remainder of the study to evaluate the water content of the tablets nondestructively on individual tablets, thereby allowing further testing on the same tablet by dissolution to investigate the correlation shown in Table 1.

While selecting a sample of amorphous erythromycin to characterize by NIR and XRD, a mesomorphic form or mesophase of erythromycin was identified which has not been previously reported. This material has a well-defined crystal habit and shows birefringence when examined by PLM but as shown in Figure 3 appears mostly amorphous by XRD showing only either a strong broad single line or multiple lines near 2 θ values of 9.4−9.6. The XRD and PLM data are consistent with a solid phase having 2-D order but lacking 3-D order. Amorphous erythromycin was produced separately by freeze-drying an aqueous solution of erythromycin. Examination of the XRD data described above suggests a possible transformation of the pattern for crystalline erythromycin dihydrate over time in the 250 mg formulation to a pattern representing a mixture of erythromycin dihydrate and the mesophase. However, since erythromycin dihydrate can produce an isomorphic dehydrated dihydrate, these XRD patterns could also represent a conversion to mesophase plus dehydrated dihydrate. This latter explanation is consistent with the parallel decrease in water content.

form	amount dissolved in 60 min, mg
dihydrate	0.8
amorphous	2.8
mesophase	5.0

A basic tenet of solubility states that higher energy level crystal forms as well as amorphous material should have high intrinsic solubility compared to the more stable forms. The data presented in Table 2 show the intrinsic solubility relationship of mesophase, amorphous, and dihydrate forms of erythromycin. These data indicate that conversion to mesophase alone should not result in dissolution failure.

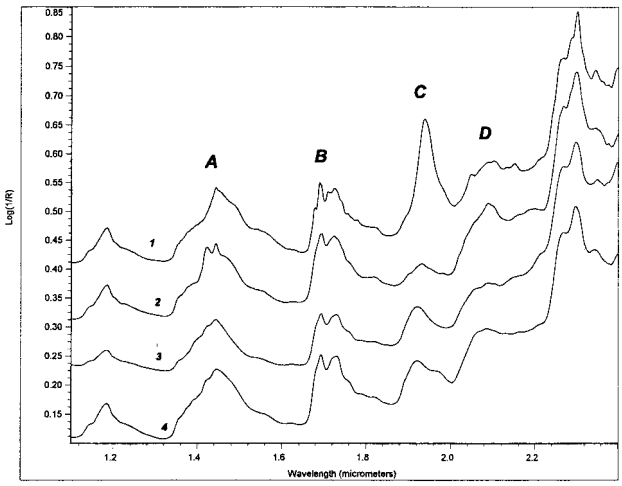

Figure 4—NIR spectra of (1) erythromycin dihydrate, (2) dehydrated erythromycin dihydrate, (3) erythromycin amorphous, and (4) erythromycin mesophase.

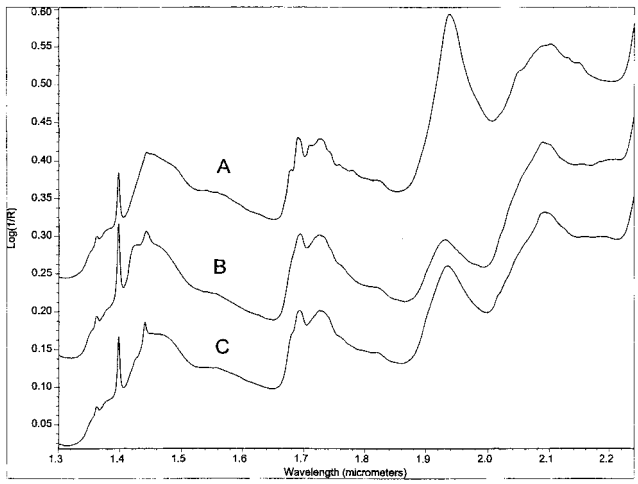

Figure 5—NIR spectra of (A) passing tablets, (B) dehydrated dihydrate, and (C) failing tablets.

Although erythromycin maintains its crystallographic order when dried, the local chemical environment is significantly influenced by the loss of water. When the dehydrated dihydrate is formed, this higher energy crystal form of erythromycin is more reactive and hygroscopic. Close examination of the NIR data (Figure 4) of bulk erythromycin dihydrate, isomorphic dehydrate, mesophase, and amorphous erythromycin indicates that each of the forms have distinguishing characteristics in the NIR spectral areas 1.45, 1.7, 1.95, and 2.1 μm (regions A, B, C, and D in Figure 4). Comparison of the NIR spectra of the passing lot, failing lot, and a dried passing lot (Figure 5) shows that the spectra of the samples are different particularly in the 1.4−1.5 μm region. These comparisons indicate that the majority of the erythromycin form in the failing lot is not dihydrate, isomorphic dehydrate, mesophase, or amorphous material.

Erythromycin tablets with greater drug load (333 and 500 mg) are prepared with corn starch and drug as the two predominant ingredients. The 250 mg tablets contain mainly drug, corn starch, and magnesium hydroxide. All other components are common to all formulations and are present in the same small quantities in all formulations. These include colorants and coatings. Samples of the higher dosage formulation were found to contain the same low (i.e., 3.3% or less) levels of water; however, no dissolution failures were observed after storage. If the reduced dis-

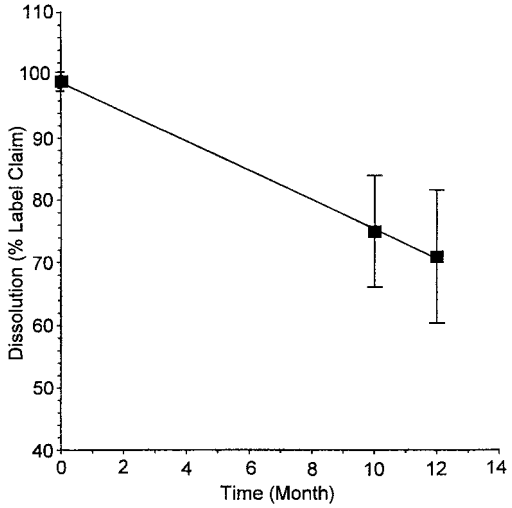

Figure 6—Comparison of failing lot 15 dissolution (% label claim) versus time.

solution rate were a result of changes in the excipients over time, for example, dehydration, the same dissolution failures would be expected with the higher dosage formulation. TGA and DMSG studies on the bulk drug and excipients indicate that the water in the formulation is preferentially lost from erythromycin upon heating rather than from the excipients.

Since the performance of the 250 mg tablet is different than that of the 333 and 500 mg tablets, an interaction with an excipient unique to the 250 mg tablet formulation was suspected. The only excipient unique to the 250 mg formulation is magnesium hydroxide, and the lack of dissolution failures in the higher dosage formulation even with low water content indicates that in the absence of this ingredient, changes in the other excipients over time do not result in dissolution failures. This could only explain part of the phenomenon, however, since only random tablets and one individual lot exhibited dissolution failures.

Dissolution of failing lot 15 was monitored over a 12-month period and analyzed at the initial and 10- and 12-month time points (Figure 6). Although only three points were obtained, there was very good linear correlation between the decrease in dissolution (% label claim) and time, with a correlation coefficient of greater than 0.99. Over the same period of time, moisture content by LOD of the coated tablets was 2.6, 2.1, and 2.4% (initial and 10- and 12-month, respectively). However, by comparison the typical passing lot 1 gave LOD values of 3.8, 3.7, and 3.8% (initial and 10- and 12-month, respectively). The decrease in dissolution can be associated with the constant low level of water in the coated tablets over time. This constant low level of water in the coated tablets prevents rehydration of the dehydrated erythromycin dihydrate and maintains erythromycin in the activated state.

When erythromycin dihydrate dehydrates to form a desolvated dihydrate, it reduces the number of hydrogen bonds in the structure dramatically from three to zero. This results in a void in the lattice which has a high hydrogen bonding potential. As noted by Stephenson et al.[16] over time the tunnels slowly relax unless either water is reabsorbed or an alternate ligand is obtained. The 250 mg tablet formulation contains $Mg(OH)_2$, a hydroxyl-rich material, as one of the excipients. Interaction of the activated dehydrated dihydrate of erythromycin with $Mg(OH)_2$ is a possible mechanism for filling the void created in the crystal lattice as a result of overdrying. This interaction in the solid state requires a finite period of time and would correlate well with the slow onset of dissolution failures in the 250 mg formulation over time.

Figure 7 shows schematically a process whereby overdrying could create dehydrated dihydrate in the tablet fill. As a result of the granulation and compaction of the tablet, the $Mg(OH)_2$ could then become associated with the same sites in the dehydrated dihydrate which tend to interact or bind with water in the dihydrate. Over time the association of $Mg(OH)_2$ with dehydrated erythromycin dihydrate could strengthen to a degree where the reversing of the binding interaction necessary for the dissolution of erythromycin becomes a progressively slower process. The extent of this binding would depend on time and the amount of overdrying. Therefore, it would account for both whole lot failure as well as isolated individual tablet failures. Close examination of the NIR spectra in the region of the $Mg(OH)_2$ peak shows discernible differences between passing lots and failing lots of the 250 mg tablets (Figure 8) and supports the model of $Mg(OH)_2$ interacting with the dehydrated dihydrate.

The extent of erythromycin/magnesium hydroxide binding in the tablets was estimated from dissolution data. Figure 6 displays the relationship between the dissolution of the tablet and time. A good linear relationship was observed. Hence, the rate of dissolution retardation in the coated tablet, lot 15, can be estimated at 2.4% per month.

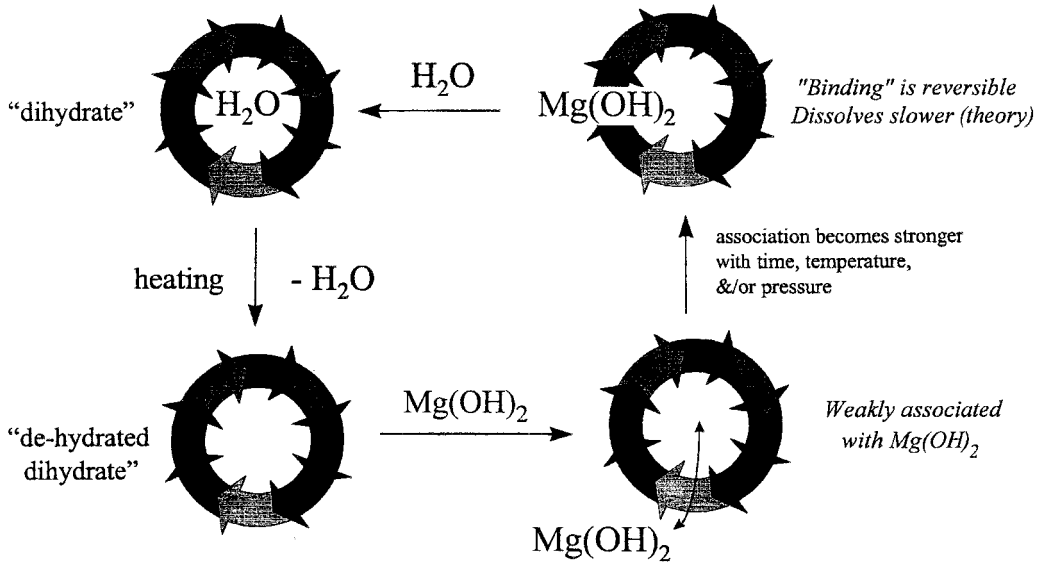

Figure 7—Schematic representation of reversible binding in erythromycin tablets.

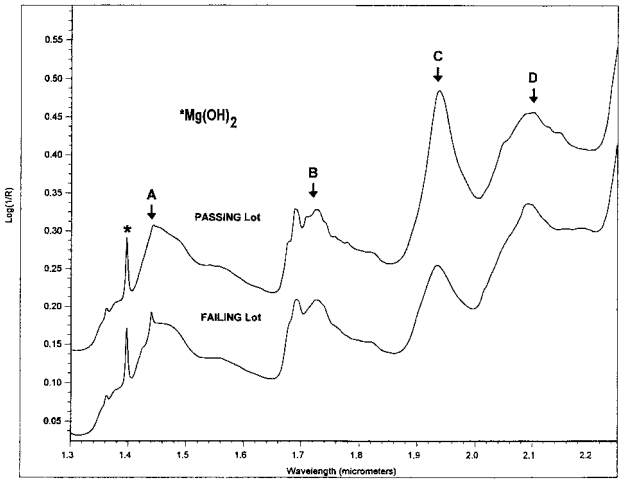

Figure 8—Four spectral regions of difference in the NIR spectra of passing and failing lots of deshelled erythromycin tablets.

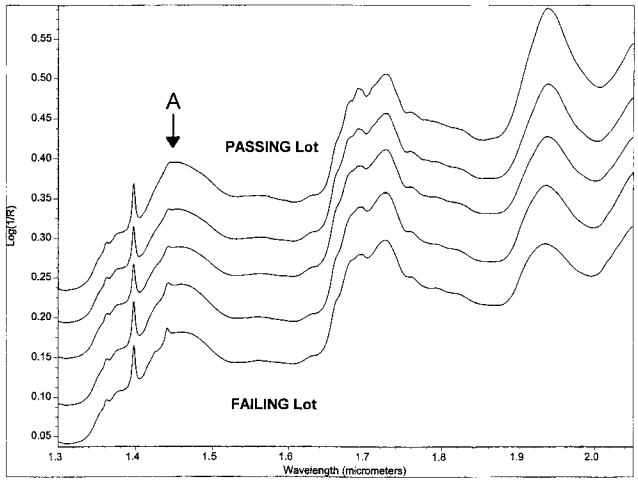

Figure 9—Series of NIR spectra of erythromycin tablets showing progression from passing to failing lot.

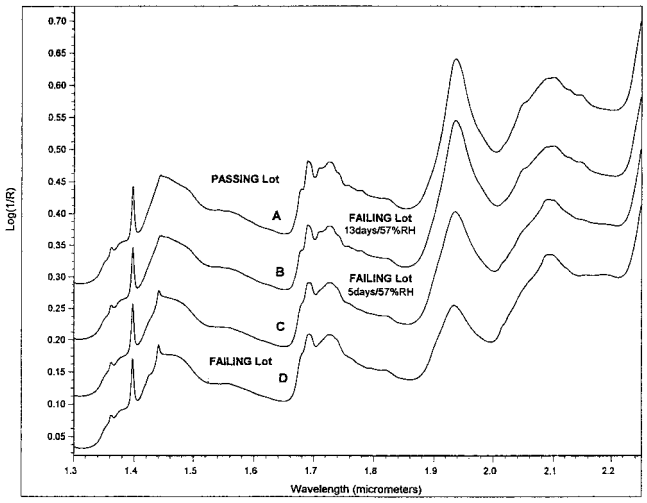

Figure 10—NIR spectra of (A) deshelled passing lot, (B) failing lot after exposure to high humidity for 5 days, (C) failing lot after exposure to high humidity for 13 days, and (D) failing lot.

Four spectral regions were examined at about 1.45, 1.7, 1.95, and 2.1 μm. The region of 1.45 μm represents overtones of hydroxyl and alkyl groups, the region at about 1.7 μm represents overtones of alkyl groups, the region near 1.95 μm represents combination bands of hydroxyl groups (and water content) of the sample, and the region near 2.1

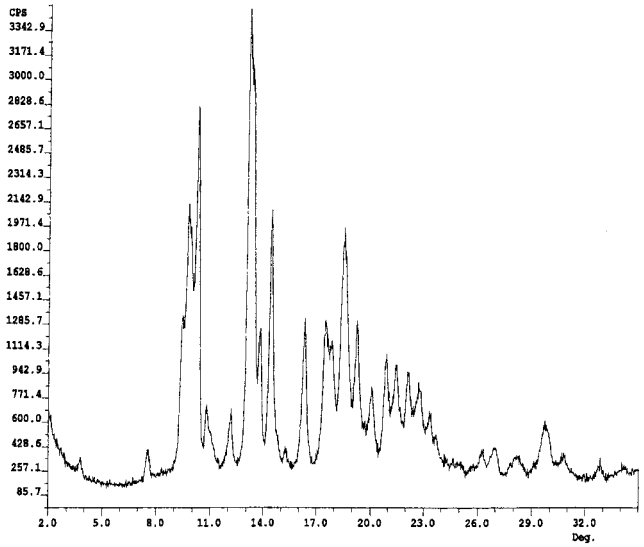

Figure 11—XRD of admixture of dehydrated dihydrate of erythromycin and magnesium hydroxide stored in a closed container for 12 months.

μm represents the first overtones of C−H stretching, and combination bands of alcohol hydroxy groups. As can be seen in Figure 8, the passing lot shows a significantly larger water peak (region C) and a broad multiplet at about 2.1 μm (region D), but not much definition in the area of 1.45 m (region A). The failing lot shows a distinct shoulder and a sharp peak in the region of 1.45 μm, a smaller peak in the water region, and a sharper and smoother peak in the 2.1 μm region. These changes indicate conformational and perhaps structural differences similar to those observed upon drying erythromycin dihydrate but more defined and sharper particularly in the 1.45 μm region. Figure 9 shows spectra of the 250 mg whole tablets for a series of lots displaying the progression (region A) from passing to failing lots.

The NIR data suggest that in the absence of water, dehydrated erythromycin dihydrate interacts with $Mg(OH)_2$ in the 250 mg tablets. This association occurs slowly over time (12 months), suggesting that it is a relatively unselective reaction. Thus, the binding process should be reversible in the presence of a more selective (or reactive) ligand. Since water forms a stable complex with erythromycin (dihydrate), it should be able to displace $Mg(OH)_2$ and reverse the complex formation.

To investigate the proposed reversibility of this phenomenon, tablets from the failing lot were exposed to high humidity (57% RH). Figure 10 shows the NIR spectra for a failing lot, the failing lot exposed to 57% RH for 5 and 13 days, and a passing lot of deshelled tablets. The NIR spectrum of the failing lot exposed to 57% RH/13 days converted to that of the passing lot after exposure to water vapor in the solid state.

Dissolution testing on these moisture-exposed tablets gave results >98% within 60 min, confirming that the binding phenomenon can be reversed.

Dried erythromycin, i.e., the dehydrated dihydrate, compressed with $Mg(OH)_2$ and stored in closed containers for a period of 12 months indicated spectral changes in the NIR spectrum similar to those detected in erythromycin tablets after 12 months. X-ray powder diffraction on the mixture showed a pattern matching that of the failing tablets (Figure 11).

Conclusion

Erythromycin dihydrate when dried is converted to an isomorphic dehydrated dihydrate which exists as an acti-

vated high energy form with a tendency to fill the void created by the loss of water. In erythromycin tablet formulations where water cannot be easily reabsorbed, this has been shown to result in binding to other hydroxyl-rich excipients such as $Mg(OH)_2$ which then adversely effects the properties of the formulation. This phenomenon can be reversed by exposing the tablets to water vapor for a relatively short period of time.

NIR spectroscopy has been shown to be a useful technique in the study of such crystal form transformation and binding. It allows a determination of such properties as drug and moisture content on individual tablets nondestructively thereby allowing further testing on the same tablet to establish a direct correlation with other properties. In addition, it has proven to be predictive of dissolution failures in erythromycin tablet formulations.

Abstract □ Information on the interaction between water and polymers is indispensable for manufacturing solid dispersion of a drug by hot-melt extrusion because this interaction affects various properties of the water–polymer mixtures, such as their viscoelastic properties. In this study, poly(vinylpyrrolidone) K30 (PVP) containing 0%, 10%, and 20% poly(ethylene glycol) 400 (PEG) was used as model amorphous polymers. The interaction of water with these polymers was assessed by the evaluation of the glass transition temperature (T_g), the point on the isotherm corresponding to the weight of sorbed water required to form a complete monolayer on the solid surface (apparent W_m), and the maximal amount of nonfreezing water, which were measured by differential scanning calorimetry and water sorption isotherms. In all of the systems with a water content below a certain water fraction (0.1 for PVP, 0.12 for PVP–PEG 10%, and 0.16 for PVP–PEG 20%), the T_g values were successfully predicted using theoretical equations, whereas the experimental T_g values were higher than predicted for those with a water content above these water fraction levels. In addition, these values of water fraction are similar to the apparent W_m values determined using the Guggenheim–Anderson–DeBoer (GAB) equation (0.110, 0.117, and 0.147 weight fraction of water for PVP, PVP–PEG 10%, and PVP–PEG 20%, respectively). Nonfreezing water is detected above 0.47, 0.49, and 0.51 weight fraction of water for PVP, PVP–PEG 10%, and PVP–PEG 20%, respectively. Miscibility between water and PVP or PVP–PEG seems to change according to the water content in the system. All parameters increase with the concentration of PEG in the sample. This may be explained by the fact that PEG has a larger number of polymer repeating units, which may therefore interact with water more than PVP.

Introduction

Recently, a hot-melt extrusion technique has been applied to produce a polymer-based solid dispersion of a drug as a drug delivery system.[1,2] Amorphous hydrophilic polymers are often used as a component of such solid dispersions for the modification of drug dissolution. During the hot-melt extrusion process, the drug is incorporated into a rubbery state of amorphous polymer mass.[2] Therefore, the glass transition temperature (T_g) of the amorphous polymer is one of the most important factors in the hot-melt extrusion process because the viscoelastic properties of the polymer, namely whether the polymer is rubbery or glassy at the manufacturing temperature, are affected by the T_g value.[3] The T_g value of the polymer can be reduced to an appropriate temperature for the manufacturing process by adding a plasticizer such as poly(ethylene glycol) to the polymer. Moreover, it has been demonstrated that the water in the polymer acts as a plasticizer to lower the T_g value of the polymer–water systems by increasing the molecular mobility and free volume.[4–6] Amorphous polymer and plasticized polymer generally contain some amount of water, and water is sometimes added during the hot-melt extrusion process. As the water content affects the T_g value of the system, it is necessary to determine the interaction between water and polymers, in particular the effect of water content on the T_g value of the systems as basic information for the hot-melt extrusion process. However, although there have been some reports describing the relationship between the water content and the T_g value of polymer–water binary systems,[7,8] there have been few reports on plasticized polymer–water ternary systems.[6]

In this study, three components, poly(vinylpyrrolidone) K30 (PVP) as a model amorphous polymer, poly(ethylene glycol) 400 (PEG) as a model plasticizer, and water, were chosen and the interaction of water with PVP containing 0%, 10% and 20% PEG was studied. The experimental T_g values of the systems containing various amounts of water were determined using differential scanning calorimetry (DSC) and were compared with those predicted by theoretical equations. The apparent W_m (the point on the isotherm corresponding to the weight of adsorbed water required to form a complete monolayer on the solid surface) was estimated by analyzing the water sorption isotherm of PVP and PVP–PEG. Furthermore, a maximal amount of nonfreezing water was calculated by DSC studies on aqueous PVP and PVP–PEG solutions.

Experimental Section

Materials—Poly(vinylpyrrolidone) K30 (viscosity average of molecular weight, 42 500), PVP (BASF) and poly(ethylene glycol) 400 (nominal molecular weight, 400), PEG (Colorcon) were used without further treatment. Aqueous solutions of PVP–PEG 0–40% were spray dried using a Mini Büchi 190 spray dryer (Büchi) to obtain homogeneous samples. The spray-dried samples were vacuum-dried at 70 °C for 48 h in an oven. After vacuum-drying, the samples were stored in closed glass bottles. The PEG concentrations are expressed as a percentage (w/w PVP). All other reagents employed were of analytical reagent grade.

Water Sorption Isotherm—Approximately 400 mg of spray dried PVP, PVP–PEG 10%, and PVP–PEG 20% mixtures were accurately weighed into glass bottles and stored at 20 °C in desiccators containing saturated inorganic salt solutions giving various equilibrium relative humidities (RH) (7–75% RH) until a constant weight was obtained (at least 5 weeks). The salts used (with their corresponding relative humidities at 20 °C) were lithium bromide (7% RH), lithium chloride (11% RH), potassium acetate (23% RH), magnesium chloride (33% RH), potassium carbonate (43% RH), magnesium nitrate (54% RH), sodium bromide (59% RH), and sodium chloride (75% RH). The water content of the samples was calculated using the initial water content and the change in weight induced by storing the samples under each relative humidity condition. The initial water content of the samples was determined by drying at 120 °C for 5 h.

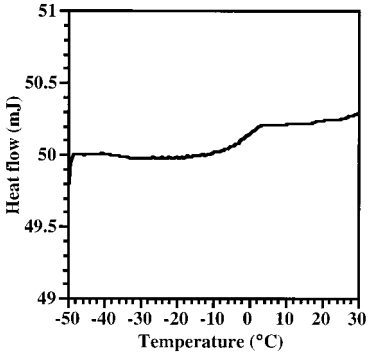

Figure 1—Typical DSC curve of a PVP–water system (glass transition).

Determination of T_g by DSC—Differential scanning calorimetry (DSC) measurements were performed using a Perkin-Elmer DSC 7 with a refrigerating system (Perkin-Elmer, Beaconsfield, UK). Samples (3−8 mg) stored under various RH were carefully transferred into aluminum pans in the desiccator, and the pans were hermetically sealed to prevent water loss during the DSC experiments. The samples were placed into the DSC under a nitrogen atmosphere and heated to 10−25 K above their T_g. The samples were subsequently cooled at 20 K/min to 273 or 223 K and then reheated. The first heating run exhibited an enthalpy relaxation endotherm at around the T_g value. Therefore, the T_g value of the samples was determined from the second heating cycle. Figure 1 illustrates a typical DSC curve of the second run for a sample of the PVP−water system (PVP stored under 75% RH). The T_g value was calculated by the half-extrapolated capacity method.[9] No endothermic peak relating to the melting of PEG was found even in the DSC curves of the PVP−PEG 10% and PVP−PEG 20% mixtures.

For determination of the T_g value of samples containing no water, samples (4−7 mg) were stored over P_2O_5 in a sealed desiccator for more than 5 weeks and DSC studies were carried out in open aluminum pans. The samples were repeatedly heated to 10−25 K above their T_g and subsequently cooled to 273 K at 20 K/min under a dry nitrogen purge. As the samples exhibited negligible differences between the T_g value determined from the second heating cycle and that from the third heating cycle, the T_g value determined from the second heating cycle was considered as the T_g value of the sample containing no water. All experiments were performed at least twice.

Determination of Freezing Water by DSC—To determine the amount of freezing water in the systems, a Perkin-Elmer DSC 7 with a cooling accessory (Perkin-Elmer, Beaconsfield, UK) was also used. Samples (5−15 mg) of various concentrations of aqueous PVP solution containing 0%, 10%, and 20% PEG were transferred into hermetically sealed aluminum pans to prevent water loss during the experiments. Samples were placed into the DSC and cooled to 223 K to promote freezing of any unbound water. Then, they were heated at 10 K/min to 303 K under a nitrogen atmosphere. Figure 2 depicts some typical melting endotherms of PVP−water systems. In the DSC curves, a small baseline change (occasionally small peak) is found at around 243 K (−30 °C). It seems that the baseline changes are caused by heterogeneity in the system, and the changes may be attributed to the glass transition or recrystallization. However, as the changes are considerably small and are not sometimes reproducible, it is difficult to determine what causes them only from the conventional DSC studies. Therefore, in this study, only the enthalpy of fusion of ice corresponding to the amount of freezing water was determined. Determination by other methods such as a modulated temperature DSC is necessary to elucidate what causes the baseline changes. The experiments were performed at least three times.

Equation To Predict the Value of the T_g^{mix} of the Systems—An equation for the prediction of the value of the T_g of a ternary system was employed. This equation is an extension of the Gordon−Taylor equation,[8,10] the equation for the prediction of the T_g value of a binary system. By assuming perfect volume additivity at the T_g and no specific interaction among the three systems, we can write

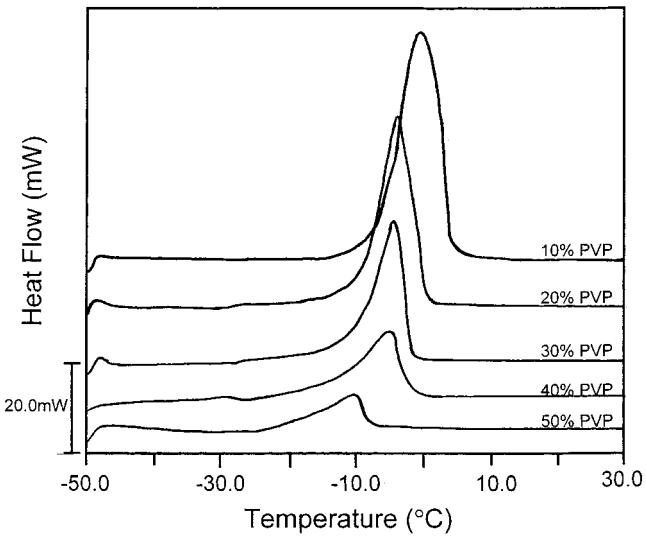

Figure 2—Typical DSC curves of PVP–water systems (melting peak).

$$T_g^{mix} = \Phi_1 T_{g1} + \Phi_2 T_{g2} + \Phi_3 T_{g3} \quad (1)$$

where F is the volume fraction of each component. As $\Phi = [(\Delta\alpha w)/\rho]$, where $\Delta\alpha$ is the change in thermal expansivity of T_g and $\Delta\alpha T_g \approx$ constant,[11] it is possible to rewrite the equation as

$$T_g^{mix} = \frac{w_1 T_{g1} + K_2 w_2 T_{g2} + K_3 w_3 T_{g3}}{w_1 + K_2 w_2 + K_3 w_3} \quad (2)$$

where w_1, w_2, and w_3 are the weight fractions, and T_{g1}, T_{g2}, T_{g3}, and T_g^{mix} are the glass transition temperatures in Kelvin of components 1, 2, 3, and the mixture.[12] The constants K_2 and K_3 can be approximated as $K_2 = (\rho_1 T_{g1})/(\rho_2 T_{g2})$ and $K_3 = (\rho_1 T_{g1})/(\rho_3 T_{g3})$, where ρ is the density of the materials. This equation is the Gordon−Taylor equation when we consider $w_3 = 0$. The constants K_2 and K_3 were calculated from the value of the T_g of 135,[13] 450, and 198 K[13] (−138, 177, and −75 °C, respectively) for water, PVP, and PEG and the densities of 1.00, 1.25, and 1.12 g/cm^3, respectively. The densities were measured using an air pycnometer (Air comparison pycnometer model 930, Beckman).

A similar equation, eq 3, can be readily derived for mixtures containing i components

$$T_g^{mix} = \frac{\sum K_i w_i T_{gi}}{\sum K_i w_i} \quad (3)$$

where $K_i = (\rho_1 T_{g1})/(\rho_i T_{gi})$.

X-ray Powder Diffraction—X-ray powder diffraction patterns were monitored by a diffractometer with Cu Kα radiation and a nickel filter at 40 kV and 40 mA (RINT 2200V, RIGAKU). The samples of spray-dried PVP, PVP−PEG 10%, and PVP−PEG 20% stored over P_2O_5 in a sealed desiccator were transferred into a sample holder and scanned at 4°/min over a range of 2°−40°. All samples exhibited halo X-ray powder diffraction patterns and were considered to be amorphous.

Multiple Regression Analysis—A nonlinear multiple regression program, MULTI, developed by Yamaoka et al.,[14] was used to carry out multiple regression analysis. The correlation coefficient (r) was calculated using the following equation

$$r = \left(1 - \frac{\mathrm{ESS}}{\mathrm{EMS}}\right)^{1/2} \quad (4)$$

where ESS is the sums of squares of the deviation of the theoretical values from the experimental values and EMS is the sum of squares of the deviation of the experimental values from their mean.

Statistical Analysis—The calculated maximal amount of nonfreezing water in PVP and PVP−PEG mixtures was statistically

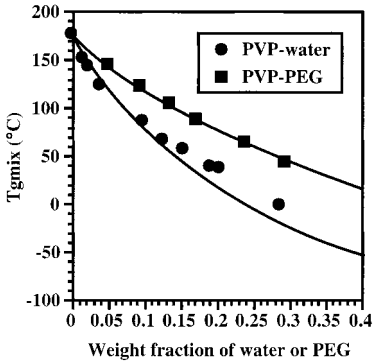

Figure 3—Effect of the weight fraction of water or PEG on the T_g^{mix} of PVP–water or PVP–PEG systems. The symbols represent experimental data points and the solid line represents the fit to the Gordon–Taylor equation (eq 2 in the text).

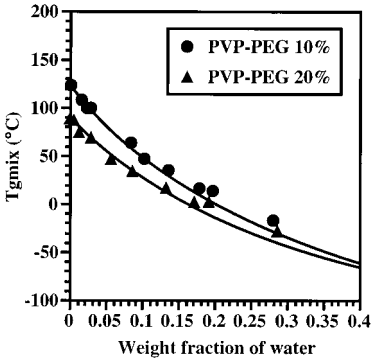

Figure 4—Effect of the weight fraction of water on the T_g^{mix} in PVP–PEG–water systems. The symbols represent experimental data points and the solid line represents the fit to the extended Gordon–Taylor equation (eq 2 in the text).

compared among each other using the Student's *t* test. Differences with $p < 0.05$ were considered significant.

Results and Discussion

Glass Transition Temperature of PVP−PEG and PVP−Water Binary Systems—Figure 3 shows the T_g value of PVP−water and PVP−PEG binary systems as a function of the weight fraction of water or PEG. The solid lines on the plots represent T_g values predicted by the Gordon−Taylor equation (eq 2). The T_g value decreases significantly with increasing weight fraction of water or PEG, showing that water as well as PEG acts as a good plasticizer. In the case of the PVP− PEG systems, the experimental T_g data fitted the predicted values well over the entire range studied. Therefore, it is considered that PVP and PEG mix ideally over the entire range studied (0−0.29 weight fraction of PEG). In the case of the PVP−water system, above a water fraction of around 0.1, the experimental T_g values for the PVP−water system were higher than predicted, whereas below this water fraction there was no difference between the experimental and theoretical T_g values. The results obtained for the PVP−water system are in excellent agreement with previous findings.[8] It is considered that PVP and water are miscible ideally up to a water fraction of around 0.1, but they mix nonideally above this water fraction. In other words, it seems that the Gordon−Taylor equation is not suitable to predict the T_g values of the PVP−water system above a water fraction of around 0.1. There could be other factors affecting the systems, which are not taken into consideration in the Gordon−Taylor equation.

Glass Transition Temperature of PVP−PEG−Water Ternary Systems—Two amorphous PVP−PEG systems containing 10% and 20% PEG (0.09 and 0.17 weight fraction of PEG in the PVP−PEG systems, respectively) were chosen to determine the effect of water on the T_g values in the PVP−PEG−water systems. At these PEG fractions, PVP and PEG mix ideally, as stated above. Figure 4 depicts the T_g value of these two ternary systems of PVP−PEG−water as a function of the weight fraction of water. The solid lines on the plots represent values of T_g^{mix} predicted by the extended Gordon−Taylor equation (eq 2). As can be seen, the T_g data fitted the predicted T_g values well up to a water fraction of around 0.12 for the PVP−PEG 10%−water system and up to a water fraction of around 0.16 for the PVP−PEG 20%−water system. Therefore, it is suggested that these three components are miscible ideally with each other at a low water content. However, above a certain water content, deviations between the experimental and theoretical T_g values of the PVP−PEG−water system were observed, as in the PVP−water system. It should be noted that the water fraction at which the deviations begin increases with the concentration of PEG (0%, 10%, 20%) in the sample.

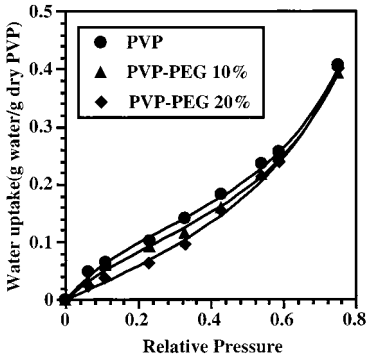

Figure 5—Water vapor absorption isotherms for PVP and PVP–PEG at 20 °C. The symbols represent experimental data points and the solid lines on the plot represent curve-fitted values using the GAB equation (eq 5 in the text).

Water Vapor Sorption Isotherms for PVP and PVP−PEG Mixtures—It is suggested that the miscibility between water and PVP or PVP−PEG systems changes at a certain water content based on the T_g studies. The interaction of water with other components has also been estimated by studies of water vapor sorption isotherms. W_m, the weight of adsorbed water required to form a complete monolayer on the solid surface, is one of the critical factors needed to characterize quantitatively the water sorption isotherms. W_m is calculated by fitting the sorption isotherm to the Brunauer−Emmett−Teller (BET) equation[15] or the Guggenheim−Anderson−DeBoer (GAB) equation,[16−18] which is an extension of the BET equation. The BET and GAB equations are generally applied to physical adsorption. The mechanism of water sorption to an amorphous solid like PVP is different from that of physical adsorption. However, even in an amorphous solid, it has been suggested that there is evidence indicating that at the point on the isotherm corresponding to the water content of W_m (apparent W_m), certain effects of water on solids change significantly and the apparent W_m value can be an important parameter relating to the interaction of polymer with water.[19−21]

Figure 5 shows the water vapor sorption isotherms for PVP containing 0%, 10%, and 20% PEG at 20 °C. The water content at each RH decreases with increasing concentration of PEG in the samples and the water uptake is significantly inhibited by the addition of PEG at 20−50% RH. All the water sorption isotherms of PVP and PVP−PEG are sigmoidal in shape (type II[22]). Therefore, the GAB equation,

given by eq 5, (where k is the GAB constant, W is the mass of gas sorbed per mass of dry solid at a relative pressure of p/p_o, and C_B is a constant which reflects the overall free energy of sorption)

$$W = \frac{kW_m\frac{p}{p_o}C_B}{\left(1 - k\frac{p}{p_o}\right)\left(1 - k\frac{p}{p_o} + kC_B\frac{p}{p_o}\right)} \quad (5)$$

was fitted to the data and the apparent W_m values were obtained by multiple regression analysis, though mixtures such as the PVP–PEG system are different from the systems for which the GAB equation was originally intended. As shown in Figure 5, the calculated W values, which are represented as a solid line, fitted the experimental W values very well for PVP containing 0%, 10%, and 20% PEG systems with a correlation coefficient greater than 0.995. The values of apparent W_m calculated are 0.124, 0.133, and 0.173 g of water/g of solid (0.110, 0.117, and 0.147 weight fraction of water, respectively) for PVP containing 0%, 10%, and 20% PEG, respectively. The relative humidities at which the W value is equal to the calculated apparent W_m value, (the RH(W_m)) was 28%, 36%, and 48% RH for PVP containing 0%, 10%, and 20% PEG, respectively. The apparent W_m value increases with the concentration of PEG in the sample. This suggests that in the sample containing a higher concentration of PEG, the interaction with water changes significantly when a larger amount of water is sorbed (the apparent W_m).

As mentioned above, the deviation of the experimental T_g values from those predicted seems to begin at a higher weight fraction of water in the sample containing a higher content of PEG. Also, the apparent W_m values increase with increasing PEG concentration in the sample. It should be remembered that the experimental T_g values were measured using a nonisothermal method (DSC), whereas the W_m values were estimated from isothermal measurements (the sorption isotherms). However, both values, the apparent W_m values and the weight fraction at which the deviation of the experimental T_g values seems to begin, are similar, which suggests that water interacts ideally with the polymer up to the higher water content in the sample containing the higher amount of PEG.

The Maximal Amount of Nonfreezing Water in PVP and PVP–PEG Mixtures—When samples contain immiscible water, the system shows a melting peak of water at 0 °C or less during heating after prior cooling. This component of water in the system can be regarded as freezing water, which is classified into two types,[23,24] type I, free, freezing water melting at 0 °C; and type II, loosely bound, freezing water with a melting point below that of pure water. Nonfreezing water is classified as type III. The PVP and PVP–PEG samples stored under conditions of RH up to 75% showed no melting peak of water in the DSC experiments. Consequently, no detectable freezing water exists in these systems, though some of them have the appearance of a transparent gel. Thus, to determine the interaction of water with PVP and PVP–PEG over a wide range, the melting peak of water in various concentrations of aqueous PVP and PVP–PEG solutions was detected using DSC, and the maximal amount of nonfreezing water which can be contained in the PVP–water and PVP–PEG–water systems was calculated.

Two methods have been applied to obtain the maximal amount of nonfreezing water in a polymer–water system.[25] Sung[26] reported that when there is a linear relationship between the enthalpies of water (J/g of dry polymer) and the ratio of water to polymer, the extrapolation to zero enthalpy gives the maximal amount of nonfreezing water in the system. Ford and Mitchell[27] also reported that when a linear relationship exists between the enthalpies of water (J/g of sample) and the percentage of water in the system, the maximal amount of nonfreezing water in the system is calculated from the extrapolation to zero enthalpy. Figure 6a,b shows Sung's plot and Ford and Mitchell's plot for the PVP–water system. In both cases, there is a linear relationship between the enthalpies of water and the ratio of water to polymer or the percentage of water. From both Sung's plot and Ford and Mitchell's plot, the maximal amounts of nonfreezing water are calculated to be around 0.47 of the weight fraction of water, corresponding to around 5.4 mol of water per polymer repeating unit (PRU) of PVP. Although the experimental T_g values could not be measured due to the limitations of the cooling system (minimum temperature 223 K), it is expected that more than one T_g value would be detected in the sample containing freezing water due to its heterogeneity.[12,28]

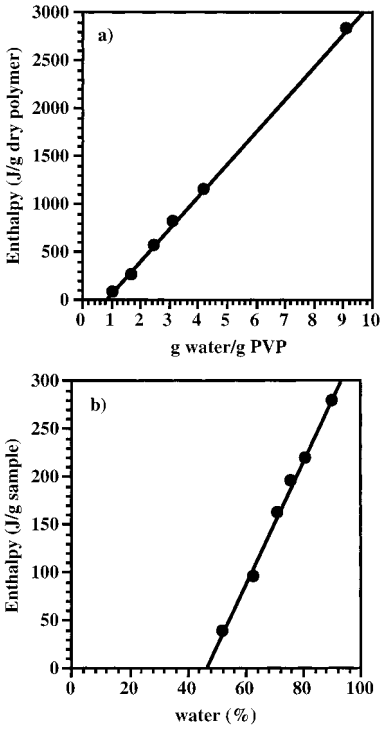

Figure 6—Relationship between (a) enthalpies of fusion and water/PVP ratio for PVP solutions (Sung's plot) and (b) enthalpies of fusion and water percentage for PVP solutions (Ford and Mitchell's plot).

In the case of the ternary systems, Sung's method does not seem to be suitable for obtaining the maximal amount of nonfreezing water, because it is impossible to calculate the enthalpies of water based on J/g of dry polymer. Therefore, only the Ford and Mitchell method was applied to obtain the maximal amount of nonfreezing water. As shown in Figure 7, there is a linear relationship between the enthalpies of water (J/g of sample) and the percentage of water in both PVP–PEG 10% and 20% systems. The maximal amount of nonfreezing water is calculated to be 0.49 and 0.51 for PVP–PEG 10% and 20% systems. These results indicate that freezing water is detected above 0.47, 0.49, and 0.51 weight fraction of water for PVP containing 0%, 10%, and 20% PEG, respectively. These values were analyzed to be significantly different. It is suggested that as PEG interacts with larger amounts of water compared to PVP, larger amounts of water can exist as nonfreezing water by adding PEG to PVP.

The Miscibility between Water and PVP or PVP–PEG Systems—From the results obtained above, the

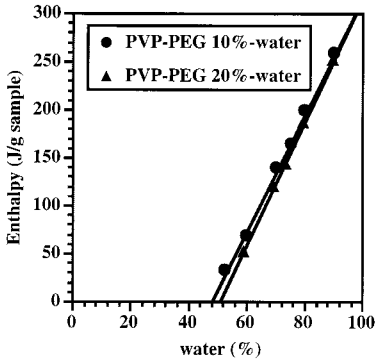

Figure 7—Relationship between enthalpies of fusion and water percentage for PVP–PEG solutions (Ford and Mitchell's plot).

miscibility between water and PVP can be expressed with certain assumptions as follows: up to the apparent W_m value (around 0.1 weight fraction of water), PVP and water mix ideally and the experimental T_g values of the PVP−water system can be estimated using the Gordon−Taylor equation. It has been reported that the interaction between the hydrophilic polymer and water may change according to the water content.[6] For example, in the case of amylose−water systems, it was assumed that the polymer−water system formed by hydrogen bonds is more compact than the polymer−polymer system with less than 10% water content and that a looser network is formed due to the occurrence of water−water interactions at a higher water content. As the miscibility of PVP and water also relates to the hydrogen bonds between them, it is speculated that the interaction between PVP and water changes at the weight fraction of around 0.1. This water fraction corresponds to the ratio of two water molecules (M_w = 18) to three PRU of PVP (PRU of PVP = 111).

On the other hand, above a 0.47 water weight fraction of water, corresponding to around 5.4 mol of water per PRU of PVP, freezing water is detected in the PVP−water system. It is expected that more than one T_g value may be detected due to the heterogeneity in the system. At a weight fraction of water of 0.1−0.47, though water still exists as nonfreezing water in the system, the miscibility of water and PVP must have decreased as the experimental T_g value did not decrease as much as predicted. In the case of maize starch and hydroxypropylmethyl cellulose, it has been reported that three states of sorbed water, internally absorbed water, monolayer-adsorbed water, and externally adsorbed water, could be estimated by analyzing the water sorption and desorption patterns using the Young−Nelson equations.[25,29] The interaction between water and solid is considered to be significantly influenced by these states of water. In the case of the PVP−water system, as the hypotheses based on the Young−Nelson equations are inadequate, the three states of water cannot be calculated using the Young−Nelson equations.

In the PVP−PEG−water systems, though the interaction among the three components are more complicated, it is speculated that the miscibility between water and the PVP−PEG system can be expressed, as in the case of PVP, except that both the apparent W_m values (or water fraction at which the deviations of the T_g values begin) and the maximal amount of nonfreezing water increase with increasing concentration of PEG in the sample. In the PVP−PEG−water systems, it may fairly be presumed that the three components interact with each other by hydrogen bonds. The PRU of PEG (CH_2OCH_2, PRU of PEG = 44) is smaller than the PRU of PVP (111) and PEG has more groups that may interact with water from the hydrogen bonds than PVP. Therefore, this may explain why PVP containing the higher concentration of PEG interacts with water up to the higher water fraction (the apparent W_m and the maximal amount of nonfreezing water).

Conclusion

The interaction between water and PVP containing 0%, 10%, and 20% PEG was studied using DSC and water sorption isotherms. The miscibility between water and PVP seems to change according to the water content in the system. Up to the apparent W_m value (around 0.1 weight fraction of water), PVP and water mix ideally and the experimental T_g values of the PVP−water system can be estimated using the Gordon−Taylor equation. From a 0.1 weight fraction of water to 0.47, which is calculated as the maximal amount of nonfreezing water, although water still exists as nonfreezing water in the system, the miscibility of water and PVP must have decreased as the experimental T_g value did not decrease as much as predicted. On the other hand, at a water weight fraction above 0.47, freezing water was present in the system and it is expected that there may be more than one T_g value due to the heterogeneity in the system. All parameters, the water fraction at which the deviation of the T_g values begins, the apparent W_m value, and the maximal amount of nonfreezing water, increase with the concentration of PEG in the sample. This may be explained by the fact that PEG has more polymer repeating units, which may interact with water more than PVP.

Disorder, Molecular Mobility, and Solid-State Kinetics: The Two-Environment Model

RAYMOND D. SKWIERCZYNSKI†

3M Pharmaceuticals 3M Center, Bldg 260-4A-04, St. Paul, Minnesota 55144-1000

Received July 28, 1998.
Accepted for publication June 9, 1999.

Solid-state reactions that yield sigmoid-shaped kinetic profiles have been described by either chemical models[1,2] that assume that the reaction occurs in a liquid layer on the surface of the solid, or by physical models[3,4] that are based on nucleation and growth or on diffusion. The objective of this communication is to introduce and apply the Two-Environment Model to describe the reaction kinetics of a crystalline solid, aspartame. The Two-Environment Model is based on the postulate that the chemical reaction can occur in two environments within the solid material and that the process in each environment is described with a simple zero-order rate constant. The second environment (E2), which is more disordered than the first environment (E1), is created by the formation of product. The Two-Environment Model, which is derived from first principles, builds on the basis of the nucleation-and-growth models by linking the chemistry of the reaction with the physical changes that occur in the solid matrix as the reaction proceeds.

In the solid-state, aspartame (A) undergoes a thermally induced cyclization to form two products, a diketopiperazine and methanol. Postulate that this reaction proceeds by parallel processes that occur in two different environments within the material. The first process is described by the following zero-order reaction, where Z represents the products.

$$A \xrightarrow{k^{(1)}} Z$$

The second process, also zero-order in A, is promoted by a physical change in the solid material that is directly proportional to the extent of the reaction at time t, $\alpha(t)$:

$$A \xrightarrow{\alpha(t)k^{(2)}} Z$$

The rate equation for the disappearance of A is

$$-\frac{dx_A}{dt} = k^{(1)} + \alpha(t)k^{(2)} \quad (1)$$

where x_A is the mole fraction of A remaining at time t, and $k^{(1)}$ and $k^{(2)}$ are the zero-order rate constants for the processes that occur in environments 1 and 2, respectively. The units on $k^{(1)}$ and $k^{(2)}$ are mole fraction/time, or simply time^{-1}. The process in E1 is predominant at the beginning of the reaction because $\alpha(t)$ is zero or small. The process in E2 becomes more important as the reaction proceeds, that is, as $\alpha(t)$ approaches unity.

The variables $\alpha(t)$ and x_A are related by eq 2.Dif-

$$x_A = 1 - \alpha(t) \quad (2)$$

ferentiating eq 2 with respect to time yields

$$\frac{dx_A}{dt} = -\frac{d\alpha(t)}{dt} \quad (3)$$

Substituting eq 3 into eq 1 gives

$$\frac{d\alpha(t)}{dt} = k^{(1)} + \alpha(t)k^{(2)} \quad (4)$$

The general solution of eq 4 is

$$\alpha(t) = \frac{k^{(1)}}{k^{(2)}}[e^{k^{(2)}t} - 1] + \alpha_o e^{k^{(2)}t} \quad (5)$$

where α_o is the extent of the reaction at $t = 0$. In practice, however, A usually does not decompose while the sample is equilibrated to the reaction temperature. For this special case in which $\alpha_o = 0$, eq 5 simplifies to eq 6.

$$\alpha(t) = \frac{k^{(1)}}{k^{(2)}}[e^{k^{(2)}t} - 1] \quad (6)$$

The rate constants are obtained by fitting the kinetic data to the integrated rate equations.

Aspartame[5,6] was chosen as the test system because its decomposition reaction is a simple unimolecular thermally induced aminolysis (Scheme 1). This reaction proceeds under anhydrous conditions. Thus water is not a reactant, does not form a liquid layer on the surface of the solid, and cannot plasticize the material. The aminolysis is quantitative, not autocatalytic, and yields equimolar ratios of diketopiperazine solid and gaseous methanol.[5]

The reaction was monitored by measuring the mass of the material under isothermal conditions by TGA (Model 2950, TA Instruments, New Castle, DE). About 14−30 mg of aspartame hemihydrate Form II (Sigma Chemical, St. Louis, MO) was placed into a (10-mm diameter × 1-mm depth) platinum TGA pan, dehydrated to produce anhydrous aspartame in situ by heating to 135 °C for 1 min,[7−9] and equilibrated at the reaction temperature. Five reaction temperatures were examined: 130.00, 140.00, 150.00, 160.00, and 170.00 °C. Isothermal conditions (±0.05 °C) were maintained until the reaction was completed. α_o was determined experimentally.

Representative kinetic curves are shown in Figures 1 and 2. The solid lines were obtained by fitting the data to eq 5 or 6 using nonlinear regression techniques**.** The fitted curves are in excellent agreement with the data. The results are reproducible and summarized in Table 1.

Note that $k^{(2)}$ is greater than $k^{(1)}$ for each temperature examined. If the chemistry were the rate-determining step, $k^{(1)}$ would equal $k^{(2)}$ because the same chemical reaction occurs in both environments. If one were to examine the reaction at the molecular level, three important steps must happen for aminolysis to occur: (1) The molecule must have mobility for the primary amine at the *N*-terminus to make contact with the carbonyl carbon at the *C*-terminus; (2) the reacting moieties must collide in the correct orientation; and (3) the moieties must have enough energy for the chemistry to occur. In this light, aminolysis of aspartame in the solid state is similar to aminolysis in solution. The difference, however, is that in solution the rate-determining

step is controlled by *chemistry*. The rate-determining step in the solid state is controlled by *physics*: the easier it is for reactants to collide, the faster the reaction will proceed.

This conclusion is consistent with Transition-State Theory.[10,11] The activation parameters listed in Table 2 were determined from an Eyring plot[11] (Figure 3). Even though the enthalpy of activation for the process in E2 is

Table 2—Activation Parameters for the Rate Processes that Occur in Each Environment

environment	$\Delta H^{\ddagger}$, kJ mol^{-1}	$\Delta S^{\ddagger}$, J K^{-1} mol^{-1}	$\Delta G^{\ddagger}$, kJ mol^{-1}
1	174	19	166[a]
2	205	119	155

[a] $\Delta G^{\ddagger}$ was calculated at 150 °C.

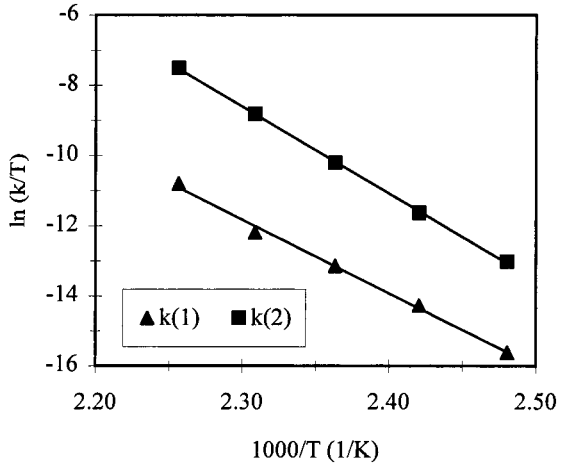

Figure 3—Eyring plot of the kinetic data.

31 kJ mol^{-1} *greater* than $\Delta H^{\ddagger}$ for the E1 process, the rate of aminolysis in E2 is faster than that in E1. This faster reaction rate can be explained by the lower Gibbs free energy of activation in E2. The rate-detemining-step for the process in E2 is entropically favored. In essence, the increased disorder in E2 serves as a "physical catalyst" for the solid-state aminolysis reaction by facilitating the mobility of the aspartame molecules.

Leung and Grant[12] also examined the solid-state demethylation of aspartame hemihydrate (form II) under isothermal conditions between 166 and 181 °C. Their data, in the range $0.1 < \alpha(t) < 0.9$, were fitted to the Prout–Tompkins equation, which models nucleation-and-growth kinetics. They reported an activation energy of 268 kJ mol^{-1}, which corresponds to a $\Delta H^{\ddagger}$ of 272 kJ mol^{-1}. In the Two-Environment Model, the process in E2 is dominant when $\alpha(t) > 0.1$. Here, as in Prout–Tompkins kinetics, new nuclei are generated by the strain that is introduced in the crystal lattice as the reaction proceeds. The large discrepancy between $\Delta H^{\ddagger}$ for E2 (205 kJ mol^{-1}) and the $\Delta H^{\ddagger}$ obtained by Leung and Grant clearly illustrates that solid-state kinetics is complex and that activation parameters are model dependent.

One advantage that the Two-Environment Model has over existing nucleation-and-growth models is that the Two-Environment Model can be used to estimate shelf-life (t_{90}) from kinetic data gathered at elevated temperatures. This advantage exists because the Two-Environment Model uses data in the region where $\alpha(t) < 0.1$, the portion of the kinetic curve that is most relevant to the pharmaceutical scientist. For example, the shelf life of aspartame at 120 °C can be estimated by first determining $k^{(1)}$ and $k^{(2)}$ from extrapolation of the fitted lines in the Eyring plot: $k^{(1)} = 1.76 \times 10^{-5}$ min^{-1} and $k^{(2)} = 1.75 \times 10^{-4}$ min^{-1}. Substituting these $k^{(1)}$ and $k^{(2)}$ values into eq 6, letting $\alpha(t) = 0.1$, and solving for t, gives an estimated t_{90} of 3900 min. The experimentally determined t_{90} was 3400 min.

In conclusion, the Two-Environment Model marries the chemistry of a solid-state reaction with the molecular mobility of the reactant. The model is consistent with transition-state theory and suggests that disorder that is induced in the solid material as the reaction proceeds acts

as a physical catalyst. The Two-Environment Model describes the solid-state aminolysis of aspartame.[13,14] The model can also serve as a practical tool for shelf life estimation.

Analytical Ultracentrifugation in the Pharmaceutical Industry

J. LIU AND S. J. SHIRE*

Contribution from *Department of Pharmaceutical Research and Development, Genentech, Inc., South San Francisco, California 94080*

Received May 7, 1999. Final revised manuscript received October 4, 1999.
Accepted for publication October 5, 1999.

Introduction

Hydrodynamic and thermodynamic techniques have been used extensively to characterize and determine the size, shape, molecular weight, and interaction of macromolecules. One of the most widely used techniques is that of analytical ultracentrifugation whereby the concentration gradients of sedimenting molecules are measured during the application of a centrifugal force. The design of instrumentation to accomplish this was a significant challenge and through the classic work of Thé Svedberg[1,2] resulted in a centrifuge that laid the foundations for modern protein chemistry and molecular biology. In particular, the early experiments on hemoglobin demonstrated conclusively that proteins were actually homogeneous macromolecular entities.[3] Since those classic experiments, great strides have been made in instrumentation as well as in analysis of sedimentation data. The purpose of this review is not to recount the huge amount of work in sedimentation in biochemistry but rather to review and discuss how analytical centrifugation has been used in the pharmaceutical industry. For those interested in a historical perspective as well as some of the latest advances in the field, several excellent recent books are available.[4−6]

Instrumentation

An analytical ultracentrifuge is a centrifuge that maintains good temperature and rotational speed control and is equipped with optical systems that allow for the determination of concentration gradients during the sedimentation experiment. The original analytical ultracentrifuge designed by Svedberg was driven by an oil turbine,[1] and despite the improvements made in the design, Svedberg wished to design a centrifuge that could attain higher rotor speeds in order to obtain greater separation of macromolecules in a high sedimentation field. Considerable effort went into redesigning the centrifuge as well as designing new rotors that could be accelerated up to 400000*g*.[7] By the mid-1930s oil turbine centrifuges were used routinely in Svedberg's and a few other laboratories. The proliferation of this technology occurred when the electrically driven ultracentrifuge was developed by Pickels and colleagues, leading to the availability of a commercial instrument, the Spinco model E in 1947, which proved to be the workhorse for analytical centrifugation technology. This centrifuge was equipped with UV absorption, Rayleigh interference, and Schlieren optical detection systems. Although the basic design of the commercial instrument did not change over the next 40 years, a few major improvements were made. Notably the old gear-driven mechanical speed control was replaced with a superior electronic control unit.

The Schlieren and interference optical systems used photographic film or glass plates for acquisition of data. This necessitated the upkeep of good darkroom facilities, as well as the use of expensive optical comparators for magnification and analysis of the images. The UV optical system also used photographic technology and subsequent densitometric scanning to convert the images into concentration gradients. Arguably, one of the key improvements was the replacement of the UV absorption system with a split beam photoelectric UV absorption optical scanning detector. The invention of the UV photoelectric scanning system[8] eliminated the need for development and processing of film and made the investigation of UV-absorbing macromolecules a less time-consuming endeavor. Moreover, the development of the photoelectric scanner enabled many researchers to acquire the data via A/D converters for input

10.1021/js9901458 CCC: $18.00
Published on Web 11/09/1999

into the newly emerging desktop computer, further decreasing the time for analysis. Additional improvements of the model E were also made by various laboratories in developing real-time Rayleigh interference optical systems that used video camera technology to acquire the data for input into computers. However, the majority of the biochemistry labs using the commercial instrument did not have the benefits of these additional improvements.

The difficulty in acquisition and analysis of centrifuge data from the model E may have resulted in a decrease in the use of analytical ultracentrifugation as more rapid, but less quantitative, techniques were developed and refined. In particular, a major use of the analytical ultracentrifuge was the determination of macromolecular mass. Techniques such as SDS polyacrylamide gel electrophoresis and gel sieving chromatography enabled researchers to obtain rough estimates of molecular weight more rapidly than with the model E.

The field of protein biotechnology that evolved, allowing researchers to express proteins in bacterial and mammalian cell culture systems, focused on many qualitative issues, such as expression and activity levels. As recombinant DNA technology evolved and became more commercialized, techniques were developed to express and purify large quantities of human proteins from mammalian cell lines. As more of the expressed proteins have entered the stage for development into human pharmaceuticals, there has been a greater need to use more sophisticated and rigorous physicochemical techniques to determine the best conditions for purification and ultimately formulation of the protein drug. In addition, the development of "rational drug design" required the use of more quantitative techniques to understand in detail the interactions of macromolecules with their biological targets. As will be discussed later, analytical ultracentrifugation remains one of the best techniques for investigation of molecular interactions. Thus, there was a need for a modern commercial ultracentrifuge that was "user" friendly and relatively maintenance free.

A new analytical ultracentrifuge, the XLA/I, has been designed that includes complete computer interface, and novel precision absorption scanning and integrated Rayleigh interference optical systems. The instrument is equipped with a highly precise and stable temperature control system and has a maximum speed of 60 000 rpm. The absorption optics uses a highly stable, UV-enhanced xenon flashlamp as the light source and a toroidal diffraction grating monochromator to provide the wavelength range from 190 to 800 nm.[9] The Rayleigh optical system uses a 30 mW, 675 nm laser as the light source.[10] It is extremely useful for analyzing the sedimentation of nonabsorbing macromolecules in solution.

Theory

The purpose of this section is to acquaint the reader with the essential and general facets of analytical ultracentrifugation theory. There are several excellent references that should be consulted for a greater in-depth treatment of the theoretical background of this field.[11–16]

The optical systems of an analytical ultracentrifuge can be used independently or in conjunction with each other to provide complementary information about the hydrodynamic and thermodynamic properties of macromolecules in solution. The analytical ultracentrifuge can be operated in two basic modes: sedimentation velocity and sedimentation equilibrium, and the type of information that can be obtained is dependent on which of the two basic modes is used.

Sedimentation Velocity—Sedimentation velocity is often conducted at relatively high rotor speeds for, at most, a few hours. The larger sedimenting species under a strong centrifugal field forms a unique sedimenting boundary in solution. The velocity and shape of the moving boundary can be used to estimate the sedimentation coefficient (s), diffusion coefficient (D) of macromolecular species, and in some case the stoichiometries and equilibrium constants of interacting systems.[17]

During a sedimentation velocity experiment, macromolecules are separated on the basis of not only the size but also the shape. The sedimentation rate of macromolecular species is directly related to the molecular mass M and translational diffusion coefficient D by the Svedberg equation,

$$s = \frac{v}{\omega^2 r} = \frac{M(1 - \bar{v}\rho)}{Rf} = \frac{M(1 - \bar{v}\rho)D}{RT} \qquad (1)$$

where v is the rate of sedimentation, ω the angular velocity, r the radial distance from the center of rotation, M the molecular weight, $\bar{v}$ the partial specific volume of solute, ρ the density of solvent, f the frictional coefficient, R the gas constant, and D the diffusion coefficient. In theory, the sedimentation coefficient of each species can be determined by analyzing the rate of movement of a midpoint in the boundaries, or more rigorously the migration of the second moment of the boundary. However, such analysis only yields an average s value for a complicated system composed of multiple sedimenting species. The diffusional spreading of the boundaries can obscure the presence of other species. These problems can be addressed at least in part by several more sophisticated sedimentation velocity methods, including the Van Holde and Weischet method,[18,19] the time derivative method,[17,20] and the whole boundary curve fitting method.[21] The sedimentation coefficient and diffusion coefficient determined from these methods can be used to study more about the shape and size of the sedimenting species.[22,23]

Sedimentation Equilibrium—Sedimentation equilibrium is performed at lower rotor speeds. Under these conditions the rate of sedimentation under the centrifugal field is opposed by the rate of diffusion, and eventually when they reach the equilibrium, a time invariant exponential concentration gradient of solute is established throughout the centrifuge cell. The concentration distribution at equilibrium can be rigorously described with thermodynamic theory and has been widely used to determine the molecular weight, stoichiometry, binding affinity, and virial coefficient. For an ideal, non-interacting multiple-component system, the concentration distribution at equilibrium can be described as

$$C(r) = \delta + \sum_{i=1}^{n} c_i(r_0) e^{M_i(1-\bar{v}\rho)\omega^2(r^2 - r_0^2)/(2RT)} \qquad (2)$$

where $C(r)$ is the concentration at radial position, r, $c_i(r_0)$ the concentration of the ith species at an arbitrary radial reference position, r_0, δ the baseline offset, M_i the molecular weight of ith species, T the temperature in kelvin, ω the angular velocity, $\bar{v}$ the partial specific volume of solute, ρ the density of solvent, and R the gas constant. For a system containing only a single sedimenting ideal species, the molecular weight measurement can be made by simply fitting the data of concentration as a function of radius position. For more complicated systems, in principle eq 2 can be further modified to allow the sedimentation equilibrium data to be fit to models that incorporate self-association or heteroassociation systems as well as correc-

tions for thermodynamic nonideality by including virial coefficients as fitting parameters.[24]

Applications

Structure-Based Drug Research and Design—Often the interactions and biological activities of proteins are regulated and impacted by their quaternary structure. Analytical ultracentrifugation has proven to be one of the most important and widely used methods for the characterization of self-association and heteroassociation of macromolecules in solution. Investigation of these interactions enables researchers to design molecules that can modulate these important functional interactions.

Examples of this approach have been discussed by Holzman and Snyder.[25] In one of the examples discussed, sedimentation equilibrium analysis was used to characterize the interaction of the ligand CTP with an enzyme, CKS (CTP:CMP-3-deoxy-D-mannooctulosonate cytidylyl transferase), responsible for growth in Gram-negative bacteria. This enzyme activates an eight-carbon sugar, KDO, for incorporation into the outer bacterial cell-wall lipopolysaccharide. These studies conclusively demonstrated that CTP modulates enzyme oligomerization and that an analogue of KDO that inhibits the enzyme activity modulates the oligomerization in a similar fashion as does CTP. In particular, the analytical ultracentrifuge studies strongly suggested that the active enzyme is a homodimer. This was further supported by the determination of the X-ray crystal structure of CKS that shows that the enzyme crystallizes as an asymmetric unit comprising two monomers.[25]

Another recent example shows how both sedimentation velocity and equilibrium techniques can be used to investigate in detail the self-association of insulin analogues under formulation conditions.[26] The implications for the pharmacokinetic and dynamic responses of these insulin analogues were discussed, and it was suggested that sedimentation analysis can help in developing improved rapid-acting insulin therapies. In addition, as already pointed out by Varley et al.,[27] the analytical ultracentrifuge is one of the few techniques whereby analysis can be performed directly on the formulation and result in quantification of the protein interactions under those conditions.

Molecular biology has provided a clearer understanding of the structure and function of target molecules on cell surfaces that are often involved in regulating biological responses. This knowledge has allowed pharmaceutical scientists involved with the research and discovery of new pharmaceutical entities to undertake a rational drug design approach. By studying the detailed interactions of receptors or cell surface molecules with their target molecules, researchers can design pharmaceuticals that can modulate these interactions. An excellent example of the application of sedimentation equilibrium analysis to characterize protein ligand and receptor interactions is the recent work by Philo and his colleagues. The heteroassociation of erythropoietin (EPO) and the extracellular domain of the EPO receptor, sEPOR (soluble form of erythropoietin receptor), was analyzed by sedimentation equilibrium[28] at several rotor speeds. Global analysis of several data sets clearly demonstrated that two sEPOR can bind to a single EPO monomer with very different binding affinity. These data suggest that dimerization of receptors by erythropoietin may be important for signal transduction and activity. Thus, it may be possible to increase the potency of the molecule be engineering a second binding site with greater affinity. Other examples of the characterization of receptor protein ligand interactions are the studies on TNF-α and -β (tumor necrosis factor) with the soluble forms of their target receptors.[29,30] Those studies demonstrated that the TNF oligomer unit is capable of binding more than one receptor.

There have been reported a wide range of applications of the use of sedimentation equilibrium to characterize protein oligomerization including the dimerization of human growth hormone by zinc,[31] the trimeric structure of TNF-α,[32] self-association of biglycan,[33] dimerization of human relaxin,[34] and self-association of human interferon alpha.[35] However, for more complicated self-assembly systems, sedimentation velocity analysis has been found to be very useful due to its sensitivity to both size and shape. This approach has been extensively applied to characterize many complicated systems, including the assembly and disassembly of cpn60,[36] salt-dependence of folding of chromatin,[37] amyloid protein aggregation,[25] and assembly of viruses.[38–40] In addition, sedimentation velocity can be used to characterize complex size distributions because of the separation power of the technique coupled with recent advances in analysis of heterogeneity by determination of the differential sedimentation coefficient distribution function.[20] Recently, this method was used to characterize a number of immune complex distributions formed by several monoclonal antibodies.[41] Not only was the size of the complexes determined, but also the potential structure of the complex was investigated by hydrodynamic modeling. This detailed structural information about protein interactions has provided an important basis for the further effort to develop and improve this drug therapy.

Stability and Homogeneity—For biopharmaceutical products, it is important to know whether they are stable and homogeneous under certain process and storage conditions. The degradation products of biopharmaceuticals often include aggregates and fragments. One possible way to identify these degradation products is to determine their average molecular weights by using sedimentation equilibrium analysis.[27,42] For highly purified and homogeneous molecules, the average molecular weights for the pure and non-self-associated macromolecules under ideal conditions should be very similar to the monomer molecular weights. On the other hand, for macromolecules that have undergone aggregation or fragmentation, the apparent average molecular weights under ideal conditions will diverge from the monomer molecular weights.

The purity of biopharmaceuticals can also be determined by sedimentation velocity analysis. Several sedimentation velocity methods have been developed to determine the distribution of protein species. Among these methods, the van Holde and Weischet analysis[18,19] has been well documented to provide a rigorous test of sample homogeneity.[43] This method has been extensively utilized by several groups to study the homogeneity of macromolecules. These include the characterization of oligonucleosomes,[44] transcription factors, sigma 70,[45] and NusA and transcription termination factor rho.[46] A different extrapolation method based on the time derivative of concentration distribution has also been found very useful to identify impurities from macromolecules.[17,20] This method has been used in combination with other techniques, such as SDS polyacrylamide gel electrophoresis and gel sieving chromatography, to help us to determine the purity and homogeneity of macromolecules in solution.[47]

Activity of Biopharmaceuticals—The binding affinity of protein interaction is an important thermodynamic parameter that will affect the activity of many biological molecules. The sedimentation equilibrium experiment is one of the most rigorous thermodynamic methods to measure binding affinity.[43] This technique generates large quantities of high-quality data with broad concentration ranges from a single experiment. Therefore, it can greatly increase the confidence of model determination with non-

linear least-squares fitting. The sedimentation equilibrium method has been successfully and extensively used by a number of investigators to determine the association constants of an interacting system.[28,48,49]

For more complicated and high-affinity bivalent antibody and antigen interactions, the sedimentation equilibrium methods are often limited, due to the sensitivity of the current analytical ultracentrifuge detectors and complication of complex distribution. Conventional methods, such as ELISA and biosensor, have often been used to determine such interactions. Analysis by ELISA is highly dependent on having the appropriate antibody for detection that does not interfere with the binding reaction that is being studied. Apparent affinity constants are often determined by using an ELISA to measure the amount of free ligand in solution. This requires extensive control experiments to ensure that the dilutions and process used in the ELISA do not perturb the interaction equilibrium.[50] In addition the immobilization of complexes onto the plate surfaces may also perturb the association equilibrium. Biosensor measurements also require immobilization of one of the reactants, and the manner in which the macromolecule is immobilized may alter the thermodynamics of interaction because of complications from molecule orientation on the surface and interference with the polymer matrix used for immobilization. The latter may alter the kinetic measurements because of mass transport through the matrix support. These complications have been discussed along with criteria needed to assess the reliability of biosensor data.[51] An alternative approach based on the sedimentation velocity method has recently been suggested by us to study the interaction of human IgE with an anti-IgE antibody.[52] In this method, a soluble form of the IgE high-affinity receptor (sFcϵRI) is used as a binding competitor to probe the IgE and anti-IgE monoclonal antibody (rhuMAb E25) interaction. Since the sFcϵRI is much smaller in size than rhuMAbE25 ($\sim$42 vs 150 kDa) and binds at or near the same site on IgE as rhuMAb E25, it is possible to distinguish the complexes formed by IgE$-$sFcϵRI and IgE$-$rhuMAb E25 by using sedimentation velocity experiments. By studying the shift of the complex distribution, we are able to distinguish the binding activity of rhuMAb E25 from that of other similar monoclonal antibodies.

Molecular Crowding Effect on Protein Drug Interaction and Formulation—Physiological media, such as human serum or cytoplasm, are very crowded environments that contain many large macromolecules. The volume exclusion arising from these high concentrations of macromolecules can have a large qualitative effect upon the equilibria and kinetics of protein drug interaction.[53] Sedimentation equilibrium is an ideal method to study protein drug interaction in a crowded environment. Although the current design of analytical ultracentrifuge optical detection systems lacks the sensitivity and specificity to distinguish a specific protein from the crowded background molecules, an alternative method that combines the sensitivity and specificity of radioisotope labeling and ELISA with preparative centrifugation techniques has been suggested.[54,55] This technology can increase the concentration range of traditional sedimentation equilibrium experiments. It has been used successfully to characterize a number of macromolecules, including ovalbumin, albumin, and γ globulin.[55,56]

The excluded volume effect resulting from small inert crowding molecules can also play an important role in protein drug formulation. Many protein drugs such as monoclonal antibodies requiring high dosing and sc administration will need to be formulated at a very high protein concentration. In addition, sugars have often been used to increase protein stability in solution[57] due to their exclusion from the surface of protein molecules. This has been attributed to a lowering of the protein free energy by minimization of exposed surface area.[58] Stabilization of the more compact folded form of the protein will obviously result in a surface area reduction. However, the surface area can also be reduced by intermolecular association, and thus, the excluded volume effect of sugars in liquid formulations can increase the propensity of proteins to self-associate. Recently it was shown, by sedimentation equilibrium analysis together with scale particle theory, that the high concentration of sugar and protein can dramatically increase the weak self-association of protein that may not be detectable at low and ideal conditions.[59] Such weak association can potentially decrease protein stability and affect other physical chemical properties.

Summary

The analytical ultracentrifuge has been cited as "still the tool of choice" to characterize associating systems.[60] The original development of the analytical ultracentrifuge helped provide the key data for the cornerstone of modern molecular biology and protein chemistry. At the height of its popularity few major labs in the country were without an analytical model E. Unfortunately, despite some of the improvements in the model E, the technology rapidly became a specialized area for researchers interested in improving the instrumentation for rapid data access and analysis. As cheaper and easier techniques were developed to measure rough molecular weights and obtain qualitative information on macromolecular association, the use of the centrifuge rapidly declined. Recently, with the advent of newer instrumentation, proliferation of user groups, workshops, and establishment of the National Analytical Ultracentrifugation Center at Storrs Connecticut, the technology has reemerged and is being used to a greater extent in academia as well as the pharmaceutical industry. This minireview, hopefully, has captured many of the recent advances and problems being investigated in the pharmaceutical and biotechnology arena.

A Convenient Assay Method for the Quality Control of Peptides and Proteins

NEIL PURDIE,* DENNIS W. PROVINCE, AND ERIN A. JOHNSON

Contribution from *Chemistry Department, Oklahoma State University, Stillwater, Oklahoma 74078-0447.*

Received June 25, 1999. Accepted for publication September 23, 1999.

Abstract □ The development of a convenient and very accurate procedure with which to discriminate among subsets of structurally similar peptides and proteins, and measure enantiomeric purities with very good accuracy, has been described in a series of recent articles. A factor preventing its general application to all peptide forms is that comparisons were originally limited to closed subsets of structurally similar types, e.g., dipeptides, tripeptides, and insulin drug forms. In the most recent of these articles, a modification to the method was described which did enable the comparisons to be extended between sets, in particular the di-and tripeptides. That same modification is extended even further in this article to include additional di- and tripeptides, glycylglycine oligomers, insulin drug forms, and neuropeptides. The same principal component analysis treatment used for data reduction and statistical comparisons in prior work enables the discrimination among 49 of the total of 51 analytes investigated.

Introduction

It was originally demonstrated that members of a series of structurally analogous dipeptides[1] and a separate series of tripeptides[2] could be differentiated one from the other by (i) complexing pure forms of the analytes to Cu(II) in aqueous pH 13 solutions and (ii) measuring the visible range circular dichroism (CD) spectra. Complete differentiation within each series was not entirely possible on the basis of just the CD spectral data. It was only achieved when two novel data reduction algorithms were applied to the experimental data. The algorithms are peculiar only to CD data and are applicable in every circumstance where multiwavelength CD detection is used.

Differentiations within groups were based upon comparisons made among the individual members and how they differed from an arbitrarily chosen reference. For the di-and tripeptides these were glycylalanine (GA) and glycylglycylalanine (GGA), respectively. Differentiation between groups was not possible because there was no ligand common to both series. This was resolved by complexing the Cu(II) ion with the auxiliary ligand D-histidine which was made to undergo ligand exchange with the same peptide analytes under the same solution conditions.[2,3] The Cu(II)-D-histidine host complex in effect acts as a chiral derivatizing agent which produces a diastereoisomer, or mixed chiral complex, on partial ligand exchange with each peptide.

Reasons for choosing D-histidine are that it forms a very stable Cu(II) complex, it undergoes rapid ligand exchange, and the Cu(II)−D-histidine host complex has a fairly intense biphasic (i.e., positive and negative bands) visible CD spectrum which affords good analytical sensitivity and an extra element of selectivity to the analyses. Although less expensive, the L-histidine enantiomer has a CD spectrum for the Cu(II)-complex that bears a closer resemblance to the spectra for Cu(II)-L-peptide forms and therefore diminishes the discrimination capability.

A second reason for choosing an auxiliary ligand is that it, rather than the analytes, takes on the thermodynamic responsibility for solubilizing the Cu(II) in strongly basic (pH 13) solutions. For the same reason racemic tartrate is used in the classical biuret test[4] which, until recently, was a method of choice to measure total blood proteins.[5] Apart from the introduction of the CD detector, the only change between this test and the biuret procedure is replacing DL-tartrate with D-histidine. All of the accepted experimental procedures that pertain to the biuret test apply to this modification. The first metal to ligand attachment is made through the N-atom of the terminal amine, with subsequent chelation through binding of the amide nitrogens of the next two peptide bonds.[6] Protein aggregation in the presence of high pH or Cu(II) ion is not a problem.[4] Auxiliary ligand concentrations are always kept in large excess over the metal ion concentration.

An added analytical advantage to using a chiral auxiliary ligand is that the CD spectrum for the host is not baseline. As a result, analytical sensitivities are increased significantly allowing for the use of much smaller quantities of the analyte for each assay. With D-histidine as the auxiliary ligand, the quantity of the analyte material can be decreased by a factor of 10−100 relative to the amounts used earlier.[2,3] This is a significant savings factor if amounts of the analytes are very small to begin with as they invariably are in the production of trial quantities of new drug forms.

The strategy of using Cu−D-histidine as a chiral derivatizing agent as a way to enhance analytical selectivity was successfully demonstrated by the total discrimination among manufactured forms of human, porcine, human Lyspro, and bovine insulins and between the A- and B-chains of bovine insulin.[7] These constitute a unique set of compounds for evaluating the analytical selectivity (even specificity) of the method since the polypeptide sequence changes are minimal and as it turns out remote from the active site, which is the coordinating to the Cu(II) ion. Human and porcine insulins differ only in the identity of the B30, acid terminus, residues which are L-threonine and L-alanine, respectively. The sequence variation is as remote as it can possibly be from the B-amine terminus, the known binding site.[6] Human insulin and the human LysPro variant forms differ only by reversal of the B28−B29 lysine-proline sequence one place removed from the acid terminus

10.1021/js990209e CCC: $18.00
Published on Web 10/28/1999

of the B-chain. Bovine and human analogues differ by two residue substitutions at points A8 (alanine for threonine) and A10 (valine for isoleucine), positions that are part of one of the cyclical sequences in the molecules. Differentiation among these structural variants is routine.

From the obvious analytical specificity of the method toward the insulins,[7] it is evident that interactions other than just the primary coordination and chelation of the residues at the amine terminus are factors to be considered in donor−receptor interactions. A possible major influence might be long-range chiral−chiral interactions between host and analyte ligands. From an analytical perspective, the evidence suggests that the general selectivity among proteins will be very broad. The simplicity of the experimental procedure and the specificity of the data reduction and data handling algorithms make the method an attractive alternative to chromatography for QC applications by manufacturers and regulatory agencies.

The modified biuret reagent and detection procedure might ultimately qualify as an Analyte Specific Reagent (ASR) as it is defined by the Food and Drug Administration in the ASR Rule[8,9] and be applicable to peptides and protein forms.

A major, new frontier in the pharmaceutical industry is the focus on the therapeutic properties of peptide and protein drug forms.[10] Because the number of chiral centers has virtually no limit,[11] the magnitude of the chirality regulatory control problem is increased almost exponentially. Since chiral derivatizations will not produce a single diastereoisomer, even the very best chiral chromatographic methods face what are probably insurmountable challenges.[12] In these circumstances a bulk spectroscopic method has many advantages. The intent of this work was to get a better sense for how general the analytical selectivity is with a special focus on QC of peptides and proteins.

Experimental Section

Chemicals—The full complement of peptide and proteins analytes used for the study is (**1**) glycyl-L-alanine (GA), (**2**) glycyl-(D)-alanine (Ga), (**3**) glycyl-(L)-phenylalanine (GF) (**4**) glycylglycine (GG), (**5**) glycyl-(L)-histidine (GH), (**6**) glycyl-(L)-isoleucine (GI), (**7**) glycyl-(L)-lysine (GK), (**8**) glycyl-(L)-methionine (GM), (**9**) glycyl-(L)-proline (GP), (**10**) glycyl-(L)-tyrosine (GY), (**11**) (L)-alanyl glycine (AG), (**12**) (L)-alanyl-(L)-alanine (AA), (**13**) (L)-alanyl-(L)-tyrosine (AY), (**14**) (L)-tyrosylglycine (YG), (**15**) (L)-tyrosyl-(L)-alanine (YA), (**16**) (L)-tyrosyl-(L)-tyrosine (YY), (**17**) glycylglycyl-(L)-alanine (GGA), (**18**) glycylglycylglycine (GGG) (**19**) glycylglycyl-(L)-histidine (GGH), (**20**) glycylglycyl-(L)-isoleucine (GGI), (**21**) glycylglycyl-(L)-leucine (GGL), (**22**) glycylglycyl-(L)-phenylalanine (GGF), (**23**) glycyl-(L)-histidylglycine (GHG), (**24**) (L)-leucylglycylglycine (LGG), (**25**) (L)-tyrosylglycylglycine (YGG), (**26**) (GGGG), (**27**) (GGGGG), (**28**) (GGGGGG), (**29**) DSLET, (**30**) DTLET, (**31**) DADLE, (**32**) DAGO), (**33**) DALDA amide, (**34**) DPDPE amide, (**35**) CTAP amide, (**36**) DynorphinA (1−9), (**37**) DynorphinA (1−11), (**38**) DynorphinA (1−13), (**39**) DynorphinA (1−13) amide, (**40**) DynorphinB (1−13), (**41**) Met^5-enkephalin amide, (**42**) Leu^5-enkephalin, (**43**) Leu^5-enkephalin amide, (**44**) (D)-Ala^2-Leu^5-enkephalin amide, (**45**) β-endorphin, (**46**) ICI 174,864, (**47**) PLO 17 amide, (**48**) human insulin, (**49**) porcine insulin, (**50**) Lyspro human insulin, (**51**) bovine insulin.

The glycine oligomers and di- and tripeptides were Sigma Chemical Co. products. Peptides were reported to have an enantiomeric purity (EP) in excess of 99.8%. Neuropeptides **29**−**41** and **45**−**47** were provided by CHIRON. Leu^5-enkephalins were obtained from Sigma. Insulins were taken from manufactured lots from Lilly, Novo Nordisk, and Sigma. Reagent grade D-histidine was from Sigma Chemical Co. and reported to have an EP better than 99.8%. Reagent grade $CuSO_4 \cdot 5H_2O$ was obtained from Fisher Scientific.

Solution Preparations—Stock solutions of the reference Cu(II)−D-histidine complex in 0.10 M NaOH were prepared in which the Cu(II) and D-histidine concentrations were 20 mM and 80 mM, respectively. KI (30 mM) was added as a stabilizer.[4] Working solutions of copper-D-histidine were prepared by diluting aliquots from the stock by a factor of 10 with 0.10 M NaOH. To simplify any future quality control QC application by making it even more amenable to automation, we chose to use equal masses of the analytes rather than equal concentrations. Normalizing the concentration of the analyte to a single value is not a critical factor when the equilibrium constants for the ligand exchange processes differ as much as they might be expected to differ for the range of materials used in this study. Aliquots of 10.0 mg were added to the copper−D-histidine stock prior to its dilution with 0.10 M NaOH. From the range of molar masses the actual analyte concentrations in the working solutions varied from 0.2 to 1.20 mM. All are intentionally lower than the total copper ion concentration and not enough to exchange completely with the D-histidine. Throughout this range the signal to analyte concentration correlation is linear.[1−3] A mass as large as 10.0 mg is prohibitively high especially when the method is to be applied to trial drugs where quantities are very limited. The problem can be alleviated to a large degree by reducing the volume of the working solution. CD signals are relatively intense. With access to more modern CD instrumentation than the Model series used here, the cell volume could be reduced by at least 10−100 fold with no loss of signal quality.

CD spectra measured after ligand exchange are simple aggregates of weighted spectra for the host and mixed ligand complexes. Any unbound ligand does not absorb in the visible range. Formation constants and complexation stoichiometries are incidental to QC quantitative interpretations. The purpose of QC methods is to ensure that the presumed chemical and enantiomeric purities of commercial drug products meet the reference standard. Provided the specified procedure for the assay is accurately defined and followed in every detail, the purity will be determined by comparing the CD spectral data for a product lot with the spectrum for reference standard material.

Measurements—CD spectra were measured using a Jasco 500-A automatic recording spectropolarimeter coupled to an IBM-compatible PC through a Jasco IF-500 II serial interface and data-processing software. Experimental parameters: wavelength range 400−700 nm; sensitivity 100 mdeg/cm; time constant 0.25 s; scan rate 200 nm/min; path length 5.0 cm; temperature ambient.

Calibrating the day to day reproduciblity of the system was done by measuring the CD spectrum for the Cu(II)−D-histidine reference working solution. Statistical data used to determine spectral reproducibilities were based on the standard deviations (SD) for the maximum ellipticities measured at the wavelengths 487 nm and 682 nm. The SD values were 7.42 ± 0.07 mdeg and −214 ± 0.60 mdeg, respectively, within and between stocks.[2,7]

Results and Discussion

CD activity in the visible range for chiral Cu(II) complexes is a result of disymmetric perturbations of the ground and excited-state ligand field orbitals by the chiral ligands.[6] Three CD-active electronic transitions are reported to occur over the wavelength range of the visible absorbance band.[6] Bands in the UV range, attributable to only the chirality in the ligands, both bound and unbound, are typically broad, very intense, and quite insensitive to changes in the environment of the coordinating metal ion. The lack of selectivity is the major reason for not exploiting the obvious analytical sensitivity advantage that is inherent in the intense UV bands.

Cu(II)−D-Histidine and Peptide Complexes—The microsymmetry of the Cu(II) ion first coordination sphere is tetragonal, or more accurately, an axially distorted octahedron, distortion being a consequence of Jahn−Teller effects.[13] In strong base D-histidine is anionic and binds to Cu(II) via the terminal amine-N, the carboxylate functional group, and a pyrimidine N-atom, to form a tridentate 1:1 complex.[6] Other coordinate positions might be occupied by hydroxide ions. The stability of the complex and the favorable mass action maintained by keeping the ligand in large excess over the metal means that virtually all of

the Cu^{2+} ion is in the form of the complex. The CD spectrum for the Cu(II)−D-histidine host chiral derivatizing agent is included for reference in Figures 1−5.

Complexing peptides to Cu(II) at high pH involves first attachment via the N-atom of the terminal amine group followed by ring closure(s) through bonding with the N-atoms of successive amide bonds until maximum thermodynamic stability is achieved.[6] Side-chain substituents on the amino acid residues lie out of the coordinate plane and are factors only in inter- and intramolecular interactions within the coordination sphere, unless a potential Lewis base is present, e.g., in L-histidine-containing peptides. Side-chain histidines are legitimate competitors for ligation positions, competing favorably with the terminal amine for the Cu(II) ion. The issue is moot if the test is restricted to QC where the binding mechanism would be the same for the reference standard and the sample. Metal to ligand stoichiometries for metal di- and tripeptide equilibria are 1:1 under pH > 12 conditions.[14] Coordinations with hydroxide ion and/or additional amide N-atoms in longer oligopeptides are variations that could affect the stoichiometry but not the analytical selectivity of the method.

Visible CD spectra for the Cu(II)−di and tripeptides in the absence of D-histidine were the objects of earlier work.[1,2]

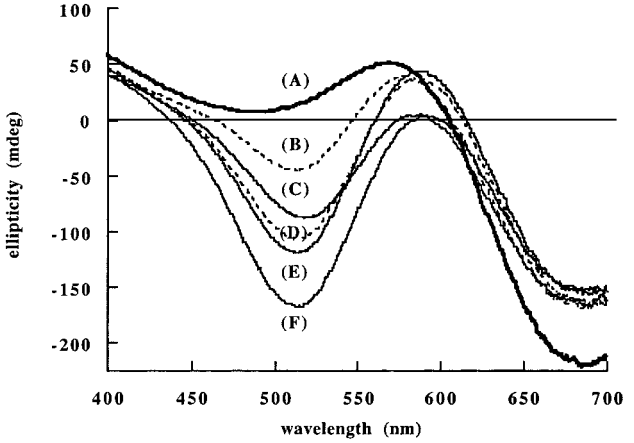

Figure 3—Visible range CD spectra for Cu(II) complexes with D-histidine and mixed D-histidine/Dynorphin neuropeptides. (A) D-Histidine, (B) Dynorphin B (1–13), (C) Dynorphin A (1–9), (D) Dynoprhin A (1–13), (E) Dynorphin A (1–11), and (F) Dynorphin A (1–13)-amide.

Spectra for Cu(II)−D-histidine and Cu(II)−(D-histidine-peptide) mixed complexes were the focus for di- and tripeptide ligands.[3,7] Evidence was provided that confirmed that the stoichiometries and the complex formation con-

stants were similar in magnitude within each series.[1,2] One would expect that for peptides to coordinate to the metal ion there has to be ligand exchange, or in some instances ligand addition with an expansion in the number of coordinating sites. Spectral variations that are the bases for the first level of analytical selectivity therefore are attributable to the individual stereochemical and conformational nature of the structures of the coordinated chiral ligands and to the relative rotational strengths of the three CD-active bands. That the CD-active electronic transitions are also sensitive to other factors besides the coordination geometry is reported for the insulins[7] in the Introduction section, where it is clear that minimal changes in peptide sequences that are remote from the binding site significantly alter the CD spectrum for the Cu(II)−D-histidine host complex.

Cu(II)−D-Histidine Ligand Exchange with Peptides:—Ligand exchange, as it is used in this context, is intended to cover all the mechanistic processes by which a peptide can become part of the Cu(II) complex entity. Total ligand exchange is not a possibility since mass action heavily favors the D-histidine ligand. Since D-histidine is bonded at three coordination sites, three other positions of the distorted octahedron are open to peptide addition reactions. Between these extremes are combinations of exchange/addition mechanisms, in which D-histidine is partially substituted, e.g., by loss of coordination to the carboxylate, and peptide is fractionally added. Nor should the possibility of outer-sphere ligand−ligand coordination be overlooked, e.g., in the insulin series.[7] The product of this ensemble of events is a compound mixture of "unreacted" histidine complex (always in excess) and a concentration distribution of peptide-containing complexes that clearly will vary with the structural properties and solution concentration of the analyte. It is the variability in the last in particular that enhances the analytical selectivity of the procedure. The method is not intended to determine the identity of any potential impurity, only to indicate that purity standards set by regulatory agencies have or have not been met.

Spectra for the mixed complexes are simple sums of the CD spectra for the components. Those that incorporate dipeptides that were not reported before[1] are shown in Figure 1. Spectra for the glycyloligomers, dynorphins, enkephalins, and structurally modified enkephalins are shown in Figures 2−5, respectively. Insulin spectra were previously published.[7] Selectivity distinctions are manifest by shifts in wavelength, sign, and signal intensity in the D-histidine band that maximizes at 550 nm. Besides the first-order chirality changes that occur within the first coordination sphere, there are others that are associated with reorganization of the tertiary structure in solution. Its disruption on ligand exchange could cause specific amino acid residues to impinge upon the 3-D architectural structure of the coordination sphere (outer-sphere complexation), adding more complexity to a mechanistic interpretation, but more diversity to the discriminations.

The broad absorbance band of Cu(II) complexes in aqueous media is known to consist of three subbands.[6] All are CD-active. Signs vary depending upon the nature of the ligands which, when taken altogether, form the basis for a broad analytical selectivity. The one obstacle to achieving total selectivity in Figure 1, for example, is separating the spectrum for GP from the spectrum for the D-histidine host complex. Whether ligands have exchanged is not known but is unlikely. For the other dipeptides in Figure 1 the general tendency is toward more negative spectra.

The only addition to the original mixed-tripeptide series[2] is the spectrum for GGG, Figure 2. As the length of the glycine-oligopeptides is increased, the characteristic shape of the host CD spectrum is retained as its intensity is diminished from GG through GGG, reaching what is essentially zero for the tetramer and the pentamer, after which the signal increases in intensity for the hexamer to reach a value that is about one-fourth of the original host complex. The hexamer result was reproducible and is not an experimental artifact. A possible explanation might be derived from an analogous result observed in a study of a series of dye-derivatized oligosaccharides where the visible range CD induction was attributed to incipient helicity (a single turn) when the oligomer length exceeded the dimension of the tetramer.[15] Whatever the mechanism, it is clear that the length of a peptide is a factor that is significant in the overall binding mechanism.

An expansion on the conclusions from the insulin study is manifested by the five Dynorphins all of which have the identical amino acid sequence through the first seven residues (YGGFLRR), far beyond what is believed to be the minimum for saturating the coordination positions on the Cu(II) ion. For the Dynorphin A analogues, the first *nine* residues in the sequence are identical, yet the spectra are easily distinguishable, Figure 3. The spectral response to an increase in length for the Dynorphin A neuropeptides is also nonmonotonic and most easily seen at 510 nm, the 1−11 analogue producing the greatest spectral change. There can be no question that ligand tertiary structures and their mutual molecular interactions with the primary architecture of the D-histidine complex are major factors in binding and therefore in broadening the analytical selectivity.

This last observation is an interesting concept to consider in the context of understanding factors that contribute to quantitative structure−activity relationships (QSAR). Interpretations of spectral changes should perhaps be revised to include, even emphasize, ligand−ligand interactions that do not involve their exchange. In other words, the *intact* Cu(II)−D-histidine complex might function as a model for a "receptor site" for peptides. If there is any validity to this concept, the possibility exists that the panorama of CD spectral changes observed in Figures 3−5 might eventually be capable of establishing in vitro correlations of molecular structure with therapeutic function. In that case visible range CD would have an important potential role as an insinuative ASR probe to better learn of the subtleties of chiral−chiral interactions in QSAR.

Data for the enkephalin analogues and β-endorphin are plotted in Figure 4. With the exception of a^2-Leu^5-enkephalin, all begin with the same YGG sequence, as do the Dynorphins. The primary coordination mechanism, therefore, will involve the same three Lewis bases, yet the spectra are unique, including an easy distinction between the acid and amide analogues of Leu^5-enkephalin. Spectra for the pentamers are dominated by positive bands over the short wavelength range. Sign inversion by these pentamers, relative to the 30-peptide protein, β-endorphin, and all of the Dynorphins, might be related to a restriction of outer sphere ligand ligand interactions. Signal enhancement is observed when D-alanine is injected into the sequence in a^2-Leu^5-enkephalin. It is surprising, but significant, that an enantiomeric switch did not cause the spectrum to be inverted in the D-histidine complex environment. This speaks to the relative importance of the retention of the chirality of the receptor in the binding mechanism.

The structurally engineered enkephalins and a few miscellaneous neuropeptides are the subjects of Figure 5. There is no evidence that ICI 174,864 and PLO 17 had sufficient influence on the D-histidine host complex to alter its spectrum. The terminal amine of ICI 174,864 is diallyl-

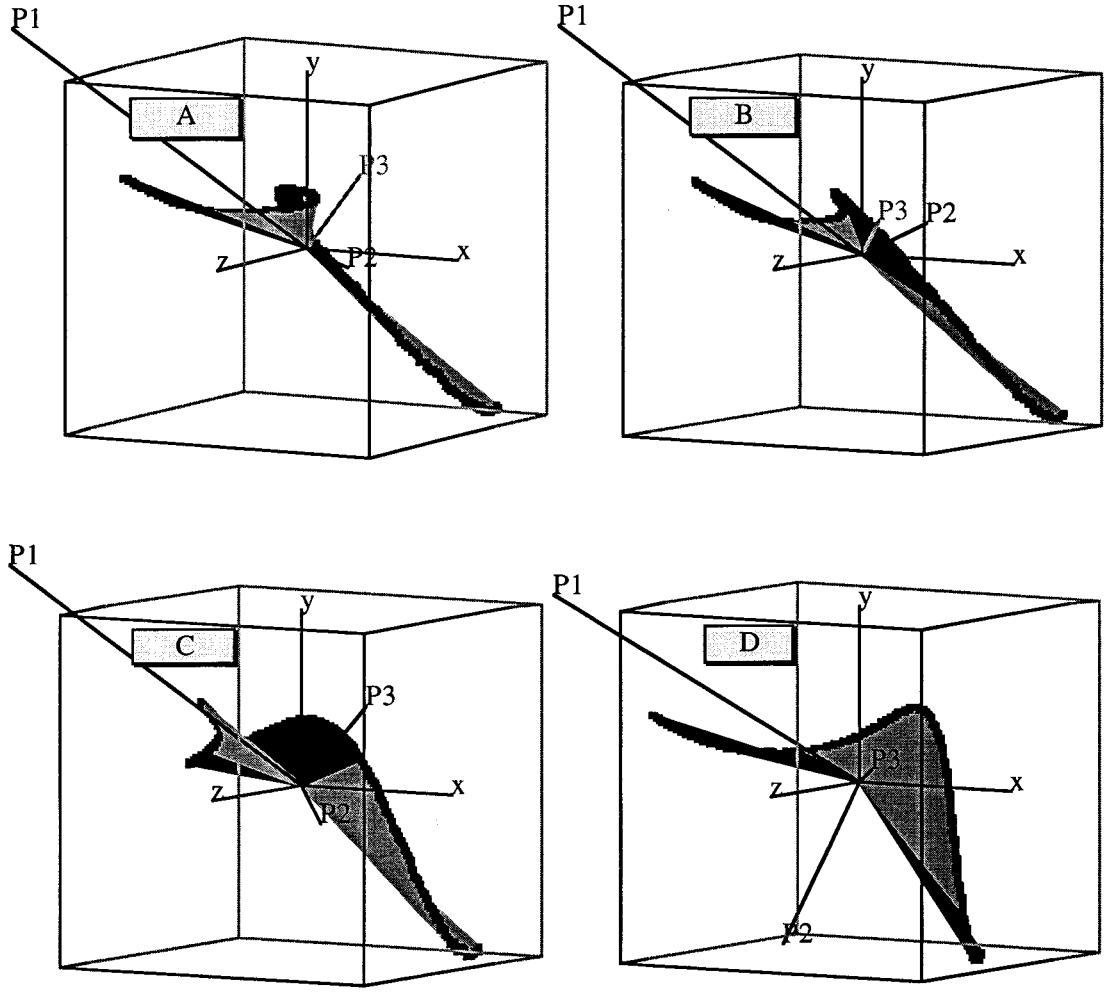

Figure 6—Representative plots resulting from the 3-D data reduction Spinning Plot algorithm for (A) Dynorphin A (1–13), (B) Dynorphin B (1–13), (C) a^2-Leu^5-enkephalin amide, and (D) CTAP. All four diagrams have the same *x*, *y*, *z* orientations. Dark lines that mark the perimeters of the curves mirror the CD spectra although the appearance is disguised by the orientation of the axes especially in A and B. P1, P2, and P3 are the eigenvectors for the principal components that are listed in Table 2. The distance from the origin to the extremity of each vector is the eigenvalue for that PC. Points to note are the different orientations in space for P2 ad P3 which are the most sensitive to the identity of the analyte.

substituted, and P^2 of PLO 17 is *N*-methylated. Both of these modifications adversely affect the primary coordination to the metal ion.

CTAP and DPDPE have disulfide rings and two D-enantiomers in their molecular structures. Between them they produce the greatest changes of any observed to date: strongly negative for CTAP and strongly positive for DPDPE. A positive signal for DPDPE is consistent with the effect of there being a D-enantiomer in the second position; see a^2-Leu^5-enkephalin. The N-terminal residue of CTAP is (D)F. There is insufficient information at this time to make a decision on whether the positional change from second to first is a major contributing factor in determining the sign of the CD spectrum.

The DSLET, DTLET, DADLE, DAGO, DALDA, and DPDPE modified enkephalins all have a D-amino acid residue in the second position. Similarities with the spectra for the natural enkephalins, Figure 4, exist, particularly the tendency toward strong positive bands at shorter wavelengths. Spectra for the DSLET, DTLET, and DADLE trio bear a strong resemblance to one another, but in what follows, they will be shown to be unique. For DALDA, a tetramer, and DAGO, which has an N-Me substituent on G3, structural differences are a bigger factor in determining spectral selectivity.

Data Reduction Algorithm—All the conclusions on analytical selectivity that have been reached so far in this paper are largely intuitive. For QC applications, a quantitative procedure is needed that will identify and/or verify a drug substance and measure its chemical and enantiomeric purities.

Two- and three-dimensional data reduction algorithms were introduced in prior work.[1,2,7] They are described as data reduction models because the objective was to reduce the 1500 data points, that make up the experimentally measured CD spectra, to a few definitive numbers which are characteristic of each analyte. Each procedure serves a special purpose. The 2-D model is effective in determining EP's with an accuracy unsurpassed by any other procedure.[1] The 3-D model, in contrast, is better suited for enantiomeric identification, and chemical purity determinations.[2,3] Only the former is considered in the context of this article.

The mathematical algorithm[16] used for the visual presentation of the 3-D data reduction is a three parameter Spinning Plot, available in a number of commercially available statistical software packages. The variables are wavelength (*x*-axis), CD data for the host complex (*y*-axis), and CD data for the mixed complexes (*z*-axis). Since CD signals are positive, negative, and zero, when two CD spectra are plotted, one against the other, four sign combinations are possible at any wavelength. Repeats of (*y*-, *z*-) coordinate points can occur at wavelength values, x_1 and x_2, that are not adjacent to each other in the spectra.

Table 1—Data Reduction by PCA of the Spinning Plot Data for the Histidine and (Histidine-a^2-Leu^5-enkephalin Amide) Mixed Complexes)

principal components	PC1	PC2	PC3
Eigenvalues	2.6942	0.2222	0.0836
Eigenvectors	–0.57655	0.59226	0.56287
	0.56405	0.78691	–0.25025
	0.59114	–0.17321	0.78776

When that occurs, plots are observed to "wrap-around" and become three-dimensional, Figure 6. To enhance the 3-D perspective, front and back quadrants are distinguished by dark and light shading. Distinctions are very evident.

With a total of 1500 data points for each variable, the system is overdetermined. In the data reduction procedure, data are subjected to a Principal Component Analysis (PCA) iterative process by which vectors of information are plotted against one another to derive principal components (PC's) which have length and directional properties that best describe the least-squares fit in the orthogonal directions of maximum variance. The number of PC's is equal to the number of variables, in this case three. PCA

solutions are expressed as three eigenvalues, over which the total variance is proportionated, and nine eigenvectors, that describe the 3-D spatial orientations of the eigenvalues. In the end, the original 1500 data points are reduced to three vectors of proportionately different lengths, the eigenvalues. The *x*- and *y*-variables are numerically the same for all analytes. Only the *z*-axis variable is analyte dependent. Taken as sets of three variables, however, the resultant PC's are all analyte dependent and as a result are the derived characteristic properties for standard reference materials against which all other preparations will be compared.

Eigenvalues and eigenvectors for PC1, PC2, and PC3, calculated for a^2-Leu^5-enkephalin amide, are given in Table 1. Their spatial projections are superimposed on the coordinate axes of Figure 6C. Eigenvectors give the most sensitive response to the identity of the analytes. Standard deviations in eigenvector values, calculated from repeated experimental measurements, are on the order of ±0.009, so considerable precision is attainable when making analytical differentiations or purity determinations.

Eigenvectors for all of the analytes are presented in Table 2. First on the list is the special case where spectral data for the host complex are plotted on both the *y*- and *z*-axes. This provides a common reference set against which values for all of the analytes can be compared. A cursory examination shows that the selectivity is least for PC11, PC12, and PC13, so the initial focus should be on the remaining six. Comparing only P22, P23, P31, and P32, the ambiguities are so few in number that it is claimed that 49 of the original 51 analytes are statistically and individually identifiable.

Nonlinearities observed in the spectral data for the glycyloligomer and Dynorphin A series are quantified in the results of the PCA.

The two exceptions to achieving total specificity among this group of polypeptides that range from 2 to 51 amino acid residues are ICI 174,846, and PLO 17. Differences between the factors for these analytes and the D-histidine reference are not statistically significant, implying that the host complex remains impervious to substitution. Sign inversions do occur for P32 and P33, but these are associated with the shortest eigenvalue PC3 and are open to uncertainty in interpretation. The same argument might be true for GP.

Quantitative applications of the 3-D Spinning Plot data reduction algorithm are discussed in prior work.[1−3] Results from these articles show that correlations between PC23 values and concentration are linear, making the analytical selectivity not only qualitative but also quantitative.

Summary

By introducing an auxiliary chiral ligand as a substitute for the achiral tartrate ion in the biuret test, a chirality-sensitive test has been created for a series of polypeptides whose sequences range from 2 to 51 residues. Sequence variations exist at both termini and internally (for the insulins[7]). In all but two instances the CD spectrum for the host is significantly altered.

D-histidine is but one of many potential auxiliary ligands. All but two of the current analytes could function in the role of host ligand. How close the already exceptional selectivity achieved by the current method can approach analyte specific reagent (ASR) status might ultimately depend on the identity of the auxiliary ligand. As the significance of the subtleties of the interligand chiral−chiral interactions become better understood, there is reason to expect that CD detection and multivariate modeling used together could contribute to a better understanding of QSAR models and predictions, receptor binding mechanisms, and drug design.

Clustering of CD Spectral Data as a Prototype QSAR Model for Neuropeptides

NEIL PURDIE* AND DENNIS W. PROVINCE

Contribution from *Department of Chemistry, Oklahoma State University, Stillwater, Oklahoma 74078-0447*

Received June 25, 1999. Accepted for publication September 23, 1999.

Abstract □ An analytical method that might eventually qualify as a general quality control assay procedure for polypeptide drug forms was described in the companion article to this paper. The detector is visible range circular dichroism spectroscopy. Multivariate data analysis reduced the spectral data to essentially four principal components (or factors) that are characteristic of each analyte. The level of analytical selectivity achieved among 51 analytes is very high. Using an alternative factor analysis algorithm, the selectivity is even more conveniently accomplished in the form of a 2-D cluster diagram presentation that has the potential of being a prototypical predictive in vitro model for correlating experimental data with structure–activity or structure–function relationships. Clustering of the analytes is a consequence not only of the chiral interactions associated with ligand exchange in the immediate primary coordination sphere of the host derivatizing reagent, but also of long-range intermolecular interactions between the coordination architecture of the host and the chiral polypeptides.

Introduction

Chirality is a common molecular property among natural products and an important factor in determining the efficacy of drug substances.[1] For an enantiomeric pair the isomer with proven clinical therapeutic value is called the eutomer, the other the distomer. Possibilities exist that a distomer can be toxic or mutagenic, making the assay of both enantiomers an essential part of regulatory tests. Measuring the chemical purity of an enantiomeric form is done by conventional standardized methods. Accurate measurement of the enantiomeric purity (EP) is a much more difficult problem. How to measure EP's quantitatively and routinely has recently become a major concern for manufacturing and regulatory agencies. The measurement of EP, or the related quantity enantiomeric excess (EE), expressed as a ratio of the two isomers, has now reached the status of being a requirement imposed by the Food and Drug Administration in new drug submissions.

Manufacturers have the option of choosing between either the enantiomeric resolution of readily synthesized racemic mixtures, or stereospecific syntheses.[1] Resolutions are typically long, demanding, and costly processes which in the end invariably fail to achieve 100% EP. Chiral chromatographic procedures significantly reduce the work load and costs for enantiomeric resolutions,[2,3] but separations that are complete are still not generally accomplished. More and more often, stereospecific synthesis has become the favored option. Since 100% EP is seldom achieved, both procedures are perhaps better thought of as enantiomeric enrichment processes. Monitoring the possible reduction of EP during the shelf life of a drug substance through racemization, especially if it is in solution or in suspension, is an analytical add-on to protocols that are submitted for approvals.

As a result, regulatory agencies are facing a rapidly increasing work load with respect to certifying and approving analytical methods to measure not only chemical purities but also EE (impurities) of chiral drug forms.[4,5] There is also the issue of defining what are the acceptably safe EE threshold levels below which a product is to be rejected from either manufacture or distribution. To ease the load, there is an urgent need for accurate and convenient routine experimental procedures that will give chemical and chiral impurity data, and preferably in an automated way if at all possible.

The problem is immense and still expanding. Pharmaceutical and biotechnology industries are investing more and more R&D resources into the production of chiral substances. With the advent and continued momentum of combinatorial chemistry,[6–9] the number of potential new chiral drug substances is increasing exponentially. Nowhere, perhaps, are these numbers increasing faster than in the area of peptide, peptidomimetic, and protein drug forms. Identifying which real or virtual compounds are worthy of further development is an exceptionally difficult problem. Culling out the few new potential drug substances by performing individual in vivo assays was not really an option and led quickly to the development of mixture assays.[7–9]

Viable alternatives, with the potential for automation, are quantitative structure−activity relationship (QSAR) screening algorithms that are based upon in vitro chromatographic or spectroscopic data of one kind or another. Exploitation of QSAR models is done in two parts, calibration and prediction. In the first step, measured experimental data and therapeutic properties of known drug forms are mathematically correlated to derive a calibration model. The calibration model is in turn exploited to predict the therapeutic potential of a new drug form. The prediction is based entirely on the measured experimental data, e.g., retention times or absorbance, for each new substance. The broader the therapeutic range represented in the calibration, the better the prediction model. These particular experimental methods, however, do not always address the question of how important molecular chirality is, in the therapeutic function of a drug.

The motivation for this study and previous related studies on peptides and proteins[10–13] was to address the lack of emphasis that is given to causal relationships between chirality and function, especially since molecular chirality is so commonplace among natural and synthetic drug substances. Protein receptor sites are chiral. How the chirality of a receptor kinetically reconfigures itself to accommodate the chirality of the drug molecule, and vice versa, is a factor in the discrimination between eutomers and distomers. That steric selectivity has been exploited, almost without recognition, in the development of a myriad of clinical assays that are based upon analytical specificities attributed to monoclonal and polyclonal antibodies and their interactions with antigens. Despite the importance

10.1021/js990210d CCC: $18.00
Published on Web 10/28/1999

of the chirality recognition, at no time has a test been based upon chirality detection. Antibodies have been elevated to the exalted rank of Analyte Specific Reagents (ASR). That same high selectivity, however, is a natural deterrent to the derivation of broad based or generally predictive QSAR models.

Direct spectroscopic methods are a more attractive option over chromatography because of their comparative simplicity of operation and consistent reproducibility in the recalibration of standards, etc. Mass spectrometry is selective but not with respect to chirality differentiation. Detectors that measure absorbance and fluorescence in the visible-UV range are notorious for their lack of analytical selectivity, but can be improved upon by using derivatization reactions, multivariate analyses methods, such as principal component analysis (PCA), factor analysis, and artificial neural networking in data handling,[14] or experimentally by introducing time as an added analytical variable.

Spectroscopic methods with the power to detect molecular chiralities are circular dichroism (CD) and optical rotatory dispersion (ORD). In the specialized area of screening peptides and proteins, however, the vast majority of CD investigative work is done on data from the UV range.[15] The purposes there are to obtain predictive information that can be used to resolve the question of 3-D structural properties of proteins in solution, apportion solution structures between helix and sheet forms, and investigate the kinetics and thermodynamics of folding–unfolding mechanisms, etc. CD bands in the UV are broad and without discrete features. Like absorbance, their potential for establishing QSAR models is limited.

In a series of recent articles, visible range CD spectral data were used to selectively differentiate among di- and tripeptides,[10,11] insulins,[12] and neuropeptides.[13] Mathematical algorithms were derived with which to determine their chemical and enantiomeric purities.[12,13] The absorbance property required for CD to occur in the visible range, was provided by first binding the peptides to Cu(II) ion in pH 13 aqueous solution. Visible absorbance spectra of Cu(II) complexes are comprised of three electronic transitions[16] all of which are CD-active. For the completed studies, peptides were either bound directly to the copper ion[10,11] or displaced an auxiliary ligand,[12,13] e.g., D-histidine. Major accomplishments from these articles that are of relevance to the goals of this one are the ability to discriminate between human and porcine insulins[12] (two 51 amino acid residue proteins whose sequences differ in the identity of one acid at the B30 terminal amino acid only) and between human insulin and the human LysPro variant form in which the order of the B29 L-lysine and B30 L-proline are reversed, and to achieve a level of *quantitative* analytical selectivity that approaches specificity among 51 peptides.[13]

The specific objective of this article was to derive a cluster correlation diagram between visible range CD data on one hand and molecular stuctures, and their corresponding clinical therapeutic functions, on the other. Success would mean we will have a prototypical in vivo predictive QSAR model of some general applicability. CD spectral data are taken from the previous companion article.[13] Only tripeptides and longer oligopeptides are included to test the general practicality of a clustering algorithm. Special mention is given to the subgroup of 19 neuropeptides, classified by their particular clinical functional actions.

Experimental Section

Chemicals—Thirty-five oligo-and polypeptides used for the study were the tripeptides GGA, GGG, GGH, GGI, GGL, GGF, GHG, LGG, and YGG; the higher oligoglycines GGGG, GGGGG, and GGG-GGG; the enkephalins DSLET, DTLET, DADLE, DAGO, DALDA amide, DPDPE amide, Met^5-enkephalin, Leu^5-enkephalin, Leu^5-enkephalin amide, (D)-Ala^2-Leu^5-enkephalin amide, and β-endorphin; the Dynorphins A (1–9), A (1–11), A (1–13), A (1–13) amide and B (1–13); and the miscellaneous CTAP amide, ICI 174,-864, PLO 17 amide, and human, porcine, Lyspro, and bovine insulins. Amino acid sequences are included in the footnote to Table 1.

Commercial sources for the oligopeptides and insulins were listed previously.[13] Reagent grade D-histidine, reported to have an EP better than 99.8%, was obtained from Sigma Chemical Co. Reagent grade $CuSO_4 \cdot 5H_2O$ was obtained from Fisher Scientific.

Solution Preparations—These are described in greater detail in the prior companion article on the 51 peptide and protein forms.[12,13] Working solutions for the assays were prepared by diluting aliquots of Cu(II)–D-histidine stock solutions by a factor of 10 with 0.10 M NaOH such that the final composition was 2.0 mM in Cu(II) ion, 8.0 mM in D-histidine, and 3.0 mM in KI added as stabilizer, in 0.1 M base. To make future quality control (QC) procedures more amenable to automation, we chose to add equal masses of the analytes (10 mg) to the aliquot of stock prior to its dilution rather than use equal concentrations. From the range of molar masses of the neuropeptides, the actual analyte concentrations in the working solutions varied from 0.2 to 1.20 mM. All are intentionally lower than the total copper ion concentration and not enough to exchange completely with the D-histidine ligand. With modern CD instrumentation, the mass of analyte can be reduced 10–100 fold.

Measurements—CD spectra were measured using a Jasco 500-A automatic recording spectropolarimeter coupled to an IBM-compatible PC through a Jasco IF-500 II serial interface and data processing software. Experimental parameters were wavelength range 400–700 nm, sensitivity 100 mdeg/cm, time constant 0.25 s, scan rate 200 nm/min, path length 5.0 cm, temperature ambient. With 2 nm spectral resolution, the full measured spectrum consists of 1500 data points.

Calibrating the day to day reproduciblity of the system was done by measuring the CD spectrum for the Cu(II)–D-histidine reference working solution. Statistical data used to determine spectral reproducibilities were based on the standard deviations (SD) for the maximum ellipticities measured at the wavelengths 487 and 682 nm. The SD values were 7.42 ± 0.07 mdeg and -214 ± 0.60 mdeg, respectively, within and between stocks.[10,11]

Results and Discussion

The assay works on the premise that chiral ligand exchange of the polypeptides for D-histidine, complexed to Cu(II) ion in strong aqueous base solution, will induce a change from the CD spectrum for the host that is characteristic of the peptide analyte. The host metal complex serves as a CD-inducing and color-derivatizing agent for the neuropeptides which otherwise would be CD transparent in the visible range. Spectra for the products,[13] uncorrected for the host spectrum, are the bases for subsequent mathematical correlations.

If there is any truth to the concept that the CD spectra for the mixed complexes correlate with molecular, and therefore therapeutic, function, there should be strong spectral similarities within specific groups and obvious dissimilarities among groups. In other words the focus is on proving a pattern recognition of polypeptides by type. With this thought in mind, we can dispense with the conventional practice of measuring metal–ligand stoichiometries which should be similar within each subset, and dispense with the need to measure formation constants, expecting the variations in these values within a group to vary very little. Therefore, provided the specified procedure for the assay is defined and followed in every detail, analyte recognition and the measured accuracy in their determinations will be considerably improved over univariate (one wavelength) determinations.

The mathematical basis for achieving the analytical selectivity claimed in the previous article[13] was data

reduction of the 1500 data points in the CD spectra for each analyte, taken separately, to twelve factors (3 eigenvalues and 9 eigenvectors) using PCA done on Spinning Plot data.[17] Spinning Plots are created by plotting wavelength, CD spectral data for the Cu(II)–D-histidine host complex, and the Cu(II)–(D-histidine-peptide) mixed complexes on the *x*, *y*, and *z* coordinate axes, respectively. Calculations are described in detail in the prior article.[13] Factors showing the most sensitivity to the identities of the analytes are the eigenvectors. The real analytical value of the tabulated data is the quantitative nature of the chemical and EP assays that can be accomplished using PCA data vs concentration correlations. Potential correlations of principal components with molecular structures are difficult to find when data are in tabular form.

PCA and Clustering Model—The model was developed using only the spectral data for the tripeptides and higher oligomers. Dipeptides were excluded because they lack the 3-D rotational conformational structures that are common to longer peptides.

In clustering, the strategy is to base correlations upon how well spectral patterns align with molecular "types" in a graphical manner. The major departure from Spinning Plot data reduction algorithm is that the spectral data for all 35 analytes are treated collectively. What follows is a description of the genesis of a possible calibration model. Spectral data for new analytes are required before the relative success of the model in making predictions can be tested.

To make modeling calculations more managable for a desktop computer, the original 1500 data points were reduced in number to 31 by choosing values at 10 nm intervals. The first step was to group the (35 × 31) CD data sets through a (correlation-of-*Y* variables) calculation, that expresses the relative strengths of successive pairwise correlations of CD signals in the form of a square matrix. PCA was then used to reduce the dimensionality of the correlation-of-*Y*'s matrix to just six factors or principal components (PC's), Table 1. These six factors account for 99.93% of the total variations among all of the *Y* variables in all 35 individual spectra. The first factor, PC1, has the maximum variation. The second factor, PC2, is orthogonal to the first and has the next greatest variation, and so on through all six factors.

Clustering is a technique of grouping together rows of PC's that share similar values across a number of variables. The hierarchical clustering option was used here. In this option, clustering starts with each point being its own "cluster". Through a series of iterative steps the two closest clusters are successively combined, by Ward's method, until ultimately all points are grouped as a single cluster. Between the extremes of 1 and 35 clusters there is an optimum number on which to base the model. As a rule of thumb the number of clusters would not exceed the number of "types" of analytes, assuming that that prior knowledge is available. Selection of the optimum cluster condition is linked to the relative magnitudes of the proportional changes between successive PC values. For this data set,

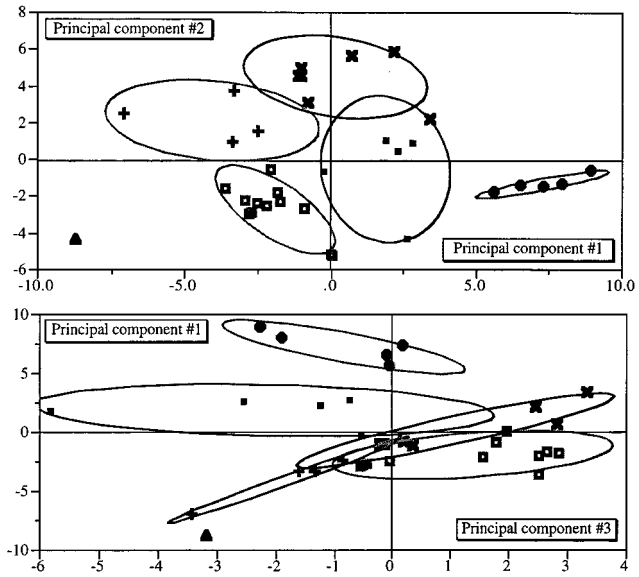

Figure 1—(a) Correlation of PC1 vs PC2 (Table 1) derived from the PCA of the correlation of *Y* matrix for the 35 peptides used for the model. Individual clusters are associated with (+) GGX tripeptides; (x) oligoglycinates and non-GGX tripeptides; (●) enkephalins; (◘) Dynorphins; (■) insulins (black); and (+) D^2-modified enkephalins. (b) Correlation of PC3 vs PC2 from the same source. The perspective is from a direction that is at right angles to the projection in part a. The same markers are used to designate the peptides by type. The special reason for part b is to demonstrate that the Dynorphins and the insulins are separable in the third dimension.

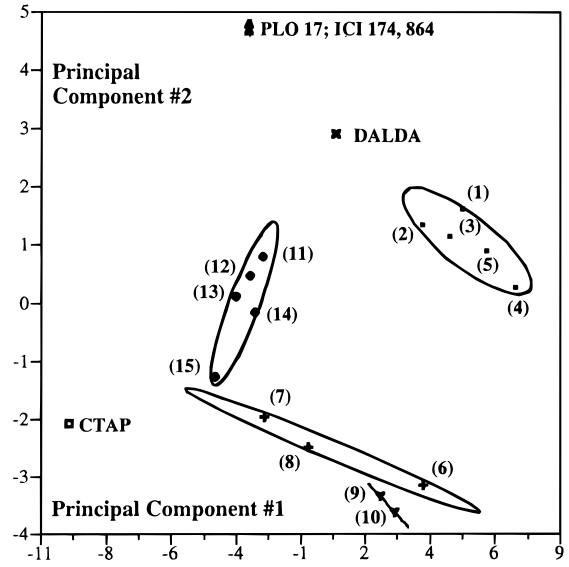

Figure 2—Repeat of the correlation of Figure 1a drawn exclusively for the 19 neuropeptides only. Cluster outliers are identified by name. Coordinates for the host D-histidine complex would correspond with the coordinates for PLO 17 and ICI 174,864. The δ-receptor cluster consists of (**1**) DTLET; (**2**) DSLET; (**3**) DADLE; (**4**) a^2-Leu^5-enkephalin; and (**5**) DPDPE. The μ-receptor cluster consists of (**6**) DAGO; (**7**) Met^5-enkephalin; and β-endorphin. The alternate δ-receptor cluster is comprised of (**9**) Leu^5-enkephalin and (**10**) Leu^5-enkephalin amide. The κ-cluster of the Dynorphins consists of (**11**) B (1–13); (**12**) A (1–13); (**13**) A (1–9); (**14**) A (1–11); and (**15**) A (1–13) amide.

the optimum number of clusters, or types, is 6; the tripeptides, oligoglycinates, dynorphins, enkephalins, insulins, and a miscellaneous group composed of the structurally unrelated CTAP, ICI 174,864, and PLO 17.

Figure 1 is a presentation of two 2-D cluster diagrams prepared by plotting different pairs of PC values, PC1 vs PC2 in Figure 1a, and PC3 vs PC1 in Figure 1b. The relationship between the two figures is that the projection of the lower diagram is from a direction that is orthogonal to the projection for the upper diagram. Together they represent two 2-D perspectives of a 3-D figure. Figure 1a shows the excellent segregation of the data points over five distinct cluster areas that encompass multiple points, and one "area" that is but a single point, i.e., CTAP. The four insulins and the Dynorphins appear to occupy a single cluster in the 2-D space of Figure 1a, but on viewing the same diagram from an orthogonal direction, Figure 1b, the types are clearly separated in the third dimension. Future studies should be able to exploit 3-D clustering option in a more direct manner for even greater discriminations.

The range in values for all PC's is very wide which enables good spatial separation of the clusters. Limits on the range of PC1 values are set by the Cys-Pen and Pen-Pen disulfide linked ring peptides, CTAP and DPDPE, which produce the greatest changes in the CD spectral data from that of the host complex.[13] Two other structural features of CTAP make it unique. It is the only peptide in the pool with an aromatic substituent on the amine terminus, and that residue is also in a D-enantiomeric form.

Neuropeptides Subgroup—Clustering of the 19 neuropeptides subgroup is shown separately from the tripeptides and insulins data in Figure 2. All except CTAP and ICI 174,864 have a Y-residue at the amine terminus. Data points on the PC1 vs PC2 plot are segregated over three distinct areas, plus a few individually distinct locations. The next question is whether these areas correlate with different protein receptor selectivities and affinities.

Three known peptide neuroreceptors, μ, δ, and κ, have been identified in the literature.[18,19] It has been proposed, but not generally agreed upon, that there is duality in the structures of potential μ and δ receptors. Neuropeptide drug forms have special affinity for one or another of the receptors. Dynorphins, for example, are structurally disposed to bind to κ receptors. Some drugs are reported to show multiplicity by binding to more than one receptor.

Beginning with the cluster outliers, CTAP is a confirmed μ-selective antagonist. DALDA on the other hand is considered to be the most selective μ-agonist known. Their relative locations are consistent with the diversity in their affinities. Distinction between PLO 17 and ICI 174,864 (a μ-agonist and a δ-selective antagonist, respectively), however, cannot be made since the spectral evidence is that they do not participate in ligand exchange. The host Cu(II)—D-histidine complex, therefore, would occupy the same coordinate position and be a natural reference point against which to "measure" relative receptor selectivities and affinities.

Compounds **1**—**5** in Figure 1 are the designer D^2-enantiomer-enkephalin analogues, DTLET, DSLET, DADLE, a^2-Leu^5-enkephalin, and DPDPE, respectively. These are recognized δ-receptor drugs. Structurally DADLE is the enantiomer of a^2-Leu^5-enkephalin because of the inversion of the chirality at the acid terminus. The chirality change appears to have little effect on their proximity in the cluster which might have been expected since it is located so far from the amine terminus which is the primary point contact between the ligand and the host metal complex. DALDA fits the description of a D^2-enantiomerically substituted enkephalin, yet it lies outside the "δ-receptor cluster". The result is consistent with the fact that DALDA favors binding to a μ-neuroreceptor (vide supra). Its absence from the "δ-receptor cluster" might be related to its being the only tetramer in the class.

The two natural Leu^5-enkephalins **9** and **10**, in which all residues are L-enantiomer forms, also show a preference for δ-receptors.[18,19] Their coordinates, however, are quite remote from the designer D^2-enkephalins "δ-receptor cluster". Effects of enantiomeric substitutions at amino acid

terminus residues may be a factor in proposing that there is structure multiplicity among neuroreceptors and among agonists.

DAGO (**6**) is yet another designer D^2-substituted enkephalin whose location is remote from the "δ-receptor cluster". Its spectral properties and PC coordinates place it in an entirely different cluster with Met^5-enkephalin (**8**) and β-endorphin (**7**) which are μ-receptors. DAGO is also classified as a μ-receptor agonist.[18,19] The locations of the Met^5 analogue, β-endorphin, and DAGO together define the "μ-receptor cluster" space. Structurally what DAGO and Met^5-enkephalin have in common is an N-Me substituent on the third and fourth residues, respectively. The substituent lies outside the plane of the primary tetragonal coordination sphere of the Cu(II) ion complex and as such adds a new chirality dimension to the ligand−ligand interactions. The observation that DAGO is a confirmed μ-receptor agonist and associates itself in space with two other μ-receptors, while its structure would suggest otherwise, is perhaps the most compelling reason for believing that a calibration model has been identified that could be the genesis of a QSAR model for predicting the receptor selectivities of new peptide drug forms.

As a general rule, Dynorphins bind to the κ-receptor.[18,19] All five included here form a tight single "κ-receptor cluster" which we suspect is related to their having identical initial sequences and a diminished outer-sphere involvement with the first coordination sphere of the metal complex. In close juxtaposition to the Dynorphins is the 30-residue β-endorphin which has the same sequence as the Dynorphins over the first four residues. Areas where the clusters impinge or intersect are conceivably indicators of possible duality in receptor binding functions.

The preliminary calibration model has provided some encouraging results. As more neuropeptides are added to the data pool, the boundaries and the compositions of the clusters will necessarily change. A much larger data pool is required before the predictive capabilities of the model can be critically and confidently tested.

Summary

An idea for a potential QSAR model for peptide drug substances is described. The model is based upon visible range CD data measured for a series of mixed Cu(II)−(D-histidine-peptide) complexes. Spectral responses to the ligand substitution reactions are a function of the identities of the coordinating bases in the analyte ligands and of the extended 3-D solution structure of the peptides. The model differs from other QSAR models in that longer range intermolecular forces that contribute to receptor−agonist interactions are a tangible part of the model. The value of the model as a predictive tool is still uncertain because the number of objects is still very small. It is quickly and easily expandable as other neuropeptides become available. The focus here was on neuropeptides. Drugs whose pharmacological functions are different will, in all likelihood, be treated as separate entities in cluster diagrams that are specific to each category or type.

Accepted for publication September 27, 1999.

Abstract □ The aqueous solubility of triclosan is only about 10 μg/mL. This very low solubility can hamper its biological activity in the oral cavity, which could explain the mixed clinical results obtained from triclosan toothpaste trials. Triclosan availability in a silica-based toothpaste was improved through cyclodextrin solubilization. The triclosan in vivo availability was optimized through a series of phase-solubility studies and triclosan release studies. It was found that in toothpastes, natural β-cyclodextrin (βCD) was just as good a solubilizer as the more water-soluble βCD derivatives. Furthermore, the amount of cyclodextrin could be reduced by as much as 60% through the addition of a small amount of carboxymethylcellulose (CMC), without affecting triclosan release from the toothpaste. Optimally, cyclodextrins resulted in an almost 3-fold enhancement of triclosan availability compared to an identical toothpaste containing no cyclodextrin. In vivo studies in humans showed that replacing triclosan with triclosan/βCD in the toothpaste resulted in only moderate improvement in triclosan substantivity. However, replacing triclosan with triclosan/βCD/CMC complex resulted in significant improvement in triclosan substantivity. Furthermore, the in vivo studies showed that replacing free triclosan with triclosan/βCD/CMC complex resulted in an almost 3-fold increase in initial triclosan concentration in saliva after brushing and about 2-fold increase in duration of activity.

Introduction

Addition of antibacterial agents to oral care products is an effective way for preventing bacterial plaque formation on tooth surfaces and consequent formation of gingivitis.[1−3] However, the antiplaque activity of an antibacterial agent is not solely related to in vitro antimicrobial activity. Other factors, such as the availability of the antibacterial agent in the oral product and its substantivity in the mouth (i.e., the magnitude and duration of antibacterial effect in saliva) appear to be important parameters.[3,4] The release rate of the antibacterial agent from the oral care product into the aqueous salvia and consequent partition of the agent into the lipophilic intraoral sites can be a crucial factor for effective plaque inhibitation. Furthermore, the concentration of the antimicrobial agent in saliva must be above the minimal inhibitory concentration to exert a bacteriostatic effect. Thus, to ensure a bacteriostatic concentration, the antibacterial agent must be soluble in the aqueous saliva and, at the same time, the agent must be lipophilic to be able to partition from salvia into the lipophilic intraoral sites. Cationic antibacterial agents which exhibit prolonged substantivity in the mouth, such as chlorhexidine, are among the most effective antiplaque agents available. However, their incompatibility with anionic surfactants, staining of teeth and disturbances of taste have limited their usage in oral care products.

Triclosan (Figure 1) is a lipophilic, water-insoluble antibacterial agent which is commonly added to toothpastes, and other oral care products, as a dental antiplaque agent. In general, the availability and substantivity of triclosan is significantly less than those of chlorhexidine and, thus, triclosan is a less effective antiplaque agent than chlorhexidine.[5] However, formulations which improve the availability and/or substantivity, such as triclosan containing liposomes[6] and triclosan/copolymer dentifrice,[7] can significantly improve the antiplaque effect. It has been shown that good delivery of an antiplaque agent, such as triclosan, requires a highly optimized formulation.[8]

Cyclodextrins are cyclic oligosaccharides with a lipophilic central cavity and hydrophilic outer surface. Cyclodextrins are able to form complexes with lipophilic water-insoluble compounds by taking up the compound, or more frequently some lipophilic moiety of the compound, into the cavity. No covalent bonds are formed or broken during the complex formation, and free (i.e., unbound) molecules are in equilibrium with molecules bound in the complex.[9,10] Cyclodextrins increase the delivery of lipophilic, water-insoluble drugs into biological membranes by increasing the drug availability at the hydrated surface of the membrane.[11] The most common natural cyclodextrins are α-cyclodextrin (αCD), β-cyclodextrin (βCD), and γ-cyclodextrin (γCD), which consist of six, seven, and eight glucopyranose units, respectively. These natural cyclodextrins, in particular βCD, and their complexes have limited aqueous solubility. Therefore, numerous water-soluble cyclodextrin derivatives have been synthesized. The complexation efficacy of cyclodextrins is rather low and, thus, relatively large amounts of cyclodextrins are frequently needed to solubilize small amounts of a lipophilic, water-insoluble compound. It is possible to enhance both the aqueous solubility of the complexes and the complexation efficacy by adding small amounts of a water-soluble polymer to the aqueous complexation media.[12] The bioavailability of lipophilic drugs in aqueous cyclodextrin solutions is, in general, improved by addition of the polymers. The purpose of this study was to enhance the availability and substantivity of triclosan through cyclodextrin complexation.

Materials and Methods

Materials—Triclosan was purchased from Ciba-Geigy (Greensboro, NC). β-Cyclodextrin (βCD), γ-cyclodextrin (γCD), and randomly methylated β-cyclodextrin (RMβCD), with a degree of substitution of 1.8, were purchased from Wacker-Chemie (Munich, Germany). α-Cyclodextrin (αCD) was obtained from Nihon Shokuhin Kato Co. (Tokyo, Japan) and 2-hydroxypropyl-β-cyclodextrin

(HPβCD), with a degree of substitution 2.9, from Janssen Biotech N.V. (Olen, Belgium). Maltosyl β-cyclodextrin (MβCD) was kindly donated by Ensuiko Sugar Refining Co. (Yokohama, Japan) and sulfobutyl ether β-cyclodextrin sodium salt (SBEβCD) by CyDex Inc. (Overland Park, KS). Hydroxypropyl methylcellulose Ph.Eur.'97 (HPMC) was purchased from Mecobenzon (Copenhagen, Denmark), and poly(vinylpyrrolidone) (PVP) of molecular weight 40 000 and carboxymethylcellulose sodium salt (CMC), low viscosity, from Sigma Chemical Co. (St. Louis, MO). All other chemicals used in this study were of reagent or analytical grade and obtained from commercial sources.

The silica-based dentifrice used throughout this study consisted of hydrated silica, sorbitol, glycerine, water, sodium lauryl sulfate, tetrapotassium and tetrasodium pyrophosphate, carbomer, poly(ethylene glycol), sodium phosphate, sodium saccharine, sodium fluoride, and xanthan gum.

Solubility Determinations—An excess amount of triclosan was added to each of the aqueous unbuffered cyclodextrin solutions. The pH of the solutions was between 5 and 6. The solutions were then heated in an autoclave in sealed vials to 121 °C for 20 min. After cooling to room temperature (22−23 °C), a small amount of solid triclosan was added to each vial to promote triclosan precipitation. Then the suspensions were allowed to equilibrate for 5 days at room temperature. After equilibration was attained, an aliquot of each suspension was filtered through a 0.45 μm membrane filter, diluted with the mobile phase, and analyzed by HPLC. Each experiment was performed three times, and the results are presented as the mean ± standard deviation (SD).

Preparation of the Dry Triclosan/βCD Complex Powder—The dry complex was prepared by heating a suspension of triclosan and βCD in an aqueous 0.5% (w/v) CMC solution, or an aqueous solution containing from 0.0 to 1.0% CMC, in an autoclave for 40 min. This was followed by equilibration, at room temperature (22−23 °C) for at least 3 days, and lyophilization.

Preparation of Triclosan/Cyclodextrin-Containing Toothpaste—Cyclodextrin solutions were made by dissolving suitable amount of cyclodextrin (the amount was calculated from the phase-solubility studies) in water or the aqueous polymer solutions. Solutions containing lower and higher cyclodextrin concentrations were also made, altogether 10 different solutions/suspensions for each cyclodextrin derivative. An appropriate amount of triclosan was then added to each solution, and these were heated (120−140 °C) in an autoclave for 40 min. The solutions were allowed to equilibrate for 2 days. A triclosan/cyclodextrin solution/suspension (7.255 g) was then mixed thoroughly with 42.745 g of the silica-based dentifrice resulting in 50 g of toothpaste containing 0.28% (w/w) triclosan. Alternatively, an appropriate amount of lyophilized triclosan/βCD was mixed with 42.705 g of the silica-based dentifrice and water added ad 50 g. After mixing, the samples were allowed to equilibrate for at least 1 day before the triclosan availability was evaluated.

Triclosan Availability Evaluations—The effect of the triclosan/cyclodextrin complex on the permeability of triclosan through a semipermeable cellophane membrane molecular weight cutoff 6 000−8 000 (Spectra/Pore, Fisher Scientific, Pittsburgh, PA) was investigated. The membrane was placed in a Franz diffusion cell (Vangard International Inc., Neptune, NJ) containing 12 mL of an aqueous isotonic pH 7.4 phosphate buffer solution containing 5% (w/v) HPβCD (to solubilize triclosan) and additional 2% (w/v) sodium chloride (to obtain isotonicity with the toothpaste) as a receptor phase. The donor phase consisted of 3 mL of the toothpaste which was applied to the membrane surface (area 3.14 cm^2). The triclosan concentration in the toothpaste was 0.28% (w/w). The assembled diffusion cells were kept at room temperature (about 23 °C), and samples (30 μL) were removed from the donor phase and analyzed by HPLC. The triclosan flux was obtained by plotting the amount of triclosan which went through the membrane against time. The results presented are the means of two experiments.

Table 1—Triclosan Solubility in Aqueous 5.0% (w/v) Cyclodextrin Solution (mean ± SD, $n = 3$) with or without 0.20% (w/v) Polymer[a]

cyclodextrin and polymer	solubility of triclosan (mg/mL)
αCD in water (no polymer)	0.32 ± 0.00

[a] *The solubility of βCD in water is 1.85% (w/v). βCD formed a 5% (w/v) suspension before addition of triclosan. **The water-soluble polymers can increase the aqueous solubility of βCD and its complexes.

Triclosan Substantivity Evaluations—Six healthy volunteers (5 males and 1 female), who were not either pregnant, receiving antimicrobial therapy, or had dental disease, were recruited for this part of the study. Sampling was separated by at least 2 days, and all the volunteers used a nontriclosan toothpaste throughout the study, with at least a two-day wash-out period prior to commencing the study. Participants were not allowed to brush their teeth for at least 2 h prior to the test occasion.

For each product evaluation, each participant gave an initial saliva sample prior to brushing with the sample toothpaste, to confirm the absence of triclosan. Each brushed for 1 min with 1.5 g of the test toothpaste and then rinsed the mouth with 20 mL of deionized water. Unstimulated saliva samples were then taken at 10, 20, and 60 min postbrushing. The saliva was weighed into 10 mL volumetric flasks, 4 mL of methanol and 2 mL of the HPLC mobile phase were added, and the sample was mixed and made to volume with methanol. Finally, the sample was filtered through a 0.45 μm membrane filter and analyzed by HPLC.

HPLC Analysis of Triclosan—The quantitative determination of triclosan was performed on a high performance liquid chromatographic (HPLC) component system from Merck Hitachi (Dramstadt, Germany), consisting of a pump (model no. L-6200A) operated at 1.5 mL/min, autosampler (model no. L-7200) with injection volume adjusted to 20 μL, LiChrosorb RP-18 (125/4 mm, 5 μm) column, UV/vis detector (model no. L-4200) operated at 283 nm, and an integrator (model no. D-2500). The mobile phase consisted of acetonitrile and 40 mM aqueous pH 3.0 disodium hydrogen phosphate (50:50). A standard curve was determined for each run.

Results

Cyclodextrin Solubilization of Triclosan—In the preliminary studies all the cyclodextrins tested, except the natural γCD, formed water-soluble complexes with triclosan. However, αCD had much less solubilizing effect than the βCDs and, thus, only the natural βCD and its derivatives were studied further (Table 1). The natural βCD and its triclosan complex have very limited solubility in water. The βCD derivatives, i.e., RMβCD, SBEβCD, HPβCD, and MβCD, formed water-soluble complexes with triclosan, and, frequently, addition of a water-soluble polymer increased the solubilizing effect of the cyclodextrin. All the βCD derivatives formed linear phase−solubility

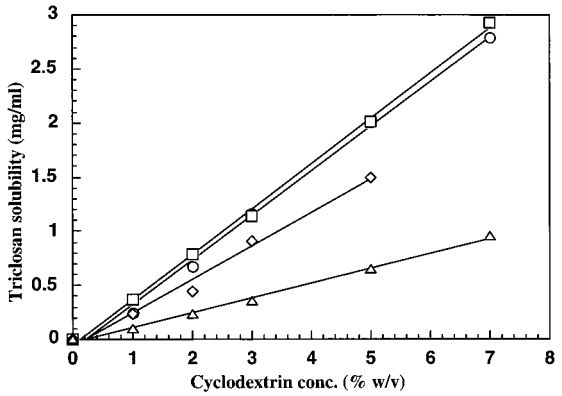

Figure 2—The phase-solubility diagrams of triclosan in aqueous cyclodextrin solutions at 22 °C. HPβCD (○), SBEβCD sodium salt (□), RMβCD (◇), and MβCD (Δ).

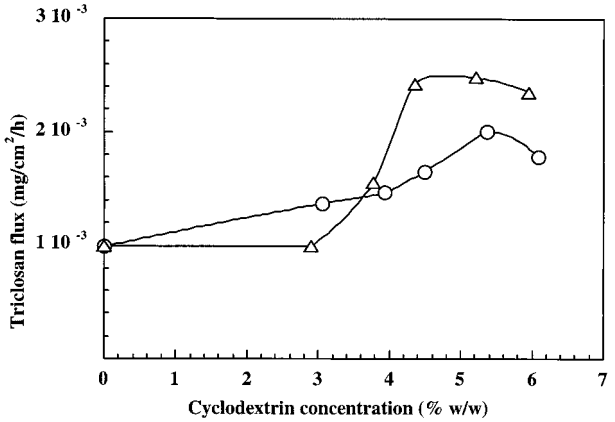

Figure 3—The triclosan flux from a toothpaste as a function of cyclodextrin concentration, RMβCD without polymer (○), RMβCD containing 0.2% HPMC (Δ). The initial triclosan concentration in the toothpaste was 0.28% (w/w).

diagrams, indicating that one cyclodextrin molecule forms a complex with one triclosan molecule (i.e., 1:1 complexes)[13] (Figure 2). The amount of cyclodextrin needed to solubilize triclosan in the toothpaste formulations was estimated from these and comparable phase−solubility diagrams.

Evaluation of Triclosan Availability in Toothpaste Formulations—On the basis of previous investigations, it can be assumed that the triclosan availability in the toothpaste formulations will be at its maximum when just enough cyclodextrin is used to solubilize triclosan in the toothpaste. Addition of too much or too little cyclodextrin will result in less than optimum triclosan availability.[11,12] The approximate amounts of the various cyclodextrins needed to dissolve 0.28% (w/w) triclosan in the toothpaste formulations was estimated from phase−solubility diagrams of triclosan in aqueous cyclodextrin solutions. Since the various constituents of the toothpaste formulation will interfere with the complexation, final adjustments of the cyclodextrin concentrations had to be based on the rate of triclosan release from the triclosan/cyclodextrin-containing toothpastes. Figure 3 shows a representative release profile observed as the flux of triclosan from the toothpaste through a semipermeable cellophane membrane. The maximum triclosan flux and the optimum cyclodextrin concentration from toothpastes containing 0.28% (w/w) triclosan and the various cyclodextrins is shown in Table 2. Optimally, the cyclodextrins resulted in 2- to 3-fold flux enhancement compared to toothpaste containing no cyclodextrin, i.e., addition of triclosan/cyclodextrin complexes to the toothpaste formulations resulted in 2- to 3-fold enhancement of the triclosan availability. Surprisingly, although βCD and its triclosan complex have limited

Table 2—The Flux of Triclosan from the Toothpastes at Optimum Cyclodextrin Concentration[a]

cyclodextrin	cyclodextrin concn (% w/w)	flux (mg/cm²/h)	flux ratio[b]
αCD	7.30	1.91×10^{-3}	1.9
αCD with PVP	7.30	1.50×10^{-3}	1.5
βCD	7.30	2.10×10^{-3}	2.1
βCD with CMC	3.00	2.20×10^{-3}	2.2
HPβCD	4.64	2.27×10^{-3}	2.3
HPβCD with PVP	6.09	2.26×10^{-3}	2.3
SBEβCD	6.09	0.57×10^{-3}	0.6
SBEβCD with PVP	4.64	1.31×10^{-3}	1.3
RMβCD	5.37	2.01×10^{-3}	2.0
RMβCD with CMC	5.22	2.48×10^{-3}	2.5

[a] The triclosan concentration in the toothpastes was in all cases 0.28% (w/v). In some cases 0.20% (w/v) polymer was added during the triclosan/cyclodextrin complex formation. The flux was determined at 22 to 23 °C. [b] The flux divided by the triclosan flux obtained from a toothpaste containing no cyclodextrin (0.99×10^{-3} mg/cm²/h).

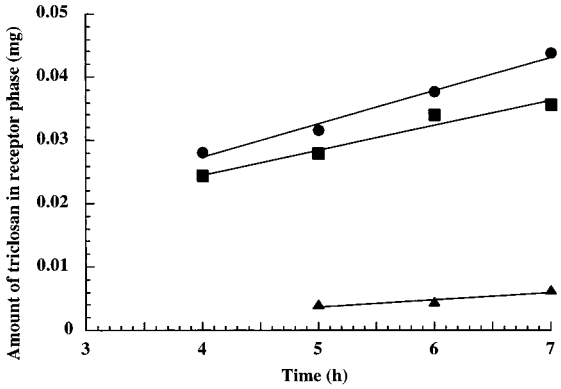

Figure 4—Representative figure which shows the release of triclosan from toothpastes containing no βCD or CMC (▲), triclosan/βCD complex (■), or triclosan/βCD/CMC complex (●) through a semipermeable cellophane membrane at 22 to 23 °C. The triclosan concentration toothpaste was kept constant at 0.28% (w/w). The βCD concentration in the toothpaste was 3.0% (w/w) when it was present in the toothpaste. When CMC was present, the CMC concentration was kept at 0.50% (w/v) during the preparation of the triclosan/βCD/CMC complex.

solubility in pure water, addition of triclosan/βCD complexes to the toothpaste resulted in significant enhancement of the triclosan availability. Furthermore, addition of CMC reduced significantly the amount of βCD needed to enhance the triclosan availability.

The effect of βCD concentration on the flux of triclosan from toothpaste formulations was investigated. During preparation of the dry triclosan/βCD complex powder, the CMC concentration was kept constant at 0.50% (w/v), but the βCD concentration was varied. The dry complex powder was then mixed into the toothpaste resulting in 0.28% (w/w) triclosan concentration in the final toothpaste formulation. The triclosan availability in the toothpaste was evaluated by determining the triclosan flux from the toothpaste through a semipermeable cellophane membrane (Figure 4). As can be seen in Figure 5 the optimum βCD concentration was 3% (w/v). Then the optimum polymer concentration was determined. Triclosan/βCD complexes were prepared in aqueous solutions containing from 0.00 to 1.00% (w/v) CMC. The βCD concentration and the triclosan concentration were kept constant in the final toothpaste formulation, at 3.0% (w/w) and 0.28% (w/w), respectively (Figure 6). Maximum triclosan flux (i.e., maximum triclosan availability) was obtained when the CMC concentration during preparation of the triclosan/βCD complex was between 0.10 and 0.20% (w/v). No further

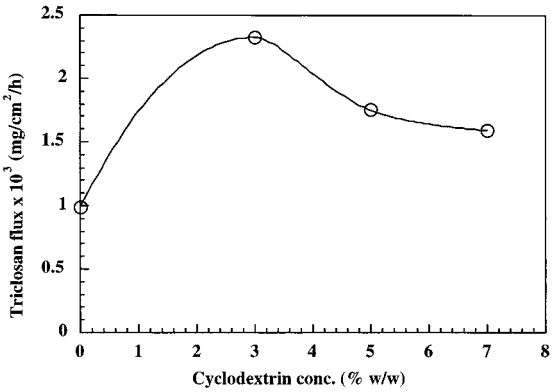

Figure 5—The effect of βCD concentration in the toothpaste formulation of the flux of triclosan through a semipermeable cellophane membrane at 22 to 23 °C. The triclosan concentration was kept constant at 0.28% (w/w), and CMC concentration was kept at 0.50% (w/v) during the preparation of the triclosan/βCD complex.

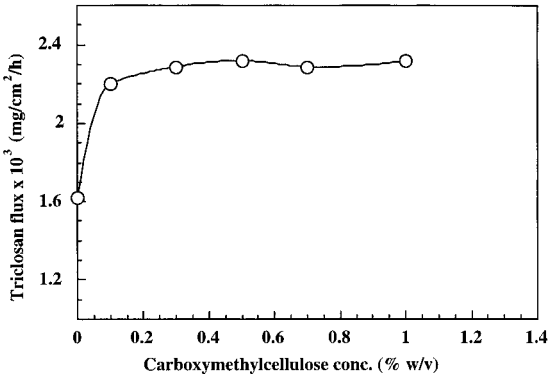

Figure 6—The effect of CMC concentration during preparation of the complex on the flux of triclosan from the toothpaste through a semipermeable cellophane membrane at 22 to 23 °C. The triclosan concentration was kept constant at 0.28% (w/v), and the βCD concentration was kept constant at 3.0% (w/v) in the toothpaste.

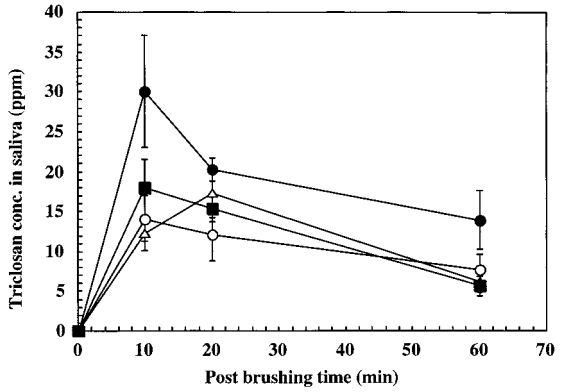

Figure 7—The triclosan concentration in saliva (mean ± SEM, $n = 6$) at various times after brushing with toothpaste containing free triclosan (no cyclodextrin or polymer complex) (○), triclosan/βCD complex without polymer (■), triclosan/HPβCD complex without polymer (Δ), and triclosan/βCD/CMC complex (●).

increase in the triclosan flux was observed from complexes prepared at higher CMC concentrations.

Triclosan Substantivity Evaluations—Figure 7 shows the effect of cyclodextrin complexation of the triclosan saliva concentration time profile after brushing with toothpastes containing four different triclosan formulations. The area under the curves (AUC) from 0 to 60 min gives a rough estimate of how much triclosan is initially retained in the mouth after brushing. Replacing triclosan by triclosan/βCD complex or triclosan/HPβCD complex results in about 10% increase in AUC, indicating only minor improvement of the triclosan retention in the mouth. This was partly due to somewhat shorter duration, i.e., faster triclosan clearance, after brushing with the triclosan/cyclodextrin-containing toothpastes. However, replacing triclosan by triclosan/βCD/CMC complex resulted in about 80% increase in the AUC. Furthermore, the duration of the antibacterial effect was improved significantly upon replacing triclosan with the triclosan/βCD/CMC complex. Thus, formulation of triclosan in the toothpaste as a triclosan/βCD/CMC complex improves significantly the substantivity of triclosan in the mouth. The minimum inhibitory concentration (MIC) of triclosan versus a variety of oral bacteria is $\leq$10 ppm.[8,14]

Discussion

Through cyclodextrin complexation it is possible to increase the aqueous solubility of lipophilic, water-insoluble drugs, and other lipophilic compounds, without changing their molecular structure. That is, the cyclodextrins do not affect their intrinsic abilities to permeate into lipophilic biological membranes or interact with pharmacological receptors. The cyclodextrin molecules are relatively large (molecular weight ranging from almost 1000 to over 1500), with a hydrated outer surface, and under normal conditions, cyclodextrin molecules will only permeate biological membranes with considerable difficulty.[15,16] It is thought that cyclodextrins act as true carriers by keeping hydrophobic molecules in solution and delivering them to the surface of a lipophilic biological membrane, e.g., the oral mucosa, where they partition into the membrane.[11,16,17] The relatively lipophilic membrane has low affinity for the hydrophilic cyclodextrin molecules, and therefore they remain in the aqueous membrane exterior, e.g., the aqueous mucus layer or saliva. However, simply adding cyclodextrins to aqueous dentifrice formulations will not automatically result in enhanced triclosan penetration through the aqueous mucus layer into the lipophilic mucosa. Frequently, formation of cyclodextrin complexes results in decreased availability of an antibacterial agent.[16] Addition of small amounts of water-soluble polymers to aqueous cyclodextrin solution and heating increase the cyclodextrin complexation of lipophilic, water-insoluble compounds. The polymers do not only increase the complexation but also increase the availability of the compound in the cyclodextrin-containing formulation.[12,18] Furthermore, in the present formulation, addition of the ionized CMC prevented the formation of association colloids, resulting in clear triclosan cyclodextrin solutions. It is well-known that the polymers, such as carbohydrates, form complexes with mono- and oligosaccharides as well as with numerous other compounds.[19] Such interactions will influence the physicochemical properties of both the polymers and the saccharides. For example, carbohydrates are known to enhance the solubilizing abilities of surfactants.[12] In this present study the polymers enhanced the triclosan release rate from cyclodextrins (Figure 4) and the triclosan retention in the buccal area (Figure 7). Macromolecules, such as CMC, and their complexes are washed more slowly from biological surfaces than comparable smaller molecules. This could explain, at least partly, the enhanced triclosan retention observed when the simple triclosan/βCD complex in the toothpaste is replaced by the triclosan/βCD/CMC complex.

The availability of triclosan in the silica-based toothpaste formulation was optimized through a series of solubility studies in aqueous cyclodextrin solutions as well as through a series of triclosan release studies from the toothpaste through a cellophane membrane. Cyclodextrin formed 1:1

complexes with βCD and its derivatives. The availability of triclosan (i.e., the triclosan release rate) was improved significantly in the toothpaste formulation although the triclosan/βCD complex has limited solubility in pure aqueous solutions. This enhanced availability could be due to the solubilizing effects of the surfactants used in the formulation. Through addition of the water-soluble polymer CMC, it was possible to reduce the amount of βCD in the formulation by as much as 60% without affecting the triclosan availability (i.e., the release rate from the toothpaste). The result was a silica-based toothpaste containing 0.28% (w/w) triclosan and only 3.0% (w/w) βCD, or only 30−50 mg of βCD per brushing.

It has been suggested that the salivary concentration decline of an agent, such as triclosan, after using a dentifrice containing the agent follows first-order kinetics which can be described by the following equation:[20−22]

$$C_t = C_0 e^{-(Ft/V)} \qquad \text{(eq 1)}$$

where C_t is the concentration of the agent at time t, C_0 is the initial concentration of the agent (i.e., the concentration at t equal to zero), F is the saliva flow rate, and V is the volume of saliva in the mouth. Other investigators have fitted triclosan salivary elimination to a two-phase model (i.e., a two-compartment open model):[2,8]

$$C_t = Ae^{-\alpha t} + Be^{-\beta t} \qquad \text{(eq 2)}$$

where the initial concentration of dissolved triclosan is the sum of A and B (i.e., $C_0 = A + B$), and α and β are hybrid first-order rate constants for the distribution phase and elimination phase, respectively. The distribution phase represents the rapid initial decline in the salivary triclosan concentration due to simultaneous (a) adsorption and absorption of the lipophilic triclosan to and into the oral mucosa, plaque, and other intraoral sites, and (b) triclosan elimination with saliva as described by eq 1. The elimination phase represents the somewhat slower decline in the salivary triclosan concentration after equilibrium has been reached between triclosan in saliva and triclosan in the various intraoral sites. According to both models, high initial concentration of triclosan dissolved in saliva should result in high oral substantivity. However, it has been shown that the concentration of triclosan at the site of biological action (i.e., in the oral mucosa or plaque) is more relevant to clinical activity than the salivary concentration profiles.[4] Triclosan must be in a hydrophilic, water-soluble form to be able to penetrate the aqueous mucous layer to the surface of the mucosa (and other intraoral sites), but at the same time triclosan must be in a lipophilic form to be able to partition into mucosa and its sites of action. High initial salivary concentration of available (i.e., dissolved) triclosan (or more precisely, high triclosan activity) will enhance triclosan delivery to the various oral triclosan reservoirs and its sites of action.

Formulating triclosan as a water-soluble triclosan/βCD/CMC complex resulted in high initial triclosan concentration and a high oral triclosan substantivity. At 10 min the triclosan salivary concentration was determined to be 13 ppm when the toothpaste contained free triclosan (i.e., without cyclodextrin), which is comparable to reported triclosan salivary levels after brushing with other triclosan-containing dentifrices[8] but at the same time point the triclosan concentration was 30.0 ppm when the toothpaste contained the triclosan/βCD/CMC complex. The profile could be fitted to a two-phase model with a short distribution phase ($t_{1/2} \approx 0.3$ h) and extended elimination phase ($t_{1/2}$ between 1 and 2 h). The duration of activity, based on MIC of 10 ppm, was extended from about 0.7 h (free triclosan) to about 1.5 h (triclosan/βCD/CMC complex). Thus, replacing free triclosan with the triclosan/βCD/CMC complex resulted in almost 3-fold increase in C_0 and about 2-fold increase in the duration of activity.

Received July 16, 1999. Final revised manuscript received September 28, 1999. Accepted for publication October 5, 1999.

Abstract □ The objective of this study was to identify the important factors that determine plasma concentrations of diphenhydramine (DPHM) in the mother and the fetus after maternal as well as fetal steady-state drug administration. Inter-relationships were evaluated between maternal and fetal placental and nonplacental clearances, plasma protein binding, and steady-state plasma concentrations of DPHM among data obtained from 18 pregnant sheep during late gestation. The major determinant of plasma DPHM concentrations in the mother after maternal as well as fetal administration appears to be maternal plasma protein binding and maternal nonplacental clearance. In contrast, the major determinant of fetal plasma DPHM concentrations after maternal drug administration was the extent of fetal first-pass hepatic drug uptake from the umbilical vein. However, after fetal drug administration, the fetal plasma concentrations were related to the extent of fetal plasma protein binding and fetal placental and nonplacental clearances. The index of fetal-to-maternal placental drug transfer after fetal drug administration (steady-state maternal-to-fetal plasma concentration ratio) was related to steady-state fetal plasma unbound fraction and fetal placental and nonplacental clearance. However, this index was not related to the magnitude of the factors operating on the maternal side of the placenta such as maternal plasma protein binding and maternal nonplacental clearance. This might indicate a lack of complete equilibration of the unbound drug concentrations on the two sides of the placenta at the exchange site.

Introduction

Although the kinetics of placental transfer of most drugs appear to follow the principles of simple diffusion across biological membranes, the extent and time course of fetal drug exposure are not related solely to the ease of placental drug transfer. Instead these are the result of a complex interplay between the kinetics of placental drug transfer as well as many other factors related to maternal and fetal components of the pregnant unit. These include the relative extent of maternal and fetal plasma protein binding of the drug, the efficiency of maternal and fetal drug elimination via metabolism or renal excretion, and recirculation of the drug between amniotic and allantoic fluid compartments and the fetal circulation.[1,2] The measurement of area under the fetal plasma concentration vs time curve (AUC) or steady-state concentration after maternal drug administration, although a clinically useful index of the extent of fetal drug exposure, does not provide any information about the different factors determining its magnitude. The computation of maternal and fetal placental and nonplacental clearances according to a two-compartment pharmacokinetic model after separate maternal and fetal steady-state drug administration provides a more detailed insight into various factors determining fetal drug exposure (Figure 1).[3] This pharmacokinetic modeling essentially partitions the complex array of these pharmacokinetic factors into three main categories, i.e., factors related to the placenta (maternal and fetal placental clearance), the mother (maternal nonplacental clearance), and the fetus (fetal nonplacental clearance). Thus, it is possible to separately examine the effect of various physicochemical (e.g., drug lipophilicity and pK_a, etc.), and maternal and fetal biological variables (e.g., plasma protein binding, placental blood flows, drug metabolism capacity) on these three categories of pharmacokinetic factors and the resultant effects on fetal drug exposure. This makes it feasible to determine the relative importance of each pharmacokinetic variable in determining fetal exposure to a particular drug, and to make comparisons among different drugs in terms of the most important factor(s). However, a detailed analysis of the importance of various placental, maternal, and fetal pharmacokinetic factors in determining fetal drug exposure has rarely been performed for any drug.

Diphenhydramine or 2-(diphenylmethoxy)-*N*,*N*-dimethylamine (DPHM) is a potent histamine H1-receptor antagonist. It has been widely used during human pregnancy for the treatment of nausea and vomiting, insomnia, allergic rhinitis, and common coughs and colds. Previous studies in our laboratory, using chronically instrumented pregnant sheep, demonstrated that DPHM readily crosses the ovine placenta and is eliminated from the fetus via both placental and nonplacental routes.[4] In continuation of these studies, we have utilized DPHM as a model high-clearance drug that undergoes rapid and extensive placental transfer, to examine the factors affecting different aspects of maternal–fetal drug disposition of this class of compounds. This includes the study of comparative maternal–fetal drug

clearance,[4] *in utero* fetal hepatic drug uptake and its relation to fetal drug clearance,[5] and *in utero* functional capacity of fetal drug metabolism pathways compared to the mother.[6] As part of these studies, we have determined DPHM placental and nonplacental clearances in 18 pregnant sheep during the final two weeks of their gestation. In the current study, we have retrospectively examined the inter-relationships between maternal and fetal clearances (placental and nonplacental) and plasma concentrations of DPHM among the data obtained from the above three studies in order to identify the most important factor(s) determining these concentrations after maternal as well as fetal drug administration.

Experimental Section

Animals and Surgical Preparation—A total of 18 pregnant sheep were employed in these studies. All studies were approved by the University of British Columbia Animal Care Committee, and the procedures performed on sheep conformed to the guidelines of the Canadian Council on Animal Care. The detailed surgical procedures employed have already been described in previous publications.[4–6] Briefly, 18 pregnant Dorset Suffolk crossbred ewes, with a maternal body weight of 76.9 ± 12.6 kg (mean ± SD), were surgically prepared between 115 and 129 days gestation (term ~145 days). Surgery was performed aseptically under halothane (1–2%) and nitrous oxide (60%) anesthesia (balance O_2), following induction with intravenous (iv) sodium pentothal (1 g) and intubation of the ewe. Polivinyl or silicone rubber catheters (Dow Corning, Midland, MI) were implanted in both fetal femoral arteries and lateral tarsal veins and a maternal femoral artery and vein. Catheters were also implanted in the fetal carotid artery ($n = 4$), common umbilical vein ($n = 2$), fetal trachea ($n = 18$), fetal urinary bladder (via a suprapubic incision, $n = 5$), and the amniotic cavity ($n = 18$) for purposes unrelated to this manuscript. In some animals, electrodes (Cooper Corporation, Chatsworth, CA) were implanted biparietally on the dura to record the fetal electrocorticogram (ECoG). In four of the animals, a transit-time 4SB blood flow transducer (Transonic Systems, Inc., Ithaca, NY) was placed around the common umbilical artery to measure umbilical blood flow. The catheters, electrodes, and flow transducer cables were tunneled subcutaneously and exteriorized via a small incision on the flank of the ewe and were stored in a denim pouch when not in use. All catheters were flushed daily with approximately 2 mL of sterile 0.9% sodium chloride containing 12 units of heparin/mL to maintain catheter patency. Intramuscular injections of ampicillin 500 mg were given to the ewe on the day of surgery and for 3 days postoperatively. Ampicillin (500 mg) was also given via the amniotic cavity immediately following surgery and daily thereafter. Following surgery, animals were kept in holding pens with other sheep and were given free access to food and water. The sheep were allowed to recover for 4–8 days prior to experimentation.

Protocol—All experiments were conducted between 124 and 140 days gestation. A total of 31 experiments were conducted in 18 pregnant sheep. Each animal received one of the following:

(1) A 90 min separate maternal and fetal steady-state DPHM (DPHM hydrochloride, Sigma Chemical Co., St. Louis, MO) infusion with an appropriate washout period between ($n = 8$, experiments from ref 4).

(2) A 6 h separate maternal and fetal steady-state DPHM infusion with an appropriate washout period between ($n = 3$, experiments from ref 6).

(3) A 6 h separate maternal and fetal steady-state [$^2H_{10}$]DPHM (a deuterium labeled analogue of DPHM synthesized in our laboratory; Tonn et al., 1993) infusion with an appropriate washout period between ($n = 2$, experiments from ref 6).

(4) A 6 h simultaneous steady-state infusion of DPHM to the mother and [$^2H_{10}$]DPHM to the fetus ($n = 5$, experiments from ref 5).

The doses were prepared in sterile water for injection and were sterilized by filtering through a 0.22 μm nylon syringe filter (MSI, Westboro, MA) into a capped empty sterile injection vial.

Drug (DPHM or [$^2H_{10}$]DPHM) was administered to the mother in each experiment as a 20 mg iv loading dose over 1.0 min, followed immediately by an infusion at 670 μg/min via the maternal femoral vein. In fetal experiments, a 5.0 mg iv loading dose of DPHM or [$^2H_{10}$]DPHM was given via the fetal lateral tarsal vein over 1.0 min, followed by an infusion of the same compound at 170 μg/min. Simultaneous serial blood samples were collected from the fetal (1.5 mL) and maternal (3.0 mL) femoral arterial catheters. Fetal femoral arterial samples (0.5 mL) were also collected at the same time intervals for blood gas analysis and measurement of glucose and lactate concentrations. All fetal blood removed for sampling was replaced at intervals during the experiment by an equal volume of maternal blood obtained prior to the start of the experiment. Amniotic and tracheal fluid (2.0 mL) and fetal (5.0 mL) and maternal urine (10.0 mL) samples were also collected in some animals to examine the excretion of DPHM into these fluids; these data have been reported previously.[4–6]

Maternal and fetal blood samples collected for drug analysis were placed into heparinized Vacutainer tubes (Becton-Dickinson, Rutherford, NJ), gently mixed, and then centrifuged at 2000*g* for 10 min. The plasma supernatant was removed and placed into clean borosilicate test tubes with poly(tetrafluoroethylene) (PTFE)-lined caps. Amniotic fluid and urine samples were also placed into clean borosilicate test tubes. All samples were stored frozen at −20 °C until the time of analysis.

Physiological Recording and Monitoring Procedures—From at least 24 h prior to and at least 24 h after each infusion period, amniotic pressure, fetal tracheal and femoral arterial pressures, and fetal heart rate were continuously monitored. In some animals with implanted cortical electrodes and fetal bladder catheters, fetal electrocortical activity and urine flow rate were also measured. Some of these data have been reported separately.[7]

Fetal blood pH, P_{O_2}, and P_{CO_2} were measured using an IL 1306 pH/blood gas analyzer (Allied Instrumentation Laboratory, Milan, Italy). Blood O_2 saturation and hemoglobin concentration were determined using a Hemoximeter (Radiometer, Copenhagen, Denmark). Blood glucose and lactate concentrations were determined with a 2300 STAT plus glucose/lactate analyzer (Y.S.I. Inc. Yellow Springs, OH). All of these fetal blood gases and metabolite concentrations have been reported in our earlier publications and were within the normal range observed in our and other laboratories at this stage of gestation in fetal sheep.[4–6]

Protein Binding of DPHM and [$^2H_{10}$]DPHM in Fetal and Maternal Plasma—The plasma protein binding/unbound fraction of DPHM (or [$^2H_{10}$]DPHM) was measured ex vivo in pooled fetal and maternal steady-state plasma samples using an equilibrium dialysis procedure as described by Yoo et al. (1993).[4] Maternal plasma protein binding was measured in plasma samples obtained during maternal drug infusion, whereas fetal plasma protein binding was measured in plasma samples obtained during fetal drug infusion.

Drug Analysis—The concentrations of DPHM in all biological fluids collected were measured using either a gas chromatographic nitrogen phosphorus detection method[8] (studies in ref 4) or by a GC-MS assay capable of measuring both DPHM and [$^2H_{10}$]DPHM simultaneously[9] (studies in refs 5 and 6). Both these assays have been shown to be comparable to each other with a similar limit of quantitation (2.0 ng/mL).[9]

Pharmacokinetic Analysis—The maternal and fetal steady-state arterial plasma DPHM and [$^2H_{10}$]DPHM concentration data were treated according to a two-compartment open model in order

to estimate the placental and nonplacental clearance parameters of DPHM (or [$^2H_{10}$]DPHM when present) in the ewe and fetus (Figure 1). This model assumes steady-state plasma concentrations and drug elimination from both the maternal and fetal compartments. The equations to estimate placental and nonplacental clearance parameters have been previously described.[3] Pharmacokinetic modeling of the data, wherever necessary, was carried out using the nonlinear least-squares fitting program ADAPT II.[10]

Statistical Analysis—All values are reported as mean ± SD. All linear correlational analyses were performed by computing Pearson correlation coefficient (r). The significance level was $p < 0.05$ in all cases. Fetal weight *in utero* at the time of experimentation was estimated from the weight at birth and the time interval between the experiment and birth.[11]

Results

The average maternal body weight was 76.9 ± 12.6 kg, and the estimated fetal body weights on the day of maternal and fetal DPHM (or [$^2H_{10}$]DPHM) infusion were 2.61 ± 0.61 and 2.56 ± 0.54 kg, respectively.

The mean gestational age on the day of maternal and fetal steady-state DPHM infusion experiments was 130.9 ± 4.1 (range 124−140) and 130.4 ± 3.7 (range 125−136) days, respectively, and these were not statistically different (paired t-test, $p > 0.05$). Average washout period between maternal and fetal DPHM infusion experiments was 2.4 ± 2.2 d. Table 1 presents maternal and fetal steady-state plasma unbound fractions and steady-state total plasma concentrations of DPHM in 18 pregnant sheep. Maternal and fetal clearances (total body, placental and nonplacental clearances) of the drug in these 18 sheep calculated using the two-compartment pharmacokinetic model are presented in Table 2. The average maternal plasma unbound fraction (M-UF) was significantly lower compared to the average fetal plasma unbound fraction (F-UF, unpaired t-test, $p < 0.0001$). Maternal and fetal steady-state unbound plasma drug concentrations were calculated by multiplying the appropriate total plasma concentration

[a] CL_{mm}, Maternal total clearance; CL_{mf}, maternal placental clearance; CL_{mo}, maternal nonplacental clearance; CL_{ff}, fetal total clearance; CL_{fm}, fetal placental clearance; CL_{fo}, fetal nonplacental clearance. [b] Per kg maternal weight. [c] Per kg estimated fetal weight at the time of fetal experiment.

with the corresponding plasma unbound fraction. The average maternal and fetal steady-state unbound plasma drug concentrations after maternal administration (C^u_m and C^u_f, respectively) were 25.1 ± 11.4 (range 8.6−45.6) and 12.0 ± 8.6 (range 1.9−40.4) ng/mL, respectively; these same unbound concentrations after fetal drug infusion (C^u_m' and C^u_f', respectively) were 3.9 ± 1.8 (range 0.9−7.2) and 89.3 ± 32.0 (range 46.1−166.2) ng/mL, respectively.

All clearances, except CL_{mm} and CL_{mo}, are normalized to the estimated fetal body weight on the day of experiment; CL_{mm} and CL_{mo} are normalized to maternal body weight. Since CL_{mo} and CL_{mf} are normalized differently, their sum does not equal CL_{mm} in Table 2. All fetal clearances were significantly higher compared to the corresponding maternal clearance parameters (unpaired t-test, $p < 0.0001$ in all cases), as reported previously.[4−6] However, the contribution of CL_{fo} to CL_{ff} (39.5 ± 10.7%) was significantly lower compared to that of CL_{mo} to CL_{mm} (96.3 ± 2.8%) (unpaired t-test, $p < 0.0001$).

Inter-Relationships between Maternal and Fetal Plasma DPHM Concentrations, Unbound Fractions and the Two-Compartment Model Clearance Estimates—DPHM concentration in maternal plasma after maternal drug infusion (C_m) exhibited a highly significant negative linear relationship with M-UF of the drug (Figure 2A). In contrast, fetal plasma concentration after maternal infusion (C_f) was not related significantly to either maternal ($r = 0.1751$, $p = 0.5$) or fetal ($r = -0.3676$, $p > 0.1$) plasma unbound fraction (data not shown). Analogous to the maternal situation, DPHM concentration in the fetal plasma after fetal drug infusion (C_f') was inversely related to F-UF (Figure 2B). Also, maternal plasma DPHM concentration after fetal drug infusion (C_m') was not related to F-UF ($r = -0.0966$, $p > 0.5$; data not shown), whereas its negative relationship with M-UF was near statistical significance ($r = 0.4612$, $p = 0.05$, data not shown). The data in Figure 3 demonstrate the relationships between maternal and fetal total body clearances (CL_{mm} and CL_{ff}, respectively) and respective steady-state plasma unbound fractions of DPHM. CL_{ff} appears to be linearly related to F-UF whereas the relationship of CL_{mm} with M-UF is closer

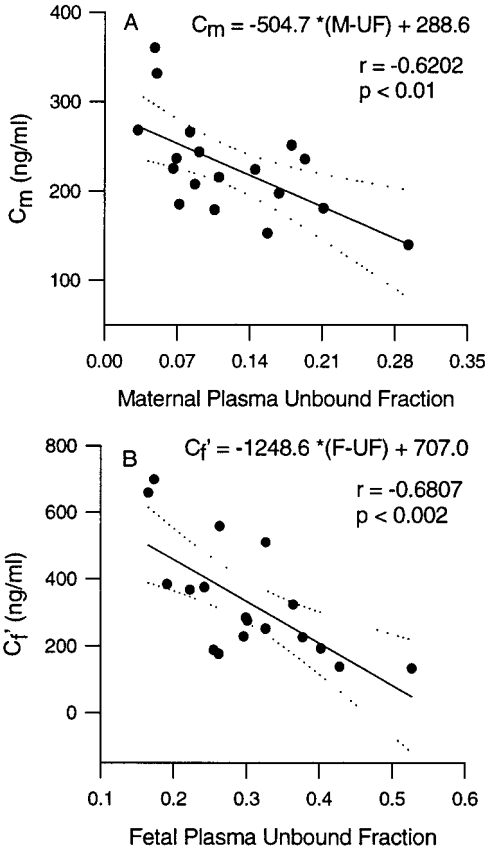

Figure 2—Relationships between (A) maternal unbound fraction and steady-state plasma concentration of the drug after maternal drug administration, and (B) fetal unbound fraction and steady-state plasma concentration of the drug after fetal drug administration. Scatter points are the experimental data in different sheep. The regression line (solid) and the 95% confidence interval (dotted) are also shown.

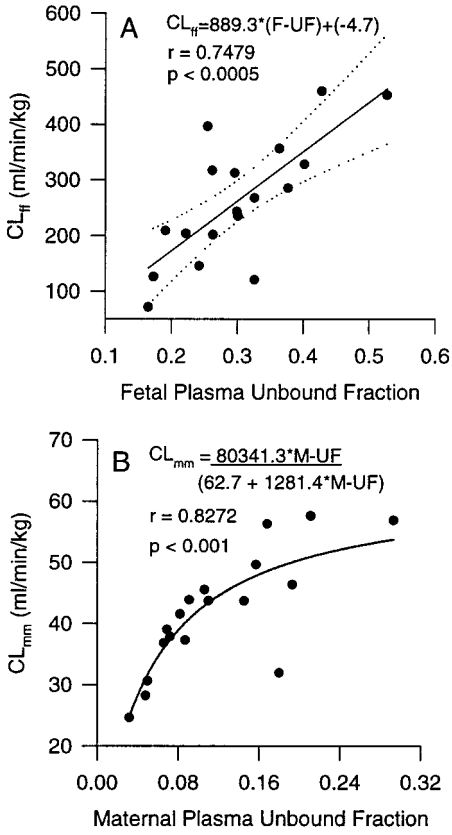

Figure 3—Relationships between fetal and maternal DPHM clearances and the corresponding plasma unbound fractions of the drug. (A) CL_{ff} vs F-UF; (B) CL_{mm} vs M-UF. The CL_{mm} vs M-UF relationship was analyzed according to the well-stirred model of organ clearance. M-UF: steady-state maternal plasma unbound fraction; F-UF: steady-state fetal plasma unbound fraction; CL_{mm}: maternal total body clearance; CL_{ff}: fetal total body clearance.

to a hyperbola. Hence, the data in Figure 3B were fitted with a well-stirred model of organ drug elimination.[12]

To determine the influence of various two-compartment clearance terms on maternal and fetal plasma DPHM concentrations after maternal or fetal drug administration, different concentration vs clearance relationships were analyzed according to the simple steady-state clearance model of the form: $CL = I_o/C_{ss}$. The majority of the interanimal variability in C_m was reflected in the estimated value of total CL_{mo} (not weight-normalized, because the total clearance is the actual determinant of plasma concentrations) as demonstrated by an excellent fit of the concentration vs clearance data to this model (Figure 4A). However, C_m was not significantly related to the other three clearance parameters of the two-compartment model (CL_{mf}, CL_{fo}, and CL_{fm}). Similarly, the majority of interanimal variability in C_f was reflected in the final estimates of CL_{mf} (Figure 4B). In contrast, when the drug was administered to the fetus, the interanimal variability in C_f' was due to relatively equal contributions from the magnitude of CL_{fo} and CL_{fm} (Figures 4C,D). Also, in contrast to the situation with C_f above (Figure 4B), the C_m' concentration was not related to the magnitude of CL_{fm} (Figure 4E). Instead the variation in C_m' among different animals was best explained by the differences in their maternal nonplacental clearance (Figure 4F).

Relationships between the Indices of Fetal Drug Exposure/Placental Transfer and Plasma Protein Binding—The average C_f/C_m ratio based on total plasma drug concentrations was 0.20 ± 0.14. The same ratio calculated using unbound drug concentrations was significantly higher (0.50 ± 0.30, paired *t*-test, $p < 0.0001$). Plasma total drug C_f/C_m ratio was not significantly correlated with maternal or fetal nonplacental clearance or F-UF; its positive relationship with M-UF was only near statistical significance ($r = 0.4029$, $p < 0.1$, data not shown). The mean C_m'/C_f' ratios during fetal drug administration based on total and unbound plasma drug concentrations were 0.14 ± 0.08 and 0.05 ± 0.02, respectively, the latter being significantly lower (paired *t*-test, $p < 0.0001$). In contrast to the C_f/C_m ratio above, the C_m'/C_f' ratio was positively correlated with total (not weight-normalized) CL_{fo} and CL_{fm} (Figures 5A,B), whereas its inverse relationship with total CL_{mo} was only near statistical significance ($r = -0.4138$, $p < 0.1$, data not shown). The C_m'/C_f' ratio also exhibited a highly significant positive relationship with F-UF (Figure 5C) but not with M-UF (data not shown).

Discussion

A number of variables such as the lipophilicity and plasma protein binding of the drug, placental blood flows (uterine and umbilical), the efficiency of maternal and fetal drug elimination/metabolism, and the gestational age of the fetus have been postulated to affect the degree of placental drug transfer and fetal drug exposure.[1,2,13] The influence of many of these variables on the kinetics of placental drug transfer and fetal drug exposure has not been extensively studied under controlled experimental conditions either in vitro or in vivo. Our objective in this study was to examine the role of different factors that determine plasma concentrations of DPHM in the mother and the fetus after maternal as well as fetal drug admin-

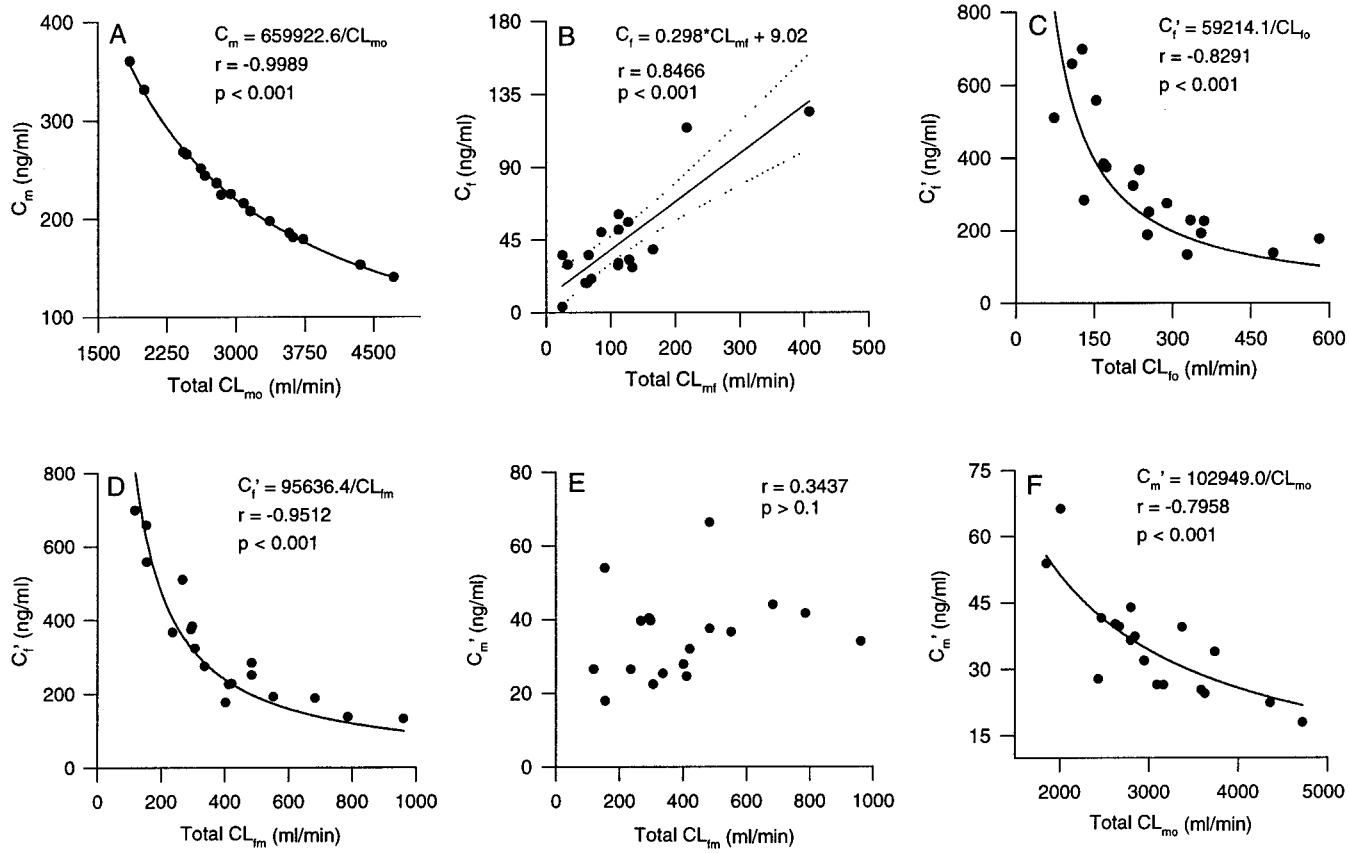

Figure 4—Influence of various clearance parameters of the two-compartment model on different maternal–fetal plasma concentrations. (A) CL_{mo} vs C_m; (B) CL_{mf} vs C_f; (C) CL_{fo} vs C_f'; (D) CL_{fm} vs C_f'; (E) CL_{fm} vs C_m'; and (F) CL_{mo} vs C_m'. All relationships except B and E were analyzed according to the steady-state clearance model, $CL = I_0/C_{ss}$; the solid lines represent the best-fit lines determined by this model. CL_{mo}: maternal nonplacental clearance; CL_{mf}: placental clearance from the mother to the fetus; CL_{fo}: fetal nonplacental clearance; CL_{fm}: placental clearance from the fetus to the mother; C_m': steady-state maternal plasma DPHM concentration after fetal infusion; C_f': steady-state fetal plasma DPHM concentration after fetal infusion.

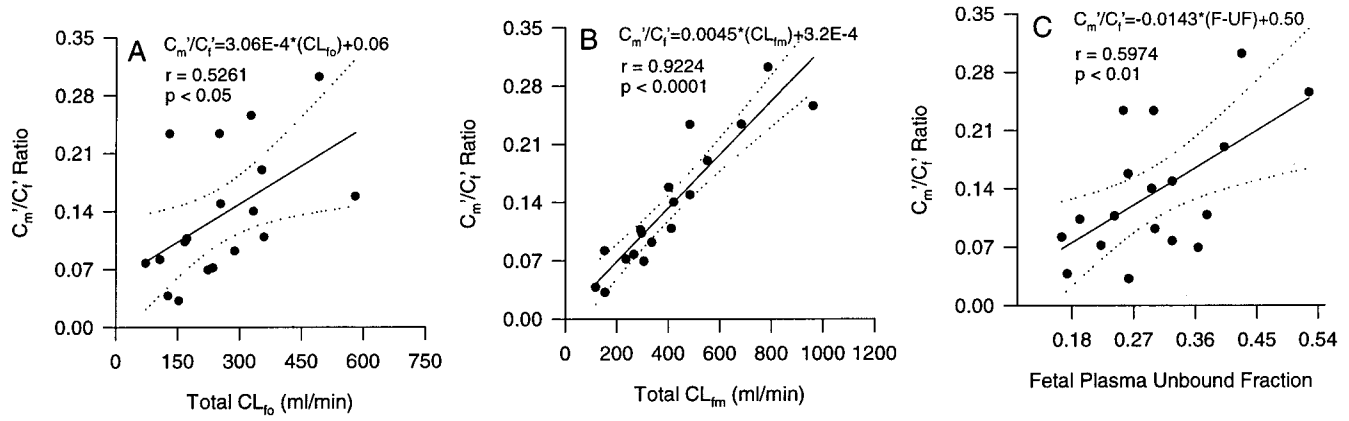

Figure 5—Relationships between the index of steady-state placental drug transfer after fetal administration (C_m'/C_f' ratio) and its determining factors. (A) C_f'/C_m' vs CL_{fo}; (B) C_f'/C_m' vs CL_{fm}; and (C) C_f'/C_m' vs F-UF. Scatter points are the experimental data in different sheep. The regression line (solid) and the 95% confidence interval (dotted) are also shown. CL_{fo}: fetal nonplacental clearance; CL_{fm}: placental clearance from the fetus to the mother; F-UF: steady-state fetal plasma unbound fraction; C_m': steady-state maternal plasma DPHM concentration after fetal infusion; C_f': steady-state fetal plasma DPHM concentration after fetal infusion.

istration in chronically instrumented pregnant sheep during late gestation. We have utilized DPHM as a model high-clearance drug that undergoes rapid and extensive placental transfer in pregnant sheep for assessing the importance of different variables The average CL_{mo} and CL_{fo} (40.2 and 102.3 mL/min/kg, respectively, Table 2) of DPHM are ~70% and 75% of the reported hepatic blood flow in pregnant sheep and late gestation fetal lambs, respectively (60 and 137 mL/min/kg, respectively).[19,20] Similarly, the average CL_{fm} of DPHM (160.7 mL/min/kg, Table 2) is ~80% of the umbilical blood flow estimates in sheep at this stage of gestation (200 mL/min/kg[21]), suggesting a high rate of DPHM placental transfer.

Inter-Relationships between Maternal and Fetal Plasma DPHM Concentrations, Unbound Fractions and the Two-Compartment Model Clearance Estimates—Although the two-compartment model is the simplest pharmacokinetic representation of the maternal–fetal unit, the exact relationships between the four clearance parameters of this model (CL_{mo}, CL_{mf}, CL_{fo}, and CL_{fm}) and various maternal–fetal plasma drug concentrations (C_m, C_f, C_f', C_m') are not directly obvious. Also, the influence of

maternal and fetal plasma drug protein binding in determining these concentrations is generally speculative and has rarely been determined experimentally. The data in Figure 2 indicate that maternal and fetal plasma protein binding is an important determinant of C_m and C_f', respectively, possibly because of its profound effects on respective clearance values (Figure 3). In contrast, C_f was not related to either M-UF or F-UF. When the drug is administered to the mother, it transfers across the placenta and enters the fetal circulation via the umbilical vein. A portion of the umbilical venous blood flow (~30−70%) passes through the fetal liver before reaching the fetal circulation. We have demonstrated earlier that after maternal dosing, a significant fraction of DPHM (~45%) transferred across the placenta and into the umbilical vein is metabolized by the fetal liver and does not reach the fetal circulation.[5] This phenomenon leads to a variable reduction in the "true" C_f and may underlie the lack of any relationship observed above.[5] Thus, for many drugs the major determinant of C_f after maternal drug administration may, in fact, be the extent of this fetal hepatic first-pass uptake/metabolism of the drug rather than maternal or fetal plasma protein binding or systemic clearance. This phenomenon also results in only a limited fetal exposure to DPHM after maternal administration (~20% compared to the mother) despite its high "near flow-limited" placental permeability. Analogous to C_f, the C_m' concentration bore no relationship with F-UF on the other side of the placenta. Instead its negative correlation with M-UF was near statistical significance, indicating that the latter could be a determinant of this concentration via its effects on maternal clearance of the drug (see below).

The estimated value of I_o from the fitting of plasma concentration vs clearance data to the $CL = I_o/C_{ss}$ relationship represents the rate of drug elimination via that clearance route. The data in Figure 4A indicate that CL_{mo} is the major determinant of C_m. This should generally be true for most high clearance drugs because the absolute magnitude of CL_{mo} will be much higher compared to any other clearance parameter (for DPHM, $CL_{mo} = 3058.5 \pm 745.5$ mL/min; $CL_{mf} = 114.5 \pm 88.6$ mL/min; $CL_{fo} = 257.5 \pm 135.0$ mL/min; $CL_{fm} = 408.5 \pm 225.1$ mL/min). The estimated value of the I_o coefficient (659.9 μg/min) relative to the total maternal drug infusion rate (670 μg/min) indicates that ~98% of the drug infused to the mother is eliminated via maternal nonplacental routes. Despite a variable underestimation of C_f, a large amount of variability in the measured C_f was carried over to the CL_{mf} parameter, indicating that this clearance parameter is also almost equally underestimated (Figure 4B). After fetal drug infusion, both CL_{fo} and CL_{fm} appear to be important determinants of C_f' (in contrast to the mother where only CL_{mo} is important, see above). The I_o coefficients of C_f' vs CL_{fo} and C_f' vs CL_{fm} relationships were 59.2 and 95.6 μg/min, respectively, which when added together approach the total fetal drug infusion rate of 170 μg/min. In contrast to the C_f vs CL_{mf} relationship (Figure 4B), the variability in C_m' was not related to the magnitude of estimated CL_{fm} (Figure 4E). This is understandable because, as discussed above, the major determinant of maternal plasma concentrations is expected to be CL_{mo}. Based on this, CL_{mo} does in fact appear to explain the variation in C_m' among different animals (Figure 4F).

Relationships between the Indices of Fetal Drug Exposure/Placental Transfer and Plasma Protein Binding—After maternal drug administration, the steady-state fetal-to-maternal arterial plasma concentration ratio (C_f/C_m) is commonly used as an index of the efficiency of placental drug transfer and fetal exposure to the drug.[1] Different total vs unbound C_f/C_m ratios indicate that the magnitude of total drug C_f/C_m ratio is partly determined by the differences in maternal and fetal plasma protein binding. It has been postulated that fetal plasma protein binding and total fetal clearance are important factors determining the steady-state C_f/C_m ratio and $C_f/C_m = CL_{mf}/[CL_{fm} + CL_{fo}]$.[1−3] However, in our experiments, the total drug C_f/C_m ratio neither exhibited any significant relationship with CL_{fm}, CL_{fo} or CL_{ff} ($CL_{fm} + CL_{fo}$), nor with F-UF. The positive relationship of C_f/C_m with M-UF approached statistical significance despite the errors in C_f, and this was mainly because of a highly significant negative correlation between C_m and M-UF (Figure 2A). The lack of expected relationships among the above variables may also be related to the errors in the measurement of "true C_f" due to fetal first-pass hepatic uptake of the drug present in the umbilical venous blood.[5]

To overcome this problem, we evaluated the factors affecting the analogous index of placental transfer after fetal drug administration, i.e., the C_m'/C_f' ratio. On similar lines to the C_f/C_m ratio above, it can be hypothesized that CL_{fm}, CL_{mo}, and CL_{mf} will be the important factors determining the C_m'/C_f' ratio, i.e., $C_m'/C_f' = CL_{fm}/(CL_{mo} + CL_{mf})$. However, the C_m'/C_f' ratio did not show any relationship with CL_{mf} (again this could be due to errors in CL_{mf} estimates), and its inverse relationship with CL_{mo} (as well as CL_{mm}) was only near statistical significance. Thus, CL_{mo} (and CL_{mm}) does not appear to be an important determinant of the C_m'/C_f' ratio. Total CL_{fo}, total CL_{fm} and F-UF are the important variables determining C_f' (Figures 4C,D and 2B). An increase in any of these variables leads to a fall in C_f' (Figures 4C,D and 2B) and hence to a significant increase in the C_m'/C_f' ratio (Figures 5A−C), C_m' being unaffected by any of these factors. In contrast, the C_m'/C_f' ratio was not significantly related to M-UF. Thus, in this situation, CL_{fo}, CL_{fm}, and F-UF appear to be the most important factors determining the C_m'/C_f' ratio, mainly via their effects on C_f'.

The two-compartment model of the maternal−fetal unit involves both maternal and fetal drug elimination (Figure 1). This system never reaches a state of "true" equilibrium (no net transfer of drug across the placenta) after maternal or fetal drug administration. It, however, does reach a steady-state where the rate of placental drug transfer becomes equal to the rate of drug elimination from the other side. For example, after maternal dosing, fetal drug elimination creates and maintains a maternal-to-fetal gradient of (unbound) drug concentrations, thus leading to a continuous passage of the drug from the mother to the fetus at steady-state. Similarly, during fetal dosing, maternal drug elimination creates a fetal-to-maternal (unbound) drug concentration gradient and leads to continuous passage of the drug from the fetus to the mother. The driving force for placental transfer is this difference in unbound drug concentrations across the placenta. For compounds such as DPHM that are rapidly diffusible across the placenta and whose placental transfer is not limited by low placental permeability, the maternal and fetal unbound concentrations at the site of placental exchange should fully equilibrate with each other and the rate of placental drug transfer should be directly related to the magnitude of unbound concentration gradient and variables affecting this gradient. However, from a number of observations, it appears that at least for fetal-to-maternal placental drug transfer, the factors operating on the opposite side of the placenta have minimal, if any, effect on the kinetics of DPHM placental transport. These observations include (i) the C_m'/C_f' ratio is not affected by CL_{mo} and M-UF, and (ii) the C_m' concentration is not at all influenced by F-UF or CL_{fm}. This is in contrast to the above "unbound drug equilibrium" hypothesis of placental trans-

port where these variables are considered the predominant factors affecting passage of the drug across the placenta. Because of errors in the measurement of C_f, it is not entirely clear if the same phenomenon occurs in the maternal-to-fetal direction of DPHM placental transfer. The presence of this phenomenon in at least the fetal-to-maternal direction may indicate that the unbound concentrations of the drug on both sides of the placenta may not be in complete equilibrium with each other at the site of placental exchange, as is generally assumed. The steady-state concentrations of a number of highly diffusible markers, which are not plasma protein bound and have blood flow limited clearance (e.g., antipyrine, ethanol, D_2O), do not equilibrate completely between the maternal and fetal placental outflow vessels (uterine and umbilical veins, respectively) in the sheep and cow.[14−16] This has generally been attributed to the inefficiencies that exist within the placental vasculature such as partial shunting of the uterine and umbilical blood flows to nonexchange areas of the placenta and to nonplacental tissues, and unequal maternal−fetal perfusion in different regions of the placenta.[15−17] However, the fact that DPHM placental transport is tightly coupled to many variables operating only on one side of the placenta and to none on the other strongly suggests that the assumption of a complete equilibrium between the unbound drug concentrations on the two sides of placenta may not be entirely accurate. The possibility of this phenomenon can be realized by considering the anatomical structure of the epitheliochorial sheep placenta, which has a number of tissue layers separating maternal and fetal blood flows. Also, the available evidence on the geometrical arrangement of maternal and fetal placental blood flows at the placental exchange site suggests a relatively less efficient concurrent (sheep and cow) and pool flow (human) arrangement in many species.[15−17] These factors along with a rapid transit time of the blood through the placental circulation may lead to incomplete equilibration of the unbound drug concentrations in maternal and fetal blood at the placental exchange site even for compounds with very high placental permeability.[18] It remains to be determined if a similar phenomenon exists during drug passage through the hemochorial human placenta which has fewer anatomical tissue layers compared to sheep.

In summary, the major determinant of plasma DPHM concentrations in the mother after maternal as well as fetal administration is maternal plasma protein binding and maternal nonplacental clearance. In contrast, the major determinant of fetal plasma DPHM concentrations after maternal drug administration appears to be the extent of fetal first-pass hepatic drug uptake from the umbilical vein. After fetal drug administration, the fetal plasma concentrations are related to the extent of fetal plasma protein binding and fetal placental and nonplacental clearances. The index of fetal-to-maternal placental drug transfer after fetal administration (steady-state C_m'/C_f' ratio) is related to steady-state fetal plasma unbound fraction and fetal placental and nonplacental clearance. However, this index was not related to the magnitude of the factors operating on the maternal side of the placenta such as maternal plasma protein binding and maternal nonplacental clearance. This might indicate a lack of complete equilibration of the unbound drug concentrations on the two sides of the placenta at the exchange site.

Accepted for publication September 16, 1999.

Abstract □ This experiment was designed to investigate the effect of pretreatment with cocaine and alcohol on cocaine pharmacokinetics and pharmacodynamics. Four groups of rats ($n = 8$ per group) received one of the following pretreatments for two weeks: none, alcohol (10% v/v in drinking water), cocaine (15 mg/kg/day ip), and alcohol+cocaine (10% v/v in drinking water+15 mg/kg/day ip). On the day of the experiment, cocaine was administered (30 mg/kg, ip) to each rat, either alone or in combination with alcohol (5 g/kg, po), in a balanced crossover experimental design. Plasma and brain ECF concentrations of cocaine and its three metabolites: benzoylecgonine, norcocaine, and cocaethylene were assayed by HPLC–UV. The percent change in brain dopamine concentration, mean arterial blood pressure, and heart rate were determined simultaneously. A sigmoid-E_{max} model was used to describe the brain cocaine concentration–neurochemical effect (dopamine) relationship, and an indirect pharmacodynamic response model was used to describe the plasma cocaine concentration–cardiovascular effect relationships. Alcohol pretreatment led to significant increase in cocaine AUC_p, $\alpha_{t1/2}$, and $\beta_{t1/2}$. Cocaine pretreatment significantly increased cocaine bioavailability, absorption rate constant, TBC, and the formation clearance of cocaethylene. Acute alcohol coadministration with cocaine increased cocaine AUC_p and bioavailability, reduced the fraction of cocaine dose converted to benzoylecgonine, and increased the formation of norcocaine. These results indicate that the pharmacokinetics of cocaine, either administered alone or in combination with alcohol, is significantly altered due to prior cocaine and/or alcohol use. Both cocaine and alcohol pretreatments increased the E_{max} for dopamine, with no effect on the EC_{50}. Acute alcohol coadministration with cocaine significantly increased the E_{max} for dopamine and reduced the EC_{50}. Cocaine pretreatment significantly decreased the I_{max} for blood pressure, IC_{50}, and R_{max}. For the heart rate response, both alcohol and cocaine pretreatments significantly increased the IC_{50}, with no effect on I_{max}. These results indicate that both cocaine and alcohol pretreatments as well as acute alcohol coadministration lead to significant alterations in cocaine pharmacodynamics that are due, at least in part, to the changes in cocaine pharmacokinetics. If similar effects occur in humans, chronic cocaine and alcohol abusers may respond differently to cocaine administration compared to naïve users and may be at higher risks of cocaine central nervous system toxicity.

Introduction

Concomitant cocaine and alcohol abuse has been associated with increased incidence of cocaine-related morbidity and mortality.[1] Studies in humans showed that alcohol consumption with cocaine led to significantly higher plasma cocaine and norcocaine concentrations and the formation of the pharmacologically active metabolite cocaethylene, whereas the concentrations of benzoylecgonine and ecgonine methyl ester were reduced.[2] In animal experiments, alcohol coadministration increased the plasma and brain cocaine concentrations and modified cocaine metabolic profile similar to what was observed in humans.[3,4] Results obtained from awake rats demonstrated that the changes in the neurochemical and cardiovascular responses to cocaine when administered with alcohol can be explained, at least partially, by the changes in cocaine pharmacokinetics and the contribution of cocaine metabolites to the pharmacological effects of cocaine.[5,6] These findings clearly indicate that factors that can alter cocaine pharmacokinetics and metabolic profile can lead to changes in the neurochemical and cardiovascular responses to cocaine administration.

Prior exposure to cocaine and alcohol has also been shown to alter cocaine pharmacokinetics, pharmacodynamics, and toxicities. We have reported previously that pretreating Wistar rats with 10% alcohol in drinking water for two weeks significantly slows the elimination rate of both cocaine and cocaethylene.[3] Several studies have demonstrated that 2−3 weeks of alcohol consumption enhances striatal [^{3}H]dopamine release and D_2 receptor binding in both the nucleus accumbens (N ACC) and striatum.[7−9] A human study has shown that alcohol pretreatment increases the preference for cocaine over monetary reinforcement, and that combined cocaine and alcohol abuse increases the risk of cardiac toxicity compared to cocaine alone.[10] In male mice, alcohol pretreatment in liquid diet for 5 days potentiates cocaine-induced hepatotoxicity, an effect dependent on the induction of the hepatic cytochrome P-450 mixed function oxidases.[11] Similar effects have also been observed in humans.[12] Cocaine absorption from the abdominal cavity to the systemic circulation after ip administration to rats is significantly faster after repeated cocaine administration.[13] Intermittent cocaine pretreatment for 1−9 days to laboratory animals augments brain extracellular fluid (ECF) dopamine, including that of the N ACC, which leads to enhancement of locomotor activity and stereotypy (i.e., sensitization).[14−16] In vitro studies in rodents have shown that cocaine pretreatment markedly induces cytochrome P-450 enzymes that are responsible for norcocaine formation.[17,18] Results from these investigations indicate that cocaine pharmacokinetics in individuals who have used cocaine and/or alcohol previously may be different from that in naïve users. This implies that alcoholics and cocaine addicts may respond differently to cocaine administration, and this may have significant clinical implications.

The primary objective of this study was to investigate the effect of alcohol, cocaine, and combined alcohol and cocaine pretreatments on the pharmacokinetic and pharmacodynamic interactions between cocaine and alcohol. This was achieved by studying cocaine absorption, brain distribution, elimination, and metabolism when cocaine was given alone and in combination with alcohol to rats that were pretreated with alcohol, cocaine, or cocaine+ alcohol. The neurochemical and cardiovascular responses to cocaine administration were monitored simultaneously during the pharmacokinetic studies. The neurochemical response was assessed by determining the changes in brain N ACC dopamine level, while the cardiovascular responses were monitored by measuring the changes in the mean arterial blood pressure and heart rate. The information obtained from this study can help to identify and predict pharmacokinetic factors that may lead to increased risks of toxicity with combined cocaine and alcohol abuse. This is the first report to investigate the effect of pretreatment with cocaine and alcohol on cocaine pharmacokinetics and pharmacodynamics. The possible interactions among these pretreatments and acute alcohol coadministration were also examined.

Materials and Methods

Chemicals and Reagents—Cocaine hydrochloride and cocaethylene hydrochloride were purchased from Research Biochemicals International (Natick, MA). Bupivacaine and sodium fluoride were obtained from Sigma Chemical (St. Louis, MO). Chloroform was supplied by Burdick and Jackson Laboratory (Muskegon, MI). The dehydrated 200 proof ethyl alcohol (USP) was purchased from McCormick Distilling (Weston, MO). All solvents were of high performance liquid chromatographic (HPLC) grade, and all chemicals were of analytical reagent (AR) grade.

Cocaine and Alcohol Pretreatments—Male Wistar rats (250−350 g, Simonsen Laboratories, Gilroy, CA) were maintained one per cage on a 12-h light/dark cycle with Purina chow pellets and water ad libitum for 7 days before use in the experiments. Water and food consumption and body weight were recorded daily. Thirty-two rats were assigned randomly to one of the following four pretreatment groups (n = 8 rats per group): control (no pretreatment), alcohol pretreatment, cocaine pretreatment, and combined cocaine and alcohol pretreatment. For the alcohol pretreatment group, the rats were allowed free access to 10% alcohol in water (v/v) as their sole source of drinking water. Cocaine pretreatment was accomplished by injecting the rats with 15 mg/kg cocaine ip once daily for 14 days, and the rats were allowed free access to drinking water. In the combined cocaine and alcohol pretreatment group, the rats were allowed free access to 10% alcohol in water (v/v) as their sole source of drinking water and were injected with 15 mg/kg cocaine ip once daily for 14 days. During the entire two weeks of pretreatments, the rats in all groups were maintained one per cage on a 12-h light/dark cycle with Purina chow pellets ad libitum. Water and food consumption and rat body weight were recorded daily. The pretreatment duration (14-day) and the daily doses of cocaine (15 mg/kg/day, ip) and alcohol (~3 g/kg/day, po) for the pretreatments were chosen based on the results of previous studies.[3,9,13−15,19]

Animal Care and Preparation—All animal preparation procedures were in accordance with the *Guide for the Care and Use of Laboratory Animals* (National Institutes of Health Publication No. 85-23, revised 1985) and were approved by the institutional animal care and use committee at Washington State University. Details of the animal preparation procedures were described previously.[20] Briefly, after 7 days of pretreatment, the brain microdialysis guide cannula was implanted in the rat brain followed, 7 days later, by femoral vein and artery cannulation, and abdominal and gastric catheter implantation. The brain microdialysis probe was inserted into the guide cannula to replace the dummy probe, and the targeted area was the N ACC. The rats from each of the four pretreatment groups were given 30 mg/kg ip cocaine alone and in combination with 5 g/kg alcohol in a crossover experimental design with 48-h washout period between treatments.

Pharmacokinetic and Pharmacodynamic Studies—On the day of the experiment, one of the femoral artery cannulae was connected to a pressure transducer linked to a blood pressure analyzer (Digi-Med Model 190, Micro-Med, Louisville, KY) for monitoring the mean arterial blood pressure and heart rate. The signals from the analyzer were collected, updated, and averaged every one minute by a system integrator (Digi-Med Model 200, Micro-Med, Louisville, KY) and were stored in a computer for subsequent analysis. Meanwhile, the brain microdialysis effluent was collected every 20 min (at 1 μL/min) into HPLC autosampler vials containing 20 μL of dopamine mobile phase and vortex-mixed. Five microliters of this mixture was injected immediately into an HPLC equipped with an electrochemical (EC) detector for dopamine analysis. Once a stable dopamine baseline was achieved, the rats were treated with either 10 g/kg normal saline or 5 g/kg alcohol (50% v/v in normal saline) through the gastric catheter. Twenty minutes later, 30 mg/kg of cocaine was administered through the abdominal catheter. After drug administration, 10 blood samples, each of 0.2 mL were collected through the femoral artery cannula at 2, 5, 10, 15, 30, 60, 90, 120, 180, 240 min in heparin and sodium fluoride pretreated vacutainers to avoid cocaine and cocaethylene hydrolysis by plasma carboxylesterases. Plasma samples were obtained by centrifugation and were stored at −20 °C until analyzed for cocaine and its metabolites by HPLC with ultraviolet (UV) detection. The effluent of the microdialysis probe was continuously collected every 20 min throughout the experiment into HPLC autosampler vials containing 20 μL of dopamine mobile phase (pH 4). The purpose of this treatment was to maintain dopamine, cocaine, and its metabolites under acidic condition to reduce their spontaneous oxidation and hydrolysis. After mixing the vial content, 5 μL was injected immediately into the HPLC-EC system for dopamine analysis, and the rest was analyzed for cocaine and its metabolites by HPLC−UV. The mean arterial blood pressure and the heart rate were continuously monitored during the entire experiment.

After the above two treatments, the rats from each of the four pretreatment groups received cocaine iv (6.8 mg/kg) and cocaethylene iv (3.9 mg/kg) through the femoral vein cannula with a 24-h washout period between the treatments. The purpose of the iv cocaine administration was to determine the systemic bioavailability for ip cocaine. The pharmacokinetic parameters for cocaethylene obtained after iv administration in this study and those for benzoylecgonine and norcocaine obtained from one of our previous studies were used to determine the effect of alcohol on cocaine metabolic profile.[6] This was accomplished by comparing the fraction of cocaine dose converted to each of the metabolites when ip cocaine was administered either alone or in combination with alcohol, in each of the pretreatment groups.

Analytical Methods—*Cocaine and Its Metabolites*—Plasma and microdialysis probe effluent were analyzed for cocaine and its metabolites using the method developed in our laboratory.[21] The actual concentrations of cocaine and its metabolites in the brain ECF were determined from the probe effluent concentration after correcting for the probe recovery which was determined from an in vitro calibration experiment.[22]

Dopamine—The microdialysis probe effluent was injected directly into an HPLC system equipped with EC detector for dopamine analysis immediately after collection. Details of the analytical procedures used for dopamine determination in the microdialysis probe effluent were described previously.[20]

Pharmacokinetic Analysis—A two-compartment pharmacokinetic model with elimination from the central compartment was used to investigate the effect of acute alcohol coadministration, and alcohol or cocaine pretreatment on cocaine absorption, distribution, and elimination after ip cocaine administration. Cocaine pharmacokinetic parameters were estimated by fitting cocaine plasma and brain ECF concentrations to the two equations that describe cocaine concentration−time profile in plasma and in the brain ECF simultaneously utilizing PCNONLIN 4.0 (SCI Software, Lexington, KY).[5,6] The bioavailability of cocaine after ip administration was calculated from the corresponding areas under the plasma concentration−time curves (AUC_p) after ip and iv cocaine administrations to each rat. The fraction of the ip cocaine dose converted to each of the metabolites was calculated as described previously.[6]

Pharmacodynamic Analysis—The sigmoid-E_{max} pharmacodynamic model was used to describe the brain ECF cocaine concentration−neurochemical response relationship. The phar-

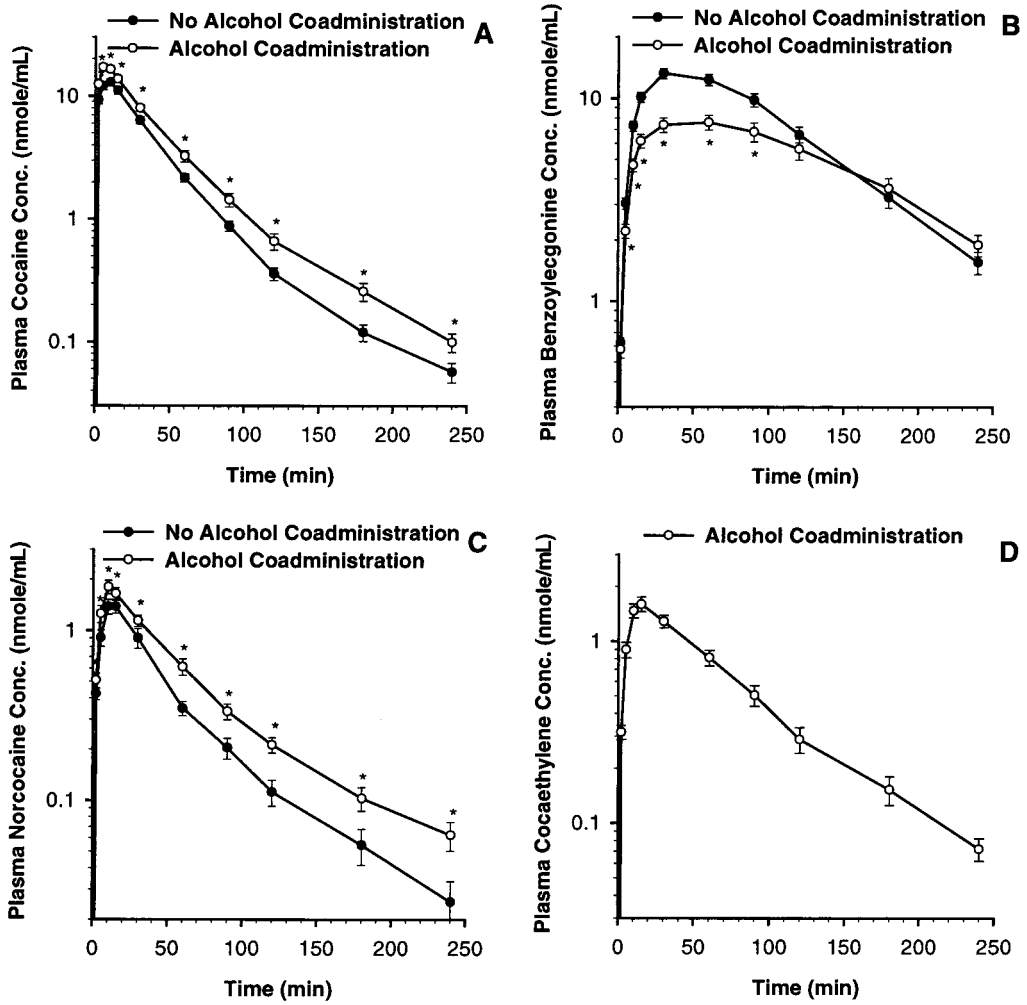

Figure 1—Plasma concentration–time profiles of cocaine (A), benzoylecgonine (B), norcocaine (C), and cocaethylene (D) after 30 mg/kg ip cocaine challenge to rats that were not (●) and were (○) coadministered with 5 g/kg acute alcohol. Each data point is presented as mean ± SE ($n = 32$). *Significantly different from that of no alcohol coadministration ($p < 0.05$).

macodynamic model parameters were estimated by fitting the percent change in dopamine brain ECF concentration and the cocaine brain ECF concentration to the model equation utilizing PCNONLIN. The relationship between plasma cocaine concentration and the change in mean arterial blood pressure and heart rate after ip cocaine administration was characterized by an indirect mechanism-based pharmacodynamic response model.[5,23] The mathematical expression that describes the relationship between the change in the pharmacological response and the drug concentration is:

$$\frac{dR}{dt} = k_{in} - k_{out}\left(1 - \frac{I_{max}C_p^n}{IC_{50}^n + C_p^n}\right)R \qquad (1)$$

where R is the observed response (percent change in mean arterial blood pressure or heart rate), k_{in} is the apparent zero-order rate constant for response production, k_{out} is the first-order rate constant for response dissipation, I_{max} is the maximum inhibition of the factor that produces the effect, IC_{50} is the plasma cocaine concentration that leads to 50% inhibition of the factor that produces the effect, C_p is the plasma cocaine concentration at the time of the observed response, and n is the sigmoidicity factor.[5,6] The maximum response that will be achieved as the ip dose is very high or IC_{50} approaches zero is:

$$R_{max} = \frac{R_0}{1 - I_{max}} \qquad (2)$$

where R_{max} is the maximum response and R_0 is the basal response (100%).

The indirect pharmacodynamic model parameters were estimated by fitting the percent change in mean arterial blood pressure or heart rate and the plasma cocaine concentration at different time points to eq 1. Nonlinear regression analysis was performed using PCNONLIN as detailed previously.[5,6]

Statistical Analysis—In this study, the control, alcohol, cocaine, and cocaine+alcohol pretreatments, together with ip cocaine administration (with and without acute alcohol coadministration), represented a four-way factorial experiment ($2 \times 2 \times 2 \times 2$) with repeated measures on the acute alcohol treatment factor. This experimental design allowed studying the effect of pretreatment with alcohol and cocaine and the effect of acute alcohol coadministration on the pharmacokinetics and pharmacodynamics of cocaine. The subgroup differences were partitioned within the analysis of variance (ANOVA) structure when examining the effect of one of the three main factors. The significance of the interaction between the two pretreatment factors (cocaine+alcohol pretreatment) and their interaction with acute alcohol coadministration factor could also be determined with the analysis of variance. Note that testing interaction effects is equivalent to testing whether there is synergism between the two treatments. Because no measurement for heart rate was made for the control (i.e., naïve) group, the analysis of variance for this response was conducted assuming no interactions between treatment factors. The statistical analyses of the estimated pharmacokinetic and pharmacodynamic parameters of cocaine and its metabolites were performed using the Statistical Analysis System Release 6.12 (SAS Institute Inc., Cary, NC). Multiple comparisons with Bonferroni correction were conducted to examine the selected statistical differences between treatments. A difference of $p < 0.05$ was considered statistically significant.

Table 1—Pharmacokinetic Parameters of Cocaine and Its Metabolites in the Rat Either with or without Alcohol or Cocaine Pretreatments or Acute Alcohol Coadministration (mean ± SE, $n = 32$)

Results

During the pretreatment period, the rats in alcohol and cocaine+alcohol groups consumed 7.14 ± 0.58 mL/kg/day and 7.83 ± 0.43 mL/kg/day of alcohol, respectively. The surgical procedures for microdialysis guide cannula implantation caused slight reduction in water and food intakes; however, these values soon returned to their preoperative levels. Meanwhile, the rats in all groups gained weight steadily, and the rate of increase was 2.1 ± 1.8 g/day for the alcohol group, 3.2 ± 1.2 g/day for the cocaine group, and 2.49 ± 0.97 g/day for the cocaine+alcohol group. There were not any significant signs of malnutrition or changes in the general health of the rats during the pretreatment period as indicated by their steady body weight gain.

The plasma concentration−time profiles for cocaine and its metabolites after ip administration of cocaine alone and in combination with alcohol are presented in Figure 1. A summary of the pharmacokinetic parameters for cocaine and its metabolites after different pretreatments is listed in Table 1. Alcohol pretreatment caused significant increase in cocaine AUC_p ($p = 0.044$), without affecting area under the brain ECF concentration−time curve (AUC_b) and brain to plasma distribution ratio (AUC_b/AUC_p). Cocaine distribution half-life ($\alpha_{t1/2}$) was increased ($p = 0.0019$), elimination half-life ($\beta_{t1/2}$) was prolonged ($p = 0.0003$), and the volume of distribution of cocaine during the elimination phase ($V_{d\beta}$) was larger ($p = 0.011$) due to alcohol pretreatment. The systemic bioavailability of cocaine (F) significantly increased ($p = 0.026$) due to cocaine pretreatment. However, the increase in cocaine bioavailability was offset by the increase in cocaine total body clearance (TBC, $p = 0.037$), causing no significant changes in cocaine AUC_p, AUC_b, or AUC_b/AUC_p after cocaine pretreatment. Cocaine pretreatment also increased k_a ($p = 0.0043$), volume of distribution of the central compartment (V_c, $p = 0.0046$), and $V_{d\beta}$ ($p = 0.022$). Alcohol coadministration with cocaine caused significant increases in cocaine AUC_p ($p = 0.0005$) and F ($p = 0.0001$), and significant decrease in AUC_b/AUC_p, which was similar to what has been reported previously.[5] Alcohol coadministration significantly decreased cocaine TBC ($p = 0.041$) and acted synergistically with alcohol pretreatment to prolong $\beta_{t1/2}$ ($p = 0.0067$) and increase $V_{d\beta}$ ($p = 0.0047$).

Pretreatment with alcohol or cocaine did not have any significant effect on benzoylecgonine formation. However, these two pretreatments acted synergistically to significantly reduce the formation of benzoylecgonine ($p = 0.048$). Meanwhile, acute alcohol coadministration with cocaine significantly reduced benzoylecgonine AUC_p ($p = 0.021$), AUC_b ($p = 0.023$), f_m ($p = 0.021$), and formation clearance (f_m·TBC, $p = 0.0029$). Norcocaine formation clearance after cocaine administration was significantly increased due to cocaine pretreatment ($p = 0.042$), and the combined pretreatment with cocaine and alcohol significantly increased norcocaine formation ($p = 0.038$). Meanwhile, acute alcohol coadministration with cocaine led to significant increase in norcocaine AUC_p ($p = 0.0002$), f_m ($p = 0.0002$), and f_m·TBC ($p = 0.0001$). Cocaine pretreatment significantly increased cocaethylene f_m·TBC ($p = 0.020$). Even though alcohol pretreatment did not have any effect on cocaine metabolic conversion to cocaethylene, it acted synergistically with cocaine pretreatment to significantly increase the formation of cocaethylene ($p = 0.033$) and f_m·TBC ($p = 0.026$).

The brain ECF dopamine concentration−time profiles after cocaine administration with and without alcohol in

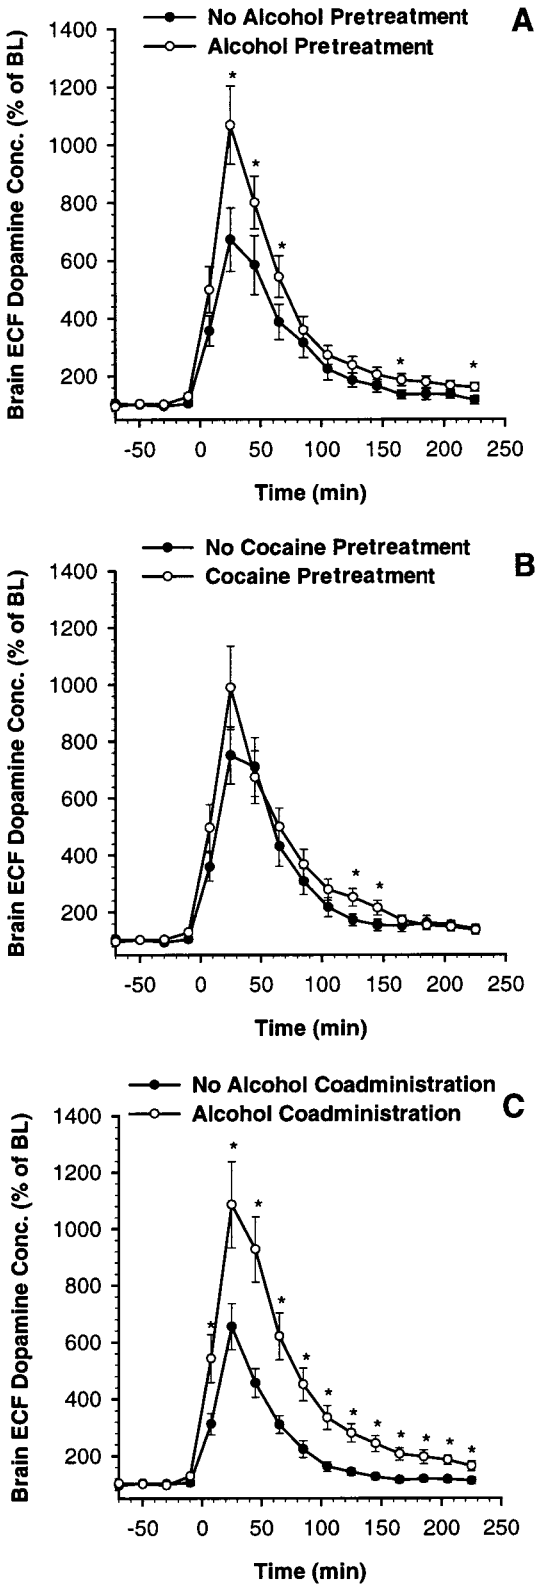

Figure 2—Brain ECF dopamine concentration–time profiles after 30 mg/kg ip cocaine challenge to (A) alcohol naive (●) and alcohol pretreated (○) rats. *Significantly different from that of alcohol naive rats ($p < 0.05$); (B) cocaine naive (●) and cocaine pretreated (○) rats. *Significantly different from that of cocaine naive rats ($p < 0.05$); (C) rats that were not (●) and were (○) coadministered with 5 g/kg acute alcohol. *Significantly different from that of no alcohol coadministration ($p < 0.05$). Each data point is presented as mean ± SE ($n = 32$). BL = Baseline.

the different pretreatment groups are shown in Figure 2. The brain ECF dopamine concentration increased rapidly after 30 mg/kg ip cocaine administration, and it gradually declined to its baseline value at the end of the 4-hour experiment period. Alcohol pretreated rats had significantly higher brain ECF dopamine concentrations in response to cocaine administration when compared to alcohol naïve rats. Cocaine pretreatment did not have any significant effects on dopamine levels after a cocaine challenge dose when compared with cocaine naïve rats. Alcohol coadministration with cocaine significantly increased the magnitude and duration of the brain ECF dopamine level augmentation when compared with cocaine administration alone. The estimated pharmacodynamic parameters of neurochemical response to cocaine are summarized in Table 2. Estimates of the sigmoid-E_{max} pharmacodynamic model parameters showed that alcohol and cocaine pretreatments increased the E_{max} for the neurochemical response to cocaine administration but these changes were not statistically significant. On the other hand, alcohol coadministration with cocaine caused significant increase in E_{max} ($p = 0.018$) and significant reduction in EC_{50} ($p = 0.014$).

The mean arterial blood pressure increased rapidly after ip cocaine challenge. It then declined slowly and did not return to its baseline value at the end of the 4-h experiment (Figure 3). Alcohol and cocaine pretreatments, as well as acute alcohol coadministration with cocaine, caused significant reduction in the mean arterial blood pressure elevation in response to cocaine administration. Since alcohol alone caused, on average, 5−10% decrease in blood pressure, we partitioned this effect from the combined effect of cocaine+alcohol and used the corrected values in the pharmacodynamic modeling.[5] The estimated pharmacodynamic parameters for the mean arterial blood pressure response to cocaine are summarized in Table 3. Analysis with the indirect pharmacodynamic inhibitory model showed that alcohol pretreatment caused reduction in IC_{50} ($p = 0.058$). Cocaine pretreatment significantly decreased the I_{max} ($p = 0.0012$), IC_{50} ($p = 0.0052$), and R_{max}, which is the maximum response to cocaine administration ($p = 0.0041$). Alcohol and cocaine pretreatments did not have any effect on the onset and dissipation rate constants of the blood pressure response. However, alcohol and cocaine pretreatments acted synergistically to reduce the IC_{50} for the pressor response ($p = 0.029$). On the other hand, acute alcohol coadministration increased the rate constant for blood pressure response production (k_{in}) ($p = 0.0093$) and its dissipation (k_{out}) ($p = 0.0085$).

The heart rate decreased rapidly after cocaine ip administration and neither alcohol nor cocaine pretreatments had any significant effect on the change in heart rate in response to cocaine administration (Figure 4A,B). Meanwhile, cocaine caused more reduction in heart rate when it was administered with alcohol (Figure 4C), even though alcohol administration alone led to increase in heart rate (data not shown). Because alcohol alone caused, on average, 10−20% increase in heart rate, we partitioned this effect from the combined effect of cocaine+alcohol, and the corrected values were used in the pharmacodynamic modeling. The estimated pharmacodynamic parameters for the heart rate response to cocaine administration are also summarized in Table 3. Alcohol and cocaine pretreatments caused significant increase in IC_{50} ($p = 0.0001$ and 0.0017, respectively). On the other hand, acute alcohol coadministration increased the rate constant for the heart rate response production (k_{in}) ($p = 0.032$) and its dissipation (k_{out}) ($p = 0.065$).

Discussion

Illicit drugs are mostly consumed by addicts who often abuse multiple drugs simultaneously. This observation

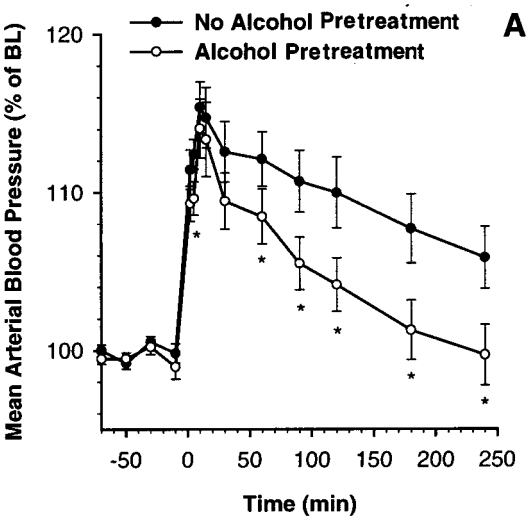
clearly illustrates the importance of studying possible interactions between illicit drugs and changes in the disposition and pharmacological effects of these substances of abuse when two or more of them are consumed simultaneously. Most of the studies conducted thus far involve administration of a single drug in naïve animals or in subjects that had been abstinent for several months from drugs. Our investigation was designed to study how prior cocaine and alcohol use, acute alcohol coadministration, and interactions among these factors can affect the pharmacokinetics and pharmacodynamics of cocaine.

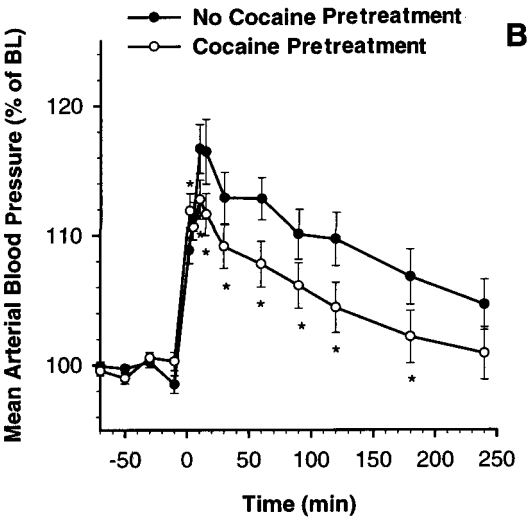
Alcohol pretreatment for two weeks significantly prolonged cocaine distribution and elimination half-lives and significantly increased cocaine volume of distribution. Similar effect on cocaine elimination half-life has been reported previously in anesthetized rats.[3] Cocaine AUC_p increased significantly after alcohol pretreatment, which may have resulted from the inhibition of cocaine metabolism because its bioavailability did not change significantly. Alcohol metabolism in mammals is mediated by cytosolic alcohol dehydrogenase, microsomal CYP2E1, and peroxisomal catalase.[24] CYP2E1 catalyzes the biotransformation of a variety of endogenous and exogenous compounds and is inducible by alcohol. It is possible that CYP2E1 induction by alcohol pretreatment may be involved in the changes in cocaine metabolism and pharmacokinetics. Studies have shown that both acute and chronic alcohol administration decrease hepatic glutathione content and shift its reduction vs oxidation ratio to an unfavorable condition for the cell.[25] Another effect related to alcohol pretreatment is the promotion of lipid peroxidation in the liver.[26] These two CYP2E1-dependent events can lead to intracellular oxidative stress and slow the liver biotransformation activity. These results imply that prior use of alcohol can lead to higher and prolonged cocaine plasma concentrations after administration of the same cocaine dose which may, in turn, increase cocaine-related toxicities.

We pretreated the rats with ip cocaine administration because it is easier than iv and more drug will reach the systemic circulation compared to oral and subcutaneous administration. Cocaine pretreatment significantly increased the rate and extent of cocaine absorption after an ip challenge dose of cocaine. However, the increase in cocaine bioavailability was not accompanied by an increased in AUC_p and AUC_b. This may be due to the significant increase in cocaine TBC. Cocaine pretreatment also increased cocaine volume of distribution which may explain why its elimination half-life was not affected by cocaine pretreatment.

Acute alcohol coadministration with cocaine significantly increased cocaine AUC_p and systemic bioavailability. Meanwhile, cocaine $\beta_{t1/2}$ and TBC were not significantly different, indicating that the increase in cocaine AUC_p was primarily due to the increase in cocaine bioavailability. The enhanced cocaine systemic bioavailability may be caused by the inhibitory effect of alcohol on cocaine presystemic metabolism which resulted in a larger fraction of the cocaine dose escaping the first-pass metabolism and reaching the systemic circulation. Examination of the significant interactions between different factors showed that acute alcohol and alcohol pretreatment acted synergistically to prolong cocaine elimination half-life and volume of distribution. The increase in the plasma cocaine concentration after alcohol coadministration with cocaine was accompanied by less than proportional increase in cocaine AUC_b and thus caused decrease in AUC_b/AUC_p. We have previously demonstrated that in the presence of much higher plasma alcohol concentration, brain ECF cocaine concentration was significantly increased in rats.[4] These results showed that combined alcohol and cocaine use can lead to higher cocaine concentrations, which may augment cocaine pharmacological effects and toxicities.

Alcohol pretreatment did not have any significant effect on cocaine metabolic profile. However, cocaine pretreatment significantly reduced benzoylecgonine formation and significantly increased the formation of the active metabolite cocaethylene. The increased formation of cocaethylene may have significant pharmacological and toxicological





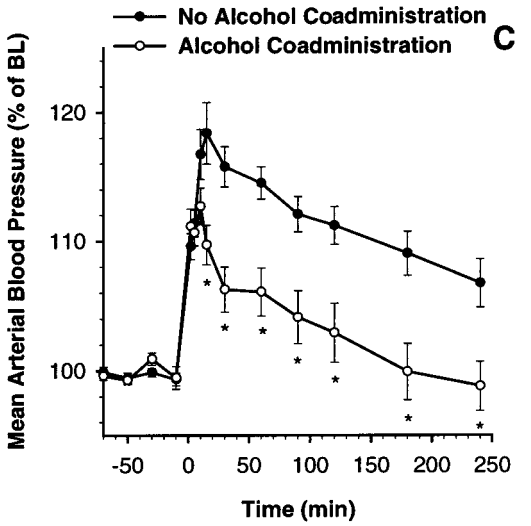


Figure 3—Mean arterial blood pressure–time profiles after 30 mg/kg ip cocaine challenge to (A) alcohol naive (●) and alcohol pretreated (○) rats. *Significantly different from that of alcohol naive rats ($p < 0.05$); (B) cocaine naive (●) and cocaine pretreated (○) rats. *Significantly different from that of cocaine naive rats ($p < 0.05$); (C) rats that were not (●) and were (○) coadministered with 5 g/kg acute alcohol. *Significantly different from that of no alcohol coadministration ($p < 0.05$). consequences. This is because, compared to cocaine, cocaethylene has been shown to be more potent with respect to the neurochemical, heart rate, and QRS interval responses and is equipotent in causing mean arterial blood

pressure increase.[6] Cocaine and alcohol coadministration significantly reduced benzoylecgonine formation, with approximately 25% of cocaine dose converted to the active metabolite cocaethylene. The fact that alcohol coadministration caused only 5% reduction in the precent of the cocaine dose converted to benzoylecgonine, but approximately 25% of cocaine dose was converted to cocaethylene indicates that cocaethylene formation is not solely on the expense of benzoylecgonine formation. These results imply that alcohol may also affect the metabolism of cocaine to ecgonine methyl ester. Another significant effect of acute alcohol coadministration on cocaine metabolism was the significant increase in the formation of norcocaine. On the other hand, cocaine+alcohol pretreatment led to more than additive effect on the reduction of benzoylecgonine and increase of norcocaine formation. The changes in cocaine metabolic profile due to alcohol coadministration, specifically the formation of cocaethylene and the increased formation of norcocaine, can significantly alter cocaine pharmacological and toxicological effects because of the contribution of these two metabolites to the neurochemical and cardiovascular effects of cocaine.[6]

The N ACC dopamine concentration enhancement in response to cocaine administration was significantly higher in the rats pretreated with alcohol for two weeks. This difference was more significant in the first hour after cocaine administration. Pharmacodynamic analysis showed an approximately 40% increase in the E_{max} for the neurochemical response to cocaine administration. This can be explained by the higher and prolonged cocaine concentrations as a result of alcohol pretreatment. Neurochemical and behavioral sensitization after repeated cocaine treatment has been well documented.[14–16] In our study, however, cocaine pretreatment continued until the day before the challenge dose of cocaine, and it did not have any significant effect on the neurochemical response to an ip cocaine challenge. This lack of neurochemical sensitization may be due to the apparent short term tolerance to the brain ECF dopamine augmentation during the early withdrawal period after repeated cocaine administration.[27]

Dopamine concentration−time profile in response to cocaine administration was significantly higher throughout the experiment period when alcohol was coadministered. The enhanced magnitude and potency of cocaine neurochemical effect was also reflected in the significant changes in the pharmacodynamic model estimates for E_{max} and EC_{50}. This may be explained by the higher cocaine concentrations achieved after combined cocaine and alcohol administration. Because both cocaethylene and norcocaine contribute significantly to the neurochemical response of cocaine,[6,28] the formation of cocaethylene and the increased formation of norcocaine due to alcohol coadministration may further enhance this pharmacological response. These findings imply that, in humans, simultaneous cocaine and alcohol abuse may increase the risk of cocaine-related toxicity in the central nervous system.

Cocaine pretreatment significantly reduced the maximum inhibitory effect of cocaine on the monoamine reuptake, significantly increased the potency of this action, and reduced the maximum mean arterial blood pressure response. These findings indicate that although the maximum increase in mean arterial blood pressure may be lower after repeated exposure to cocaine, the increase in mean blood pressure will be higher for a given cocaine dose after this pretreatment. Alcohol pretreatment increased the potency of the effect of cocaine on the blood pressure. Cocaine and alcohol pretreatments acted together to cause more than an additive effect on increasing the potency of cocaine effect on the mean arterial blood pressure. This may imply that prior use of both cocaine and alcohol can increase the risk of cardiovascular complications in response to cocaine use. Acute alcohol administration with cocaine increased the onset and the dissipation rate constants for the effect of cocaine on the mean arterial blood pressure. This means that alcohol coadministration caused faster increase in the mean arterial blood pressure and faster return to baseline after ip cocaine challenge. The clinical significance of these findings should not be underestimated. Simultaneous administration of cocaine and alcohol may cause higher risks of developing stroke and seizure due to sudden and faster increase in vascular resistance during the first few minutes. Meanwhile, the faster decrease in blood pressure is accompanied by lower vascular tone of the cerebral and epicardial coronary arteries. This may explain the reduced dysphoria such as migraine and chest pain that are often described by abusers of this drug combination as compared to cocaine alone.

The effect of cocaine on heart rate is dependent on its dose. In rats, intra-arterial cocaine doses of up to 0.5 mg/kg increased heart rate, whereas doses above 1.0 mg/kg decreased heart rate.[29] Due to the high cocaine challenge dose used in our study, the heart rate was reduced in all the three groups of rats under investigation. High concentrations of cocaine can block the sodium channel in sensory neurons as well as affect the cardiac action potential leading to slower heart rate and slower cardiac conduction.[30,31] Decreased heart rate may also be caused by activation of vagal baroreceptor reflex.[29] In this study, the time course of the decrease in heart rate in reponse to cocaine administration was not affected by alcohol or cocaine pretreatment. However, pharmacodynamic model parameters showed decreased potency of cocaine effect on the heart rate. On the other hand, alcohol coadministration caused significantly lower heart rate compared to cocaine administration alone, with the most outstanding difference shown in the first hour. Changes in cocaine pharmacokinetics, especially the increase in cocaine AUC_p, the formation of cocaethylene and the increased formation of norcocaine may be responsible for the changes in cocaine pharmacodynamics when alcohol was given with cocaine. Cocaethylene is believed to be implicated in the increased cocaine-related mortality when alcohol is coabused. Cocaethylene has been proven to be more potent than cocaine in mediating lethality in mice.[32] In anaesthetized dogs, cocaethylene causes significant myocardial depression and slight heart rate increase.[33] The reduction in myocardial contractility may lead to a remarkable decrease in hepatic blood flow and, consequently, reduce metabolism of both cocaine, cocaethylene, and norcocaine in the liver. Therefore, changes in the pharmacodynamics with cocaine+alcohol coadministration may in return affect the pharmacokinetics and metabolism of cocaine. However, caution should be exercised when extrapolating these observations in animals to humans. Studies in humans have shown that the appearance of cocaethylene in plasma does not alter subjective and cardiovascular effects of cocaine,[34] and that cocaethylene alone produces milder subjective effects and comparable cardiovascular effects to those of cocaine alone.[35,36]

In conclusion, alcohol pretreatment increases the plasma and brain cocaine concentrations due to inhibition of cocaine elimination. Cocaine pretreatment enhances the systemic bioavailability and clearance of cocaine and increases the formation of norcocaine and cocaethylene. Alcohol coadministration with cocaine increases the plasma and brain cocaine concentrations due to the increase in cocaine systemic bioavailability and reduction of its clearance. Meanwhile, benzoylecgonine formation is significantly reduced, and norcocaine formation is significantly increased. Cocaine and alcohol pretreatments and acute

alcohol coadministration lead to alterations in cocaine pharmacodynamics that are due, at least in part, to the changes in cocaine pharmacokinetics. Alcohol coadministration with cocaine caused significant changes in cocaine neurochemical and cardiovascular responses, and repeated cocaine and alcohol users may respond differently to cocaine administration compared to naïve users. If prior use of alcohol and/or cocaine has similar effects on cocaine pharmacokinetics and pharmacodynamics in humans, the findings of this investigation would indicate that alcoholics and cocaine addicts are at higher risks of cocaine toxicity. The risks may be even higher in these abusers when they consume cocaine and alcohol simultaneously.

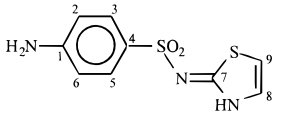
Received June 4, 1999. Accepted for publication August 30, 1999.

Abstract □ The literature on sulfathiazole polymorphs has many confusions and inconsistencies. These are largely resolved by the distinctive appearance of ^{13}C magic-angle spinning NMR spectra, which immediately show the number of molecules in the crystallographic asymmetric unit. The spectra presented include those of a newly-recognized form. The assignments of the spectra are established and discussed in relation to such factors as electronic structure of the aromatic ring, second-order quadrupolar effects originating from the nitrogen nuclei, and hydrogen bonding. The results are compared to literature information on the crystal structures. When the amino group acts as a hydrogen bond acceptor, there is a shielding effect on C-4 to the extent of ca. 8 ppm (which should be compared to a further shielding by ca. 10 ppm for sulfathiazole sulfate). The fact that the spectrum of form III is similar to the sum of those of forms IV and V is rationalized in relation to the crystal structures. Some surprising variability of spectra with temperature and with specific sample is reported.

Introduction

The polymorphism of sulfathiazole has been the subject of investigation for almost 60 years.[1−7] It has been described as the classic polymorphic system.[3] We have recently demonstrated that there are at least five polymorphs of sulfathiazole, and we have carried out a single-crystal structure determination of the fifth polymorph,[7,8] although it now appears that this polymorph was the one first synthesized,[9] first described in a patent,[10] and first published in the literature by two independent groups,[11,12] but subsequently overlooked for more than 40 years.[13] It would seem that all five polymorphs had been seen and described by 1947, but not clearly differentiated.[1,2,11,12,14] Furthermore, we have shown that the common material of commerce does not have the polymorphic structure described by Kruger and Gafner,[15] as has been assumed for a quarter of a century, but has the structure first determined by Babilev et al.[16] The sources of confusion which have led to this unusual situation are 5-fold, namely the irreproducibility of the crystallization, the tendency to crystallize as mixtures, the close similarity in structure and properties of three of the polymorphs, the sample-to-sample variability in stability, and the differences between the pharmaceutical and crystallographic enumeration of the polymorphs. In order for the present discussion to be clear, Table 1 sets out the nomenclature of the polymorphs. Only minimal information for differentiating between them is incorporated in the table, since it is intended to publish further details of the physical characteristics elsewhere. The crystal structures of all five have now been published,[7,8,15,16] so confusion should now be minimal. Samples of all sulfathiazole polymorphs (particularly of I and IV) show huge variation in stability. During this investigation we have also prepared and characterized over 100 solvates of sulfathiazole, as well as numerous salts, and have determined the crystal structures of many of these.[17] It has therefore appeared highly desirable to determine definitively, to collate, to record, and to correlate the physical properties of the multiple solid forms of sulfathiazole. In this article the solid-state NMR spectra of the five polymorphs of known structure, purity, and provenance are presented and interpreted: previously only the spectra of four polymorphs, determined by one of us (D.C.A.), have been briefly mentioned[4] but not seriously discussed. For the purposes of discussing the NMR spectra, the carbon-atom numbering is shown below (note that some authors[5] invert the numbering of C-8 and C-9).



However, this figure is not intended to convey conformational information. Note that in all cases the sulfonimido tautomer is present, rather than the sulfonamido structure.

Polymorphs I−III each have two molecules in the asymmetric unit. The supramolecular structure of polymorph I may be described in broad terms as consisting of two orthogonal planes of crystallographically distinct but rather similar sulfathiazole molecules, and that of polymorph II as two parallel interleaved planes of somewhat differently bonded molecules. Polymorph IV has only one molecule in the asymmetric unit in a distinctive supramolecular pattern based on a layered hydrogen-bonded ring system. Polymorph V is of a similar structure but with a different ring system. Polymorph III in effect combines[5] the ring systems of IV and V. Consequently, the three polymorphs are very similar in all their spectral and physicochemical

behavior, and the properties of polymorph III are to a large extent either the average or the superposition of those of polymorphs IV and V. Great care is therefore needed to distinguish between them as they almost invariably occur as mixtures.

Recently, Blagden et al.[5] have discussed the hydrogen-bonding networks and other packing arrangements of four of the forms using a graph-set approach. Anwar, Tarling, and Barnes[4] have collated powder XRD and Raman spectra of four sulfathiazole polymorphs, though the relationships to those of Blagden et al. are not totally clear.

Experimental Section

Origin of Samples—*Polymorph I*—For almost 60 years, the single reliable preparation of a pure sulfathiazole polymorph by crystallization has been of form I from a solution in 1-propanol. The characteristics of commercial material have changed recently, as noted below, and useful samples can no longer be made this way, as has been independently encountered by Blagden et al.[5] The sample used here was made by heating commercial material at 180 °C for 15 min. This procedure is reliable. The product is often pink, but this does not interfere with the NMR spectral characteristics. An earlier sample made by crystallization from 1-propanol proved to be sensitive to spinning and partly converted to form IV during NMR examination. Polymorph I is not the themodynamically stable form at room temperature. Its kinetic stability varies enormously between samples, from hours to years. Transformation on spinning is rare but for that very reason is all the more noteworthy.

Polymorph II—A supersaturated aqueous solution was evaporated to dryness in a beaker.[4] It is desirable not to let the temperature drop below 100 °C at any time until the sample is totally dry. The supersaturated solution is best prepared by boiling down an undersaturated (<2 g per 100 cm^{-3}) solution, itself made in the presence of trace surfactant, otherwise only a mixture of III/IV/V may result. The nature of the material from this experiment is dependent on the history of the solution. Solutions made initially by dissolution in an organic solvent followed by displacement of the solvent by water have not yielded polymorph II in our hands. It has been suggested that cocrystals of urea with sulfathiazole produce form I on dissolution,[18] but in our experience addition of urea encourages the formation of form II. Polymorph II has and continues to be mistaken for form I, despite its distinctive melting point and infrared spectrum.

Polymorph III—Recent commercial sulfathiazole from Aldrich has been of form III of a polymorphic purity (ca. 99%) which cannot be achieved in small-scale laboratory preparations. The size of vessel is a significant factor in the preparation of sulfathizole polymorphs. A sample made by the replacement of acetone by dichloromethane in boiling solution as well as one from Aldrich batch HN 3506 were used here: the crystallization history of the latter is unknown.

Polymorph IV—The stability of sulfathiazole polymorphs is a characteristic not of the form in question, but of the specific sample, related to the stability of the individual crystals, as can be deduced from the observations of Anwar,[19] presumably because the transitions are defect-mediated. Of over 50 samples of polymorph IV in our hands few were better than 90% polymorphically pure and none better than 98% when originally prepared, as determined by powder XRD. The usual impurities are polymorphs III and V. Furthermore, many have altered on storage. The sample used here was crystallized from acetonitrile.

Polymorph V—For many decades, bulk sulfathiazole was purified by dissolution in alkali followed by neutralization. The product on a laboratory scale is of variable polymorphic composition, but on a commercial scale this procedure gives form V in better than 90% polymorphic purity. Batch 61376 from Aldrich, of 98% polymorphic purity, was used here.

The polymorphic status of our samples was checked first by NIR/IR DRIFT spectra of the solids.[20] Infrared and near-infrared spectroscopy can distinguish between the polymorphs but are poor at assessing the polymorphic purity, particularly of polymorphs III–V, because of the close similarity of the spectra and many near coincidences. The polymorphic purity of the samples was determined by XRD powder diffraction on unground samples using the intense peaks at 21.9, 21.7, and 22.1° 2θ characteristic of polymorphs III, IV, and V, respectively. Grinding causes polymorphic transition,[21,22] and it obscures the distinctions between polymorphs in the 22° 2θ region. Polymorph I also has its strongest band at 21.9° 2θ but can readily be distinguished elsewhere in the pattern.

Nuclear Magnetic Resonance—Solid-state ^{13}C NMR spectra were recorded with cross polarization, magic-angle spinning, and high-power proton decoupling using a Varian Unity Plus 300 spectrometer operating at 75.43 MHz and ambient probe temperature (ca. 26 °C). A probe using 7 mm o.d. rotors made of zirconia was employed. Typical operating conditions: contact time 3 ms; recycle delay 30 s for some spectra but 300 or 400 s for those obtained later; number of transients 100–1000; spin rate 4.5–5.5 kHz. The total accumulation times were optimized by the use of a flip-back pulse after each acquisition.[23] For assignment purposes, spectra of nonprotonated and protonated carbons were separately obtained using a dipolar dephasing pulse sequence.[24] Carbon chemical shifts were referenced to the signal for tetramethylsilane via a replacement sample of solid adamantane (methylene carbon, $\delta_C = 38.4$ ppm).

Values of T_1 for the protons were measured by the inversion–recovery method on static samples and were found to be between 200 and 500 s at ambient probe temperature. Proton relaxation times in the rotating frame were estimated to be <20 ms for form I but >100 ms for the other polymorphs.

Solution-state ^{13}C NMR spectra were obtained at 100.58 MHz using a Bruker DPX 400 spectrometer at ambient probe temperature (ca. 25 °C). Solutions in both DMSO-d_6 and CD_3OD were examined, with chemical shifts referenced to the signal for tetramethylsilane. Approximately 20 000 transients were accumulated in each case, with a pulse angle of 90° and a recycle delay of 1s (though this resulted in reduced intensity for the quaternary carbons).

Powder X-ray Diffraction—The XRD traces were obtained using a Philips X′pert MPD diffractometer with a θ–2θ goniometer fitted with an Anton Paar TTK variable temperature camera. Cu Kα radiation of wavelength 1.54056 Å was used, with a diffracted beam monochromator. A sealed xenon detector was employed. Diffractograms were collected over the range 5–35° for 2θ, using a step size of 0.02° and a count time of 1 s.

Results and Discussion

The 75 MHz ^{13}C-{^1H} CPMAS spectra of the five polymorphic forms of sulfathiazole are shown in Figure 1. The relevant data are listed in Table 2. The resonances cover a relatively narrow range of chemical shifts ($\delta_C = 106$–172 ppm) because only sp^2-hybridized carbon atoms are involved. The spectra are all noticeably different, so that solid-state NMR is an excellent technique for monitoring the polymorphic form of sulfathiazole. Indeed, we propose that the solid-state NMR spectra, as presented here, be used in future alongside X-ray powder diffraction to define the polymorphic form of sulfathiazole samples. It is feasible to analyze mixtures of forms semiquantitatively (Figure 2) though the usual precautions regarding cross-polarization conditions need to be borne in mind. Assignment of the spectra (Table 1) may be readily made using three criteria:

(a) Comparison with solution-state shifts (see Table 2).

(b) The spectra obtained using the dipolar dephasing ("nonquaternary suppression") pulse sequence,[24] which show peaks arising from C-1, C-4, and C-7 only. Such edited spectra give even clearer distinction between the forms than the complete spectra, since then the resonances of C-4 are clear of all other peaks and are readily distinguishable in chemical shifts and/or splittings between the various polymorphs (Figure 2). The only difficulty that might occur is differentiating between form III on one hand and a combination of forms IV and V on the other.

(c) The broadening induced for the resonances of C-1, C-7, and C-8 by the second-order effects arising from dipolar coupling to quadrupolar ^{14}N nuclei ("residual dipolar splitting").[25] Although in principle such effects give

[a] Bonded to ^{14}N, so second-order splittings occur. Some peak maxima are listed. [b] Double intensity peak.

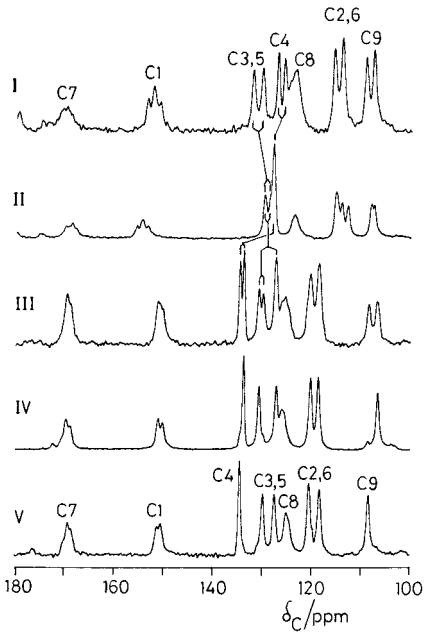

Figure 1—Carbon-13 CPMAS spectra, recorded at 75.43 MHz and ambient probe temperature with high-power proton decoupling, for the five polymorphs of sulfathiazole. The recycle delays were 30 s. Assignments are indicated for forms I and V. For the others, see Table 2.

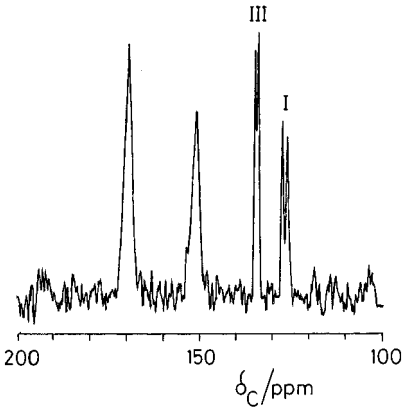

Figure 2—Carbon-13 CPMAS spectrum at ambient probe temperature for a mixture of sulfathiazole polymorphs I and III. The recycle delay was 30 s. The dipolar dephasing pulse sequence was used. Integration of the peaks assigned to C-4 suggests that the mixture contains ca. 46% of form I (assuming the CP and dipolar dephasing characteristics of the two polymorphs are similar).

rise to 1:2 or 2:1 doublets in ^{13}C spectra (for coupling to one ^{14}N), at our magnetic field for most of the sulfathiazole samples the relevant signals are merely broadened, with some ill-defined fine structure. It may be noted that C-7 is dipolar-coupled to two ^{14}N spins.

These considerations result in unambiguous assignments for nearly every peak in all polymorphs, though there are some accidental near-equivalences which result in overlapping signals.

A cursory glance at the spectra already conveys substantial information. Thus, for C-9 the resonance is clearly split into two for forms I−III but not for forms IV and V, showing that the asymmetric crystallographic unit consists of two molecules in the former cases, but only one in the latter. These conclusions are supported by the detailed X-ray structures. Other signals are also split for forms I−III, which generally have a more complex appearance than those for forms IV and V, but complications affect the situation except for C-4, which gives a clear doublet for forms I and III. However, the signal for this carbon is only a singlet for form II (as for forms IV and V), presumably because of accidental near-equivalence of the two expected peaks for II. The spectrum of form IV shown in Figure 1 indicates that the sample contains a small amount (ca. 5%) of form V (or ca. 10% of form III) as an "impurity".

Another factor potentially influencing the spectra and worthy of note at this point is internal rotation of the phenylene ring about the S−C bond. If this is slow on the NMR time scale, C-2 and C-6 will be nonequivalent (given the unsymmetrical nature of the molecule as a whole), thus giving rise to two lines for forms IV and V, but four lines for the other three forms. A similar situation exists for C-3 and C-5. At ambient probe temperature, the spectra for forms IV and V do indeed show the four lines for the phenylene CH carbons which are expected on the basis of slow internal rotation. However, there are obviously accidental degeneracies for forms II and III, since **three** lines are observed for C-2,6 for the former and for C-3,5 for the latter, while for the remaining phenylene C−H carbons in these two forms only **two** lines are resolved. At all events, these observations show that at ambient probe temperature, internal rotation is slow on the NMR time scale. The situation is somewhat different for form I. The spectrum displayed in Figure 1 shows only two lines for each of the carbon pairs C-2,6 and C-3,5, but on lowering the temperature to −40° and below, three lines are observed for C-2,6 (Figure 3a), which at first sight suggests that fast phenylene-group internal rotation is occurring for form I at room temperature. However, a more-detailed study shows that the spectrum of form I has a complex temperature variation which cannot be simply attributed to the slowing of internal rotation. In fact, we link these changes to those observed[19] in the powder XRD pattern at elevated temperatures, which indicate strong anisotropic lattice expansion. We have extended such measurements to low temperatures, confirming the significant changes. Thus, Figure 4 shows powder XRD traces of sulfathiazole polymorph I at 150, 25, and −85 °C. However, on carrying out MAS NMR experiments at elevated temperature (+80 °C, nominal), the spectrum changed considerably (Figure 3b), indicating that internal rotation probably is becoming rapid on the NMR time scale. Thus the resonance for C-2,6 has

become broad, while that arising from C-3,5 is so broadened as to be scarcely visible. The other signals show only small shift changes but no broadening. The phenomenon is reversible. The crystallographic changes indicated by the variable-temperature powder XRD patterns presumably facilitate the internal rotation.

As stated above, the spectra of the five forms all differ significantly. Clearly this must be caused by a combination of intramolecular and intermolecular (packing) considerations. Since the two rings are essentially planar in all

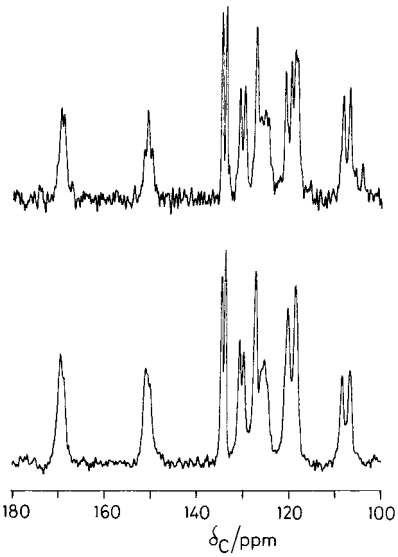

Figure 5—Carbon-13 CPMAS spectra at ambient probe temperature, showing a small variability between different samples of polymorph III.

cases, variations in intramolecular effects arise mainly from differences in (a) conformation expressed by dihedral angles about the S−C and S−N bonds, or (b) electronic structure of the phenylene ring. The S−N bond itself is approximately in the plane of the thiazole ring (maximum deviation just under 20°). The important intermolecular effects arise from the nature of the hydrogen bonding network and from the relationship of the rings in one molecule to the carbon atoms in a neighboring molecule. During the course of this work, we have found a small variability in spectra between different samples of form III (Figure 5). This particularly relates to the peaks assigned to C-2,6. Powder XRD patterns and near-infrared spectra also showed some distinctive characteristics in different samples. We have no current explanation for this variability, which is being further investigated. It is conceivable that two different "type-III" polymorphs with similar structures are involved. The unusual relationship between the structures of III−V suggest ways in which other variations are possible.

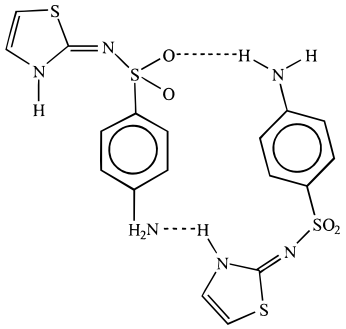
The largest difference between the spectra concerns the signals of C-4, which are at significantly lower frequencies for forms I and II than for the others. Indeed there is a crossover with the C-3,5 peaks for forms I and II compared to the other polymorphs. Such a difference between I and II on one hand and the other forms can also be observed for the C-2,6 signals. However the high-frequency shifts for C-3,5 in form I distinguishes it from all other forms. The position of the C-9 signal clearly differs between forms IV and V. The chemical shifts of C-1, C-7, and C-8 are harder to characterize because of the complicating effects of residual dipolar splittings arising from coupling to ^{14}N.

Table 3 lists the two sets of dihedral angles of relevance, which we have derived and collated from the published

crystal structures for forms I and III−V, as given in the Cambridge Crystallography Database and from detailed work on form II, as yet unpublished.[7,8] The major variations between the polymorphs seem to be for C3−C4−S1−N2 in both molecules of form I and for the three angles related to the N2−S1 bond for one of the inequivalent molecules of form II. It is difficult to see how these differences could account for the observed chemical shift variations.

A close look at the C−C bond lengths around the phenylene ring[8] shows that they distinctly alternate for form II, being 1.427, 1.354, and 1.416 Å for the averages of the C-1 to C-2/C-1 to C-6, C-2 to C-3/C-6 to C-5 and C-3 to C-4/C-5 to C-4 bonds, respectively. Such alternation does not appear to occur for polymorphs III and IV, though this conclusion is hampered by the relative inaccuracy of the structure determinations (that for III contains a scarcely believable distortion, with 1.386 Å quoted for C-1 to C-2 and 1.430 Å for C-6 to C-1 in the case of one of the inequivalent molecules, with estimated errors of 0.007 Å). Unfortunately the quoted errors for the relevant bonds in form I are even higher (ca. 0.013 Å), so the bonding situation is rather uncertain.

A more likely origin for the difference in the chemical shifts for forms I and II on one hand and the remaining polymorphs on the other lies in the hydrogen-bonding variations involving the NH_2 group. In forms III−V, the amino nitrogen acts as a hydrogen bond acceptor (the donor atom being the ring NH nitrogen of another molecule), leading to a partial positive charge on the amino nitrogen. This H-bonding occurs as part of a dimeric ring structure referred to by Davey and co-workers[5] as a β dimer (see below). Hydrogen bonding of this type also causes a low-frequency shift in the infrared spectrum for these three polymorphs, giving bands at ca. 3280 cm^{-1}. The NMR effect of charge on the amino nitrogen can be attested from ^{13}C CPMAS measurements on solid sulfathiazole monosulfate hemihydrate. The chemical shift of C-4 in this case is δ_C = 144.8 ppm, a full 17 ppm to higher frequency of those found for forms I and II, but only ca. 10 ppm higher than those for forms III−V. A similar effect is seen on the signal for C-1, which, for the sulfate, is at δ_C =135.7 ppm.



A β-ring dimer

Figure 1 shows that the spectrum of form III is remarkably similar to the sum of those for polymorphs IV and V, suggesting that the conformations and environments of the two molecules in the asymmetric unit of form III are similar to those of the unique molecules of the other two forms. Davey and co-workers[5] showed that III, IV, and V (which are referred to as III, II, and IV, respectively in their, crystallographic, notation) contain chains of β-ring dimers. These chains are linked into two-dimensional sheets, by additional amine nitrogen to imide nitrogen hydrogen bonds between each chain in form V, and between alternate chains in form III. However, there are no such H-bonds between chains in form IV. This difference between the forms will have associated structural changes, which appear to provide a satisfactory explanation for our comment that the form III spectrum closely resembles the sum of those of forms IV and V. The structural differences give rise to a chemical shift of ca. 0.8 ppm for C-4, 1.6 ppm for C-9, and 0.9 ppm for either C-3 or C-5 (these being the splitting magnitudes for form III).

Conclusion

We have shown that the five known polymorphs of sulfathiazole are clearly distinguished by their ^{13}C MAS NMR spectra. However, there are substantial changes in the spectrum of form I with temperature and of that of form III with sample. The spectra have been fully assigned and their appearance rationalized in terms of their crystal structures. The differences in hydrogen bonding explain why spectra of forms III−V are similar but differ substantially from those of forms I and II. Moreover, the fact that the spectrum of form III (which shows clearly the existence of two molecules in the asymmetric unit) is closely similar to the superposition of the spectra of forms IV and V may also be attributed to the hydrogen bonding network variations.

Accepted for publication October 5, 1999.

Abstract □ To determine the contribution of the *mdr*1a gene product to digoxin pharmacokinetics, we constructed a physiologically based pharmacokinetic model for digoxin in *mdr*1a (–/–) and *mdr*1a (+/+) mice. After intravenous administration, total body clearance and tissue-to-plasma concentration ratios for muscle and heart were decreased in *mdr*1a (–/–) mice as compared with *mdr*1a (+/+) mice, and in particular, the digoxin concentration in the brain was 68-fold higher than that in *mdr*1a (+/+) mice at 12 h. On the other hand, *mdr*1a gene disruption did not change the contributions of renal and bile clearances to total clearance, the plasma protein binding, or the blood-to-plasma partition coefficient. Brain concentration–time profiles in *mdr*1a (+/+) and *mdr*1a (–/–) mice showed a different pattern from those in plasma and other tissues, indicating digoxin accumulation in the brain tissue. Because there was no difference in the uptake or release of digoxin by brain tissue slices from the two types of mice, we assumed the brain tissue compartment to consist of two parts (a well-stirred part with influx and efflux clearance and an accumulative part). Simulation with this model gave excellent agreement with observation when active efflux clearance across the blood–brain barrier was assumed to be zero in *mdr*1a (–/–) mice. The observations in other tissues in both types of mice were also well simulated.

Introduction

The *MDR*1 gene encodes human P-glycoprotein. In mice, two P-glycoproteins (encoded by the *mdr*1a and *mdr*1b genes) appear to perform the function of the single human protein.[1−5] The tissue distribution of these two isoforms in the mouse is different but partly overlapping. The mouse *mdr*1a gene is predominantly expressed in the intestine, liver, and capillary endothelial cells of brain and testis, whereas the *mdr*1b gene is predominantly expressed in the adrenal, placenta, ovary, and pregnant uterus.[3,6] Similar levels of *mdr*1a and *mdr*1b expression are found in the kidney. Schinkel et al. reported that the absence of the *mdr*1a P-glycoprotein has a pervasive influence on the tissue distribution and pharmacokinetics of drugs such as ivermectin, vinblastine, cyclosporin A, digoxin, etc.[7,8] The most striking effects were observed in the brain, owing to the high level of *mdr*1a P-glycoprotein at the blood−brain barrier. The use of *mdr*1a (−/−) mice allowed us to investigate pharmacokinetically the in vivo function of P-glycoprotein.

Digoxin is widely used in the treatment of congestive heart failure and is a substrate of P-glycoprotein.[9] Schinkel et al. reported a 35-fold higher concentration of digoxin in *mdr*1a (−/−) mouse brain than in *mdr*1a (+/+) mouse brain 4 h after intravenous administration.[8] They also suggested that the pharmacokinetics of digoxin in *mdr*1a (−/−) mice was quite different from that in *mdr*1a (+/+) mice. Mayer et al. also found that the brain level of [^{3}H]digoxin in *mdr*1a (−/−) mice continuously increased over a period of 3 days, resulting in a 200-fold higher concentration than in *mdr*1a (+/+) mice.[10] Clinically, digoxin may be coadministrated with other drugs which potentially inhibit P-glycoprotein in the treatment of cancer in elderly patients, and this may lead to dangerous side effects of digoxin, including nausea, tremor, or heart failure.

In this study, we investigated the pharmacokinetics of digoxin in *mdr*1a (−/−) mice by modifying the physiologically based pharmacokinetic model in rats reported by Harrison and Gibaldi,[11] in order to reveal the role of the *mdr*1a gene product in relation to tissue distribution and renal or biliary clearance. In particular, we tried to simulate the change of brain digoxin concentration due to loss of active efflux across the blood−brain barrier in *mdr*1a (−/−) mice.

Materials and Methods

Chemicals—[^{3}H]Digoxin (555 GBq/mmol) and SOLVABLE were obtained from New England Nuclear (Boston, MA), digoxin from Sigma Chemical Co. Ltd. (St. Louis, MO), and Clear-sol I, a liquid scintillation fluid, from Nacarai-Tesque Inc. (Kyoto, Japan). Other drugs and chemicals were commercial products.

Animals—Male *mdr*1a (−/−) mice (body weight 25−30 g) were obtained from Taconic Farms Inc. (Germantown, NY). Male C57BL/6 mice (body weight 25−30 g) obtained from Sankyo Laboratory Co. Ltd. (Hamamatsu, Shizuoka, Japan) were used as the control mice because genetically compatible wild-type *mdr*1a (+/+) mice, F2 and F3 generations of 129/Ola and FVB mice, were not available in Japan at the time when we started this study. We confirmed in a preliminary study that male C57BL/6 mice showed similar disposition kinetics of several drugs, P-glycoprotein substrates including tacrolimus, digoxin, and cyclosporin A, to the wild-type (+/+) mice (data not shown). Animals were maintained with free access to water and food in an air-conditioned room in the Institute for Experimental Animals, Faculty of Medicine, Kanazawa University.

Digoxin Pharmacokinetic Study—[^{3}H]Digoxin at 1 mg/kg (2.96 MBq/kg, 0.5 mg/mL in 40% ethanol solution) was administered to each mouse via a 29 G syringe into a jugular vein. At each sampling time, a midline incision was made under ether anesthesia, and whole blood was taken into a heparin-coated syringe from the inferior vena cava. Blood samples were centrifuged at 12 000 rpm for 3 min to obtain plasma. Brain, heart, liver, kidney, and muscle were isolated, washed in ice-cold saline, and then weighed. The contents of the intestine were removed and washed in ice-cold saline. About 0.1 g of each tissue was weighed and then dissolved by vibration (100 strokes/min) in SOLVABLE

at below 60 °C for 2 h. After decolorization with H_2O_2, Clear-sol I and 5 N HCl were added, and the radioactivity was measured with a liquid scintillation counter (LSC-3500, ALOKA, Tokyo, Japan).

Tissue Slice Uptake Study—Preparation of tissue slices for uptake or release experiments was performed according to Gutierrez and Delgadoo-Coello.[12] Brain or skeletal muscle was collected from the completely bled mouse and was sliced with a razor blade 5−8 mm in diameter and 0.2−0.5 mm in thickness, in ice-cold Krebs-Ringer's Tris buffer (pH 7.4). Tissue slices weighing 5−20 mg were preincubated at 37 °C for 10 min in the presence or absence of 500 μM ouabain with continuous bubbling with 95% O_2/5% CO_2. Uptake experiments were started by replacing the buffer with [^{3}H]digoxin (7 nM)-containing buffer in the presence or absence of ouabain (500 μM). To terminate the uptake, tissue slices were washed three times with ice-cold buffer and solubilized with 5% sodium dodecyl sulfate in the counting vial, then Clear-sol I was added, and the radioactivity was measured with a liquid scintillation counter. Release experiments were carried out in a similar way, preincubation was done at 37 °C for 90 min in the buffer solution containing [^{3}H]digoxin, and then the buffer solution was exchanged for digoxin-free buffer at the starting time for the release study.

Plasma Protein Binding and Blood-to-Plasma Partition Coefficient—Plasma-free fraction of digoxin was measured by ultrafiltration. Two and one-half microliters of 40% ethanol solution containing [^{3}H]digoxin was added to 100 μL of plasma obtained from mice to produce a final concentration of 0.1−1000 ng/mL. After incubation at 37 °C for 30 min, samples were filtered with a Centrifree (Amicon Inc., Beverly, MA) at 1000 g, 37 °C for 10 min. Digoxin-free fraction was calculated according to the equation

$$f_p = C_f/C_p$$

where f_p, C_f, and C_p are digoxin-free fraction in the plasma, concentration of free digoxin in plasma calculated from the radioactivity in the filtrate, and total digoxin concentration in plasma, respectively.

Blood-to-plasma partition coefficient (R_B) was measured in vivo. One milliliter of blood samples was collected at 4 and 12 h after administration of [^{3}H]digoxin at 1 mg/kg (2.96 MBq/kg, 0.5 mg/mL in 40% ethanol solution). The blood sample was divided into two parts. One part was solubilized with SOLVABLE. The other part was centrifuged at 12 000 rpm for 3 min, and the radioactivity in solubilized whole blood and plasma was measured. The value of R_B was calculated as follows:

$$R_B = C_{blood}/C_p$$

where C_{blood} and C_p are digoxin concentrations in whole blood and in plasma, respectively.

Measurement of Renal and Bile Clearances—To determine the renal and bile clearances, mice were midline-incised and the renal artery or bile duct was ligated under ether anesthesia according to Harrison and Gibaldi.[11] [^{3}H]Digoxin was injected at a dose of 1 mg/kg (2.96 MBq/kg, 0.5 mg/mL in 40% ethanol solution), and the blood was sampled at 0.25, 0.5, 1, 2, and 4 h after the administration. Plasma samples were obtained by centrifugation at 12 000 rpm for 3 min, and then the radioactivity was measured with a liquid scintillation counter. Bile clearance was calculated from the difference between total clearance and the clearance obtained in bile-duct-ligated mice. Renal clearance was calculated from the difference between total clearance and the clearance obtained in renal-artery-ligated mice.

Physiologically Based Pharmacokinetic Model—A physiologically based pharmacokinetic model was constructed according to Harrison and Gibaldi,[11] including enterohepatic recirculation. As shown in Figure 1, the brain compartment was additionally modified in this study for investigation of the influence of *mdr*1a gene disruption. Since the digoxin plasma concentration−time profile was assumed to be biexponential up to 4 h (see Figure 2), we predetermined the pharmacokinetic parameters between plasma and brain with a hybrid model shown in Figure 3. In this hybrid model analysis, it was assumed that the drug penetrates by passive diffusion bidirectionally in both types of mice and is actively excluded by P-glycoprotein from the brain only in *mdr*1a (+/+) mice. The passive diffusion was defined as uptake clearance, and the efflux by P-glycoprotein was defined as efflux clearance

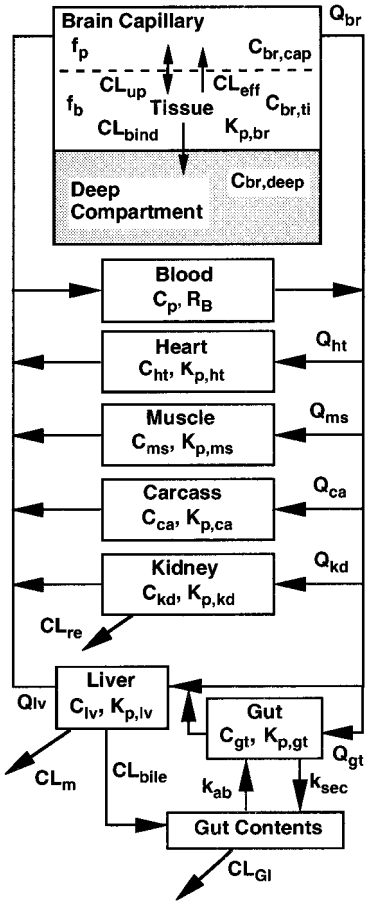

Figure 1—Physiologically based pharmacokinetic model for digoxin in mice: Q_i, CL_i, C_i and $K_{p,i}$ represent plasma flow rate, clearance, tissue drug concentration, and tissue-to-plasma concentration ratio for tissue i, respectively. The brain compartment was divided into three parts; CL_{up}, CL_{eff}, and CL_{bind} are the uptake clearance by passive diffusion, the efflux clearance by P-glycoprotein, and the binding clearance by accumulation, respectively.

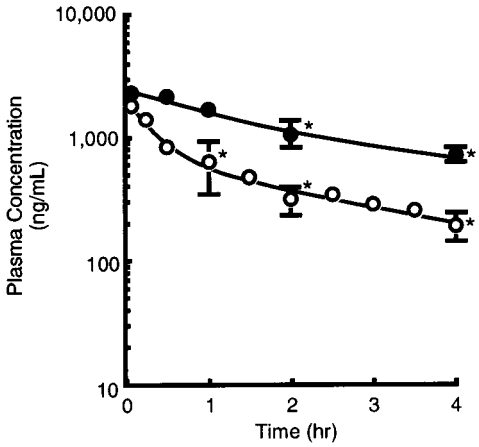

Figure 2—Plasma concentration–time profiles of [^{3}H]digoxin after 1 mg/kg intravenous administration in *mdr*1a (+/+) and *mdr*1a (–/–) mice. Drug solutions were administered to the lightly anesthetized *mdr*1a (+/+) and *mdr*1a (–/–) male mice via a jugular vein. Plasma concentrations were determined from the radioactivity. Open (○) and closed (●) symbols represent the results obtained in *mdr*1a (+/+) mice and *mdr*1a (–/–) mice, respectively (n = 3–5 for points marked with an asterisk (*); n = 1 for other points).

in this study. Two steps were taken in this determination. (1) The brain concentration−time profile in *mdr*1a (−/−) mice was simulated by means of the Runge−Kutta−Gill integration method using the hybrid model which employed a least-squares biexponential fitting to the plasma concentration−time profile. (2) The efflux clearance was estimated from the brain concentration−time

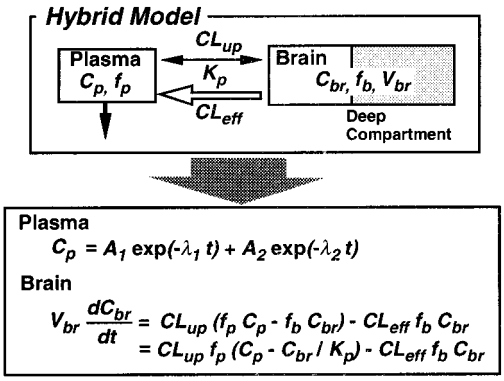

Figure 3—Hybrid pharmacokinetic model for brain distribution of drugs excluded by an active efflux system in mice. This model was employed for estimation of the values of CL_{up} and CL_{eff} in the brain under the condition that the distribution volume of brain was too small to affect significantly the systemic disposition of a test drug. In this model, it was assumed that the drug penetrates by passive diffusion with an uptake clearance (CL_{up}) bidirectionally in both types of mice and is actively excluded with an efflux clearance (CL_{eff}) by P-glycoprotein from the brain tissue only in *mdr*1a (+/+).

Table 1—Pharmacokinetic Parameters for Digoxin after 1 mg/kg Intravenous Administration in *mdr*1a (+/+) and *mdr*1a (–/–) Mice

	*mdr*1a (+/+)	*mdr*1a (–/–)
AUC (μg·min/mL)	155.4	439.8
MRT (min)	169.2	214.8
CL_{tot} (mL/min/kg)	6.44	2.27
V_d (L/kg)	1.09	0.488

profile in *mdr*1a (+/+) mice. Recently, Chen and Pollack have reported the simulation study of pharmacokinetics–pharmacodynamics of [D-penicillamine[2,5]]enkephalin[13] by a similar manner in *mdr*1a (–/–) mice.

As reported by Schinkel et al. the brain digoxin concentration in *mdr*1a (–/–) mice was very much higher than those in other tissues at 4 h after the administration.[8] Digoxin seems to be accumulated in brain tissue in *mdr*1a (–/–) mice. Then, the brain compartment was divided into three parts. The first compartment is brain capillary, the second is well-stirred brain tissue (interstitial fluid and intracellular space), and the third is a digoxin strongly binding deep compartment. The accumulation clearance to the deep compartment was determined by trial-and-error simulation.

Differential equations (see Appendix) were solved simultaneously by a FACOM-M776/20 in Kanazawa University Information Processing Center.

Results

Plasma Concentration–Time Profiles of Digoxin in *mdr*1a (+/+) and *mdr*1a (–/–) Mice—Figure 2 shows the plasma concentration–time profiles of digoxin after 1 mg/kg intravenous administration in *mdr*1a (+/+) and *mdr*1a (–/–) mice. Pharmacokinetic parameters were determined by moment analysis and are listed in Table 1. In *mdr*1a (–/–) mice, total clearance of digoxin was decreased to 30% of that in *mdr*1a (+/+) mice, and the distribution volume was also decreased to 50%. We also studied antipyrine plasma concentration–time profiles, which is considered as a marker of passive diffusion; there was no difference in these parameters between *mdr*1a (+/+) and *mdr*1a (–/–) mice (data not shown).

Tissue Distribution Study—Plasma and tissue digoxin concentration–time profiles were measured after 1 mg/kg administration in *mdr*1a (+/+) and *mdr*1a (–/–) mice. Tissue-to-plasma concentration ratios (K_p) were determined from the elimination phase according to Chen and Gross.[14] As shown in Table 2, K_p values of heart, muscle, intestine, and carcass were decreased largely in *mdr*1a (–/–) mice, being about half of those in *mdr*1a (+/+) mice. On the other hand, the K_p values of kidney and liver were slightly changed.

Table 2—Tissue-to-Plasma Concentration Ratios of Digoxin in *mdr*1a (+/+) and *mdr*1a (–/–) Mice

	*mdr*1a (+/+)	*mdr*1a (–/–)
brain	9.4	*a*
heart	1.13	0.626
muscle	0.804	0.424
kidney	1.07	0.797
liver	1.87	2.09
intestine	2.59	0.535
carcass	1.12	0.309

[a] K_p value of *mdr*1a (–/–) mice could not be determined by the method of Chen and Gross,[14] because it failed to reach the terminal phase.

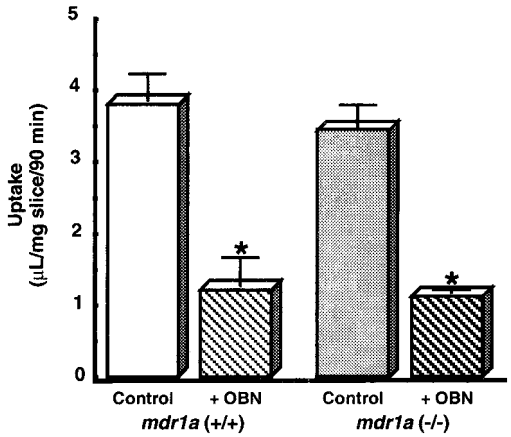

Figure 4—Effect of ouabain on the uptake of digoxin by brain slices from *mdr*1a (+/+) and (–/–) mice. Both types of mice were decapitated, and the brains were isolated and sliced with a razor blade in ice-cold buffer. The slices were preincubated at 37 °C for 10 min in the absence or presence of ouabain (500 μM), and then the uptake of [^{3}H]digoxin (7 nM) was measured for 90 min. Each column represents the mean ± SEM ($n = 4$). (*) Significantly different from control *mdr*1a (+/+) mice by Student's *t*-test ($p < 0.05$).

Brain and Muscle Slice Uptake Study—To clarify whether the changes in K_p values are related to the participation of P-glycoprotein, tissue binding, or other factors, an uptake study with brain and muscle slices was carried out.

As shown in Figure 4, there was no significant difference between digoxin uptake by brain slices of the two types of mice. In the presence of 500 μM ouabain, which completely inhibits digoxin binding to Na^+/K^+-ATPase, digoxin uptake was decreased to 30% of the control. It is likely that uptake clearance and binding of digoxin in the brain are not affected by the *mdr*1a gene product. The release of digoxin from brain slices was also at the same level in both types of mice. Although approximately 90% of digoxin still remained after 60 min, the amounts were decreased to 50% in the presence of 500 μM ouabain (data not shown). The brain digoxin concentration in *mdr*1a (+/+) mice was little changed at 12 h after administration in vivo, while the plasma digoxin concentration was decreased. These results strongly suggest that digoxin accumulation in the brain tissue results from binding of the drug with Na^+/K^+-ATPase, the contribution of which was estimated from the in vitro uptake study to account for approximately 70% of total brain digoxin concentration.

As shown in Figure 5, digoxin uptake by muscle slices was significantly decreased in *mdr*1a (–/–) mice, being about half of that in *mdr*1a (+/+) mice. This is the same as the in vivo distribution, indicating that the distribution

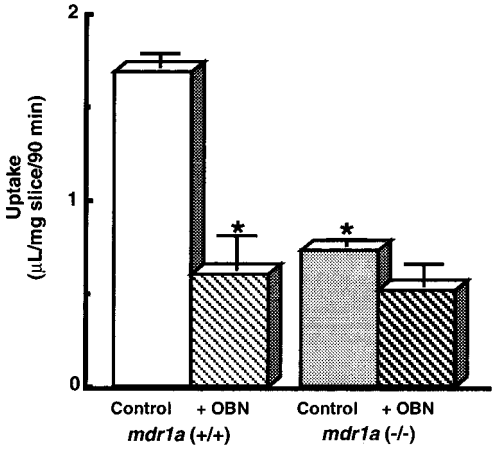

Figure 5—Effect of ouabain on the uptake of digoxin by muscle slices from *mdr*1a (+/+) and (–/–) mice. Muscle slices from both types of mice were preincubated at 37 °C for 10 min in the absence or presence of ouabain (500 μM), and then the uptake of [^{3}H]digoxin (7 nM) was measured for 90 min. Each column represents the mean ± SEM ($n = 4$). (*) Significantly different from control *mdr*1a (+/+) mice by Student's *t*-test ($p < 0.05$).

Table 3—Renal and Bile Clearances in *mdr*1a (+/+) and *mdr*1a (–/–) Mice[a]

clearance	*mdr*1a (+/+) (mL/min/kg)	*mdr*1a (–/–) (mL/min/kg)
CL_{tot}	5.64 (100)	1.91 (100)
CL_{re}	3.15 (55.9)	0.99 (51.8)
CL_{bile}	2.30 (40.8)	0.84 (44.0)
CL_m	0.19 (3.4)	0.08 (4.2)

[a] Renal and bile clearances of both types of mice were determined from the decrease in apparent total clearance in renal-artery-ligated and bile-duct-ligated mice, respectively. Percentage contributions to total clearance are shown in parentheses. Metabolic clearance was assumed to be residual clearance.

volume has decreased in *mdr*1a (−/−) mice. Digoxin uptake by muscle slices of both types of mice was decreased to the same level in the presence of 500 μM ouabain. Approximately 80% of digoxin was released after 60 min (data not shown).

Plasma-Free Fraction and Blood-to-Plasma Partition Coefficient of Digoxin—Plasma-free fraction (f_p) of digoxin was estimated to be about 0.78 in both types of mice, and there was no significant change with digoxin concentration from 0.1 to 1000 ng/mL. The R_B values of *mdr*1a (+/+) and *mdr*1a (−/−) mice were 0.898 ± 0.040 and 0.883 ± 0.033 ($n = 5-6$, mean ± SEM), respectively. These results suggest that plasma protein binding and binding to blood cells were not affected by the *mdr*1a gene product.

Estimation of Renal and Bile Clearances—To determine the contributions of renal and bile clearances, 1 mg/kg digoxin was administered intravenously to renal artery- or bile-duct-ligated mice. Renal or bile clearance was estimated from the difference from total clearance, and the results are listed in Table 3. Renal and bile clearances were 55.9% and 40.8% of total clearance in *mdr*1a (+/+) mice, and 51.8% and 44.0% in *mdr*1a (−/−) mice, respectively. In *mdr*1a (−/−) mice, total clearance was decreased to 30% of the control, while there was little change in the contribution of renal and bile clearances to total clearance.

Plasma, urine, and bile samples were analyzed by high-performance liquid chromatography. No metabolite was detected by HPLC in urine, bile, or plasma. Metabolic clearance in both types of mice seems to be very small. Furthermore, as shown in Table 3, the sum of renal and biliary clearances was nearly equal to the total clearance in both types of mice, supporting the above findings.

Physiologically Based Pharmacokinetic Model for Digoxin in Mice—After the determination of renal and bile clearances, enterohepatic clearances were estimated. GI tract clearance was estimated by scaling down from the data reported by Harrison and Gibaldi for rats.[11] The absorption and secretion rate constants were assumed to be the same as those in rats. In *mdr*1a (−/−) mice, the secretion clearance was assumed to be zero, because there was no P-glycoprotein expression in the small intestine of *mdr*1a (−/−) mice.

The brain digoxin concentration−time profile showed a quite different pattern from that of plasma. In *mdr*1a (+/+) mice, the brain digoxin concentration increased rapidly after administration and then decreased slowly after 4 h. In *mdr*1a (−/−) mice, the brain digoxin concentration increased slowly to a plateau. Therefore, the brain digoxin pharmacokinetics was considered to be complex. Because this phenomenon could not be described by a uniform compartment, the brain compartment was divided into three parts. The first is the capillary blood space compartment, the second is the well-stirred interstitial and intracellular compartment, and the third is the digoxin strongly binding compartment (deep compartment). The volumes of the capillary blood space and interstitial fluid or brain tissue were taken from the literature. Since the amount of digoxin uptake by brain slices decreased to 30% of the control in the presence of ouabain, the Na^+/K^+-ATPase-related binding space was estimated to be about 70% of brain tissue volume. Estimated uptake and efflux clearances (see Figure 3) were 2.5 μL/min and 0.4 mL/min, the accumulation clearance to the deep compartment was 0.1 μL/min determined by trial-and-error simulation. All parameters used in this pharmacokinetic model are listed in Table 4.

Finally, plasma and tissue digoxin concentration−time profiles in both types of mice were simulated according to the physiologically based model illustrated in Figure 1 and in the Appendix, and the results are shown in Figure 6a,b. All tissues and plasma concentration−time profiles up to 12 h after administration were well predicted.

Discussion

We have shown here that the conspicuous difference of brain digoxin concentration between *mdr*1a (−/−) and (+/+) mice can be simulated with this physiologically based model. It is noteworthy that the efflux clearance determines the distinctive pharmacokinetics of digoxin in *mdr*1a (−/−) mice. P-Glycoprotein in the kidney and liver acts as a secretion pump, while it acts as an absorption barrier or efflux pump in the small intestine for a variety of structurally unrelated hydrophobic and neutral or cationic compounds, including many cytotoxic drugs, and also as a transporter of steroid hormones in the adrenals and placenta.[9,15−23] Furthermore, P-glycoprotein in brain capillary endothelial cells acts as a blood−brain barrier to lipophilic drugs.[1,24−30] As P-glycoprotein is expressed in almost all tissues of the body, the absence of P-glycoprotein may cause remarkable changes in drug pharmacokinetics. In fact, Schinkel et al. reported that the pharmacokinetics of substrates of P-glycoprotein was changed in several tissues and dramatically in the brain of *mdr*1a (−/−) mice.[7,8]

Schinkel et al. reported that there are no physiological abnormalities in *mdr*1a (−/−) mice.[7] We also confirmed that the plasma protein binding, blood-to-plasma partition ratio, and metabolic feature of digoxin were the same in both types of mice. However, the digoxin concentration in the brain of *mdr*1a (−/−) mice was markedly increased, owing to the absence of efflux clearance via P-glycoprotein at the blood−brain barrier. Moreover, the digoxin concen-

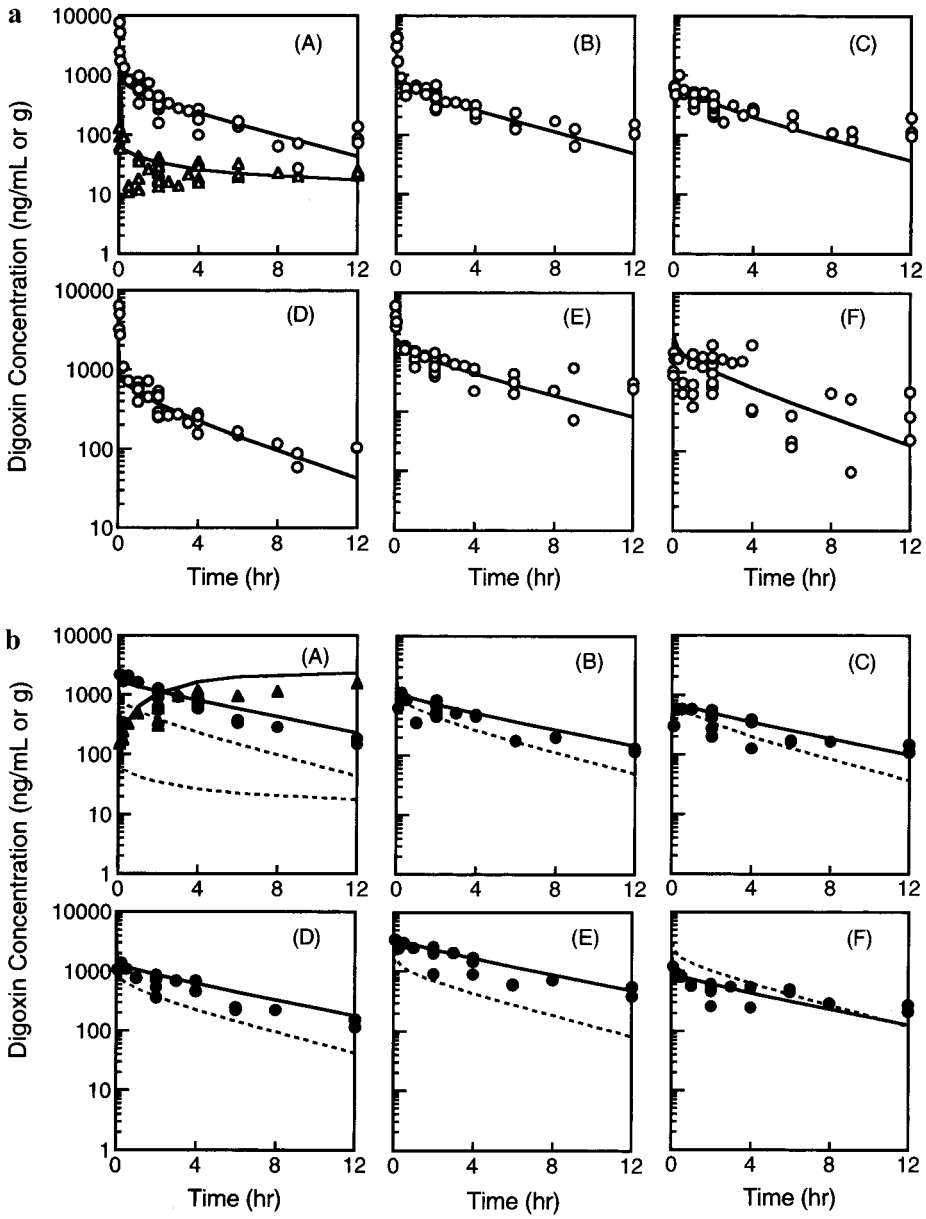

Figure 6—(a) Predicted and observed plasma and tissue concentrations of digoxin in *mdr*1a (+/+) mice after 1 mg/kg intravenous administration: (A) plasma (○), brain (△), (B) heart, (C) muscle, (D) kidney, (E) liver, and (F) gut. Solid lines represent the simulation curves from the physiologically based pharmacokinetic model. (b) Predicted and observed plasma and tissue concentrations of digoxin in *mdr*1a (–/–) mice after 1 mg/kg intravenous administration. (A) plasma (●), brain (▲), (B) heart, (C) muscle, (D) kidney, (E) liver, and (F) gut. Solid and dashed lines represent the simulation curves for *mdr*1a (–/–) mice and for *mdr*1a (+/+) mice, respectively.

tration in the brain of both types of mice remained high after 4 h. This phenomenon suggests that there is a deep compartment concerned with digoxin accumulation, and this is consistent with the conclusion from the brain slice study that digoxin binds to Na^+/K^+-ATPase.

Mayer et al. reported that urinary excretion of digoxin in *mdr*1a (−/−) mice was increased twice that of *mdr*1a (+/+) mice, and fecal excretion was decreased.[10] More than 16% of the administered digoxin was directly excreted in the intestinal lumen of *mdr*1a (+/+) mice within 90 min and at least 20% of metabolite was excreted in urine in their study. We also reported active secretion from the small intestine in rats.[22] However the contribution of renal clearance to total clearance was little changed in this study. Furthermore, we could not detect any metabolite in urine, bile, or plasma in either type of mouse. The reasons for these differences are unclear, but total radioactivity recovered was almost 100% of initial radioactivity. Although we used literature values for the active secretion and absorption rate constant of the intestine,[11] we could successfully simulate the digoxin pharmacokinetics in *mdr*1a (−/−) mice by neglecting the efflux clearance in the brain and intestine.

Plasma and tissue digoxin concentrations were increased and total body clearance was decreased in *mdr*1a (−/−) mice. However, the K_p values of kidney and liver were little changed. As Schinkel et al. reported that the *mdr*1b gene is up-regulated in liver and kidney of *mdr*1a (−/−) mice,[7] we also observed an increase of *mdr*1b gene expression in those organs (data not shown). This result suggests that digoxin clearance in *mdr*1a (−/−) mice may be supported by the up-regulated *mdr*1b gene in these organs.

In conclusion, we constructed a physiologically based pharmacokinetic model of digoxin in mice by adding a subdivided brain compartment based on the model of Harrison and Gibaldi in rats.[11] Our model could simulate the pharmacokinetics of digoxin in all tissues of *mdr*1a (+/+) and *mdr*1a (−/−) mice. The difference of the brain

[a] All parameters were estimated for mice with 22.0 g body weight. [b] Measured. [c] Estimated from ref 11. [d] Rate (h^{-1}). [e] Cited from Mordenti, J., et al. *J. Pharm. Sci.* **1986**, *75*, 1028–1040.

digoxin concentration between *mdr*1a (+/+) and *mdr*1a (−/−) mice could be explained completely in terms of the existence or absence of efflux clearance at the brain capillaries. Since P-glycoprotein regulates the distribution of digoxin into the brain by active efflux transport, co-administration with P-glycoprotein reversal drugs may cause serious side effects of digoxin.

Appendix

Mass balance equations are listed below.

blood pool:

$$V_p R_B(dC_p/dt) = R_B[(Q_{ht}C_{ht}/K_{p,ht}) + (Q_{ms}C_{ms}/K_{p,ms}) + (Q_{kd}C_{kd}/K_{p,kd}) + (Q_{li}C_{li}/K_{p,li}) + (Q_{ca}C_{ca}/K_{p,ca}) + Q_{br}C_{br,cap}] - R_B Q_{blood}C_p$$

brain capillaries:

$$V_{br,cap}R_B(dC_{br,cap}/dt) = R_B[Q_{br}(C_p - C_{br,cap}) - CL_{up}f_p(C_{br,cap} - C_{br,ti}/K_{p,br}) + CL_{eff}f_bC_{br,ti}]$$

brain tissue:

$$V_{br,ti}(dC_{br,ti}/dt) = CL_{up}f_p(C_{br,cap} - C_{br,ti}/K_{p,br}) - CL_{eff}f_bC_{br,ti} - CL_{bind}C_{br,ti}$$

brain deep compartment:

$$V_{br,deep}(dC_{br,deep}/dt) = CL_{bind}C_{br,ti}$$

heart, muscle, carcass:

$$V_i(dC_i/dt) = R_B Q_i(C_p - C_i/K_{p,i})$$

kidney:

$$V_{kd}(dC_{kd}/dt) = R_B Q_{kd}(C_p - C_{kd}/K_{p,kd}) - CL_{re,int}f_pC_{kd}/K_{p,kd}$$

liver:

$$V_{li}(dC_{li}/dt) = R_B(Q_{li} - Q_{gt})C_p + R_B Q_{gt}C_{gt}/K_{p,gt} - R_B Q_{li}C_{li}/K_{p,li} - (CL_m + CL_{bile,int})f_pC_{li}/K_{p,li}$$

gut wall:

$$V_{gt}(dC_{gt}/dt) = R_B Q_{gt}(C_p - C_{gt}/K_{p,gt}) + k_{ab}C_{gc}V_{gc} - k_{sec}C_{gt}V_{gt}$$

gut contents:

$$V_{gc}(dC_{gc}/dt) = k_{sec}C_{gt}V_{gt} + CL_{bile,int}f_pC_{li}/K_{p,li} - k_{ab}C_{gc}V_{gc} - CL_{GI}C_{gc}$$

where R_B = blood to plasma partition coefficient for digoxin, V_i = volume for tissue i, C_i = concentration for tissue i, Q_i = blood flow rate for tissue i, $K_{p,i}$ = tissue to plasma concentration ratio for tissue i, f_p (f_b) = plasma (tissue) free fraction, k_{ab} (k_{sec}) = absorption (secretion) rate constant, CL_{re} = renal clearance, CL_m = metabolic clearance, CL_{bile} = biliary clearance, CL_{up} = brain tissue uptake clearance, CL_{eff} = brain tissue efflux clearance, CL_{bind} = brain deep compartment binding clearance, and CL_{GI} = GI clearance (fecal clearance).

Abstract □ The monolayer-forming, human choriocarcinoma cell line, BeWo, was used to study the mechanisms of monocarboxylic acid transport across the human trophoblast. Benzoic acid, acetic acid, and lactic acid were used as markers for monocarboxylic acid carrier-mediated transport. The uptake of benzoic acid by BeWo cells was saturable ($K_t = 0.6 \pm 0.3$ mM) at higher concentrations and significantly inhibited by typical metabolic inhibitors, sodium azide and 2,4-dinitrophenol. A selection of different monocarboxylic acids, including a natural substrate lactic acid, also substantially inhibited the uptake of benzoic acid and acetic acid by BeWo cells, whereas dicarboxylic acids did not affect the uptake of either marker. Monocarboxylic acid uptake was pH-dependent and inhibited by carbonyl cyanide *p*-trifluoromethoxyphenylhydrazone (FCCP), a protonophore. Kinetic analysis using Lineweaver–Burk plots revealed that monocarboxylic acids competitively inhibited the uptake of benzoic, lactic, and acetic acid by BeWo cells. In transport experiments, the permeation of benzoic acid from apical-to-basolateral side was greater than the permeation from the basolateral-to-apical side, and the transport of benzoic acid from apical-to-basolateral side was inhibited by monocarboxylic acids. The findings obtained in the present study confirm the existence of an asymmetric, carrier-mediated transport system for monocarboxylic acids across the BeWo cell, a representative of the human trophoblast.

Introduction

The placenta, in part, serves as a semipermeable barrier separating the maternal and fetal circulations. The placental barrier is comprised of a single layer of trophoblasts that have an important role in controlling the passage of molecules from mother to fetus. In general, the absorption of drugs across the single layer of trophoblasts can be explained in terms of the pH-partition hypothesis which is well illustrated by passive diffusion mechanisms.[1,2] However, with the use of brush-border-membrane vesicle techniques or cultured cells,[3] it has become increasingly clear that there are a number of carrier-mediated transport mechanisms present at the placental barrier including systems for amino acids,[3,4] transferrin,[5] and dopamine.[6] These carriers take on pharmaceutical relevance due to the fact that nutrients and hormones, as well as drugs and drugs of abuse, can be transported across the placental barrier by these mechanisms.[7]

Carrier-mediated transport mechanisms for monocarboxylic acids exist in many cell types.[8−10] In fact, there are known to be at least seven putative monocarboxylic acid transporter (MCT) isoforms. The mRNA representing five of the seven MCTs has been shown in human placenta.[11] Using brush border membrane preparations, a functional, proton-dependent MCT has been observed in tissues from rat[12,13] and human[14] placenta. A functional, bidirectional, and carrier-mediated mechanism for lactic acid, presumably a MCT, has also been demonstrated in the perfused human placental lobe model.[15] In addition to the transport of lactic acid,[11,14,15] a MCT at the placental barrier presents a potential mechanism by which monocarboxylic acid drugs and drugs of abuse may readily distribute between maternal and fetal compartments. Therefore, the characterization of a placental MCT system can contribute to an understanding of the trophoblast transport mechanisms controlling fetal exposure to substances possessing a monocarboxylic acid constituent.

The objective of this study was to investigate the presence of a functional MCT in BeWo cell monolayers, a representative human trophoblast culture system.[16] BeWo cell monolayers have been applied to studies of the polarized trans-trophoblast transport of serotonin and transferrin, monoamine uptake processes, and relevant nutrient uptake and transport systems.[16−18] The existence of MCT systems in the BeWo cells would provide an in vitro tool representative of the human trophoblast to characterize trans-placental transport mechanisms that influence drug distribution in pregnancy. The BeWo cell line is particularly attractive for the studies of drug distribution at the placenta barrier because it is stable, relatively easy to maintain by passage, and grows to a confluent monolayer in a relatively short period of time. Indeed, in contrast to primary cultures, the cell line is one of the few existing trophoblast cell culture systems to form a confluent monolayer that allows trans-trophoblast transport studies. More importantly, the BeWo cell displays morphological properties and biochemical marker enzymes and hormone secretion common to normal trophoblasts.[16]

Materials and Methods

Materials—[^{14}C]Benzoic acid (55 Ci/mol), [^{14}C]-L-lactic acid (150 Ci/mmol), and [^{14}C]acetic acid (55 Ci/mol) were obtained from American Radiolabeled Chemicals (St. Louis, MO). Fetal bovine serum (FBS) was from JRH Bioscience (Lenexa, KS). Penicillin–streptomycin as a mixture was from Gibco (Gaithersburg, MD). Translucent polycarbonate filters (13 mm diameter, 0.4 μm pore size) were purchased from Fisher Scientific. All other chemicals were of the purest available analytical grade and purchased from Fisher or Sigma (St. Louis, MO).

Cell Culture—The BeWo cell line was originally derived from a human choriocarcinoma. The BeWo clone (b30) was obtained from Dr. Alan Schwartz (Washington University, St. Louis, MO). The cells were cultured by the methods previously described, and the cells used in these experiments were from passages 28 to 40.[16] Briefly, the cells were cultured in Dulbecco's modified Eagle's medium (DMEM) with 10% heat-inactivated FBS containing 0.37% sodium bicarbonate and 1% antibiotics (10 000 U/mL penicillin and 10 mg/mL streptomycin). The cells were maintained

in 175-cm^2 flasks at pH 7.4 under 5% CO_2 and 95% humidity at 37 °C. The cells were harvested by exposure to a trypsin−EDTA solution (0.25% trypsin and 0.02% EDTA in HBSS) and passed onto 12-well tissue culture plates or polycarbonate membranes coated with rat tail collagen in 100-mm culture dishes. With the seeding density of 10 000 cells/cm^2, the cells formed confluent monolayers between 2 and 3 days and were used for experiments at that time.

Uptake Experiments—The BeWo cells at confluence were washed twice with Hank's balanced salt solution (HBSS; 136.7 mM NaCl, 0.385 mM Na_2HPO_4, 0.441 mM KH_2PO_4, 0.952 mM $CaCl_2$, 5.36 mM KCl, 0.812 mM $MgSO_4$, 25 mM D-glucose, and 10 mM HEPES (2-[4-(2-hydroxyethyl)-1-piperazinyl]ethanesulfonic acid) for adjustment to pH 7.0 or 7.5 or 10 mM MES (2-morpholinoethanesulfonic acid, monohydrate) for adjustment to pHs < 6.5 and then the test solution containing [^{14}C]benzoic acid or [^{14}C]acetic acid or [^{14}C]-L-lactic acid was added at 0.25 μCi/mL as a marker for monocarboxylic acid carrier-mediated transport. The pH of the test solution was 6.0 except in the pH-dependent uptake experiments. After 30 s, the test solution was aspirated away, and the cells were washed with ice-cold HBSS three times. For quantitation of drug uptake, the cells were suspended in 1.0 N NaOH, and the suspension was incubated at 37 °C overnight at which point a half volume of 2.0 N HCl was added. Radioactivity was quantitated using a liquid scintillation counter. Cellular protein was quantified using a protein assay kit (Pierce) with bovine serum albumin as a standard. Details of the conditions for each experiment are given in the figure legends or table footnotes.

In one series of experiments, an equivalent amount of choline chloride replaced sodium chloride in the HBSS and was used as a sodium-depleted buffer.

Transport Experiment—A horizontal Side-Bi-Side diffusion apparatus (Crown Glass) was used to measure the transmonolayer permeability of cells grown on the surface of 0.4 μm pored polycarbonate filters, as previous described.[16] The cells faced the donor chamber as the apical side, and the polycarbonate membrane faced the receiver chamber as the basolateral side. The water jacket surrounding the donor and the receiver chambers was thermostated at 37 °C. The contents of each chamber were continuously stirred at 600 rpm with magnetic stir bars. When the apical-to-basolateral transport studies were performed, the pH of the donor (apical) side was 6.0 and that of receptor (basolateral) side was 7.4. When the basolateral-to-apical transport studies were performed, the pH of the donor (basolateral) side was 6.0 and that of the receptor (apical) side was 7.4. The concentration of added [^{14}C]benzoic acid was 0.25 μCi/mL. A 0.2-mL aliquot from the receiver chamber was taken at several time points up to 60 min.

Calculation of Apparent Permeability Coefficients—Apparent permeability coefficients for the monolayers of cells, P_e, were calculated from the following relationship

$$1/P_t = 1/P_e + 1/P_m \quad (1)$$

where P_t is apparent permeability coefficient for the collage-coated membrane in the presence of monolayers, and P_m is the apparent permeability coefficient for collagen-coated polycarbonate membrane alone.[19]

Michaelis−Menten Parameters—To estimate the values of the kinetic parameters of saturable uptake by BeWo cells, the uptake rate (J) was fitted to the following equation, which consists of both saturable and nonsaturable linear terms, using a nonlinear least-squares regression analysis program MULTI:[20]

$$J = J_{max} \times C/(K_t + C) + k \times C \quad (2)$$

where J_{max} is the maximum uptake rate for a carrier-mediated process, C is the benzoic acid concentration, K_t is the half-saturation concentration (Michaelis constant), and k is a first-order rate constant.

Statistical Analysis—All results were expressed as means ± standard deviation (SD). Statistical analysis between two groups was performed using Student's t-test, and one-way analysis of variance (ANOVA) was used for single and multiple comparisons. P values of 0.05 or less were considered to indicate a statistically significant difference.

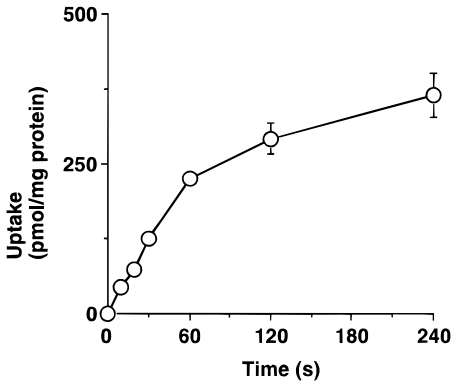

Figure 1—Time course of [^{14}C]benzoic acid uptake by BeWo cells. The vertical bar through each point represents the SD for four replicate experiments.

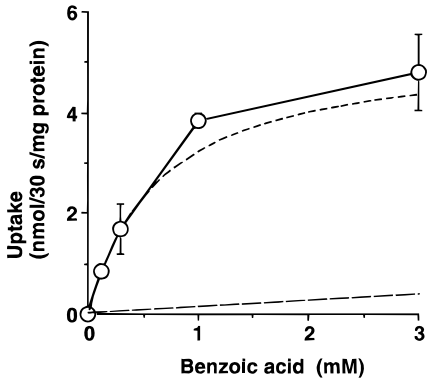

Figure 2—Concentration dependency of [^{14}C]benzoic acid uptake by BeWo cells. The uptake of [^{14}C]benzoic acid by BeWo cells was measured at 37 °C for 30 s. The upper dotted line represents the uptake for the saturable component calculated from the kinetic parameters obtained as described in the text. The lower dotted line represents the uptake for the nonsaturable component calculated from the kinetic parameters. The vertical bar through each point represents the SD of four replicate experiments.

Results

[^{14}C]Benzoic acid was rapidly accumulated in BeWo cells with time (Figure 1). The uptake was linear initially and reached equilibrium at about 2 min. Therefore, all subsequent uptake studies and kinetic analysis were performed from data collected through 30 s.

Figure 2 shows the relationship between the initial rate of uptake of [^{14}C]benzoic acid and its concentration in the incubation buffer. The results indicated that the uptake of benzoic acid consisted of two processes, a saturable process evident at low concentrations and an apparently nonsaturable process evident at high concentrations. The uptake processes were analyzed according to eq 2. The kinetic parameters calculated for benzoic acid uptake were a J_{max} of 0.52 ± 0.22 nmol/30 s/mg of protein, a K_t of 0.64 ± 0.26 mM, and a k of 0.11 ± 0.06 μL/30 s/mg of protein. The upper dotted line represents the uptake for the saturable component calculated from the kinetic parameters. The lower dotted line represents the uptake for the nonsaturable component calculated from the kinetic parameters. At any given concentration, the uptake by saturable component was higher than that by nonsaturable one.

The effects of metabolic inhibitors on the uptake of [^{14}C]-benzoic acid were studied to determine whether this uptake required cell-dependent energy expenditure (Table 1). Sodium azide (10 mM), a respiratory chain inhibitor, or 2,4-dinitrophenol (1 mM), an uncoupler of oxidative phosphorylation, significantly inhibited the uptake of [^{14}C]-benzoic acid by the BeWo cells. Moreover, carbonyl cyanide

Table 1—Effects of Metabolic Inhibitors, Ionophore (carbonyl cyanide *p*-(trifluoromethoxy)phenylhydrazone; FCCP), anion-exchange (4,4′-diisothiocyanostilbene-2,2′-disulfonic acid; DIDS) Inhibitors, and Sodium-Depleted Buffer on [^{14}C] Benzoic Acid Uptake by BeWo Cell Monolayers at 37 °C[a]

inhibitor	concn	relative uptake (percent of control)[b]
sodium azide	10 mM	20.1 ± 5.2[c]
2,4-dinitrophenol	1 mM	13.3 ± 7.4[c]
FCCP	50 μM	9.3 ± 1.4[c]
DIDS	100 μM	117.5 ± 8.1
sodium-depleted buffer	no treatment	101.7 ± 11.7

[a] BeWo cells were pretreated with these agents for 15 min prior to performing an uptake experiment. [b] Each value represents the mean ± standard deviation of four experiments. [c] $P < 0.001$ versus untreated control (100%).

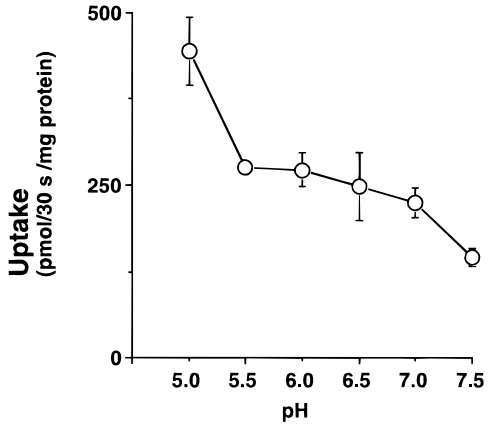

Figure 3—pH dependence of [^{14}C]benzoic acid uptake by BeWo cells. The uptake of [^{14}C]benzoic acid by BeWo cells was determined at the indicated pH at 37 °C. The vertical bar through each point represents the SD of four replicate experiments.

p-(trifluoromethoxy)phenylhydrazone (FCCP; 50 μM), a protonophore, significantly inhibited the uptake (Table 1), whereas 4,4′-diisothiocyanostilbene-2,2′-disulfonic acid (DIDS; 0.1 mM), an anion-exchange inhibitor, had no inhibitory effect on benzoic acid uptake. Finally, the uptake of benzoic acid in a sodium-depleted buffer was not different from the control, suggesting the mechanism was not sodium-dependent (Table 1). Figure 3 illustrates the effect of incubation buffer pH in the range from 5.0 to 7.5 on [^{14}C]-benzoic acid uptake by BeWo cells. The rate of [^{14}C]benzoic acid uptake decreased with increasing pH from an acidic to a neutral pH. These findings, together with the concentration dependence and sensitivity to metabolic inhibitors, strongly suggested that [^{14}C]benzoic acid uptake by BeWo cells was dependent on a proton gradient and was carrier-mediated.

To investigate the properties of the carrier involved in [^{14}C]benzoic acid uptake by BeWo cells, we studied the effects of various mono- and dicarboxylic acids on this uptake (Table 2). Each monocarboxylic acid, including lactic acid, significantly inhibited the uptake of [^{14}C]benzoic acid, whereas none of the dicarboxylic acids had a significant inhibitory effect on the uptake of the marker. We also found that the BeWo cells take up [^{14}C]acetic acid and that this uptake was significantly inhibited by monocarboxylic acids, including lactic acid (Table 2). In contrast, dicarboxylic acids had no marked effect on the uptake of [^{14}C]acetic acid by BeWo cells. These results implied that the carrier that mediates monocarboxylic acid uptake by BeWo cells was a nonspecific monocarboxylic acid carrier. Additionally, the carrier is relatively stereoselective as distinguished by the variable inhibition by the two lactic acid isomers.

Table 2—Effects of Selected Carboxylic Acids on [^{14}C]Benzoic Acid or [^{14}C]Acetic Acid Uptake by BeWo Cell Monolayers at 37 °C[a]

		relative uptake (percent of control)[b]	
		[^{14}C]benzoic acid	[^{14}C]acetic acid
monocarboxylic acids	benzoic acid	10.8 ± 0.2[c]	19.5 ± 2.7[c]
	D-lactic acid	20.4 ± 1.8[c]	26.5 ± 4.2[c]
	L-lactic acid	6.1 ± 1.3[c]	13.4 ± 1.5[c]
	propionic acid	12.7 ± 0.9[c]	18.9 ± 2.6[c]
	acetic acid	10.1 ± 2.0[c]	36.9 ± 2.9[c]
	p-aminobenzoic acid	5.5 ± 0.1*	20.7 ± 3.4*
	acetylsalicylic acid	12.3 ± 1.3*	11.1 ± 1.0*
	salicylic acid	3.5 ± 0.1*	9.3 ± 0.7*
dicarboxylic acids	glutaric acid	91.0 ± 8.5	107.2 ±12.8
	fumaric acid	113.8 ± 5.5	98.4 ±10.4
	maleic acid	92.1 ± 7.3	102.4 ±28.4

[a] [^{14}C]Benzoic acid or [^{14}C]acetic acid uptake by BeWo cells were performed in the presence of 10 mM (2000-fold excess) of the indicated carboxylic acid. [b] Each value represents the mean ± standard deviation of four experiments. [c] $P < 0.001$ versus untreated control (100%).

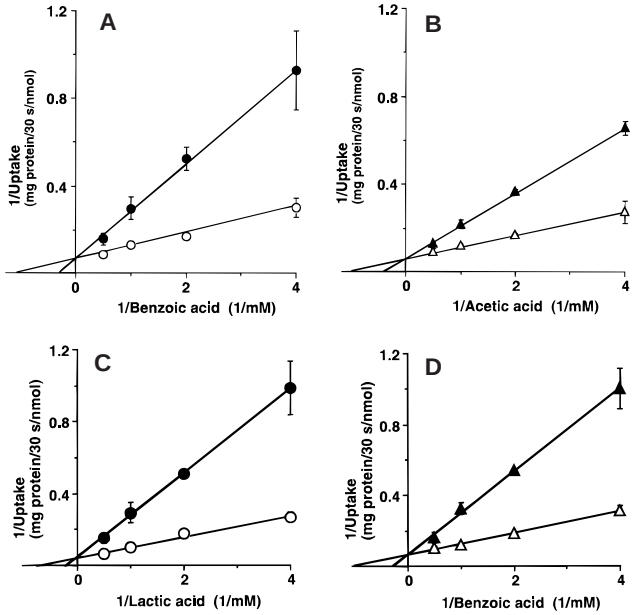

Figure 4—Lineweaver–Burk plots. (A) The concentration-dependent uptake of [^{14}C]benzoic acid by BeWo cells. Uptake was measured in the absence (open circles) or presence of 2 mM acetic acid (closed circles). (B) The concentration-dependent uptake of [^{14}C]acetic acid by BeWo cells. Uptake was measured in the absence (open triangles) or presence of 2 mM benzoic acid (closed triangles). (C) The concentration-dependent uptake of [^{14}C]-L-lactic acid by BeWo cells. Uptake was measured in the absence (open circles) or presence of 2 mM benzoic acid (closed circles). (D) The concentration-dependent uptake of [^{14}C]benzoic acid by BeWo cells. Uptake was measured in the absence (open circles) or presence of 2 mM L-lactic acid (closed circles). The vertical bar through each data point in the figures represents the SD of four replicate experiments.

To study the mechanism of the benzoic acid or acetic acid or lactic acid uptake inhibition by the monocarboxylic acids, we analyzed the inhibitory effect kinetically. Figure 4A shows a Lineweaver–Burk plot for the uptake of [^{14}C]-benzoic acid by BeWo cells in the absence or presence of 2 mM acetic acid. Acetic acid competitively inhibited the uptake of benzoic acid by the BeWo cells. Figure 4B shows a Lineweaver–Burk plot for the uptake of [^{14}C]acetic acid by BeWo cells in the absence or presence of 2 mM benzoic acid. Similarly, Figures 4C and 4D confirm that lactic acid and benzoic acid interact with the BeWo uptake mechanism by a competitive process. Table 3 summarizes the kinetic data and indicates that the K_m's and K_i's for benzoic,

Table 3—Lineweaver–Burke Uptake and Inhibition Constants for Monocarboxylic Acid Uptake by BeWo Cell Monolayers at 37 °C

	k_m (mm)[b]	benzoic acid k_i (mm)[b]	acetic acid k_i (mm)[b]	lactic acid k_i (mm)[b]
[^{14}C]benzoic acid[a]	1.0 ± 0.1	–	1.1 ± 0.2	0.7 ± 0.3
[^{14}C]acetic acid[a]	0.8 ± 0.2	0.8 ± 0.3	–	–

[a] [^{14}C]Benzoic acid or [^{14}C]acetic acid or [^{14}C]lactic acid uptake by BeWo cells were performed alone and in the presence of 2 mM (1- to 8-fold excess) of the indicated monocarboxylic acid. [b] Each value represents the mean ± standard deviation of four experiments.

Table 4—Apparent Permeability Coefficients for the Passage of [^{14}C]Benzoic Acid across BeWo Cell Monolayers at 37 °C

direction of benzoic acid permeation across monolayer	treatment	permeability coefficient ($\times 10^3$ cm/s)
apical to basolateral	none	4.90 ± 1.01
	+ benzoic acid[a]	0.45 ± 0.04[b]
	+ valproic acid[a]	0.64 ± 0.21[b]
basolateral to apical	none	1.06 ± 0.70[b]

[a] [^{14}C]Benzoic acid permeation across BeWo cell monolayers was performed in the presence of 10 mM (2000-fold excess) of the indicated carboxylic acid in the apical chamber. [b] $P < 0.001$ versus untreated benzoic acid permeation apical to basolateral.

acetic, and lactic acid for the apparent moncarboxylic acid uptake mechanism were similar.

The trans-trophoblast passage of [^{14}C]benzoic acid across the BeWo monolayer was found to be asymmetric, with the permeability coefficient greater in the apical-to-basolateral direction than that in the basolateral-to-apical direction, as shown in Table 4. The passage of [^{14}C]benzoic acid across the BeWo monolayers was inhibited by an excess amount of unlabeled benzoic acid or other monocarboxylic acid (valproic acid) as shown in Table 4, affirming that the transcellular passage of the monocarboxylic acid appeared similar to the uptake process.

Discussion

Passive diffusion is the primary mechanism by which xenobiotics cross the placental barrier.[1] However, some carrier-mediated transport systems in the trophoblast have been described using brush-border membrane vesicles or cultured cells,[3,5,6] including functional MCTs.[12−14] These carrier systems are notable for mediating the distribution of both endogenous and exogenous substances across the placental barrier.[7] Recent studies in knockout mice have effectively illustrated the relevance of placental transport mechanisms, e.g., P-glycoprotein, in protecting the fetus from exposure to chemicals.[21] Consequently, the recognition of transport mechanisms is important for developing an understanding of the molecular mechanisms and role of the trophoblast in regulating drug passage across the placental barrier. There is also a critical need for in vitro systems of human origin that allow characterization of mechanisms regulating drug distribution between mother and fetus to aid in the future design and development of drugs that can be safely administered in pregnancy.[22,23]

In the present study, we used benzoic acid uptake and transport, as a marker for the monocarboxlic acid transport[8] in BeWo cell monolayers. The establishment of functional MCT mechanisms in the BeWo cells offers the opportunity to characterize mechanisms of monocarboxylic acid transport at the molecular and biochemical level, extending limited studies performed with brush border preparations[12−14] and the perfused human placental lobe.[15]

The processing of benzoic acid by the BeWo monolayers was characterized by saturable uptake and transport. The processes were significantly inhibited by metabolic inhibitors and indicated that benzoic acid uptake is energy dependent. Benzoic acid transport and uptake were also significantly inhibited by in a competitive manner by unlabeled benzoic acid, acetic acid, and lactic acid. Further, benzoic acid uptake and transport were significantly inhibited by monocarboxylic acids but not selected dicarboxylic acids. The competitive nature of the transport, evidenced by the kinetic parameters, was consistent with observations reported for the transport of monocarboxylic acids in placental brush border vesicles.[12−14]

The advantage of the BeWo monolayer system is that trans-trophoblast transport properties can be characterized in a polarized cell.[16] We were able to show the passage of benzoic acid across the BeWo monolayers was bidirectional and of a faster rate going in the apical-to-basolateral side direction across the monolayers in the presence of a pH gradient. These observations are in good agreement with the lactate transport studies performed in the perfused human placental lobe model.[15] Further, our studies suggested a functional asymmetry in the carrier mechanism.

Caco-2 cells, which are a well-characterized model of the intestinal epithelium, possess a monocarboxylic acid transport system which is pH dependent.[8] The activation of benzoic acid uptake by acidic pH can be explained by H^+ cotransport, OH^- exchange system, or a possible change in affinity to the carrier protein depending on the extracellular pH. The uptake of benzoic acid by BeWo monolayers increased with a decreased pH. The lack of an inhibitory effect of DIDS, an inhibitor of anion exchange, suggests that an OH^- exchange system with benzoic acid was not involved in uptake or transport by BeWo cells. Many types of transporters are Na^+ dependent. However, benzoic acid uptake by BeWo cells was also not inhibited in the Na^+-depleted buffer in this study. Benzoic acid is an acidic compound; therefore, a decrease in pH increases the fraction of nonionized benzoic acid. According to the pH-partition hypothesis, this increase in the fraction of nonionized form increases the passive accumulation of benzoic acid across the BeWo cell membrane. Data presented here (e.g., Figure 3), and other studies conducted in absence of pH gradients, where the rate of transfer and asymmetry of transport for representative monocarboxylic acid drugs (e.g, acetylsalicylic acid and ibuprofen) is substantially diminished (data not shown), are alone insufficient to conclude that the uptake of benzoic acid is proton-gradient-dependent. However, the need for a proton gradient was affirmed with our results that showed FCCP, a protonophore, strongly inhibited the uptake of benzoic acid. Collectively then, our results indicated that monocarboxylic acid uptake was proton-gradient-dependent and were entirely consistent with similar studies conducted with human trophoblast brush border membrane preparations.[14] From a pharmacological and physiological perspective, this is significant since a pH gradient does develop across the placenta with advancing pregnancy. The developing pH gradient does influence drug distribution across the placenta[24] and may possibly influence the MCT carrier's role in regulating the distribution of monocarboxylic acids between the mother and fetus. The physiological role of a MCT in the trophoblast is likely related to the regulation of the distribution of L-lactic acid and related substrates across the placental barrier.[14,15]

Monocarboxylic acids are transported out of muscle and into liver (i.e., the so-called Cori cycle) by proton-coupled transporters, MCTs, that exhibited distinct substrate specificities and could be differentially inhibited by α-cyanocinnamates. MCT1 isolated from a Chinese hamster ovary cell cDNA library, is found in cardiac muscle, erythrocytes, basolateral intestinal epithelium, and skeletal

muscle. MCT2, cloned from hamster liver, is functionally similar to MCT1 in terms of transport capabilities, but its tissue distribution is significantly different.[25] A third transporter isoform, MCT3, was identified in chick retinal pigment epithelium. More recently, four new MCT homologues have been cloned and sequenced in human tissue (MCT3-MCT7).[11] There is currently no direct information of the type of functional MCTs associated with BeWo cells or human trophoblasts. Thus, further studies with molecular probes and selective substrates, when available, will be required to precisely identify which of the seven monocarboxylic acid transporter isoforms may be present in the human placental barrier. Elucidating the precise forms of functional MCTs in the trophoblast remains an ongoing objective of our laboratory.

In summary, our present results support limited evidence in the literature[12−15] that monocarboxylic acids and nutrients, drugs, drugs of abuse, and other xenobiotics that have a monocarboxylic acid constituent have the potential to be substrates for proton-gradient-dependent transport across the human trophoblast. This work further demonstrates the possible utility of a human, monolayer-forming cell line, BeWo, to characterize putative trans-trophoblast transport mechanisms and their potential roles in controlling nutrients, drugs, and drugs of abuse distribution across the placental barrier.

Abstract □ In a recent paper,[1] we demonstrated that molecular interactions between biopolymers and other smaller molecules can be detected by means of dynamic surface tension measurements. In the present paper, we demonstrate that the same methodology can be employed for investigating dose effects and specificity of molecular interactions. Three similar lipids were chosen for this study: 12(*S*)-hydroxy-5(*Z*),8(*Z*),10(*E*),14(*Z*)-eicosatetraenoic acid (12(*S*)-HETE-free acid), methyl 12(*S*)-hydroxy-5(*Z*),8(*Z*),10(*E*),14(*Z*)-eicosatetraenoate (12(*S*)-HETE-methyl ester), and 5(*Z*),8(*Z*),11(*Z*),14(*Z*)-eicosatetraenoic acid (arachidonic acid-free acid). These substances were added to a fatty acid free bovine serum albumin (BSA) aqueous solution at different lipid concentrations. The characteristic tension response indicates that molecular interactions between 12(*S*)-HETE-free acid and BSA exist. The detected interactions are concentration dependent: at a molecular ratio of lipid to protein of 1:1, the binding of 12(*S*)-HETE-free acid to BSA is hydrophobic in nature; at the molecular ratio of lipid to protein of 10:1, a secondary binding occurs and is hydrophilic in nature. Similar molecular interactions were not detected between 12(*S*)-HETE-methyl ester or arachidonic acid-free acid and BSA, indicating that the interactions between 12(*S*)-HETE-free acid and BSA are specific. As an independent means, surface elasticity is used to probe the molecular interactions at the interface. In the case of 12(*S*)-HETE-free acid but not its methyl ester or arachidonic acid, distinct higher surface elasticities were observed at lipid concentrations in excess of a molecular ratio of lipid to protein of 1:1. This finding reinforces the above stipulations.

1. Introduction

Intermolecular interactions between macromolecules and smaller organic molecules at different surfaces are of fundamental importance to various industrial and biological processes. Mixtures of polymers and surfactants and their surface adsorption kinetics often play a vital role in emulsions or dispersions of a large number of chemical engineering products.[2−5] The interplay between proteins and lipids or lipidlike biomolecules is central to one of the most important functions of proteins, namely the adsorption at biological interfaces, and the structure of biomembranes.[6−8] Although a large amount of work has been done in this area,[5,9−12] the fundamental understanding of the mechanisms is limited. This is partially because most studies have focused on the isotherm, i.e., the equilibrium behavior of polymers or proteins and smaller molecules at interfaces. The dynamic processes, which are far more important in many biological and engineering systems, have been largely ignored.

Recently, we have developed a dynamic surface tension method for studying the dynamics of protein−lipid interactions at interfaces.[1] This method depends on the measurement of dynamic surface tension response to a saw-tooth change in surface area, where both protein and lipid are competing to adsorb. By analyzing the tension response, one can obtain information about both surface competitive adsorption and molecular interactions between the two molecules. Using this method, we studied the binding of Hepoxilin, a newly developed lipidic biomolecule derived from arachidonic acid, to bovine serum albumin.[1]

The dynamic surface tension has been measured by axisymmetric drop shape analysis (ADSA).[13−16] This approach to obtaining surface tension is based on the shape of a sessile or pendant drop. In essence, the shape of a drop is determined by a combination of surface tension and gravity effects. Surface forces tend to make drops spherical whereas gravity tends to elongate a pendant drop or flatten a sessile drop. When gravitational and surface tensional effects are comparable, then, in principle, one can determine the surface tension from an analysis of the shape of the drop. ADSA is devised specifically for drops with axial symmetry. Over the last 15 years, this technique has been developed to allow for measurement of a wide range of surface tensions under both static and dynamic conditions.[13−16]

The advantages of ADSA are numerous as compared with conventional surface tension techniques such as the Wilhelmy plate, the du Noüy ring tensiometer, and those based on the volume or weight of a pendant drop.[8,16] For example, in comparison with the Wilhelmy plate technique, ADSA requires only small amounts of the sample liquid; this becomes significantly advantageous when the sample is rare and expensive to obtain, such as in the case of many biological studies. ADSA also easily facilitates the study of both liquid−vapor and liquid−liquid interfacial tensions; it has been applied to materials ranging from organic liquids to molten metals, and from pure solvents to concentrated solutions. Measurements with ADSA have been satisfactorily made over a wide range of temperature and pressure.[13−16] In addition, since the profile of liquid drops may be recorded by photographs or digital image representation, it is possible to study surface tension in dynamic systems where the properties are time-dependent.

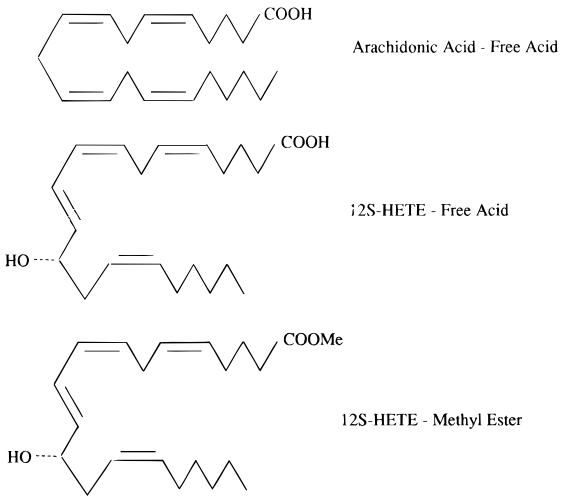

Figure 1—Schematic of molecular structures for (a) 12(*S*)-hydroxy-5(*Z*),-8(*Z*),10(*E*),14(*Z*)-eicosatetraenoic acid (12(*S*)-HETE-free acid), (b) methyl 12(*S*)-hydroxy-5(*Z*),8(*Z*),10(*E*),14(*Z*)-eicosatetraenoate (12(*S*)-HETE-methyl ester form), and (c) 5(*Z*),8(*Z*),11(*Z*),14(*Z*)-eicosatetraenoic acid (arachidonic acid-free acid). It is seen that 12(*S*)-HETE-free acid differs from arachidonic acid-free acid by having an additional hydroxyl group and a cis–trans conjugated diene system, while the difference between 12(*S*)-HETE-free acid and 12(*S*)-HETE-methyl ester is at the carboxyl end.

A number of studies have been carried out on biological interfaces using ADSA.[17−20] For example, the interfacial tension, and hence the surface energetics, of human serum albumin at the water−decane interface was studied as a function of temperature and protein concentration.[17,18] The results allow one to infer protein affinity for such an interface as well as a surface charge distribution of the protein molecules. Incorporating a captive bubble method and ADSA, one can also study low surface tension phenomena in lung surfactant systems and hence draw physiological significance of these substances.[21,22] The study of intermolecular interactions between proteins and lipids has been a recent application of ADSA dynamic surface tension measurements.[1]

In most biological systems, two questions are usually asked in connection with molecular interactions such as binding: one, is there a dose effect, i.e., is there a concentration dependence of the binding; the other is the specificity, i.e., is such binding specific to the molecules under study. In this paper, we demonstrate that the dynamic surface tension method[1] can be employed for the study of dose effects and specificity of molecular interactions. We investigate the molecular interactions between delipidated bovine serum albumin (BSA) and three slightly different lipids: 12(*S*)-HETE-free acid, 12(*S*)-HETE-methyl ester form, and arachidonic acid-free acid. Figure 1 shows their molecular structures; it can be seen that 12(*S*)-HETE-free acid differs from arachidonic acid by having an additional hydroxyl group and a cis−trans conjugated diene system, while the difference between 12(*S*)-HETE-free acid and 12(*S*)-HETE-methyl ester is at the carboxyl end. It was interesting to investigate whether these subtle structural differences would distinguish one molecule from another in terms of their interactions with bovine serum albumin at the surface.

Biologically, the study of the molecular interactions between lipids and protein also has important practical implications. The binding of lipid to a membrane protein would significantly alter the surface properties of the membrane, such as hydrophobicity, and hence affect membrane-assisted enzymatic reactions involving, for example, phospholipases,[23,24] i.e., possibly ion channel behavior and adhesion of cells. Indeed 12(*S*)-HETE has been shown to affect phospholipases[23,24] and potently causes tumor cells to adhere to the vascular endothelium.[25]

The objectives of this paper are (1) to measure dynamic surface tension response to a saw-tooth change in the surface area of solution drops using axisymmetric drop shape analysis (ADSA); (2) to probe the molecular interactions or binding between BSA, as a model protein, and three lipids; (3) to investigate the concentration dependence and specificity of the molecular binding; (4) to present a new means to characterize surface molecular interactions by calculating surface elasticity. The last objective is not only an additional means to detect molecular interactions but also provides a further physical/mechanical property of the lipid−protein monolayer.

2. Materials and Methods

A. Materials—The sample of bovine serum albumin (Sigma Chemical Co., St. Louis, MO) was essentially fatty acid and globulin free, with an average molecular weight of 67 000. It was used without further purification. Deionized and glass-distilled water was used. 12(*S*)-HETE-free acid and arachidonic acid were purchased from Cayman Chemicals (Ann Arbor, MI). The methyl ester derivative was prepared with an ether solution of diazomethane.[26] The reaction for methyl ester synthesis was complete as judged by the layer chromatography. The material was purchased from Cayman Chemicals as the free acid and converted into the methyl ester by methods used routinely in our laboratory, i.e., ethereal diazomethane. The molecular weights of these compounds are 320, 304, and 334, respectively. Since these lipids are not soluble in water, they have been initially dissolved in 1 μL of dimethyl sulfoxide (DMSO) before addition to 1 mL BSA aqueous solutions. Three types of mixed solutions were prepared: (1) 0.02 mg/mL BSA aqueous solution containing 12(*S*)-HETE-free acid at a concentration ranging from 0.001 to 1.0 μg/mL. Note that, within this range, a concentration of 0.1 μg/mL corresponded to a molecular ratio between 12-HETE-free acid and BSA of approximately 1:1; (2) 0.02 mg/mL BSA aqueous solution containing 12(*S*)-HETE-methyl ester at a concentration ranging from 0.01 to 1.0 μg/mL; (3) 0.02 mg/mL BSA aqueous solution containing arachidonic acid at a concentration ranging from 0.001 to 1.0 μg/mL. Two control experiments were performed using the following two solutions: (1) a pure BSA aqueous solution at a concentration of 0.02 mg/mL and 1 μL of DMSO; (2) a BSA-free solution of 1 μg of 12(*S*)-HETE-free acid in a mixture of 1 μL of DMSO in 1 mL of water (instead of a BSA solution).

B. Axisymmetric Drop Shape Analysis-Profile (ADSA-P)—The dynamic surface tension response to a saw-tooth variation in surface area was measured by ADSA-P. Detailed descriptions of ADSA-P are given elsewhere.[13−20] Briefly, ADSA-P fits the theoretical drop profile dictated by the Laplace equation of capillarity to the experimentally determined drop profile. An objective function is constructed which describes the deviation of the theoretical profile from the experimental one. This function is minimized by a nonlinear least-squares regression procedure, yielding the interfacial tension. The program also provides the drop volume, surface area, and the radius of curvature at the apex. The program requires several randomly chosen coordinate points along the drop profile, the value of the density difference across the interface, and the magnitude of the local gravitational constant as input. Each single image of a drop is analyzed 10 times with 20 different, arbitrary profile coordinate points each time.

During the experiment, the sample solution formed a pendant drop at the tip of a Teflon capillary, enclosed in a quartz cuvette which was mounted in an environmental chamber. The surface area of the drop was varied in a saw-tooth pattern through the volume change produced by a motorized syringe connected to the other end of the Teflon capillary.[1] In each run, drop images were captured at 0.3 to 1 s intervals for 6 min. Within this time period, repeated tension response cycles were established, based on which the analyses for molecular interactions were conducted. All the experiments were performed at 37 °C.

3. Results and Discussion

A. Molecular Interactions and Dose−Effects—Figure 2 shows the dynamic surface tension response to

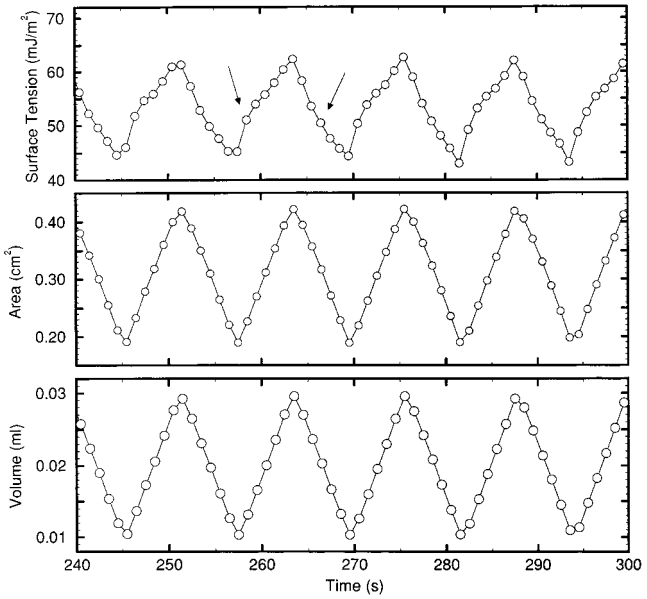

Figure 2—Dynamic surface tension response to a saw-tooth change in surface area, within the time range of 240 to 300 s from the beginning of the experiment with the BSA aqueous solution at a concentration of 0.02 mg/mL and 1 μL DMSO. Each cycle shows a characteristic, skewed shape in the tension response, with two kinks in the two branches corresponding to surface expansion and compression, respectively.

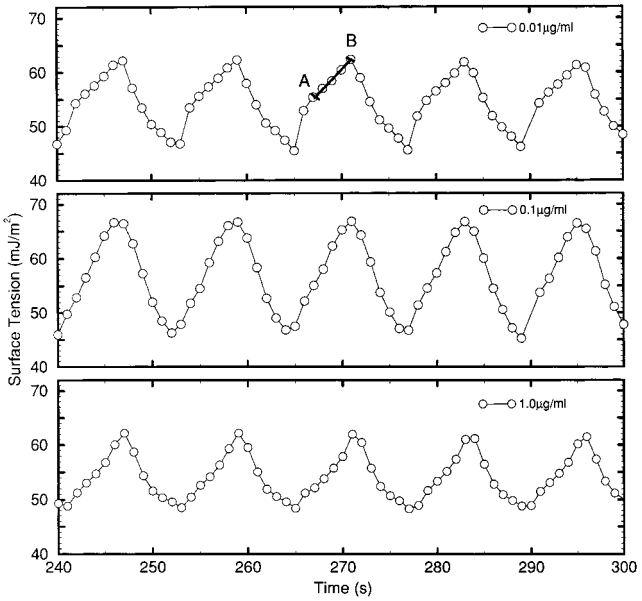

Figure 3—Dynamic surface tension response to the same saw-tooth variation in surface area as that in Figure 2 for the BSA solution to which 12(*S*)-HETE-free acid had been added. A series of 12(*S*)-HETE-free acid concentrations were measured: 0.001, 0.005, 0.01, 0.02, 0.05, 0.1, and 1.0 μg/mL of BSA aqueous solution; however, only three concentrations are shown here since for concentrations below 0.1 μg/mL the tension response is similar to that of 0.01 μg/mL. It is seen that at low 12(*S*)-HETE-free acid concentrations the tension response to the area variation is similar to that observed in Figure 2. However, at the concentration of 0.1 μg/mL, a distinct pattern change is observed in the dynamic surface tension response: the skewed pattern in the tension response of the BSA solution is replaced by a rather symmetric one. As the concentration of 12(*S*)-HETE-free acid increases to 1.0 μg/mL, yet another different, symmetric pattern is observed in the tension response, indicating a dose effect on the surface tension behavior and hence on the surface physicochemical properties.

the saw-tooth change in surface area within the time range from 240 to 300 s from the beginning of the experiment with the aqueous BSA solution at a concentration of 0.02 mg/mL. It has been shown[1] that at early times (less than 60 s) the tension response reflects the initial adsorption process of BSA to the surface and does not repeat itself from cycle to cycle. Only after 120 s does the tension response start showing constant cycles, as shown in Figure 2. Each cycle shows a characteristic, skewed shape, with two kinks occurring in the two branches corresponding to surface expansion and compression.

As demonstrated in a previous paper,[1] the error associated with each individual surface tension value is generally small, less than 0.2 mJ/m^2 at the 95% confidence level; hence, the tension response to the saw-tooth variation in surface area (Figure 2) reliably represents the true physicochemical properties of the surface of a protein and/or lipid adsorption film.

Figure 3 shows the dynamic surface tension response to the same saw-tooth variation in surface area as that in Figure 2 for the BSA solution to which 12(*S*)-HETE-free acid had been added. A series of 12(*S*)-HETE-free acid concentrations were used in the experiment: 0.001, 0.005, 0.01, 0.02, 0.05, 0.1, and 1.0 μg/mL BSA aqueous solution; however, only three concentrations are shown in Figure 3 since for concentrations below 0.1 μg/mL the tension response was found to be similar to that of the concentration of 0.01 μg/mL. It can be seen that at low 12(*S*)-HETE-free acid concentrations ($\leq$0.05 μg/mL) the tension response to the area variation is similar to that observed in Figure 2 for the pure BSA solution: the characteristic, skewed shape indicates that the surface is covered mainly with BSA molecules. However, at the concentration of 0.1 μg/mL, a distinct pattern change is observed in the dynamic surface tension response: the skewed pattern of the BSA solution is replaced by a rather symmetric one. This indicates that the surface properties are not determined solely by BSA, i.e., the added 12(*S*)-HETE-free acid plays a role. It is noted that the 0.1 μg/mL concentration corresponds to a molecular ratio between 12(*S*)-HETE-free acid and BSA of approximately 1:1. As the concentration of 12(*S*)-HETE-free acid increases to 1.0 μg/mL, yet another asymmetric pattern emerges in the tension response. Clearly, there is a dose–effect on the surface tension behavior and hence on the physicochemical properties. At concentrations above 0.1 μg/mL, the tension response to the area change provides a useful tool to probe possible molecular interactions between 12(*S*)-HETE-free acid and BSA.

To investigate further the effects of 12(*S*)-HETE-free acid, a control experiment was performed, in which 1 μg of 12(*S*)-HETE-free acid dissolved in 1 μL of DMSO was added to 1.0 mL water, i.e., in the absence of BSA. The results are shown in Figure 4, where minimal changes in dynamic surface tension pattern are observed in response to the same saw-tooth variation in surface area as that in Figures 2 and 3. If there were no interaction between 12-(*S*)-HETE-free acid and BSA in the mixed solution, the resulting surface tension would have to be a superposition of the surface tensions of the individual lipid and protein solution. However, from Figures 2–4, the tension response of the mixture at a concentration of 12(*S*)-HETE-free acid of 0.1 μg/mL does not reflect the pattern of the pure BSA solution at all. Therefore, molecular interactions must exist between 12(*S*)-HETE-free acid and BSA, likely forming lipid–protein complexes due to 12(*S*)-HETE-free acid interacting with BSA. These complexes, being species different from albumin alone, no longer show the skewed shape of BSA, presumably caused by conformational changes.

In general, the appearance of kinks in the tension response to surface area variations (e.g., Figure 2) reflects a phase or structural transition of the surface molecules.[8] Disappearance of the kinks, at the lipid concentration of

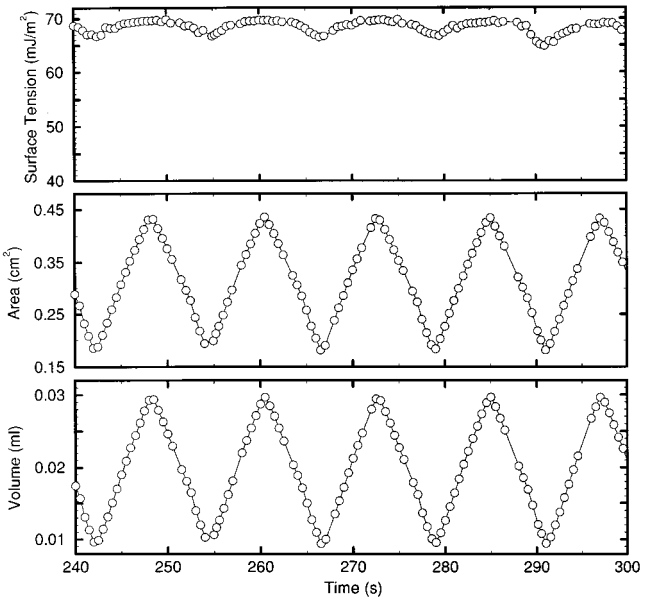

Figure 4—Dynamic surface tension response to the same area variation as that in Figure 2 for a control experiment in which 1 μg of 12(*S*)-HETE-free acid dissolved in 1 μL of DMSO was added to 1.0 mL of water, in the absence of BSA. Rather symmetric cycles with small amplitudes are observed for the tension response.

0.1 μg/mL (Figure 3), indicates that the binding of lipid to protein stablizes the surface phase at one molecular configuration. Furthermore, since the distinct change in the tension response pattern of BSA occurs at the concentration of 0.1 μg/mL of 12(*S*)-HETE-free acid, corresponding to a molecular ratio of 1:1, such interactions between 12-(*S*)-HETE-free acid and BSA are presumably connected with a single binding site (see also below).

Another observation in Figure 3 is that the tension value reached at the peaks for the concentration 0.1 μg/mL is significantly higher than that for the other concentrations including the pure BSA solution (Figure 2). This indicates that the mixture, at the 1:1 molecular ratio, is more hydrophilic than BSA itself; therefore, the molecular interactions between 12(*S*)-HETE-free acid and BSA may be hydrophobic in nature, such that the hydrophobic end of the lipid attaches to a similar part of the protein, leaving the hydrophilic end of the lipid exposed to the surrounding water environment.

At the 12(*S*)-HETE-free acid concentration of 1.0 μg/mL (Figure 3), the molecular ratio between lipid and protein is roughly 10:1. One might think that the resulting dynamic surface tension should predominantly be due to the presence of 12(*S*)-HETE-free acid at the surface. However, the tension response of the lipid alone (Figure 4) shows a very different response, with a much smaller amplitude. If we were to assume that BSA has only one binding site for 12(*S*)-HETE-free acid, then 9 out of 10 lipid molecules would exist in water freely, and the resulting surface properties of the mixture would have to be dominated by the surface properties of the free lipid. However, from Figure 4, the free lipid solution has high surface tension values, above 65 mJ/m^2; from Figure 3, the maximum tension value is also above 65 mJ/m^2 for the mixture of the lipid and the protein at the concentration of 0.1 μg/mL. If there were no interaction between lipid and protein−lipid complex, the tension response of the combination would be expected to be at the same high level. This, however, is not the case; the maxima for 1.0 μg/mL in Figure 3 are clearly below 65 mJ/m^2. Therefore, one needs to conclude that not all additional lipid molecules remain free, but rather bind to BSA, at least to such a degree that the surface tension is significantly lowered. Since the maximum tension value at the 1.0 μg/mL concentration is smaller than that at the 0.1 μg/mL concentration, the new complex, as a result of the new binding of the lipid to the protein, is more hydrophobic, compared with the protein−lipid complex of 1:1 ratio, i.e., 0.1 μg/mL of 12(*S*)-HETE. Hence, the additional binding of the lipid to the protein is presumably hydrophilic in nature.

It should be noted that, even at 12(*S*)-HETE-free acid concentrations lower than 0.1 μg/mL, one may not rule out the possibility of the aforementioned new binding of lipid to protein, or secondary binding of lipid to protein. Such binding is presumably associated with some low affinity sites, and hence it does not amount to any sizable extent and contributes little to the tension response. At 1:1 molar ratio (corresponding to 0.1 μg/mL) or less, 12(*S*)-HETE-free acid mainly interacts with BSA at the single binding site of high affinity; this will predominantly dictate the properties of the surface molecules and affect the pattern of the tension response. Only at higher molar ratios, e.g., 10:1, as the high affinity binding site has already been occupied, this secondary binding becomes important in changing the tension response (Figure 3).

In the above analysis leading to the conclusion of 12(*S*)-HETE-free acid binding to BSA and the dose-dependence of such molecular binding, we tacitly assumed that the DMSO, used as dissolving agent for the lipid, does not interact with BSA, nor does the DMSO play a role in the surface tension response after the initial few cycles. It has been established that, for a mixture of DMSO and BSA, the surface molecular population is dominated by small DMSO molecules only at early stages of the cycling experiment below 60 s, due to DMSO's much higher diffusion coefficient.[1] With the passage of time, BSA gradually adsorbs at the surface, and BSA molecules stay at the surface once they adsorb. This leads to a squeeze-out of the DMSO molecules from the surface. After repeated cycles, the surface properties are essentially determined by the BSA molecules adsorbed at the surface, and no DMSO contribution to the surface tension response can be detected. This indicates that DMSO is merely a vehicle for carrying lipids, and it does not contribute to the tension response at late stages of the cycling experiment, as shown in Figures 2−6.

B. Specificity—To study the possible specificity of the molecular binding of 12(*S*)-HETE-free acid to BSA, two similar lipids, 12(*S*)-HETE-methyl ester and arachidonic acid-free acid, were used to perform the same tension response experiment as that for 12(*S*)-HETE-free acid. The results for 12(*S*)-HETE-methyl ester are shown in Figure 5 for three concentrations at 0.01, 0.1, and 1.0 μg/mL. Again, 0.1 μg/mL corresponds to a molecular ratio of lipid to protein of approximately 1:1. All three concentrations show a skewed pattern, similar to that of the pure BSA solution (Figure 2). This suggests the dominance of protein adsorption at the surface, while 12(*S*)-HETE-methyl ester molecules play little role in producing the surface tension response. When comparing Figure 5 with Figure 3 at the same concentrations, the disappearance of kinks in the tension response differentiates the two lipids in their interations with BSA.

It has been established that there are generally one to two high affinity fatty acid-binding sites on albumin and a number of low affinity sites.[27−29] The distinct difference between Figure 5 and Figure 3 indicates that the lipid−protein interactions depend on the type of lipid, and a slight variation in molecular structure can significantly alter the lipid binding to albumin and hence the surface physical chemical properties, as reflected in surface tension. Con-

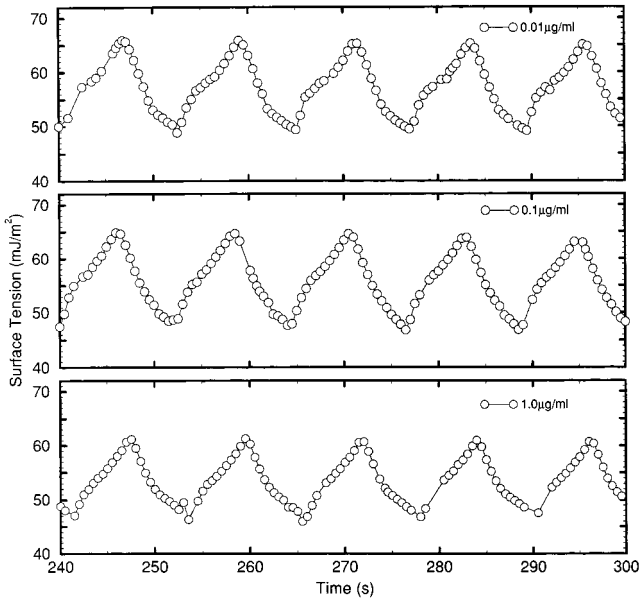

Figure 5—Dynamic surface tension response to the same area variation as that in Figure 2 for the BSA solution to which 12(*S*)-HETE-methyl ester had been added at three concentrations of 0.01, 0.1, and 1.0 μg/mL. At all three concentrations a skewed pattern is seen, similar to that of the pure BSA solution.

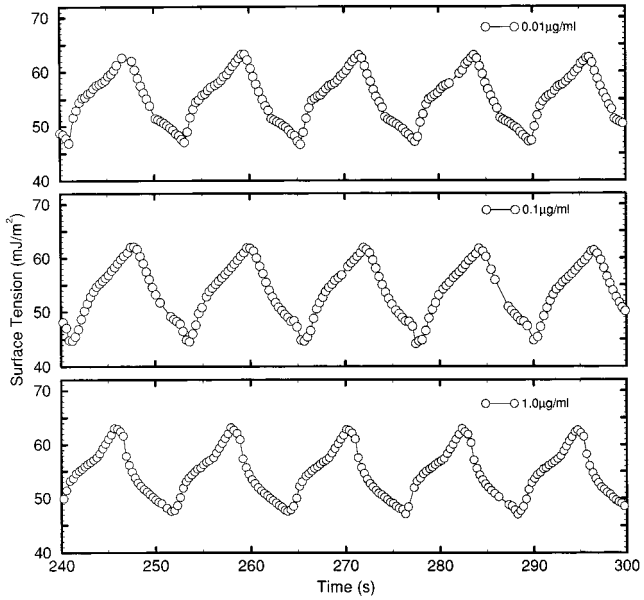

Figure 6—Dynamic surface tension response to the same area variation as that in Figure 2 for the BSA solution to which arachidonic acid-free acid had been added. Three lipid concentrations are shown: 0.01, 0.1, and 1.0 μg/mL. It was found in the experiment that at concentrations of 0.001, 0.005, and 0.05 μg/mL, the tension response is similar to that of 0.01 μg/mL. For all these concentrations, a skewed shape is always observed in the cycling tension response.

versely, surface tension measurement would provide a useful tool to differentiate lipid interactions with albumin, particularly to detect possible conformational changes as a result of the lipid binding to albumin.

Figure 6 shows the dynamic surface tension response to the same saw-tooth area variation that was used above, with arachidonic acid-free acid added to the BSA solution. A series of arachidonic acid concentrations were used: 0.001, 0.005, 0.01, 0.05, 0.1, and 1.0 μg/mL; however, only three concentrations are shown since for concentrations below 0.1 μg/mL the tension response is very similar to that of 0.01 μg/mL. Throughout these concentrations, a skewed

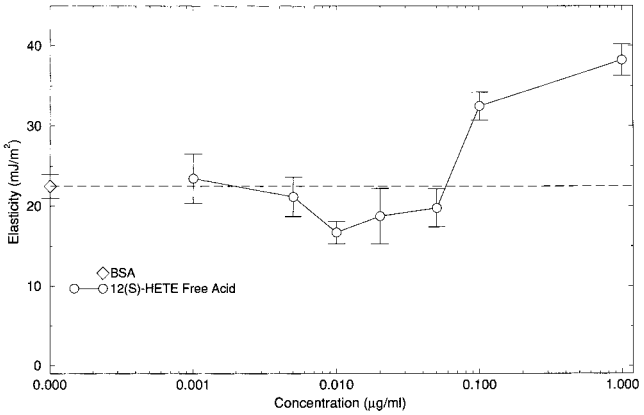

Figure 7—Surface elasticity as a function of the 12(*S*)-HETE-free acid concentration. The error bars in elasticity result from a statistical analysis, based on the Student's *t*-distribution, of a series of linear curve fits to the expansion branches of different cycles, at the 95% confidence level. There is a distinct increase in elasticity at the 12(*S*)-HETE-free acid concentration of 0.1 μg/mL, corresponding to the dose effect as observed in the dynamic surface tension response to the saw-tooth area change (Figure 3).

shape is always observed in the cycling tension response. In contrast to the observation in Figure 3 for 12(*S*)-HETE-free acid, there is no distinct change in the tension response as the arachidonic acid concentration passes 0.1 μg/mL, corresponding to a molecular ratio between lipid and protein of approximately 1:1. As previously shown with 12-(*S*)-HETE-methyl ester, Figure 6 indicates that molecular interactions between these concentrations of arachidonic acid and BSA is significantly different from those between 12(*S*)-HETE-free acid and BSA. This implies that the detected molecular binding of 12(*S*)-HETE-free acid to BSA is rather specific, and that a subtle variation in the lipid molecular structure leads to significantly different interaction properties between the lipid and the protein.

It should be noted that, in the above comparison or analysis, several less significant features are neglected, and the emphasis is placed on the high affinity binding between BSA and 12(*S*)-HETE-free acid. For example, the magnitude of changes seems slightly greater for 12(*S*)-HETE-methyl ester than for 12(*S*)-HETE-free acid at the concentration of 0.01 μg/mL (Figure 5, top panel vs Figure 3, top panel). This indicates that the interactions between the methyl ester and BSA might be slightly different from those between the free acid and BSA. Further, for the free acid, the disappearance of kinkiness at 0.1 μg/mL and higher does not seem to be complete, and a slight trace of kink remains at these concentrations. This might indicate that the high affinity interaction between the lipid and the protein does not completely block the BSA properties, although a significant change has been induced and resulted in the tension response variations. To explain all these detailed features in the tension response, more work will be conducted with respect to the mechanisms of surface molecular interactions and dynamic surface tension response to surface area changes.

C. Elasticity—As stated in the Introduction, surface elasticity is an important surface physicochemical property; it can be used as a measure of interfacial molecular interactions. The definition of the Gibbs surface elasticity, E, is

$$E = A\frac{\mathrm{d}\gamma}{\mathrm{d}A}$$

where γ is the surface tension, and A is the surface area. Figure 7 shows the surface elasticity as a function of the 12(*S*)-HETE-free acid concentration. The slope in the

surface elasticity definition was obtained through a linear curve fit to the relatively straight portion of the expansion branch, after the kink appears (Figure 3, from point A to B). The error bars in the elasticity result from a statistical analysis, based on the Student's *t*-distribution, of a series of expansion branches of different cycles, at the 95% confidence level. It can be seen that there is a distinct increase in elasticity at the 12(*S*)-HETE-free acid concentration of 0.1 μg/mL, corresponding well to the dose−effect observed in the dynamic surface tension (Figure 3). At lipid concentrations above 0.1 μg/mL, the formation of lipid−protein complexes not only changes the dynamic surface tension response to the area variation but also increases the elasticity of the adsorbed layer.

4. Conclusions

1. From the dynamic surface tension response to a patterned variation in surface area, molecular interactions between 12(*S*)-HETE-free acid and BSA have been observed.

2. The molecular interactions between 12(*S*)-HETE-free acid and BSA are concentration dependent. At the concentration corresponding to a molecular ratio of lipid to protein of 1:1, a distinct surface tension response was detected, indicating that such molecular interactions are based on one binding site for 12(*S*)-HETE on BSA. The binding appears hydrophobic in nature, i.e., the hydrophobic end of the lipid attached to a similar part of the protein.

3. At the concentration corresponding to a molecular ratio of lipid to protein of 10:1, secondary binding of 12(*S*)-HETE-free acid to BSA was detected from the dynamic surface tension response. This secondary binding appears to be hydrophilic in nature.

4. Comparison with two similar lipid molecules, 12(*S*)-HETE-methyl ester and arachidonic acid-free acid, indicates that the molecular interactions between 12(*S*)-HETE-free acid and BSA are specific.

5. Surface elasticity can be independently used for detecting molecular interactions and dose effects. In the case of 12(*S*)-HETE-free acid in BSA solution, distinctly higher surface elasticities were found at lipid concentrations in excess of the molecular ratio of lipid to protein of 1:1.

Abstract □ In the preparatory stage of structure–activity relationship (QSAR) studies of anti-platelet aggregant pyrazine derivatives, log *P* values (*P*: 1-octanol/water partition coefficient) of diarylpyrazines were measured by a newly developed HPLC column-switching technique. The system consists of two processes: (1) adsorption of the sample at the top end of a short precolumn, and then (2) quantifying the enriched analyte by a conventional analytical column. By using the log *P* values thus obtained, the correction factor for the steric hindrance caused by the vicinal diphenyl groups was estimated. The log *k* values (*k*; retention factor) were also measured with methanol-buffer (pH 7.4) eluents and related to log *P*. The eluent of 50% methanol content (M50) gave a good linear relationship over a wide range of log *P* ($-0.3 < \log P < 5.2$), indicating that log k_{M50} parameter is useful for predicting the log *P* value.

Introduction

The logarithm of 1-octanol/water partition coefficient, log *P*, has been used as a measure of hydrophobicity of organic compounds and has played an important role in structure–activity relationship studies.[1,2] A conventional procedure for measurement of log *P* is the shake-flask method which consists of determining the equilibrium concentration of a substance in the aqueous or in both the aqueous and the octanol phases. This method, however, is not usually applicable to highly lipophilic compounds (log $P > 3$) because of extremely low concentrations of test compounds in the aqueous phase. To solve this problem, some procedures, such as re-extraction of the aqueous phase before the measurement of concentrations and the use of radiolabeled solutes, have been used to get a satisfactory response with the detector used.[3]

In addition to direct measurements, the log *P* value is often estimated by calculations or by retention parameters derived from reversed-phase HPLC, hereafter referred to as the HPLC method. The most widely used methodology for calculating log *P* was first proposed by Fujita et al., being based on an additive-constitutive, free energy related property of log *P*.[4] Thus, by using π defined as the difference in log *P* between a derivative with a given X substituent (RX) and the parent compound (RH),

$$\pi_X = \log P_{(RX)} - \log P_{(RH)} \quad (1)$$

log *P* values for multisubstituted compounds might be expressed as:

$$\log P_{(YRX)} = \log P_{(HRH)} + \pi_X + \pi_Y \quad (2)$$

Although many other empirical ways for log *P* calculations have been proposed subsequently,[5–8] most of them essentially assume such additivity. In accord with expectation, eq 2 fails in solute systems which involve electronic and/or steric interactions between the substituents, and various correction methods are proposed so that the predicted log *P* values may approach the experimental results.[6,7]

In HPLC approaches, the logarithm of the retention factor, *k*, is used as a hydrophobicity parameter. Usually C-18 bonded silica is used as a stationary phase with methanol–water mixtures as the mobile phase, and a Collander type relationship as shown by eq 3 is assumed.[9]

$$\log P = a \log k + b \quad (3)$$

Since the log *k* value depends on the mobile phase composition, extensive studies have been made to find optimal mobile phase conditions producing a good linear relationship.[10–15] Many investigators have used the log k_W parameter, (log *k* extrapolated to 0% methanol) to eliminate organic solvent effects.[10,11,16,17] On the other hand, other reports use isocratic log *k* values at an appropriate methanol concentration.[13–15,18,19] It is very often observed that hydrogen bonding effects of solutes with the surrounding molecules break a linearity, making the HPLC approach less effective for the estimate of log *P*. In an attempt to establish a standard HPLC procedure for predicting reliable log *P* values, we have studied the relationship between log *P* and log *k* for various series of fundamental heteroaromatic compounds, such as monosubstituted pyridines, diazines, and thiophenes, under various HPLC conditions.[13–15,20] Our results have demonstrated that hydrogen donating solutes (amphiprotics) usually behave differently from nonamphiprotics and should be treated separately.[13–15] Moreover, the log k_W method tends to overestimate log *P* for strong hydrogen acceptors. For this reason, most of pyridines and diazines which have *N*-atom(s), a strong hydrogen acceptor, in the parent rings have been found to yield values for log k_W much higher than that corresponding to the true value for log *P*. Instead, we have found that isocratic log *k* obtained with an eluent containing around 50% methanol usually results in a good linear relationship with log *P*, permitting us to reliably predict values for log *P* over the range, $-1 < \log P < 3$.[13–15,20]

Even when such empirical predictive methods are known to be reliable, accurate experimental values of log *P* for several compounds are required.

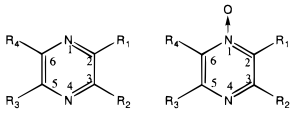
Published on Web 10/22/1999

In the course of our QSAR studies of bioactive compounds, we were interested in analyzing the structure–activity relationship of a series of diaryl pyrazines which has recently been found, by one of the authors, to have potent anti-platelet aggregation activity.[21] Knowing reliable log *P* values of these compounds was a prerequisite for this purpose. We, therefore, undertook measurement and evaluation of log *P* values for these compounds. The conventional shake-flask method failed not only because of their high lipophilicity but also of very low solubility of some compounds even in octanol. Although we were well experienced in predicting the log *P* value of pyrazines with log $P < 3$ by the HPLC method, it seemed dangerous to apply our relationship to a wider lipophilicity range (log $P > 4$). Accordingly, we attempted to develop a method to determine experimentally log *P* values for highly lipophilic compounds by using the HPLC column-switching system. The column-switching technique is widely used for on-line sample enrichment and cleanup, and has been increasingly applied to environmental analyses and the isolation of clinical samples.[22,23] We expected that this method would be applicable to our measurements of log *P* by loading large volumes of the sample solutions onto a precolumn and succeeded in obtaining log *P* values ranging from 3.5 to 5.2.



This report describes a novel procedure to measure log *P* values above 3 by using HPLC with a column-switching system. The log *P* values thus obtained were evaluated in terms of the additivity of π values and also related to log *k* values to examine how the log *P* values might be predicted by the HPLC approach. For comparison, some pyrazine *N*-oxides (PR→O) were also studied.

Materials and Methods

Materials—Compounds used in this study are given in Tables 1 and 2. Most of the diaryl pyrazines in Table 1 (**1**, **3**, **4**, **8**, **10**, **12**, **13**, **15**–**17**, **20**-**22**, and **24**) and monosubstituted pyrazines (**28**–**35**) in Table 2 were prepared as previously described.[21,24] Compounds **5**, **6**, **18**, and **19** were prepared by treatment of the 5-Cl derivatives with an appropriate sodium alkoxide according to the method for preparing the corresponding monosubstituted pyrazines.[24] Alkylpyrazines (**36**–**45**) were purchased from Tokyo Kasei Organic Chemicals (Tokyo, Japan). The references for preparation of the other compounds are given in the footnotes to Tables 1 and 2. HPLC-grade methanol and water, 1-octanol of the grade for log *P* measurements, and a phosphate buffer solution (pH 7.4) were purchased from Nacalai Tesque.

Measurement of log *P*: Conventional Shake-Flask Method—The log *P* for compounds with medium or low hydrophobicity (log $P < 3$) was measured by a conventional shake-flask method. The concentration of samples in both of the water and octanol phases was determined by HPLC.

Column-Switching Method—Samples (0.5–30 mg) were dissolved in 1 mL of octanol and then shaken with 100 mL of distilled water. The phases were allowed to separate overnight at 25 °C. Persistent emulsions were not observed to occur with our compounds. After pipetting off the octanol phase, the aqueous phase was collected into centrifuge tubes, preventing contamination by octanol, and then centrifuged twice for 5–10 min. As the solute concentration of lipophilic compounds in the aqueous phase was too low to detect by HPLC, sample enrichment on a precolumn was performed before conventional quantitative analysis by using a column-switching technique as follows.

HPLC System—The column-switching system (Figure 1) consisted of two isocratic HPLC pumps (LC 9A, Shimadzu, Kyoto), an autoinjector (IS-25, Kyoto Chromato, Kyoto,

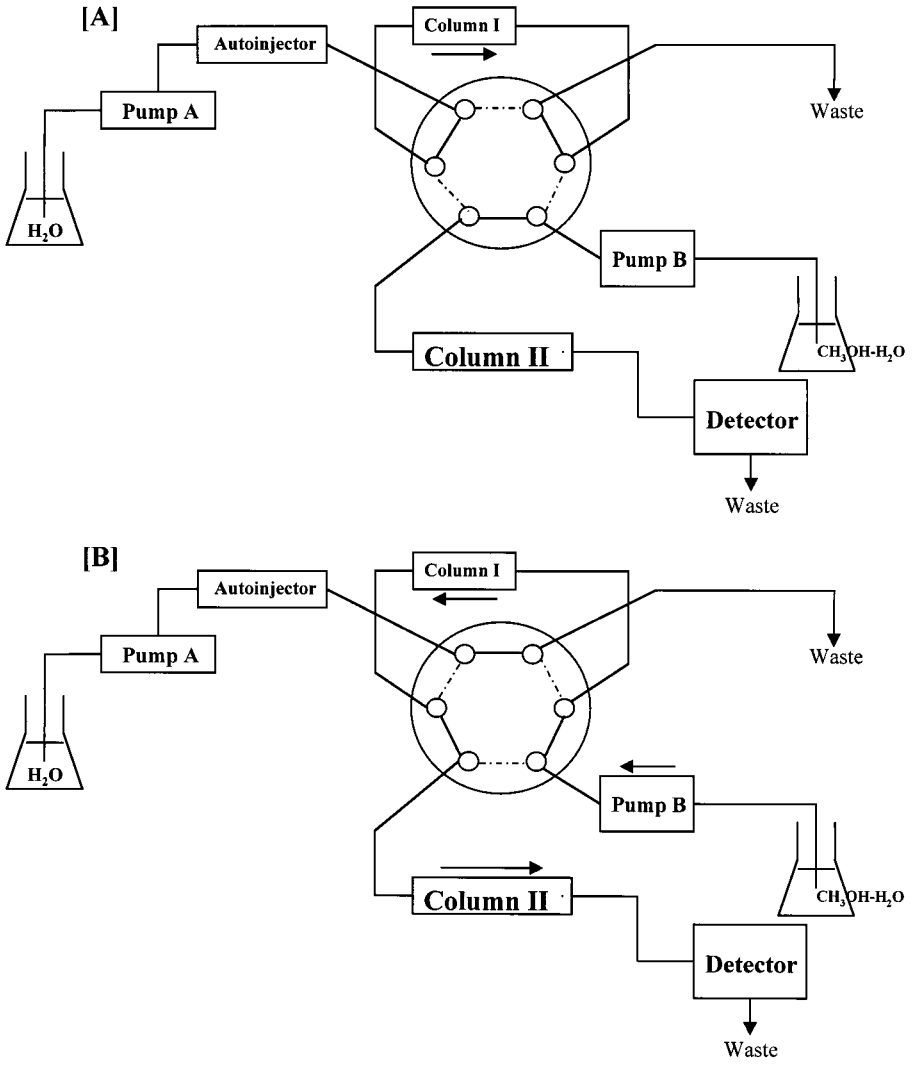

Figure 1—Schematic representation of the HPLC column-switching system. (A) Sample enrichment process. (B) Analytical process.

Japan) fitted with a 10 mL sample loop, a 10 mL syringe and a Rheodyne 7125 injection valve, and a universal valve-switching module ACP 1010 with a Rheodyne 7000 six-port, two-position valve (Anachem, Luton, England). The following columns were connected to the six-port valve. Column I (precolumn for concentration): Capcell Pak C18, UG 80 (Shiseido, Tokyo, Japan), 35 × 4.6 mm i.d. Column II (analytical column): Cosmosil 5C18-AR−II (Nacalai Tesque, Kyoto, Japan). 150 × 4.6 mm i.d.

Column-Switching HPLC Analysis—A 5−9 mL aliquot of the centrifuged aqueous phase, giving an appropriate peak area on the final chromatogram, was automatically injected onto column I by pump A using pure water as the mobile phase at a flow rate of 5.0 mL/min (at position A, Figure 1). This process allowed the solute to be adsorbed at the top end of the column I. After 4 min, the valve was switched to the position B (Figure 1), and the preconcentrated (adsorbed) analyte was eluted to the analytical column II (back flush mode) with an aqueous solution containing 70−90% methanol delivered by pump B. The signals were analyzed by a photodiode array detector SPD-MV10A (Shimadzu, Kyoto, Japan). Eluent compositions were chosen so that the analytical time would be less than 10 min for each sample. The average peak area of a given sample for the aqueous phase, A_W, was obtained from repeated 5−7 cycles. To analyze the corresponding octanol phase under comparable conditions to those for the aqueous phase, the following two-step dilution was performed. First, a 200 μL aliquot of the octanol phase was diluted with methanol to 1.00 mL. The methanolic solution thus obtained was then diluted with pure water by an appropriate factor as described below. The resulting homogeneous solution was analyzed quantitatively in the same manner as in the analysis of the aqueous phase. Injection volume was the same as that for the aqueous phase. The second dilution with water was done at two dilution factors so that the resulting peak areas, A_o (1) and A_o (2), obtained as described above would be $A_o(1) < A_W < A_o(2)$ and also the ratio of $A_o(2)/A_o(1)$ would be 2−5. With these data, the P value was calculated as $P = fA_o/A_W$, where f represents the overall dilution factor. Agreement of log P from two A_o values, A_o (1) and A_o (2), was usually obtained to within 0.05 log unit. The mean value was taken as the P value. For each compound, measurements were carried out at least in duplicate, and the P values thereby obtained were reproducible to within ±0.1 log unit for most cases.

Measurement of log *k*—The log k value was determined as previously described with a Capcell Pak C18 column (50 × 4.6 mm i.d., Shiseido, Tokyo, Japan) at 25 °C.[13] Methanol−0.01 M phosphate buffer (pH 7.4) mixtures containing 50, 60, and 70% MeOH (hereafter designated as M50, M60, and M70, respectively) prepared by volume were used as the eluent. Log k parameters were determined by $k = (t_R - t_0)/t_0$, where, t_0 and t_R are retention times of methanol and a given analyte, respectively.

Results and Discussion

log *P* of Diarylpyrazines—Before measuring log *P* values for our compounds, we attempted to determine the log *P* value of curcumin with our column-switching system. Curcumin has attracted our interest in the previous structure−activity relationship study,[25] and its experimental log *P* value is reported to be 4.26.[26] We obtained a value of 4.28, very close to 4.26, indicating that this newly developed procedure works satisfactorily. Therefore, we applied this method to determining log *P* values of diaryl pyrazines (Table 1). Inspection of Table 1 shows that introduction of two hydrophobic aryl substituents increases extensively the hydrophobicity of molecules. We have previously shown[24] that the π value in the pyrazine system (Table 3), derived from the log *P* values of monosubstituted pyrazines and pyrazine itself, often differs from the widely used benzene-π values and, therefore, that pyrazine-π values should be used in the analysis of log *P* values of pyrazines. By using pyrazine-π values, where available, estimated log *P* values, log P_{add}, were calculated on assumption of the additivity, that is, the sum of log *P* of pyrazine (−0.26) and pyrazine-π values of the substituents (Table 1).

It is noteworthy that experimental log *P* values of all compounds in Table 1 were much lower than log P_{add} values. In particular, in 2,3-diarylpyrazines, **3**−**7** and **14**−**22**, the difference was over one log unit. Steric hindrance between the two benzene rings may contribute to reducing the hydrophobicity of molecules (*ortho*-diaryl effect). This argument would also be supported by comparing the log *P* values of the three isomeric diphenyl-methylpyrazines (**4**, **23**, and **24**). Among them, only the isomer **4** having two adjacent phenyl groups gave a log *P* value (3.52) much smaller than those for **23** (4.28) and **24** (4.29), which have two phenyl substituents at 2,5- and 2,6-positions, respectively. An X-ray analysis of 2,3-diphenylpyrazine **3** has demonstrated that the dihedral angles between the two phenyl substituents and the pyrazine ring are approximately 50° and 40°.[27] Our semiempirical MO calculations of 2,3-diphenylpyrazine by the AM1 method[28] (the MOPAC 93 program package incorporated in an ANCHOR II modeling system, Fujitsu, Japan) gave a similar result. Such nonplanar conformation would cause resonance inhibition, decreasing the degree of conjugation and consequently reducing hydrophobicity below expectations for a molecule with full delocalization of π-electrons. The use of the additivity rule overestimated log *P* for **3** by 1.2 and that for **14** by 1.3, suggesting that the steric hindrance between the two vicinal benzene rings makes a negative contribution of about −1.2 to log *P*. This finding conforms to a well-known phenomenon that an extension of the resonating system requires a positive correction factor.[2]

[a] Sum of log *P*(**3**) and pyrazine-π(R_3). [b] Sum of log *P*(**14**) and pyrazine-π(R_3).

We also examined the substituent effect of R_3 on log *P* when R_3 is introduced to 2,3-diarylpyrazines, **3** and **14**, in terms of the *ortho*-diaryl effect discussed above and pyrazine-π values. As the R_3 substituent hardly suffers from steric effects, we may expect normal substituent effects in these pyrazines. The sum of log *P* of **3** or **14**, and pyrazine-π of R_3 was calculated (log $P_{pred.}$) and compared with the experimental log *P*. As shown in Table 4, they were in fairly good agreement. It is not unexpected that the deviation from the experimental value is somewhat larger than the expected experimental error in some compounds because some additional minor corrections for the electronic interactions between the substituents and the ring *N*-atoms as well as for the steric effect between R_2 and R_3 should be taken into account for detailed analysis.[24] These results revealed that the pyrazine-π is very helpful in making a rough estimate of log *P* of even highly lipophilic pyrazines, provided severe steric effects are not involved. It should be emphasized that the use of benzene-π instead of pyrazine-π for the substituent on the pyrazine ring would lead to erroneous estimated values.

Comparisons of log *P* for a series of variously substituted alky-diphenylpyrazines (**4** and **23**−**27**) indicates that steric repulsion by the vicinal alkyl and phenyl substituents also requires a correction of −0.6 to −0.7 in log *P*. As the corresponding reduction in log *P* in the vicinal dialkyl substituents is very small (∼−0.15),[29] large correction factor suggests twisting of the benzene ring even in this case. Nonplanar conformations were also indicated by the MO calculations. Measurements and more quantitative analyses of log *P* for a larger size data set including more lipophilic compounds are now in progress.

Log *k*: Prediction of log *P* by the HPLC Approach—Our previous studies on several series of monosubstituted heteroaromatic compounds have revealed that the relationship between log *P* (−1 < log *P* < 3) and log *k* obtained with various compositions of methanol−water eluents usually require some correction terms for hydrogen-bonding effects and can be expressed by the following general equation for nonamphiprotics:[30]

$$\log k = a \log P + \rho\sigma_I + sS_{HA} + \text{const} \qquad (4)$$

In this equation, the σ_I parameter represents Charton's electronic substituent constant,[31] and the S_{HA} parameter is that we have recently proposed as the hydrogen-accepting indicator for the substituent.[30] In general, contributions of the two correction terms are of minor importance when the eluent contains 50% MeOH (M50), so that we could assume the log *k*−log *P* linearity. However, these contributions are found to increase with decreasing methanol content. Strong hydrogen-accepting substituents, such as COOR and $CONMe_2$, deviate substantially from the line formed by non-hydrogen bonders and weak hydrogen acceptors in the plot of log *k* against log *P*. If such a predictive capability of M50 eluent holds for compounds

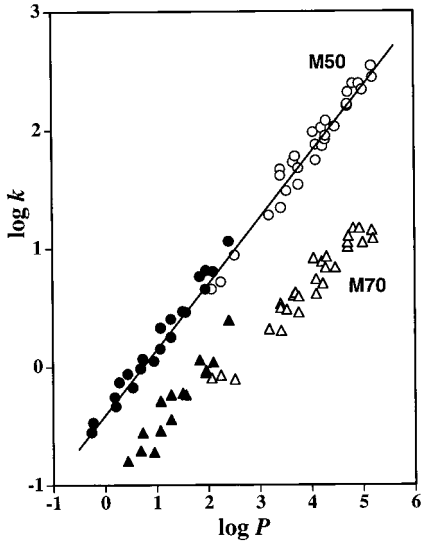

Figure 2—Relationship between log *k* and log *P* for variously substituted pyrazines. Open symbols represent (di)arylpyrazines, and closed symbols represent the other pyrazines.

with much higher log *P* values, the log k_{M50} approach would be of practical value in prediction of log *P*. Accordingly, we measured log *k* values for the present compounds under the same conditions and studied the relationship between log *P* and log *k*. To make the results comparable with those previously studied, we selected from many of the related compounds studied earlier, typical compounds including esters and *N*-oxides which were previously classified as deviants in water rich eluents.[13] Some *N*-oxides of diarylpyrazines were also added to the data set. Compounds used for log *k* measurements in addition to the (di)arylpyrazines in Table 1 are listed in Table 2 with their log *P* values. It should be noted that the compounds studied in this work are non-hydrogen bonding or hydrogen accepting. Log *k* values of all the compounds in Tables 1 and 2 obtained with the M50 and M70 eluents are plotted against log *P* in Figure 2. The M50 eluent again produced a satisfactory linear relationship of the form shown in eq 5:

$$\log k_{M50} = 0.554 \log P - 0.384 \quad (5)$$
$$n = 51,\ r = 0.996,\ s = 0.085$$

The relationship for the M60 eluent was somewhat inferior to eq 5 (the data not shown). As the data set contains molecules having strongly hydrogen-accepting substituents and/or a sterically hindered conjugated system, finding a simple linear equation covering a range of hydrophobicity of 6 log units seems to be rather surprising. It is of interest to notice that our earlier work on a series of monosubstituted pyrazines found the value of 0.58 as the slope of the log *P* term, being very close to the value of 0.55 shown by eq 5, in the corresponding equation. Although measuring log *k* values of monosubstituted pyrazines in more methanol-rich eluents such as M60 and M70 has been technically difficult, it has now become very clear, by combination of all the results obtained so far, that an optimum eluent composition yielding almost linear relationships would be at 50% MeOH or at methanol concentrations near 50%. Since the measurement of log *k* is easier and quicker than log *P*, particularly in very hydrophobic compounds, the log k_{M50} parameter can be expected to be a powerful tool for predicting the log *P* value. Care should be taken, however, in treating amphiprotic compounds by the HPLC method. When alkyl-bonded stationary phases are used, amphiprotics often give separate lines parallel to that for nonamphiprotics in the log *k*−log *P* plot.[13,15] This phenomenon is unavoidable because octanol is more hydrogen accepting than the stationery phase. Finding an effective procedure for treating these is still to be investigated.

Conclusion

In this study, we developed a novel procedure for measuring the log *P* value of highly lipophilic diaryl pyrazines by the HPLC column-switching technique. This method enabled us to measure the extremely low concentration of solutes by direct injection of a large volume (5−9 mL) of aqueous phase onto a precolumn. The log *P* values thus obtained ranged from about 3 to 5.2. By using these data, a large correction factor of about −1.2 was estimated as the *o*-diphenyl effect, which was thought to be attributable to the loss of coplanarity. The effects of sterically unhindered substituents attached to the pyrazine ring on log *P* could be well estimated by using the pyrazine-π value obtained in our earlier work.[24] The log *k* values were also measured with different compositions of methanol−buffer (pH 7.4) eluents, and a good linear relationship between log *P* and log *k* was found to hold at 50% MeOH, in conformity with our previous finding,[13,14] over the log *P* range from −0.3 to 5.2. To our knowledge, there have been no previous studies where log *k* values for a set of compounds determined under exactly the same HPLC conditions have been related to experimentally measured log *P* values over such a wide range. The present result seems to afford a nice example demonstrating that the use of the k_{M50} parameter provides reliable and practical method to predict quickly the log *P* value.

Development of procedures for obtaining reliable log *P* values for lipophilic compounds has become increasingly important not only in QSAR studies of bioactive compounds but also in environmental chemistry and toxicology where the log *P* is used as a parameter for evaluating the fish bioconcentration and toxicity.[32−34] Our present study would be also expected to be helpful for research in such fields.

Abstract □ Lipophilicity scales were characterized by an approach using vectors provided from solvation energy descriptors (SED) of solutes such as an excess molar refraction, the dipolarity/polarizability, the hydrogen-bond acidity, the basicity, and the McGowan characteristic volume. The five components of the SED vector were obtained from the coefficients of the five SED terms of the linear solvation energy relationship (LSER) equation for the lipophilicity scales. The analogy between two lipophilicity scales was expressed as the angle between the two SED vectors, while the difference in the contribution of the five independent SEDs to these two lipophilicity scales was quantified by the difference of the unit vectors of the SED vectors. These approaches were applied to several lipophilicity scales measured using microemulsions, micelles, an immobilized artificial membrane column, and an octanol–water system. As a result, the quantitative classification of these scales was successfully carried out, and the difference in the scales was well characterized. In addition, this vector approach was extended to the estimation of the contribution of each constituent of the microemulsions to the lipophilicity scale. Furthermore, some biological parameters such as skin permeability and the distribution between blood and brain could be predicted by the summation of the SED vectors obtained from the chromatographic systems. These results suggest that complex biological systems can be expressed quantitatively by simple chemical models with their SED vectors.

Introduction

In the passage of drugs throughout the body, the permeability of cell membranes is quite important for the prediction of their in vivo activities from their in vitro results. Therefore, the lipophilicity of drugs such as the logarithm of the partition coefficients between 1-octanol and water (log P_{ow}) has been used as a parameter for the structure optimization of the drug candidates. Because recent developments in combinatorial chemistry allowed the synthesis of a large number of compounds as drug candidates, the demand for high-throughput measurement of biologically appropriate lipophilicity is steadily increasing.

In our previous study, the lipophilicity scale by electrokinetic chromatography (EKC) with the microemulsion of sodium dodecyl sulfate (SDS), 1-butanol, *n*-heptane, and a buffer provided the excellent correlation with log P_{ow} for neutral compounds with various hydrogen-bonding abilities.[1] In quantitative structure−activity relationship studies (QSAR) for some bioactivities of the drugs, their lipophilicity from the microemulsion provided a better correlation with their bioactivities than other lipophilicity scales.[2,3] In addition, it was suggested that the lipophilicity scales from the microemulsions could be designed by selecting the constituents and their concentration.[4]

On the other hand, other lipophilicity scales such as the logarithm of the capacity factors (log k') in various chromatographic systems including HPLC[5−7] and micellar EKC (MEKC)[8−15] have been developed, and they provided diverse and unique properties as lipophilicity scales. In optimizing the structure of drug candidates, these lipophilicity scales often provided different results, although they have viability for high-throughput analysis. Therefore, selecting the lipophilicity scales suitable for predicting the bioactivities of drug candidates is quite important for optimizing their structures. For this purpose, the characterization and classification of these scales were required.

The correlation coefficients of the linear relationship between two scales have been often used for the comparison between these two scales. It is, however, well-known that the correlation coefficient strongly depends on the test set of solutes. Alternatively, the linear solvation energy relationship (LSER) analysis has been used for the characterization of the retention behaviors of solutes in many chromatographic media, and the quantitative prediction of the retention times of the solutes from their structure was performed.[16−18] Recently, this approach was applied to MEKC to classify the separation selectivity of the micelles[19−22] and was also used for evaluating the correlation between log P_{ow} and migration index (MI) measured by microemulsion EKC (MEEKC).[4]

The general equation of LSER based on the solvation energy descriptors (SED) of solutes is as follows:

$$\log \mathrm{SP} = c + rR_2 + s\pi_2^{\mathrm{H}} + a\sum\alpha_2^{\mathrm{H}} + b\sum\beta_2 + vV_x \quad (1)$$

where log SP is the dependent variable, i.e., the lipophilicity scales (LS) such as log k' and MI in this case, and the independent variables are solute descriptors as follows: R_2 is an excess molar refraction, π_2^{H} is the solute dipolarity/polarizability, $\sum\alpha_2^{\mathrm{H}}$ and $\sum\beta_2$ are the solute hydrogen-bond acidity and basicity, and Vx is the McGowan characteristic volume in units of cm^3 mol^{-1}/100.[17] The obtained coefficients of eq 1 were used for characterization of the lipophilicity scales as well as the prediction of the separation selectivity in the chromatographic media. To classify these scales, the ratios of the coefficients such as *r*/*v*, *a*/*v*, *b*/*v*, and *s*/*v* were calculated and compared with those from another scale. This approach was quite useful to judge the analogy between two scales. Unfortunately, however, it was difficult to simultaneously compare the set of the coefficients or coefficient ratios between the plural scales. For example, Abraham et al. reported on the following scales:[4]

(*r*/*v*, *s*/*v*, *a*/*v*, *b*/*v*) =
(0.12, −0.23, 0.01, −0.94) for log P_{ow}

(*r*/*v*, *s*/*v*, *a*/*v*, *b*/*v*) =
(0.18, −0.24, 0.00, −0.87) for log *P* (pentanol−water)

(*r*/*v*, *s*/*v*, *a*/*v*, *b*/*v*) =
(0.09, −0.23, −0.02, −0.92) for log k' (microemulsion)

It was impossible to judge which was similar to octanol−water, pentanol−water, or the microemulsion. Therefore, an approach for analyzing these scales simultaneously was required.

[a] buffer: 50 mM sodium phosphate and 100 mM sodium borate (pH 7.0).

Recently, Valko et al. reported on the characterization of the various HPLC columns using the gradient retention parameter named chromatographic hydrophobicity indices (CHI) and their SED coefficients.[23] They described that the principal component analysis and the nonlinear mapping technique provide an appropriate tool for comparison of various HPLC partition systems.

In this paper, we demonstrate that the lipophilicity scales could be characterized using the coefficients of the five SED terms of the LSER equation as vector components. The analogy of the lipophilicity scales was evaluated using the scalar product of the vectors, and the difference in the five independent factors which affect the lipophilicity scales was quantified by these unit vectors. This vector approach was also employed to obtain the actual structural information of the microemulsions from the vectors of their individual constituent system. Furthermore, it was applied to predict some biological systems according to the summation of plural vectors from simple chemical systems.

Experimental Section

Capillary electrophoresis was performed using P/ACE 2100 (Beckman, Fullerton, CA). For three microemulsions (ME) and three micelles (MC), EKC was used for the determination of the lipophilicity scales from these systems. The experimental details were described in previous papers.[1−3,8] In all cases, 50 mM phosphate−100 mM borate solution (pH 7.0) was used as the buffer. The ME and MC solutions employed are listed in Table 1. Uncoated fused silica capillary with 50-μm i.d. and 27-cm length (GL Sciences, Tokyo, Japan) was employed. The capillary was thermostated at 25 °C. The applied voltage was 7.5 kV, and the detection wavelength was 214 nm. The injection was performed by pressure (0.5 psi, 2 s). In the cases of the micellar systems, the values of log k' were used as lipophilicity scales, while in the cases of the microemulsions, the migration indexes (MI) were calculated from the log k' of test solutes and references.[1−3]

A Shimadzu LC-10A system (Kyoto, Japan) equipped with an SPD-10A UV detector (Shimadzu) was used for the measurement of the lipophilicity scale from immobilized artificial membrane (IAM) column (4.6-mm i.d., 100-mm length, Resis, Morten Grove, IL). In this case, log k' was used as a lipophilicity scale using a phosphate buffer at pH 7.0 (ionic strength: 0.05) as a mobile phase and UV 220 nm as a detection wavelength. All tested samples listed in Table 2 were purchased from Aldrich (Milwaukee, WI), Sigma (St. Louis, MO), Wako (Osaka, Japan), and Tokyo Kasei Kogyo (Tokyo, Japan).

The measured log P_{ow} values were obtained from the database of Mac-logP ver. 1.0.3 (BioByte Corp., Claremont, CA).

Methodology

To obtain the set of the five coefficients (r, s, a, b, v) of eq 1, a regression analysis is performed using the measured lipophilicity values and the SED values of solutes listed in Table 2. The SED coefficient vector of lipophilicity scale i (LS_i), $\vec{\omega}$, is defined as follows:

$$\vec{\omega}_i = (r_i, s_i, a_i, b_i, v_i) \tag{2}$$

The analogy between LS_i and LS_j is expressed as cos θ_{ij} between $\vec{\omega}_i$ and $\vec{\omega}_j$ as follows:

$$\cos\theta_{ij} = \frac{\vec{\omega}_i.\vec{\omega}_j}{|\vec{\omega}_i||\vec{\omega}_j|} = \frac{r_i r_j + s_i s_j + a_i a_j + b_i b_j + v_i v_j}{\sqrt{r_i^2 + s_i^2 + a_i^2 + b_i^2 + v_i^2}\sqrt{r_j^2 + s_j^2 + a_j^2 + b_j^2 + v_j^2}} \tag{3}$$

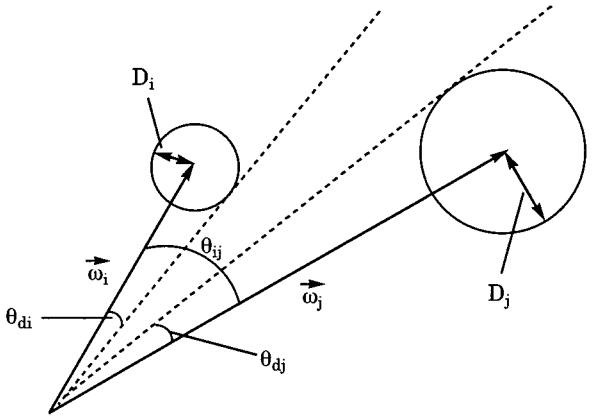

Figure 1—Two-dimensional model space of SED vectors.

Thus, as the correlation is higher, the value of cos θ_{ij} becomes closer to 1. When the analogy of LS_j ($j = 1, 2, ...$) to LS_i is examined, the analogy ranking of LS_j ($j = 1, 2,...$) to LS_i is established according to cos θ_{ij}. However, to judge the analogy between LS_i and LS_j, cos θ_{ij} is insufficient and the deviation of the vector should be also considered. In this study, D, which is a 95% confidence level of the coefficients of SED, is used as the deviation of each vector as follows:

$$D = TINV(0.05, N) \times \mathrm{SE} \quad (4)$$

where TINV is the inverse of the Student's t-distribution for the specified degrees of freedom, N, and SE is the average of the standard errors of the coefficients of SED.

Therefore, the analogy between two systems can be evaluated by the following equation:

$$J = \cos\theta_{ij} - \cos(\theta_{di} + \theta_{dj}) \quad (5)$$

where θ_{di} and θ_{dj} are the angles of the deviations of $\vec{\omega}_i$ and $\vec{\omega}_j$, respectively, as shown in Figure 1. The value of $\cos(\theta_{di} + \theta_{dj})$ can be calculated as follows:

$$\cos(\theta_{di} + \theta_{dj}) = \sqrt{\left(1 - \frac{D_i^2}{|\vec{\omega}_i|^2}\right)\left(1 - \frac{D_j^2}{|\vec{\omega}_j|^2}\right)} - \frac{D_i D_j}{|\vec{\omega}_i||\vec{\omega}_j|} \quad (6)$$

In eq 5, when J is greater than zero, these two systems are found to be analogue systems, and in the opposite case, these systems should be distinguished. This vector algorithm is based on the commercial UV spectra database searching program in Shimadzu CLASS−VP Chromatography Data System (Kyoto, Japan).

Concerning the difference in each SED factor of the lipophilicity, the unit vector, $\vec{\omega}_u$, is employed:

$$\vec{\omega}_u = \frac{\vec{\omega}_u}{|\vec{\omega}_u|} = (r_u, s_u, a_u, b_u, v_u) \quad (7)$$

To quantify the difference in each SED factor, the difference in the components of the unit vectors between LS_i and LS_j is evaluated as follows:

$$\Delta\vec{\omega}_u = (\Delta r_u, \Delta s_u, \Delta a_u, \Delta b_u, \Delta v_u) = (r_{ui} - r_{uj}, s_{ui} - s_{uj}, a_{ui} - a_{uj}, b_{ui} - b_{uj}, v_{ui} - v_{uj}) \quad (8)$$

Using the vector, the contribution of each SED factor to the lipophilicity from one system can be compared with that from other systems.

Results and Discussion

Characterization of Lipophilicity Scales by Vector Approaches—lipophilicity scales measured in this study are summarized in Table 1. As for the microemulsion (ME) systems, an anionic ME using SDS as a surfactant and two cationic MEs using CTAC and DTAC, which have different hydrocarbon chain length with the same hydrophilic group, were employed to measure the lipophilicity of 53 compounds listed in Table 2. For micelles (MCs), three different surfactants, anionic SDS, cationic DTAC, and neutral Brij 35, were used. In these MC systems, the capacity factors of several hydrophobic compounds could not be measured because they coeluted with the MC tracers (AO-10-dodecyl bromide).[1,24] Therefore, only 49 compounds were used in this study. Concerning the IAM column, which has the zwitterionic phosphatidyl choline moiety as the stationary phase, 53 compounds were used although analysis was quite time-consuming because no organic modifier was used. The results of LSER regression analyses are listed in Table 3. The correlation coefficients of the analysis were quite high, except for IAM and MC(S/B). The results of MC(SDS) and IAM by others[18] are also listed in Table 3 to compare with our results. For these two MC(SDS)s, little difference was observed, whereas obvious difference was observed between two IAM systems. This might be caused by the difference in the mobile phase, i.e., 10% acetonitrile was employed in ref 18, whereas no organic modifier was used in this study. This was supported by another LSER result from the fast-gradient IAM system recently reported.[23] In this study, considering the reasonability, the results from the IAM system without organic modifier were used in further study.

Regarding cos θ values between SED vectors, it would be necessary to indicate what value of cos θ could be regarded as "good" analogy because this parameter was not familiar. Therefore, for the eight scales described in Table 1, cos θ values were compared with the corresponding correlation coefficients (r). As shown in Figure 2, $r = 0.90$ corresponds to about cos $\theta = 0.96$, while this relationship was only a yardstick and some deviation was observed for this linear relationship.

Using the LSER coefficients and their D values, analyses of the SED vectors were performed. In Table 4, analogy ranking between one system and the other systems are performed using cos θ. The values of cos θ between three ME systems were quite close to 1, while the values of cos

OW	○	×	×	○					
IAM	×	×	×	×	○				
MC(SDS)	×	×	×	×	×	○			
MC(DTAC)	×	×	×	×	×	×	○		
MC(S/B)	×	×	×	×	△	×	×	○	
MC(SC)[a]	×	△	△	○	×	×	×	×	○

[a] $J \geq 0$: ○, $J < 0$: ×, Out of Judgment: △. When either the analogy of LS_i to LS_j or the analogy of LS_j to LS_i was out of judgment, △ was indicated. [b] Data were cited from ref 22; original data were reported by ref 19.

θ between four different MC systems were not more than 0.98. As for IAM system, higher analogy to systems using cationic surfactants such as ME(CTAC), MC(DTAC), and ME(DTAC) was observed. This would be caused by the cationic choline moiety of the packing material of the IAM column. In Table 5, the results of analogy judgment using the J values are indicated. Note that varied D values may provide the ranking/judgment reversal, which is the phenomenon that the high-ranked vector with larger cos θ and smaller D value provides $J < 0$ and low-ranked vector with smaller cos θ and larger D value provides $J > 0$ when the deviations of the LSER regression analyses for these LSs are varied. Therefore, the accuracy of the analogy judgment

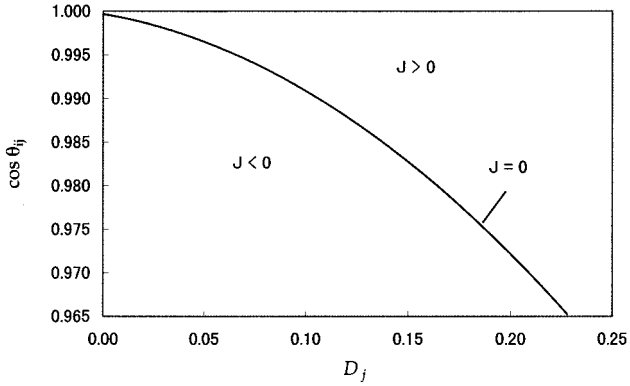

Figure 3—Relationship between cos θ_{ij}, D_j, and J values using the SED unit vectors of ME(SDS) ($\vec{\omega}_i$) and simulated unit vectors ($\vec{\omega}_j$). $\vec{\omega}_i$ = (0.015, 0.018, 0.012, 0.022, 0.021), D_i = 0.035.

depended on D values of SED vectors employed. The relationship between cos θ, D, and J values was simulated using the unit vector of ME(SDS)(LS_i) and the unit vectors of the other scales(LS_j). As shown in Figure 3, the ranking/judgment reversal would occur when D_j of lower-ranked LS_j is large enough. Therefore, the restriction to judge the analogy between two LSs was required, considering the purpose of the study. In this case, to prevent the ranking/judgment reversal, the analogy judgment was restricted by the rule that if the J value of one of the ranked vectors is less than zero, the judgment of the lower-ranked vectors with $J > 0$ should not be performed, i.e., "Out of Judgment" should be indicated for the lower-ranked vectors with $J > 0$. In Table 5, this rule was applied and the ranking/judgment reversal between some SED vectors was prevented.

Concerning the analogy to OW, so far as we know, the ME(SDS)[1,4] and sodium cholate micelle (MC(SC))[12,25] systems provided the best correlation. In this study, the LSER data from MC(SC) was cited from the report by Poole et al.[22] Using the data, the vector analyses were performed. As a result, both ME(SDS) and MC(SC) were each correlated with OW, whereas the J value between ME(SDS) and MC(SC) indicated that the analogy between them was not found despite a large cos θ value (0.9947). From the J values, two cationic ME systems were different from the anionic ME(SDS) although the cos θ values between these three systems were quite close to 1. The relationship between three MEs, OW, and MC(SC) on the basis of their J values is roughly illustrated in Figure 4. ME(SDS) should

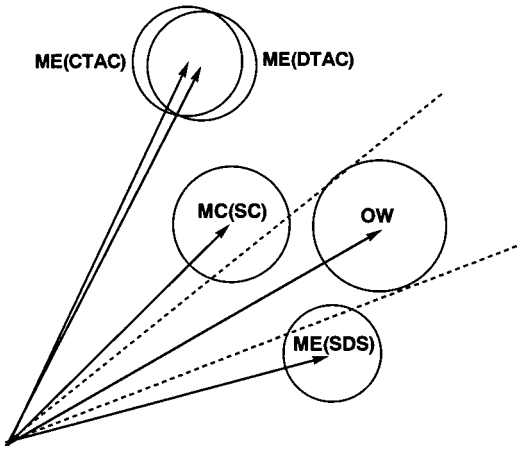

Figure 4—Relationship between ME(SDS), OW, MC(SC), ME(DTAC), and ME(CTAC) in two-dimensional model space of SED vectors. The angles and the length of these vectors are not accurate, because the actual space of these vectors are five-dimensional.

be, in the strict sense, distinguished from MC(SC) and cationic ME systems, while Poole et al. classified ME(SDS) and MC(SC) as the same group.[22]

Next, the unit vectors of the SED vectors were calculated to evaluate the difference in each independent descriptor of these LSs. Using the vector approach, it was quite easy to analyze plural scales simultaneously, and the contribution of each SED between all scales could be compared. The results of the unit vector analysis are shown in Figure 5. Note that this approach was based on the assumption that these five descriptors were almost equivalent to each other. This assumption would be valid because LSER descriptors of solutes had been originally adjusted to be almost the same order, and no artifact caused by the LSER descriptors has been reported so far.[16,17,26,27] Additionally, because the results were used only for the comparison in the same descriptor between the different scales, the assumption would not cause inappropriate evaluation. As shown in Figure 5a, among the components of the unit vector, the a_u component, i.e., the contribution of the hydrogen-bond basicity of the systems or hydrogen-bond acidity of the solutes to their lipophilicity scale was the most diverse between the employed scales. The scale with the most positive contribution of the a_u component was MC(CTAC), and the most negative one was MC(SDS). On the other hand, the b_u component was almost independent of the scales. These three MEs, OW, and MC(SC) systems provided almost the same values in all components, whereas IAM, MC(SDS, DTAC, and S/B) provided different values. The difference in each component of the unit vectors between OW and other scales is shown in Figure 5b. As expected from Figure 4, the a_u and r_u components of MC(SC) were larger than those of OW, while the a_u and r_u components of ME(SDS) were smaller than those of OW. The b_u, v_u and s_u components of MC(SC) were smaller than those of OW, while the b_u, v_u and s_u components of ME(SDS) were larger than those of OW.

As a consequence, the analogy between these employed scales and the difference in the contribution of each descriptor to the lipophilicity scales were well quantified by the SED vectors and their unit vectors, respectively.

Application of These Vector Approaches—The approach using the SED vectors and their unit vectors from various chemical two-phases partition models would be useful to express other scales using plural and diverse vectors because the independent vectors are suitable to describe another vector by addition or subtraction of these vectors with a certain ratio. Two typical examples are shown below:

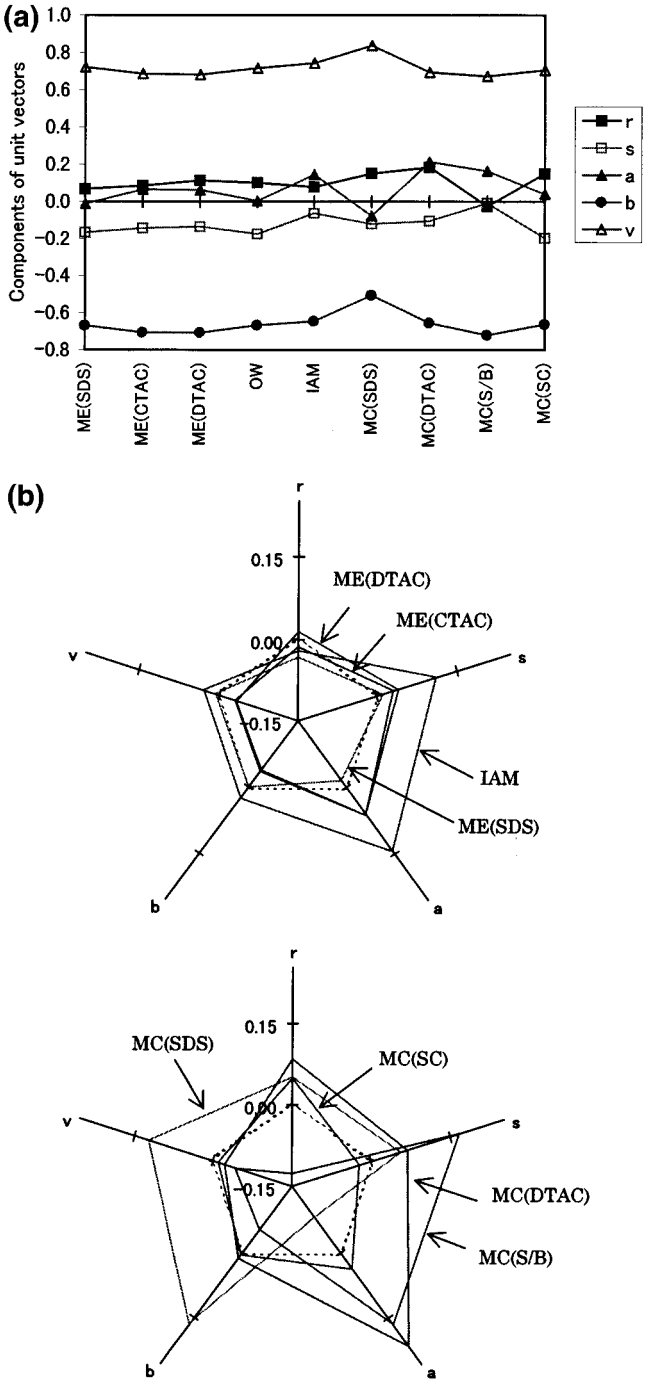

Figure 5—(a) Component of unit vectors. (b) Difference in the unit vector of OW from those of other systems. The dot lines indicate OW.

(1) Structural Information of Microemulsion from Each Constituent Vector—It was previously reported that the partition behaviors of solutes in ME(SDS) could be expressed by the behavior in each constituent system such as water−surfactant, water−alcohol, and water−alkane systems.[4] In this study, the same results were obtained using this vector approach for not only ME(SDS) but also ME(DTAC) as shown in Tables 6 and 7. In this approach, reproducible MI could be directly used as the lipophilicity scale, while MI had to convert to irreproducible log k' in a previous study because the lipophilicity scales such as MI and log P were not equivalent (e.g., log P = 0.518MI − 0.854 for ME(SDS)).[1] As a result, ME(DTAC) as well as ME(SDS) could be expressed by the summation of the SED vectors of the constituents with actual mixing molar ratio. In addition, the vector approach allowed the

Table 6—Estimation of Lipophilicity Scales from ME(SDS) by Its Constituents

system	SED coefficients					ME constituent ratio[a]	
	r	*s*	*a*	*b*	*v*	actual	regressed

ME (calcd with actual ratio)	0.594	–0.842	–0.224	–2.992	3.312		
ME (calcd with regressed ratio)	0.701	–0.638	0.227	–2.928	3.069		

analogy	cos θ
ME (obs) and ME (calcd with actual ratio)	0.9897
ME (obs) and ME (calcd with regressed ratio)	0.9963

[a] These ratios were expressed as molar ratio. The regressed ratio was calculated from the regression analysis described in the text.

regression analyses using the mixing ratio of the constituents as a variable parameter to obtain the minimum values of $(1 - \cos\theta)$. The comparison of the obtained regressed mixing ratio with the actual ones would provide the structural information of the microemulsion. As shown in Table 6, the contribution of SDS was more suppressed than that expected by the actual mixing ratio. Interestingly, however, in the case of ME(DTAC), the contribution of DTAC in the mixing ratio was more increased than the actual one. This would be caused by the influence of the bulkiness of the hydrophilic portion of the surfactants on the surface-shielding effect of 1-butanol.[1,2] A similar phenomenon was observed in the case of micelles.[8] Although ME(SDS) and ME(DTAC) provided the large cos θ value, the analogy was not found according to the *J* value, as previously shown. The results of the regressed mixing ratio in ME(SDS) and ME(DTAC) supported the reasonability of the *J* value analysis, and this approach would be useful to investigate complex partition systems such as microemulsions.

(2) Prediction of Biological Systems from Chemical Systems—it is important to predict the scales from complex biological systems whose lipophilicity scales are difficult or time-consuming to measure with high reproducibility. Using the vector approach, the SED vectors from the biological systems would be promptly expressed by the vectors from some chemical systems, although the partition behavior of the minimum test set of solutes in the biological systems had to be measured to obtain the SED coefficients. In this study, two biological systems, skin and blood–brain barrier (BBB), were investigated.

(2.1) Skin—Water/skin partition coefficients (K_m) of some alcohols and steroids (22 compounds) were measured using excised human skin, and the LSER equation was calculated by Abraham et al.[26] as follows:

$$\log K_m = -(0.03 \pm 0.14) - (0.37 \pm 0.11)\pi_2^H + (0.33 \pm 0.15)\sum\alpha_2^H - (1.67 \pm 0.16)\sum\beta_2 + (1.87 \pm 0.17)V_x \quad (9)$$

$$n = 22,\ r^2 = 0.943,\ \mathrm{sd} = 0.166,\ F = 70$$

In this case, *R* was removed because each descriptor of the compounds employed was not independent. Using the four SED coefficients, the analogy ranking of various chemical systems to the skin system was evaluated (Table 8). Interestingly, the skin system showed the high-ranked analogy to cationic IAM, cationic ME(CTAC), and ME(DTAC). In this case, the analogy judgment was not performed because the *D* value of the skin SED unit vector was quite large (0.06). Next, the analysis of their unit vectors was performed (Figure 6). As a result, the a_u, b_u, and v_u components of the skin system were between IAM and others (cationic MEs). Thus, the skin system was examined to be expressed by IAM and ME(CTAC). To obtain the ratio of IAM and ME(CTAC), a regression analysis for the unit vector of the skin system using the ratio as a variable parameter was performed, and the results are shown as follows:

$$\vec{\omega}_u(\mathrm{skin}) = 0.746\vec{\omega}_u(\mathrm{ME(CTAC)}) + 0.252\vec{\omega}_u(\mathrm{IAM}) \quad (10)$$

$$\cos\theta = 0.9960$$

The value of cos θ was improved in comparison with that by each single vector. Thus, the skin permeation of the drug candidates would be efficiently predicted by the two chromatographic systems such as ME(CTAC) and IAM with higher reproducibility, although the preliminary LSER regression analysis was not accurate enough to judge the analogy between the observed skin vector and the regressed skin vector.

[a] The data were cited from ref 22. LiPFOS: lithium perfluorooctanesulfonate. [b] The data were cited from ref 27. AW: alkane–water. [c] cos θ (reg): the angle between BBB vector and regressed BBB vector which was calculated by the summation of alkane–water and the indicated system with the regressed ratio.

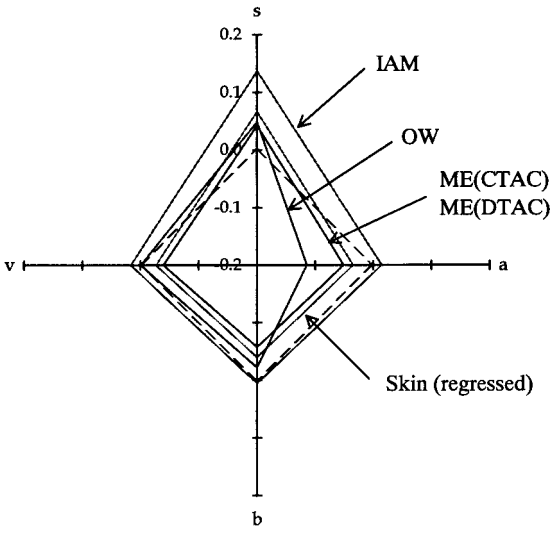

Figure 6—Difference in the unit vector of skin from those of other chemical systems including the regressed skin system.

(2.2) Blood−Brain Barrier—Young et al.[28] and Abraham et al.[27] determined the distribution coefficients between blood and brain (K_{BB}) for 57 compounds, and the following LSER equation was found:

$$\log K_{BB} = -(0.04 \pm 0.06) + (0.20 \pm 0.10)R_2 - (0.69 \pm 0.12)\pi_2^H - (0.71 \pm 0.33)\sum\alpha_2^H - (0.70 \pm 0.11)\sum\beta_2 + (1.00 \pm 0.10)V_x \quad (11)$$

$$n = 57,\ r^2 = 0.907,\ \mathrm{sd} = 0.197,\ \mathrm{F} = 99$$

Using these SED coefficients, the analogy ranking of various chemical systems was investigated (Table 9). In this case, the values of cos θ was not so close to 1 except the case of AW. In addition, the analogy judgment was not also performed because the D value of the BBB SED unit vector was 0.10. Next, the combination of AW with another system was employed to express the BBB system. The ratio of the two vectors was calculated by regression analysis using the ratio as a variable parameter to obtain the minimum value of (1 − cos θ) between the regressed and actual vectors from the BBB. The obtained values of cos θ are also listed in Table 9. As a result, the best combination for the BBB system was MC(SDS) and AW, and the cos θ was slightly improved as follows:

$$\vec{\omega}_u(\mathrm{BBB}) = 0.107\vec{\omega}_u(\mathrm{MC(SDS)}) + 0.861\vec{\omega}_u(\mathrm{AW}) \quad (12)$$

$$\cos\theta = 0.9558$$

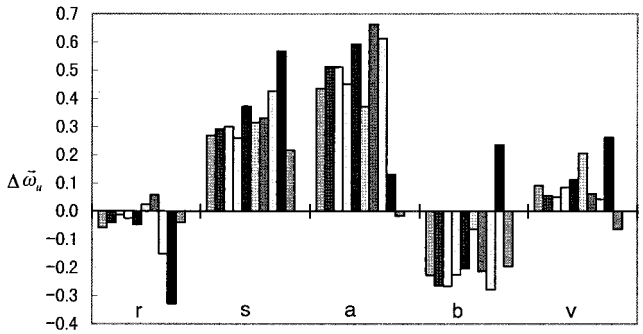

Figure 7—Difference in the unit vector of BBB from those of other chemical systems. Columns: (left) ME(SDS), ME(CTAC), ME(DTAC), OW, IAM, MC(SDS), MC(DTAC), MC(S/B), MC(LiPFOS), and AW.

This equation was not sufficient to express the complex BBB system by the simple chemical systems because the s_u and a_u components of the unit vector of BBB were smaller than those of other 10 unit vectors employed in this study (Figure 7). It would be necessary to search other simple chemical scales with smaller s_u, a_u, and v_u and larger r_u and b_u components as well as to improve the accuracy of the LSER regression analysis for log k_{BB}.

Conclusions

We developed the vector approaches to treat LSER analysis data more efficiently and quantitatively. This allows us to characterize various lipophilicity scales simultaneously. Using the vector approach, not only a complex chemical system such as a microemulsion, but also biological systems such as the skin and BBB, could be expressed by some simple chemical systems, although some improvement on the accuracy of the biological SED vectors would be required. These approaches would facilitate the selection of the chemical systems suitable for the prediction of the hydrophobic interaction of drugs in the body.

Received March 5, 1999. Final revised manuscript received September 20, 1999.
Accepted for publication September 24, 1999.

Abstract □ The objective of this study was to evaluate the gum from *Hakea gibbosa* (hakea) as a sustained-release and mucoadhesive component in buccal tablets for a model peptide, namely, salmon calcitonin. Flat-faced core tablets containing either 12 or 32 mg of hakea and 40 μg (200 IU) of salmon calcitonin (sCT) per tablet were formulated using a direct compression technique and were coated with Cutina on all but one face. The in vitro release profiles were sigmoidal in nature and according to a mathematical model indicated super Case II transport as the primary mechanism of release. The resulting plasma sCT and calcium concentrations were determined following both intravenous administration and buccal application of mucoadhesive tablets in rabbits. Following intravenous administration, the mean values determined for $t_{1/2}$ (α), $t_{1/2}$ (β), V_d, and CL for sCT were 0.76 ± 0.06 min, 67 ± 18 min, 1484 ± 454 mL/kg, and 19 ± 2 mL/min·kg, respectively. Following the application of the mucoadhesive buccal tablets which contained 40 μg of sCT and either 12 or 32 mg of hakea, the calculated apparent bioavailability (F) and clearance (CL) were 37 ± 6% and 19 ± 3.3 mL/min·kg and 16 ± 8% and 18 ± 0.4 mL/min·kg, respectively. Serum calcium concentrations indicated that biologically active sCT was delivered across the rabbit buccal mucosa. The strength of mucoadhesion of the tablets was also quantitated in terms of the force of detachment as a function of time. The force of detachment for the mucoadhesive buccal tablets containing either 12 or 32 mg of hakea and 40 μg of sCT increased from 4.47 ± 0.68 to 8.41 ± 1.0 N and 8.23 ± 1.62 to 14.98 ± 1.63 N, respectively, from 5 to 90 min following application to excised rabbit intestinal mucosa. These results demonstrate that the novel, natural gum from *Hakea gibbosa* may be used to sustain the release of sCT from a unidirectional-release buccal tablet. The mechanism of in vitro release is likely to involve peptide diffusion/polymer dissolution. The mucoadhesive strength, as measured by the force of detachment, can be modulated by altering the amount of hakea in the tablet. The mucoadhesive buccal tablets described in this paper represent an improved transbuccal delivery system for therapeutic polypeptides.

Introduction

Proteins and peptides are currently emerging as a major class of future therapeutic drugs. With the advent of and improvement in techniques like solid-phase synthesis, combinatorial chemistry, and protein biotechnology, more and more proteins and peptides are being made available in large quantities. Pharmaceutical scientists are facing increasing challenges with respect to the formulation of new and novel delivery systems and exploring new routes to successfully deliver these bioactive agents. Noninvasive delivery of proteins and peptides has been met with limited success for a variety of reasons[1,2] including (a) low permeability due to hydrophilicity, globular structure, and size, (b) inactivation by enzymes at the site of delivery or absorption prior to reaching the systemic circulation, and (c) short residence time of the drug as well as the delivery system at the site of absorption, all leading to subtherapeutic levels in the systemic circulation.

Calcitonin (CT) is a single-chain 32 amino acid polypeptide with a disulfide bridge between cysteine residues at positions 1 and 7 and has a molecular weight of 3432 Da. The hormone is secreted by the parafollicular cells of the thyroid glands in mammals and by the ultimobronchial glands in birds and fishes. CT functions as a hypocalcemic agent by inhibiting bone resorption and reducing the renal tubular reabsorption of calcium, and it is used in the treatment of Paget's disease, hypercalcemia, and osteoporosis.[3,4] Treatment calls for daily or alternate day subcutaneous or intramuscular injections for an extended period. This is bothersome and inconvenient for patients. Salmon calcitonin (sCT) is one of the calcitonins and is currently available in a sterile solution for injection and nasal spray form. Lee et al.[5] reported to have developed biodegradable porous PGA microspheres of sCT which provide sustained levels of sCT for over 5 days following a single subcutaneous (sc) injection. The buccal mucosa has been investigated recently for the delivery of this bioactive peptide.[6] Buccal mucosa is an easily accessible tissue, which is less sensitive to irritation or irreversible damage.[7] It also provides drug delivery by avoiding the harsh environment of the gastrointestinal tract and first-pass metabolism.[7]

The risk of accidental swallowing and salivary washout limits the use of solutions or conventional buccal tablets, and it has led to the development of self-adhesive buccal tablets as the preferred dosage form.[8] Mucoadhesive dosage forms retain the dosage form in intimate contact with the mucosa (absorbing membrane) thereby increasing the total amount of drug which penetrates the mucosa.[9]

Previous studies[10,11] have shown the efficacy of a novel, natural gum from *Hakea gibbosa* as a sustained-release and mucoadhesive component in mucoadhesive buccal tablets for the delivery of a low molecular weight organic compound. Thus, the present study was undertaken to investigate the possibility of using this novel excipient as a sustained-release and mucoadhesive component of buccal tablets for peptide and protein delivery. Hakea gum is a polysaccharide exudate from the tree *Hakea gibbosa* (Family: Proteaceae). The trees are indigenous to New South

Wales, Australia. The gum has a molecular weight of greater than 2×10^6 and is totally water soluble at a concentration of 2% w/v. The gum is composed of sugars such as galactose, mannose, xylose, arabinose, and glucuronic acid. The chemical structure of the gum has been previously reported.[10,12]

Materials and Methods

Materials—Salmon calcitonin sCT (5001 IU/mg) was a generous gift from Rhone-Poulenc-Rorer (Vitry Sur Seine Cedex, France). All solutions were prepared in deionized distilled water. The hakea gum was a gift from Dr. Peter Eagles of the University of the Western Cape, Cape Town, South Africa. The gum was obtained from the Kirstenbosch Botanical Gardens. All other materials, except for the gum, were used as received. The gum was purified by first dissolving it in water and then filtering the 2% solution through muslin cloth. The filtered solution was freeze-dried using a model 10-MR SAVirtis tabletop freeze drier (Gardiner, NY).

Cutina (castor oil, hydrogenated) was obtained from Henkel Corporation, NJ. Xylazine (100 mg/mL), ketamine (100 mg/mL), and pentobarbital sodium (50 mg/mL) solutions were provided by the Laboratory Animal Center at the University of Missouri—Kansas City (Kansas City, MO). Heparin sodium injection (10000 units/mL) was purchased from Elkins-Sinn, Inc. (Cherry Hill, NJ). I-Cath intravenous placement units with stylet attachment (catheter, 22G × 12 in.; needle 19G × 21 in.) was purchased from Charter Med, Inc. (Lakewood, NJ), and tuberculin syringes (1 cc) were obtained from Becton and Dickinson (Sandy, UT).

Blood samples were collected into 1.5 mL Eppendorf tubes containing heparin sodium (100 units/mL) and centrifuged using a Beckman GS-15R centrifuge (Palo Alto, CA).

Male New Zealand albino rabbits, weighing between 2.0 and 2.5 kg, were purchased from Myrtle's rabbitry (Thompson, TN). The animals were housed individually for at least 1 week prior to experimentation and allowed food and water ad libitum. The average weight of the rabbits at the time of the study was 2.8 ± 0.3 kg ($n = 9$).

The bioadhesion experiments were carried out on a model LTC universal tension-compression stand (John Chatillon and Sons, Inc., Greensboro, NC) equipped with a model DFM-10 digital force gauge (John Chatillon and Sons, Inc., Greensboro, NC).

Methods—*Tablet Preparation*—Flat-faced core tablets were prepared by direct compression, and the tablets were coated with Cutina on all but one face using a compression coating technique. Release of sCT was unidirectional, occurring from only the uncoated tablet face.

(a) Direct Compression—The tablets were prepared by initially mixing the sCT and hakea for 10 min. Subsequently, spray-dried lactose (hydrous N.F. grade, Fast-Flow 316) and Cab-o-sil (M-5 grade, amorphous fumed silica) were incorporated and the powder was mixed for an additional 10 min. Finally, magnesium stearate was added and the mixing continued for an additional 5 min. Mixing was performed by mechanical rotation at 225 rpm.

(b) Tablet Compression—Both core and coated tablets were prepared on a model B, No. 0-24R carver press (Summit, NJ). The core tablets (weight: 101.5 mg) had a diameter of 1 cm and a thickness of 0.1 cm and were compressed at a force of 5000 psi. The coated tablets (final weight: 202.5 mg) were compressed at 2000 psi force to generate a final diameter of 1.2 cm and a thickness of 0.2 cm.

(c) Release Study—The in vitro release studies were performed using jacketed glass vessels (250 mL) obtained from Fisher Scientific (Pittsburgh, PA). The dissolution medium consisted of 200 mL of deionized water (pH 7.0) at 37 °C. The dissolution medium was stirred with a magnetic stir bar at a speed of 50 rpm. Sink conditions were maintained throughout the duration of release study. The in vitro release samples (1 mL) were analyzed for sCT using an enzyme immunoassay kit (EIAH-6003) obtained from Peninsula Laboratories (Belmont, CA) after appropriate dilutions were made with deionized water. The release studies were carried out for 90, 420, and 600 min for buccal tablets containing 40 μg of sCT and 0, 12, and 32 mg of hakea, respectively.

Animal Preparation—The animals were prepared for both intravenous and buccal sCT studies by anesthetizing with an im injection of a 1:5 mixture of xylazine (1.9 mg/kg) and ketamine (9.3 mg/kg). Following induction of anesthesia, a catheter was placed in the marginal ear vein for blood sample collection. After the collection of each sample, the cannula was flushed with 0.2 mL of a 10% (v/v) heparin/normal saline solution to keep the cannula patent. A light plane of anesthesia was maintained by an im injection of one-third of the initial dose of xylazine and ketamine mixture as needed. All the blood samples were centrifuged at 3000 rpm for 10 min to separate the plasma and the retrieved plasma, was stored at −20° C until the time of analysis. At the end of the experiments the rabbits were euthanized by injecting an overdose of pentobarbital solution (3−5 mL) into the catheter.

The research adhered to the principles of Laboratory Care (NIH publication no. 85-23, revised 1985), and the animal protocol was approved by the animal care and use committee of the University of Missouri—Kansas City.

Intravenous sCT Study—Following the induction of anesthesia, sCT (40 μg) was administered as a bolus through the cannulated ear vein of the rabbit. A blood sample (2 mL) was obtained 5 min before and then at 5, 10, 20, 45, 60, 90, and 120 min following the injection.

Buccal sCT Study—Upon the induction of anesthesia, a tablet was applied to the buccal mucosa of the rabbit by pressing it firmly against the mucosa for 1.5 min. A drop of water was placed on the releasing face of the tablet before it was applied to the buccal mucosa. A blood sample (2 mL) was obtained 5 min before and then at 5, 10, 20, 45, 60, 90, 120, and 180 min following the application of the mucoadhesive buccal tablets containing 40 μg of sCT and 12 mg of hakea. The tablet was removed at 180 min, and additional blood samples were obtained at 210, 240, 270, and 300 min following the removal of the buccal tablet. For tablets containing 40 μg of sCT and 32 mg of hakea, a similar blood sampling protocol was followed until 180 min as with 12 mg hakea.

Quantitation of Plasma sCT—Plasma samples were analyzed for sCT using an enzyme immunoassay kit (EIAH-6003) obtained from Peninsula Laboratories (Belmont, CA). The sensitivity of the assay ranged from 0 to 25 ng/mL. The assay was linear over the range 0.04−2.0 ng/mL. The sCT contained in the samples was extracted using C18 Sep columns (Peninsula Laboratories Belmont, CA) before being analyzed by enzyme immunoassay. The reason for the inclusion of an extraction step was to avoid a precipitation reaction between rabbit IgG present in the samples and goat anti-rabbit IgG coated on the EIAH plates. The extraction procedure was obtained from Peninsula Laboratories (Belmont, CA) and was followed without any modification. The samples were appropriately diluted with the EIA buffer prior to analysis.

Quantitation Of Plasma Calcium—Plasma calcium was quantitated by the *o*-cresolphthalein complexone method using a Sigma diagnostics kit for calcium (Sigma, St. Louis, MO). The method involves colorimetric determination of calcium at 575 nm (Procedure No. 587, Sigma Diagnostics).

Bioadhesion Study—Rabbit small intestine was selected as a model membrane since the intestine provided a flat and uniform surface and the surface area of the buccal mucosa in a rabbit is only slightly larger than the buccal tablets evaluated in these studies. A 2 cm long piece of intestinal mucosa was mounted on the platform of the tension-compression stand. The tablet was applied using super glue to the bottom face of a stainless steel disk attached to the force gauge. The mucosal surface was hydrated by placing 20 μL of distilled water on the tissue surface. The tablet and the mucosal surfaces were brought into contact, and a constant force of 20 N was applied. The tablet was pulled off the tissue surface at 5, 10, 20, 30, 45, 60, and 90 min following application of force. The value for the force of detachment was measured in newtons by lowering the platform of the tension-compression stand at a constant rate of 1 mm min^{-1}.

Data And Statistical Analysis—The in vitro release from the unidirectional buccal tablets was modeled using the basic equation $F = kt^n$,[13] and from the values of n, the mechanism of in vitro release was determined.

The plasma sCT concentrations obtained after both intravenous and buccal administration were not corrected for baseline levels of sCT (~0.41 ± 0.21 ng/mL, $n = 6$) for the ease of comparison with previous published findings. The plasma sCT concentration versus time data obtained following intravenous administration

were fit to a polyexponential equation using the R STRIP program. The data were fit to a two-compartment model with elimination from the central compartment. The model-dependent phamacokinetic parameters AUC, *A*, *B*, $t_{1/2}$ (α), and $t_{1/2}$ (β) were obtained from the fit, whereas the volume of the central compartment (V_c) and the volume of distribution in the β-phase (V_d (β)) were obtained using standard equations.[14]

The area under the plasma sCT concentration versus time curve was calculated using the trapezoidal rule within the time periods of 0−2 h following buccal administration although the experiments were carried out beyond 2 h. In an attempt to estimate the apparent bioavailability, the data was truncated at 2 h following buccal administration because the total duration of the intravenous experiments was 2 h. Equations 1 and 2 were used to estimate the apparent bioavailability and clearance of sCT following buccal administration.[15,16] The C_{max}, C_{min}, and t_{max} were estimated directly from the plasma sCT versus time profiles following buccal administration. In eqs 1 and 2, *F* denotes the

$$F = \frac{(\text{dose}_{IV})\,(\text{AUC}_{0-t_{buccal}})}{(\text{dose}_{buccal})\,(\text{AUC}_{0-t_{IV}})} \quad (1)$$

$$\text{CL} = \frac{FD}{\text{AUC}_{0-t_{buccal}}} \quad (2)$$

apparent bioavailability, *D* is the dose of sCT contained in the buccal tablets, and $\text{AUC}_{0-t_{buccal}}$ represents the area under the plasma sCT concentration vs time curve following buccal administration from 0 to 2 h. A dose of 40 μg of sCT was used to calculate the apparent bioavailability as the amount of sCT remaining in the tablet after buccal administration was not estimated.

The area above the calcium reduction curve from 0 to 2 h (AAC) was obtained as described previously.[17,18] The plasma calcium concentration at each time point after the administration of sCT was subtracted from the baseline calcium concentration, which was obtained prior to administration of sCT. Next, the AAC was calculated using the trapezoidal method. The data was again truncated at 2 h following buccal administration for ease of comparison with the intravenous data.

All experiments were conducted in triplicate, and the results were expressed as the mean value ± the standard deviation. Mean values were compared for statistical significance at the 5% level using Student's one-tail *t*-test.

Results

In Vitro Release Study—In vitro release profiles from buccal tablets containing 0, 12, and 32 mg of hakea with 40 μg of sCT are shown in Figure 1. The release profiles are sigmoidal in nature for buccal tablets with 40 μg of sCT and either 12 or 32 mg of hakea. The mechanism of in vitro release was determined from the values of *n* obtained by modeling the first 60% of the release to the equation $F = kt^n$.[13] The values of *k* (kinetic constant) and *n* (diffusional exponent) are listed in Table 1. The values of *n* are greater than 1, indicating super Case II transport as the mechanism of sCT release.

Intravenous sCT Study—The plasma sCT concentration versus time profile following intravenous administration was best explained using a biexponential equation and is shown in Figure 2. The values of the model-dependent phamacokinetic parameters are listed in Table 2. The change in the plasma calcium concentration is also depicted in Figure 2, and the relative AAC_{0-2h} is listed in Table 2. It can be noted from the pharmacokinetic parameters that the extravascular distribution of sCT was very rapid.

Buccal sCT Study—The plasma sCT concentration vs time profiles following administration of the 40 μg sCT buccal tablets with either 12 or 32 mg of hakea are shown in Figures 3 and 4, respectively. The relevant pharmacokinetic parameters are listed in Table 3. From Figures 3 and 4, it is apparent that hakea effectively sustained the release of sCT from the buccal tablets and also maintained an elevated plasma sCT concentration during the entire application period. The apparent bioavailability (*F*) of sCT from the tablets with 12 mg of hakea was significantly ($p < 0.05$) greater than that from the tablets with 32 mg of hakea. The C_{max} and C_{min} decreased while the t_{max} increased with an increase in the amount of hakea contained in the tablet (Table 3). The change in the plasma calcium concentration has also been illustrated in Figures 3 and 4, and the mean values of AAC_{0-2h} are listed in Table 3. AAC_{0-2h} for sCT tablets with 12 mg of hakea was not significantly different ($p > 0.05$) from AAC_{0-2h} for tablets with 32 mg of hakea.

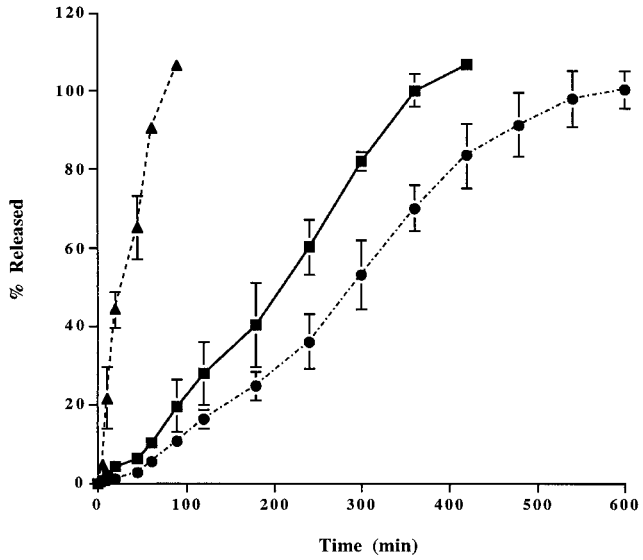

Figure 1—In vitro release profiles of sCT from directly compressed tablets which contained 40 μg of sCT and 0 mg of hakea (▲), 12 mg of hakea (■), or 32 mg of hakea (●). All data points represent the mean value ± standard deviation of three experiments. Lines through mean values are included to illustrate the trend and do not represent a mathematical fit of the data.

Table 1—Diffusional Exponent (*n*) and Kinetic Constant (*k*) Values[a]

parameters	40 μg of sCT and 12 mg of hakea	40 μg of sCT and 32 mg of hakea
n	1.24 ± 0.07	1.37 ± 0.05*
$k \times 10^{-7}$	2.0 ± 1.8	3.4 ± 1.3

[a] Mean ± SD, $n = 3$. The * symbol indicates a statistically significant increase in the mean value of the diffusional exponent when a 40 μg sCT tablet containing 12 mg of hakea was compared with a tablet containing 32 mg of hakea at $p < 0.05$ using Student's one-tail *t*-test.

Bioadhesion Study—A profile showing the mean values of the force of detachment of the sCT buccal tablets following their application to excised rabbit intestinal mucosa is shown in Figure 5. It can be noted that the mean values of the force of detachment increased with time and reached a plateau at later time points. The mean values of the force of detachment were significantly ($p < 0.05$) greater at each time point for tablets containing 32 mg of hakea when compared to the tablets which contained 12 mg of hakea and were significantly greater for tablets containing 12 mg of hakea when compared to the tablets which contained no hakea.

Discussion

In the present study, controlled release of sCT both in vitro and in vivo was successfully demonstrated using the natural gum, hakea as an excipient. The in vitro release profiles were sigmoidal in nature and consisted of an initial slow-releasing phase followed by a linear phase, where the

release appeared to follow zero-order kinetics (Figure 1). The values for the diffusional exponent (n) were greater than 1 (Table 1), indicating that the mechanism of sCT release was super Case II transport.[19] That is, the release of sCT from the buccal tablets is likely due to the combination of polypeptide diffusion and polymer relaxation/dissolution. This mechanism also explains the initial slow-releasing phase, where the polymer was not completely hydrated, resulting in an incomplete relaxation of the side chains. Insufficient hydration would lead to the creation of an aqueous pore through which the free diffusion of sCT would be hindered. Upon complete hydration, the polymer presumably began to dissolve with subsequent relaxation of the side chains. Relaxation of hakea's numerous side chains would then allow free diffusion of sCT from the tablet matrix. This mechanism would tend to support zero-order release kinetics during the linear portion of Figure 1. Banga et al.[20] reported that the diffusion of three polypeptides, vasopressin, calcitonin, and insulin, from hydrogel formulations was dependent on their molecular size.

The intravenous profile in this study was best described by a two-compartment model which is consistent with the work of Heiber et al. using dogs[6] and Sinko et al. using rats.[18] Sinko et al.[18] using a noncompartmental pharmacokinetic analysis reported the values (mean value of three different doses) for CL, $t_{1/2}$, k_e, and V_{ss} of 2.58 ± 0.34 mL/min, 40 ± 7.8 min, 0.02 ± 0.002 min^{-1}, and 0.14 ± 0.001 L, respectively, in rats. Beveridge et al.[21] reported terminal elimination half-lives ranging between 60 and 90 min following iv, im, and sc administration of 35 μg of sCT to humans.

The tablets which contained 32 mg of hakea demonstrated a significantly ($p < 0.05$) lower mean value of the apparent bioavailability (F) compared to tablets which contained 12 mg of hakea. The C_{max} and C_{min} decreased while the t_{max} increased when the amount of hakea in the tablet was increased from 12 to 32 mg (Figures 2 and 3;

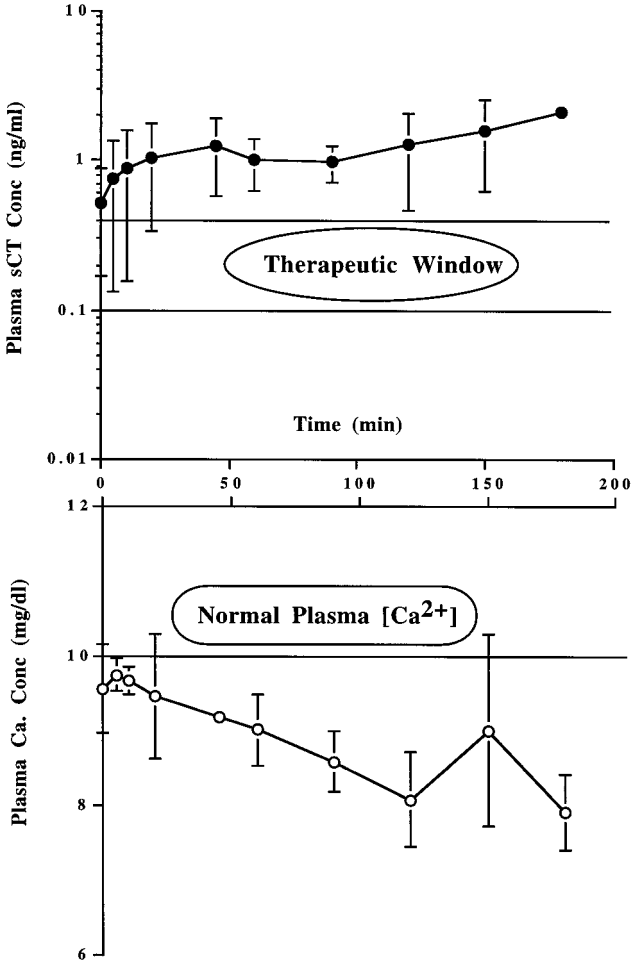

Figure 4—Plasma profiles of sCT (●) and calcium (○) in rabbits following the application of buccal tablets containing 40 μg (200 IU) of sCT and 32 mg of hakea. All data points represent the mean value ± standard deviation of three experiments. Lines through mean values are included to illustrate the trend and do not represent a mathematical fit of the data. Therapeutic window of sCT = 0.1–0.4 ng/mL (from ref 6).

Table 3—Pharmacokinetic Parameters[a] of sCT after Buccal Administration in New Zealand Albino Rabbits for a Two-Compartment Open Model

pharmacokinetic parameters	40 μg of sCT and 12 mg of hakea	40 μg of sCT and 32 mg of hakea
AUC_{0-2h} (ng·min/mL)	273 ± 49*	125 ± 63
CL (mL/min·kg)	19 ± 3.3	18 ± 0.4
F (%)	37 ± 6†	16 ± 8
C_{max} (ng/mL)	2.50 ± 0.5	1.33 ± 0.65
C_{min} (ng/mL)	2.00 ± 0.2	0.68 ± 0.41
t_{max} (min)	70 ± 17	140 ± 17
AAC_{0-2h} (mg·min/dL)[b]	74 ± 35	71 ± 59

[a] Mean ± SD, n = 3. The * symbol indicates a statistically significant increase in the mean value of the area under the curve from 0 to 120 min when a 40 μg sCT tablet containing 12 mg of hakea was compared with a tablet containing 32 mg of hakea at $p < 0.05$ using Student's one-tail t-test. The † symbol indicates a statistically significant increase in the mean value of the apparent bioavailability (F) when a 40 μg sCT tablet containing 12 mg of hakea was compared with a tablet containing 32 mg of hakea at $p < 0.05$ using Student's one-tail t-test. [b] Area above the calcium reduction curve.

Table 3). The results tend to suggest that hakea effectively retarded the rate of release of sCT from the dosage form. The values of F (%) calculated in the present study were 37 ± 6 and 16 ± 8 for buccal tablets with 12 and 32 mg of hakea, respectively. Dua et al.[22] reported percent bioavailability values of 0.16, 0.80, and 0.71 for low viscosity (1

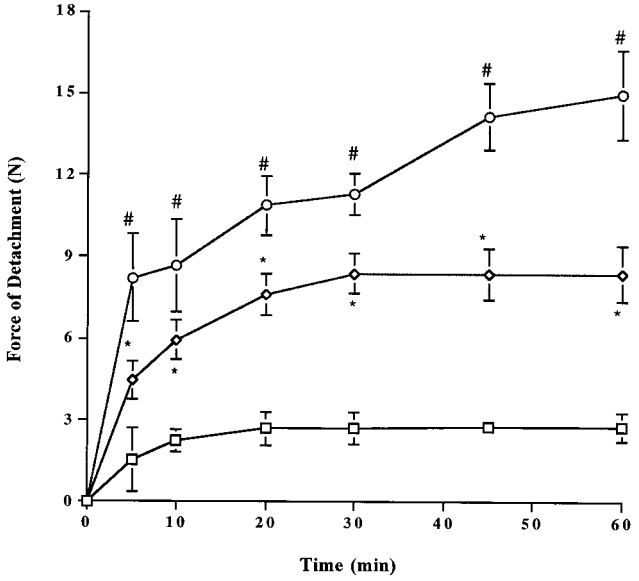

Figure 5—The force of detachment from excised rabbit intestinal mucosa for directly compressed buccal tablets which contained 40 μg of sCT and 0 mg of hakea (□), 12 mg of hakea (◇), or 32 mg of Hakea (○). All data points represent the mean value ± standard deviation of five experiments. Lines through mean values are included to illustrate the trend and do not represent a mathematical fit of the data. The * symbol indicates a statistically significant increase in the mean value of the force of detachment of a tablet containing 12 mg of hakea from that of a tablet containing 0 mg of hakea at $p < 0.05$ using Student's one-tail t-test. The # symbol indicates a statistically significant increase in the mean value of the force of detachment of a tablet containing 32 mg of hakea from that of a tablet containing 12 mg of hakea at $p < 0.05$ using Student's one-tail t-test.

cps) isotonic, hypertonic, and hypotonic formulations, respectively, after intranasal administration of salmon calcitonin at a dose of 2000 IU in rabbits. The percent bioavailability values were 0.14, 0.62, and 0.81 following intranasal administration of high-viscosity (76 cps) formulations prepared with 1% methylcellulose containing 2000 IU of salmon calcitonin in rabbits.[22] Heiber et al.[6] reported the delivery of 550 IU of sCT across canine buccal mucosa but did not report a value for bioavailability. Sinko et al.[18] reported a bioavailability of 16.2 ± 5.1% following subcutaneous (mean value of four different doses) and 0.022 ± 0.018% following intraduodenal administration (mean value of two different doses) in rats. An absolute bioavailability of 1.6% was reported without any permeation enhancer at a dose of 200 IU (40 μg) and 10.3% with 0.5% sodium tauro-24, 25-dihydrofusidate as a permeation enhancer at a dose of 405 IU (90 μg) following intranasal administration of sCT in humans.[23] Estimates of the absolute bioavailability of several other therapeutic polypeptides following buccal administration are 1−5%, 0.1%, and 1% for thyrotropin releasing hormone (TRH) in humans,[24] oxytocin in rabbits,[16] and buserelin in pigs,[17] respectively.

The plasma sCT levels obtained in this investigation using sCT buccal tablets which contained hakea were greater than therapeutic plasma levels (0.1−0.4 ng/mL). These levels were achieved without the use of a permeation enhancer. Heiber et al. also reported sCT plasma levels in excess of the therapeutic range when buccal tablets were evaluated in dogs.[6] The present study demonstrated that the buccal route provided a greater systemic bioavailability than the other routes of sCT administration discussed previously and that the buccal tablets which contained hakea not only achieved therapeutic plasma levels but also sustained the plasma concentration of sCT for 2−3 h. However, in the present study, the authors did observe a departure of plasma sCT concentrations following buccal

administration which would have been anticipated on the basis of our in vitro release studies. More recent findings in our laboratory (unpublished observations) suggest that the increased bioavailability of sCT in the present study may potentially result from hakea inhibiting proteolytic enzymes located in the oral cavity which are responsible for chemical degradation of sCT and/or inhibition of the polypeptide's biological activity. The mechanism of enhanced bioavailability will be the subject of future experimentation.

In the present study, the drug-releasing, uncoated surface adhered to the buccal mucosa during the entire application period. This mucosal binding possibly minimized the loss of drug into the surrounding oral cavity and the gastrointestinal tract in the event that sCT dissolved in saliva were potentially swallowed. Upon the removal of buccal tablets with 40 μg of sCT and 12 mg of hakea, the plasma sCT concentration did not decrease as observed following an intravenous dose suggesting that the sCT may accumulate in the buccal mucosa resulting in a reservoir effect. This has also been observed by Heiber et al.[6]

The pharmacodynamic response to biologically active sCT represents a reduction in plasma calcium concentrations. Figures 3 and 4 illustrate the absorption of biologically active sCT across the buccal mucosa of rabbits. The results demonstrated that the dual compaction process during the manufacturing of the tablet did not affect its biological activity adversely. The values of AAC_{0-2h} for the 40 μg sCT buccal tablets with 12 and 32 mg of hakea were not significantly different ($p > 0.05$), which may be due to the potency of sCT, i.e., the dose required to elicit the maximum pharmacological response is very small. As such, this pharmacological response reaches a maximum beyond which further lowering of plasma calcium concentrations does not occur as the dose is increased (negative feedback control of plasma calcium).[25] Sinko et al.[16] estimated that the maximal lowering of plasma calcium occurs at a plasma sCT concentration of 10 pg/mL in rats. Dua et al.[22] obtained a similar maximal percent decrease in plasma calcium concentrations (% max_d) following intranasal administration of different formulations in rabbits, although the (%) values reported for the bioavailability were quite different. This may have resulted from homeostasis and negative feedback control. Many investigators rely on the pharmacodynamic response to assess the absolute bioavailability[26–29] which may result in an overestimation for the reasons cited above.

Sustained-release, mucoadhesive dosage forms have the advantage of not only adhering to the mucus membrane for the required length of time but also sustaining the release of drug substances. In the present study, the amount of hakea incorporated into the buccal tablet was observed to be a critical factor in defining the resulting bioadhesive strength. A potential reason for an increase in the mucoadhesive bond strength with increasing hakea content (Figure 5) may be due to enhanced water uptake by the gum resulting in tablet swelling and mobilization of flexible polysaccharide chains for interpenetration and physical entanglement with the mucus.

Hakea possesses both hydroxyl and carboxyl terminal groups which can contribute to bioadhesion. Both these functional groups have to be in the un-ionized form in order for it to optimally interact with the negatively charged mucin molecule (under neutral or slightly acidic conditions). The bioadhesive strength increased with time and reached a plateau (Figure 5), suggesting that the process of bioadhesion is saturable and that the mechanism of bioadhesion is likely due to chain interpenetration and physical entanglement[30] of hakea with mucus rather than secondary bond formation (e.g., hydrogen bonding). The fact that the bioadhesive strength reaches a plateau at later time points could be due to the limited surface area of the tablet and exhaustion of the sialic acid residues of the mucin molecule with which the gum can interact in the circular surface area covered by the tablet.

In conclusion, the ability of the novel gum to sustain the release of sCT has been demonstrated both in vitro and in vivo. Moreover, in vitro bioadhesive strength versus time measurements demonstrated that the gum possessed excellent mucoadhesive properties. The tablets were convenient to apply and remove from the buccal mucosa and did not appear to damage the underlying tissue. The mechanism of bioadhesion may potentially result from chain interpenetration and physical entanglement of hakea with the mucus layer. The rate of release of the drug substance as well as the bioadhesive bond strength of the formulation can be modulated by varying the amount of hakea included in the tablet. Thus, the polysaccharide bioadhesive gum hakea may be utilized for not only the sustained delivery of a variety of water-soluble, low molecular weight drug substances but also therapeutic polypeptides.

Abstract □ The objective of this study was to investigate the behaviors of proteins at the water/methylene chloride interface to better understand denaturing effects of emulsification upon proteins. Ribonuclease A (RNase) and human serum albumin (HSA) were used as model proteins throughout this study. Their behaviors at the interface were studied in terms of protein recovery after emulsification, interfacial protein aggregation, and dynamic interfacial tension. This study demonstrated that protein instability during emulsification was traced to consequences of the adsorption and conformational rearrangements of proteins at the water/methylene chloride interface. Compared to HSA, RNase was much more vulnerable to the interface-induced aggregation reactions that led to formation of water-insoluble aggregates upon emulsification. Even though HSA was almost completely recovered from the emulsified aqueous phase, the protein underwent dimerization and oligomerization reactions to some extent. The results also demonstrated that the extent of interfacial RNase aggregation was affected by its aqueous concentration and the presence of HSA. Interestingly, RNase stability during emulsification was almost achieved by dissolving an adequate quantity of HSA in the RNase solution. HSA seemed to compete for the interface site and to effectively keep RNase out the interface, minimizing the likelihood of the interface-induced RNase aggregation. These results indicated that competitive adsorption modes of proteins could be used to stabilize a protein of interest against the denaturing effects of emulsification.

Introduction

The field of protein and vaccine delivery systems based on emulsions and biodegradable poly-*d*,*l*-lactide-*co*-glycolide (PLGA) microspheres has grown exponentially. However, increasing concerns about the issues of protein instability during manufacturing processes exist. Maintaining protein stability is of paramount importance, because destabilized proteins lose biological efficacy and aggregate to increase the possibility of an unwanted immune response. Among a variety of manufacturing processes, emulsification of an aqueous protein solution in an organic solvent is considered a major risk factor that presents an obstacle to the successful development of emulsion- and microsphere-based protein delivery systems.[1−4] It is generally agreed that the observed instability stems from exposure of proteins to cavitation, heat, or shear produced during emulsification.[5,6] Protein inactivation is also speculated to arise from protein denaturation at the aqueous solution−organic solvent interface and protein interaction with polymer residuals dissolved in the organic solvent.[7−9] Another possible mechanism suggested elsewhere is that an organic solvent diffuses to an aqueous protein solution and interacts with hydrophobic domains of the protein, eventually disrupting its structural integrity.[10−12]

The current study suggests that protein instability during emulsification is traced to consequences of protein contact with the water/organic solvent interface around emulsion droplets. Because of amphipathicity and flexible conformation, proteins are surface active so that they tend to adsorb at water/organic solvent interfaces.[13] This event seems not only to disturb the delicate conformation of proteins but also to trigger various physicochemical transformations, leading to protein destabilization reactions. Currently, however, many questions remain unanswered with regard to the origins of protein instability against the interfaces, mechanisms that govern protein destabilization at water/organic solvent interfaces, and competitive protein behavior at the interfaces. As a starting point to tackle these important issues, this study sought to investigate the behavior of model proteins ribonuclease A (RNase) and human serum albumin (HSA) at the water/methylene chloride (W/MC) interface.

Materials and Methods

Materials—Ribonuclease A (RNase; type III-A from bovine pancreas; R5125) and human serum albumin (HSA; A3782) were obtained from Sigma Chemical Company (St. Louis, MO). Major physicochemical properties of the two proteins are compared in Table 1. A precast, 1.5-mm thick Tris-glycine gel (8−16%) was purchased from Novex (San Diego, CA). Methylene chloride of HPLC grade was used throughout this study.

Emulsification to Generate the Water/Methylene Chloride (W/MC) Interface—A protein sample was dissolved in distilled water to make 0.2−1.5 mg/mL concentrations. Aliquots (3 mL) of the solution were placed inside a 20-mL vial containing methylene chloride (12 mL). The mixture was emulsified for 1 min at room temperature by a rotor/stator-type VirtiShear Tempest IQ2 homogenizer (The VirTis Co., Gardiner, NY) equipped with a 10-mm shaft. During emulsification, the rotational speed of the homogenizer rotor was set at 16 000 rpm.

Quantitation of Protein Distribution between Water and the W/MC Interface—Emulsification led to the formation of water-insoluble RNase aggregates that resided in the interface. To determine the aqueous protein concentration and the amount of the aggregates, the aqueous phase was separated from the methylene chloride phase by centrifugation at 3500 rpm for 10 min (IEC Centrifuge/International Centrifuge Company, Needham Heights, MA). A protein sample collected from the aqueous phase was subjected to a native size exclusion chromatography (SEC)-HPLC experiment which was described later. Equation 1 was used to determine the percentage of a protein recovered in the aqueous phase after emulsification. The amount of interfacially aggregated protein was equal to that of protein disappearing from the aqueous phase after emulsification.

the aggregates differed from native RNase. Before the experiments, the water-insoluble aggregates were dissolved in a 0.5% SDS aqueous solution or 6 M urea. For the UV spectral experiment, a HP 8453 UV−visible spectrophotometer (Hewlett-Packard Company, Palo Alto, CA) was used to monitor the spectra of native and aggregated RNase molecules over the wavelength of 200 to 320 nm. In addition, their first derivative spectra were also obtained using a Savitsky−Golay algorithm offered by the spectrophotometer software.

For the dynamic light-scattering experiment, RNase sample solutions in 0.5% SDS or 6 M urea were filtered through a Whatman Anotop Plus filter with 0.1 μm porosity. The sample solutions were placed inside the microsample chamber of a DynaPro-801TC (Protein Solutions, Inc., Charlottesville, VA) and were illuminated by the laser. The instrument determined the hydrodynamic radius by analyzing the scattered light (the angle of detection was 90°).

Homogenization Effects on Protein Recovery—A 0.5 mg/mL RNase or HSA solution (15 mL) was put into a 20-mL size vial and was homogenized in the absence of methylene chloride under the same experimental conditions described earlier. Later, protein concentration was determined by SEC−HPLC analysis. The protein sample was also subjected to SDS−PAGE experiments.

Dissolved Methylene Chloride Effect on Protein Recovery—To prepare an aqueous solution saturated with methylene chloride, 4 mL of methylene chloride was added to 16 mL of water. The mixture was then vigorously shaken for 1 h at room temperature with an Eberbach shaker (Eberbach Co., Ann Arbor, MI) and was centrifuged to obtain the methylene chloride−saturated aqueous phase. RNase was then dissolved in the solution phase at a 0.5 mg/mL concentration. After the methylene chloride−saturated aqueous RNase solution (15 mL) was homogenized as described earlier, its concentration was determined by SEC−HPLC analysis and was compared with that of unhomogenized RNase solution.

SEC−HPLC—This experiment was performed to measure the total protein content and to assess the composition of water-soluble protein species before and after emulsification. When water-insoluble protein aggregates were analyzed, they were dissolved in a 0.5% SDS aqueous solution before the SEC−HPLC experiment. Protein samples were eluted from a TSK Gel G3000 SW analytical column (7.5-mm inner diameter × 60-cm length) by a mobile phase consisting of 50 mM phosphate buffer solution containing 0.1 M NaCl (pH 7.0). The flow rate was maintained at 0.8 mL/min, and the elution of protein samples was monitored by a UV detector set at 280 nm. The concentration of each protein species was determined by a calibration curve constructed by peak area integration of protein standards with known concentrations. Throughout this study, the average of at least three experimental determinations was reported with a standard deviation.

SDS−PAGE—A gradient 8−16% Tris-Glycine gel was placed inside Novex Xcell II Mini-Cell. RNase samples were mixed well with a Laemmli Tris-Glycine loading buffer and were housed inside the gel wells. The running buffer consisted of 25 mM Tris, 192 mM glycine, and 0.1% SDS at pH 8.3. After being run at a 125 V constant voltage (Power PAC300/Bio-Rad Laboratories, Hercules, CA) for 125 min, the gel was stained for 30 min with a 0.1% Coomassie Blue solution containing 10% glacial acetic acid and 50% methanol. Protein bands were visualized after the gel was destained overnight with an aqueous solution containing 20% methanol and 10% glacial acetic acid.

Inhibition of RNase Interfacial Aggregation—To investigate the effect of HSA upon the degree of RNase recovery, 0.2−5.0 mg/mL HSA was dissolved in a 0.35 mg/mL RNase solution before emulsification. After the aqueous protein mixture solution was emulsified in methylene chloride, the degree of RNase recovery was determined following the SEC−HPLC analysis mentioned earlier.

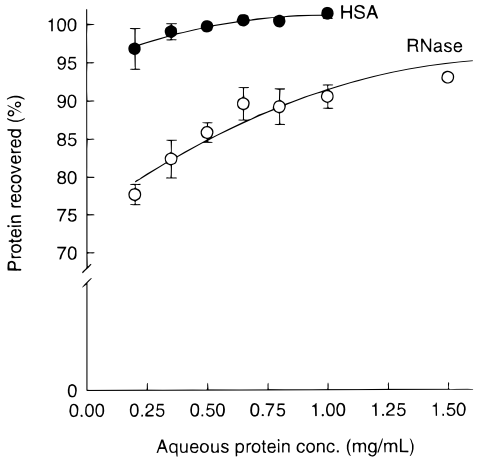

Figure 1—The percentage of protein recovery after emulsification. After an aqueous protein solution was emulsified in methylene chloride, the degree of protein recovery was determined by eq 1.

Measurement of Dynamic Interfacial Tension—Protein adsorption at the W/MC interfaces was investigated by a drop volume tensiometer (Model DVT-10/Krüss USA, Charlotte, NC). The tensiometer was considered suitable for studying the adsorption of surface active materials at interfaces, when they slowly attained equilibrium interfacial tension.[17,18] In this experiment, an aqueous 0.5 mg/mL RNase or HSA solution was placed in a 100-μL size gastight Hamilton syringe. A pump (Model 44/Harvard Apparatus, South Natick, MA) was used to deliver the protein solution at a constant rate to methylene chloride phase via a bore capillary (0.254-mm inner diameter) with a specially tapered tip. The flow rate ranged from 15 to 0.5 mL/h. As the protein solution was pumped into the methylene chloride phase, a drop grew and detached off the tip of the bore capillary. The time required for detachment of each droplet was defined as interface development time. Combined knowledge on the interface development time and the flow rate allowed us to calculate the volume of each droplet. Interfacial tension was then determined by eq 2.[19]

$$\sigma = \frac{V_{\text{drop}}\,(\rho_{\text{m}} - \rho_{\text{w}})g}{\pi d} \tag{2}$$

where σ was interfacial tension; V_{drop}, the volume of an aqueous droplet; g, the acceleration due to gravity; d, diameter of the bore capillary; ρ_{m}, methylene chloride density; and ρ_{w}, the density of water phase. The interfacial tension measurement was repeated five times, and their mean ± standard deviation was reported.

Results

Under our SEC−HPLC experimental conditions, only one peak representing monomeric RNase species was observed when the protein solution was not subject to emulsification. The same monomeric peak was detected with RNase solutions emulsified in methylene chloride, but there was a substantial reduction in the content of RNase monomer. A loss in its aqueous content was found to be caused by the formation of water-insoluble aggregates residing in the W/MC interface. Besides, the extent of RNase recovery was affected by changes in its aqueous concentration prior to emulsification (Figure 1). For instance, 77.7 ± 1.4% (mean ± standard deviation) of RNase was recovered after a 0.2 mg/mL RNase solution was emulsified in methylene chloride. An increase in its concentration to 1.5 mg/mL before emulsification enhanced its

protein concn (mg/mL)	monomer %	dimer %	oligomer % (total μg)[b]
0.20	71.2 ± 0.3	24.3 ± 0.2	4.6 ± 0.1 (27.3 ± 0.4)
0.35	75.8 ± 0.2	21.2 ± 0.1	3.1 ± 0.2 (32.0 ± 2.2)
0.50	78.5 ± 0.4	19.2 ± 0.4	2.4 ± 0.1 (36.0 ± 0.1)
0.65	79.8 ± 0.2	18.1 ± 0.1	2.2 ± 0.1 (42.0 ± 1.4)
0.80	80.8 ± 0.2	17.3 ± 0.3	1.9 ± 0.1 (45.6 ± 0.1)
1.00	80.8 ± 0.2	17.2 ± 0.4	2.1 ± 0.1 (63.0 ± 4.2)

[a] All determinations are performed at least three times, and mean ± standard deviation is reported. Before emulsification, HSA consisted of 86.7 ± 0.5% monomer and 13.3 ± 0.5% dimer. [b] The actual amount of a new water-soluble HSA oligomer is in parentheses.

degree of recovery up to 92.9 ± 0.2%. The data in Figure 1 were likely to give a false impression that fewer RNase molecules became aggregated at high concentrations. The amount of RNase aggregates in fact increased at high concentrations: emulsifying 0.2 and 1.5 mg/mL RNase solutions resulted in the formation of 133.9 ± 8.2 and 317.4 ± 10.8 μg of water-insoluble RNase aggregates, respectively.

Similar experiments were repeated to investigate the behavior of HSA at the W/MC interface developed during emulsification. From the viewpoint of percentage of protein recovery, HSA exhibited stronger resistance toward emulsification-induced aggregation reactions than RNase did (Figure 1). HSA was almost completely recovered in the aqueous phase. For instance, when a 0.2 mg/mL HSA solution was emulsified, protein recovery was 96.8 ± 2.7%. Moreover, at ≥0.35 mg/mL concentrations, at least 99.1% of HSA was recovered from the aqueous phase emulsified. However, it was found that some proportion of HSA molecules underwent dimerization and oligomerization reactions on emulsification (Table 2). Unemulsified HSA contained 86.7 ± 0.5% monomer and 13.3 ± 0.5% dimer, and homogenization of an aqueous HSA solution alone did not cause any change in the protein composition. On the contrary, after a 0.2 mg/mL HSA solution was emulsified in methylene chloride, the protein consisted of 71.2 ± 0.3% monomer, 24.3 ± 0.2% dimer, and 4.6 ± 0.1% oligomer. It should also be mentioned that the extent of HSA oligomerization also was concentration-dependent, such that the actual amount of the new water-soluble HSA oligomer species increased at high concentrations (Table 2).

Before carrying out the SEC−HPLC experiment, water-insoluble RNase aggregates obtained from the W/MC interface were dissolved using SDS which is known to disrupt the quaternary structures of most proteins and dissociate them into monomeric species. Figure 2 illustrates the SEC−HPLC chromatograms. The appearance of new RNase aggregates, despite the SDS treatment, indicated that the emulsification-associated RNase aggregation was an irreversible process, and the aggregates were not easily dissociable. To further back up this supposition, the hydrodynamic radius of monomeric RNase was compared with that of the water-insoluble RNase aggregates (Table 3). RNase monomer in 0.5% SDS solution was estimated to have the hydrodynamic radius of 2.0 nm. In contrast, the mean hydrodynamic radius of the water-insoluble RNase aggregates was determined to be 12.7 nm. In addition, an increase in the polydispersity observed with water-insoluble RNase aggregates represented that the aggregates were polydisperse in size and consisted of species with different hydrodynamic radii (the polydispersity in Table 3 indicates the standard deviation of the spread of sample sizes about the reported mean hydrodynamic radius). In particular, the DynaPro-801TC seemed to overestimate the hydrodynamic radius of RNase samples in 6 M urea. This result may have arisen from the fact that RNase species in 6 M urea exist in unfolded states.

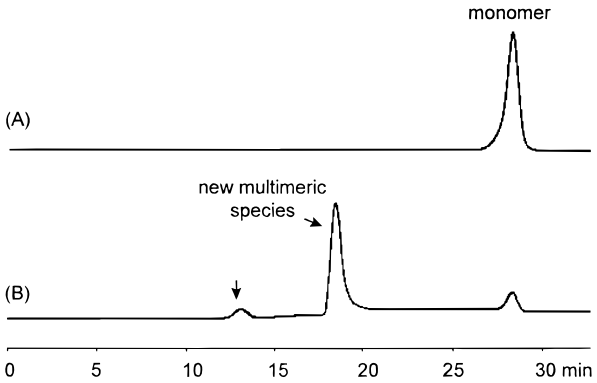

Figure 2—SEC–HPLC chromatograms of (A) standard RNase before emulsification and (B) water-insoluble RNase aggregates collected from the W/MC interface after emulsification. RNase aggregates were dissolved in a 0.5% SDS aqueous solution before injection to the SEC–HPLC.

Figure 3 illustrates the UV spectra of monomeric RNase and water-insoluble RNase aggregates. The spectrum and its first derivative for RNase aggregates were different from those of monomeric RNase (these differences were confirmed by a linear regression-based spectral match function provided by the HP 8453 UV−Visible spectrophotometer). Especially, the broadening of bands and shifts in wavelength were observed with RNase aggregates in comparison to RNase monomer. It can be inferred from the result that RNase aggregation might have changed the local environment of the chromophores, e.g., peptide groups, aromatic amino acids, and disulfide bonds, in RNase molecules.

To test whether the observed RNase aggregation might be caused by mechanical shear stress and/or the continual creation of a new air/water interface, a 0.5 mg/mL RNase solution (15 mL) was homogenized in the absence of methylene chloride. Slight foaming was observed after the treatment, but the foam dissipated rapidly. No considerable change in the content of RNase monomer was observed after homogenization (the aqueous solution homogenized was found to contain 99.67 ± 0.72% of the initially used amount of RNase). In addition, the SDS−PAGE results shown in Figure 4 demonstrated that RNase samples before and after homogenization exhibited the same gel patterns. A similar trend was observed when homogenization was performed on the methylene chloride−saturated aqueous RNase solution. Foaming also occurred during homogenization, but the foam disappeared when the solution was kept still. In this case, 99.0 ± 0.1% of the initial RNase amount was found in the solution.

So far, it has been suggested in this study that exposure of proteins at the W/MC interface initiated protein destabilization reactions. To prove this supposition, protein adsorption and conformational changes at the interface were demonstrated by analyzing the W/MC interfacial tension. In our study, the Krüss DVT-10 tensiometer determined the interfacial tension to be 27.84 ± 0.38 mN/m when the aqueous phase did not contain any protein molecules. At the same time, the volume of a single water droplet was found to be 7.17 ± 0.10 μL. The presence of either RNase or HSA at a 0.5 mg/mL concentration in water led to a considerable reduction in the interfacial tension, as well as the volume of an aqueous droplet (Table 4). Besides, changes in the interfacial tension were affected by interface development time that was manipulated by the flow rate of pumping a protein solution into methylene chloride. A lower flow rate, which provided a longer

interface development time, led to a greater reduction in the aqueous droplet volume and the interfacial tension (a linear relationship between the volume of an aqueous droplet and the W/MC interfacial tension is well depicted by eq 2). A longer interface development time—more prolonged exposure of proteins to the interface—seemed to permit more protein molecules to adsorb and undergo conformational rearrangements at the interface. An additional interesting point observed in Table 4 was that, at relatively higher flow rates, the surface activity of RNase was greater than that of HSA. By contrast, the same conclusion did not remain valid when the flow rate was decreased below 1 mL/h. HSA was found to be more surface active when exposed to the interface for longer periods of time.

In terms of the degree of protein recovery, HSA exhibited superior stability over RNase against the W/MC interface-induced aggregation reactions (Figure 1). It was also speculated that owing to their surface activity, proteins would compete for adsorption sites at the W/MC interface. On the basis of these considerations, different levels of HSA (0.2 ~ 5.0 mg/mL) were codissolved in a 0.35 mg/mL RNase solution before emulsification to minimize RNase instability toward the W/MC interface. When RNase was the only protein species present in the aqueous phase, 82.4 ± 2.5% of RNase was recovered from the emulsified aqueous phase. When a sufficient quantity of HSA was added into the aqueous phase, the degree of RNase recovery was increased considerably (Figure 5). At ≥0.8 mg/mL HSA concentrations, more than 96.6 ± 1.2% of RNase was recovered from the emulsified aqueous phase. These data indicated that the use of HSA contributed to stabilizing RNase against the interface-triggered destabilizing reactions.

Discussion

Water/oil interface is ascribed to be highly mobile in comparison to water/air and water/solid interfaces so that proteins are less likely to adsorb irreversibly and destabilize at the water/oil interface.[20] However, our experimental results demonstrate that the W/MC interface developed during emulsification is detrimental to the stability of RNase molecules. Our control experiments also demonstrated that homogenization-associated effects (e.g., cavitation, shear, and continual creation of a new air/water interface) and methylene chloride molecules dissolved in water are not the main causes of RNase instability observed with emulsification. Exposure of RNase molecules to the W/MC interface is held accountable for inducing considerable conformational changes leading to aggregation reactions and a subsequent reduction in its monomer content. In addition, a series of experiments provides evidence that the interface-triggered aggregation reactions are essentially irreversible (Figure 2 and Table 3). It remains to be investigated whether the formation of these RNase aggregates is induced by noncovalent, physical associations or by intermolecular covalent linkages.

It was previously reported that, although some proteins and vaccines were stable in organic solvents, they became inactivated either upon exposure to water—organic solvent mixture or during the emulsion-based microencapsulation process.[21,22] Most reports ascribed that organic solvent molecules dissolved in an aqueous phase could interact with hydrophobic domains of proteins, thereby triggering structural rearrangements detrimental to protein integrity. On the basis of this consideration, a rapid microsphere hardening process is recommended to maintain protein

Table 4—Effects of the Flow Rate on Dynamic Changes in the W/MC Interfacial Tension (mN/m) and the Volume (μL) of an Aqueous Droplet. Figure 5—The effect of HSA on RNase recovery. Prior to emulsification, HSA (0.2 to 5.0 mg/mL) was codissolved in a 0.35 mg/mL RNase solution. The solution was emulsified in methylene chloride, and the percentage of RNase recovery was determined.

stability by minimizing exposure time of a protein to methylene chloride.[23] However, our results clearly substantiate that protein destabilization reactions occur primarily over a very short emulsification time scale that lasted for only 1 min in our experiment. This conclusion is in line with other reports suggesting that emulsification of preparing a primary w/o emulsion is the main risk factor responsible for protein inactivation when microspheres are prepared by the w/o/w microencapsulation process.[1–3,7]

In the current study, it has also been shown that the degree of the interfacial RNase aggregation is influenced by aqueous protein concentrations and the presence of another protein, HSA. With regard to the effect of protein concentration upon its stability, two hypotheses have been proposed to explain that a smaller fraction of proteins becomes inactivated at high concentrations. The first one takes into consideration that only a limited amount of a protein could interact at water/oil interfaces.[3] Under this condition, the protein is suggested to act as a self-protectant at high concentrations, thereby inhibiting its interaction with the interface. The other hypothesis elaborates on the role of energy barrier on protein adsorption.[24] At low protein concentrations, there is no barrier to adsorption and subsequent interfacial reactions. By contrast, at high protein concentrations, an energy barrier comes into play to prohibit further protein adsorption. At 0.2 to 1.5 mg/mL RNase concentrations used in our study, the protein aggregation increased with its aqueous concentration increasing. This result suggests that, in dilute concentrations, protein adsorption at the interface is enhanced by an increase in its aqueous concentration, because a great concentration gradient facilitates the mass transfer of RNase to the interface. As a consequence, collision frequencies and reactions among RNase molecules are increased. This contention agrees well with a widespread assertion that the extent of protein aggregation is kinetically controlled and the rate of aggregation is proportional to protein concentration.[25]

Serum albumins, particularly bovine serum albumin, have been popularly coencapsulated with therapeutic proteins into PLGA microspheres via the w/o/w emulsion and the spray-drying processes.[1,7,26–28] In these studies, it was reported that serum albumins improved the encapsulation efficiency of proteins and vaccines and contributed to preserving their activities. Currently, little information is available with regard to stabilization mechanisms of serum albumins for therapeutic proteins and their behaviors at the W/MC interface. From the data on the effect of HSA concentration upon the degree of RNase recovery (Figure 5), it can be inferred that the mass transfer phenomenon influences the kinetics of protein adsorption. According to this theory, a protein present in excess should occupy an interface first, because a steeper concentration gradient provides a greater diffusion rate to the protein. As a result of this, HSA at higher concentrations seems to effectively keep RNase molecules out of the W/MC interface, minimizing the likelihood of the interface-induced RNase aggregation. The other possible stabilizing function of HSA is that the protein molecules may adsorb preferentially at the interface and strip the adsorbed RNase molecules off the interface. In studies of protein behavior at solid/water interfaces, it has been demonstrated that HSA displaces IgG and fibrinogen adsorbed at solid surfaces.[29–31] The so-called "Vroman effect" describes this phenomenon that proteins can replace one another at biomaterial surfaces.[32,33]

Another important discussion should be made with regard to the quantity of serum albumins to be used for protecting therapeutic proteins. In most studies, a large quantity of serum albumins—their aqueous concentrations range from 50 to 400 mg/mL—has been used to enhance the stability of therapeutic proteins and vaccines during the emulsion-based microencapsulation procedure.[1,7,26–28] The data in Figure 5 indicate that the denaturing effects of the W/MC interface upon RNase can almost be avoided at HSA concentrations as low as 0.5 mg/mL. One should caution that the use of an excess amount of HSA leads to the generation of more HSA oligomer, as evidenced in Table 2. Therefore, a minimal quantity of HSA should be used to rule out the possibility of an untoward immune response toward the new HSA oligomer.

Finally, the tensiometer data in Table 4 provide direct evidence on the adsorption of proteins at the W/MC interface. Dynamic changes in the interfacial tension as a function of the interface development time also indicate that adsorbed protein molecules undergo conformational rearrangements in a way to minimize the free energy of the system. During the initial development of the W/MC interface, RNase seems to diffuse more rapidly to the

interface than HSA does, as indicated by their respective diffusion coefficients (Table 1). This is the reason that a lower W/MC interfacial tension is seen with an aqueous RNase solution over relatively short interface development times. Once adsorbed in the interface, HSA displays a much faster rate of the interfacial tension decrease. These results indicate that HSA possesses quite a flexible conformation and undergoes a fast conformational rearrangement at the interface, whereas rigid RNase undergoes a slow conformational rearrangement process. As a result, with the aging of the interface, an aqueous HSA solution provides a lower W/MC interfacial tension than an aqueous RNase solution does. This conclusion is consistent with a previous assertion that RNase has a relatively greater conformational stability than HSA.[34] On the basis of the results of the recovery of these two proteins after emulsification (Figure 1), however, it can be suggested that the conformational flexibility and the W/MC interface-induced aggregation are not closely related. Further investigations need to be performed to unravel their different behaviors at the interface.

In summary, protein adsorption at the W/MC interface and its effect upon protein integrity have been corroborated to explain protein instabilization observed with emulsification. Competitive protein adsorption modes have been used to stabilize a protein of interest—RNase in this study—against the denaturing effects of the W/MC interface. Information reported in this study might aid in the successful development of protein delivery systems such as emulsions and PLGA microspheres.

Skin Penetration of Nonsteroidal Antiinflammatory Drugs out of a Lipophilic Vehicle: Influence of the Viable Epidermis

BERNHARD P. WENKERS AND BERNHARD C. LIPPOLD*

Contribution from *Institut für Pharmazeutische Technologie, Heinrich-Heine-Universität, Universitätsstrasse 1, 40225 Düsseldorf, Germany.*

Received January 30, 1999. Accepted for publication September 20, 1999.

Abstract □ The skin penetration of 10 nonsteroidal antiinflammatory drugs (NSAIDs) was investigated after application in the lipophilic vehicle light mineral oil. The skin permeabilities and maximum fluxes, which were calculated from the concentration decreases of the applied solutions in the steady state phases, were correlated with physicochemical parameters, mainly the vehicle solubilities and the partition coefficients of the model drugs according to the Fickian diffusion laws. The objective of the study was to characterize the barrier function of the stratum corneum and the viable epidermis and to predict their influences on the skin permeabilities and the maximum fluxes of the NSAIDs by model equations. The permeability of the human skin for NSAIDs applied in a lipophilic vehicle is a function of their hydrophilicity, while the maximum flux is primarily dependent on their vehicle solubilities. The viable epidermis was found to represent the decisive resistance to the drug transport.

Introduction

The percutaneous treatment of rheumatic diseases with nonsteroidal antiinflammatory drugs (NSAIDs) causes less side effects than the peroral application. It has been controversially discussed whether NSAIDs applied to the skin will directly penetrate into tissues and joints deeper than 1 cm.[1−4] Based on this background, the question shall be investigated of whether skin penetration of the NSAIDs as model drugs out of the lipophilic vehicle light mineral oil can be described by the same physicochemical parameters according to the Fickian diffusion laws as out of a hydrophilic vehicle. The stratum corneum is considered as the main barrier for the percutaneous drug transport.[5−7] Thus, for the prediction of skin permeability, the partition coefficient between the stratum corneum and the vehicle $PC_{SC/V}$ is of particular importance. It is often related to the in vitro partition coefficient between octanol and the vehicle $PC_{Oct/V}$.[8−10] Consequently, drugs of similar size and high lipophilicity show high permeabilities out of aqueous solutions, as it has been repeatedly shown in the literature.[8−12] In contrast, the permeabilities of lipophilic drugs out of lipophilic vehicles should be low,[11,12] which was demonstrated for the first time by Blank.[13] The additional resistance of the viable epidermis has not yet been investigated. In this case, it must be considered that the permeant has to partition not only out of the vehicle into the stratum corneum but subsequently from the stratum corneum into the barrier of the viable epidermis, not behaving like a sink. Accordingly, the partition coefficient between the stratum corneum and the viable epidermis $PC_{SC/E}$ or the partition coefficient between the viable epidermis and the vehicle $PC_{E/V}$ must be taken into account.[14]

For the prediction of the maximum flux of a drug, its solubility in the rate-limiting barrier(s) is decisive, being independent of the applied vehicle.[6,15] Because the solubility in the barrier(s) is unknown, the maximum flux of the drug is expressed as the product of its barrier permeability and its vehicle solubility and thus can be correlated with physicochemical parameters.[6,11,12,14,15]

Theory

Permeability—The permeability of a membrane for a diffusing substance is defined by its resistance. To characterize the influences of the resistances of the stratum corneum SC and the viable epidermis E, respectively, on the drug transport out of a lipophilic vehicle V in the steady state or the pseudo-steady-state,[15] respectively, three model equations can be derived.[14,16]

Model 1—The stratum corneum alone is decisive

$$R_{skin} = \frac{1}{P_{skin}} = \frac{d_{SC}}{D_{SC} PC_{SC/V}} \leftrightarrow P_{skin} = \frac{D_{SC} PC_{SC/V}}{d_{SC}} \leftrightarrow \lg P_{skin} = \lg\left(\frac{D_{SC}}{d_{SC}}\right) + \lg PC_{SC/V} \quad (1)$$

where R_{skin} is the skin resistance, P_{skin} is the skin permeability, d_{SC} is the thickness of the stratum corneum, D_{SC} is the diffusion coefficient in the stratum corneum, and $PC_{SC/V}$ is the partition coefficient between the stratum corneum and the vehicle.

Model 2—The viable epidermis alone is decisive

$$R_{skin} = \frac{1}{P_{skin}} = \frac{d_E}{D_E PC_{E/V}} \leftrightarrow P_{skin} = \frac{D_E PC_{E/V}}{d_E} \leftrightarrow \lg P_{skin} = \lg\left(\frac{D_E}{d_E}\right) + \lg PC_{E/V} \quad (2)$$

where d_E is the thickness of the rate-limiting layer in the viable epidermis, D_E is the diffusion coefficient in the viable epidermis, and $PC_{E/V}$ is the partition coefficient between the viable epidermis and the vehicle.

Model 3—Both the stratum corneum and the viable epidermis contribute to the skin resistance

10.1021/js990032o CCC: $18.00 *Published on Web 10/26/1999*

$$R_{skin} = \frac{1}{P_{skin}} = \frac{d_{SC}}{D_{SC} PC_{SC/V}} + \frac{d_E}{D_E PC_{E/V}} \Leftrightarrow$$

$$P_{skin} = \frac{D_{SC} D_E PC_{SC/V}}{d_{SC} D_E + d_E D_{SC} PC_{SC/E}} \quad (3)$$

$$\Leftrightarrow \lg P_{skin} = \lg(D_{SC} D_E) + \lg PC_{SC/V} - \lg(d_{SC} D_E + d_E D_{SC} PC_{SC/E}) \quad (4)$$

where $PC_{SC/E}$ is the partition coefficient between the stratum corneum and the viable epidermis, equal to $PC_{SC/V}/PC_{E/V}$.

The in vivo partition coefficients $PC_{SC/V}$, $PC_{E/V}$, and $PC_{SC/E}$ can be approached in vitro by partition coefficients with octanol (for the stratum corneum) and phosphate buffer (pH 7.4) (for the viable epidermis), respectively, in a linear regression equation according to Collander[17] (eqs 5−7)

$$\lg PC_{SC/V} = a \lg PC_{Oct/MO} + b \quad (5)$$

$$\lg PC_{E/V} = a' \lg PC_{PBS/MO} + b' \quad (6)$$

$$\lg PC_{SC/E} = a'' \lg PC_{Oct/PBS} + b'' \quad (7)$$

where $PC_{Oct/MO}$ is the partition coefficient between octanol and the vehicle light mineral oil, (for its determination see the Experimental Section), $PC_{PBS/MO}$ is the partition coefficient between phosphate buffer (pH 7.4) and light mineral oil, $PC_{Oct/PBS}$ is the partition coefficient between octanol and phosphate buffer (pH 7.4), a, a', a'' are regression coefficients according to Collander, and b, b', b'' are intercepts according to Collander.

From the substitution of the in vivo partition coefficients in the model eqs 1, 2, and 4 by the Collander terms in eqs 5−7, eqs 8−10 result.

$$\text{model 1: } \lg P_{skin} = \lg\left(\frac{D_{SC}}{d_{SC}}\right) + a \lg PC_{Oct/MO} + b \quad (8)$$

$$\text{model 2: } \lg P_{skin} = \lg\left(\frac{D_E}{d_E}\right) + a' \lg PC_{PBS/MO} + b' \quad (9)$$

$$\text{model 3: } \lg P_{skin} = \lg(D_{SC} D_E) + a \lg PC_{OCT/MO} + b - \lg(d_{SC} D_E + d_E D_{SC} PC_{Oct/PBS}{}^{a''} 10^{b''}) \quad (10)$$

Correlations of the experimentally determined skin permeabilities with the partition coefficients of eqs 8−10 give information about the importance of the resistances of the stratum corneum and the viable epidermis, respectively, for the transport of the NSAIDs through the skin. The diffusion coefficients of the NSAIDs in eqs 8−10, which are mainly dependent on the molecular size, represented by the molecular volume, are assumed to be equal. On the basis of the theory of the required volume for free diffusion, Cohen and Turnbull[18] derived an exponential relationship between the diffusion coefficient D and the molecular volume MV (eq 11)

$$D = D^0 e^{-\beta MV} \quad (11)$$

where D is the diffusion coefficient, D^0 is the diffusion coefficient of a hypothetical molecule with a molecular volume 0, β is the regression coefficient of the molecular volume, and MV is the molecular volume.

With the help of eq 11 the model equations for the models 1 and 2 (eqs 8 and 9) can be rewritten as eqs 12 and 13

$$\text{model 1: } \lg P_{skin} = \lg\left(\frac{D^0_{SC}}{d_{SC}}\right) - \frac{\beta_{SC}}{2.303} MV + a \lg PC_{Oct/MO} + b \quad (12)$$

$$\text{model 2: } \lg P_{skin} = \lg\left(\frac{D^0_E}{d_E}\right) - \frac{\beta_E}{2.303} MV + a' \lg PC_{PBS/MO} + b' \quad (13)$$

where β_{SC} and β_E are regression coefficients of the molecular volumes concerning the stratum corneum and the viable epidermis, respectively.

The contributions of the molecular volumes in eqs 12 and 13 can be determined by a multiple linear regression analysis.

Maximum Flux—The maximum flux J_{max} results from the multiplication of the skin permeability with the vehicle solubility (eq 14)

$$J_{max} = P_{skin} c_{sMO} \quad (14)$$

where J_{max} is the maximum flux, and c_{sMO} is the solubility in the vehicle light mineral oil.

After finding the logarithms for eq 14, $\lg J_{max}$ is the sum of the skin permeability term and the vehicle solubility term, which can again be evaluated by a multiple linear regression analysis with $\lg P_{skin}$ being expressed by the model eqs 8−10.

$$\lg J_{max} = \lg P_{skin} + \lg c_{sMO} \quad (15)$$

Experimental Section

Materials—The following NSAIDs were used: aspirin (Merck, Darmstadt, Germany), diclofenac free acid (Novartis, Basel, Switzerland), diflunisal (MSD, Rahway, NJ), flufenamic acid, ibuprofen (Sankyo, Pfaffenhofen, Germany), ketoprofen (Bayer, Leverkusen and Rhône Poulenc Rorer, Cologne, Germany), naproxen (PharmActiv, Feldkirchen-Westerham, Germany), nabumeton (SmithKline Beecham, Worthing, Great Britain), piroxicam (Pfizer, Karlsruhe, Germany), tenoxicam (Hoffmann-La Roche, Basel, Switzerland). Light mineral oil was a gift of Parafluid Mineralölgesellschaft, Hamburg, Germany.

Solubilities—For the determination of the solubilities of the NSAIDs in the vehicle light mineral oil an excess amount of substance was suspended in 25 mL of light mineral oil, and the suspension was moved in a water bath of 32 °C in rotating bottles (30 min^{-1}) for 24 h. The suspension was filtered through warmed cellulose acetate filters with 0.45 μm pore diameter (Sartorius, Göttingen, Germany) in a warmed flask. After the appropriate dilution, the concentrations of the saturated solutions were measured spectrophotometrically (DMR 10, Carl Zeiss, Oberkochen, Germany). The solubilities were calculated as the mean of three determinations with a standard deviation less than 10%.

Partition Coefficients—The partition coefficients between octanol (Oct) and the aqueous phase (W*) $PC_{Oct/W*}$, between light mineral oil (*MO*) and the aqueous phase W* $PC_{MO/W*}$, and between octanol and phosphate buffer (pH 7.4) $PC_{Oct/PBS}$ were determined after shaking at 32 °C and spectrophotometric measurement of the separated, clearly centrifuged phases (Varifuge, Heraeus, Osterode, Germany). W* stands for the aqueous phase containing the NSAIDs in the undissociated form, i.e., 0.1 M hydrochloric acid and citrate buffer (pH 3.6 for piroxicam and 3.2 for tenoxicam), ionic strength 0.1, containing citric acid and sodium hydroxide, respectively. *PBS* stands for phosphate buffer (pH 7.4), ionic strength 0.17, containing monobasic potassium phosphate and dibasic sodium phosphate. The experiments were performed as triplicate, and the standard deviations were generally less than 10%. The partition coefficients between octanol and the vehicle light mineral oil $PC_{Oct/MO}$ were calculated by dividing $PC_{Oct/W*}$ by $PC_{MO/W*}$.[19] The partition coefficients between phosphate buffer (pH 7.4) and light mineral oil $PC_{PBS/MO}$ were obtained from the quotients of $PC_{Oct/MO}$ and $PC_{Oct/PBS}$. The $PC_{Oct/W*}$ could be confirmed by R_{MW}-values obtained with TLC[4,20,21] and by calculation with

the fragmental constant system according to Rekker and Mannhold.[4,22,23] All partition coefficients mentioned above could be described by the corresponding solubility ratios[24,25] with a good correlation.[4]

Molecular Volumes—The molecular volumes of the NSAIDs were calculated from the incremental van der Waals volumes according to Bondi.[26,27]

In Vivo Studies—Twenty-four healthy volunteers, their ages ranging from 20 to 40, took part in the study, which was approved by the ethics committee of the University of Düsseldorf. Every volunteer gave written consent after detailed information. The skin penetration of the NSAIDs was investigated according to the statistical plan of a 4 × 4 × 2 Latin rectangle in three series with eight volunteers and diclofenac as reference drug in every series. Every volunteer could take four substances on his upper arms whose positions were varied systematically. Special glass chambers for the reception of the test solutions were fixed on every volunteer's upper arms with wire frames and elastic bandages, preventing leakage.[9,28] After conditioning with the vehicle light mineral oil for 2 h (renewed hourly) to elute most of the extractable material, the drug solutions with concentrations[4] between 0.45 and 126 mg·100 mL^{-1} were filled in the glass chambers over a time period of 7 or 8 h and exchanged by the original solutions every 1 to 2 h, respectively. The concentration depletion in the glass chambers varies between 2 and 33% per hour in the steady state, depending on the respective drug.[4] The solutions of the NSAIDs taken out of the glass chambers were diluted and their concentration decreases measured spectrophotometrically. The skin permeabilities were calculated as geometrical means from the last three or four data points of the steady-state phases,[9,28] which became apparent after 3 or 4 h, respectively (Figure 1).[4] Changes of the chamber volumes and UV-active material extracted from the skin were taken into account by correction factors.[4,28] The maximum fluxes were calculated from eq 14.

Statistical Calculations—A linear regression analysis was performed for the models 1 and 2 using Excel 8.0 (Microsoft Corporation, Redmond, WA) and PlotIt 3.0 (Scientific Programming Enterprises, Haslet, MI). The nonlinear regression analysis for model 3 and the multiple linear regression analyses of eqs 12, 13, and 15 were calculated with the statistical program SPSS 6.1.3 (SPSS, Inc., Chicago, IL).

Results

The molecular volumes MV, vehicle solubilities c_{sMO}, skin permeabilities P_{skin}, and maximum fluxes J_{max} of the investigated NSAIDs are shown in Table 1. The geometrical standard deviations s_g are also listed for the skin penetration data. Most of them amount up to ±60%, as already documented by Southwell et al.,[29] and partially exceed this range (ketoprofen, naproxen). The skin permeabilities were found to be log-normally distributed.[4,30–32] The logarithms of the skin permeabilities, maximum fluxes, $PC_{Oct/MO}$, $PC_{PBS/MO}$, $PC_{Oct/W*}$, and $PC_{Oct/PBS}$, all necessary for the correlations according to eqs 8–10, are arranged in Table 2.

Table 2. —Logarithms of the Partition Coefficients between Octanol and the Vehicle Light Mineral Oil $PC_{Oct/MO}$, between Phosphate Buffer (pH 7.4) and Light Mineral Oil $PC_{PBS/MO}$, between Octanol and Phosphate Buffer (pH 7.4) $PC_{Oct/PBS}$ and between Octanol and Water with the Drug in Its Undissociated Form $PC_{Oct/W*}$, Skin Permeabilities P_{skin} (in $cm \cdot h^{-1}$), and Maximum Fluxes J_{max} (in $\mu g \cdot cm^{-2} \cdot h^{-1}$) of the Investigated NSAIDs

NSAID	lg $PC_{Oct/MO}$	lg $PC_{PBS/MO}$	lg $PC_{Oct/PBS}$	lg $PC_{Oct/W*}$	lg P_{skin}	lg J_{max}
diclofenac	2.91	0.93	1.98	4.32	–1.87	–0.42
flufenamic acid	1.93	–0.22	2.15	4.67	–2.38	0.60
ibuprofen	1.15	–0.07	1.22	4.21	–2.34	2.07
ketoprofen	3.54	3.57	–0.03	3.35	–1.79	0.32

tenoxicam	1.67	2.51	–0.84	0.78	–1.14	–0.36
aspirin	3.96	5.94	–2.04	1.26	–0.96	0.53
diflunisal	3.36	2.78	0.58	4.24	–1.28	–0.05

Permeabilities—The results of the correlations according to the models 1–3 (eqs 8–10) are presented in eqs 16–18 and graphically shown in Figures 2–4:

model 1 (Figure 2, eq 8):

$$\lg P_{skin} = 0.28 \lg PC_{Oct/MO} - 2.37 \quad (16)$$
$$r = 0.615,\ s = 0.42,\ p_{slope} = 0.058,\ n = 10$$

model 2 (Figure 3, eq 9):

$$\lg P_{skin} = 0.19 \lg PC_{PBS/MO} - 2.05 \quad (17)$$
$$r = 0.856,\ s = 0.28,\ p_{slope} = 0.0016,\ n = 10$$

model 3 (Figure 4, eq 10):

$$\lg P_{skin} = 4.50 + 0.10 \lg PC_{Oct/MO} - \lg(5.40 \times 10^{-7} + 2.03 \times 10^{-3}(PC_{Oct/PBS})^{0.25}) \quad (18)$$
$$r = 0.876,\ s = 0.26,\ n = 10$$

(assumptions:

$$D_{SC} = 10^{-10}\ cm^2 \cdot s^{-1} \text{ and } D_E = 10^{-7}\ cm^2 \cdot s^{-1})^{4,9}$$

The insignificant influence of the molecular volumes on the diffusion coefficients is described by the results of the multiple linear regression analyses according to eqs 12 and 13, which are presented in eqs 19 and 20.

model 1 (eq 12):

$$\lg P_{skin} = -2.72 - 0.00154MV + 0.30 \lg PC_{Oct/MO} \quad (19)$$
$$r = 0.622,\ s = 0.45,\ n = 10$$

model 2 (eq 13):

$$\lg P_{skin} = -2.41 - 0.00177MV + 0.20 \lg PC_{PBS/MO} \quad (20)$$
$$r = 0.863,\ s = 0.29,\ n = 10$$

The contributions of the different molecular volumes (Table 1) to the skin permeabilities and the improvement of the correlation coefficients compared with eqs 16 and 17 are not statistically significant ($F = 0.0989$ and $F =$

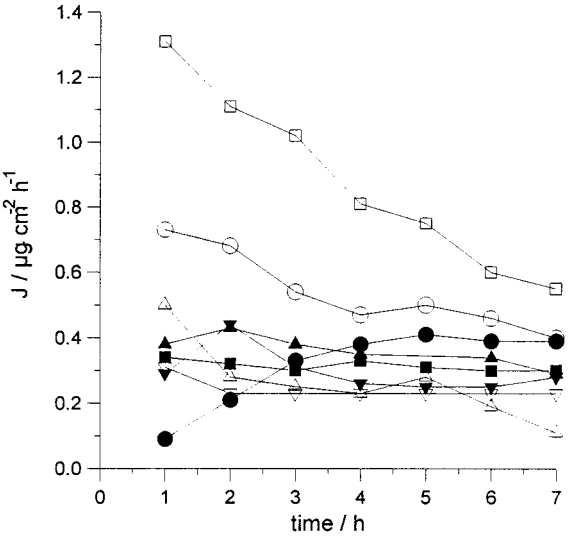

Figure 1—Penetration profiles of tenoxicam, vehicle light mineral oil, c = 0.45 mg·100 mL^{-1}, n = 8 volunteers.

0.330).[33] Thus, the diffusion coefficients of the investigated NSAIDs can be considered as constant.

Maximum Fluxes—According to eqs 15 and 16−18, the regression eqs 21−23 result for the maximum fluxes J_{max} (Table 2). In the equations of model 1 and 2 (eqs 21 and 22) the logarithms of the skin permeabilities have been substituted by eqs 16 and 17, respectively.

model 1 (eq 16, eq 15):

$$\lg J_{max} = 0.08 \lg PC_{Oct/MO} + 0.67 \lg c_{sMO} - 1.18 \quad (21)$$
$$r = 0.939,\ s = 0.29,\ n = 10$$

model 2 (eq 17, eq 15):

$$\lg J_{max} = 0.11 \lg PC_{PBS/MO} + 0.78 \lg c_{sMO} - 1.44 \quad (22)$$
$$r = 0.970,\ s = 0.21,\ n = 10$$

model 3 (eq 18, eq 15):

$$\lg J_{max} = 0.64 \lg P_{skin\ calcd} + 0.78 \lg c_{sMO} - 0.15 \quad (23)$$
$$r = 0.978,\ s = 0.18,\ n = 10$$

The regression coefficients of the vehicle solubilities c_{sMO} in all three models contribute most significantly ($p \ll 0.001$) to the regressions, while the significance of the regression coefficients of the partition coefficients and the calculated skin permeabilities $P_{skin\ calcd}$, respectively, increases from an insignificant ($p = 0.4849$, model 1) to a significant ($p = 0.0270$, model 2) and finally to a highly significant level ($p = 0.0085$, model 3).

Discussion

Permeabilities—As expected, the experimentally determined permeabilities P_{skin} generally decrease with increasing lipophilicity of the NSAIDs expressed as $PC_{Oct/W*}$ (Table 2). For example, aspirin and tenoxicam, the two drugs with the highest permeabilities (Table 1), show the lowest $PC_{Oct/W*}$ (Table 2). Vice versa, flufenamic acid and ibuprofen, the two drugs with the lowest permeabilities (Table 1), exhibit rather high $PC_{Oct/W*}$ values. However, assuming the stratum corneum as the decisive barrier, the respective regression equation relating the permeabilities to $PC_{Oct/MO}$ according to model 1 (Figure 2, eq 16) leads to an unsatisfactory correlation ($r = 0.615$). In contrast, Hagedorn-Leweke and Lippold[9] found a good correlation ($r = 0.949$) for the skin permeabilities of sunscreens and

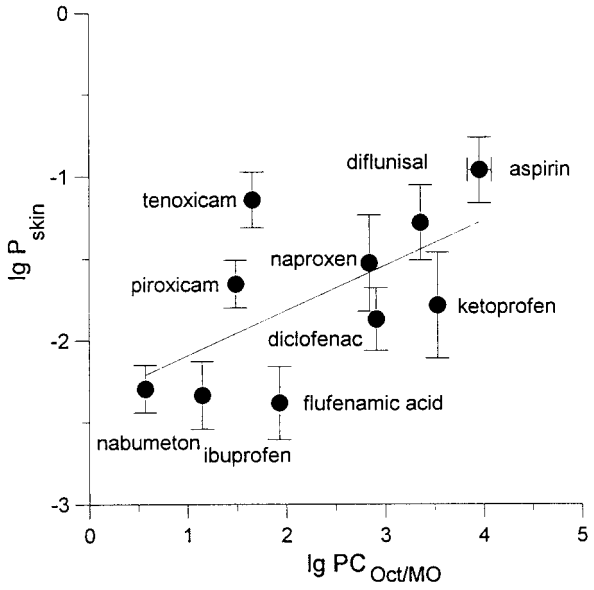

Figure 2—Correlation of the skin permeabilities P_{skin} (in cm·h^{-1}) with the partition coefficients between octanol and the vehicle light mineral oil $PC_{Oct/MO}$ according to model 1 (eq 16).

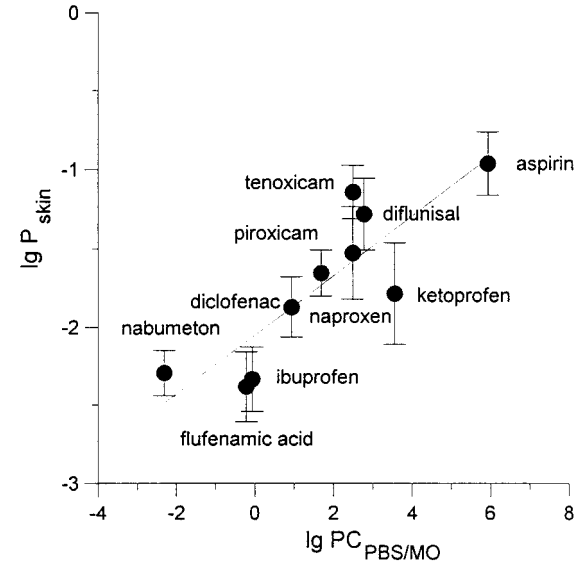

Figure 3—Correlation of the skin permeabilities P_{skin} (in cm·h^{-1}) with the partition coefficients between phosphate buffer (pH 7.4) and the vehicle light mineral oil $PC_{PBS/MO}$ according to model 2 (eq 17).

other compounds out of a propylene glycol−water mixture 30:70 (v/v) with the same study design using the partition coefficients between octanol and the hydrophilic vehicle $PC_{Oct/V}$ for the calculations in analogy to model 1 (eq 1). When using the lipophilic vehicle light mineral oil, the stratum corneum does not seem to represent the decisive resistance to the skin penetration of the NSAIDs. Considering the viable epidermis as the rate-limiting barrier to the drug transport (model 2), the correlation of the skin permeabilities with the respective partition coefficient between phosphate buffer (pH 7.4) and the vehicle light mineral oil $PC_{PBS/MO}$ clearly improves ($r = 0.856$, eq 17, Figure 3). A nonlinear regression analysis with $PC_{Oct/MO}$ and $PC_{Oct/PBS}$ (model 3) also leads to a very good correlation concerning the permeability data ($r = 0.876$, eq 18, Figure 4). The proportion between the resistances of the stratum corneum and the viable epidermis can be calculated from eqs 3 (overall resistance R_{skin} of stratum corneum and viable epidermis), 17 (estimate of the permeability of the

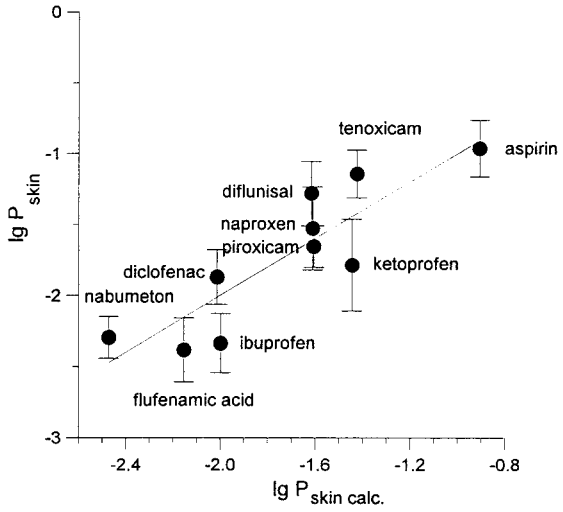

Figure 4—Correlation of the skin permeabilities P_{skin} (in cm·h^{-1}) with the skin permeabilities calculated from eq 18 $P_{skin\ calcd}$ (in cm·h^{-1}) according to model 3.

viable epidermis alone, equal to the reciprocal of its resistance), and 18 (overall permeability P_{skin} of stratum corneum and viable epidermis) and amounts to about 1:5. Thus, the viable epidermis seems to be the decisive barrier to the skin penetration of the NSAIDs out of the lipophilic vehicle light mineral oil.

Altogether, the skin permeabilities of the NSAIDs out of light mineral oil are determined by their hydrophilicity, which is under the assumption of the viable epidermis as the main barrier a function of the $PC_{PBS/MO}$. However, when using a hydrophilic vehicle, the permeabilities will primarily depend on the lipophilicity of the penetrating substances according to model 1.[8,9] This is in accordance with the observations documented by Blank[11−13] that the skin permeabilities of homologous alkanols decrease with their chain length out of lipophilic vehicles (isopropyl palmitate, mineral oil, olive oil) but increase out of hydrophilic vehicles (buffer solution, poly(ethylene glycol) 600).

Maximum Fluxes—The correlation coefficients of the maximum fluxes in eqs 21−23 are higher than those of the skin permeabilities in eqs 16−18, but they do not differentiate as clearly as those of the skin permeabilities between the three assumed models. Obviously, the maximum fluxes are more influenced by the vehicle solubilities c_{sMO}, which enclose about 4 orders of magnitude (Table 1), than by the partition coefficients. The regression coefficients of the vehicle solubilities in eqs 21−23 are highest significant, while the regression coefficients of the partition coefficients and the respective calculated skin permeabilities increase from insignificant to significant and finally to highly significant. Additionally, the latter are numerically lower than the regression coefficients of the vehicle solubilities. Thus, the maximum fluxes of the NSAIDs out of the lipophilic light mineral oil are primarily dependent on the vehicle solubilities. The increase of the significance levels of the regression coefficients of the skin permeabilities calculated from eqs 16−18 additionally confirms the importance of the viable epidermis as a barrier for the drug transport. Hagedorn-Leweke and Lippold[9] also found the decisive influence of the solubility of their investigated sunscreens in the hydrophilic vehicle on the measured maximum fluxes. Therefore, for the investigated cases, it can be concluded that the maximum flux is primarily dependent on the vehicle solubility and after that a function of the hydrophilicity or lipophilicity, expressed as octanol−vehicle partition coefficient, of the penetrating substances. For the development of cutaneous preparations, drugs with high vehicle solubilities can be recommended. In the case of a lipophilic vehicle, they should have a high partition coefficient between octanol and the vehicle and not a too high partition coefficient between octanol and phosphate buffer (pH 7.4) according to model 3.

The apparent diffusion distance of the NSAIDs out of the vehicle light mineral oil in the viable epidermis and dermis, that is, the thickness of the respective barrier d_E (eq 10) can be calculated from eq 18 (model 3) to about 2.6 mm. Obviously, real sink conditions in the skin can only be achieved beyond this distance. Singh and Roberts[1] found a direct penetration depth of about 3−4 mm from dermopharmacokinetic measurements with NSAIDs in vivo in rats. Therefore, a direct penetration of NSAIDs into deeper tissues and joints at high concentrations, as intended with the percutaneous treatment of relevant rheumatic diseases (see Introduction), does not seem to be realistic.

Conclusions

The viable epidermis, not the stratum corneum, is the rate-limiting barrier for the transport of NSAIDs out of a lipophilic vehicle. The skin permeability of NSAIDs is a function of the hydrophilicity of the drugs, i.e., of their partition coefficients between phosphate buffer (pH 7.4) and the lipophilic vehicle. However, the maximum flux of NSAIDs is primarily dependent on their vehicle solubility. For the development of cutaneous preparations, drugs with high vehicle solubilities and skin permeabilities as high as possible should be preferred.

Accepted for publication September 7, 1999.

Abstract □ Emulsification of mineral oil by phospholipids donated by liposomes composed of dimyristoyl phosphatidylcholine, dimyristoyl phosphatidylglycerol, cholesterol, and lipid A by extrusion resulted in the formation of oil-in-water liposomal emulsions containing a substantial number of intact liposomes. Increasing the proportion of liposomes from 25 mM to 150 mM phospholipid and increasing the oil content from 2.5% (v/v) to 42.5% (v/v) changed the flow characteristics of the emulsions from fluid liquidlike to viscous. Likewise, the degree of stability of the emulsions was liposomal phospholipid concentration-dependent, ranging from partial emulsification in the range 25–100 mM to complete stabilization in the range 125–150 mM. Despite some loss of liposome integrity, as evidenced by the release of liposomal trapped glucose, emulsification of liposomes containing encapsulated prostate-specific antigen (PSA) exhibited antigen-specific immunostimulation in mice. These results suggest that liposomes containing encapsulated antigen can serve as constituents for the formulation of oil-in-water vaccines.

Introduction

For many years, liposomes have been utilized as carriers of vaccines for inducing high titers of antibodies and for induction of cytotoxic T-lymphocytes.[1−4] The purpose of the present study was to examine the emulsifying characteristics of liposomes as constituents of oil-in-water emulsion adjuvants for vaccines. We and others have also previously reported that liposomes could be emulsified directly within incomplete Freund's adjuvant and other water-in-oil emulsions and that depending on the proportion of liposomes, such emulsification resulted in the formation of stable emulsions containing a large fraction of intact liposomes.[5,6] The liposomes that were destroyed by the emulsification process donated phospholipid molecules to assist the stabilizing properties of Span 80 and Arlacel A, respectively.[5,6] Thus, if liposomes containing encapsulated antigen were emulsified within Freund's adjuvant or any other water-in oil emulsion, at least some of the antigen would be released free into the emulsion and might thereby lose the beneficial immunostimulatory effects derived from encapsulation in liposomes. These observations raised the question whether the emulsification of oil by nondegraded liposomes in oil-in-water emulsions for vaccine design could be more difficult to achieve than with water-in-oil emulsions such as Freund's adjuvant because of more efficient donation of phospholipid molecules to effect droplet dispersion.

‡ Jenner Biotherapies.

The fact that liposomes can be emulsified directly by an oil emulsion such as incomplete Freund's adjuvant or any oil without being either completely degraded themselves or without degrading the emulsion itself is very appealing in adjuvant technology. The immunogenic power of emulsions is well-known, as they are extremely powerful for inducing antibodies to emulsified antigens.[7−10] However, although emulsions are not noted for inducing cytotoxic T-lymphocyte (CTL) responses,[7−10] liposomes are among the most potent carriers for inducing CTLs.[3,4] Therefore, if the properties of each were additive, formulations of liposomes with water-in-oil or oil-in-water emulsions could have potential for being versatile adjuvants.

The data reported herein demonstrate that emulsification of mineral oil by phospholipids donated by liposomes results in the formation of oil-in-water emulsions that still contain substantial amounts of intact liposomes. Furthermore, it is also shown that formulations of liposome-encapsulated antigen in the oil-in-water emulsions exhibited strong immunostimulating activity for induction of antibodies and an antigen-specific lymphoproliferative response in mice.

Materials and Methods

Lipids—Dimyristoyl phosphatidylcholine (DMPC), dimyristoyl phosphatidylglycerol (DMPG), cholesterol (CHOL), and lipid A (LA) were purchased from Avanti Polar Lipids (Alabaster, AL). The fluorescent phospholipid *N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)-1,2-dihexadecanoyl-*sn*-glycero-3-phosphoethanolamine, triethylammonium salt (N-NBD-PE) was purchased from Molecular Probes (Eugene, OR). LA was stored at −20 °C and dissolved in chloroform containing 10% methanol (v/v) before use. Solutions of phospholipids and CHOL were prepared in chloroform containing 0.75% ethanol (v/v) and stored at −20 °C until use. The phospholipid concentration in stock solutions, liposomes, and liposomal emulsions was determined by assaying aliquots for organic phosphorus by using the procedure of Bartlett[11] as modified by Gerlach and Deuticke.[12] Cholesterol content of stock solutions, liposomes, and liposomal emulsions was determined as described elsewhere.[13]

Emulsion Constituents—Materials used in emulsion preparations included light mineral oil (Sigma Chemical Co., St. Louis, MO) and liposomes containing or lacking PSA. Occasionally, trace amounts of N-NBD-PE-labeled liposomes were used in the formulation of emulsions to determine the presence of liposomal spherules.

Other Reagents—Chloroform was redistilled before use. After distillation, ethanol was added to chloroform as a preservative at 0.75% (v/v). Sodium deoxycholate from Sigma was purified by crystallization from hot acetone−water. All other reagents were reagent grade and were used without further purification.

Antigen—Protein-specific antigen (PSA) from donor human seminal fluid (M_r 30 000), which had been purified to a single gel band by extensive precipitation and column chromatography steps, including inhibition of protease activity, was purchased from Cortex Biochem, Inc. (San Leandro, CA). The antigen was exten-

10.1021/js990011u CCC: $18.00
Published on Web 10/21/1999

sively dialyzed against isotonic Tris-glycine (20 mM)/NaCl (150 mM) buffer, pH 7.4, and stored at 4 °C until use. Its purity was checked by sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) using 15% acrylamide gels and silver stain.[14] The results showed that the sample had one predominant band corresponding to the enzyme and two to three minor bands indicating degradation products.

The relative concentration of PSA was determined by the method of Lowry et al.[15] using bovine serum albumin as a standard. The amount of antigen encapsulated in liposomes was determined by using a modification of the Lowry protein assay.[16]

Animals—BALB/c mice were from Jackson Laboratory (Bar Harbor, ME). The animals were handled and housed according to a protocol approved by the Laboratory Animal Care and Use Committee of the Walter Reed Army Institute of Research. They were given standard laboratory food and water ad libitum.

Preparation of Liposomes—Liposomes (multilamellar vesicles) and liposome-encapsulated glucose or PSA were prepared essentially as described elsewhere.[6,16,17] Multilamellar liposomes were made from a mixture of DMPC/DMPG/CHOL in molar ratio of 9:1:7.5. LA was incorporated at a dose of 2.5 μg/μol of phospholipid. Fluorescent liposomes contained a phospholipid, N-NBD-PE, at 2 mol % with respect to the phospholipid concentration.

Preparation of Oil-in-water Liposomal Emulsions— Oil-in-water (o/w) liposomal emulsions were prepared by the stepwise addition method, as described elsewhere,[18] using two 3- or 5-mL B−D syringes connected by a three-way stopcock with rotating male Luer-lock adapter and a switch-key. The Luer-lock adapter (bore diameter = 0.10 cm) supported the 18 gauge needle for sample drawing. Liposomes containing or lacking PSA were added in a stepwise fashion and extruded backward and forward (2 passes/s) with light mineral oil under shear forces for 5 min. Liposomal emulsions (1−3 mL total volume) were also occasionally prepared by vortex-mixing at 2500 rpm for 5 min in 1.5 cm × 10 cm glass tubes. The amounts of liposomes and oil used were such that the final liposomal phospholipid concentration in the emulsions was in the range 25−150 mM and the oil concentration was varied from 2.5 to 42.5% (v/v). The quality of the emulsion was tested by placing a few drops of the sample on the surface of cold (iced) distilled water, as described by Freund.[19] A satisfactory o/w emulsion was produced if the drops lost their integrity by spreading on the surface of the water.

Measurement of Emulsion Viscosity—The viscosity of the emulsions was measured immediately after manufacture using the Cannon model LV 2000 rotational viscometer. The measurement temperature was controlled at 25 °C with a circulating water bath. The Cannon rotational viscometer operates on the principle of a spindle rotating while immersed in the material being tested and measuring the torque necessary to overcome the viscous resistance to rotation. From the spindle speed, torque measurements, and spindle characteristics, the viscometer calculates and displays the viscosity in centipoise (cP) or milliPascal sec (mPa·s). Using TL5 and TL7 spindles for less and more viscous emulsions, respectively, the shear rates were varied in the range 0.084−79.2 s^{-1}.

Emulsion Stability—Emulsion (1−3 mL) was poured from the syringe into 1.0 cm × 10 cm screw-cap glass tubes and incubated at 37 °C. This temperature was chosen for its physiological relevance to antigen stability in immunization studies. The stability of the emulsion was assessed by detection of phase separation with time. The height of the oil phase above the emulsion was measured using a ruler, and the results were expressed in % oil separated using the following formula:

$$\frac{\text{height of oil (upper phase)}}{\text{total height of emulsion sample} \times F}$$

where the factor F stands for the initial fraction of oil in the emulsion. The value of F was in the range 0.025−0.425. The smallest amount of separated oil that could be measured was ≤5%.

The rates of separation of the emulsions were expressed in % oil per minute as reported previously.[20,21] These rates were calculated from the slopes of the time of the percent of oil separated using the initial velocity data.

Liposome Stability—Liposome stability in the o/w emulsions was assayed spectrophotometrically by enzymatic assay of trapped glucose released, as previously described,[16] with the following modification. Normal saline (2 mL) was added to the emulsion (1 mL), and the mixture was vortexed for 2 min at 2000 rpm. Following centrifugation at 27 000 × g for 15 min at 25 °C, the oil phase was removed and the pellet was resuspended in the aqueous supernatant and glucose. As this procedure completely separated the oil from the water and lipids, all of the released glucose was detected in the liposomes resulting from resuspension of the pellet in the aqueous phase. This was confirmed in control experiments by demonstrating that the total amount of trapped glucose detected in emulsified liposomes was identical to the amount detected in the absence of an emulsion after disruption of the liposomes with chloroform and 10% Triton X-100.[16] Glucose release values of emulsified liposomes above 5% compared to baseline were judged to be positive.

The presence of liposomal spherules in the emulsion was determined by fluorescence microscopy using trace amounts of N-NBD-PE-labeled liposomes in the emulsion. A few drops of the sample were spread on a microscope slide immediately after manufacture and visualized by fluorescence with an Olympus (VANOX-S) microscope using an oil immersion 100× objective, or with an Olympus IX70 inverted microscope with a 40× objective. Images were collected with an Olympus camera and digitized from the 35-mm slides. The particle diameter of the emulsions was determined by measuring 50 emulsion droplets from photomicrographs prepared by fluorescence microscopy using oil immersion 100× objective.

Immunization Studies—BALB/c mice (five mice per group) were immunized intramuscularly (posterior thigh) with 100 μL of either liposome-encapsulated PSA (PSA-liposomes) or PSA-liposomes formulated in o/w emulsions. Each of these formulations contained 25 μg of antigen and 25 μg of LA per dose. Mice were bled by tail vein at 0, 2, and 5 weeks and the serum samples were analyzed for antibody titers by ELISA as described in detail elsewhere.[22]

For splenic T-lymphocyte proliferation studies, mice were euthanized by CO_2 followed by cervical dislocation and bleeding by cardiac puncture. The freshly removed spleens were placed in Hank's balanced salt solution [HBSS (Gibco Laboratories, Grand Island, NY)], and a single cell suspension was prepared. Following centrifugation, the cells were resuspended at 5 × 10^6 cells/mL in RPMI-1640 (Gibco Laboratories, Grand Island, NY):EHAA (Whittaker Bioproducts, Walkersville, MD) (1:1, v/v) supplemented with 8 mM L-glutamine, 100 units/mL pencillin, 100 μg/mL of streptomycin, 1 mM sodium pyruvate, 1X MEM nonessential amino acids, 100 μM 2-mercaptoethanol, and 0.5% BALB/c normal mouse serum. Subsequently, the cells were seeded at a density of 5 × 10^5 cells/well in 96-well fat-bottom tissue culture plates (Costar, Cambridge, MA) containing several dilutions of PSA in triplicate, in a total volume of 0.2 mL. Following 4 days of incubation at 37 °C in 5% CO_2 and 95% relative humidity, the cells were labeled with 1 μCi/well of [^{3}H]Thymidine [TdR, specific activity 6.7 Ci/mM (NEN, Boston, MA)]. The plates were then incubated overnight at 37 °C and the cell cultures harvested onto glass fiber filters with the Skatron cell harvester and processed for scintillation spectrometry. Radioactivity was quantified using the Pharmacia LKB liquid scintillation counter. Data were expressed in stimulation index, i.e., the ratio of counts from cells incubated with PSA over counts from the control.

Results

Rheological Properties of Liposomal Emulsions—The flow characteristics of liposomal emulsions were established using samples formulated with 42.5% (v/v) of mineral oil and liposomes containing different concentrations of phospholipid. Figure 1 shows that values of the viscosity increased slowly, but gradually with the lipid composition from 0.03 × 10^3 cP to 1.53 × 10^3 cP in the range 25−100 mM. Further increase of liposomal phospholipid concentration to from 125 mM to 150 mM resulted in an abrupt change of viscosity from the value of 7.80 × 10^3 cP to the value of 98.10 × 10^3 cP.

Figure 2 shows that with samples containing 50 mM and 100 mM liposomal phospholipid, values of the viscosity were very low and their increase with the oil concentration was negligible, with the change being from the mean of

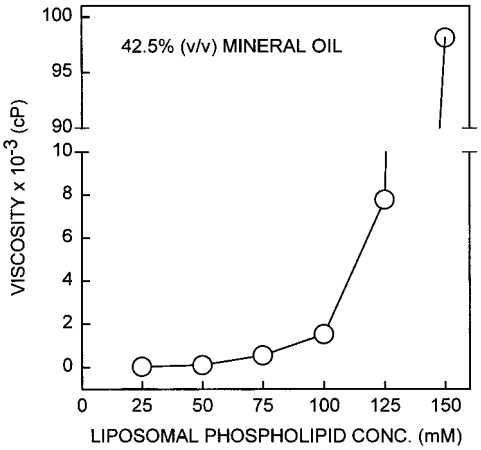

Figure 1—Viscosity characteristics of emulsions versus liposomal phospholipid concentration. The emulsions were formulated by extrusion with 42.5% (v/v) of mineral oil and liposomes containing different concentrations of phospholipid. The final liposomal phospholipid concentration used in the emulsions varied from 25 to 150 mM. Viscosity values were measured at 25 °C immediately after manufacture of the emulsions. The data were the mean of two to four determinations with a variability of ≤5%.

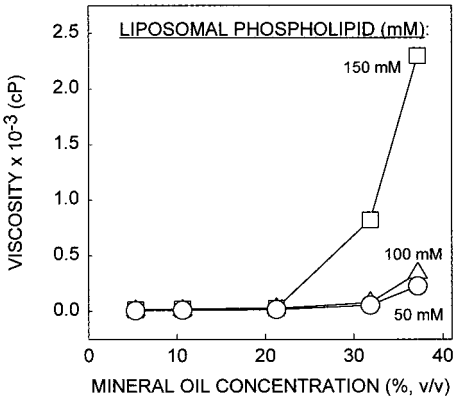

Figure 2—Viscosity characteristics of emulsions versus mineral oil concentration. The emulsions were formulated by extrusion with increasing amounts of oil in the range 5.3–37.5% (v/v) and liposomes containing different concentrations of phospholipid. The final liposomal phospholipid concentrations in the emulsions were 50 mM, 100 mM, and 150 mM as indicated in the figure. Viscosity values were measured at 25 °C immediately after manufacture of the emulsions. The data were the mean of two to four determinations with a variability of ≤5%.

0.01×10^3 cP to the mean of 0.23×10^3 cP in the range 5.3−37.5% (v/v). However, for samples formulated with 150 mM phospholipid, the viscosity which was also low at 0.02×10^3 cP did increase significantly with the oil concentration only beyond 21.3% (v/v) until it reached the value of 2.30×10^3 cP at 37.5% (v/v).

Stability Characteristics of Liposomal Emulsions—Emulsions containing 42.5% (v/v) of mineral oil and 25 mM to 150 mM of liposomal phospholipid were prepared by vortex-mixing at 2500 rpm and incubated at 37 °C. Figure 3 shows the time course of oil separated in percent of the total added, and Table 1 summarizes the rates of separation of the samples versus phospholipid concentration. Samples containing 25 mM and 50 mM liposomal phospholipid were rapidly destabilized with the percent oil separated increasing with time at rates of 1.434% and 1.184% separation per minute to complete separation after 1 and 5 h, respectively. Emulsions formulated with 100 mM and 125 mM phospholipid were slowly destabilized up to 48 h at rates of 0.003% and 0.002% separation per minute; they were thereafter destabilized rapidly to complete separation after 96 h. Interestingly, sample emulsion

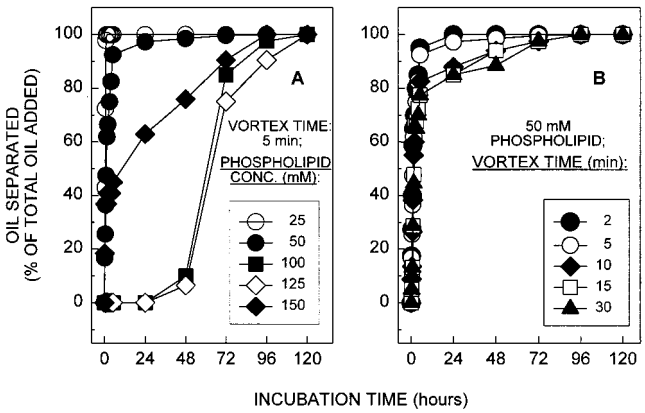

Figure 3—Time course of the degree of stability of emulsions formulated by vortex-mixing with 42.5% (v/v) of mineral oil and liposomes containing different concentrations of phospholipid. The final liposomal phospholipid concentration in the emulsions was varied from 25 mM to 150 mM as indicated. Emulsion samples were incubated at 37 °C, and their stability was assessed by detection of phase separation with time. The data were the means of two determinations with variability of ≤5%.

Table 1—Rates of Separation in % Oil Per Minute versus Phospholipid Concentration for o/w Liposomal Emulsions Prepared by Vortex-Mixing [a]

50	1.184
100	0.003
125	0.002
150	1.227

[a] Liposomal emulsions were prepared with 42.5% (v/v) of mineral oil and liposomes containing different concentrations of phospholipid. The resulting samples were incubated at 37 °C, and their stability was assessed by the appearance of phase separation with time. The rates of separation were calculated from the slopes of the time of the % of oil separated using initial velocity data.

containing 150 mM liposomal phospholipid was destabilized at a rate of 1.227% per minute to complete separation after 96 h, suggesting that at the higher phospholipid concentration used where the viscosity of the sample was substantially increased, vortex of the sample was inefficient to adequately promote mixing of the components. Thus, none of the emulsions formulated by vortex-mixing was stable.

Emulsions prepared by syringe extrusion containing 42.5% (v/v) of mineral oil and 25 mM to 150 mM liposomal phospholipid were incubated at 37 °C and examined for the appearance of phase separation. Figure 4 illustrates the gross physical appearance of these emulsions following a 72-h incubation period, while Figure 5 depicts the phospholipid dose dependence of their degree of stability for the same time period. The degree of stability of the dispersions ranged from complete separation at lower phospholipid concentrations, i.e., 25 mM and 50 mM (Figure 4A,B and Figure 5), to complete stabilization at higher phospholipid content, i.e., 125 mM and 150 mM (Figure 4E,F and Figure 5). However, while the sample formulated with 75 mM liposomal phospholipid was near complete separation with 87.5% of the oil becoming separated (Figure 4C and Figure 5), the dispersions containing 100 mM phospholipid were relatively stable with only 5% of the oil being separated (Figure 4D and Figure 5).

Figure 6 shows the time course of oil separated in percent of the total added following incubation at 37 °C of emulsion samples formulated with liposomes lacking (Figure 6A) or containing PSA (Figure 6B), and Table 2 summarizes the

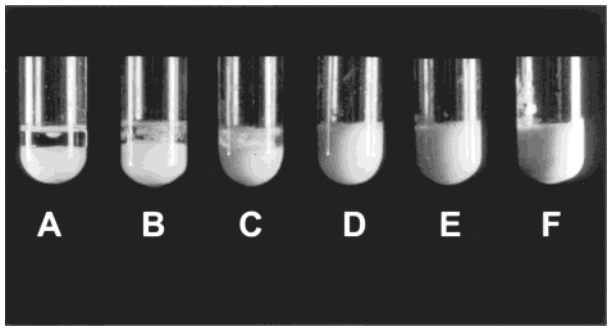

Figure 4—Gross physical appearance of emulsions formulated by extrusion with 42.5% (v/v) of mineral oil and liposomes containing different concentrations of phospholipid, following 72 h of incubation at 37 °C. The final liposomal phospholipid concentrations in the emulsions were (A) 25, (B) 50, (C) 75, (D) 100, (E) 125, and (F) 150 mM. Phase separation was evidenced by the development of two phases: a clear oil phase at the top and a milky aqueous phase containing liposomes at the bottom.

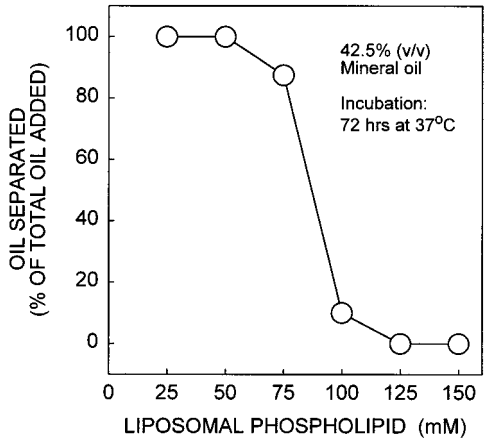

Figure 5—Phospholipid concentration dependence of the degree of stability of liposomal emulsions following 72 h of incubation at 37 °C. The emulsions were formulated by extrusion with 42.5% (v/v) of mineral oil and liposomes containing different concentrations of phospholipid. The final liposomal phospholipid concentration used in the emulsions varied from 25 to 150 mM. Stability of the emulsions was assessed by detection of phase separation.

rates of separation of the samples versus lipid composition. These rates were calculated from the slopes of the time of the percent of oil separated using the initial velocity data plotted in Figure 6A,B. Samples containing 25 mM and 50 mM liposomal phospholipid were rapidly destabilized with the percent of oil separated increasing with time (Figure 6A,B). For emulsions formulated with liposomes lacking PSA (Figure 5A), phase separation occurred at rates of 1.322% and 0.381% per minute (Table 2) to complete separation after 12 and 48 h, respectively (Figure 6A). Emulsions formulated with PSA-liposomes (Figure 6B) were destabilized more rapidly at rates of 1.895% and 0.919% per minute (Table 2) to complete separation after 2 and 24 h, respectively (Figure 6B). For the emulsions formulated with liposomes lacking (Figure 6A) or containing PSA (Figure 6B) at 75 mM phospholipid, the percent of oil separated increased gradually and almost linearly with time (Figure 6A,B), at rates of 0.012% and 0.045% per minute, respectively (Table 2), to complete separation after 96 h (Figure 6A,B). Furthermore, the samples prepared with liposomes lacking (Figure 5A) or containing PSA (Figure 6B) at 100 mM phospholipid were stable up to 72 and 24 h of incubation, respectively, after which they became destabilized toward 5% and 39% of oil separated at 120 h at rates of 0.001% and 0.003% per minute,

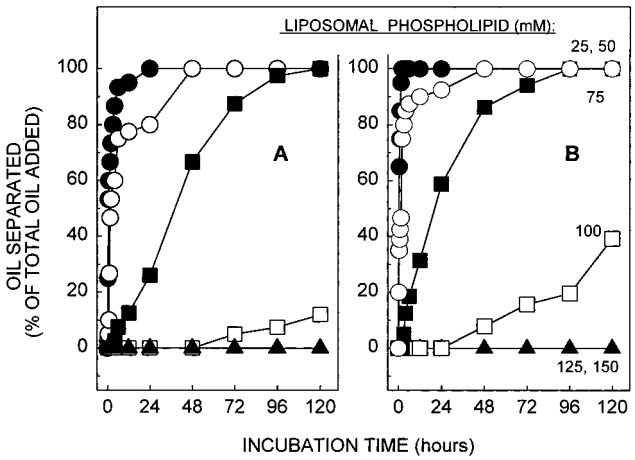

Figure 6—Time course of the degree of stability of emulsions formulated by extrusion with 42.5% (v/v) of mineral oil and empty liposomes (Figure 6A) or PSA-liposomes (Figure 6B), containing different concentrations of phospholipid. The final liposomal phospholipid concentration used in the emulsions varied from 25 to 150 mM as indicated in the figure. Emulsion samples formulated with PSA-liposomes contained 6.5 μg PSA per 100 μL. The samples were incubated at 37 °C, and their degree of stability was assessed by detection of phase separation with time. The data were the mean of two to three determinations with a variability of $\leq$8%.

Table 2—Rates of Separation in % Oil Per Minute versus Phospholipid Concentration for o/w Liposomal Emulsions[a]

liposomal phospholipid concentration in o/w emulsions (mM)	rate of separation (in % oil per min) of emulsions formualted with	
	empty liposomes	PSA-liposomes
25	1.322	1.895
50	0.381	0.919
75	0.012	0.045
100	0.001	0.003
125	0.000	0.000
150	0.000	0.000

[a] Liposomal emulsions were formulated with 42.5% (v/v) of mineral oil and empty liposomes or PSA-liposomes containing different concentrations of phospholipid. Emulsion samples formulated with PSA-liposomes contained 6.5 μg PSA/100 μL. The samples were incubated at 37 °C, and their stability was assessed by the appearance of phase separation with time. The rates of separation were calculated from the slopes of the time of the % of oil separated using initial velocity data.

respectively. However, emulsions formulated with 125 mM and 150 mM liposomal phospholipid were stable over the 120-h incubation period regardless of the lack or addition of PSA.

Effect of Mineral Oil Concentration on the Stability of the Emulsions—The oil concentration dependence of the degree of stability of the dispersions was established using emulsion samples containing various amounts of mineral oil and 25−150 mM liposomal phospholipid. Figure 7 shows that samples containing 25 mM and 50 mM liposomal phospholipid were unstable regardless of the oil concentration and the incubation time, with 91−100% of the oil becoming separated following 6 to 72 h of incubation at 37 °C. For emulsions formulated with 75 mM liposomal phospholipid, the percent oil separated increased with time and was inversely proportional to mineral oil concentration, until it reached the plateau of 88% after 72 h over the range 10−42.5% (v/v) of oil. The 100 mM-liposomal phospholipid sample was stable at all mineral oil concentrations following 6 and 24 h of incubation, but was relatively stable after 72 h, with only 5−15% of the oil being separated over the range 5−42.5% (v/v) of oil. However, samples containing 125 mM and 150 mM liposomal phospholipid were stable up to 72 h regardless of the oil content.

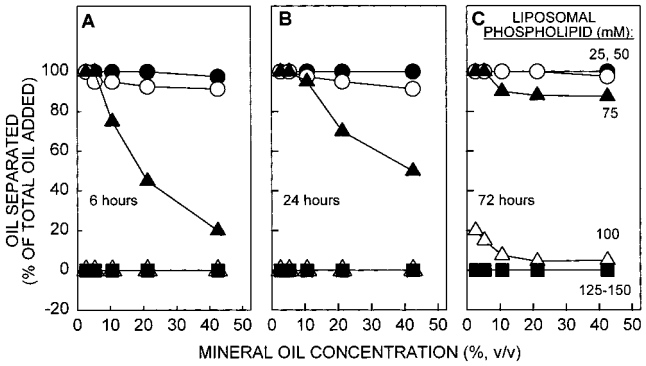

Figure 7—Mineral oil concentration dependence of the stability of liposomal emulsions. The emulsions were formulated by extrusion with increasing amounts of mineral oil in the range 2.5–42.5% (v/v) and liposomes containing different concentrations of phospholipid. The final liposomal phospholipid concentration in the emulsions was varied from 25 to 150 mM as indicated in the figure. The samples were incubated at 37 °C, and their stability was assessed by detection of phase separation following 6, 24, and 72 h of incubation. The data were the mean of two determinations with a variability of ≤5%.

Appearance of Fluorescent Liposomes in Emulsions—Fluorescent liposomes that were nearly spherical in shape were easily observed surrounding the surface of oil droplets in the emulsions (Figure 8B–D). Figure 8A shows, as a control experiment, the photomicrograph of fluorescent, nonemulsified liposomes.

Stability of Liposomes As Determined by Release of Trapped Glucose—In the previous experiment with N-NBD-PE, liposome-like structures appeared to be present in the emulsions (Figure 8B–D), but the experiment could not determine whether intact liposomes remained that retained their permeability properties. Figure 9A shows that release of liposomal trapped glucose, measured immediately after manufacture of the emulsions, increased gradually with the liposomal phospholipid concentration from 16% to 43% in the range 25–125 mM. Furthermore, Figure 9B depicts the shelf life characteristics of the liposomes formulated in the emulsions at selected lipid compositions following incubation at 37 °C. The increase of release of trapped glucose with time was not substantial irrespective of the phospholipid composition, with the average increase being in the range 5.5–7% over the 20-day incubation period.

Antibody Response to PSA Encapsulated in Emulsified and Nonemulsified Liposomes—PSA-liposomes formulated in emulsions were tested for their ability to induce antibodies to PSA. Figure 10 shows that immunization of mice with the unencapsulated PSA formulation did not induce antibodies to PSA over a period of 5 weeks. In contrast, the use of liposome-encapsulated PSA resulted in a level of serum IgG that increased gradually over 5 weeks to reach a final concentration of approximately 120 μg/mL. When mice were immunized with the liposomal emulsion formulations, the serum IgG titers were in the range 35–137 μg/mL depending on the phospholipid composition at 5 weeks (Figure 10). It is clear that the liposomes in the emulsion retained their potent activities as carriers of antigen.

Proliferative Response of Splenic T-Lymphocytes—The ability of PSA to induce splenic T-lymphocyte proliferation in vitro was investigated by immunizing mice with unencapsulated PSA, liposome-encapsulated PSA, and PSA-liposomes formulated in the emulsion containing 150 mM phospholipid. Figure 11 shows the PSA concentration dependence of stimulation index in vitro. There was no

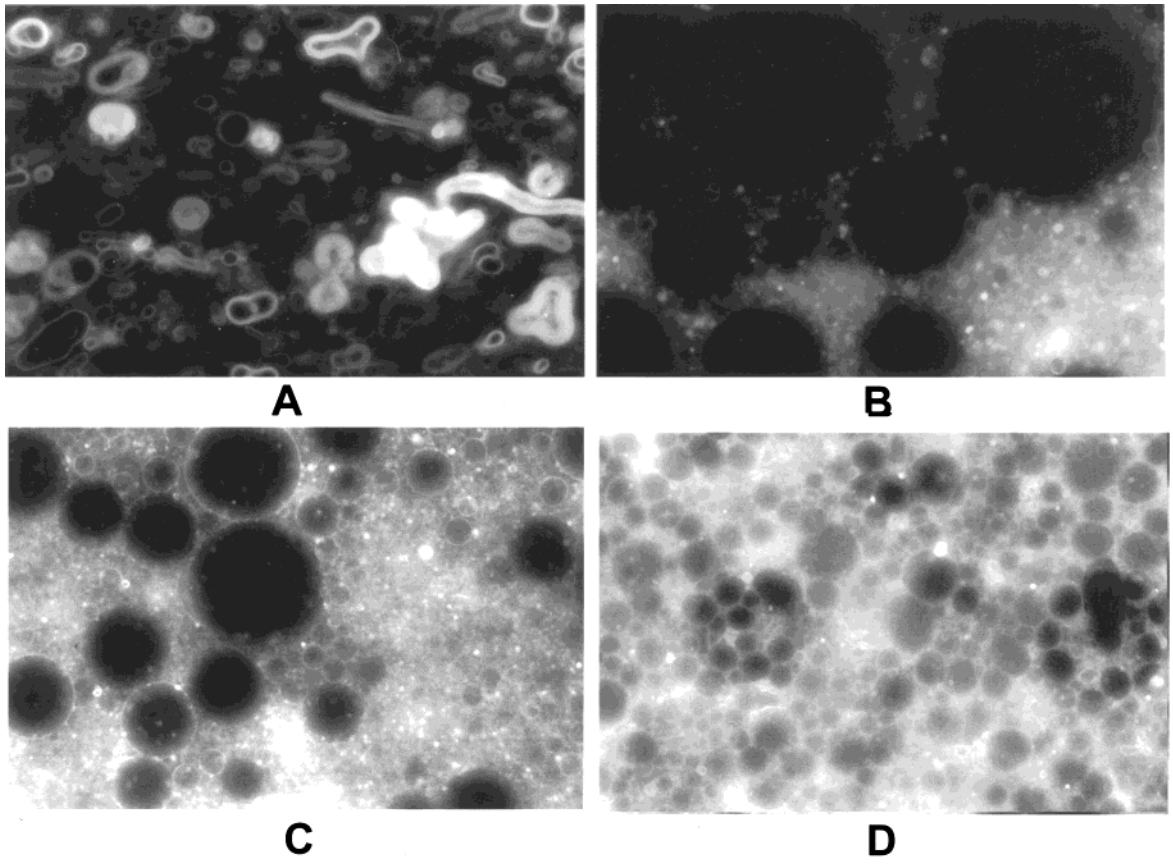

Figure 8—Photomicrographs of nonemulsified fluorescent liposomes (Figure 8A), and emulsions (Figure 8B–D) formulated with 42.5% (v/v) of mineral oil and liposomes containing trace amounts of N–NBD-PE. The final liposomal phospholipid concentrations in the emulsions were 25 (Figure 8B), 50 (Figure 8C), and 125 mM (Figure 8D). Fluorescent microscopy was performed immediately after manufacture of the samples.

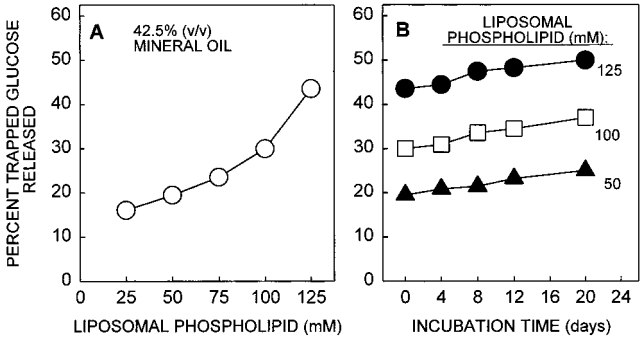

Figure 9—Phospholipid concentration (Figure 9A) and time (Figure 9B) dependencies of the stability of liposomes within the emulsions as determined by measurement of release of liposomal trapped glucose. The emulsions were formulated with 42.5% of mineral oil and liposomes containing different amounts of phospholipid. The final liposomal phospholipid concentration in the emulsions was varied from 25 to 125 mM. Liposomal trapped glucose released was determined immediately after manufacture (Figure 8A) and following incubation of the samples at 37 °C up to 20 days (Figure 8B). The data were the mean of 2 determinations with a variability of ≤5%.

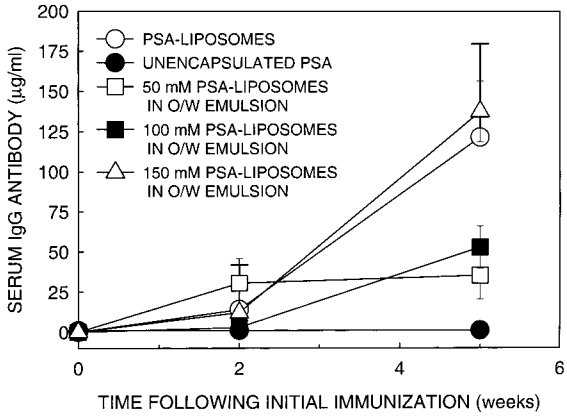

Figure 10—Antibody response to PSA; PSA was encapsulated in emulsified and nonemulsified liposomes. BALB/c mice (n = 5) were immunized intramuscularly with the indicated formulations each of which contained 25 μg of antigen and 25 μg of LA per dose. The final liposomal phospholipid concentrations in the emulsions were 50 mM, 100 mM, and 150 mM as indicated in the figure. Sera were collected at weeks 0, 2, and 5, and analyzed for antigen-specific antibodies by ELISA.

splenic T-cell proliferation when mice were immunized with the unencapsulated PSA formulation. Stimulation index values were low and remained close to 1.0 with increasing PSA concentration (Figure 11). However, when mice were immunized with liposome-encapsulated PSA and emulsified PSA-liposomes, stimulation index values increased gradually for both formulations in a PSA concentration-dependent manner toward 4.1 and 5.7, respectively. Stimulation index data obtained with the liposomal emulsion were slightly higher than those obtained with liposomes themselves (Figure 11), but the relative differences observed were not statistically significant. No proliferation occurred in a set of in vitro control experiments using ovalbumin instead of PSA (data not shown).

Discussion

This work is part of a larger effort to develop a variety of liposome-based adjuvant and carrier combinations for vaccines. It describes an approach for the creation of practical emulsified oil-in-water liposomal vaccines. The important factors for formulation were the degree of stability of the emulsions, the integrity of the liposomes

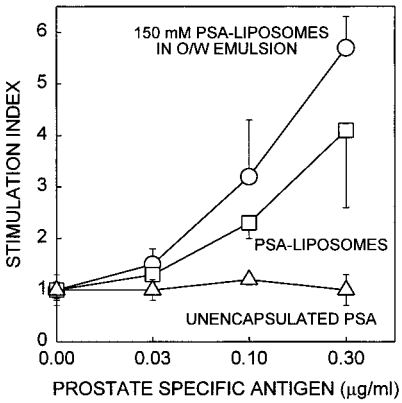

Figure 11—Lymphocyte proliferation response to PSA; PSA was encapsulated in emulsified and nonemulsified liposomes. BALB/c mice (n = 5) were immunized intramuscularly with the indicated formulations which each contained 25 μg of antigen and 25 μg of LA per dose. The final liposomal phospholipid concentration in the emulsion was 150 mM as indicated in the figure. Spleens were removed from mice at week 5 and processed for T-lymphocyte proliferation as described in the material and methods section. Data were expressed in stimulation index, i.e., the ratio of counts from cells incubated with PSA over counts from nonstimulated cells. Nonstimulated cells had about 190 to 250 counts per minute.

within the emulsion, and the ability of emulsified liposome-encapsulated antigen to exhibit immunostimulating activity.

The results show that the physicochemical properties, including viscosity and stability, of the emulsions changed with the liposomal phospholipid concentrations. At lower concentrations, over the range 25−100 mM, the emulsions were less viscous or fluid-liquidlike (Figure 1) and had different degrees of stability, ranging from complete to partial destabilization (Figures 4, 5, and 6A). Conversely, at higher concentrations, over the range 125−150 mM, they were viscous (Figure 1) and stable (Figures 4, 5, and 6A). Because rheological properties can affect the flow of emulsions through a needle or a catheter, the stable and viscous emulsions were so thickened that they could not be easily handled. This simply calls for formulation of emulsions of low viscosity for ease of injection. Our data showed that stable emulsions of low viscosity could be formulated over the range 125−150 mM liposomal phospholipid by lowering the oil concentration up to 2.5% (v/v) (Figures 2 and 7).

The rates of separation of the unstable emulsions which were inversely proportional to phospholipid concentration, were much higher with emulsified PSA-liposomes (Figure 6 and Table 2), probably due to perturbation of the bulk phase as well as the interfacial region brought about by released PSA from liposomes. Proteins are well-known to induce long-range electrostatic forces as well as variations in several physicochemical parameters, including surface potential and surface viscosity.[23] Thus, PSA could behave like a detergent displacing phospholipid molecules from the surface of oil droplets, thereby increasing the van der Waals attractive forces in the medium.

Fluorescence studies showed that the emulsions retained liposomal structures (Figure 8), but the integrity of liposomes within the emulsion was not maintained completely intact, as shown by the release of as much as 16% to 43% of the trapped marker with increasing lipid composition (Figure 9A). As suggested by the shelf life characteristics of liposomes within the emulsions (Figure 9B), no substantial leakage of intact liposomes occurred during incubation. Thus, the partial degradation of liposomes in the emulsions was not due directly to interaction or collision of liposomes with the oil droplets, but solely due to shear forces of the extrusion process involved in the manufacture of the dispersions. This conclusion is also supported by the

observation that no substantial degradation of liposomes occurred when, in control experiments, the emulsion samples were prepared by vortex-mixing. As expected, none of the latter emulsions was stable regardless of the liposomal phospholipid concentration (Figure 3). However, its possible that the slight increase in the release of glucose with time (Figure 9B) could be due to diffusion from the remaining intact liposomes. Alternatively, the glucose could be released by Brownian motion induced collision of oil droplets with intact liposomes resulting in the destruction of the liposomes.

The partial degradation of liposomes in the emulsions (Figure 9A) donated phospholipid molecules that provided partial or complete emulsification of the oil. Phospholipids, which form the bulk phase of liposomes, have been classically viewed as being particularly effective as emulsifiers for oil-in-water emulsions.[24] The photomicrographs shown in Figure 8 support the view that emulsification of liposomes with the oil was more effective with increasing the proportion of liposomes, with subsequent reduction of the size of the oil drops. The mean values of the particle diameters of the emulsion containing 25, 50, and 125 mM phospholipid were 12.5, 2.5, and 0.625 μm, respectively. These values were obtained by measurement of the oil droplets. The tiny continuous dots coating the oil droplets could be part of the phospholipid monomolecular layers at the interface which have been reported to impart a significant steric stabilization to the emulsion droplets.[25,26] The protective effect of phospholipid monolayers against coalescence and coagulation would be quite analogous to the reported repulsive forces arising from purely osmotic and finite-volume restricting effects of compressed coils of polymer-covered surfaces.[27,28]

The integrity of liposomes is a critical aspect of the vaccine formulation because, as demonstrated by some reports,[29−31] ingested liposomes provide intracellular targeting in phagocytic cells, with distribution of the liposomal antigen both to the cytoplasm and Golgi apparatus via the major histocompatibility (MHC) class I antigen presentation pathway and to low pH compartments. Despite the partial degradation of liposomes in the emulsions, the data showed that both PSA-liposomes formulated in emulsions and nonemulsified PSA-liposomes exhibited a comparable immunostimulating activity with regard to induction of not only antibody titers (Figure 10), but also antigen-specific lymphoproliferative responses (Figure 11) in mice. The relative differences observed in both responses were not statistically significant. Although the three liposomal emulsion formulations tested, which were administered to mice immediately after manufacture, had different degrees of stability in vitro, they exhibited comparable immunogenic properties in vivo (Figure 11). Similar results were reported on the adjuvant activity of o/w emulsions stabilized by a combination of Tween 80/Span 80 surfactants and for which the degree of stability did not affect antibody response as long as an emulsion was formed; stable emulsions were as effective as unstable ones.[32] Moreover, experiments are currently underway to examine the influence, if any, of the degree of stability of o/w liposomal emulsions on their immunogenic properties.

Overall, the data presented in this work show that emulsification of liposomes with mineral oil resulted in the formation of o/w liposomal emulsions containing a substantial number of intact liposomes that could still exhibit some immunostimulating activity in mice. These results are very encouraging for examining further biochemical and immunogenic properties of the emulsified o/w liposomal formulation and its extension to other vaccines. Further experiments will address the effect of oil concentration, the nature of the antigen, and the integrity of the liposomes as well as the degree of stability of the emulsion on the quality of the immune response generated by these formulations. Because oil emulsions induce predominantly humoral immunity[7−10] through their capacity to concentrate and orient antigens on oil droplets for effective delivery to cells of the immune system,[33,34] and liposomes are known as the best carriers for cell-mediated immune responses[3,4] through the MHC class I pathway,[29−31] combination of both mechanisms in a single vaccine could lead to a synergistic adjuvant effect.[35,36] The PSA-liposomal vaccine formulated in the emulsion has exhibited the highest immunostimmulating activity for induction of antibody titers and antigen-specific lymphoproliferative response in current clinical trials of prostate cancer patients (unpublished data).

Abstract □ Studies on transcellular transport across epithelial cell layers are performed mostly by discontinuous sampling of the transported compound. This has several drawbacks, e.g., it gives disturbances in volume, it limits the time-resolution, and is often laborious. In this report we introduce a method to measure transepithelial transport of fluorescent compounds continuously. The time-resolution is at the (sub)minute scale, allowing the measurement of the change in transport rate before and after transport modulation. We will describe how we used the method to measure transcellular and paracellular transport. For highly membrane-impermeable compounds, the paracellular transport and the regulation of the tight junctions was studied in wild-type and MDR1 cDNA transfected epithelial canine kidney cells (MDCKII). The effect of the multidrug transporter P-glycoprotein (Pgp) on the transepithelial transport was studied. Addition of the Pgp inhibitor SDZ PSC 833 showed a modulation of the idarubicin (IDA) and daunorubicin (DNR) transport, which was larger during transport from the basolateral to the apical side than in the reverse direction. By modeling the transepithelial transport, we found that in these cells Pgp had more effect on the basolateral to apical transport than vice versa, which can be attributed to a relatively large passive permeation coefficient for the cellular basolateral plasma membrane.

Introduction

Compartmentalization is important for multicellular organisms' functioning, so that the different biochemical tasks necessary for life are performed in the proper place under the proper conditions. The barriers between such compartments are often such that only regulated biochemical transport and communication can take place between the different compartments. Examples of such barriers are the epithelial cells in the gut and the endothelial cells of the blood−brain barrier.[1−4] Characteristic for these cell layers is that a-specific transport can hardly take place, due to the architecture of these layers. Tight junctions connect neighboring cells firmly to each other and hardly leave any (paracellular) space between the cells. Thereby a barrier is created with high transepithelial electrical resistance (TER) that is highly impermeable for most hydrophilic compounds.[5−8] Specific transporters and carriers regulate the transport of this class of compounds across these barriers.[6,8] For lipophilic compounds, which are able to passively diffuse across the cellular plasma membrane, epithelia and endothelia are often equipped with specialized proteins that regulate the transcellular transport (through the cells) of this class of compounds. An important example of such a transporter is P-glycoprotein (Pgp)[9−11] which functions as an ATP-dependent multispecific cellular drug efflux pump. Pgp was discovered as a transmembrane protein that induced cellular multidrug resistance (MDR),[11] i.e., resistance against several different anticancer drugs, e.g., daunorubicin (DNR), vincristine, taxol. However, not only are some anticancer drugs substrates, but many other types of compounds also interact with Pgp, e.g., cardiac drugs (verapamil, diltiazem), immunosuppressors (cyclosporins) and anti-AIDS drugs.[12,13] Epithelia and endothelia, with MDR1 Pgp localized in their apical plasma membrane, are found at several strategic sites in the body. Examples of such sites are the endothelial cells of the blood−brain and the blood−testes barrier and the epithelial cells lining the gut, where Pgp mediates drug transport out of the brain, the testes, and the body, respectively.[13−16]

Much knowledge on transepithelial transport has come from in vivo studies. However, ethical constraints limit the type of experiments that can be conducted in vivo. Also, because of the complexity of the multicellular organisms, it is often difficult to pinpoint which phenomena are related to specific molecular processes. In vitro models simulate the in vivo situation and do not have these drawbacks. Until now transepithelial transport has been measured discontinuously in time, mainly by measuring either the amount of substrate (mostly radioactively labeled, or fluorescent) transported from the apical to the basolateral (A to B) side of the cells (or vice versa) or by measuring the TER.[17−20] By combining knowledge of the study of MDR,[21,22] the use of fluorescence for detection, and the experience in developing in vitro techniques,[23,24] we developed a technique that can be used to study transepithelial transport continuously. The method makes use of commercially available plasticware and a fluorometer, equipment present in most biochemical laboratories. The method detects the transport of fluorescent substrates on-line, it has a high time-resolution, and effects of transport modulators can be studied within one experiment, thereby reducing the number of parameters that may give rise to errors.

With the method we successfully studied transepithelial transport in several different cell lines (Caco-2, LLC-PK1, and MDCKII). Here we describe how the technique is performed, and we report results obtained with the epithelial Madin−Darby canine kidney cell line MDCKII. We applied the method to carry out two types of experiments: (1) experiments in which the regulation of the tight junction is studied and (2) experiments in which the control of Pgp on the transepithelial transport is studied. Using a 70 kDa plasma membrane-impermeable fluorescein isothiocyanate-

labeled dextran (FITC-dextran) or the highly negatively charged organic anion calcein (Cal), the paracellular transport (through the space between the cells) was studied, both in the wild-type MDCKII cells and the MDR1 cDNA transfected MDCKII-MDR1 cells. The influence of Pgp on the transcellular transport (involving the plasma membrane) was studied in the MDCKII-MDR1 using the membrane-permeable, fluorescent anticancer drugs daunorubicin (DNR) and idarubicin (IDA). While highly similar in chemical structure, these anthracyclines differ in their lipophilicity and membrane permeability, with IDA being more lipophilic than DNR. For both DNR and IDA, the transport from the basolateral to the apical (B to A) compartment and vice versa (A to B) and the effect of Pgp inhibition were studied. A drug transport model was developed to explain the differences in kinetics that were observed.

Experimental Section

Chemicals—Verapamil (Vp), diltiazem (Dil), calcein (Cal), fluorescein isothiocyanate labeled dextran (FITC-dextran) (MW = 70 kDa), 2-deoxy-D-glucose (deoxyglucose), and digitonin were obtained from Sigma (St. Louis, MO). DNR and IDA were from Farmitalia Carlo Erba (Brussels, Belgium). SDZ PSC 833 was obtained from Novartis (Basel, Switzerland). Cell culture media and supplements were obtained from Flow (Irvine, UK), and culture plastics from Nunc (Roskilde, Denmark). Fetal calf serum (FCS) was from Gibco (Paisley, UK), 4-(2-hydroxyethyl)-1-piperazine ethanesulfonic acid (HEPES) was from Serva (Heidelberg, Germany), and sodium azide (NaN_3) and ethylenediaminetetraacetic acid (EDTA) were from Baker Chemicals (Deventer, The Netherlands). Sodium penicillin G was from Yamanouchi (Leiderdorp, The Netherlands), and streptomycin sulfate was from Radiumfarma-Fisiopharma (Italy). Microporous polycarbonate membrane inserts (transwell No. 3413) with a pore size of 0.4 μm and a diameter of 6.5 mm were from Corning Costar (Badhoevedorp, The Netherlands). Plastic fluorescence cuvettes were from Falcon (Leiden, The Netherlands).

Cell Culture and Media—MDCKII cells, wild-type and MDR1 cDNA transfected (MDCKII-MDR1),[25] were obtained from Drs. Evers and Borst (NKI, The Netherlands) and cultured as previously described.[18] Cells were cultured in a cell incubator in humidified air (supplemented with 5% CO_2) at 37 °C, in DMEM with 20 mM HEPES (pH 7.4), supplemented with 7.5% heat-inactivated FCS, and penicillin (0.05 mg/mL) and streptomycin (0.1 mg/mL). For the transepithelial transport experiments, the cells were seeded on transwell membrane inserts (transwell vial) at 2500 cells/mm,^{2} and the medium was refreshed every day. Confluency of the cell monolayer on the microporous membrane was monitored by measuring the transepithelial electrical resistance (TER) using a Millicell electrical resistance meter (Millipore). On the basis of this measurement, the cells could be used for transport assays between day 3 to 6, when TER values were between 600 and 300 $\Omega \cdot mm^2$ and approximately $80-90 \times 10^3$ cells were present on the microporous membrane.

Experimental Setup—A transwell vial with cells grown to confluency was placed in a fluorescence cuvette. To fit a transwell vial (Costar), the cuvette was composed of a well of a 24-well polystyrene plate (Costar) placed on top of a polystyrene fluorescence cuvette (Falcon). A square, with the inner measurement of the cuvette, was taken out of the bottom of the 24-well plate well, creating a free opening between the cuvette and the well (see Figure 1). The cuvette was placed in a thermostated cuvette holder equipped with a magnetic stirrer, the latter situated under the cuvette holder. After each experiment the cuvette was cleaned and sterilized with ethanol for reuse. The medium in the lower compartment (cuvette) was stirred with a Teflon-coated magnetic stirrer bar. The medium in the upper compartment (transwell vial) was stirred with a small Teflon stirrer, attached to a small 24 V electric motor. The motor was attached to a metal plate with a free space fitting the top of the cuvette (see Figure 1). This ensured that the motor was placed properly. The Teflon stirrer speed was controlled at 100–150 rpm. During the experiments 3100 μL medium was present in the cuvette and 250 μL in the transwell

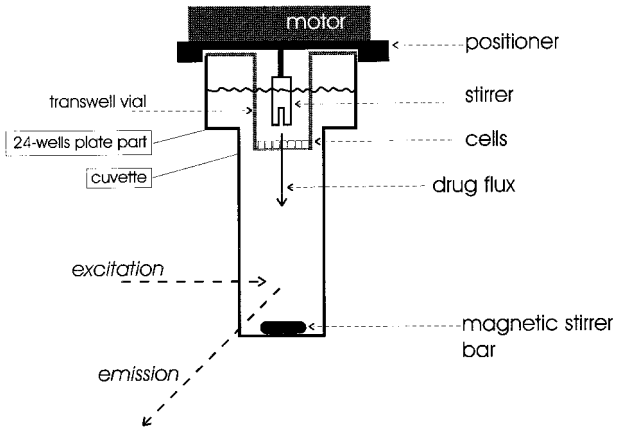

Figure 1—Schematic drawing of the experimental measurement setup. The cuvette used for the transepithelial experiments was composed of two parts: (1) a 24-well plate well on top of (2) a plastic fluorescence cuvette. The medium in the cuvette had a volume of 3100 μL and that in the transwell vial 250 μL. A Teflon stirrer driven by a 24 V electric motor stirred the medium in the transwell vial and a magnetic stirrer bar that in the cuvette. Transepithelial transport was monitored by measuring the fluorescent substrate (added to the transwell vial) that appeared in the cuvette.

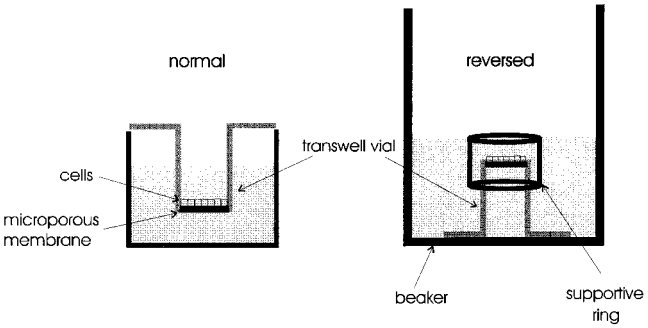

Figure 2—Normal and "reversed" growth of cells on a microporous membrane is illustrated. The left panel shows how cells are normally grown. The transwell vial is hanging in a 24-well plate well, and the cells are grown at the inside of the transwell vial. The right panel shows the "reversed" growth. Now the transwell vial is turned upside down and is completely immersed in growth medium. A polyethylene ring is placed over the transwell vial creating a compartment in which cells can be seeded.

vial. Transport experiments were performed in medium A with 1% FCS. Medium A is a phosphate-buffered saline (PBS) based medium supplemented with essential amino acids for MEM (Flow) with 5.5 mM glucose, 4 mM L-glutamine, and 20 mM HEPES, without bicarbonate (pH 7.4). To remove dust particles, which gave extra background noise during the transport measurements, the medium was filtered (0.22 μm, Millipore).

The detection was most sensitive when fluorescent compounds were added to the transwell vial (upper compartment), and the appearance of the substrate was monitored in the cuvette (the lower compartment). To measure transport from the apical to the basolateral side of the cells (A to B), cells were seeded in the transwell insert. After attachment and growth of the cells, with the basolateral side facing the microporous membrane, the transwell vial was suited to measure transport from A to B. To measure the reversed process, transport from B to A, cells were grown "reversed", at the opposing side of the microporous membrane. In Figure 2 the difference between both ways of growing the cells is illustrated. Before seeding, the transwell was placed in a beaker filled with ±15 mL of growth medium. The transwell was placed upside down, in such a way that there was no air present under the membrane. Then a plastic (polyethylene) supportive ring, which loosely fitted the transwell, was placed around the transwell and approximately 5000 cell/mm^2 were brought within the supportive ring. After 1 day the supportive ring was removed, and confluency was checked by measuring the TER.

Transepithelial Efflux Experiments and Calculations—Just before the start of the transepithelial transport experiment the cells were washed with medium A (at 37 °C), and the growth

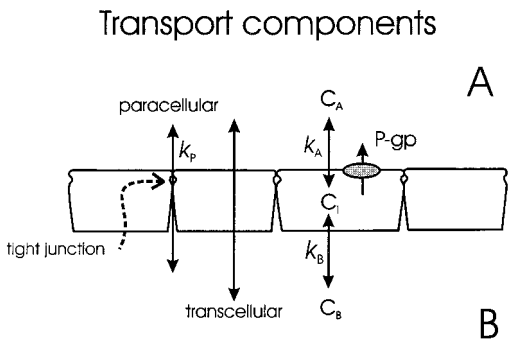

Figure 3—Schematic presentation of an epithelial cell monolayer and the different transport components. Tight junctions are indicated. Pgp is localized in the apical plasma membrane and is modeled using Michaelis–Menten kinetics. The free substrate concentrations in the different compartments are defined as C_A, the apical compartment concentration; C_i, the intracellular concentration; and C_B, the basolateral compartment concentration. Passive plasma membrane transport across the apical membrane is dependent on C_A and C_i and proceeds with a first-order rate constant k_A. Similarly, passive transport across the basolateral membrane takes place, depending on C_B and C_i, and proceeds with a first-order rate constant k_B.

medium was replaced by medium A supplemented with 5% FCS and antibiotics. Then the transwell vial was placed in the cuvette, and the fluorescent substrate was added to the transwell vial. The fluorescence in the cuvette was measured on a computer-controlled fluorometer (FluoroMax, SPEX Industries, Edison, NJ) at excitation and emission wavelengths of 480 and 590 nm for DNR and IDA and 480 and 525 nm for Cal and FITC-dextran. At the end of the experiment both the cells (with 25 μM digitonin) and the microporous membrane (mechanically) were disrupted, and then the equilibrating fluorescence (F_{eq}) was measured, which was used for calibration. The normalized fluorescence (F_n) was calculated according to $F_n = (F - F_b)/(F_{eq} - F_b)$, with F = measured fluorescence and F_b = background fluorescence. From this normalized trace, representing the normalized increase in fluorescence in time ($\Delta F_n/\Delta t$), the flux (J) in pmol/min·cm^2 was calculated using $J = (\Delta F_n/\Delta t)C_T V_T V_C(V_T + V_C)^{-1}A^{-1}$, in which C_T = the applied concentration at the start of the experiment; V_T = volume of the medium in the transwell vial; V_C = volume of the medium in the cuvette; A = surface (0.33 cm^2). (Note: the substrate is diluted in V_C ($V_C \gg V_T$), and therefore backflux from the cuvette compartment is neglected.) Dividing J by C_T gives the permeability (k) (length·time^{-1}).[17] Alternatively, the permeation coefficient (volume·time^{-1}·number of cells^{-1}) may be calculated when reference is made to the amount of cells instead of surface.[23,24]

Octanol/Water Partition Coefficient—The octanol/water partition coefficient is the ratio of the anthracycline concentration in the octanol phase divided by that in the water (= phosphate-buffered saline (PBS)) phase at equilibrium. The ratio was determined at ambient temperature (20–25 °C), by adding 750 μL octanol to 750 μL of a 10 μM anthracycline solution prepared in PBS (pH 7.3). The two phases, which do not mix, were then vigorously shaken for 1 min and centrifuged to separate both phases again. Aliquots of 25 μL of both phases were separately dissolved in 150 μL ethanol (70% solution in water) in a 96-well plate. To obtain an equal medium composition in all the wells, 25 μL PBS was added to the wells containing the 25 μL octanol anthracycline solution, and 25 μL octanol was added to the wells containing the PBS anthracycline solution. The fluorescence of the plate was determined on a Spectrafluor plate reader (Tecan, Austria), using an excitation filter of 492 nm and an emission filter of 595 nm. After background correction, the octanol/water partition coefficient was calculated by the fluorescence of the octanol phase divided by the fluorescence of the water phase.

A Model for Transepithelial Drug Transport—A biomathematical transport model was developed to describe transepithelial transport and the effect of Pgp inhibition by SDZ PSC 833 for transepithelial drug transport from A to B and vice versa. Figure 3 shows a schematic presentation of epithelial cells, with C_A = the apical compartment concentration; C_i = the intracellular concentration; and C_B = the basolateral compartment concentration. The paracellular flux is the concentration in the transwell vial times the paracellular permeation coefficient k_p (per unit surface). The passive plasma membrane flux over the apical membrane is the difference between C_A and C_i times the passive permeation coefficient of the apical membrane k_A (per unit surface). Similarly, the passive flux across the basolateral membrane is the difference between C_B and C_i times the passive permeation coefficient of the basolateral membrane k_B (per unit surface). Pgp is expressed at the apical side of the cell. The Pgp-mediated transport rate (v_{Pgp}) is supposed to follow Michaelis–Menten kinetics:

$$v_{Pgp} = \frac{V_{max} C_i}{K_M + C_i} \tag{1}$$

with K_M = the Michaelis constant and V_{max} = the maximum transport rate. When $C_i \ll K_M$, eq 1 can be simplified to

$$v_{Pgp} = \frac{V_{max}}{K_m} C_i \tag{2}$$

For the transport from A to B, $R_{A\rightarrow B}$ is defined as the transepithelial flux after inhibition (J_{-Pgp}) divided by the transepithelial flux before inhibition (J_{+Pgp}):

$$R_{A\rightarrow B} = \left(\frac{J_{-Pgp}}{J_{+Pgp}}\right)_{A\rightarrow B} \tag{3}$$

At quasi-steady-state (either with or without Pgp transport), the flux across the apical membrane (= $C_o k_A - C_i k_A$) equals the flux across the basolateral membrane (= $C_i k_B$) and $R_{A\rightarrow B}$ can be described in terms of the fluxes across the basolateral membrane plus the paracellular flux. Then eq 3 becomes

$$R_{A\rightarrow B} = \frac{C_i k_B + C_A k_p}{C_i' k_B + C_A k_p} \tag{4}$$

with C_i = the free intracellular concentration in the presence of SDZ PSC 833 and C_i' = the free intracellular concentration in the absence of SDZ PSC 833. (Note that since DNR is strongly diluted in the cuvette compartment the backflux into the cells is neglected.)

In the quasi-steady-state ($dC_i/dt = 0$) the intracellular concentration is constant and is determined by the influx from the apical compartment and the efflux out from the cellular compartment, which gives

$$0 = C_A k_A - C_i' k_A - C_i'\left(\frac{V_{max}}{K_M}\right) - C_i' k_B \tag{5}$$

The possibility that the "unstirred" cytosol acted as an additional barrier was neglected. Based on Fick's first law of diffusion, a diffusion coefficient at 37 °C of 4×10^{-6} cm^2/s, and an average diffusion path length of 5×10^{-6} m, it can be calculated that for the examples mentioned the cytosol forms less than 5% of the total resistance (= the reciprocal permeability) of the cell monolayer. When eq 5 is rewritten, the equation for the intracellular concentration evolves to:

$$C_i' = \frac{C_A}{1 + \frac{k_B}{k_A} + \left(\frac{V_{max}}{K_M k_A}\right)} \tag{6}$$

Equation 6 gives the equation for the intracellular concentration when Pgp is active. When Pgp is inactive ($V_{max} = 0$), the last term in the denominator is zero. Substitution into eq 4 and dividing by ($C_A k_B$) gives the equation for the SDZ PSC 833 induced slope change in terms of k_A, k_B, k_p, and V_{max}/K_M:

$$R_{A\rightarrow B} = \frac{\left[1 + \frac{k_B}{k_A}\right]^{-1} + \frac{k_p}{k_B}}{\left[1 + \frac{k_B}{k_A} + \left(\frac{V_{max}}{K_M k_A}\right)\right]^{-1} + \frac{k_p}{k_B}} \tag{7}$$

An equation for $R_{B\rightarrow A}$, defined as the flux without SDZ PSC 833

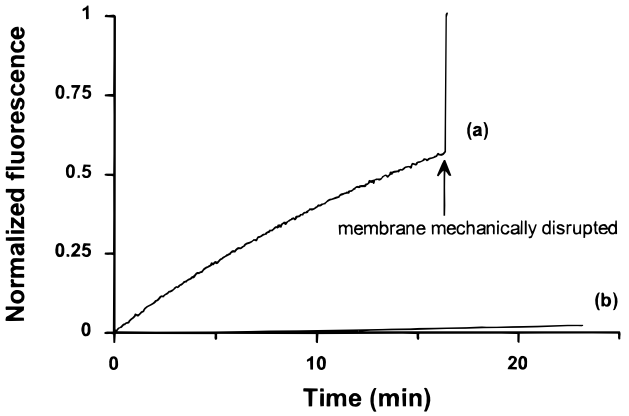

Figure 4—DNR (2 μM) transport from the upper to the lower (cuvette) compartment (a) without cells and (b) with MDCKII cells grown on the microporous membrane.

divided by the flux with SDZ PSC 833, can be derived in a similar way as was done for $R_{A\rightarrow B}$. $R_{B\rightarrow A}$ is given by

$$R_{B\rightarrow A} = \frac{k_B(C_B - C_i') + C_B k_p}{k_B(C_B - C_i) + C_B k_p} \quad (8)$$

C_i and C_i' are now given by

$$C_i' = \frac{C_B}{1 + \frac{k_A}{k_B} + \left(\frac{V_{max}}{K_M k_B}\right)} \quad (9)$$

Substitution of eq 9 into eq 8 gives the equation for $R_{B\rightarrow A}$:

$$R_{B\rightarrow A} = \frac{\left[1 + \left(\frac{V_{max}}{K_M k_A}\right)\right]\left[1 + \frac{k_A}{k_B} + \left(\frac{V_{max}}{K_M k_B}\right)\right]^{-1} + \frac{k_p}{k_A}}{\left[1 + \frac{k_A}{k_B}\right]^{-1} + \frac{k_p}{k_A}} \quad (10)$$

Results and Discussion

Transport with and without Cells on the Microporous Membrane—Figure 4 shows the transport of daunorubicin (DNR) with and without cells present in the transwell vial. Without cells the DNR transport is much faster than with cells on the microporous membrane. Without cells on the membrane, the influence of stirring or not stirring of the upper compartment was clearly reflected in the transport rate after turning the stirrer on and off (data not shown). With cells on the membrane this effect was hardly visible for DNR transport, indicating that diffusion in the transwell compartment was not limiting for the transepithelial transport of DNR. To ensure good mixing of a broad range of compounds, the medium was always gently stirred.

After adding DNR to the transwell compartment with cells on the membrane, a lag time of approximately 30 min was first observed. Thereafter the transport rate became virtually constant. During the lag time, the intracellular free DNR concentration increases until the cellular influx of DNR equals the cellular efflux from the cells. When this is the case, both the transepithelial transport and intracellular free drug concentration stay constant and are at quasi-steady-state. For the DNR transport in wild-type and MDR1 cDNA transfected MDCKII-MDR1 cells, this quasi-steady-state continued for at least 2 h. From $\Delta F_n/\Delta t$ (see Figure 4) at quasi-steady-state the permeation coefficient in cm/min was determined (see Experimental Section). For the DNR transport from A to B the transepithelial permeation coefficients were 0.67 ± 0.05 ($\times 10^{-3}$) cm/min for the wild-type MDCKII cells and 0.44 ± 0.3 ($\times 10^{-3}$) cm/min for the MDCKII-MDR1 cells (Table 1). The increased expression of Pgp in the apical[25] membranes of the MDCKII-MDR1 cells, after transfection of wild-type cells with the MDR1 cDNA, led to a lower A to B transepithelial transport rate compared to the untransfected MDCKII cells (due to backward pumping to A).

Table 1—Transepithelial Transport for MDCKII-MDR1 Cells

	Direction	MDCKII-MDR1 ($\times 10^{-3}$) cm/min	MDCKII ($\times 10^{-3}$) cm/min
DNR	A to B	0.44 ± 0.3[a]	0.67 ± 0.05
Cal	A to B	0.17 ± 0.01	0.04, 0.07
FITC-dextran	A to B	0.04 ± 0.02	0.02, 0.01

[a] Data are given as the mean ± SD of at least three experiments or stated otherwise.

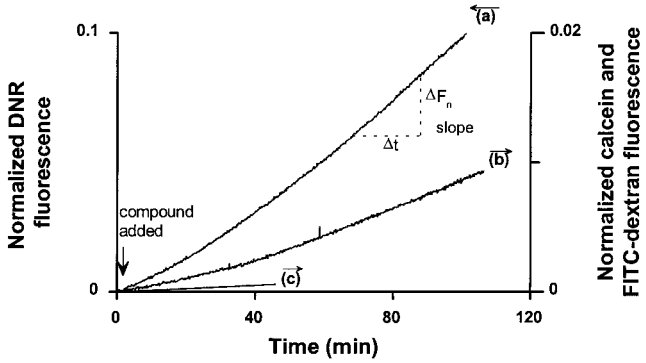

Figure 5—Comparison of (a) DNR (2 μM), (b) Cal (0.4 μM) and (c) FITC-dextran (8 μM) transport across MDCKII wild-type cells grown on microporous membranes. Fluorescent compounds were added to the upper compartment, and transport from the apical to the basolateral side of the cells was measured by monitoring the fluorescence in the cuvette. Representative traces are shown.

Paracellular Transport—To investigate the tightness of the monolayers, the transport of the plasma membrane permeable DNR was compared with that of highly plasma-membrane-impermeable compounds. Figure 5 shows the A to B transport of the organic anion calcein (Cal), the bulky compound FITC-dextran (70 kDa), and DNR for the MDCKII cells. Table 1 presents the transepithelial permeation coefficients for the wild-type and the MDCKII-MDR1 cells for the transport from A to B. The transepithelial transport of Cal for the MDCKII-MDR1 cells is approximately 4 times faster than for the wild-type cells. For FITC-dextran the transepithelial permeation for the wild-type cells was approximately 2 times slower. Why there are these differences between the two lines is not clear. It cannot be explained by differences in TER values of the batches of cells that were used since these were comparable. Possibly components cotransfected or the MDR1 gene itself causes this difference in the epithelial permeability. More certainty about this may be obtained by a detailed mechanistic study, but this does not lie within the scope of this study.

To show the tightness of the cell monolayer, the effect of opening the tight junctions by the calcium chelator EDTA[8,27] was studied. Figure 6 shows the effect of EDTA on the transepithelial transport of FITC-dextran. After a constant flux was observed, EDTA was added as indicated in the figure. A lag time of ~15 min after the EDTA addition was observed, and then the increased transport rate became constant. The inset shows transepithelial transport during the transition from closed to opening of the tight junctions in more detail.

From the constant fluxes before and after addition of EDTA, transepithelial permeation coefficients were calculated. Table 2 gives the transepithelial permeation coef-

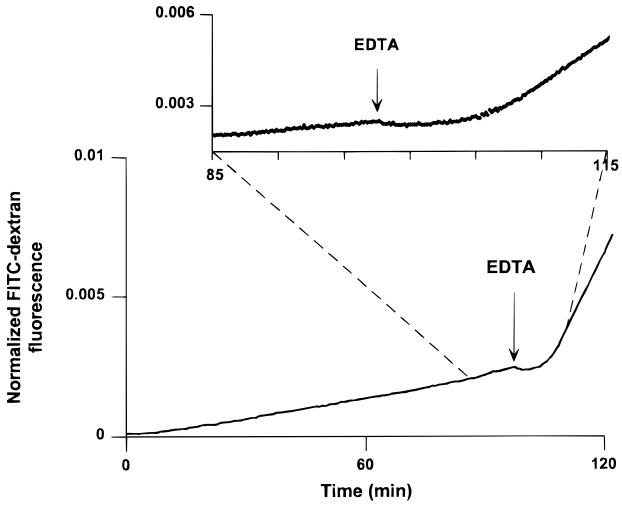

Figure 6—The effect of binding the extracellular calcium with EDTA (2 mM) on the transport FITC-dextran (8 μM) across MDCKII-MDR1 cells. FITC-dextran was added to the upper compartment, and the transport from the apical to the basolateral side of the cells was measured by monitoring the fluorescence in the cuvette. The inset shows the transition from closed to open tight junctions in more detail (85 to 115 min). The traces are representative for at least three experiments.

Table 2—Permeation Coefficients: The Effect of Opening of the Tight Junctions (TJ) for MDCKII-MDR1 Cells

	direction	control[b] ($\times 10^{-3}$) cm/min	TJ open with EDTA[b] ($\times 10^{-3}$) cm/min	R_{TJ}[c]
DNR	B to A	0.8 ± 0.4[a]	2.9 ± 1.0	5.3 ± 2.6
IDA	B to A	1.6 ± 0.2	2.1, 2.9	1.3, 1.7
DNR	A to B	0.7 ± 0.3	4.0 ± 1.1	5.3 ± 1.7
IDA	A to B	2.2 ± 0.9	2.4, 2.9	0.9, 1.1
FITC-dextran	both	0.04 ± 0.02	0.5 ± 0.2	13.1 ± 4.7

[a] Data are given as the mean ± SD of at least three experiments or stated otherwise. [b] SDZ PSC 833 (5–20 μM) was present to inhibit Pgp. [c] Please note that R_{TJ} cannot be derived from the first two columns, because R_{TJ} was calculated from individual (paired) data.

ficients for FITC-dextran, DNR, and IDA for the transport from A to B and vice versa, both in the presence and absence of EDTA. DNR and IDA were used because they are highly similar in chemical structure, but differ in lipophilicity. The difference in lipophilicity was measured by their octanol/water partition coefficient. The partition coefficients were 16.6 ± 0.2 for IDA (mean ± SEM; n =3) and 4.9 ± 0.1 for DNR. The IDA transepithelial transport in the presence of SDZ PSC 833 was a factor 2−3 larger than that of DNR, reflecting the difference in lipophilicity. In all tested cases the permeability increased after addition of EDTA. This increase of the paracellular transport component is expected to be independent of the lipophilicity. It therefore reduces the relative difference between total transport of DNR and IDA through the cellular layer. Measurement of transport from A to B showed a slightly larger permeability for DNR than for IDA. We attribute this to biological variations between cellular layers. To partially avoid effects of these biological variations, the ratio (R_{TJ}) of the fluxes before and after addition of EDTA was calculated within the same experiment. R_{TJ} is presented in Table 2 and decreased in the order FITC-dextran > DNR > IDA. For the hydrophilic compound FITC-dextran the transepithelial flux was strongly dependent on the paracellular route, while for the highly lipophilic IDA, opening of the tight junction hardly influenced the flux, which is in accordance with what can be expected from an increase in lipophilicity (comparing DNR and IDA). This illustrates that the dependence of total transport on the

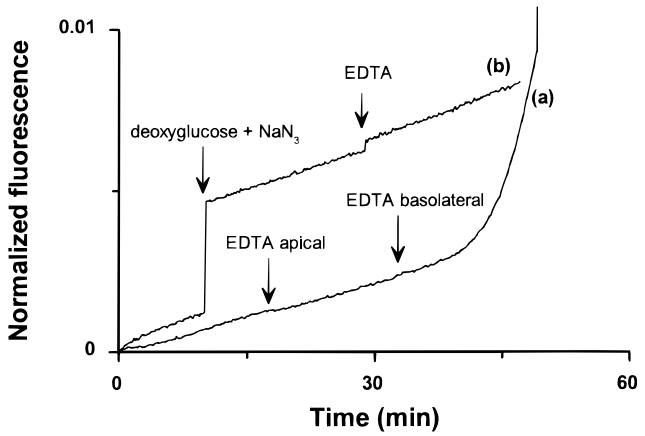

Figure 7—Specificity of the EDTA effect on transepithelial transport of FITC-dextran (8 μM) of MDCKII cells. (a) Effect of adding EDTA apically or basolaterally. As indicated, EDTA (2 mM) was first added to the apical side and then to the basolateral side. (b) Effect of ATP-depletion by the addition of deoxyglucose (6 mM final concentration) and NaN_3 (10 mM final concentration) on the EDTA effect. Deoxyglucose and NaN_3 were added to both the apical and basolateral compartments. Thereafter, EDTA (2 mM) was added (apically and basolaterally). The traces are representative for at least three experiments.

paracellular transport decreases as the lipophilicity/passive membrane permeability increases. From the effects of the tight junctions on the transport, we may conclude that the cell layers stayed intact under the applied conditions. Note that the data presented here were obtained with the MDCKII-MDR1 cells in the presence of SDZ PSC 833 to inhibit Pgp. Similar results were also found for the wild-type MDCKII cells and LLC-PK1[20] cells (data not shown).

Cellular Control of the Tight Junction—The tightness of epithelia and endothelia may be regulated by the cells in order to control the flux of certain molecules (or cells).[8,9] The mechanism by which EDTA triggers the cells to open the paracellular transport route is still under investigation.[6,7,26,28] Extracellular calcium and calcium-dependent protein kinases (PKC) have shown to be directly or indirectly involved in the tight junction tightness.[27,29–31] To show the usefulness of the current method in such regulations studies, we examined (1) the effect of adding EDTA to either side of the monolayer and (2) the influence of ATP-depletion-induced metabolic inhibitors.

Figure 7 (line a) shows the transport of FITC-dextran and the effect of EDTA added to the apical or to the basolateral side. Addition of EDTA to the apical side had no effect. Only when EDTA was present at the basolateral side, then the tight junction opened and an increased FITC-dextran transport was observed. These results are similar to recent observations on the basolateral side specificity of Ca^{2+}.[32,33] Figure 7 (line b) shows the effect of adding an excess of both the nonmetabolizable deoxyglucose (6 mM) and the respiratory inhibitor NaN_3 (10 mM), added to both compartments, on the FITC-dextran transport. It can be seen that addition of NaN_3/deoxyglucose caused an instant increase in the background fluorescence, which may be related to the yellowish color. Looking at the fluxes, it can be seen that the ATP-depletion itself did not affect the FITC-dextran transport rate. However, under these conditions EDTA did not open the tight junctions anymore. Similar results were also obtained for LLC-PK1 cells both measuring the transepithelial transport and measuring the TER (data not shown). This strongly suggests that the effect of EDTA on the tight junctions is ATP-dependent and most probably involving ATP dependent phosphorylation mechanisms.[31,34–36] However, at this point we cannot exclude direct interactions between deoxyglucose or NaN_3

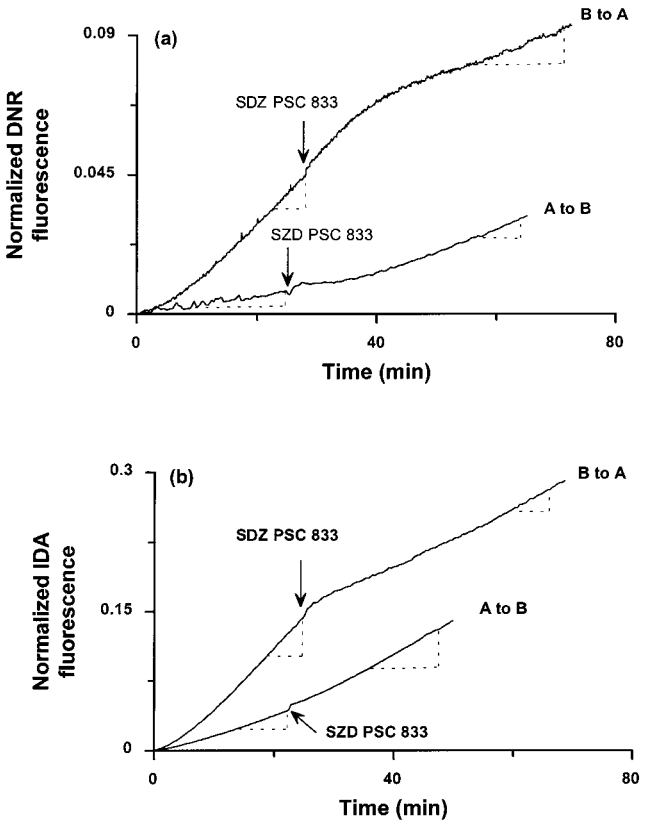

Figure 8—SDZ PSC 833 modulation of (a) the DNR (2 μM) and (b) the IDA (2 μM) transepithelial transport across MDCKII-MDR1 cells. The effect of SDZ PSC 833 was measured for the transport from A to B and from B to A, as indicated. After reaching the quasi-steady-state, SDZ PSC 833 (5–20 μM) was added to the cells to inhibit Pgp. The traces are representative for at least three experiments.

and EDTA. These experiments show that our system can be useful for further elucidating mechanisms of paracellular transport. This application shows that the method can be useful to study (1) compounds that diffuse rapidly (e.g., when the tight junctions are open) and (2) modulators that induce rapid changes (in the minute time range) in the transepithelial transport.

Effect of Pgp on Transepithelial DNR and IDA Transport—The apical localization of Pgp results in a decreased flux from A to B and an increased flux from B to A. Consequently, inhibition of Pgp will lead to an increase in transepithelial flux from A to B and to a decrease from B to A. To be able to perform experiments in which Pgp can be modulated, three Pgp inhibitors, verapamil (Vp), diltiazem (Dil), and SDZ PSC 833, were tested for their effect on the paracellular transport of FITC-dextran across MDCKII-MDR1 cells. At concentrations needed to rapidly inhibit Pgp, Dil (>0.5 mM) and Vp (>200 μM) increased the FITC-dextran transport (not shown). Pgp inhibitor SDZ PSC 833 (1−25 μM) did not influence the FITC-dextran (and Cal) transport and was used for further study of the effect of Pgp inhibition on the transepithelial transport of DNR and IDA. Figure 8 shows the transepithelial transport using the MDCKII-MDR1 cells for DNR (Figure 8a) and IDA (Figure 8b) for transport from A to B and vice versa. After the quasi-steady-state was reached, the effect of Pgp inhibition was measured by adding SDZ PSC 833 (5 μM) to both compartments, as is indicated in Figures 8a and 8b. The addition of SDZ PSC 833 to the cuvette gave rise to an increase of the background fluorescence, due to the weak fluorescence of SDZ PSC 833. In later experiments it was found that addition of 5−20 μM SDZ PSC 833 only to the transwell compartment was sufficient to inhibit Pgp with a lower disturbance of the background signal. After the addition of SDZ PSC 833, the transepithelial flux changed slowly and stabilized after approximately 30 min. In the case of A to B transport, the flux increased, and in the case of B to A transport, the flux decreased (Figure 8; Table 3). From the fluxes at quasi-steady-state, the transepithelial permeation coefficients were calculated, which are presented in Table 3. To be able to compare the effect of Pgp inhibition for the different compounds, the effect of SDZ PSC 833 was quantified by the ratio of the fluxes before and after Pgp inhibition. This ratio was called the SDZ PSC 833-induced slope change (R). To be able to compare R for the transport from A to B and vice versa, the R was defined as the larger slope divided by the smaller slope. Table 3 shows the obtained SDZ PSC 833-induced slope changes. For FITC-dextran, addition of SDZ PSC 833 did not lead to change in the flux. For IDA and DNR, addition of SDZ PSC 833 led to changes in the transepithelial fluxes. Moreover, it was found that for both IDA and DNR the effect of Pgp inhibition was largest for the transport from B to A.

Table 3.—Permeation Coefficients: the Effect of SDZ PSC 833-Induced Pgp Inhibition for MDCKII-MDR1 Cells

	direction	control ($\times 10^{-3}$) cm/min	with SDZ PSC 833 ($\times 10^{-3}$) cm/min	R[b]
DNR	B to A	2.6 ± 1.0[a]	0.8 ± 0.4	3.7 ± 1.4
IDA	B to A	3.8 ± 1.3	1.6 ± 0.2	2.4 ± 0.6
DNR	A to B	0.44 ± 0.3	0.7 ± 0.3	1.6 ± 0.5
IDA	A to B	1.4 ± 0.5	2.2 ± 0.9	1.5 ± 0.2
FITC-dextran	both	0.04 ± 0.02	0.04 ± 0.02	1.1 ± 0.3

[a] Data are given as the mean ± SD of at least three experiments. [b] Please note that R cannot be derived from the first two columns, because R was calculated from individual (paired) data.

Comparison of Experimental Data with the Model—To seek an explanation for the difference in effects of SDZ PSC 833 on the transport from A to B and vice versa, a biomathematical transport model was developed (see Experimental Section). Figure 3 shows a schematic presentation of an epithelial monolayer. Using eqs 7 and 10, which describe R for transport from A to B ($R_{A\rightarrow B}$) and from B to A ($R_{B\rightarrow A}$), respectively, the theoretical differences between the transport from the A to B and transport vice versa were studied for nonsaturating conditions. Figure 9a shows a simulation of the relationship between R and the Pgp concentration ($\sim V_{max}/(K_M k_A)$). In this simulation the passive permeation coefficients were kept constant and equal. The figure shows a linear relationship between the Pgp concentration and $R_{A\rightarrow B}$. A nonlinear relationship was found for $R_{B\rightarrow A}$. In the lower range ($V_{max}/(K_M k_A) \ll 1$) $R_{B\rightarrow A}$ increases almost linearly with increasing Pgp concentration. At values of $V_{max}/(K_M k_A) > 1$, $R_{B\rightarrow A}$ goes to a plateau and Pgp loses control over the transepithelial flux. The latter can be explained by the high Pgp activity, resulting in C_i values approaching zero and the basolateral membrane getting more and more in control of the transcellular flux. In the extreme case Pgp completely clears the cell of almost all drug, while the transcellular flux becomes equal to the flux across the basolateral membrane ($= C_B k_B$). When also paracellular transport is taking place, R decreases (dashed lines Figure 9a) and $R_{A\rightarrow B}$ seems to be more affected by the paracellular flux than $R_{B\rightarrow A}$. The simulations in Figure 9a show that in general one may expect that Pgp has a higher control over the transport from A to B than vice versa, which seems in contradiction with our experiments. However, k_B and k_A may not be equal for these cells. Figure 9b shows the relationship between k_B/k_A and both $R_{B\rightarrow A}$ and $R_{A\rightarrow B}$. At low ratios of k_B/k_A, $R_{A\rightarrow B}$ is larger than $R_{B\rightarrow A}$; however, at higher ratios of k_B/k_A (>2)

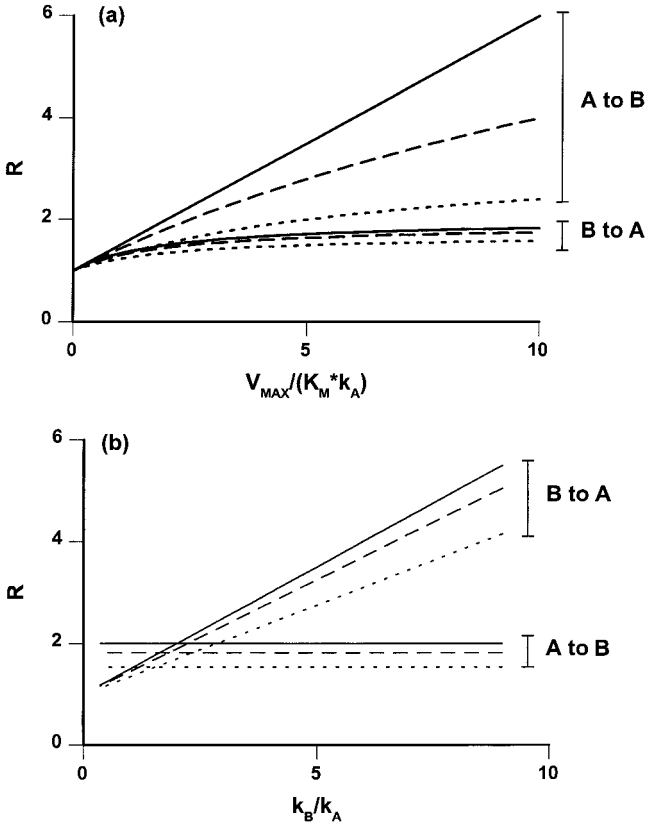

Figure 9—Simulations of the SDZ PSC 833-induced slope change for the transport from A to B and from B to A. In (a) Pgp was varied by changing the dimensionless factor $V_{max}/(K_M k_A)$, while k_A and k_B were both kept constant at 6.25×10^{-3} cm/min. These relative estimates correspond to those of moderately multidrug resistant cells.[21] (b) Simulation of the dependence R on the ratio of the basolateral over the apical membrane permeation coefficient (k_B/k_A). V_{max}/K_M was kept constant at 12.5×10^{-3} cm/min; ($k_B + k_A$) was set at 12.5×10^{-3} cm/min, and the ratio k_B/k_A was varied. In both a and b three conditions are shown: (1) when there is no paracellular transport (solid lines); (2) when the paracellular permeability is 10% (long dashes); (3) 30% (short dashes) of the total transepithelial permeability.

the situation is reversed and $R_{B\to A}$ becomes larger than $R_{A\to B}$. When the paracellular transport of DNR and IDA are approximately equal to the transepithelial transport of Cal, then the paracellular transport will make up 10−30% of the total transepithelial transport of DNR and IDA. Introducing a paracellular flux in the model leads to an overall decrease of the ratios (dashed lines Figure 9b). However, the crossing of the lines for $R_{A\to B}$ and $R_{B\to A}$ occurs at approximately the same k_B/k_A (range 1.6−2). At $k_B > 2k_A$ the model predicts similar results as found in the experiments. Although the relations plotted in Figure 9b still are dependent on the V_{max}/K_M, the passive membrane permeabilities, and the paracellular permeability, these results show that for both DNR and IDA, $k_B > k_A$. On the basis of our transport data for DNR and IDA, k_B will be approximately 3−7 times larger than k_A, and this estimate tends to be larger for DNR than for IDA. This difference could be due to the differences in passive membrane permeation coefficients (Figure 9a).

An explanation for the larger k_B may be a larger basolateral membrane than apical membrane surface. The simplest model of a cell is a cube, with the tight junction localized to the top rim of the cells, with 1/6 of the membrane localized apically and 5/6 localized basolaterally. However, most epithelial cells contain microvilli at their apical side and basolateral clefts at their basolateral side, making it more complicated to compare both surface areas. A low number of microvilli when compared to basolateral clefts may also explain our observation. However, different compositions in lipids or proteins of the apical and basolateral membranes may also explain such differences in membrane permeabilities. For instance basolaterally located transport proteins, like the organic cation transporter (Oct1),[37] may increase the basolateral transport for neutral as well as for the protonated[38] form of DNR and IDA. Recent studies have shown that such transport proteins may be involved in the basolateral uptake of organic cations and are present in renal cell lines.[39]

In summary, we present here a new method to measure the transepithelial transport of fluorescent compounds online and at (sub)minute time resolution. It makes use of commercially available plasticware and a fluorometer, equipment present in most biochemical laboratories. It is simple to perform and relatively inexpensive. To reduce the influence of stagnant layers[17] on the transport, the media in both the apical and basolateral compartments can be continuously stirred and thermostated. We have shown that both paracellular and transcellular transport and modulation of both types of transport can be studied. Moreover, the paracellular transport studies showed that the monolayer stayed intact during the experiments (up to 4 h) and was not disrupted by the stirring of the medium, which was confirmed by microscopy (not shown). Related to this point we like to bring up that when the cell monolayer was already leaky at the beginning of the experiment (less than 5% of the cases) this became directly evident from the transport that was observed. Thus the method allowed us to terminate and discard such experiments. Comparing the fluorescent compounds DNR, IDA, Cal, and FITC-dextran, we found the highest transepithelial transport rate for the highly membrane-permeable IDA and the lowest for bulky and membrane-impermeable FITC-dextran. Site specificity for the EDTA-induced opening of the tight junctions was bound to basolateral side of the cells, which has also been reported by other groups.[32,33] Moreover, we found that adding an excess of metabolic inhibitors could inhibit the effect EDTA on the tight junctions. These experiments show that the method can be useful to study paracellular transport. For the transepithelial transport of DNR and IDA with the MDCKII-MDR1 cells, we found that Pgp inhibition was most effective for transport form B to A. Modeling showed that this was possible at $k_B > 2k_A$. We estimated that k_B was approximately 3−7 larger than k_A. The biomathematical transport model showed that the effect of Pgp on the transepithelial transport is dependent on the Pgp concentration and on the ratio of k_B/k_A. At higher Pgp concentrations and at lower ratios of k_B/k_A, Pgp gets more control over the A to B transepithelial transport, but loses control over the B to A transport. Extrapolation of these results to the in vivo situation of patients receiving anticancer drugs such as DNR or other Pgp-interacting drugs suggests that decreased efflux from the blood or increased influx from the lumen of the gut by treatment with Pgp modulators can differ quantitatively, depending on the contribution of transport components for uptake and efflux across the apical or basolateral membrane. Where there is a basolaterally localized uptake system involved in the transport, it may be worthwhile to inhibit this transport, thereby indirectly reducing the Pgp-mediated excretion. Moreover, inhibition of Pgp after an intravenous bolus injection of Pgp substrate drugs may lead to unexpected differences in clearance from the blood and uptake into the brain, depending on the (passive) permeation properties of the drug that is used. Using the method described here, one may study these properties in greater detail and so may understand and predict the in vivo situation better.

Accepted for publication September 20, 1999.

Abstract □ A near-infrared spectroscopic method to quantify drugs or excipients within polymeric matrixes is proposed. Cylindrical implants were fabricated by a melt-mold technique containing various ratios of poly(ϵ-caprolactone) (PCL) and poly(ethylene glycol) (PEG) and various loadings of lomefloxacin HCl with a constant ratio (70:30 w/w) of PCL/PEG. Near-infrared (NIR) spectra were obtained on intact sections of larger implants using a Foss NIRSystems Model 5000 monochrometer equipped with a Rapid Content Analyzer. Spectral data were treated with second derivative transformation followed by linear regression and PLS to obtain correlation with lomefloxacin or PEG content. Lomefloxacin content was separately determined by UV analysis (287 nm) using a validated extraction procedure. The NIR method was tested by comparing predicted loadings of test implants with either theoretical values based on weight (PEG) or with UV analysis results (lomefloxacin). Second derivative spectral values at particular wavelength ratios (PEG, 2064 nm/1698 nm; lomefloxacin, 2172 nm/2226 nm and 1824 nm/1862 nm) yielded linear results for PEG or lomefloxacin content. PEG content determined by NIR spectroscopy was in excellent agreement with theoretical content. Lomefloxacin content determined by NIR spectroscopy was also in excellent agreement with UV analysis. NIR analysis is interpreted through the use of corresponding mid-infrared spectral data.

Introduction

Polymeric drug delivery systems such as implants and microspheres are finding widespread use in drug delivery. Quantitative analysis of excipients or active ingredients within these dosage forms usually involves destructive extraction procedures followed by an assay, typically HPLC or UV spectroscopy. In cases where only small amounts of drug are available, as in early formulation development, or in cases where dose uniformity is an issue, a nondestructive analytical technique would be useful, allowing subsequent use of the dosage form.

Near-infrared (NIR) spectroscopy is a rapid and nondestructive analytical tool which is gaining acceptance in the pharmaceutical industry as a technique for qualitative and quantitative analysis. NIR applications in the pharmaceutical industry include qualitative identification of raw materials,[1,2] quantitative analysis of drug content in tablets and powder blends,[3−10] determination of moisture content,[11−16] detection of degradation products within solid formulations,[17] and determination of crystallinity.[18] Although quantitative analysis of drugs and excipients has been demonstrated for intact tablets, NIR spectroscopy has not been utilized in quantitative analysis of polymeric dosage forms.

Polymeric dosage forms are often used to provide sustained release of various pharmaceutical entities. When the polymer acts as a solid matrix, the rate of release may be controlled by addition of inert, water-soluble excipients such as poly(ethylene glycol) or sodium chloride. These excipients rapidly dissolve and release upon exposure to water, increasing the effective diffusion coefficient and the release rate of the drug. Because the rate of release is related to the quantity of these pore-forming excipients as well as the quantity of drug in the system, it is important to be able to assess both the quantity and uniformity of these excipients within a polymeric dosage form. The application of NIR spectroscopy for quantitation of excipients and actives within polymeric drug delivery systems would provide a rapid and nondestructive alternative to other analytical techniques. This work investigates the use of diffuse reflectance near-infrared spectroscopy as a nondestructive analytical tool for quantifying poly(ethylene glycol) and lomefloxacin hydrochloride within intact polymer implants.

Experimental Section

Materials—Poly(ϵ-caprolactone) flakes (Scientific Polymer Products Inc., Ontario, NY), poly(ethylene glycol) 600 NF (Union Carbide, Danbury, CT, Lot 578269), and lomefloxacin HCl (G. D. Searle, Skokie, IL., Lot NA007) were used as received. Methylene chloride (Fisher Scientific, Lot #963694), 0.1 N hydrochloric acid (Fisher Scientific, Lot #924316-24), and distilled water were used in the extraction procedure as received. Borosilicate glass disposable culture tubes were used as received for fabrication of implants.

Poly(ϵ-caprolactone)/Poly(ethylene glycol) Implant Preparation—Poly(ϵ-caprolactone) (PCL) and poly(ethylene glycol) (PEG) (0, 5, 10, 15, 20, 25, and 30% w/w) were placed in a 20 mL glass scintillation vial. The materials were melted by placing the vial in a water bath at 75 °C. Upon melting, the two phases were thoroughly mixed with an overhead mixer to ensure uniform dispersion of PEG within the polymer melt. The resulting dispersion was transferred to a 10 mL Becton-Dickenson syringe and injected into precut 5 mm diameter borosilicate tubes. After cooling to room temperature, the implants were removed from the tubes and stored in a vacuum desiccator until use. Implants containing 12.5% and 22.5% w/w PEG were formed using the procedure described for use in validating the near-infrared standard curve.

Poly(ϵ-caprolactone)/Poly(ethylene glycol)/Lomefloxacin Hydrochloride Implant Preparation—Implants containing lomefloxacin HCl were prepared using PCL and PEG 600 at a constant weight ratio of 70:30. After complete dispersion of PEG within the polymer melt, powdered lomefloxacin HCl (5, 10, 15, 20, and 25% w/w) was slowly added with continuous agitation from an overhead mixer to ensure uniform dispersion of drug. The resulting dispersion was injected into the precut borosilicate tubes,

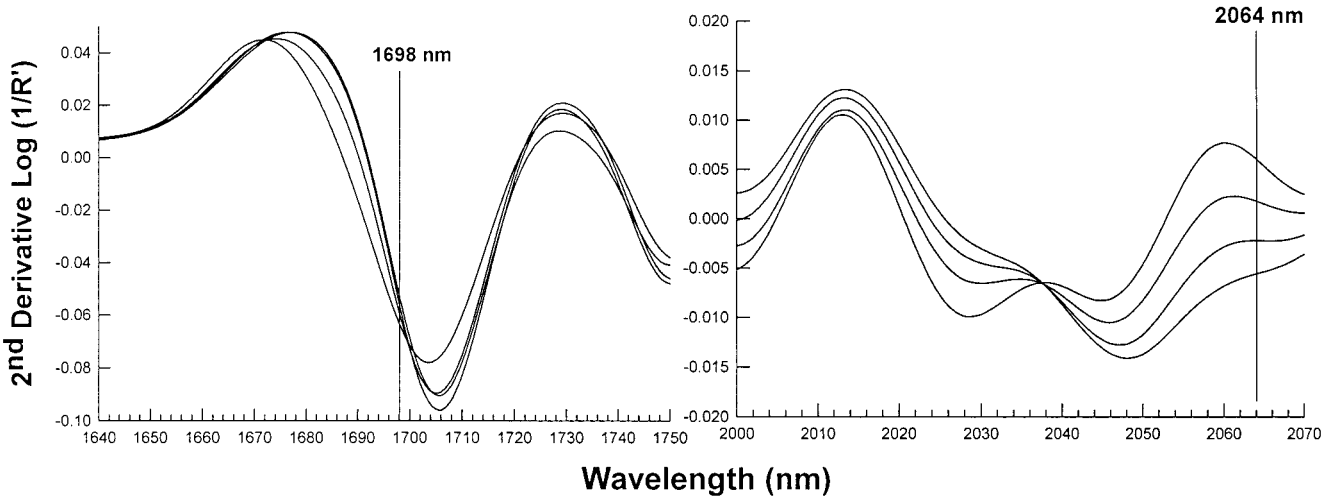

Figure 1—Expanded second derivative NIR spectra for implants containing various poly(ethylene glycol) (PEG) contents. PEG contents from top to bottom at 2064 nm are 0, 10, 20, and 30% w/w PEG 600; the normalizing wavelength (1698 nm) is indicated.

cooled to room temperature, removed from the tubes, and stored in a vacuum desiccator.

Near-Infrared Analysis—Two implants from each batch were selected at random. A surgical scalpel was used to cut two 5 mm slices from each implant. Each slice was placed on a glass cover slip and placed in the center of the sample holder using the iris centering device. Both radial surfaces from each slice were scanned in reflectance mode from 1100 to 2500 nm using a Foss NIRSystems Model 5000 monochrometer equipped with a Rapid Content sampler. Reflectance values obtained were relative to that from a nominally 80% reflective Coors standard ceramic disk. Relative reflectance values (R') were transformed by $\log(1/R')$.

Extraction and Chemical Assay for Lomefloxacin Hydrochloride Implants—After acquiring NIR spectra, each polymer slice was weighed and dissolved in methylene chloride (10 mL) in a 125 mL separatory flask. Hydrochloric acid (1 mM, 50 mL) was added to the separatory flask, forming two phases. The flask was shaken thoroughly, and the two phases were allowed to separate. Upon separation, the aqueous phase (top) was removed and placed into a 250 mL volumetric flask. This extraction procedure was repeated four times, and the resulting pooled extracts were diluted to volume with 1 mM HCL. An appropriate dilution was made and lomefloxacin quantified by measuring its absorbance at 287 nm using a Hewlett-Packard UV/Vis Spectrophotometer (Model 8450). An extraction efficiency of 99.6%, with a standard deviation of 0.85% ($n = 3$), was determined by separately adding known amounts of each component of the implant to a separatory flask and performing the extraction procedure.

NIR Spectral Analysis and Standard Curve Generation—A second derivative transformation of each NIR spectrum was performed using the NIRSystems Spectral Analysis Software (NSAS Version 3.50). The software was also utilized to scan the resulting second derivative spectra to determine a ratio of wavelengths which provided high correlation between the second derivative response and the theoretical PEG content or lomefloxacin content from extraction and UV analysis. A ratio of responses at two wavelengths was chosen rather than the response at a single wavelength to correct for baseline shifts. Baseline shifts are attributable to subtle changes in path length resulting from sample variations such as surface roughness, changes in sample positioning, or changes in sample density. The use of wavelength ratios has been shown to normalize spectra and yield more reproducible results.[19,20] A standard curve was generated by plotting the second derivative ratio versus PEG or lomefloxacin HCl content.

Partial least squares (PLS) analysis on second derivative spectra[21] was also performed for comparative purposes. Derivatized spectra have been shown to produce calibration models with more accurate and reproducible results.[22] A PLS calibration equation was generated using NSAS Version 3.50 and then utilized to predict lomefloxacin loadings in the validation data set.

Validation Set Generation—A separate batch of implants (20% w/w lomefloxacin HCl) was produced using the procedure described above in order to validate the standard curve generated. These implants were not used in the generation of the standard curve. Four implants from this batch were selected at random, and NIR spectra were obtained on two slices from each implant, as described previously. Lomefloxacin content was determined using the extraction and UV assay described above. The lomefloxacin content determined from the UV assay was then compared to the calculated lomefloxacin content using the NIR methods.

Statistical Analysis—A paired *t*-test was employed for comparison of lomefloxacin HCl content predicted by the NIR method and the results from extraction/UV assay. Using the paired *t*-test, 95% confidence intervals were constructed for the difference in the lomefloxacin hydrochloride content predicted by the NIR method and the results from the extraction/UV assay (i.e., NIR results − UV results). The null hypothesis (H_o) for this test was that of no significant difference while the alternative hypothesis (H_a) was that of significant difference. The results of a paired t-test give an indication of the accuracy of the NIR method compared with the extraction/UV assay. To perform a more robust statistical analysis on a small sample set, a nonparametric statistical analysis (Wilcoxon signed rank test at 95% confidence) was also employed.[23] The results of this statistical test provided a 95% confidence interval and a *p*-value which may be used in a manner similar to that obtained from the parametric paired *t*-test. An *F*-test for sample variance was employed at a 95% significance level to compare the precision of various NIR methods with the extraction/UV assay. In addition to the tests described above, standard error of calibration (SEC) and standard error of prediction (SEP) values were calculated for single wavelength and PLS models. Statistical analyses were performed on a microcomputer using MINITAB for Windows (Release 12.1), SAS, Version 6.12 (SAS Institute, Cary, NC), and Microsoft Excel 97.

Results and Discussion

NIR for Determination of PEG Content in PCL/PEG Implants—NIR spectra for PCL implants containing various PEG contents were obtained. To correct for the baseline shifts apparent in the samples and to amplify small spectral differences attributable to PEG content, a second derivative transformation of the NIR spectra was performed. Using the NSAS software, the spectra were analyzed to determine a wavelength ratio which best correlated with the known PEG content. A ratio of the responses at 2064 nm/1698 nm provided the highest correlation with PEG content. This region of the second derivative NIR spectrum is shown in Figure 1. The second derivative values at 2064 nm correspond well with changes in PEG content. A standard curve was constructed from the second derivative ratio of responses at 2064 nm/1698 nm versus the theoretical PEG content (% w/w) of each implant. The resulting standard curve is shown in Figure 2. The calibration data was analyzed by linear regression

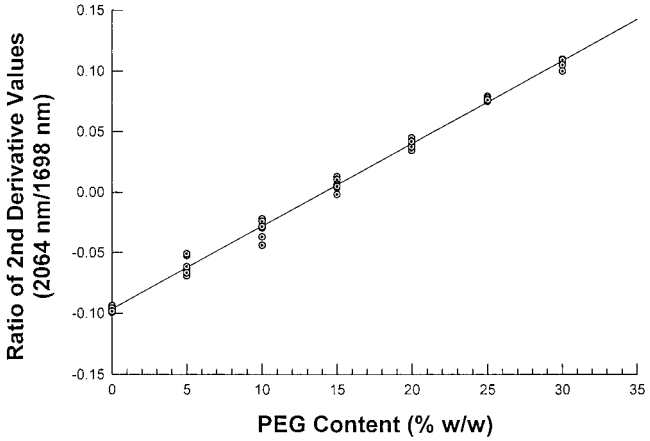

Figure 2—NIR standard curve for poly(ethylene glycol) (PEG) content in poly(ϵ-caprolactone) implants using a ratio of second derivative values (2064 nm/1698 nm) (R^2 = 0.998, S. E. = 0.0045).

Table 1—Comparison of NIR Predicted and Theoretical PEG 600 Content in Poly(ϵ-caprolactone) Implants

theoretical content (% w/w)	predicted content (% w/w) (n = 16)	standard deviation (% w/w) (n = 16)	relative error (%)
12.50	12.68	0.31	1.44
22.49	22.76	0.56	1.20

and excellent linearity throughout the entire range of PEG loadings (0−30% w/w) was obtained (R^2 = 0.998, SE = 0.0045).

Predicting PEG Content in PCL/PEG Implants from NIR Spectra—To test the robustness and accuracy of the NIR technique for the prediction of PEG content within a PCL implant, two batches of implants with theoretical PEG loadings of 12.5% and 22.5% w/w were prepared. NIR spectra were obtained and a second derivative transformation was performed. Using the second derivative of the response at 2064 and 1698 nm and the standard curve in Figure 2, PEG content was calculated and compared to theoretical PEG content. Table 1 shows the PEG content determined by the NIR method is in excellent agreement with the theoretical content. This method provides a rapid analytical technique for measuring PEG content with low relative error (1.2−1.4%) which is significant for two reasons. First, the technique is nondestructive, allowing subsequent use of the implant in other studies such as stability studies, in vitro/in vivo release studies, or polymer/excipient interaction studies, etc. Second, this technique provides an analytical method for quantitation of an excipient lacking a UV chromophore. Typical approaches to quantification of PEG or other excipients lacking a chromophore rely on methods such as refractive index detection with HPLC[24] or chemical reaction methods, which are more time-consuming and destroy the dosage form.

NIR for Determination of Lomefloxacin HCl Content in PCL/PEG Implants—NIR spectra for PCL/PEG implants containing various contents of lomefloxacin HCl are shown in Figure 3. A second derivative transformation of the NIR spectra of implants containing lomefloxacin was performed. The extraction procedure, previously described, was used to determine lomefloxacin content, and the results are summarized in Table 2. To determine a wavelength ratio which provided the best correlation between the second derivative NIR values and lomefloxacin content (Table 2), second derivative spectra were analyzed using the NSAS software. A ratio of the responses at 2172 nm/2226 nm provided the highest correlation with lomefloxacin content. This region of the second derivative NIR spectrum has been expanded in Figure 4A. A standard curve was constructed from the second derivative ratio of responses at 2172 nm/2226 nm versus lomefloxacin content determined from the extraction/UV assay results. The resulting standard curve, shown in Figure 4B, demonstrates excellent linearity (R^2 = 0.992, S. E. = 0.036).

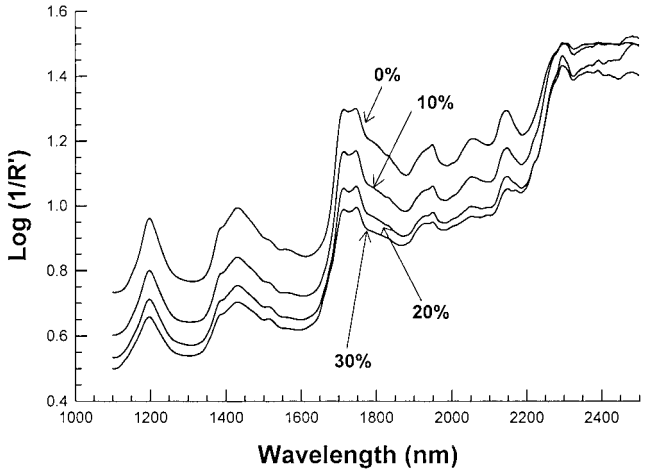

Figure 3—NIR spectra for poly(ϵ-caprolactone) implants containing various lomefloxacin HCl contents (% w/w) as indicated on each spectrum.

Table 2—Lomefloxacin HCl Content of Calibration Samples As Determined by the Extraction Procedure with UV Analysis

implant no.	lomefloxacin HCl content (% w/w)	implant no.	lomefloxacin HCl content (% w/w)
5-1	5.75	15-3	15.04
5-2	5.55	15-4	15.08
5-3	4.62	20-1	19.13
5-4	4.84	20-2	18.92
10-1	10.05	20-3	17.75
10-2	10.25	25-1	25.11
10-3	9.82	25-2	23.83
10-4	9.87	25-3	24.82
15-1	14.80	25-4	24.66
15-2	14.70		

In addition to using single wavelength analysis, partial least squares analysis was performed on second derivative spectra for comparison. A three-factor calibration equation was developed with an R^2 of 0.998 and a standard error of 0.66.

Predicting Lomefloxacin HCl Loading in PCL/PEG Implants—Implants containing approximately 20% w/w lomefloxacin HCl were produced to test the predictive ability of the NIR method. NIR spectra and second derivative spectra were obtained on 5 mm slices of four implants, as described previously, and subjected to extraction and subsequent UV assay. The second derivative response at 2172 nm/2226 nm was then used with the standard curve (Figure 4B) to predict lomefloxacin HCl content. The three-factor PLS calibration equation was also used to determine lomefloxacin content using the "Predict Percent" feature of the NSAS software. Lomefloxacin contents determined from both NIR methods and the extraction/UV method are shown in Table 3. These results were statistically analyzed for significant differences in the accuracy and precision of the two methods. Results of the statistical analysis are summarized in Table 4. The paired t-test and Wilcoxon signed rank test gave 95% confidence intervals containing zero and p-values greater than 0.05, indicating that results for lomefloxacin content predicted by NIR were not statisti-

SEP	1.05	1.73	0.70
paired *t*-test			
•95% interval	(–0.545, 1.137)	(–1.412, 1.480)	(–0.059, 0.864)
•*p*-value	$p > 0.05$	$p > 0.05$	$p > 0.05$
Wilcoxon signed rank test			
•95% interval	(–0.42, 1.07)	(–1.26, 1.57)	(–0.015, 0.810)
•*p*-value	$p > 0.05$	$p > 0.05$	$p > 0.05$
F-test	$p < 0.05$	$p < 0.05$	$p > 0.05$

cally different than results from UV analysis in terms of accuracy. SEC and SEP values (Table 4) for each calibration model were similar to one another and low in value (i.e. < 2%), further validating the calibration models. The NIR calibration models may be compared by means of the *F*-test shown in Table 4. While both single wavelength and PLS methods give results comparable in accuracy to the extraction/UV method, the PLS method yields more precise results (*p*-value > 0.05) than the single wavelength method. The smaller SEC and SEP values for the PLS model further verify this result. This finding suggests that PLS models may be more useful when accurate and precise mean content is required.

NIR Spectral Interpretation—The results above demonstrate the utility of NIR spectroscopy for determination of lomefloxacin HCl within polymer implants. To structurally interpret NIR results, it is advantageous to utilize a portion of the NIR spectrum unique to the compound of interest and that is predictable from mid-infrared data. With this approach, a nondestructive analytical technique directly related to structural features of the analyte could be developed. Interpretation is often accomplished with the use of wavelength tables which relate common functionalities to corresponding NIR absorption bands.[20,25–28] One disadvantage of using these tables is that absorption bands for a given functionality are often broad, resulting in several functionalities which may be expected to have overtone transitions within the same region. This ambiguity may be alleviated through the use of the corresponding mid-infrared data. NIR absorption bands are the result of overtones or combinations of overtones originating in the fundamental midrange (4000−600 cm^{-1}) infrared region of the spectrum.[29] When frequencies of fundamental transitions in the mid-infrared region of the spectrum are known, the position of expected near-infrared absorption bands may be calculated. The overtone transitions (λ) will occur at integer multiples (n) of fundamental vibrational frequencies (ν_{IR}), which may be estimated from known mid-infrared absorption bands using:

$$\lambda = \frac{10\,000\,000}{n\nu_{IR}(cm^{-1})} \quad (1)$$

Sanzgiri et al. obtained the mid-infrared spectrum for lomefloxacin HCl and assigned mid-infrared absorption bands to various functionalities (Table 5).[30] Overtone transitions from the mid-infrared absorption bands were calculated using eq 1.

As shown previously, the NIR response at a wavelength ratio of 2172 nm/2226 nm correlated well with lomefloxacin content, and these results were comparable to UV analysis. These wavelengths do not correspond to the predicted overtone transitions of the assigned bands (Table 5). Because the use of infrared data did not provide a useful interpretation of the 2172 nm region, various NIR tables

Table 5—Mid-Infrared Transitions and Calculated Overtone Transitions for Lomefloxacin HCl[a]

infrared fundamental[a]	assignment	theoretical 1st overtone (nm)	theoretical 2nd overtone (nm)
3703 nm (2700 cm^{-1})	NH_2^+ stretch	1852	1235
6172 nm (1620 cm^{-1})	carbonyl stretch (pyridinone ring)	3086	2058
8278 nm (1208 cm^{-1})	aryl fluorides	4139	2759

[a] Mid-infrared absorption peaks and assignments are from Sanzgiri et al.[30]

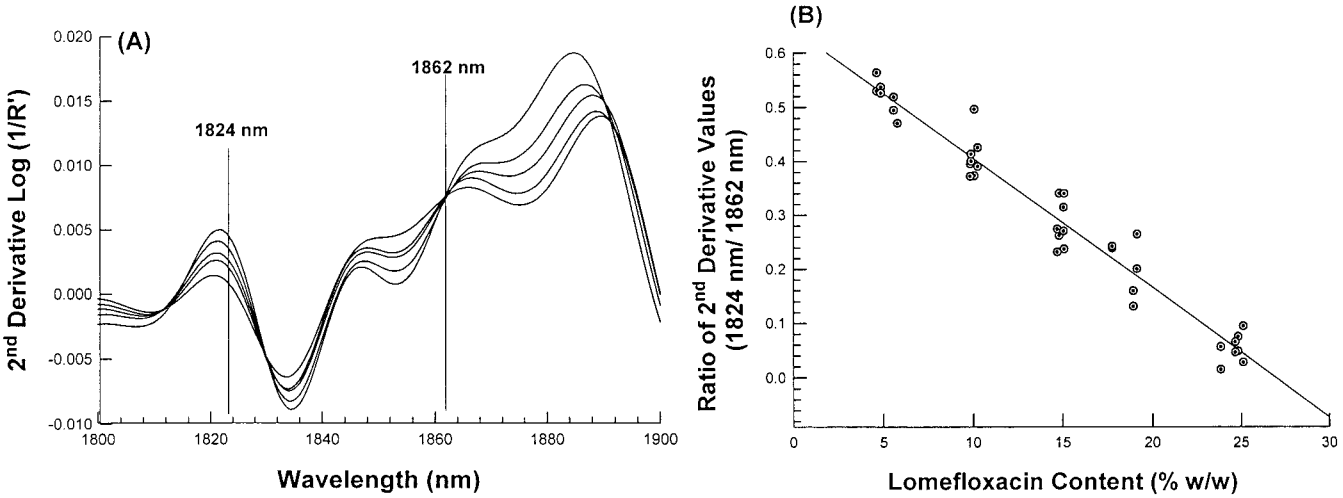

Figure 5—(A) Expanded second derivative NIR spectra for PCL:PEG implants containinglomefloxacin HCl contents. Content from top to bottom at 1824 nm: 25, 20, 15, 10, and 5% w/w; the normalizing wavelength (1862 nm) is indicated. (B) NIR standard curve for lomefloxacin HCl content in PCL:PEG implants using a ratio of second derivative values (1824 nm/1862 nm) (R^2 = 0.955, S. E. = 0.0364).

were utilized to provide an interpretation of why this provided good correlation. Amines are reported to have an combination N−H stretch in the region of 2100−2200 nm.[14] Lomefloxacin HCl is the only amine-containing species within these implants, and thus we may interpret our correlation at 2172 nm as being due to N−H combination frequencies within the NIR. It should be noted that increasing relative reflectance values within the NIR spectra will lead to decreasing second derivative values. The 2172 nm wavelength could not be predicted from mid-IR data since the mid-IR data will only provide information about overtone transitions occurring from specific functional groups, not from combination frequencies.

Since a reasonable correlation attributable to an amine combination was found at 2172 nm, we may also expect to find good correlation in the region where a first overtone may be expected from the mid-IR data. From Table 5, a protonated amine vibrational stretch would be expected to have a theoretical first overtone transition at 1852 nm. The second derivative spectra of lomefloxacin-containing implants were investigated for correlation with lomefloxacin content in the range of 1800 to 1900 nm corresponding with the theoretical first overtone transition as predicted from the known IR spectrum. Another wavelength ratio (1824 nm/1862 nm) also provided good correlation with lomefloxacin content. This region of the NIR spectra has been expanded and is shown in Figure 5A. A standard curve was constructed from the second derivative ratio of responses at 1824 nm/1862 nm versus lomefloxacin content determined from the extraction/UV assay results. The resulting standard curve (R^2 = 0.955, S. E. = 0.036) is given in Figure 5B. The increased scatter in the data may be attributable to the weaker absorbance found in the 1800−1900 nm range. Various other transitions such as carbon−hydrogen first overtone transitions also occur in this region and may also contribute to the increase in scatter of the data at 1824 nm.[14] To test the predictive ability of the NIR at this new wavelength ratio, second derivative responses at 1824 and 1862 nm were obtained from the test set of implants and used with the standard curve in Figure 5B to predict lomefloxacin content as shown in Table 3. A statistical analysis was performed to compare these results with previous NIR and extraction/UV results. Results from this statistical analysis are shown in Table 4. As can be seen from Table 4, the paired *t*-test and Wilcoxon signed rank test give 95% confidence intervals containing zero and *p*-values greater than 0.05. Furthermore, the SEC and SEP values for the NIR calibration at this new wavelength are similar to one another and small in value. These results indicate that there is no statistical difference in the accuracy of mean lomefloxacin content predicted by NIR (1824 nm/1862 nm) or UV analysis. The significance of this is that the wavelengths correlated well with first overtone expectations for a protonated amine as calculated from mid-infrared data. This ratio also provided reasonable correlation with results from extraction/UV analysis. The high correlation in the 1800−1900 nm region where an expected N−H first overtone transition would occur supports the proposed N−H combination interpretation for the 2172 nm/2226 nm ratio. These results demonstrate that mid-infrared data may be useful in structural interpretation of NIR spectra and can help to verify interpretation of NIR combination transitions not predictable from mid-IR spectra alone.

Although the 1824 nm/1862 nm wavelength ratio provides results with comparable accuracy as the extraction/UV technique, the *F*-test demonstrates the single wavelength NIR method (1824 nm/1862 nm) does not give results with the same precision (i.e. p-value < 0.05). The PLS method appears to be the most robust method in terms of accuracy and precision; however, it should be noted that the PLS method does not allow for a similar direct interpretation of the NIR data.

Conclusions

NIR spectroscopy is an accurate and nondestructive method for quantifying components within polymeric implants and provides a useful alternative to traditional destructive techniques. This nondestructive technique may be particularly useful in the early stages of product development when drug supply is limited or when dose uniformity is an issue within test formulations. In the case of polymer matrix systems, excipients such as poly(ethylene glycol) are not normally assayed. Given the importance these excipients have in controlling the release rate of active components, it is critical to assess both the quantity and uniformity of these excipients within the polymeric dosage form. NIR seems to provide an excellent and rapid nondestructive method for quantitation of poly(ethylene glycol), an excipient which is tedious and time-consuming to quantify by other analytical methods.[24] Preliminary work suggests that similar results may be obtained for quantifying actives within other polymeric dosage forms such as microspheres or films.[31] Selection of analytical wavelengths in the near-infrared region corresponding to structural features of the analyte may be accomplished with the use of corresponding mid-infrared spectral data and NIR frequency (wavelength) tables.

Abstract □ The objective of this study was to identify critical formulation and processing variables affecting aggregation of bovine IgG during freeze-drying when no lyoprotective solute is used. Parameters examined were phosphate buffer concentration and counterion (Na versus K phosphate), added salts, cooling rate, IgG concentration, residual moisture level, and presence of a surfactant. No soluble aggregates were detected in any formulation after either freezing/thawing or freeze-drying. No insoluble aggregates were detected in any formulation after freezing, but insoluble aggregate levels were always detectable after freeze-drying. The data are consistent with a mechanism of aggregate formation involving denaturation of IgG at the ice/freeze–concentrate interface which is reversible upon freeze–thawing, but becomes irreversible after freeze-drying and reconstitution. Rapid cooling (by quenching in liquid nitrogen) results in more and larger aggregates than slow cooling on the shelf of the freeze-dryer. This observation is consistent with surface area measurements and environmental electron microscopic data showing a higher surface area of freeze-dried solids after fast cooling. Annealing of rapidly cooled solutions results in significantly less aggregation in reconstituted freeze-dried solids than in nonannealed controls, with a corresponding decrease in specific surface area of the freeze-dried, annealed system. Increasing the concentration of IgG significantly improves the stability of IgG against freeze-drying-induced aggregation, which may be explained by a smaller percentage of the protein residing at the ice/freeze–concentrate interface as IgG concentration is increased. A sodium phosphate buffer system consistently results in more turbid reconstituted solids than a potassium phosphate buffer system at the same concentration, but this effect is not attributable to a pH shift during freezing. Added salts such as NaCl or KCl contribute markedly to insoluble aggregate formation. Both sodium and potassium chloride contribute more to turbidity of the reconstituted solid than either sodium or potassium phosphate buffers at similar ionic strength, with sodium chloride resulting in a substantially higher level of aggregates than potassium chloride. At a given cooling rate, the specific surface area of dried solids is approximately a factor of 2 higher for the formulation containing sodium chloride than the formulation containing potassium chloride. Turbidity is also influenced by the extent of secondary drying, which underscores the importance of minimizing secondary drying of this system. Including a surfactant such as polysorbate 80, either in the formulation or in the water used for reconstitution, decreased, but did not eliminate, insoluble aggregates. There was no correlation between pharmaceutically acceptability of the freeze-dried cake and insoluble aggregate levels in the reconstituted product.

Introduction

Freeze-drying is usually the method of choice for manufacture of protein pharmaceutical and diagnostic agents which are physically or chemically unstable in aqueous solution and may be used in protein purification for concentration of proteins and to store the process intermediate in a relatively nongrowth promotive state. However, a major challenge in development and manufacture of such products is minimization of damage to proteins due to stresses arising from the freeze-drying process itself. Much of the published literature on freeze-drying of proteins deals with the use of protective solutes, particularly disaccharides, to minimize freeze-drying-induced damage.[1−4] There is only a small body of literature on the effects of processing conditions on protein integrity in the absence of protective solutes.[5−7]

Immunoglobulins represent a class of proteins which are important both as pharmaceuticals and as diagnostic agents. Immunoglobulins are also prone to formation of aggregates during freezing[8] and freeze-drying.[3,9] While protective solutes have been shown to be effective in minimizing aggregation, the use of sucrose, for example, as an excipient should be approached with caution for IgG formulations intended to be administered in large doses due to reported acute renal toxicity.[10] In addition, some immunoglobulins for which the final formulation is a sterile solution are freeze-dried as a process intermediate, where it may be desireable to minimize added solutes.

Within the limited body of published literature on aggregation of immunoglobulins in response to freeze-drying, variation in the immunoglobulin used as well as experimental conditions (protein concentration, buffer composition, added salts, and specific freezing and freeze-drying conditions) makes the formulation of general conclusions regarding the relative impact of these variables on aggregate formation uncertain. For example, Hansson[8] reported that high levels of insoluble aggregates (42%) were formed after multiple freeze−thaw cycles at −20 °C as measured by ultracentrifugation. In this study, IgG was dissolved in 0.05 M phosphate buffer and 0.5 N NaCl at pH 7. The buffer salt used (sodium or potassium) was not specified, and the buffer contained an unusually high level of added salts. Paborji et al.,[9] using 0.05 M sodium phosphate buffer and 0.5 N NaCl, investigated the impact of multiple freeze/thaw cycles on aggregation of a chimeric

L6 mouse−human monoclonal IgG_1 antibody by size exclusion HPLC (HPSEC). Loss of monomer and the formation of soluble dimers (2.5−16%) were observed under these conditions. Higher buffer concentration favored dimer formation, but the effect of pH change during freezing on dimer formation was uncertain. IgG concentration in the range of 1−10 mg/mL was reported not to have a significant effect on aggregation.

Identification of critical solution attributes and processing factors is essential in order to minimize empiricism in the development of formulation and processing conditions for protein pharmaceuticals. The broad objective of this project was to develop a better understanding of the role of formulation and process parameters in development of aggregates during freezing and freeze-drying of bovine IgG when no lyoprotectant is present. The specific objectives were to determine the relative importance of the following factors in aggregate formation after freeze/thaw and freeze-drying of bovine IgG formulations: IgG concentration, phosphate buffer composition, added salt, cooling rate, residual moisture, and the presence of surfactants typically used to minimize surface denaturation.

Experimental Section

Materials—Bovine IgG was obtained from Calbiochem-Novabiochem Corporation (La Jolla, CA) as a solution of concentrated bovine IgG in 0.01 M sodium phosphate buffer (pH 7.2) containing 0.15 N NaCl. The IgG solution was dialyzed against various buffer compositions using a dialysis cassette (Slide-A-Lyzer, Pierce Chemical Company, Rockford, IL) for at least 12 h at 4 °C with gentle stirring. IgG concentration was determined at 280 nm using a molar absorption coefficient of 1.3 mg^{-1} mL cm^{-1} (obtained from Calbiochem-Novabiochem Corporation). Disodium, monosodium, dipotassium, monopotassium phosphate, potassium chloride, and sodium chloride salts were obtained from Mallinckrodt Chemical (Paris, KY). Urea and sodium n-dodecyl sulfate (SDS) were obtained from Sigma Chemical Company (St. Louis, MO) and Calbiochem-Novabiochem Corporation (La Jolla, CA), respectively. Polysorbate 80 was obtained from Sigma Chemical Co (St Louis, MO). All materials were reagent grade or better.

Methods—The pH was adjusted at 25 °C with 0.1 N KOH, NaOH, or HCl to 7.1 for solutions of IgG in the presence of 0.22 N KCl and 0.22 N NaCl. The concentration of IgG was 1 mg/mL except where noted.

Freezing and Freeze-Drying—IgG solutions (1.5 mL fill volume) were placed in 5 mL serum vials (Baxter Scientific, McGaw Park, IL). Two freezing methods were investigated. Fast cooling was carried out by dipping vials in liquid nitrogen before transferring to a freeze-dryer shelf precooled to −45 °C. Slow cooling was accomplished by placing vials directly on the shelf of the lyophilizer at room temperature and decreasing the shelf temperature at a rate of 2 °C/min. For freeze−thaw experiments, thawing was carried out by allowing frozen solutions to thaw at room temperature.

Frozen solutions were held at −45 °C for at least 6 h before beginning freeze-drying (Lyoflex 08, BOC Edwards Calumatic, Tonawanda, NY or Dura-Stop, FTS Systems, Inc., Stone Ridge, NY). The system was evacuated to a pressure of 100 mTorr at −40 °C and held for 26 h (primary drying). The shelf temperature was then increased to 25 °C at a heating rate of 0.1 °C/min and held for a period of 24 h. Type T thermocouples were placed in the bottom center of two different vials to monitor product temperature. A sample thief was used to withdraw vials at different times during drying without disturbing the cycle. At the end of secondary drying, the samples were stoppered under vacuum and analyzed within 24 h.

Annealing experiments were carried out by rapidly cooling vials containing solutions of IgG in 0.01 M potassium phosphate buffer with 0.22 N NaCl (pH 7.1) by dipping in liquid nitrogen, followed by placing on the freeze-dryer shelves at −45 °C. Vials were then warmed to −15 °C at a rate of 2 °C/min for 3 h, followed by decreasing the shelf temperature to −45 °C. Rapidly cooled vials that were not annealed were used as a control. Freeze-drying was carried out as described above.

Measurement of pH Changes during Freezing—A method similar to that described by Gomez[11] was used to measure pH in frozen solutions. A special combination pH electrode (Ingold, Mettler-Toledo, Wilmington, MA) using a reference solution consisting of a mixture of glycerol and potassium chloride permits measurement of pH at temperatures as low as −30 °C. Calibration was done at room temperature with buffers of pH 4, 7, and 10 (Baxter Diagnostics, Inc., Deerfield, IL). A universal pH indicator solution (Fisher Scientific, NJ) was also used to visually verify the results, particularly for quench-cooling in liquid nitrogen. A 5 mL serum vial containing 4 mL of the appropriate formulation, two type T thermocouples (32 gauge), and the pH electrode was placed on the lyophilizer shelf at room temperature. The shelf temperature was decreased from 25 °C to −30 °C at a rate of 2 °C/min and held at −30 °C for at least 4 h. The results of pH changes obtained under these conditions were reproducible (standard deviation of ±0.17 at −30 °C).

Determination of Insoluble Aggregates—Absorbance was measured at 350 nm by a UV/visible spectrophotometer (Shimadzu Model 160U, Kyoto, Japan). All measurements were carried out in triplicate, and the appropriate buffer solution without IgG was used as a blank. To study the effect of bovine IgG concentration on aggregation, concentrations ranging from 0.5 to 8 mg/mL in the same buffer system were freeze-dried as described above and reconstituted with distilled water. A limited number of studies were also carried out where reconstituted freeze-dried solids were filtered and the absorbance measured at 280 nm in order to compare the two methods.

Size Exclusion Chromatography—High performance size exclusion chromatography (HPSEC) was used to measure soluble aggregates. The system consisted of a solvent pump, injector, UV detector and integrator (Waters Inc, Milford, MA). A Bio-Sil TSK-400 column (300 × 7.8 mm) from Biorad (Hercules, CA) was used with detection at 280 nm. The mobile phase consisted of 0.1 M Na phosphate buffer containing 0.01 M sodium azide and 150 mM NaCl at a final pH of 6.8. The flow rate was 1 mL/min and analysis time was approximately 20 min. The column was calibrated with molecular weight standards (Biorad Inc, Hercules, CA), including thyroglobulin (670 000), bovine γ globulin (158 000), chicken ovalbumin (44 000), horse myoglobulin (17 000), and vitamin B-12 (1350). Before injection, samples were filtered through a 0.22 mm filter (Acrodisc LC, Waters Corporation, Ann Arbor, MI). The injection volume was 100 μL.

Other Methods—Water content was determined by Karl Fischer (KF) analysis with coulometric end point detection (Model 150, Denver Instruments, Arvada, CO). All measurements were carried out in triplicate. Dynamic light scattering studies on reconstituted IgG solutions were done by Protein Solutions, Inc. (Model SEM F60, Charlottesville, VA) using a He Ne laser at 633 nm. Scattering was measured at 60° from the incident beam.

The specific surface area of freeze-dried powders was measured by nitrogen adsorption (Model ASAP 2010 Micromeritics, Norcross, GA). Five data points were used to determine the adsorption isotherm. Lyophilized samples were outgassed at 30 °C for at least 48 h to remove moisture. Four replicates were determined for each sample. Environmental scanning electron microscopy was used to examine lyophilized powders (Model 2020, Philips, Inc., Wilmington, MA). Ten milligrams of the appropriate lyophilized powder was spread on a conductive carbon tape and placed on an aluminum mount. The accelerating voltage was 15 kV at a chamber pressure of 5 Torr.

Results and Discussion

Characterization and Quantitation of Aggregates—Absorbance at wavelengths ranging from 350 to 650 nm[7,12−14] is commonly used as a convenient measure of relative levels of insoluble aggregates in protein formulations, particularly at low levels of aggregation.[15] Absorbance vs wavelength data are presented in Figure 1 for IgG at 1 mg/mL in 0.01 M potassium phosphate buffer containing 0.22 N NaCl after freeze−thawing and after freeze-drying and rehydration following both slow and fast cooling. Note that absorbance is negligible for freeze/thawed samples in the range of 325−500 nm. A sharp increase in optical density due to scattering from insoluble

Table 1—Summary of Absorbance at 350 nm, Percent Aggregate after Filtration, and Surface Area of Freeze-Dried Solids

buffer formulations with 1 mg/ml IgG	freezing conditions	absorbance (350 nm)	% aggregate	surface area (m^2/g)
0.01 M KPB + 0.22 N NaCl	slow	0.71 ± 0.04	20.0 ± 1.9	6.6 ± 1.4
0.01 M KPB + 0.22 N NaCl	quench cooled	0.81 ± 0.06	29.9 ± 0.7	10.9 ± 1.3
0.01 M KPB + 0.22 N KCl	slow	0.36 ± 0.02	10.0 ± 2.0	3.6 ± 0.2
0.01 M KPB + 0.22 N KCl	quench cooled	0.5 ± 0.03	14.0 ± 2.0	5.3 ± 0.1
0.01 M KPB + 0.22 N NaCl	quench cooled and then annealed 3 h at –15 °C	0.55 ± 0.02	12.2 ± 1.0	7.7 ± 1.3
0.01 M KPB + 0.22 N NaCl	quench cooled	1.0 ± 0.01	32.7 ± 1.7	17.6 ± 0.5

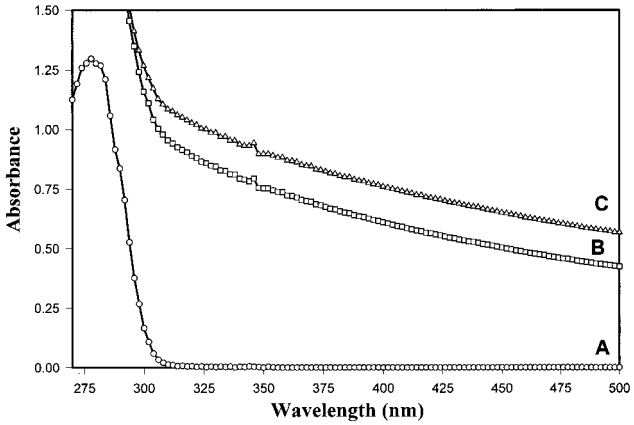

Figure 1—Absorbance vs wavelength of samples containing IgG (1 mg/ml) in a 0.01 M potassium phosphate buffer containing 0.22 N NaCl: (A) after freezing/thawing, (B) after freeze-drying following cooling at 2 °C/min, (C) after freeze-drying following quench-cooling in liquid nitrogen.

aggregates is observed after freeze-drying and, as expected, the extent of scattering increases with decreasing wavelength. Freeze-drying following rapid cooling consistently results in higher absorbance compared with slow cooling. On the basis of these data, 350 nm provides the best sensitivity for measuring turbidity while avoiding absorption due to the protein itself. This wavelength was used in all subsequent studies. A good rank order correlation was observed between absorbance at 350 nm and the quantity of protein remaining after filtration of reconstituted freeze-dried solids (Table 1).

HPSEC chromatograms of the formulation represented in Figure 1 are shown in Figure 2, where the peak at 9.8 min represents the IgG monomer. No soluble aggregates are observed after either freeze–thawing or freeze-drying. The monomer peak area is the same after freeze–thawing as that for the unfrozen solution, but decreases after freeze-drying because of formation of insoluble aggregates which are filtered out during sample preparation. Again, rapid cooling results in higher levels of insoluble aggregates than slow freezing, as reflected by the smaller peak area of the rapidly cooled, freeze-dried material. A peak arising (12.5 min retention time) from an IgG fragment with an apparent molecular weight less than about 6000 was always observed in chromatograms of freeze-dried IgG, but was not characterized further in this study.

The insoluble aggregates were completely dissolved by either 6 M urea or by 0.4% (w/v) sodium dodecyl sulfate (SDS). Only one peak, corresponding to the IgG monomer, was observed in the HPSEC chromatogram of solubilized aggregated material (data not shown). These observations support the conclusion that only noncovalent aggregates are observable under the experimental conditions reported here.

Dynamic light scattering data for insoluble aggregates formed by both fast and slow cooling are shown in Figure 3. Rapid freezing consistently results in larger aggregates, with an average particle size of about 1 μm, as compared

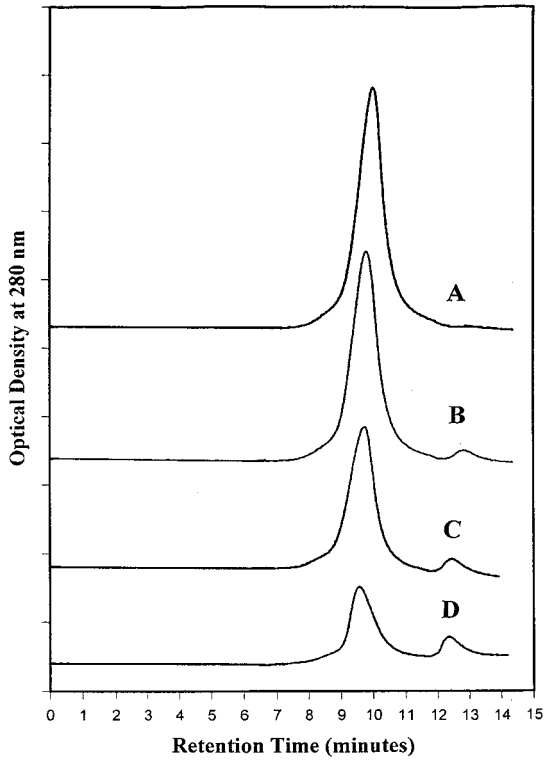

Figure 2—HPSEC chromatograms of bovine IgG in 0.01 M potassium phosphate buffer containing 0.22 N NaCl: (A) solution before any treatment, (B) after freezing/thawing, (C) after freeze-drying (slow cooling at 2 °C/min), (D) after freeze-drying (quench-cooling in liquid nitrogen).

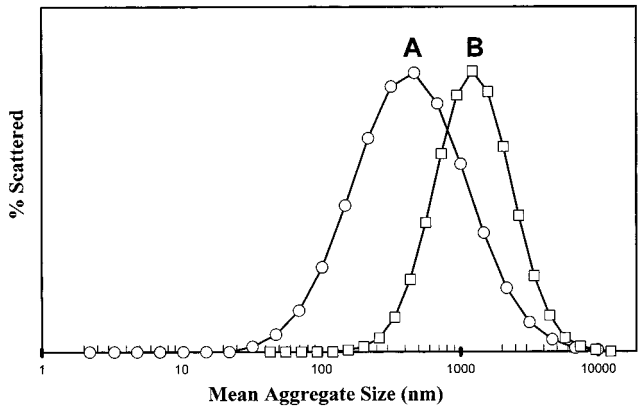

Figure 3—Effect of freezing rate on mean aggregate size of IgG, determined by dynamic light scattering: (A) slow cooling, (B) quench-cooling in liquid nitrogen.

with an average particle size of about 400 nm for slow cooling. The reason for the difference in average particle size is not known at present.

The data in Figures 1–3 demonstrate that fast cooling consistently results in higher levels of aggregated protein in a buffer containing 0.01 M potassium phosphate (pH 7.1)

with 0.22 N NaCl as compared with slow cooling. Similar results were obtained with 0.01 M potassium phosphate buffer (pH 7.1) and 0.22 N KCl (absorbance values of 0.36 vs 0.50 for slow and rapid cooling, respectively). These data add to the growing body of published data supporting the conclusion that rapid freezing can be detrimental to protein integrity. Eckhardt et al.,[14] using several formulations of human growth hormone and an apparatus for controlling cooling rate, demonstrated that the level of insoluble aggregate after freeze/thawing is directly related to the freezing rate over the range of 0.5 °C to 50 °C/min. Hsu et al.,[12] using formulations of tissue plasminogen activator (tPA), reported a direct relationship between freezing rate and development of turbidity in reconstituted samples during storage. These investigators postulated that denaturation takes place at the solid/void interface, which results in aggregate formation upon reconstitution. Chang and co-workers,[7] using multiple freeze−thaw cycles of phosphofructokinase, lactate dehydrogenase, glutamate dehydrogenase, interleukin-1 receptor antagonist, tumor necrosis factor, and ciliary neurotropic factor demonstrated that slow freezing resulted in less turbidity in thawed samples than freezing in liquid nitrogen. Jiang and Nail,[6] using lactate dehydrogenase and β-galactosidase, also reported that rapid freezing in liquid nitrogen resulted in lower recovery of enzyme activity after freeze−thawing compared with freezing in a freeze-dryer.

Strambini and Gabellieri[16] have proposed a mechanism for freezing-induced damage to proteins involving partial unfolding of proteins after adsorption to the ice surface. If this mechanism is operative, then more rapid freezing would be expected to result in a higher ice/freeze-concentrate interfacial area, a greater extent of protein adsorption, and more damage to the protein. While no aggregation is detected in bovine IgG after freeze/thawing under the conditions reported here, our data are consistent with this mechanism, where partial denaturation following adsorption to the ice surface is reversible after freeze/thawing. However, subsequent drying would result in a partially denatured protein in the solid state, which forms aggregates upon reconstitution.

To test the hypothesis that rapid freezing inhibits sodium phosphate precipitation, a pH universal indicator was used. No difference was observed after slow vs fast cooling (both showing an acidic pH shift) despite a significant difference in the amount of aggregates after freeze-drying and reconstitution.

Environmental SEM photomicrographs (Figure 4) show distinctly different morphologies for the freeze-dried powders following cooling at different rates. The slowly cooled specimen appears as relatively large filaments, whereas the rapidly cooled material appears to be more finely divided.

Table 1 summarizes specific surface area data for freeze-dried solids from 1 mg/mL bovine IgG in potassium phosphate buffer containing both NaCl and KCl. The specific surface area of freeze-dried solids is significantly higher for quench-cooled relative to slowly cooled solutions. An unexpected result is that the specific surface area of freeze-dried solids from solutions containing NaCl is significantly higher than those containing KCl. The reason for this is not known at present, but the reduced specific surface area of solids containing KCl correlates with a lower degree of aggregation in the KCl system. This is further support for an aggregation mechanism involving partial denaturation at the ice/freeze−concentrate interface.

Effect of Annealing—If protein denaturation, and subsequent aggregation upon reconstitution, is promoted by a high ice/freeze−concentrate interfacial area following freezing, then annealing the system after fast freezing should decrease aggregation by decreasing the interfacial area. Results of an experiment to test this hypothesis are shown in Table 1. Note that the decrease in specific surface area of the annealed material relative to the quench-cooled control (17.6 vs 7.7 m^2/g) is accompanied by a decrease in percent aggregates in the reconstituted solids from 32% to about 12%. These data lend further support to an aggregation mechansim involving denaturation at the ice/freeze-concentrate interface that becomes irreversible upon drying.

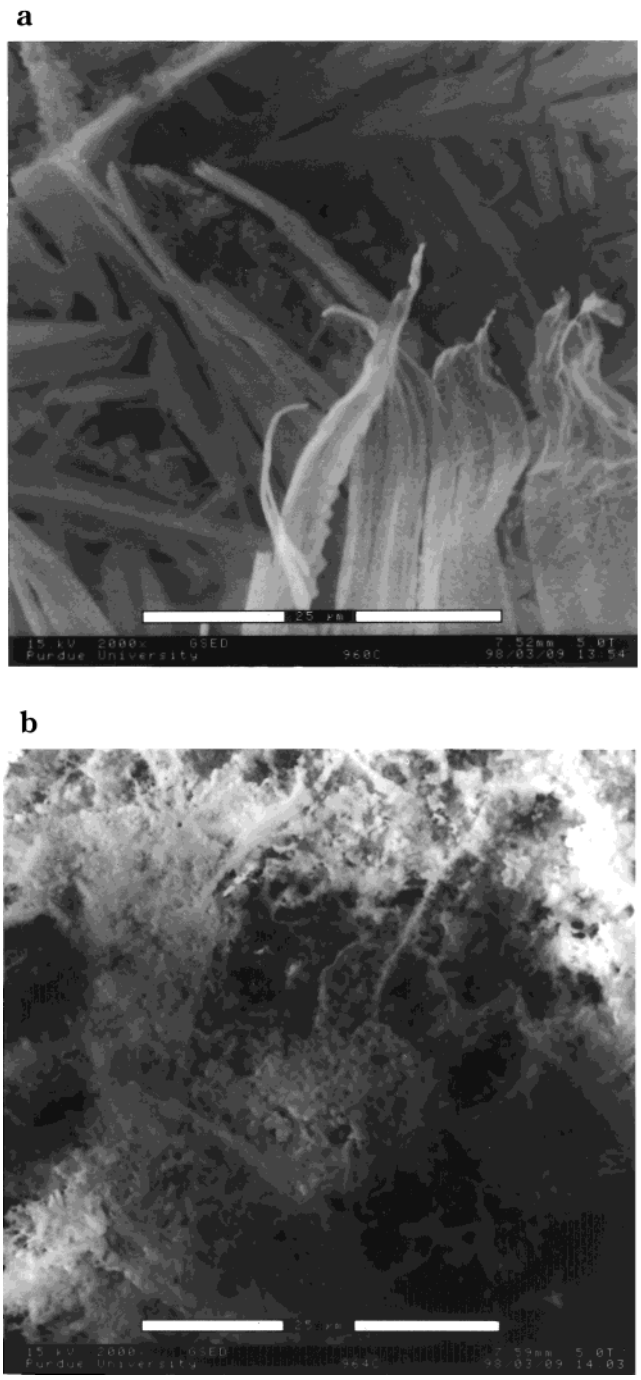

Figure 4—ESEM photomicrographs of freeze-dried IgG following (A) slow cooling, and (B) quench-cooling in liquid nitrogen. Magnification 2000×.

Effect of IgG Concentration—The effect of IgG concentration on both absorbance at 350 nm and on percent aggregate as determined by measuring the absorbance after filtration of the reconstituted solution after freeze-drying is shown in Figure 5 for solutions in 0.01 M

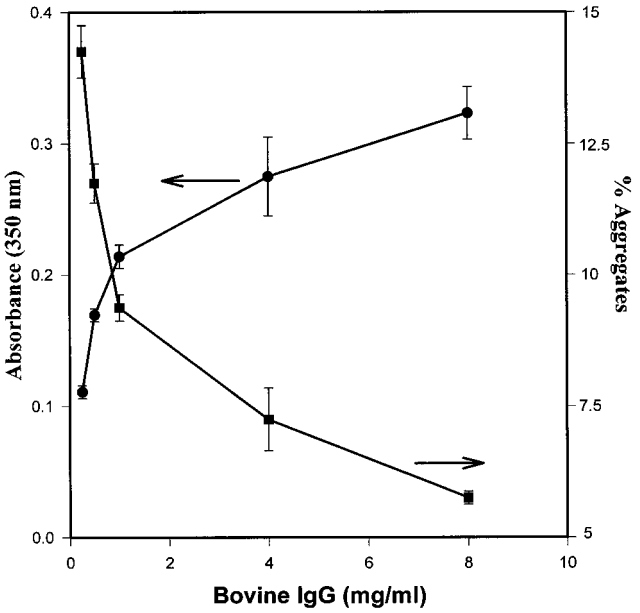

Figure 5—Effect of IgG concentration on absorbance at 350 nm and percent aggregated IgG after lyophilization. Buffer system was 0.01 M potassium phosphate with 0.22 N NaCl, frozen at a cooling rate of 2 °C/min. Error bars represent standard deviation of triplicate measurements from three separate vials.

Table 2—Residual Moisture vs IgG Concentration

bovine IgG concentration (mg/mL) before lyophilization	residual moisture
0.5	1.25 ± 0.13
1	1.32 ± 0.14
2	1.4 ± 0.2
4	2.5 ± 0.02
8	2.5 ± 0.2

potassium phosphate buffer containing 0.22 N NaCl at pH 7.1. Even though absorbance at 350 nm increases as protein concentration increases from 0.5 to 8 mg/mL, the level of insoluble aggregates decreases by more than half. This direct effect of protein concentration on stabilization against damage caused by freeze-drying has been reported by other investigators. Hansson[17] reported that the quantity of aggregate formed in human IgG after multiple freeze−thaw cycles decreased with increasing IgG concentration until, at 50 mg/mL IgG, no aggregation was observed after multiple freeze−thaw cycles. Chang et al.[7] reported that increasing the concentration of interleukin-1 receptor antagonist (from 1 to 100 mg/mL) diminished the level of aggregates from 50% to 0.01%. This effect has also been reported for β-galactosidase[6,18] and lactate dehydrogenase.[6,19] However, to our knowledge, this concentration effect has not been explained.

Residual moisture level at each concentration was measured in order to test the hypothesis that higher concentrations of protein, under the same process conditions, will result in higher residual moisture levels and prevent damage caused by "overdrying". Data are summarized in Table 2. The data do indicate that residual moisture increases with increasing concentration. However, the range of residual moisture levels is only from 1.25% to 2.5%. In the range of 4 to 8 mg/mL IgG, the residual moisture level is approximately constant, but the amount of insoluble aggregate decreases significantly. It appears that residual moisture is, at most, only a partial explanation for the concentration effect.

Anchordoquy and Carpenter[20] reported that dissociation of lactate dehydrogenase subunits, and subsequent loss of activity, was due to the large pH decrease associated with the phosphate buffer during freezing. This effect was inhibited by protective levels of polymers such as bovine serum albumin and poly(vinylpyrrolidone). To test the hypothesis that higher protein concentration inhibits crystallization of buffer salts, pH shift during freezing was measured for the lowest and highest protein concentrations used in this study. Minimal difference in pH shift was observed between the lowest and highest concentrations (4.0 vs 4.2 for 0.5 mg/mL and 8 mg/mL, respectively). Therefore, pH change during freezing does not appear to be a likely explanation for the concentration effect. The data need to be interpreted with some caution, however, since the freezing conditions were different for the experiments in which the apparent pH during freezing was measured (freezing to −30 °C) versus the freezing conditions prior to freeze-drying (freezing to −45 °C).

Increasing IgG concentration was associated with an increase in specific surface area of the freeze-dried solids (from 6.6 m^2/g at 1 mg/mL to 9.0 m^2/g at 8 mg/mL) over the concentration range studied. Combined with the absorbance data in Figure 5, these data suggest that the concentration effect may be another manifestation of aggregation as an interfacial phenomenon. The increased specific surface area of freeze-dried solids with increased concentration is accompanied by increased absorbance at 350 nm of the reconstituted solution, suggesting that the increased turbidity arises from a larger amount of protein at the ice/freeze−concentrate interface during freezing. However, the fractional amount of protein at the interface must decrease with increasing concentration, given that the specific surface area increases by a factor of about 1.5 while the concentration increases by a factor of 8. The lower percentage of protein at the interface would explain the decrease in percent aggregated protein with increased concentration.

Another explanation for the protein concentration effect that was considered is the influence of protein concentration on T_g' (the glass transition of the maximally freeze-concentrated solute), where increased protein concentration would be expected to increase T_g'. However, as with many protein formulations not containing a lyoprotectant, thermal analysis of the frozen systems did not reveal a glass transition (data not shown). The freeze-drying conditions used for the study (primary drying at −40 °C) represent the approximate lower temperature limit for production scale freeze-drying. While the low primary drying temperature should minimize collapse during freeze-drying, the potassium phosphate buffer system without added salt did exhibit collapse. As discussed below, we observed no effect of collapse during freeze-drying on level of aggregation upon reconstitution. We conclude that any protein concentration effect on T_g' would not explain the observations reported here.

Effect of Buffer Composition on Aggregation—The effect of systematic variation in solution composition at a constant IgG concentration and nearly constant ionic strength on turbidity of the reconstituted solid is shown in Figure 6. The effect of the phosphate buffer (Na vs K salt) at two concentrations (0.1 M vs 0.01 M) is examined where ionic strength is adjusted with either NaCl or KCl. At a constant buffer concentration, the potassium salt consistently results in a significantly lower level of aggregate relative to sodium phosphate ($P < 0.001$). Adding either NaCl or KCl results in increased aggregation relative to buffer alone, and sodium chloride always results in more aggregation than the same concentration of potassium chloride.

pH was measured during the freezing process in order

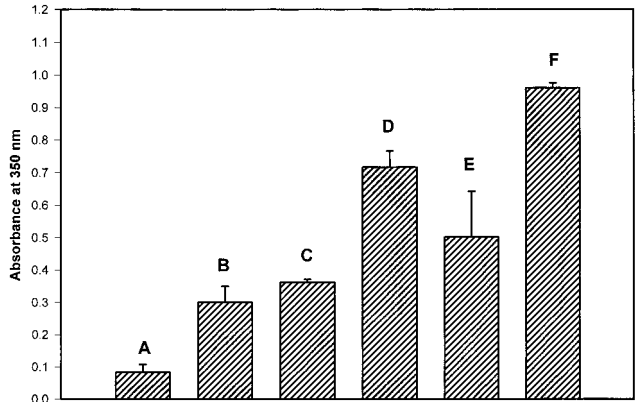

Figure 6—Effect of solution composition at similar ionic strength ($I = 0.24$ M) on IgG aggregation after freeze-drying in (A) 0.1 M potassium phosphate, (B) 0.1 M sodium phosphate, (C) 0.01 M potassium phosphate containing 0.22 N KCl, (D) 0.01 M potassium phosphate containing 0.22 N NaCl, (E) 0.22 N KCl, and (F) 0.22 N NaCl. Error bars represent standard deviation based on measurements from three separate vials.

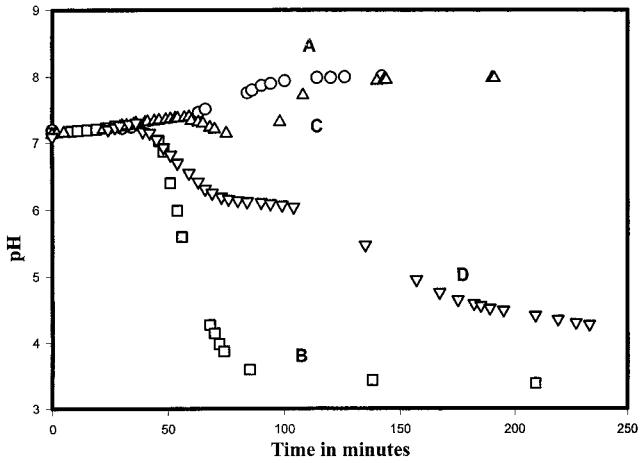

Figure 7—Apparent pH during freezing for (A) 0.1 M potassium phosphate buffer, (B) 0.1 M sodium phosphate buffer, (C) 0.01 M potassium phosphate buffer containing 0.22 N KCl, and (D) 0.01 M potassium phosphate buffer containing 0.22 N NaCl.

to examine the relationship between aggregation and pH shift during freezing. The data are summarized in Figure 7. As expected, pH increases somewhat (from 7.2 to about 8) during freezing for the potassium phosphate buffer, whereas pH decreases for the sodium phosphate buffer system (from 7.2 to about 3.5). The effect of added salt is to delay crystallization of both monobasic potassium phosphate and dibasic sodium phosphate. For potassium phosphate containing KCl, the pH of the frozen system reaches a similar pH to that of potassium phosphate buffer alone after about 100 min. For sodium phosphate buffer alone, the apparent pH reaches its equilibrium value after 100 min, but the sodium phosphate buffer containing NaCl is still slowly decreasing after 4 h. These data are in agreement with data reported by Gomez,[11] where an inhibition of disodium phosphate dodecahydrate precipitation was observed in the presence of 8 mM Na phosphate buffer containing 0.15 N NaCl.

As mentioned above, comparison of the data in Figures 6 and 7 should be made with some caution, because the pH measurements were made at −30 °C, whereas freezing of the IgG solutions was carried out at −45 °C. However, the data in Figure 7 support the conclusion that pH shift during freezing does not affect aggregation. Comparing curves B and D in Figure 7 with corresponding data in Figure 6, the level of aggregate is considerably greater for the solution containing NaCl relative to that containing sodium phosphate alone. Even if it is assumed that the solution containing sodium chloride eventually reaches the same pH during freezing as that containing buffer alone, the aggregate levels would be expected to be the same for the two systems if the pH shift during freezing were driving the aggregation process. Curves A and C in Figure 7 show that the two potassium phosphate buffer solutions reach the same apparent pH after about 2 h, but, again, the solution containing added salt results in a significantly higher level of aggregated protein. The absence of an effect of pH shift upon freezing on IgG aggregation is further illustrated in Figure 6, where 0.22 N KCl or NaCl alone (pH adjusted to 7.1) is compared to the corresponding solutions containing 0.01M potassium phosphate. Aggregate levels are significantly greater for solutions containing salt alone, where the apparent pH at −30 °C after 4 h is 6.4 and 7.0 for 0.22 N NaCl and KCl, respectively.

In studying the effect of formulation variables on the stability of freeze-dried human growth hormone, Pikal and co-workers[21] noted that the destabilizing effect of added NaCl could be attributed to either ionic strength or a specific ion effect of Na^+ or Cl^- and concluded that Cl^- is the most likely cause of the adverse effect. Our data support the conclusion that the effect of buffer solution composition on IgG aggregation is neither a pH shift effect nor an ionic strength effect, but rather a specific ion effect. Further work is in progress to test the hypothesis that the effects of added salts on IgG aggregation resulting from freeze-drying is predicted by the Hofmeister series, where destabilizing ions promote aggregation.

The freeze-dried cakes resulting from 0.1 M potassium phosphate buffer were collapsed, whereas freeze-dried solids resulting from 0.1 M sodium phosphate buffer retained their macroscopic structure. For potassium buffer systems containing NaCl or KCl, no collapse was observed. Besides illustrating that collapse during freeze-drying does not necessarily correlate with decreased integrity of a freeze-dried protein, this observation suggests that an alternative explanation for the data in Figure 6 is that residual moisture levels are different for the formulations, and that this difference in residual moisture level influences aggregation. Residual moisture levels were significantly different (2.8 ± 0.3% for 0.1 M potassium phosphate vs 1.5 ± 0.4% for 0.1 M sodium phosphate alone). To study this effect further, two formulations containing 0.01 M potassium phosphate (pH 7.1) and either 0.22 N KCl or NaCl, were compared with respect to both residual moisture level and insoluble aggregate levels by using a sample thief to remove samples during secondary drying. All samples retained their macroscopic structure. Data are summarized in Figure 8. The top panel shows that the difference in absorbance at 350 nm between the two buffer solutions is not distinguishable until the 49 h sample, at which time the absorbance of the sodium chloride system is significantly higher and remains so throughout the drying cycle. Although the residual moisture level in the potassium chloride formulation is higher than the sodium chloride formulation early in secondary drying, the residual moisture levels in the two formulations are not significantly different by the end of the cycle. The data in Figure 8 support the conclusion that the salt effect becomes evident only as the residual moisture level is decreased to 2−5%. Below this level, there is a significant effect of the added salt which is not explained by differences in residual moisture. No difference in cake appearance was observed between time 1, time 2, and samples taken at the end of the cycle (Figure 9). These data are consistent those of Hsu et al.[22] for tPA, where protein integrity is lost by overdrying.

Effect of a Surfactant on Aggregation—Nonionic

Table 3—Effect of Polysorbate 80 on IgG Aggregation

sample information	medium of reconstitution	absorbance (350 nm)
0.01 M KPB + 0.22 N NaCl, pH 7.1 containing 1 mg/mL bovine IgG	distilled water	0.54 ± 0.06
0.01 M KPB + 0.22 N NaCl, pH 7.1 containing 1 mg/mL bovine IgG and 0.02% w/w Tween 80	distilled water	0.18 ± 0.02
0.01 M KPB + 0.22 N NaCl, pH 7.1 (25 °C) containing 1 mg/mL bovine IgG and 0.1% w/w Tween 80	distilled water	0.18 ± 0.05
0.01 M KPB + 0.22 N NaCl, pH 7.1 containing 1 mg/mL bovine IgG	0.02% w/w Tween 80	0.15 ± 0.01

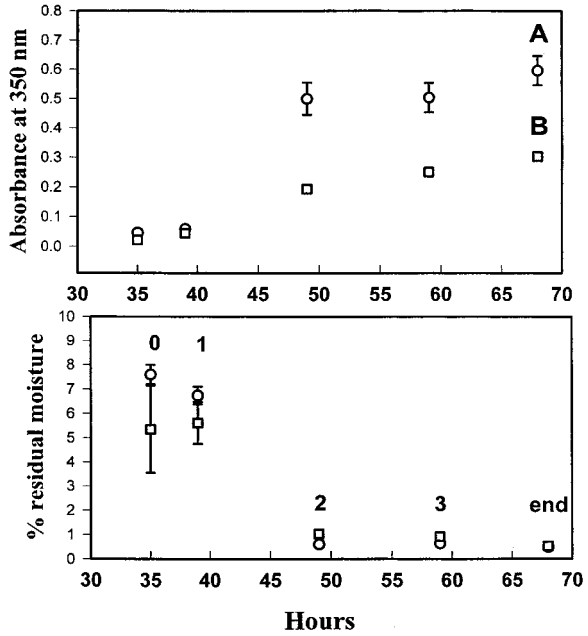

Figure 8—Effect of secondary drying time on absorbance at 350 nm and residual moisture: (A) 0.01 M potassium phosphate containing 0.22 N NaCl, (B) 0.01 M potassium phosphate containing 0.22 N KCl. Error bars represent the standard deviation of triplicate measurements from three separate vials.

Figure 9—Reconstituted vials of lyophilized bovine IgG in 0.01 M potassium phosphate with 0.22 N NaCl removed during secondary drying, showing development of turbidity in the reconstituted product.

surfactants are commonly used in formulations to prevent protein adsorption to surfaces and to minimize interfacial denaturation by preferentially adsorbing to hydrophobic surfaces and to hydrophobic regions of proteins. Table 3 summarizes absorbance data at 350 nm obtained for reconstituted solids with and without polysorbate 80 in the medium of reconstitution or in the formulation before freeze-drying. Use of a surfactant—either in the reconstitution medium or in the formulation—significantly decreases, but does not eliminate, aggregation. No difference is observed in aggregation between a formulation containing 0.02% or 0.1% w/w polysorbate 80. No significant difference was observed between incorporation of the surfactant in the formulation and incorporation in the medium of reconstitution. These data contrast with those of Chang and co-workers,[7] who reported essentially complete protection of six different proteins by incorporation of 0.01% polysorbate 80 into the formulation prior to freezing. Incorporation of surfactant into the reconstitution medium instead of the formulation was less effective in the case of interleukin-1 receptor antagonist, but still reduced the quantity of aggregate relative to reconstitution with water alone (23% vs 50% aggregate, respectively).

Practical Considerations—The data reported here are consistent with the body of literature pointing to protein aggregation resulting from freezing and freeze-drying as an interfacial phenomenon. While further investigation is warranted, particularly in the area of specific ion effects, several broad conclusions may serve as guidelines for development of protein formulations and processing conditions. First, keep the protein concentration as high as practical. Second, minimize the buffer concentration and do not use additional salts unless necessary. From the standpoint of aggregation, potassium phosphate buffer appears to be preferable to sodium phosphate buffer, and potassium chloride is preferable to sodium chloride. Identification of critical process parameters should include thermal history of freezing, since a number of reports suggest that rapid freezing should be avoided. Particular attention should be given to establishment of residual moisture specifications, particularly since the conventional wisdom that "the dryer, the better," is not always true.

Abstract □ The dispersion model has been widely used to analyze local pharmacokinetics in the organs and the tissues since the 1980's. However, an ambiguity still remains in selecting the boundary conditions which are necessary to solve the basic equation of the model. In this note, theoretical considerations are given to this problem and we present here some deficiencies of the mixed boundary conditions. It seems that theoretical confusion exists in the literature for the mixed boundary conditions. It is well-known that the solution of the dispersion model with a bolus input is the inverse Gaussian distribution for the mixed boundary conditions. However, it is rarely recognized that the inverse Gaussian distribution requires an open boundary at either the inlet or the outlet. For the analysis of local pharmacokinetics, the use of the classical Danckwerts (or closed) boundary conditions is recommended.

Introduction

To predict in vivo organ clearances from in vitro findings, a mathematical model that assumes certain structured blood flow is indispensable. It has been reported that the convection dispersion model[1,2] and distributed tube model[3,4] are sound models which give appropriate predictions of organ clearance in various situations. These two models afford similar predictions in linear kinetics,[5] but not in nonlinear kinetics.[4−6] This is because the distributed tube model does not assume any micromixing of the blood stream in the bed. In contrast, micromixing is incorporated naturally into the dispersion model.

The dispersion model was proposed by Roberts et al. in the 1980s[1,2] and has been used to analyze local pharmacokinetics in various situations.[7−11] The dispersion model is expressed by a partial differential equation, and to obtain its solution, the entrance and the exit boundary conditions are necessary. A drawback of the dispersion model is an ambiguity in selecting the boundary conditions.[4] Roberts et al. initially chose the Danckwerts (or closed) boundary conditions (DBC) because it satisfies the extremes of the well-stirred and tube model predictions,[1] but later favored the mixed boundary conditions (MBC).[5] MBC have also been preferred by several other investigators.[4,7−9]

The solution for MBC is apparently equivalent to a probabilistic distribution of the rate of first passage of particles moving randomly (as a random walk) that is referred to as the inverse Gaussian distribution.[2] A random walk is a discrete process but is superimposed on a convection flow by limiting the size of the steps and by expanding the basic equation in a Taylor series.[12] Accordingly, MBC has been related to the first passage time.[5] However, there is a pitfall, as will be discussed later.

In this correspondence, theoretical considerations are given to the ambiguity of the boundary conditions of the dispersion model. Some deficiencies of MBC will be discussed. We recommend the use of DBC.

Deficiencies of the Mixed Boundary Condition

The dispersion model is described by a partial differential equation as follows:[1,2]

$$\frac{\partial C}{\partial T} = D_N \frac{\partial^2 C}{\partial Z^2} - \frac{\partial C}{\partial Z} - R_N C \qquad (1)$$

where C is the normalized concentration of a substance at the normalized cross-section Z and at the normalized time T, D_N is the dispersion number, and R_N is the efficiency number. DBC is defined as follows:[2,5,13]

$$C - D_N\, \partial C/\partial Z = C_{in} \text{ at } Z = 0 \text{ for } T \geq 0 \qquad (2)$$

$$\partial C/\partial Z = 0 \qquad \text{at } Z = 1 \text{ for } T \geq 0 \qquad (3)$$

where C_{in} is the concentration in the entering stream. MBC is expressed as follows:[2,5,14]

$$C = C_{in} \qquad \text{at } Z = 0 \text{ for } T \geq 0 \qquad (4)$$

$$C \rightarrow 0 \text{ or } \partial C/\partial Z \rightarrow 0 \text{ as } Z \rightarrow \infty \text{ for } T \geq 0 \qquad (5)$$

The analytical solution of the dispersion model after bolus input with MBC is given by:[2]

$$C(T,Z) = \frac{Z}{2}\left(\frac{1}{\pi D_N T^3}\right)^{1/2} \exp\left(-\frac{(Z-T)^2}{4D_N T}\right) \qquad (6)$$

where the elimination is not considered. As described above, eq 6 also represents the inverse Gaussian distribution.[15]

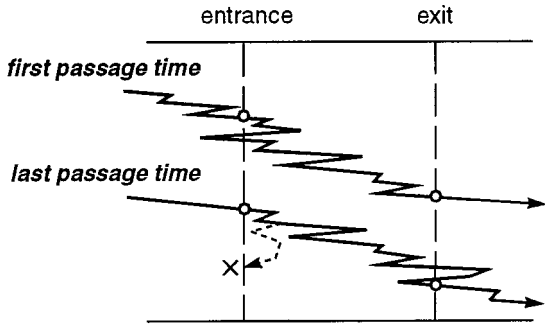

Figure 1—Schematic representation of a first passage time and a last passage time of a particle moving randomly in the bed. The first passage time starts when the particle first enters the bed and continues until it first reaches the exit. The last passage time starts when the particle last leaves the entrance and continues until it exits from the bed, never to return. Note that these sojourn times may include some time spent outside the bed. The dotted line indicates the trajectory of a lost particle in the case of MBC.

It should be noted, however, that the probabilistic distribution of first passage times of a random walk becomes the inverse Gaussian distribution where the inlet boundary is open.[12] The situation of MBC is distinct from the first passage time because its inlet is not open as indicated by eq 4. In reality, MBC is equated to the last passage times.[12] As shown in Figure 1, these two sojourn times are different but apparently equivalent because the time for roaming on the inlet in the first passage times corresponds to that for the outlet in the last passage times.

The dispersion assumed in the dispersion model represents mixing of the blood streams flowing through the microcapillaries in the tissue.[5] Accordingly, dispersion occurs within the tissue but must end at the boundaries. In this instance, both the first and the last passage times are inappropriate because an open boundary is postulated. As MBC is the last passage time, the dispersion is assumed across the exit,[10] which is physiologically irrelevant because the blood never returns from the distal vessels.

Another deficiency of MBC is that it cannot properly control the transfer of mass across the inlet. The peculiarity is obvious for a bolus case. The total mass of the drug is given by integration of eq 6:

$$\int_0^\infty C(T,Z)\,dZ = \{1 + \mathrm{erf}(\alpha^{1/2}/2)\}/2 + (\pi\alpha)^{-1/2}e^{-\alpha/4} \quad (7)$$

where $\alpha = T/D_N$. Equation 7 takes a minimum value of 1 when $\alpha \to +\infty$, namely $T \to +\infty$ and/or $D_N = 0$, but scatters to $+\infty$ as α or T approaches 0. It implies that the mass retained in the bed becomes infinity at the time of injection (Figure 2).

It is generally agreed in the field of chemical engineering that the correct boundary conditions are those that show the flux

$$\phi = C - D_N \partial C/\partial Z \quad (8)$$

to be continuous at the boundary.[12] Since the differential term in eq 8 is ignored for the inlet of MBC (eq 4), the implicit flux occurs when $\partial C/\partial Z \neq 0$ at $Z = 0$. This is the reason for the excessive mass in eq 7. The mass is increased explosively at the time of injection when $\partial C/\partial Z$ becomes $-\infty$ at the inlet and then evaporates gradually after the injection when $\partial C/\partial Z > 0$.

Availability predictions of the dispersion model at steady-state for any boundary conditions in linear kinetics have been reported (eqs 6 and 7 in reference 16). However, they are irrelevant for MBC. If $\partial C/\partial Z$ is less than zero at the inlet of MBC, which occurs when $R_N > 0$, the mass needs to be pored into the bed more than the flow rate allows to satisfy eq 4. This is impossible. In other words, MBC does not have a reasonable solution for steady-state conditions when $R_N > 0$ because of the improper inlet definition.

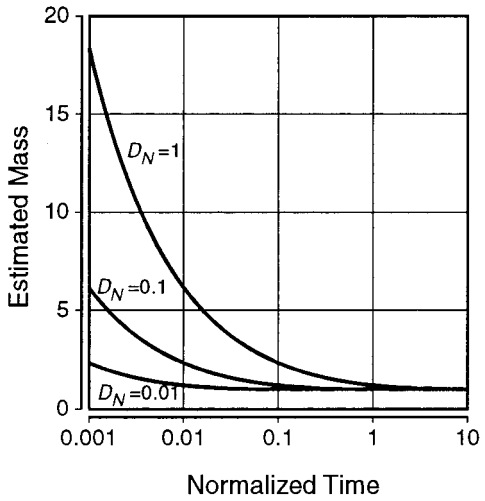

Figure 2—Overestimation of mass retained in the bed by the dispersion model with the mixed boundary condition after bolus input. Note that the mass must be 1.0 independently of time or dispersion number (D_N). The mass is calculated by eq 7.

Danckwerts Boundary Condition

DBC is a necessary consequence of the restrictions for mass conservation and discontinuity of mixing at the boundary.[17] This is currently the most physiological assumption for the solutes that are carried by the bloodstream in the organ, because micromixing of the blood never occurs across the boundaries. In the future, however, DBC might be reexamined for unnatural discontinuities at the boundaries. Continuous or stepwise change of dispersion has been considered theoretically.[18,19] These conditions are advantageous to simulate the real dynamics in the organ, although they are inapplicable to the current analyses because the change of the dispersion in the organ is unknown.

A major shortcoming of DBC is that its analytical solution is mathematically complex.[2] Yet a solution is possible for linear kinetics with inverse Laplace transformation techniques that are used frequently to solve the two-compartment dispersion model.[7,20,21] In addition, several numerical methods have been introduced to calculate the dispersion model for nonlinear kinetics.[14,22–24] It is now possible to obtain non-steady-state solutions of nonlinear multicompartment dispersion models with any input function.[23]

Practical Considerations

Despite the evident theoretical defects, it must be emphasized that most of the analyses done with MBC in the literature are still relevant because its solution is very similar to that of DBC where the dispersion number is small[5] (especially for $D_N \leq 0.2$). However, the results of some studies need to be interpreted cautiously.

First of all, it must be recognized that MBC offers unrealistically spreading outflow curves at higher D_N. After a bolus dose, the dimensionless variance of the outflow curves for MBC is calculated by:[2]

$$CV^2 = 2D_N \quad (9)$$

Equation 9 implies CV^2 exceeds that for even the well-

stirred situation ($CV^2 = 1$) when $D_N > 0.5$. This overspreading occurs primarily because the excessive mass is transferred to the outlet very rapidly in the early period. Another reason is the long-lasting nature of the curve generated with the open outlet condition. Therefore, it is an error caused by the improper definitions. CV^2 of the dispersion model for DBC is calculated by:[2]

$$CV^2 = 2D_N - 2D_N2(1 - e^{-1/D_N}) \quad (10)$$

in which CV^2 never exceeds 1, increases monotonically as D_N grows, and reaches the well-stirred situation at infinity (refer to Figure 3 in ref 10). All theoretical considerations that relate to the shape of the outflow curves of MBC may have potential problems.

Several investigators simulated availabilities with MBC and DBC for various situations and discussed the difference between the two conditions.[5,25] However, the physiological meaning of the difference is obscure. In linear pharmacokinetics, availability is determined by the residence time distribution of the solute (namely, the shape of the outflow curves),[5] and as Nauman concluded, both open and closed systems afford the same residence time distribution when time spent outside the system boundaries is excluded from the total,[12] which is a reasonable assumption for clearance of drugs. Consequently, availability is independent of boundary conditions for linear kinetics if the conditions are realistic. Unfortunately, MBC is not. The difference between MBC and DBC simply represents the extent of errors raised by MBC. Analogous consideration needs to be paid to interpretation of the dispersion numbers calculated with MBC and DBC.[10]

It is advocated that the extent of intrahepatic mixing is very close to the well-stirred situation because the "mixedness" of solutes is maximized at usual dispersion numbers and then decreases as the dispersion number increases, and this suggestion of maximum mixedness in the liver may explain the discrepancy between the apparent validity of the well-stirred model.[26] In this report, "mixedness" was evaluated based on the relative entropy of the outflow curves predicted by the dispersion model of MBC. However, the curves predicted by MBC may become unrealistic as discussed above. For this reason, the evaluation of "mixedness" seems to be erroneous. The conclusion of this report needs some modification.

In the extended use of the dispersion model, MBC would be more troublesome. In nonlinear kinetics, availability predictions by MBC could be inaccurate because clearance depends on the mass retained in the bed. Moreover, it is difficult to calculate nonlinear differential equations with boundary conditions that do not conserve mass. The assumption of MBC is incompatible with physiologically based pharmacokinetics because organs cannot be connected in a tandem manner due to the requirement of the open outlet.

The inverse Gaussian distribution is frequently adopted as a distribution function for parallel tube models.[4,5,9,10,14,25] From an empirical viewpoint, it is relevant if the model explains real data properly. However, for greatly spreading curves, the appropriateness of the shape needs to be verified because the influence of the improper boundary definitions of its generating function becomes apparent.

The dispersion model has been criticized for its inability to explain the tail part of the dilution curves after bolus input.[8–10] In this instance, the characteristic does not differ between DBC and MBC. However, it seems more reasonable to consider the temporal adsorption of substances to the surface of the vasculature as a possible reason for deviation from the model.[11] If such adsorption occurs, the dilution curve needs to be analyzed with the multicompartment dispersion model[7,23] even for vascular references.

Conclusion

MBC has theoretical deficiencies both at the entrance and the exit. Although analyses performed thus far with MBC are still relevant as approximations in most cases, the use of DBC is recommended to avoid theoretical confusion. Considering the recent progress in the development of numerical methods, the calculation of DBC is not a major problem. When the inverse Gaussian distribution is applied in pharmacokinetic considerations, it should be recognized that an open boundary is assumed at the inlet or the outlet.
