If ΔT^f approaches −30 K, the racemic species is likely to be a racemic conglomerate, such as PE·S, ME, BT·Cl and HPL, identified as the filled squares in Figure 4a. This generalization is not conclusive for (±)-PN·Cl and (±)-E·Cl, which are racemic compounds. The nature of these racemic species was determined by a comparison of the experimental PXD pattern with the PXD pattern calculated from the crystal structures, as derived from single-crystal X-ray analysis.[19a] Positive values of $\Delta\Delta H^f$, i.e., $\Delta H^f_R > \Delta H^f_A$, are found for all the racemic compounds, including (±)-PN·Cl and (±)-E·Cl, reflecting their preferential formation (Figure 4b). The racemic compound of t-SB is an exception to this trend; the very small negative value of $\Delta\Delta H^f$ (−0.07 kcal·mol^{-1}) may lie within experimental error.[13] For those racemic species that are identified as racemic conglomerates, e.g. PE·S, ME, BT·Cl, and HPL, their $\Delta\Delta H^f$ values are negative.

Two chiral compounds in this study do not belong to the above series. Pindolol, (PD entry 21) forms a pseudoracemate with a maximum melting point (Figure 1d(2)), and shows exceptionally large values of ΔT^f = 77.2 K and of $\Delta\Delta H^f$ = 7.7 kcal·mol^{-1}.[8] Atenolol (AN entry 15), whose racemic species was not identified, has a negative value of $\Delta\Delta H^f$, similar to those of racemic conglomerates, but has a small value of $-\Delta T^f$ (3.0 K), too small for a stable racemic conglomerate.[12] The formation of a pseudoracemate is suggested for (±)-AN.

Large differences in the melting points (ΔT^f approaching −30 K) between the homochiral and racemic species have been observed for all the racemic conglomerates examined and for a few of the racemic compounds. Therefore, the melting point phase diagram is not an adequate single criterion for identifying the nature of the racemic species. A positive value of $\Delta\Delta H^f$ may be a more reliable indicator of the formation of a racemic compound, which evidently is the enthalpically favorable species. This finding is consistent with the conclusion from lattice energy calculations that the racemic compound has a greater stabilization energy than the individual enantiomers.[19a,b]

Thermodynamic Properties of Racemic Species—The thermodynamic quantities for the formation of the racemic compound and the entropy of mixing of the enantiomers in the liquid state for racemic conglomerates were derived from the equations shown previously. Assuming that the nature of the racemic species is unknown, the thermodynamic calculations were carried out for all 25 chiral compounds in Table 3 to reveal any trends in the calculated values for different racemic species.

Table 3 presents the calculated thermodynamic values, ΔH°, ΔS°, ΔG°, and ΔS^m_l. The ΔH° and ΔS° values were calculated using eqs 4 and 5 assuming an average heat capacity difference of 20 cal·mol^{-1}·K^{-1} for ($C^l - C^s$) in each case.[20] The ΔG° values were obtained using eq 6, in which the heat capacity terms are neglected because they practically cancel in the free energy of formation as explained in the preceding section. The entropy of mixing in the liquid state, ΔS^m_l, was calculated by eq 1.

Comparison of the data in Table 3 reveals that ΔG° and ΔS^m_l show interesting trends between different racemic species, but the trends in the enthalpy of formation and the entropy of formation between racemic species are difficult to interpret.

Free Energy Formation, ΔG°—The calculated ΔG° values are shown in Figure 5. The free energy of formation for racemic compounds, ΔG°, is negative for 23 of the 25 entries, because, as expected, the majority of the racemic species are racemic compounds. However, not every negative ΔG° indicates a racemic compound.

In Figure 5, the five ΔG° values within the range of −0.05 to 0.05 kcal·mol^{-1} correspond to the four compounds (entries 6, 11, 20,[21] 25 in Table 3) which are identified as racemic conglomerates; the fifth is the racemic compound

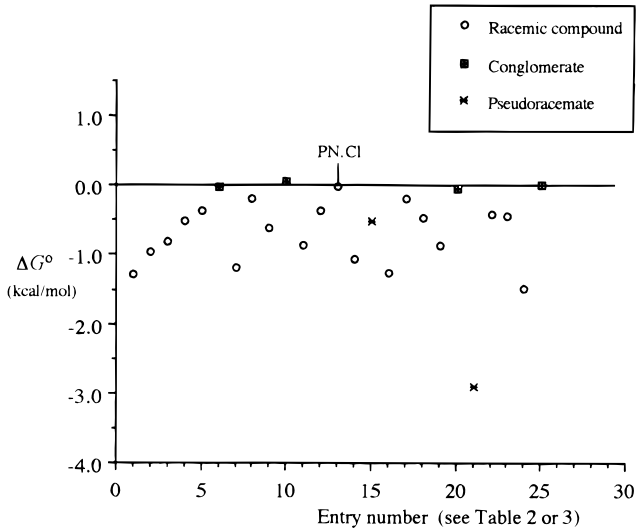

Figure 5—The free energy of formation, $\Delta G°$, of the racemic compound.

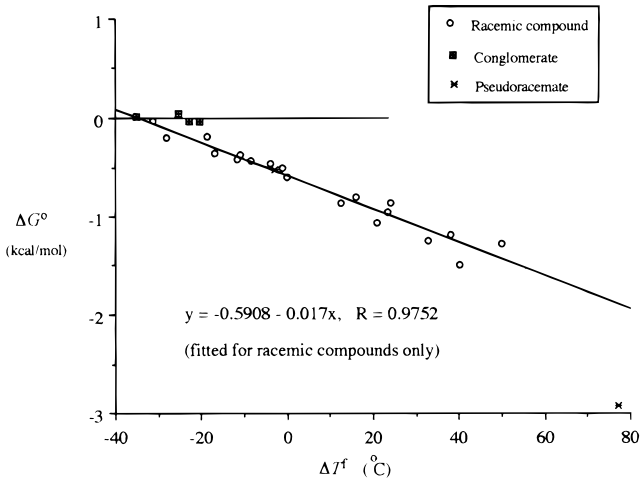

Figure 6—A plot of free energy of formation of racemic compounds, $\Delta G°$, as a function of the difference in melting temperatures, ΔT^f.

of PN·Cl (entry 13 in Table 3). Although PN·Cl forms a racemic compound, its thermodynamic properties are similar to those of racemic conglomerates. The fact that its $\Delta G°$ value is close to zero (-0.027 kcal·mol^{-1}) indicates lack of driving force for the formation of the racemic compound, (±)-PN·Cl. Such a small value may be within experimental error. In such a case, it is proposed that the formation of the racemic compound may be reversed under controlled conditions. Thus, to achieve resolution of this type of racemate by crystallization, the kinetic factors may be very important to offset the possible formation of the racemic compound.

Combining eqs 6a and 6b, a general expression for $\Delta G°$ as a function of the difference in melting points, ΔT^f, can be derived:

$$\Delta G°_{T^f} = -\Delta S^f \Delta T^f - T^f R \ln 2, \text{ where } \Delta T = T^f_R - T^f_A \quad (8)$$

ΔS^f and T^f are the mean entropy of fusion and the mean melting temperature, respectively, of the racemic compounds in the series studied. Figure 6 demonstrates a significant linear correlation for the 19 racemic compounds used in this study. In Figure 6, the negative free energy of formation (reflecting the stability) of a racemic compound is proportional to the difference in the melting temperatures between the racemic compound and its enantiomers.

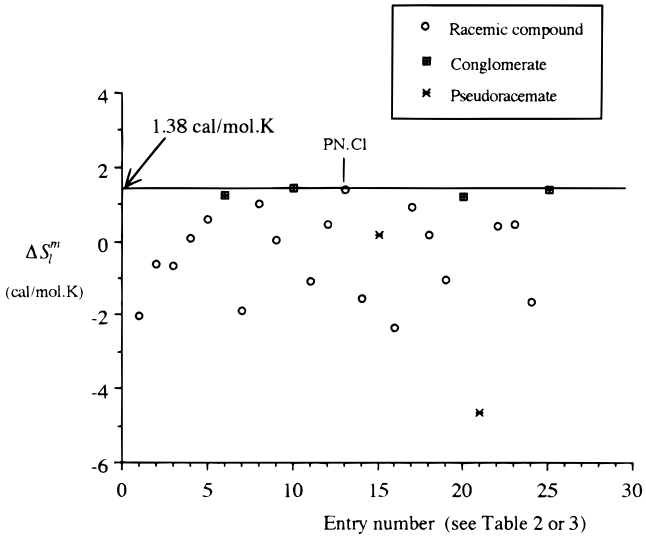

Figure 7—The entropy of mixing in the liquid state, ΔS^m_l.

This apparent linearity was observed previously for a number of organic racemic compounds.[3,5,22] According to eq 8, the slope of the regression line can be identified as the mean entropy of fusion, $\langle \Delta S^f \rangle = 17.04$ cal·mol^{-1}·K^{-1}. Similarly, the intercept represents the contribution of the ideal entropy of mixing, $\Delta S^m_l = 1.38$ cal·mol^{-1}·K^{-1}, at the average melting temperature of $\langle T^f \rangle = 427$ K (154 °C).

In eq 8, as ΔT^f approaches -30 K, the $\Delta G°$ values become close to zero. The entropy of mixing term, the second term on the right, is always negative and contributes to stabilize the racemic compound over its enantiomers. When the pure enantiomer and the racemic compound have the same melting temperature, $\Delta T^f = 0$, the racemic compound is stabilized by a $\Delta G°$ value of -0.59 kcal·mol^{-1}. This result suggests that the entropy of ideal mixing in the liquid state is the driving force for the formation of racemic compounds.

The calculated $\Delta G°$ values for all the racemic conglomerates (PE·S, ME, BT·Cl, and HPL) are approximately zero, which may serve as an indicator for identifying racemic conglomerates. However, the $\Delta G°$ value may be close to zero for racemic compounds, such as (±)-PN·Cl. To identify the nature of the racemic species which show $\Delta T^f \sim -30$ K, further characterization by X-ray diffraction and/or spectroscopic methods is necessary.

Entropy of Mixing in the Liquid State, ΔS^m_l—Values of the entropy of mixing in the liquid state, calculated by eq 1 are given in Table 3 and are shown in Figure 7. The average value of ΔS^m_l for the racemic conglomerates (PE·S, ME, BT·Cl, and HPL) is 1.30 ± 0.10 cal·mol^{-1}·K^{-1}, close to the ideal entropy of mixing of liquid enantiomers ($R \ln 2 = 1.38$ cal·mol^{-1}·K^{-1}). The small deviations of the entropy of mixing of the liquid enantiomers from the ideal value for racemic conglomerates may be related to deviation of these systems from the assumption that the corresponding enthalpy of mixing has the ideal value of zero. For racemic species which are not racemic conglomerates, with the exception of (±)-PN·Cl, their ΔS^m_l values (<1.0 cal·mol^{-1}·K^{-1}) deviate significantly from, and are smaller than, the ideal value. In other words, the assumptions made for racemic conglomerates are invalid for racemic compounds.

Pseudoracemates, i.e., Racemic Solid Solutions—A single, macroscopically homogeneous, crystalline phase may occasionally be formed by mixtures of the two enantiomers in any proportion, i.e., a racemic solid solution, termed a pseudoracemate. This miscibility in the solid state may be demonstrated by the melting point phase diagrams

shown in Figure 1d. Three types of solid solution are observed: (1) ideal, (2) nonideal with a maximum melting, and (3) nonideal with a minimum melting temperature. The few available crystallographic data show that the lattice parameters of a solid solution are very similar to that of the enantiomers, though not identical. In addition, each type of solid solution may be related to a given structural type, namely disordered for type 1, short range ordered for type 3, and nonstatistical inverse symmetry for type 2.[3]

The melting point phase diagram with no eutectic melting shows that the chiral compound pindolol, PD (entry 21 in Tables 2 and 3), forms a type 2 solid solution.[8] The calculated thermodynamic quantities of this pseudoracemate have unusually large negative values in comparison with the other compounds in this study. These unusual values are indicative of the unique properties of the racemic species. In the structure of this type of solid solution, one enantiomer can substitute for the other at one site only, forming a real (nonstatistical) inverse symmetry element.[3] The structure of this pseudoracemate may be similar to that of the racemic compound. The maximum difference in melting temperature of the pseudoracemate of PD, $\Delta T^f = 77.2$ K in Table 1, suggests more favorable interactions between the paired enantiomers in the racemic solid than in the single enantiomers.

The racemic species of atenolol, AN (entry 15 in Tables 2 and 3), was found to be a quasi-ideal solid solution ($\Delta T^f = -3$ K, not zero). Its negative $\Delta\Delta H^f$ (-0.266 kcal·mol^{-1}) seems to follow the trend of racemic conglomerates, but ΔT^f is small and $\Delta G°$ is negative, suggesting a nonconglomerate phase. The DSC trace of mixtures containing unequal amounts of the two enantiomers of AN showed no eutectic melting, which supports the predication from thermodynamic calculations that the racemic species of AN is a racemic solid solution. Unlike PD, AN with small ΔT^f corresponds to a quasi-ideal solid solution of type 1. The structure of a type 1 solid solution is almost identical to that of the pure enantiomer with the two enantiomers randomly occupying the lattice sites. Such a structural feature implies negligible differences in the intermolecular interactions between molecules with the same or opposite handedness in the solid state, i.e., lack of chiral recognition in the solid state.

Characterization of Racemic Species by Powder X-ray Diffractometry and ^{13}C Solid-State Nuclear Magnetic Resonance Spectroscopy—Powder X-ray diffractometry (PXD) and ^{13}C solid-state nuclear magnetic resonance (SSNMR) spectroscopy are two complementary techniques for the structural characterization of powder samples.[23,24] PXD patterns reveal differences of long range order in the packing of the crystal lattice. SSNMR spectra, on the other hand, can probe the short range order of the molecular environments in the solid and can effectively differentiate dynamic or static disorders.[25] The information from ^{13}C chemical shifts can be particularly useful for identifying conformational changes and structural differences, especially when they are difficult to recognize from the PXD patterns.

A number of racemic species in this study were investigated using both PXD patterns and ^{13}C SSNMR spectra. The PXD patterns of the enantiomers and of their racemic species for all the available compounds were first determined and compared. The two opposite enantiomers have identical PXD patterns because their crystal structures are identical, apart from their handedness which confers mirror symmetry. On the other hand, a racemic compound has a PXD pattern different from that of the two enantiomers. A close match of the 2θ values of the peaks in the PXD patterns of the enantiomers and of their racemic species indicates the same crystal structure, suggesting that the racemic species is a racemic conglomerate. Differences in in relative intensity of the PXD patterns may arise from differences in crystallinity and/or preferred orientation. A pseudoracemate displays a PXD pattern closely resembling that of the enantiomers but with some peak broadening. In this work, the findings from the PXD patterns were further confirmed by the ^{13}C SSNMR spectra.

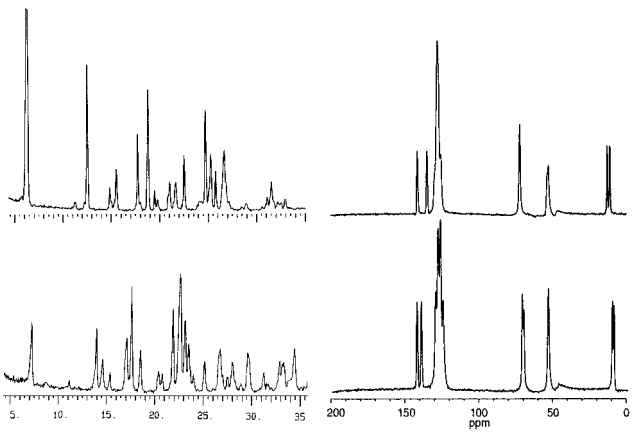

Figure 8—Powder X-ray diffraction patterns (left) and ^{13}C solid-state nuclear magnetic resonance spectra (right) of the racemic compound (upper traces) and of the (–)-enantiomer (lower traces) of norephedrine hydrochloride (NE·Cl).

The PXD patterns and SSNMR spectra of the enantiomers and of their racemic species, for the three possible racemic species: racemic compound, racemic conglomerate, and pseudoracemate, are illustrated in Figures 8, 9, and 10, respectively.

Figure 8 refers to a racemic compound, norephedrine hydrochloride, (±)-NE·Cl (entry 2 in Tables 2 and 3). The PXD pattern of the enantiomer is significantly different from that of the racemic compound. Likewise, the ^{13}C chemical shifts for the enantiomer and the racemic compound are markedly different. For both the homochiral and racemic crystals, the asymmetric unit contains two molecules with different conformations[19a] which are crystallographically nonequivalent.[26] Each carbon in the molecule should theoretically have two chemical shifts, one for each conformation. However, the chemical shifts for two conformations may or may not differ substantially to give distinct peaks. In this case the two peaks are distinguishable for both the aliphatic carbons and the substituted aromatic carbons.

An example of a racemic conglomerate, methylephedrine (ME entry 10), is given in Figure 9. Most of the peak positions in the PXD patterns show a good match between (−)-ME and (±)-ME. Difference in peak intensity may be ascribed to preferred orientation of the thin plates (−)-ME. The ^{13}C chemical shifts in the SSNMR spectra of the homochiral and racemic species agree well, except for the two *N*-methyl carbons. Crystallographically, the two *N*-methyl carbons are nonequivalent in the unit cell, so two peaks are expected. The two *N*-methyl carbons of the racemic species show two peaks. In (−)-ME, the two *N*-methyl carbon signals coalesce into one broad peak. The relatively broad peaks of the *N*-methyl carbons indicate mobility of the methyl groups. In conjunction with X-ray data, NMR results suggest that (±)-ME is a racemic conglomerate, although the nature of the small difference for the *N*-methyl carbons is unclear.

The PXD pattern of atenolol (AN entry 15) in Figure 10 also demonstrates no substantial differences between the enantiomers and the racemic species; only minor differ-

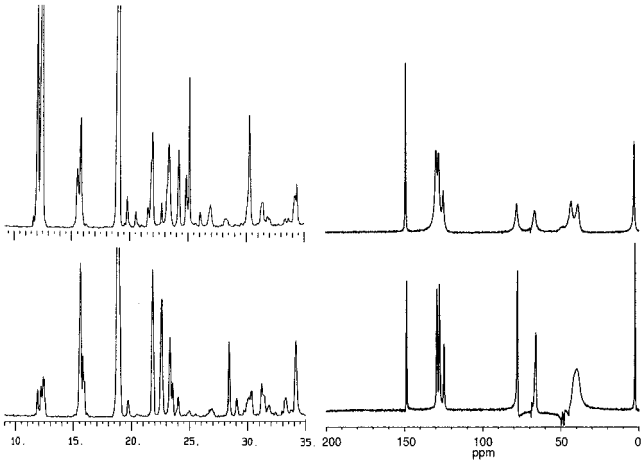

Figure 9—Powder X-ray diffraction patterns (left) and ^{13}C solid-state nuclear magnetic resonance spectra (right) of the racemic conglomerate (upper traces) and of the (–)-enantiomer (lower traces) of methylephedrine (ME).

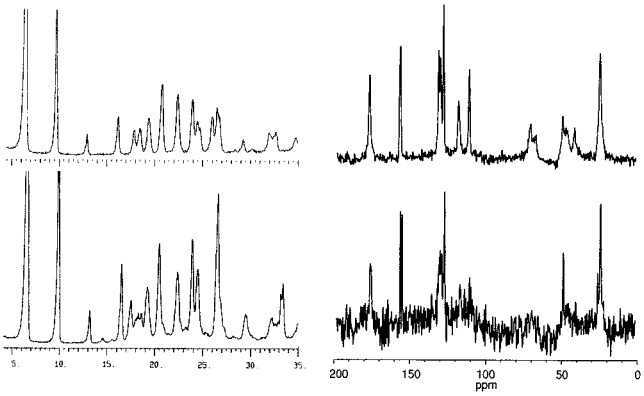

Figure 10—Powder X-ray diffraction patterns (left) and ^{13}C solid-state nuclear magnetic resonance spectra (right) of the pseudoracemate (upper traces) and of the (–)-enantiomer (lower traces) of atenolol (AN).

ences are noted at 17.5° and 33.3° 2θ. Most of the ^{13}C chemical shifts of the enantiomer and racemic species match well, but a few peaks in (−)-AN are difficult to detect above the noise in the spectrum. The reasonably good agreement between the two PXD patterns and between the two SSNMR spectra for racemic and enantiomeric AN suggests that these two forms have very similar crystal structures. The minor differences observed are attributed to decreased crystallinity of the single enantiomer, (−)-AN. Moreover, both the DSC analyses and the thermodynamic calculations indicate that the racemic species of AN is a pseudoracemate, confirming the deduction made above.

In summary, the structural identification of the chiral compounds studied has, in all cases, confirmed the nature of the racemic species suggested by the thermodynamic calculations. However, for differentiation between a racemic conglomerate and a pseudoracemate, PXD and SSNMR may not be adequate. Identification of the pseudoracemate is then shown by the absence of eutectic melting in DSC.

Phase Diagrams and Thermodynamic Aspects—Among the 25 chiral pharmaceutical compounds included in this study as a subset of chiral compounds, 19 racemic species are racemic compounds, corresponding to a 76% frequency. The lower frequency of racemic compounds among these 25 chiral drugs, as compared with 90% among chiral organic compounds in general, is partly explained by the sample collection, of which seven are salts. Nevertheless, this lower frequency of racemic compounds may reflect their occurrence among chiral pharmaceuticals because many drugs are formulated as salt forms.

Several compilations of racemic and enantiomeric pairs of organic chiral compounds have been published.[3,5,22,27] In many respects, the results of the thermodynamic calculations in this study with 25 chiral pharmaceutical compounds are in general agreement with those reported previously for a much larger set of other organic compounds.[3]

The free energy calculations show that the entropy of mixing is the driving force for the formation of racemic compounds. This interpretation can be given from a different point of view in terms of phase separation. Considering crystallization of a racemic conglomerate from a racemic liquid, separation of the two enantiomers as homochiral crystals is not entropically favorable. In some cases, this entropic cost for the phase separation may be merely compensated by the slightly lower enthalpy of the pure crystalline enantiomer as compared with the racemic compound, resulting in an approximately zero value of $\Delta G°$, indicating approximately equal stability of the racemic compound and racemic conglomerate. Hence, crystallization of conglomerates is unlikely to be thermodynamically favored in most cases, but may be controlled by the kinetics of the solid−liquid interface as well as by nucleation and crystal growth.

Emphasis has been placed on those systems whose racemic species are ambiguous in nature, particularly racemic conglomerates or racemic compounds for which $\Delta T^f \approx -30$ K. The reason for this emphasis is that this type of system is particularly important in the resolution of racemates by crystallization. In theory, such systems exist as a thermodynamic equilibrium between the racemic conglomerate and the racemic compound. It may be possible to vary the temperature and kinetic factors to steer the crystallization in the desired direction, so as to facilitate the separation of enantiomers by crystallization. For example, the small difference in the stability of the racemic compound and enantiomeric crystals in the racemic conglomerate may give rise to a significant difference in their solubilities at certain temperatures, which may be utilized for preferential crystallization.[3,9]

It is known that conversion of a free acid or base into a salt increases the likelihood of a racemic conglomerate.[3] In the present study, all the hydrochloride salts in Table 2 show substantially smaller values of ΔT^f values than their free bases or acids. The thermodynamic calculations show that the negative free energy change, $\Delta G°$, approaches zero as $T_R^f - T_A^f$ approaches −30 K. This result provides the thermodynamic basis for the greater frequency of racemic conglomerates among the salts than among the free acids or bases, corresponding to a significant reduction of the difference in melting point between the racemic and homochiral species.

The use of salts to facilitate the resolution of racemates has been attempted.[9] Conglomerates, resolvable by preferential crystallization, were sought by Coquerel and coworkers[28] among various salts of fenfluramine, whose *R* enantiomer is an anorectic agent, and among norfenfluramine, its precursor. Numerous salts of these bases with achiral acids were tested, and several were found to form conglomerates, resolvable by preferential crystallization. Another proposed method for increasing the occurrence of racemic conglomerates is the use of a pressure-induced transition of a racemic compound to a conglomerate.[5] Both methods rely on a significant reduction of the difference in melting point between the racemic compound and its enantiomers. Therefore, a rational procedure for the resolution of racemates by crystallization requires, first, the conversion of the chiral drug into a suitable salt with $T_R^f - T_A^f$ approaching −30 K, and second, a search for the optimal crystallization conditions to facilitate separation

of the two enantiomers by thermodynamic and kinetic factors, such as solubility differences at various temperatures or nucleation, which may be probed by seeding with homochiral crystals.

Conclusions

The free energy of formation of a racemic compound from its pure enantiomers is always negative, indicating that the racemic compound, if it exists, is the thermodynamically favored racemic species. For a racemic conglomerate the entropy of mixing of the two enantiomers in the liquid state is close to the ideal value of R ln 2 (1.38 cal·mol^{-1}·K^{-1}). In comparison to racemic compounds and racemic conglomerates, unusual thermodynamic behavior was observed for racemic solid solutions. Furthermore, thermodynamic calculations reveal that the contribution of the nonideal entropy of mixing to the free energy of formation is the driving force for the formation of racemic compounds. The results show that the combination of thermal analysis with thermodynamic calculations provides a powerful tool to identify the three racemic species: racemic compound, racemic conglomerate, and racemic solid solution. A dynamic equilibrium exists between the racemic compound and the racemic conglomerate when the difference in the melting points between the racemic and homochiral species, ΔT^{f}, approaches −30 K and ΔG°_{Tf} becomes approximately zero. Structural studies using powder X-ray diffraction patterns and solid-state NMR are valuable for distinguishing between a racemic compound and either a racemic conglomerate or a pseudoracemate. Thermal analysis can be used to differentiate between a pseudoracemate and the other two types of racemic species. A preliminary report of this work has been presented as a poster at the 1996 Annual Meeting of the American Association of Pharmaceutical Scientists.[29]

Abstract □ The present study characterized Chinese hamster ovary cells overexpressing a human intestinal peptide transporter, CHO/hPEPT1 cells, as an in vitro model for peptidomimetic drugs. The kinetic parameters of Gly-Sar uptake were determined in three different cell culture systems such as untransfected CHO cells (CHO–K1), transfected CHO cells (CHO/hPEPT1) and Caco-2 cells. V_{max} in CHO/hPEPT1 cells was approximately 3-fold higher than those in Caco-2 cells and CHO–K1 cells, while K_m values were similar in all cases. The uptake of β-lactam antibiotics in CHO/hPEPT1 cells was three to twelve fold higher than that in CHO–K1 cells, indicating that CHO/hPEPT1 cells significantly enhanced the peptide transport activity. However, amino acid drugs also exhibited high cellular uptake in both CHO–K1 and CHO/hPEPT1 cells due to the high background level of amino acid transporters. Thus, cellular uptake study in CHO/hPEPT1 cells is not sensitive enough to distinguish the peptidyl drugs from amino acid drugs. The potential of CHO/hPEPT1 cells as an in vitro model for peptidomimetic drugs was also examined through the inhibition study on Gly-Sar uptake. Peptidomimetic drugs such as β-lactam antibiotics and enalapril significantly inhibited Gly-Sar uptake whereas the nonpeptidyl compounds, L-dopa and α-methyldopa, did not compete with Gly-Sar for cellular uptake within the therapeutic concentrations. In conclusion, the present study demonstrates the further characterization of CHO/hPEPT1 cells as an uptake model as well as inhibition study and suggests their utility as an alternative in vitro model for drug candidates targeting the hPEPT1 transporter.

Introduction

Since peptide transporters are potential targets for improving oral drug absorption through chemical modification due to the broad substrate specificity,[1,2] an efficient screening tool is necessary for rapid evaluation of peptidyl drug candidates arising from rational drug design.

The advantages of in vitro cell cultures over conventional techniques have been summarized by Audus et al.,[3] which include (a) rapid evaluation of the permeability and metabolism of a drug, (b) the opportunity to characterize the molecular mechanism(s) of drug absorption /or drug metabolism, (c) rapid evaluation of strategies for enhancing drug absorption and minimizing drug metabolism, (d) the opportunity to use human cells, rather than animal tissues, and (e) the opportunity to minimize time-consuming, expensive, and sometimes controversial animal studies. Therefore, mammalian cell cultures are increasingly attractive to pharmaceutical scientists as a suitable in vitro model for drug transport and metabolism studies.

Caco-2 cells are well-characterized[4] and currently the most widely used in vitro cell culture system for intestinal drug transport studies. However, this cell line exhibits various transport systems other than peptide transporters,[5,6] and it may be difficult to distinguish the responsible transport system for the test compound. In addition, the expression level of peptide transporters in Caco-2 cells is low, variable, and rather insufficient for the screening of peptidyl drug candidates.[7] The advances in the cloning of peptide transporters and recombinant DNA technology have recently triggered several attempts to develop a cell culture model having enhanced peptide transport activity.[8−14] For instance, a human intestinal peptide transporter, hPEPT1, has been functionally expressed in HeLa cells[13] and also stably transfected into the CHO cells.[14] These overexpression systems provide the analytical advantage in verifying possible drug candidates with transport activity mediated via hPEPT1 transporter. Since the stable transfected cell line, CHO/hPEPT1 has been characterized only through inhibition studies using some peptidyl compounds,[14] further characterization is necessary for its wide application as a screening tool of peptidomimetic drugs.

In the present study, the functional expression level of hPEPT1 transporter in CHO/hPEPT1 cells was evaluated by the kinetic study of Gly-Sar uptake and compared with those in untransfected CHO cells (CHO−K1) and Caco-2 cells. The potential of CHO/hPEPT1 cells as a screening tool was examined through the uptake and the inhibition studies using both peptidyl and nonpeptidyl compounds as substrates of the hPEPT1 transporter.

Experimental Section

Materials—Glycyl-[^{3}H]-sarcosine (specific radioactivity, 400 mCi/mmol) was purchased from Moravek Biochemicals Inc. (Brea, CA). Cephalexin, cephradine, cefaclor, ampicillin, enalapril, glycylsarcosine, L-dopa, and α-methyldopa were purchased from Sigma Chemical Co. (St. Louis, MO). All tissue culture reagents were obtained from Gibco (Grand Island, NY). Other chemicals were either analytical or HPLC grade.

Cell Cultures—CHO/hPEPT1 cells were cultured in F-12 nutrition mixture (HAM) containing 10% fetal bovine serum (FBS), penicillin (100 U/ml)/streptomycin (100 mg/mL), and 200 mg/mL G418. CHO−K1 cells were cultured in the same media without G418. Caco-2 cells were routinely maintained in Dulbecco's modified Eagle's medium (DMEM) containing 10% FBS, 1% nonessential amino acids, 1 mM sodium pyruvate, 1% L-glutamine, and penicillin (100 U/ml)/streptomycin (100 mg/mL). All cells were

maintained in an atmosphere of 5% CO_2 and 90% relative humidity at 37 °C.

Kinetic Study of Gly-Sar Uptake in the Different Cell Culture Systems—CHO/hPEPT1 cells were seeded in 12-well culture plates at a density of 10^5 cells/cm^2. At 2 days postseeding, the cells were washed twice with pH 6.0 uptake buffer containing 1 mM $CaCl_2$, 1 mM $MgCl_2$, 150 mM NaCl, 3 mM KCl, 1 mM NaH_2PO_4, 5 mM D-glucose, and 5 mM MES. Gly-Sar solution was prepared at seven different concentrations (0.01 mM to 50 mM, 0.4 μCi/mL). Each drug solution was added to each well and incubated at 25 °C. At each time point, cells were washed with ice-cold pH 6.0 uptake buffer three times to stop the cellular uptake. One milliliter of 1.5% ice-cold Triton X solution was added to each well and incubated for 30 min at 25 °C. Cells were harvested and transferred into vials containing 4 mL of the scintillation cocktail. Samples were analyzed by a scintillation counter, and the protein amount of each sample was measured by the method of Lowry et al.[15] Kinetic parameters of Gly-Sar uptake were also determined in CHO−K1 cells and Caco-2 cells following the same protocol as was performed in CHO/hPEPT1 cells.

Uptake Study in Both Untransfected and Transfected CHO Cells. Cells were seeded in six-well culture plates (9.6 cm^2, growth area) at a density of 10^5 cells/cm^2. At 2 days postseeding, the medium was removed and cells were washed twice with pH 6.0 uptake buffer. Independent studies were performed for each drug solution at 1 mg/mL made in pH 6.0 uptake buffer. At each time point (10, 20, 30, 45, 60, 90 min), drug solution was removed and cells were washed three times with ice-cold pH 6.0 uptake buffer. One milliliter of Milli-Q water was added to each well and incubated for 30 min at 25 °C. Cells were harvested and sonicated for 1−2 min. $ZnSO_4$ solution (8%, 200 mL) was added to the cell lysate, vortexed rigorously, and centrifuged for 5 min at 3000 rpm. After filtration of the supernatant through a membrane filter (0.45 mm), samples were analyzed by HPLC. The protein amount of each sample was determined by the method of Lowry et al.[15]

Inhibition of Gly-Sar Uptake in CHO/hPEPT1 Cells. Cells were seeded in 12-well culture plates at a density of 10^5 cells/cm^2. At 2 days postseeding, the cells were washed twice with pH 6.0 uptake buffer. Each inhibitor solution (0.01 mM to 50 mM) containing ^{3}H-Gly-Sar (20 mM, 0.4 μCi/ml) was added to each well and incubated for 30 min at 25 °C. After removing the drug solution, the cells were washed with ice-cold pH 6.0 uptake buffer three times to stop the cellular uptake. One milliliter of 1.5% ice-cold Triton X solution was added to each well and incubated for 30 min at 25 °C. Cells were harvested and transferred into vials containing 4 mL of scintillation cocktail. Samples were analyzed by a scintillation counter (Beckman instruments Inc., Model LS-9000), and the protein amount of each sample was measured by the method of Lowry et al.[15]

HPLC Assay—The instrument consists of a pump (Waters, Model 510, Milford, MA) and automatic sampler (Model 712 WISP, Waters) and an UV detector (Waters, 990 Photodiode Array Detector, Milford, MA). Data acquisition and integration was carried out using the Millennium software. All compounds were separated on a reversed phase C-18 column (Beckman Ultrasphere, 5 μm, 4.6 × 250 mm) under the conditions published by Walter et al.[16]

Data Analysis—*Estimate of IC_{50}*—In this study, IC_{50} is defined as the drug concentration to show the 50% inhibition of Gly-Sar uptake. As described by De Lean et al.,[17] it was determined from nonlinear regression of dose−response curve by the Sigma Plot program (Jandel Scientific, San Rafael, CA) using the equation $f = (a - d)/(1 + (x/c)^b) + d$, where a and d represent the maximum and minimum uptake, respectively, x is the inhibitor concentration, and b is the slope factor.

Determination of K_m and V_{max}—K_m and V_{max} for the uptake of each drug was determined by the nonlinear regression of $V = V_{max} \cdot C/(K_m + C) + K_dC$, where K_dC represents a diffusional uptake rate.

Statistical differences between two means were evaluated using a *t*-test assuming unequal variance.

Results and Discussion

Uptake Kinetics of Gly-Sar in the Different Cell Culture Systems—Due to the broad substrate specificity of the peptide transporter, a wide range of structurally unrelated molecules have exhibited significant binding affinity and are transported by the peptide transporter.[18−21] Therefore, chemical modification targeting a peptide transporter to improve oral drug absorption is increasingly attractive to the pharmaceutical scientists. Thus, an efficient and rapid screening tool is needed to support the drug discovery process targeting the peptide transporters. The present study quatitatively evaluated the enhancement of peptide transport activity in CHO/hPEPT1 cells through the kinetic study of Gly-Sar uptake. Kinetic parameters of Gly-Sar uptake were determined in CHO/hPEPT1 cells and compared with those in untransfected CHO cells and Caco-2 cells which is the most prevalent in vitro cell culture system for intestinal drug absorption (Figure 1). As summarized in Table 1. K_m values for Gly-Sar uptake are similar in all three systems, which are comparable to those in other literatures.[11,22] V_{max}/K_m was 380 for CHO/hPEPT1 cells, which is 2-fold higher than that for CHO−K1 cells and four times higher than that for Caco-2 cells. Compared with K_d that indicates the contribution of passive diffusion, V_{max}/K_m was approximately 210-fold, 24-fold, and 17-fold higher in CHO/hPEPT1 cells, CHO−K1 cells and Caco-2 cells, respectively, indicating that Gly-Sar uptake was predominantly carrier-mediated. Furthermore, as shown in Eadie−Hofstee plot (Figure 2), the cellular uptake of Gly-Sar appeared to be mediated by a single transporter, even though there are more than one peptide transporters in CHO/hPEPT1 cells (i.e., hPEPT1 and endogenous peptide transporter) and Caco-2 cells (i.e., PEPT1 and HPT1). This is probably due to the wide overlap of the substrate specificity among peptide transporters and consequently similar affinity of Gly-Sar to each peptide transporter. Taken all together, the Gly-Sar kinetic study indicated that CHO/hPEPT1 cells significantly enhanced the capacity of the peptide transport system while retaining the substrate specificity and that this system may be useful as an in vitro model for the rapid screening of peptidyl drugs.

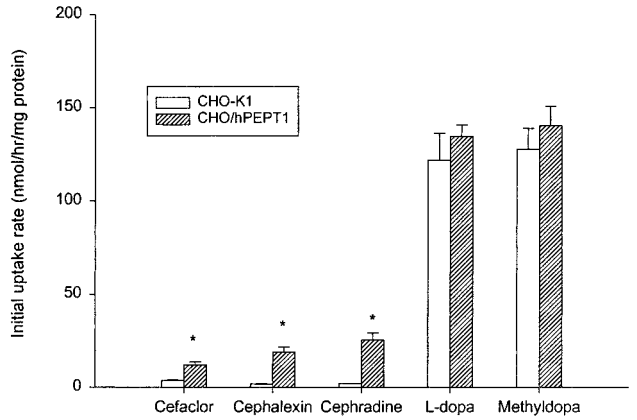

Figure 3—Cellular uptake of peptidyl and nonpeptidyl drugs in CHO/hPEPT1 cells (hatched bars) and in CHO–K1 cells (open bars) ($n = 3$, mean ± SE). (*) indicates $p < 0.01$.

Uptake Studies in Both Transfected and Untransfected CHO Cells—The validity of CHO/hPEPT1 cells as an uptake model was examined using nonpeptidyl drugs as well as peptidyl compounds. Cellular uptake of β-lactam antibiotics was evaluated in CHO/hPEPT1 cells and compared with that in CHO−K1 cells. Initial uptake rate of each drug was determined from the linearity of time versus uptake curve. Estimated uptake ratio between CHO/hPEPT1 cells and CHO−K1 cells (uptake $rate_{CHO/hPEPT1}$/uptake $rate_{CHO-K1}$) was 3.3 for cefaclor, 10.3 for cephalexin, and 12.1 for cephradine (Figure 3). The cellular uptake of β-lactam antibiotics was significantly ($p < 0.01$) increased in CHO/hPEPT1 cells compared with that in CHO−K1 cells. These results demonstrated that CHO/hPEPT1 cells greatly enhanced peptide transport activity via the transfection of hPEPT1 gene.

The cellular uptake of L-dopa and α-methyldopa which are known to be substrates of amino acid transporters[23,24] was also evaluated in both CHO/hPEPT1 cells and CHO−K1 cells. As shown in Figure 3, amino acid analogues, L-dopa and α-methyldopa, showed significant cellular uptake in both CHO−K1 cells and CHO/hPEPT1 cells which were even higher than β-lactam antibiotics. These results implicated that CHO/hPEPT1 cells expressed a high background level of the amino acid transport system which is inherited from the native CHO cells. This explanation is also supported by other report that CHO cells exhibited some amino acid transport systems such as system A, ASC, and L.[25] For clarification, the expression level of amino acid transporters in CHO/hPEPT1 cells should be further evaluated by using antibodies specific for these transporters. Collectively, due to the high expression of amino acid transporters, uptake study alone in CHO/hPEPT1 cells is insufficient for screening peptidomimetic drug candidates.

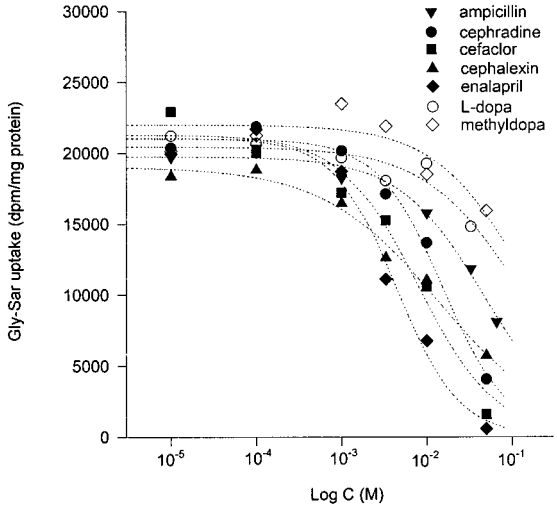

Figure 4—Inhibition of Gly-Sar uptake in CHO/hPEPT1 cells (mean ± SE): two independent studies were done for each inhibitor and every independent study had $n = 3$. Log *C* represents the inhibitor concentration.

Table 2—Inhibition Effect of Peptidomimetic Drugs on Gly-Sar Uptake in CHO/hPEPT1 Cells

	IC_{50} (mM)[a]
Gly-Sar	0.7 ± 0.1
enalapril	4.5 ± 0.7
cefaclor	8.2 ± 1.8
cephalexin	13.7 ± 3.0
cephradine	15.3 ± 2.4
ampicillin	47.4 ± 6.0
L-dopa	141.2 ± 40.4
methyldopa	151.6 ± 21.4

[a] IC_{50} was determined from two independent studies, and each study has $n = 3$, mean ± SE.

Inhibition of Gly-Sar Uptake in CHO/hPEPT1 Cells—The potential of CHO/hPEPT1 cells as a rapid screening tool for peptidyl drug candidates was further examined through inhibition studies using peptidomimetic drugs (e.g., β-lactam antibiotics, enalapril) as well as nonpeptidyl drugs such as L-dopa and α-methyldopa (Figure 4). IC_{50} was determined as the drug concentration to demonstrate 50% inhibition of Gly-Sar uptake and summarized in Table 2. While L-dopa and α-methyldopa did not inhibit Gly-Sar uptake within the therapeutic concentrations, β-lactam antibiotics and enalapril exhibited significant inhibition of Gly-Sar uptake (low IC_{50}), implying that Gly-Sar and the peptidyl derivatives share the same peptide transport system for cellular uptake. Lower IC_{50} indicates higher binding affinity to the peptide transporter, and thus enhancement of peptide transporter-mediated absorption is expected from lower IC_{50} values. Carrier-mediated permeability values (P_C*) of β-lactam antibiotics and enalapril from our previous studies[26–28] were compared with inhibition effects on the peptide transporter (Figure 5). As shown in Figure 5, IC_{50} values of peptidomimetic drugs were reciprocally correlated to the intestinal permeability in rats ($r^2 = 0.91$, $p < 0.05$). These results suggest that inhibition studies on Gly-Sar uptake in CHO/hPEPT1 cells may rapidly elucidate the ability of a drug to interact with the hPEPT1 transporter.

Generally speaking, inhibition studies are not always a good predictor for the actual cellular uptake of drug candidates, since binding to a transporter does not neces-

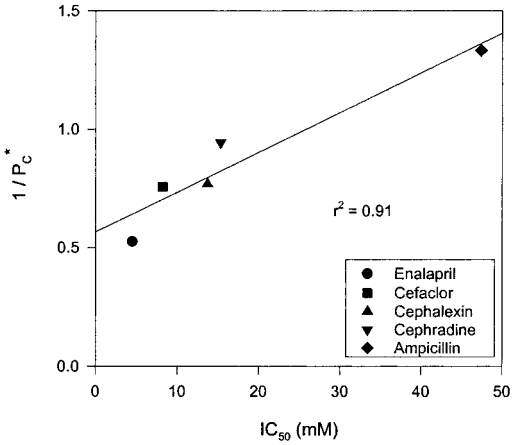

Figure 5—Correlation between IC_{50} in CHO/hPEPT1 cells and the intestinal permeability in rats: P_c * represents the dimensionless carrier-mediated permeability in rats. Permeability data were selected from refs 25–27.

sarily guarantee drug transport into cells. However, false positives may do little harm in the discovery of drug candidates for oral administration, since they can be excluded by further evaluation. Therefore, competitive inhibition studies in CHO/hPEPT1 cells as well as Caco-2 cells could be used for the initial screening of promising candidates from the various drug derivatives, and then more rigorous studies are necessary for further screening of drug candidates.

In conclusion, our present study can be summarized as follows. First, CHO/hPEPT1 cells significantly enhanced peptide transport activity via overexpression of hPEPT1 gene. Second, due to the high background level of amino acid transporters, the cellular uptake study alone in CHO/hPEPT1 cells is insufficient for the screening of peptidyl drugs. Third, inhibition study in CHO/hPEPT1 cells can be served as an alternative in vitro model to support the drug discovery process targeting the peptide transporter.

Abstract □ The preparation and processing of protein pharmaceuticals into powders may impose significant stresses that could perturb and ultimately denature them. In many cases their stabilization through added excipients is necessary to yield native and active proteins. In this study, the effect of spray drying on the structure and activity of a model protein (trypsinogen) was investigated. In the absence of excipients, spray drying resulted in small losses of its enzymatic activity. Protein conformational rearrangements in the solid state (observed via FTIR) and irreversible aggregation (upon reconstitution) constituted the major degradation pathways. The irreversible unfolding in the solid state was also confirmed by solution calorimetric studies that indicated a decreased thermal stability of the spray-dried protein after reconstitution. The presence of sucrose, a thermal and dehydration stress stabilizer, induced a concentration-dependent protective effect. Protein protection was afforded even at low carbohydrate concentrations, while at specific mass ratios (sucrose-to-protein = 1:1) complete activity preservation was achieved. However, at the high end of sucrose concentrations, a small destabilization was evident, indicating that excluded volume effects may be undesirable during preparation of protein microparticles via spray drying. The profile of both the protein conformational changes and thermal stability in the solid state closely followed that of the incurred activity losses, indicating that protein stabilization during dehydration is crucial during processing of these polypeptides.

Introduction

The increased needs for accurate, on-site, and controlled delivery of therapeutic peptides and proteins have led to novel strategies for their release.[1,2] However, their application and successful commercial development may require the formulation of these labile pharmaceutics into alternative forms to improve their bioavalability as well as to achieve stability levels beyond the conventional shelf life requirements. One such approach is their preparation into solid microparticle forms. In the particular case of pulmonary delivery via dry powder inhalers, this requirement becomes even more important since the efficient deposition to the lung, and therefore the therapeutic benefit, requires particles in the range of 1 to 3 μm.[3–5] Further, to minimize physical and chemical degradation reactions and maintain the finished product's physical properties during long-term storage, the protein powders must be produced and maintained at low moisture contents.[6–9]

Several methods have been employed for microparticle production including spray drying,[10,11] spray freeze-drying,[12] ball or jet milling of lyophilized powders, precipitation in supercritical antisolvents,[13] and coprecipitation with water-soluble starch.[14] Of these, spray drying appears to be one of the most promising because of its capacity to produce particles with appropriate characteristics, narrow particle size distribution, process simplicity, and energy efficiency. Moreover, previous efforts have demonstrated the feasibility of its use for processing of pharmaceutical proteins.[11] In contrast to lyophilization, which utilizes freezing and sublimation processes to produce a cake during an energy-intensive and time-consuming process, spray drying is a fast and cost-effective dehydration process. During this operation, heat from a preheated gas stream is used to evaporate microdispersed droplets produced by atomization of a continuous liquid feed.

Among the main drawbacks in the production of protein solid state formulations are the severe stresses that may be imposed during processing. Previous studies have indicated that lyophilization, although it exerts significantly smaller thermal effects than spray drying, can have a significant impact on the structure and stability of several proteins.[15–17] Due to their nature, the processes involved in spray drying impose several stresses that can potentially destabilize labile biological molecules such as proteins. During atomization, proteins are exposed to high pressure and to potentially harmful air–liquid interfaces; both such stresses are known to compromise protein structural integrity[11,18] and decrease their enzymatic or biological activity.[18–20] Previous studies have suggested that heating and subsequent dehydration during the drying step constitute the major degradative stresses.[10] In particular, the outlet temperature during spray drying has been correlated with activity losses of heat-sensitive materials.[10,21,22] Although sucrose would be expected to aggravate interfacial denaturation during atomization via an increase of the solution surface tension,[23,24] it is known to exert an effective baroprotective effect.[25] Finally, well documented is the ability of disaccharides to preserve protein structure and activity in the solution state via their excluded volume effects,[24–26] as well as during thermal and dehydration stresses.[15,16,19,28]

In this effort, the effect of spray drying on the stability of a model protein, trypsinogen, and the impact of a common thermal and dehydration stress stabilizer, sucrose, were investigated. Through a variety of biophysical, chromatographic, and thermal methods of analysis, the degradation pathways of the protein in the presence and absence of sucrose during processing were investigated. Further, through examination of the conformation of spray-dried trypsinogen and its stability both in the solid state and after complete rehydration, we attempted to discern activity–stability relationships for the protein in the sucrose-containing microparticles. The results of the present study are expected to have further implications in production and stabilization of spray-dried pharmaceutical proteins.

Experimental Section

Chemicals—Trypsinogen (1× crystallized, dialyzed against 1 mM HCl and lyophilized; lot no. 38E273N), trypsin (2× crystallized, dialyzed against 1 mM HCl, and lyophilized; lot no. M5K669) and lysozyme (2× crystallized, dialyzed, and lyophilized) were purchased from Worthington Biochemical Corporation (Freehold, NJ). Myoglobin, ovalbumin (crystallized and lyophilized), and bovine serum albumin (Cohn fraction V, 96% purity) and ultrapure sucrose (>99.5% purity via HPLC, lot no. 35H03582) were purchased from Sigma Chemical Co. (St. Louis, MO). All proteins were used without further purification. Potassium phosphate, calcium chloride, and sodium chloride salts were purchased from J. T. Baker (Phillipsburg, NJ). FTIR grade potassium bromide was purchased from Aldrich Chemicals (St. Louis, MO).

Experimental Design—Protein solutions were spray-dried at different protein-to-sucrose mass ratios in order to examine and compare the processing effect on protein stability as well as to determine the optimum range of sucrose concentrations within which the maximum stabilizing effects are exerted. The carbohydrate-to-protein weight ratios examined in this study were no sucrose, 0.25:1, 0.5:1, 1:1, 2:1, 4:1 and 8:1, which correspond to sucrose concentrations of 0, 0.015, 0.029, 0.058, 0.117, 0.234, and 0.47 M, respectively. All the results in this study are reported in terms of sucrose-to-protein mass ratios.

Spray Drying—Trypsinogen particles were prepared by spray drying in a Yamato mini spray dryer model ADL-31 (Yamato Scientific, Orangeburg, NY). The proteinaceous solutions (at different sucrose mass ratios) were prepared at constant protein concentration of 2% w/v in 1 mM HCl. The pH of all prepared solutions ranged from 3.05 to 3.15; this low pH is necessary to minimize autolysis of the enzyme.[29] Before operation, they were filtered through 0.2-μm nylon filters to remove contaminants or aggregates formed during the solution preparation. The solutions were continuously fed to the spray dryer at an approximate flow rate of 3 mL/min and were dried at an inlet temperature of 120 °C; outlet temperatures ranged from 85 to 90 °C. Both the drying and atomization processes utilized room air with relative humidities (RH) that during the experiments ranged between 35% and 55%. Powders were collected in a collection vessel through a cyclone trap and were then aliquoted in lyophilization vials into a drybox (Ray Products, Inc., El Monte, CA); the latter was operated under constant nitrogen purge, providing an atmosphere of 1% to 10% RH. The vials were then capped, sealed, and stored at −20 °C until further analysis.

Particle Size Analysis—The particle size of the spray-dried trypsinogen−sucrose powders prepared for this study was determined with a Horiba LA-900 (Irvine, CA) laser light size analyzer. Small amounts of powders were dispersed in an excess of poly(ethylene glycol) 400 by overnight stirring. The suspension concentration was adjusted to attain optimal obscuration. The samples were then analyzed in a static mode; measurements were repeated in triplicates over a 20-min period, to ensure that no dissolution or powder agglomeration occurred. The size distribution was expressed in terms of volume median diameter, particle size range, and span. The latter represents a measure of the width of the volume distribution relative to the median diameter and was defined as [D(v, 90)-D(v, 10)]/D(v, 50), where D(v, 90), D(v, 50), and D(v, 10) are the equivalent volume diameters at 90, 50, and 10% cumulative volume, respectively.

Moisture Analysis—The moisture content of the spray-dried trypsinogen powders was analyzed via Karl Fisher titration; assays were performed on an Aquatest 10 Karl Fisher Coulorimetric Titrator (Seradyn, Indianapolis, IN), that was calibrated with anhydrous methanol. The moisture content of the protein microparticles was monitored in triplicate using a methanol-extraction protocol. One milliliter of anhydrous methanol was added in 2-mL lyophilization vials containing known amounts (approximately 10 to 50 mg) of powder. The vials were then subjected to brief sonication and mild shaking, to facilitate the moisture extraction process. For the moisture determinations, 200 to 500 μL of the samples were injected in the Karl Fischer coulorimeter. The moisture content was calculated after subtraction of the background moisture of methanol, and results were expressed on a percent total weight basis.

Protein Concentration Determination—Protein concentration in solution was determined by UV/vis spectroscopy; spectra were recorded on a Beckman model DU 640 (Beckman Instruments Inc., Fullerton, CA) spectrophotometer equipped with an automatic six-cell holder, set up with the appropriate transport mechanism. The cells were thermostated via a constant temperature Neslab circulator, model RTE-111M (Neslab Instruments Inc., Newington, NH). Spectra were recorded at 25 °C between 240 and 400 nm at 50-second intervals with a scan speed of 240 nm/min using 1-cm path length quartz cuvettes. Protein concentrations were determined using the absorbance at 280 nm of the light scattering-corrected spectra and an extinction coefficient of 1.54 mL mg^{-1} cm^{-1};[30] light scattering corrections were performed using a built-in function.

Enzymatic Activity Assay—The proteolytic activity of trypsinogen was determined via an appropriate modification of an established assay.[31,32] Briefly, trypsinogen activity was analyzed by first activation to trypsin by addition of the equivalent of 20 μg of trypsin to a 1 mL solution of 0.5 mg/mL trypsinogen in 10 mM Tris-HCl, 20 mM $CaCl_2$ with 100 mM KCl, pH 8.0. Activation was allowed to reach a maximum by incubating for 4 h at room temperature. The activation process was then stopped by addition of 10 μL of 1 N HCl. The activity determination reaction was initiated by adding 33 μL of an appropriate dilution of the activated trypsinogen to 967 μL of *p*-toluenesulfonyl-L-arginine methyl ester (TAME) (Worthington Biochemical Corp., Freehold, NJ). Enzymatic activity rates were followed by the rate of absorbance increase at 247 nm for 5 min at 25 °C. All activity assays were performed in triplicate, and the reported results were corrected for the intrinsic trypsin activity in the reaction mixture.

Aggregation Status—The presence and amount of soluble (covalent and noncovalent aggregates) in the spray-dried trypsinogen powders were determined via size exclusion HPLC analysis as follows: the stationary phase was a 300 Å, 30 cm × 7.8 mm Progel-TSK Supelco column (molecular weight range 10−120 kDa). The mobile phase consisted of a 10 mM phosphate buffer at pH 7.4 prepared in deionized water; the flow rate was set at 0.5 mL/min. Typically, 10 μL of the spray-dried protein samples reconstituted at approximately 5 mg/mL in 1 mM HCl were loaded onto the column and were eluted with the mobile phase at a flow rate of 0.5 mL/min. Experiments were performed on a Waters (Bedford, MA) system equipped with a 626 model pump and a 996 photodiode array detector. Prior to determination, the samples were loaded to a 717 Plus autosampler (Waters, Bedford, MA), which was thermostated at 4 °C; the column was maintained at room temperature. Trypsin, lysozyme, myoglobin, bSA, and ovalbumin were used as internal standards for molecular weight determination. The relative amount of monomeric trypsinogen was determined by comparison of the percent peak area to that of a standard solution of the protein.

In an effort to examine the presence of insoluble aggregates, 0.5 mL of the reconstituted solutions was centrifuged at 12000 rpm for 20 min in an Eppendorf centrifuge model 5415C (Brinkmann Instruments, Westbury, NY). The supernatant (400 μL) was carefully removed and filtered through 0.2 μm nylon filters; the filtrate was then diluted in 1 mM HCl, and its concentration was determined via UV−vis spectroscopy. The amount of insoluble (covalent and noncovalent) trypsinogen aggregates was determined via mass balance from the protein concentration before and after the centrifugation and filtration steps. All determinations were performed in triplicate.

Protein Secondary Structure—The secondary structure of the spray-dried trypsinogen powders was determined via Fourier transform infrared (FTIR) spectroscopy. FTIR spectra were recorded on a Nicolet Magna 550 spectrophotometer (Madison, WI) equipped with a DTGS detector. The spectrometer and the sample compartment were continuously purged, at a constant rate of 50 ft^3/min, with air that was dried via a Balston air-dryer (Whatman, Pleasanton, CA). Double-sided interferograms (1024) were collected in the 4000−900 cm^{-1} range at 4 cm^{-1} resolution, coadded, apodized with a Happ−Genzel function, and Fourier transformed.

Solution state FTIR spectra were recorded at room temperature in the transmission mode using CaF_2 windows with a 6 μm Mylar spacer (Graseby Specac, Smyrna, GA). The spectral solvent contributions in the solution state were removed by subtraction of a solvent spectrum, which was recorded under identical conditions; spectral subtractions were performed with the OMNIC software (Nicolet, Madison, WI) Version 2.0. The subtractions were performed in order to remove the combination water band at 2150 cm^{-1}. The resulting spectra, as well as the calculated second derivative spectra, were smoothed with a nine-point Savitzky-

Table 1—Particle Size and Size Distribution of Spray-Dried Trypsinogen-Sucrose Powders[a]

sucrose:trypsinogen mass ratio	median diameter[b] (μM)	size range (μM)	span[c]
no sucrose	5.0 ± 2.2	1.1–17.4	1.04 ± 0.02
0.25:1	5.2 ± 2.3	1.3–17.4	1.14 ± 0.03
0.5:1	5.6 ± 2.3	1.5–19.9	1.05 ± 0.03
1:1	5.7 ± 2.8	1.5–26.1	1.06 ± 0.01
2:1	6.4 ± 1.8	1.5–17.3	0.91 ± 0.05
4:1	6.0 ± 1.9	1.5–39.2	1.36 ± 0.04

[a] Values represent averages and standard deviations of triplicate measurements. [b] Volumetric median diameter (D(v, 50)). [c] Span = [D(v, 90) − D(v, 10)]/D(v, 50), where D(v, 90), D(v, 50), and D(v, 10) are the equivalent volume diameters at 90, 50, and 10% cumulative volume, respectively.

Golay convolution window. FTIR spectra of trypsinogen powders were collected in the transmission mode using KBr pellets via a computer-controlled automatic sample wheel (Spectra Tech Inc., Shelton, CT). Both the original absorbance spectra and their second derivatives were smoothed via a nine-point Savitzky-Golay window. The spectral second derivatives in the amide I region (1600−1700 cm^{-1}) were used for the calculation of correlation coefficients (r^2 values).[16] These coefficients provide an estimate of the deviation of the structure of the examined sample from the native state by comparison of the second derivatives of the examined sample with that of the native protein in solution.

Solution State Protein Stability—The thermal stability of the trypsinogen−sucrose solution formulations before and after spray drying followed by reconstitution at 20 mg/mL in 1 mM HCl was examined by differential scanning calorimetry. Approximately 750 μL of protein solutions were loaded on preweighed stainless steel pans, were hermetically sealed, and were loaded on the sample compartment of a model 4207 Calorimetry Sciences DSC (Provo, UT). For each measurement a blank cell was loaded with 750 μL of 1 mM HCl solution at the appropriate sucrose concentration. The samples, after a 30-min equilibration step at 10 °C, were heated to 90 °C at a rate of 60 °C/hr and were subsequently cooled at the same rate down to 10 °C.

The midpoint of temperature denaturation ($T_{unfolding}$) was determined at the peak maximum, while the enthalpies of the transitions ($\Delta H^0_{unfolding}$ and $\Delta H^0_{folding}$ for the unfolding and refolding reaction, respectively) were determined by integration of the heat capacity curves after subtraction of a polynomial baseline drawn between 30 and 75 °C.

Powder Thermal Stability—The thermal stability of trypsinogen in the spray-dried formulations was determined by the endotherm ($T_{melting}$) obtained by solid state differential scanning calorimetry (DSC). The endothermic thermal transitions were assigned to protein denaturation, as per previous literature studies.[33−35] For the data analysis, we also assumed complete miscibility of protein and sucrose in the solid state formulations, as demonstrated in previous studies of lyophilized sucrose-protein mixtures.[36] The experiments were performed on a Pyris 1 Perkin-Elmer DSC (Norwalk, CT) equipped with an intracooler; the instrument was calibrated with indium before sample analysis. Approximately 10−20 mg of the samples was loaded under ambient conditions in sealed aluminum pans. After a short preequilibration at 10 °C, the samples were heated to 200 °C at a heating rate of 5 °C/min. All measurements were performed in triplicate.

Results

Particle Size Analysis—The size distribution analysis of the spray-dried trypsinogen−sucrose particles is given in Table 1. The results indicate that spray drying of trypsinogen produces a homogeneous monomodal distribution of protein particles of an approximate diameter of 5 μm and a narrow size distribution (1.1−17.4 μm). The addition of sucrose appears to have a rather minor effect on the particle dimensions. At the highest sucrose mass ratio examined (total solids loading of 180 mg/mL), the median particle diameter reached 6.6 ± 1.9 μm. The small deviations of the particle size with the addition of sucrose would be expected since the primary determinant of the final particle size is the atomization process, indicating the suitability of this process for microparticle production.

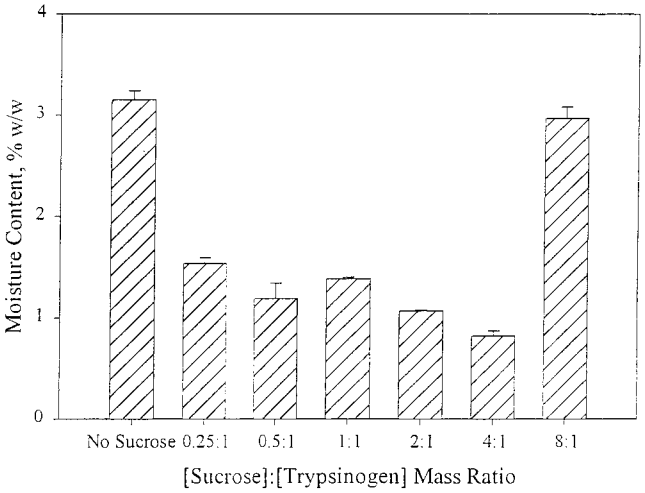

Figure 1—The effect of sucrose on the moisture contents of the spray-dried trypsinogen formulations. Error bars represent (±) one standard deviation of triplicate determinations.

Moisture Content—The moisture content of the spray-dried trypsinogen powders as a function of the protein-to-sucrose mass ratio is shown in Figure 1. The results suggest that even in the absence of secondary drying processes, such as oven drying (which has been employed as a complimentary process following an incomplete drying operation[37]), spray drying can provide powders of low moisture contents.

The final moisture content achieved when trypsinogen was spray-dried in the absence of excipients is 3.1 ± 0.1% w/w (or 3.2 ± 0.2% w/w on a dry protein basis). This amount is even lower than the calculated equivalent water monolayer value of 5.4%; these calculations assume the attachment of one water molecule per charged amino acid.[38] However, this approximation assumes that all charged amino acids are accessible to water vapor. Moreover, spray drying is a flash process, and therefore the obtained moisture contents do not reflect an equilibrium value.

Gradual addition of sucrose progressively decreases the attained moisture content. This is surprising, as one would expect that the presence of a hygroscopic substance like sucrose would increase the amount of residual sorbed moisture. This decrease indicates a possible specific hydrogen bonding interaction between the two substances. At the highest end of sucrose concentrations examined (mass ratio of 8:1), however, the final moisture content increased to 2.9 ± 0.1% w/w; the increased relative humidity during collection and aliquoting may have contributed to this increase.

Activity Profile—The effect of spray drying on the activity profile of trypsinogen at different sucrose mass ratios is shown in Figure 2. When processed in the absence of excipients, trypsinogen loses part of its enzymatic activity, as compared to the unprocessed material (85.1 ± 3.3%). However, the addition of sucrose to the spray-dried solution appears to exert a concentration-dependent stabilizing effect.

Even small amounts of sucrose, sucrose-to-protein mass ratio of 0.25:1, appear to partially stabilize the protein, which recovers part of its initial activity. Increasing concentrations of the carbohydrate further protect trypsinogen in a concentration-dependent fashion. At equal mass ratios of protein and sucrose, the complete restoration of the initial enzymatic activity (99.9 ± 1.5%) was achieved,

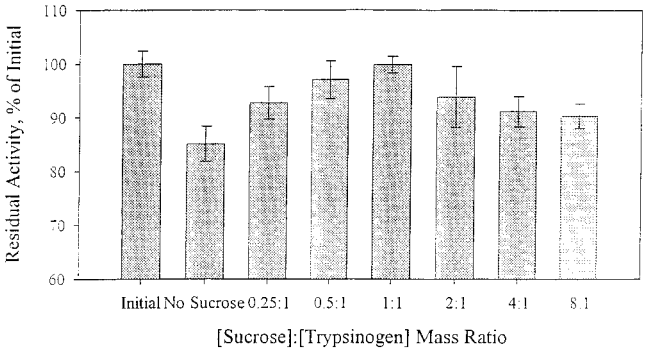

Figure 2—The effect of sucrose on the residual activity of trypsinogen after spray drying. Error bars represent (±) one standard deviation of triplicate determinations.

indicating the complete stabilization of the protein. However, at higher sucrose mass ratios, a small destabilization of trypsinogen is evident. The destabilizing effect is intensified with increasing sucrose concentrations, since the recovered activity of trypsinogen in the spray-dried formulations decreases with increasing sucrose mass ratio. At the high end of the examined carbohydrate concentrations (sucrose-to-protein mass ratios of 4:1 and 8:1), the activity losses approach those observed in the absence of the carbohydrate (91.13 ± 2.82% and 90.33 ± 2.3% of initial, respectively), implying the vast elimination of the protective action of sucrose.

The presence of sucrose in the assay reaction mixture does not have any effect by itself on the determined enzymatic activity of trypsinogen (data not shown). Thus, the observed activity profiles of the spray-dried protein powders truly represent the effects of sucrose on the protein stability during processing rather than an effect of the carbohydrate on the enzymatic activity assay.

Aggregation Profile—The size exclusion chromatography results indicate the presence of high and low molecular weight trypsinogen products in the starting material after reconstitution at pH 3.0; only 89.3 ± 0.3% of the commercial preparation is monomeric trypsinogen. Part of the protein forms an aggregate; the main species appearing to be a dimer (9.6 ± 0.5%). Smaller fragments (approximate molecular weights of 8−12 kDa) account for the remainder of the material. The amount of monomeric and aggregated trypsinogen after reconstitution of the spray-dried powders, relative to the starting material, is shown in Figures 3a,b, respectively. When trypsinogen is spray-dried in the absence of sucrose, it fails to completely recover its initial monomeric state upon reconstitution, as indicated by the decrease of the relative peak area corresponding to the native protein. This loss represents an 8.4 ± 0.3% reduction in the relative amount of the monomeric protein as compared with the unprocessed material; this decline is fully accounted for by an increase of the relative concentration of the dimer (+8.3 ± 0.5%) after spray drying.

Addition of sucrose decreases the extent of aggregation in a concentration-dependent manner. Even small amounts of sucrose partially inhibit dimerization. Increasing concentrations of the carbohydrate progressively diminish the dimer content, up to a sucrose-to-protein mass ratio of 1:1, at which almost complete stabilization of the native protein is achieved. The monomeric state is fully retained at all higher sucrose concentrations examined (up to the highest examined mass ratio of 8:1).

In contrast, formation of insoluble aggregates does not appear to be an operative degradation pathway, as indicated by the small amounts of these species, as shown in Figure 3b. Although some insoluble aggregates were detected when trypsinogen was spray-dried without sucrose and at a sucrose-to-protein mass ratio of 8:1 (1.3 ± 2.0% and 1.64 ± 2.6%, respectively, relative to the unprocessed material) these values are well within the errors of the HPLC analysis method. To further identify the nature of aggregates, we performed SDS−PAGE electrophoresis under both native and reduced conditions. The results (not shown) indicated the absence of covalent disulfide bonds in the high molecular weight species, supporting the formation of hydrophobic aggregates.

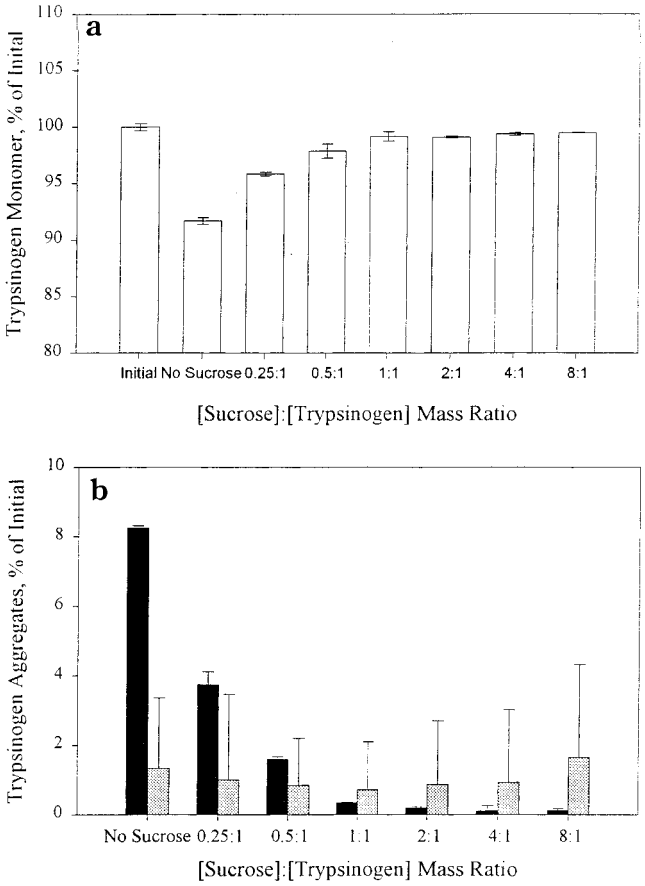

Figure 3—Aggregation status of trypsinogen following spray drying at different sucrose mass ratios and subsequent reconstitution at 5 mg/mL in 1 mM HCl: (a) Relative amount of monomer; (b) Relative amounts of dimer (black bars) and insoluble aggregates (grey bars). Error bars represent (±) one standard deviation based on triplicate determinations.

Solid State Secondary Structure—The second derivative spectra of the amide I band of trypsinogen in the spray-dried powders are displayed in Figure 4, and the calculated correlation coefficients are given in Table 2. The second derivative of the amide I band of native trypsinogen denotes the presence of a major β-sheet band centered at 1636 cm^{-1}, and other components at 1664 and 1685 cm^{-1} signifying primarily β-turn structures. When trypsinogen is spray-dried in the absence of sucrose, it undergoes a significant departure from its native solution structure. As indicated in Figure 4, the second derivative of the amide I band has lost its sharp features as the separation between the bands has diminished. Moreover, the major bands appearing in the native spectrum have all been shifted: the characteristic β-sheet band is shifted approximately 7 cm^{-1} to 1642 cm^{-1}, indicating a rearrangement of the native β-sheet structures of the protein molecule. A similar shift, but of smaller magnitude (+5 cm^{-1}), is evident for the high frequency β-turn band, which is now located at 1689 cm^{-1}. This overall departure from the native state is depicted in the low value of the computed correlation coefficient (0.54 ± 0.05).

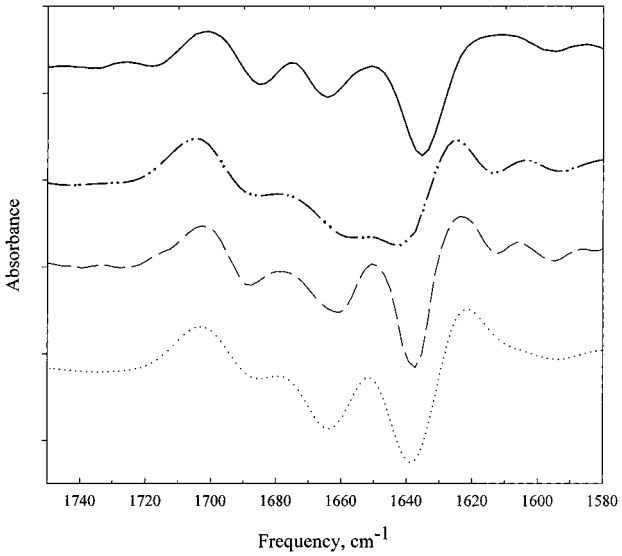

Figure 4—Amide I second derivatives of native trypsinogen in solution (solid line), and in the solid state after spray drying: in the absence of sucrose (– • • –), and with sucrose at 1:1 (– –) and 8:1 (• • • •) mass ratios.

Table 2—Correlation Coefficient Analysis of the Second Derivative Spectra of Spray-Dried Trypsinogen-Sucrose Powders

sucrose:trypsinogen mass ratio	correlation coefficient[a]
no sucrose	0.54 ± 0.05
0.25:1	0.74 ± 0.04
0.5:1	0.88 ± 0.01
1:1	0.93 ± 0.01
2:1	0.87 ± 0.06
4:1	0.78 ± 0.06

[a] Values represent averages and standard deviations of triplicate measurements.

Upon addition of sucrose in the spray-dried trypsinogen formulation (carbohydrate-to-protein mass ratios of 0.25:1−1:1), there is significant recovery of native structural features, as indicated by the increased values of the correlation coefficient. The most remarkable effect is the restoration of the sharpness of the spectral features in the amide I region. Further, the band shifts observed in the absence of sucrose are now, at least partially, reversed. As such, the major β-sheet band has shifted by +3−5 cm^{-1} to 1638 cm^{-1}, closer to its initial position in solution. Likewise, the composite band is centered at 1662 (+2 cm^{-1}) and the high frequency β-turn band at 1688 (+2 cm^{-1}). The observed band shifts occur rather abruptly upon sucrose addition, though a minor improvement appears with increasing sucrose concentration. The profile of the observed spectral restoration of the native structural features is further depicted in the profile of the correlation coefficients (0.8−0.93).

However, upon addition of larger amounts of sucrose in the protein formulation, a small destabilization of the native structure is evident, as indicated by the decreased values of correlation. This observation is in agreement with the determined residual activity results. Moreover, as indicated in Figure 5, the profile of the observed structural alterations of the spray-dried powders follows closely that of the enzymatic activity retention with titrating amounts of sucrose ($r^2 = 0.84$). This correlation provides corroborative evidence that the protein structural deformation in the solid state may be at least partially responsible for the incurred activity losses. Further, it provides indirect evidence that some of the protein molecules may not be

able to refold to their native, fully active state upon reconstitution.

Solid State Thermal Stability—The denaturation temperature ($T_{melting}$) of trypsinogen in the spray-dried powders is given as a function of the sucrose mass ratios in Table 3. The results indicate that spray drying induces a significant destabilizing effect on trypsinogen, as indicated by the decrease in the denaturation temperature, which reaches 143.5 ± 3.4 °C in the absence of sucrose. However, in agreement with the activity assays and size exclusion results, the addition of sucrose exerts a concentration-dependent stabilizing effect. When small amounts of sucrose were added to the trypsinogen solution before processing, they induced a structural stabilization of the protein in the solid state, as indicated by the continuous increase of its denaturation temperature. The maximum stabilization occurs, in agreement with the enzymatic activity determinations, at a sucrose-to-protein mass ratio of 1:1, as indicated by the highest denaturation temperature of 190.6 ± 3.3 °C.

However, further addition of sucrose decreases $T_{melting}$, indicating a reduction in the thermal stability of trypsinogen in the spray-dried powders (denaturation temperatures of 158.6 ± 5.3 °C and 161.6 ± 3.3 °C at sucrose-to-protein mass ratios of 4:1 and 8:1 respectively). The overall profile of the thermal stability of the protein in the solid state closely resembles that observed for the activity of the reconstituted protein, indicating again that the mechanism of the incurred enzymatic activity losses proceeds via reduction of the protein stability in the solid state. As indicated in the linear regression shown in Figure 6, there appears to be a good correlation between these two phenomena, as indicated by the high value of the obtained correlation coefficient ($r^2 = 0.88$). In agreement with the similar correlation of the FTIR results, this observation provides additional evidence for the involvement of solid-

state destabilization in the mechanism of the induced activity losses of trypsinogen.

Solution Thermal Stability—The above observations prompted the further examination of the possibility of the involvement of irreversible (upon reconstitution) protein denaturation in the activity losses. We examined this hypothesis by determining the solution state thermal stability of trypsinogen at different sucrose mass ratios before spray drying and after reconstitution of the spray-dried powders. The results, which are shown in Figures 7a,b and given in Table 4, indicate the multiple effects of sucrose on the thermal stability of the protein before and after processing and reconstitution.

In the solution state, the midpoint of the thermal unfolding of trypsinogen occurs at 61.8 ± 0.3 °C. Unfolding of this protein appears to be a two-state transition as indicated by the similitude of the experimental enthalpy of the transition and that calculated by the van't Hoff equation: indeed, a second derivative of the thermogram (data not shown) indicates the presence of a single transition. Further, the transition appears to be highly reversible, as indicated by the large value of the ratio of the enthalpies of the unfolding and folding transitions ($\Delta H_{unfold}/\Delta H_{fold}$ = 86.9 ± 7.5%). Addition of small amounts of sucrose (up to a mass ratio of 1:1) does not appear to have a significant impact on the thermal stability of the protein, as indicated by the rather small deviations of both the temperature and enthalpy of unfolding. However, higher concentrations of sucrose appear to exert a protein-stabilizing effect. The magnitude of this phenomenon is largest at the highest sucrose mass ratio (8:1), as indicated by the 2.6 ± 0.1 °C elevation of $T_{unfolding}$.

The thermal stability of trypsinogen when spray-dried without sucrose and reconstituted at the initial conditions was compromised, as indicated by the decreased $T_{unfolding}$ (59.3 ± 0.3 °C). Although the enthalpy of unfolding does not change significantly, spray drying appears to exert a significant effect on the reversibility of the transition: only 52.8 ± 3.9% of the unfolded protein can reversibly refold after thermal treatment. This indicates that a significant proportion of the protein molecules was significantly perturbed from the native state during spray drying. When small amounts of sucrose (mass ratios of 4:1−1:1) were incorporated in the spray-dried formulation however, the reduction of the thermal stability of the protein molecules was alleviated, as indicated by the smaller decrease of trypsinogen's $T_{unfolding}$. The minimal destabilization appears to occur at a sucrose-to-protein mass ratio of 1:1, in agreement with the previous observations with the residual activity and solid state thermal stability analyses. However, higher sucrose concentrations fail to stabilize the protein, as indicated by the decreased values of the unfolding temperatures. Again, minimal stability is observed at the highest sucrose mass ratio, as indicated by the reduction of $T_{unfolding}$ by 5.8 ± 1.6 °C and $\Delta H_{unfolding}$ by 12.9 ± 5.4 kcal/mol relative to the native protein. The destabilization becomes even more profound when we compare it with the $T_{unfolding}$ of the same formulation prior to spray drying.

Discussion

The preparation of solid state protein formulations frequently results in their destabilization due to the stresses imposed on them during processing.[15,16] Trypsinogen appears to follow this trend when processed for microparticle production via spray drying. Protein aggregation, a frequently encountered pathway of protein destabilization during solid-state processing,[39,40] upon reconstitution can account only in part (55.8 ± 2.7%) for the observed activity losses. Another destabilization pathway must be responsible for the unaccounted inactivation. The loss of the native protein structure, as observed by the FTIR correlation analysis, during processing along with the observation of decreased stability of the reconstituted protein offers a potential elucidation of the unaccounted activity losses: it is possible that some of the spray-dried protein has departed from its native state and fails to recover its structural integrity, conformational stability, and enzymatic activity upon reconstitution. This argument is further supported by the decrease of the enthalpy of unfolding of trypsinogen after spray drying: from 87.2 ± 5.4 before to 75.4 ± 3.3 kcal/mol after processing. This represents a 13.6 ± 5.4% decrease of $\Delta H_{unfolding}$, which is, within experimental error, close to the extent of the observed activity losses (14.9 ± 3.2%). Therefore, the amount of native protein available to unfold has decreased by 13.6% after spray drying; part of this reduction must be due to the aggregated protein (8.4 ± 0.3%), while the rest can be assigned to irreversibly unfolded protein (5.5 ± 2.1%). The reason for the irreversibility is rather unclear;

it is possible that a chemical degradation reaction of a folding-crucial residue during spray drying may have impaired the correct folding of the protein upon reconstitution. Alternatively, the protein may have reached a partially unfolded state representing a local energetic minimum along its folding pathway, which cannot be overcome after reconstitution.

The addition of sucrose appears to exert a concentration-dependent stabilization effect. At low to moderate sugar-to-protein mass ratios (up to 1:1), sucrose stabilizes the protein. The stabilization appears to occur through impediment of the aggregation pathway, as indicated by the sucrose concentration-dependent decrease of the aggregated molecules, along with a stabilization of the native structure of the protein, as shown by the increased values of the FTIR correlation coefficients during processing. The stabilizing action of disaccharides has been well documented in studies of protein lyophilization.[15,16,28] In addition, sucrose and trehalose have been shown to efficiently protect hemoglobin (from oxidation via protection of its native structure)[19] and β-galactosidase during spray drying.[20]

The solution calorimetry studies of the commercial protein preparation indicated that at high concentrations, sucrose stabilizes the native state of trypsinogen. This finding is in agreement with previous studies that reported a rise of the thermal transition temperature of α-chymotrypsin, chymotrypsinogen, and ribonuclease-A upon addition of sucrose.[27] Moreover, there appears to be a linear dependence of the transition temperature on the concentration of added sucrose ($r^2 = 0.98$); a similar correlation was also suggested by Lee and Timasheff[27] on the three above-mentioned proteins. Again in agreement with these studies, the observed stabilizing effect of sucrose does not appear to be enthalpic in nature, as indicated by the little variation of the $\Delta H_{\text{unfolding}}$. The same authors[27] concluded that the stabilizing effect of sucrose arises from an increase in the apparent activation energy for the thermal perturbation of the proteins, which in turn reflects changes in the physicochemical properties of the system and in particular of the solvent structure. This is a manifestation of the excluded volume effects exerted by sucrose, which, as a natural consequence of the Le Chatelier principle, become evident at these concentrations of the carbohydrate.

However, at this concentration regime (above 2:1, or 0.117 M), the protective action of sucrose appears to have somewhat dissipated, as there is a substantial reduction of the activity of trypsinogen in the spray-dried formulations. The activity losses cannot be assigned to protein aggregation, since the protein remains essentially monomeric; this provides corroborative evidence that protein dilution in the solid matrix by the addition of sucrose molecules is the aggregation-stabilizing mechanism. Nor is a gross conformational change evident in the FTIR spectra, but rather a small departure from the native state, as indicated by the decreased values of the determined correlation coefficients. Yet, the stability of the protein in the spray-dried formulations has been considerably compromised as indicated by the decreased values of T_{melting}, shown by solid-state DSC. Upon reconstitution of these formulations, the protein fails to recover its conformational integrity, as indicated by the decreased $T_{\text{unfolding}}$ and enthalpies of unfolding. Although the activity losses in this sucrose formulation regime are smaller than those incurred in the absence of sucrose, the $T_{\text{unfolding}}$ results indicate a larger destabilization of the protein when high amounts of sucrose are incorporated in the formulation. Further, the decrease of $\Delta H_{\text{unfolding}}$ after processing provides an additional indication of the extent of the departure of the protein from its native state: at a sucrose-to-protein mass

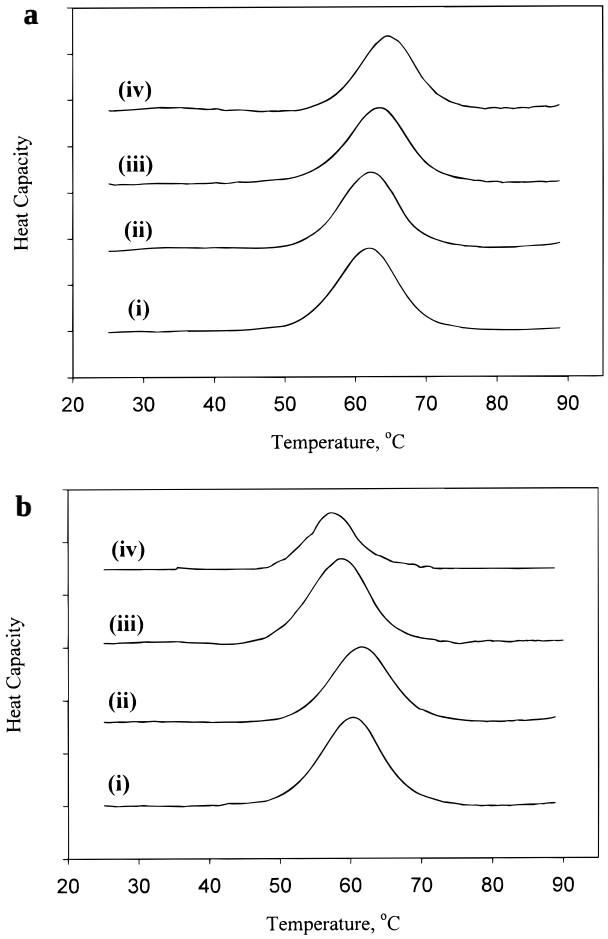

Figure 7—DSC thermograms of trypsinogen–sucrose formulations before (a) and after (b) spray drying: (i) in the absence of sucrose, and at [sucrose]:[trypsinogen] mass ratios of (ii) 1:1, (iii) 4:1 and 8:1.

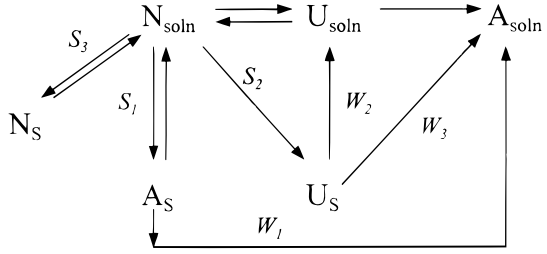

Figure 8—Proposed protein degradation mechanism during spray drying. Subscripts S and soln denote the native (N), unfolded (U), and aggregated (A) protein molecules in the solid and solution states, respectively.

ratio of 8:1 the enthalpy of unfolding has decreased from 86.2 ± 7.3 to 75.7 ± 0.5 kcal/mol, indicating an approximate decrease of 12.2% of the unfolding enthalpy. This value is again in good agreement with the incurred activity losses, indicating that irreversible structural destabilization of trypsinogen in the solid state is the degradation pathway at this end of sucrose concentrations.

Our observations seem to support the destabilization mechanism illustrated in Figure 8. Spray drying of a native protein (N_{soln}) may result in partial protein aggregation (state A_S) and unfolding (state U_S) in the solid state, via pathways S_1 and S_2, respectively. These states are supported by the intermolecular β-sheet band observed in the FTIR spectra and by the departure from the native state into a state of reduced conformational stability (observed by solid-state DSC and FTIR) data, respectively. Alternatively, some protein molecules may still retain their native state in the solid, as illustrated via pathway S_3 (state N_S).

After rehydration, some of the intermolecular contacts persist, leading to formation of soluble, hydrophobic aggregates (state A_{soln}) via pathway W_1. Moreover, some of the unfolded molecules in the solid state fail to adopt their native structure and stability and remain partially unfolded in solution (state U_{soln}) via pathway W_2. Alternatively, some unfolded molecules may participate in self-association reactions via pathway W_3. Finally, molecules that retained their native conformation and structural integrity are able to return in their native solution state (N_{soln}). Addition of sucrose appears to stabilize the protein by blocking both pathways S_1 and S_2, as indicated by both decreased aggregation, nativelike conformationally stable structures in the solid state. However, high concentrations of sucrose, while still effective in impeding aggregation, fail to efficiently stabilize the protein structure in the solid state, rendering pathway S_2 operative.

A consideration of the nature of the destabilizing stresses is particularly interesting. Protein denaturation at the air−liquid interface has been previously considered as the potential degradation pathway of human growth hormone (hGH) during spray drying.[11] Since it is well established that sucrose increases the surface tension of water,[23,24,27] one would expect that its presence would lead to preferentially increased interfacial interactions and consequent destabilization. Yet, the observed stabilizing action of sucrose contradicts this hypothesis, thereby discounting the presence of interfacial inactivation phenomena. Neither heat appears to be the destabilizing stress. If thermal stresses were responsible for the observed destabilization, then, based on the solution DSC results, it would be expected that addition of sucrose at 1:1 mass ratio would not significantly impact the stability of trypsinogen during processing. However, this is contrast with our observations, which indicated complete stabilization of the protein during spray drying at this mass ratio of sucrose, thereby ruling out the involvement of thermal stresses on trypsinogen destabilization. Finally, pressure-induced denaturation during atomization does not appear to be an operative destabilization pathway, since the addition of high concentrations of sucrose, a well-known baroprotectant,[25] would be expected to provide adequate stabilization, which is inconsistent with our observations. The elimination of these potential stresses provides corroborative evidence that dehydration is the major stress responsible for the observed structural destabilization of trypsinogen during spray drying. These observations are in agreement with studies of protein lyophilization, which indicated that the dehydration was the major stress responsible for protein denaturation.[16,41]

Protein destabilization in the solid state in the presence of large amounts of protectants has been previously observed during lyophilization of β-galactosidase with mannitol.[39] The observed activity losses were assigned to excipient crystallization in the solid state. It was thought that the decreased stabilizing effect of crystallized protectants was due to the preferential replacement of the protein−excipient with excipient−excipient interactions. Moreover, this process frequently results in increased water content of the protein-rich phase arising from its exclusion from the excipient crystals, eventuating increased protein molecular mobility and therefore a higher propensity for degradation and inactivation.

The results further indicate that spray drying of trypsinogen under conditions where excluded volume effects dominate results in compromised protein stability and resultant reduction of its enzymatic activity. If crystallization or phase separation were responsible for the protein destabilization, as was previously observed with lyophilized β-galactosidase,[39] these must arise from the exclusion of sucrose from the protein surface. As a result of this phenomenon, the sucrose molecules preferentially interact with themselves (presumably via hydrogen bonding) rather than with the protein surface, leading to the formation of separate phases: a protein-rich and a sucrose-rich phase. Indeed, exclusion is a form of phase separation at the molecular level; this separation precedes the processing step. Despite the high surface area produced during atomization, the solution distribution of each excipient in the droplets should not be expected to alter dramatically, and the microphase separation should remain. This implies that during the spray drying process, the sucrose molecules are not available to hydrogen bond efficiently with the protein, since they remain in their carbohydrate-rich regions, resulting in insufficient protection of the protein. We therefore hypothesize that it is the solution separation that is responsible for the departure from the native state and the decreased stability patterns in the solid state. This hypothesis suggests that when the dispersed droplets are dried, a similar molecular-level separation must exist in each dried particle. These observations indicate that, at high sucrose concentrations, excluded volume effects are destabilizing during protein processing in microparticles via spray drying. These are phenomena that warrant further exploration.

Abstract □ The preparation of stable solid protein formulations presents significant challenges. Ultimately, the interactions between incorporated excipients and the pharmaceutical protein determine the formulation stability. In this study, moisture was utilized to probe the interactions between a model protein, trypsinogen, and sucrose in the solid state, following spray drying. Through investigation of the physical properties of the spray-dried formulations, we attempted to elucidate the mechanisms underlying the previously observed[1,2] stabilizing and destabilizing effects of the carbohydrate during spray drying. Both dynamic and equilibrium moisture uptake studies indicated the presence of an optimal protein–sugar hydrogen bonding network. At low sucrose contents, a preferential protein–sucrose hydrogen bonding interaction was dominant, resulting in protein stabilization. However, at high carbohydrate concentrations, preferential sugar–sugar interactions prevailed, resulting in a phase separation within the formulation matrix. The preferential incorporation of the sucrose molecules in a sugar-rich phase reduced the actual amount of the carbohydrate available to interact with the protein and thereby decreased the number of effective protein–sucrose contacts. As a consequence, the protein could not be effectively protected during spray drying. We hypothesize that the observed phase separation at this sucrose concentration regime originates from its exclusion from the protein in solution before spray drying, further accompanied by preferential clustering of the sucrose molecules.

Introduction

The development of solid state dosage forms of biopharmaceutical molecules presents considerable challenges since the processing environments impose severe stresses that may destabilize and ultimately denature these labile biomolecules. Previous studies have indicated that lyophilization can extensively perturb the structure and diminish the activity and physical stability of several proteins.[3−5] Similarly, spray drying and precipitation in supercritical antisolvents, methods frequently used for production of protein microparticles, have been shown to disrupt the native structure and compromise the enzymatic activity of various proteins.[1,2,6−10] Indeed, the processes involved in spray drying impose stresses that can potentially have detrimental effects on protein stability: pressure effects and exposure to air−liquid interfaces during atomization, as well as heat and dehydration stresses during the drying process, have all shown capacity to denature proteins.[1,3−5,11]

In many cases, formulation excipients are required to preserve the protein native structure and stability in the solid state and to ensure physical stability during either long-term storage or delivery. Research efforts over the past decade have indicated that carbohydrates, and in particular disaccharides, can provide significant protection during lyophilization by preserving the native protein structure during the dehydration process.[3,4,12] Similarly, sucrose and trehalose have shown efficacy in stabilizing several proteins, such as trypsinogen, lysozyme, and soybean trypsin inhibitor (STI) during spray drying.[1,2,13,14] The stabilization was shown to occur via preservation of the native protein structure in the solid state along with impediment of protein aggregation on reconstitution.[1,2] Although the formation of a glassy matrix has been proposed as a stabilization mechanism, the "water replacement" theory is the only one that accounts for specific interactions between the proteins and carbohydrates in a mechanistic fashion. In terms of the latter, disaccharide-induced protein stabilization during drying is thought to occur via hydrogen bonding between sugar and protein molecules, thereby satisfying the hydrogen bonding requirements of the protein during the dehydration step.[3,4,12,15,16]

However, our previous studies[1,2,13,14] have shown that at high concentrations of both disaccharides, the stabilizing effects were partially dissipated: at increasing sucrose-to-protein mass ratios the activity losses approached those observed in the absence of the excipient. Similar activity profiles were observed for STI and trypsinogen when spray-dried in excess of trehalose.[13,14] The incurred losses could not be accounted by aggregation or major conformational perturbations, leading to the hypothesis of process-mediated, irreversible enzyme destabilization.[1]

In effort to account for the destabilizing carbohydrate effects, moisture was used to probe the interactions between trypsinogen and sucrose in the solid state following spray drying. The utilization of moisture as a probe is of particular interest since water is a key determinant of both the solid matrix integrity and the excipient−protein interactions. Dynamic and equilibrium moisture sorption analyses were used to characterize the nature and strength of trypsinogen−sucrose interactions, while physicochemical and thermal methods of analysis were used to probe the state of sucrose in the solid state. The phenomenon of the reduced stabilization of trypsinogen during spray drying at high sucrose concentrations was also examined. The results presented in this study are expected to improve the understanding of protein−excipient interactions in the solid state and to aid the design of stable spray-dried protein formulations, with implications for other solid-state processing methodologies.

Experimental Section

Chemicals—Trypsinogen (1× crystallized, dialyzed against 1 mM HCl and lyophilized; Lot no. 38E273N) was purchased from Worthington Biochemical Corporation (Freehold, NJ). Ultrapure

sucrose (>99.5% purity via HPLC, Lot no. 35H03582) was purchased from Sigma Chemical Company (St. Louis, MO). Lithium chloride, potassium carbonate, potassium phosphate, calcium chloride, and sodium chloride salts were purchased from J. T. Baker (Phillipsburg, NJ). Barium chloride and ammonium chloride were purchased from Mallinckrodt (St. Louis, MO).

Experimental Design—Protein powders were prepared by spray drying formulations at different sucrose-to-protein mass ratios: no sucrose, 0.25:1, 0.5:1, 1:1, 2:1, 4:1, 8:1, and no protein, which correspond to sucrose concentrations of 0, 0.015, 0.029, 0.058, 0.234, 0.47, and 0.53 M, respectively. In all cases, the protein concentration was held constant at 20 mg/mL. All results in this study are reported in terms of sucrose-to-protein mass ratios.

Spray Drying—Trypsinogen particles were prepared by spray drying in a Yamato minispray dryer model ADL-31 (Yamato Scientific, Orangeburg, NY). The proteinaceous solutions were prepared in 1 mM HCl, achieving a pH around 3.1 for all formulations in order to minimize the autolysis of the enzyme.[1,17] The solutions were continuously fed to the spray dryer at an approximate flow rate of 3−5 mL/min and were dried at an inlet temperature of 120 °C; outlet temperatures ranged from 85 to 90 °C. Powders were aliquoted in lyophilization vials in a drybox (Terra Universal, Anaheim, CA) at <1% relative humidity (% RH).

Particle Size Analysis—The particle size of the spray-dried powders was determined with a Malvern Mastersizer S (Southborough, NH) laser-light scattering analyzer. Small amounts of powders were dispersed in an excess of octanol; the suspension concentration was properly adjusted to attain optimal obscuration. The samples were then analyzed in a static mode; measurements were repeated in triplicate over a 20-min period, to ensure that no dissolution or powder agglomeration occurred. The size distribution was expressed in terms of volume median diameter, particle size range, and span.

Moisture Analysis—The moisture content of the spray-dried powders was analyzed via Karl Fisher titration; assays were performed on an Aquatest 10 Karl Fisher Coulorimetric Titrator (Seradyn, Indianapolis, IN), calibrated with anhydrous methanol. The moisture content of the protein microparticles was monitored in triplicate using a methanol extraction protocol.

Moisture Sorption Isotherms—Dynamic moisture sorption isotherms were determined by gravimetric measurement of water uptake using an Integrated Microbalance System, model MB-300G (VTI Corporation, Hialeah, FL), equipped with a digital Cahn ultra-microbalance model 13200-1 (Cahn Instruments, Madison, WI). The microbalance was calibrated with poly(vinylpyrollidone) (PVP) standard. The temperature of the sample chamber throughout the experiment was maintained at 37 °C by circulating water from a constant temperature Neslab circulator, model RTE-100 (Neslab Instruments Inc., Newington, NH) in a water jacket built around the sample compartment. Five to ten milligrams of sample was loaded onto the microbalance, carefully minimizing the sample exposure to ambient conditions. The powder was first subjected to a drying cycle, in which the residual water was removed by vacuum, until equilibrium was attained; the equilibrium criteria were set to reflect sample weight fluctuations of less than 5 μg (representing <1% of the loaded sample) within 5 min. Following drying, the samples were exposed to incremental changes in relative humidity from 0 → 95 → 0% RH at 5% RH intervals. The %RH level was automatically incremented only after complete sample equilibration at each RH level, as dictated by the set equilibrium conditions of less than 3 μg weight change every 10 min with a maximum equilibration time of 400 min. All sorption profiles were determined in triplicate.

The monolayer amount of sorbed water molecules was calculated by a fit of the adsorption data between 0 and 30% RH to the two-state Brunauer−Emmet−Teller (BET) equation[18]

$$W = \frac{W_m C_B (P/P_o)}{1 - (P/P_o)[1 - (P/P_o) + C_B(P/P_o)]} \quad (1)$$

where W is the weight of water adsorbed per unit weight of dry solid at a relative pressure of P/P_o, P and P_o are the vapor pressure and saturation vapor pressure of water, respectively, at the experimental temperature, W_m is the monolayer capacity of the adsorbent, and C_B is a constant related to the heat of adsorption. The latter provides an indication of the affinity of water molecules for the solid sample[19,20] and is given by:[18,21]

$$C_B = k \exp\frac{H_1 - H_L}{RT} \quad (2)$$

where H_1 is the heat of adsorption of the first vapor molecule adsorbed to a substrate site, H_L is the heat of condensation of bulk adsorbate, R is the universal gas constant, T is the absolute temperature, and k is a constant, usually assumed to be close to unity.[21] The approximate water sorption-based sample surface area was calculated from the BET monolayer value assuming 12.5 Å^2 for the cross-sectional area of each water molecule.[19]

BET Surface Area Measurements—The measurements were carried out on a Gemini 2360 surface area analyzer (Micromeritics Instrument Corporation, Norcross, GA) based on the multi-point BET gas adsorption method. For each measurement 0.4−1.5 g of spray-dried powders were loaded onto the sample holder. The surface area was determined using nitrogen as the adsorbate at five different relative pressures (P/P_o range of 0.1−0.3). Prior to the measurements, the samples were degassed under high vacuum at room temperature for at least 24 h, until no further gas or vapor evolved, as judged by the stabilization of the instrument readings.

Equilibrium Sorption Experiments—The spray-dried samples were stored for 10 days at room temperature in sealed desiccators equilibrated with the appropriate saturated salt solutions. The humidity was maintained at 12, 43, 75, and 84% RH with saturated aqueous solutions of LiCl, K_2CO_2, NH_4Cl, and $BaCl_2$, respectively. The physical state of the powders was characterized by X-ray diffraction and thermal analysis.

Powder Thermal Stability—The thermal stability of the spray-dried formulations was determined by the glass transition (T_g) and crystallization exotherms (T_{cryst}) obtained by solid state DSC. The experiments were performed on a TA Instruments (New Castle, DE), Model 2920 DSC, which was calibrated with indium prior to sample analysis. Approximately 10−50 mg of the samples were loaded under environmentally controlled conditions in 50-μL hermetically sealed aluminum pans. After a short preequilibration step at −20 °C, the samples were heated to 200 °C. In effort to deconvolute relaxation events during the glass transition, the samples were analyzed by modulated DSC (MDSC) at a heating rate of 5 °C/min with a modulation frequency of ±2 °C every 60 s. The glass transition temperatures were extracted in triplicate using the transition midpoints.

X-ray Diffraction Experiments—X-ray diffractograms (Coors Ceramics Analytical Laboratory, Golden, CO) were collected using a Scintag Pad X θ-θ diffractometer under the following conditions: copper tube operated at 45 kV, 40 mA; goniometer radius 250 mm; beam divergence slits of 6 and 1 mm and scatter and receiving slits of 0.5 and 0.3 mm; germanium solid state detector bias 1000 V; the PHA was set to accept only K-α radiation. The samples were loaded on a zero-background quartz plate mounted on a special sample holder. Diffractograms were collected between 3° and 90° 2θ at a scan speed of 2.0° 2θ per minute and a chopper increment of 0.03° 2θ. The temperature at the time of the experiments was approximately 23−25 °C. The percent crystallinity of the samples was calculated by numerical integration of the sample and amorphous X-ray diffraction data over the 5−80° range. After background subtraction, utilizing a cubic spline fit, the integrated peak areas were determined using a Lorentzian profile fitting routine, and % crystallinity was assessed by calculating the relative percentage of crystalline peak areas to the total area under the diffractograms.[22]

Results

Particle Size Analysis—The size distribution analysis of the spray-dried particles is given in Table 1. In agreement with our previous observations,[1,14] spray drying of the trypsinogen−sucrose formulations produced a homogeneous monomodal distribution of an approximate diameter of 3−5 μm and a narrow range (0.8−20 μm). The addition of sucrose had a rather minor effect on the particle average diameter: a small increase of the particle size was observed with increasing amounts of added sucrose, however, within the error of the measurements.

Moisture Content—The moisture content of the spray-dried trypsinogen powders as a function of the protein-to-

Table 1—Particle Size and Size Distribution of Spray-Dried Trypsinogen–Sucrose Powders[a]

[a] Values represent averages and standard deviations of triplicate measurements. [b] Volumetric median diameter (D(v, 50)). [c] Span = [D(v, 90) − D(v, 10)]/D(v, 50), where D(v, 90), D(v, 50), and D(v, 10) are the equivalent volume diameters at 90, 50, and 10% cumulative volume, respectively. [d] Nominal specific particle surface area estimated based on the particle size distribution.

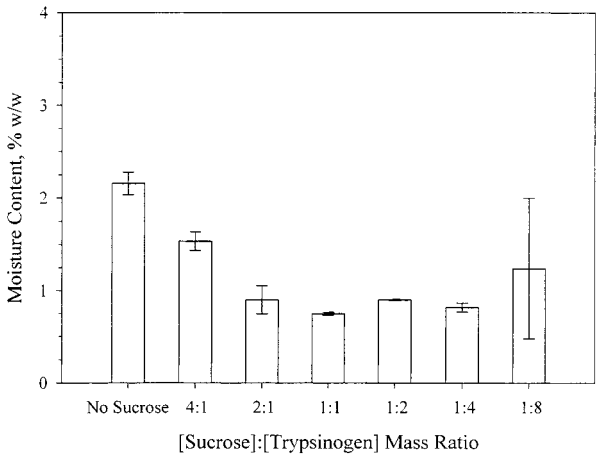

Figure 1—The effect of sucrose on the moisture contents of the spray-dried trypsinogen formulations. Error bars represent (±) one standard deviation of triplicate determinations.

sucrose mass ratio is shown in Figure 1. In agreement with our previous studies,[1,14] spray drying yielded powders of very low residual moisture. The moisture content achieved when trypsinogen was spray-dried in the absence of sucrose was 2.2 ± 0.1% w/w. This is lower than the calculated water monolayer value of 5.4% w/w, which assumes the attachment of one water molecule per charged amino acid, as suggested by Leeder et al.[23]

The addition of sucrose, up to a sucrose-to-protein mass ratio of 1:1, progressively decreased the attained moisture content; thereafter, it remained constant up to the highest sucrose concentration examined. The observed reduction in the final moisture content indicates that the dehydration process is more efficient in the presence of sucrose. This could indicate an increase of the effective heat transfer coefficient as a consequence of the increased surface tension of the droplets, caused by the addition of sucrose. Alternatively, it may reflect facilitation of the removal of water, thereby providing an indirect indication of specific hydrogen bonding interactions between the spray-dried components.

Particle Surface Area Analysis—The nitrogen adsorption analysis results are given in Table 2. The surface area of pure protein particles was 14.5 ± 0.02 m^2/g, which is larger than what would be expected for perfectly spherical particles of this volumetric size distribution (given in Table 1). Since nitrogen sorption is a purely surface phenomenon, this suggests that the particle surface is not perfectly smooth or alternatively the presence of blowholes and cracks. Upon addition of sucrose the surface area decreased: at a sucrose mass ratio of 1:1, it became half of that in the absence of the carbohydrate, while at the highest sugar mass ratio examined, the mean particle surface area decreased 4-fold. A similar trend was observed for the estimated values of W_m, which decreased with increasing sucrose content, thereby providing further evidence of a decrease in the available surface sites for nitrogen adsorption. Scanning electron microscopy (SEM) analysis (data not shown) confirmed that this was due to the increased smoothness of the sucrose-containing particles compared to the wrinkled surface of those in the absence of the carbohydrate; no cracks or blowholes were observed. In contrast, the affinity of the adsorbate for the particle surface did not appear to change with the addition of sucrose, as suggested by the relatively invariable values of the constant C^N_B, indicative of similar heats of nitrogen adsorption to the particle surface.

Dynamic Moisture Sorption Isotherms—The moisture adsorption/desorption isotherms are shown in Figures 2a–f and the BET analysis results are given in Table 2. Spray-dried trypsinogen in the absence of sucrose exhibited a sigmoidal-Type II adsorption isotherm (Figure 2a), which is characteristic of amorphous protein and protein–sugar systems.[24–31] The estimated monolayer of 5.3 ± 0.6 g/100 g solid is in excellent agreement with that calculated by assuming strong adsorption sites on the protein surface (5.4 g/100 g solid). This suggests that at the monolayer, approximately 67 ± 5 water molecules are bound per trypsinogen molecule. The adsorption curve also indicates that the amount of moisture sorbed in the multilayer region (>20–25% w/w) is much larger than what would be expected from the particle surface area. This is also implied by the calculated water sorption-based specific surface area, which is much larger than that determined by the nitrogen adsorption experiments. These observations provide corroborative evidence that moisture actually penetrates into the amorphous solid in contrast to the purely surface-limited adsorptive phenomenon.[20,30] Absorption phenomena have been previously described for lyophilized lysozyme, recombinant bovine somatotropin (rbST), ovalbumin, β-lactoglobulin, and microcrystalline cellulose.[24,30,32,33] The moisture sorption profile of trypsinogen also revealed the presence of hysteresis $[W^{desorption} - W^{adsorption}]_{RH}$ between the sorption and desorption isotherms, which is generally thought to be a consequence of water absorption. The hysteresis loop appeared at 80% RH and closed at 0% RH, indicating the complete reversibility of water sorption, under the experimental conditions.

On addition of low-to-moderate concentrations of sucrose (carbohydrate-to-protein mass ratios of 2:1 and 1:1), the sorption curves retained their Type II profile, as shown in Figures 2b and 2c, respectively. However, the amount of moisture sorbed at low vapor pressures appeared to decrease with increasing sucrose content, and it reached a minimum at a mass ratio of 1:1. This was also reflected in the values of W_m, which decreased to 4.8 ± 0.1, 4.6 ± 0.1, and 4.4 ± 0.1 g H_2O/100 g solid at sucrose-to-protein mass ratios of 0.25:1, 0.5:1, and 1:1, respectively, indicating a reduction of the number of sorbed water molecules per unit weight of the solid at monolayer conditions. The same trend was observed for the water sorption-based particle surface areas, which, however, remained higher than the actual surface areas, indicating that absorption is still the main mode of water interaction with the solid. The gradual addition of sucrose appears to also progressively reduce the magnitude of the hysteresis loop: the loop areas decreased from 135 ± 4.4 units in the absence of sucrose, to 103.2 ± 9.9 and 93.2 ± 3.3 units for sucrose-to-protein mass ratios of 0.25:1 and 0.5:1, respectively. The hysteresis loop disappeared at a mass ratio of 1:1 (area of 1.2 ± 1.1 units).

In contrast, at high sucrose contents (mass ratios > 1:1),

[a] Standard errors represent standard deviations from the fit of the five-point gas sorption curve. [b] Values represent averages and standard deviations of triplicate measurements ($n = 3$) except [c]$n = 2$, and [d]$n = 5$. [e] $\Delta W_m = W_m^{protein} - W_m^{protein/sucrose}$.

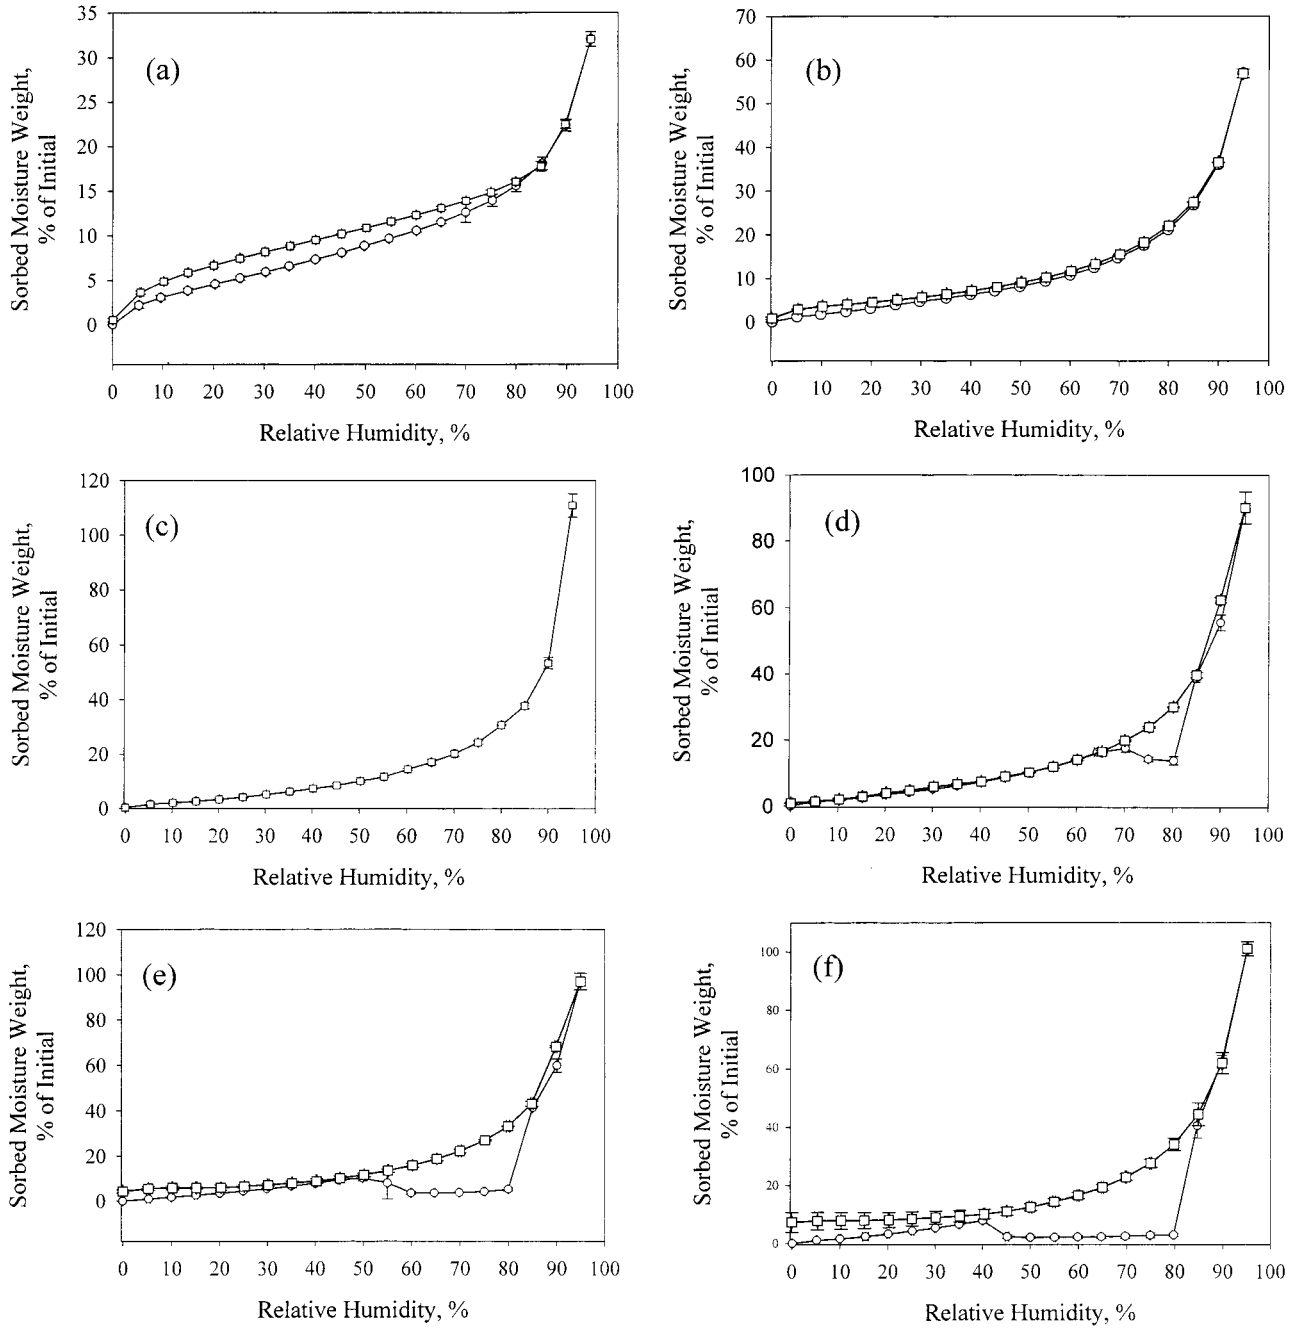

Figure 2—Dynamic moisture absorption (○) and desorption (□) isotherms of spray-dried trypsinogen-sucrose formulations (a) in the absence of sucrose, and sucrose-to-protein mass ratios of (b) 0.25:1, (c) 1:1, (d) 2:1, (e) 4:1, and (f) 8:1. Error bars represent (±) one standard deviation of triplicate determinations.

the amount of sorbed moisture at low vapor pressures increased with increasing sucrose concentration. This was also reflected in the increasing values of the water-based BET surface areas as well as the estimated equivalent monolayer values. The latter gradually increased from 4.4 ± 0.1 g/100 g solid at a mass ratio of 1:1, to 4.7 ± 0.1, 5.1

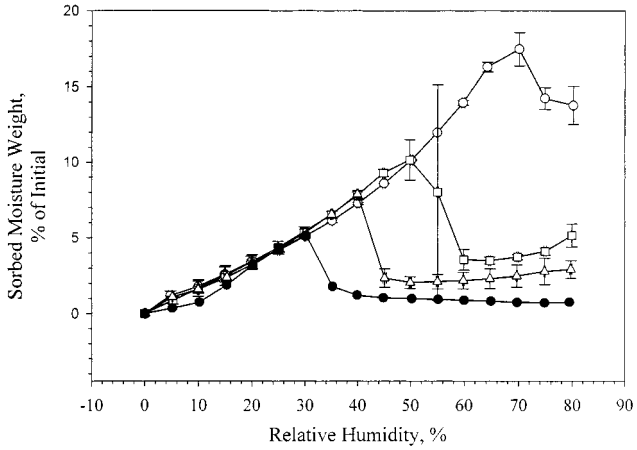

Figure 3—Comparison of the sucrose crystallization phenomenon for the spray-dried formulations at sucrose-to-trypsinogen mass ratios of (a) 2:1, (b) 4:1, (c) 8:1, and (d) in the absence of protein. Error bars represent (±) one standard deviation based on triplicate determinations.

± 0.6 and 5.4 ± 0.4 g/100 g solid at mass ratios of 2:1, 4:1, and 8:1, respectively. Therefore, at this sucrose concentration regime, the available water sorption sites progressively increased with increasing sucrose content. At the highest sucrose-to-protein mass ratio, W_m reached the value determined for the spray-dried pure protein, potentially implying that all the initial sorption sites in the mass of the solid have been reinstated. This is further demonstrated by the decreasing value of the constant C^W_B, which indicates a decline of the heat of water sorption, and thereby decreased affinity of water for the particles, with increasing sucrose concentrations.

One of the most significant features of the sorption isotherms at this sucrose concentration regime is the discontinuity appearing at high vapor pressures. For the 2:1 formulation, the discontinuity occurred at approximately 75% RH. This break is thought to be due to the release of water following the phase transition of sucrose from the amorphous glass to its crystalline state.[24,31,34–36] The formed crystals persisted up to 80% RH; upon further increase of the vapor pressure, the powder resumed its sorptive behavior, as large amounts of water were absorbed: this is indicative of the dissolution of the sucrose crystals and the formation of a saturated solution.[31,35,36] On reversal of the sorption driving force, this formulation exhibited a desorption pathway that followed closely the absorption curve. With the exception of the absence of the discontinuity in the desorption curve, no hysteresis phenomena were observed, and therefore sorption of moisture was fully reversible, as also indicated by the return to the initial conditions.

Crystallization was also observed at all higher sucrose concentrations (Figures 2e,f). However, it occurred at lower critical RH: 55 and 45% for the spray-dried samples at sucrose-to-protein ratios of 4:1 and 8:1, respectively. The crystallization process began at moisture contents of 10.2 ± 1.4 and 7.9 ± 0.3% w/w and completed at 80% RH at 5.1 ± 0.76 and 2.9 ± 0.6% w/w for the 4:1 and 8:1 formulations, respectively. In agreement with the observations with the 2:1 formulation, the sucrose crystals dissolved and the powders resumed their sorptive behavior at 85% RH. However, the desorption isotherms of these samples did not follow the absorption portions, while the loops did not close upon return to the initial conditions, potentially indicating irreversible changes in the state of the powder during the sorption process. In comparison, in the adsorption isotherm of spray-dried pure sucrose (Figure 3) the crystallization discontinuity occurred at approximately 30–35% RH. The crystallization process began at a moisture content of 5.4 ± 0.6% and completed at 0.8 ± 0.3% w/w. This result is very similar to that observed in previous studies of sucrose crystallization by Saleki–Gerhardt et al.,[34] which indicated crystallization of sucrose at approximately 32% RH (equilibrium water content of 6% w/w) at 25 °C, which is within experimental error from our observations.

Table 3—Glass Transitions of the Spray-Dried Sucrose–Trypsinogen Powders before and after Exposure to Controlled Relative Humidity Levels[c]

sucrose:trypsinogen mass ratio	glass transition (T_g)[a]		
	no. exposure	12%	43%
0.25:1	80.4 ± 1.3	44.2 ± 0.8	ND[b]
1:1	75.1 ± 1.9	44.6 ± 0.5	ND[b]
2:1	71.3 ± 1.9	39.2 ± 1.6	5.6 ± 2.7
4:1	69.5 ± 2.7	39.9 ± 2.9	3.1 ± 1.1
8:1	67.4 ± 2.6	42.3 ± 3.4	ND[b]

[a] No glass transitions were detected for the samples exposed to 75 and 84% RH. [b] No glass transitions were detected.

The results, as illustrated in Figure 3, indicate that increased sucrose concentration in the spray-dried mixtures facilitates its moisture-induced crystallization. From a different perspective, the addition of protein inhibits the carbohydrate state transition, as indicated by the decreasing critical crystallization RH with increasing protein concentration in the solid matrix. Similar results have been reported for binary mixtures of sucrose with other proteins, such as recombinant consensus interferon (rConIFN) and recombinant human granulocyte colony stimulating factor (rhG-CSF),[37] rbST,[38] and several polymers, such as starch and celluloses.[39] However, in the case of the rbST–sucrose system, the exact value of the critical %RH of sucrose crystallization at different protein contents was generally higher than that observed in our studies; the different experimental temperatures as well as the differences of the initial states of the spray-dried and lyophilized powders may account for the observed differences.

X-ray Diffraction Analysis—The diffractograms of all spray-dried formulations (results not shown) were characterized by two broad humps and the absence of any sharp peaks over the entire 2θ range, which are indicative of their amorphous nature, confirming the water sorption findings. Even at the highest sucrose-to-protein mass ratio of 8:1, the carbohydrate retained its amorphous character, as would be expected from the nature of the process and the very low moisture contents attained. These results are in agreement with previous studies that indicated the amorphous character of spray-dried rConIFN and rhG-CSF formulations even when they were prepared at high concentrations of trehalose (90% w/w).[37]

Powder Thermal Analysis—The glass transitions of the spray-dried sucrose–trypsinogen formulations, as obtained by DSC thermal analysis, are given in Table 3. The glass transition of the spray-dried pure trypsinogen could not be determined. This is a common problem with protein glasses in the absence of excipients,[37,38] which presumably arises from their large internal heterogeneity and results in an extremely broad distribution of their relaxation times.[40] However, the determination of T_g was possible for the sucrose-containing formulations. In all thermograms, only a single glass transition was observed, implying the complete miscibility of the protein and sucrose in the amorphous matrixes or, alternatively, that a second phase, if present, exists in small amounts that cannot be detected by DSC. Increasing sucrose concentrations gradually decreased the glass transition from 80.4 ± 1.3 °C at a mass ratio of 2:1 to 68.4 ± 3.2 °C for the 8:1 formulation. This observation provides further evidence of the miscibility of

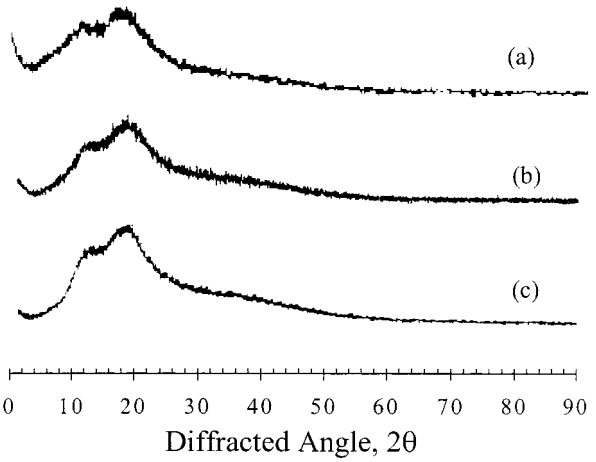

Figure 4—X-ray diffractograms of spray-dried trypsinogen formulations before exposure to elevated moisture: (a) in the absence of sucrose and at sucrose-to-protein mass ratios of (b) 0.5:1, (c) 1:1, (d) 2:1, (e) 4:1, and (f) 8:1.

the two formulation components in the solid matrix.[38] In contrast with the other spray-dried powders, the formulation at a sucrose-to-protein mass ratio of 8:1 exhibited a stress relaxation endotherm, indicating increased molecular mobility of its components.[34]

The formulations at high sucrose concentrations further exhibited an exothermic transition, which is characteristic of sucrose recrystallization. The exact temperature and magnitude of the transition, however, varied with the formulation: 173.9 °C, 160.4 °C, and 142.9 °C for the formulations at sucrose-to-protein mass ratios of 2:1, 4:1, and 8:1, respectively. These results are in agreement with previous studies,[38] and further confirm the hypothesis of protein-induced inhibition of sucrose crystallization, as observed in the dynamic moisture sorption experiments.

Equilibrium Water Sorption Studies—These studies were performed to confirm the dynamic sorption isotherms, which do not represent true equilibrium events; the "non-equilibrium" attributes arise from the limitations of user-defined equilibrium criteria of the "dynamic sorption" experiments prevent the system from reaching true equilibrium. The diffractograms of the moisture-exposed samples are shown in Figures 5–7, and the sample crystallinity analysis is given in Table 4. The X-ray diffraction analysis of the moisture-exposed samples confirmed the dynamic sorption experiments, indicating the appropriateness of this technique. When the spray-dried particles were exposed to 12% RH, the formulations retained their amorphous character; the diffractograms illustrated in Figure 4 are characterized by two broad humps and the absence of any sharp features. This is expected from the dynamic moisture sorption studies, which indicated the absence of any state changes in all formulations at this %RH level. Further, these results are in agreement with moisture sorption studies of protein–disaccharide systems, which demonstrated the absence of state transitions (for both sucrose and trehalose) upon exposure to low relative humidities.[37,38] However, the absorbed water plasticized the solid matrixes, as indicated by the decreased glass transitions given in Table 3. For all examined powders, T_g was reduced to almost half of its original value, while all formulations exhibited a relaxation endotherm during the glass transition.

As indicated in Figure 5, even after exposure to 43% RH most spray-dried powders (sucrose-to-protein mass ratios of 1:1, 2:1, and 4:1) remained amorphous, again in good agreement with the dynamic moisture sorption studies. In contrast, the diffractogram of the highest sucrose-containing powder (8:1) exhibited crystalline patterns dominated

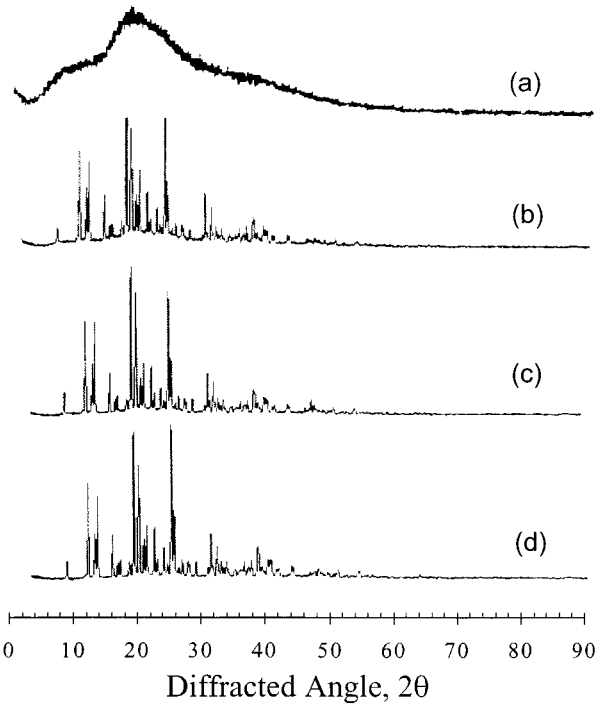

Figure 5—X-ray diffractograms of spray-dried trypsinogen formulations after equilibrium exposure to 12% RH for 10 days. Formulations are at sucrose-to-protein mass ratios of (a) 2:1, (b) 4:1, and (c) 8:1.

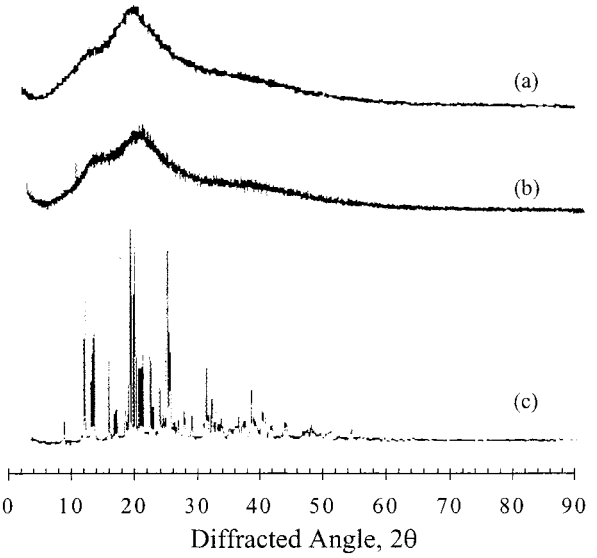

Figure 6—X-ray diffractograms of spray-dried trypsinogen formulations after equilibrium exposure to 43% RH for 10 days. Formulations illustrated are at sucrose-to-protein mass ratios of (a) 2:1, (b) 4:1, and (c) 8:1.

by sharp peaks located at 11.6°, 12.8°, 18.8°, and 24.7°, which are indicative of sucrose crystals.[39] The incurred phase transformation was expected, since the dynamic sorption results indicated the occurrence of a crystallization event at 40–45% RH. Sample crystallinity was determined at 76% w/w solid, indicating that under these conditions, most of the sucrose in the formulation has crystallized. As illustrated in Table 3, the formulation T_gs further decreased, as would be expected by the increased amounts of sorbed water.

Even after exposure to 75% RH, no state transition became apparent for the 1:1 formulation (Figure 6a), indicating that when the protein concentration in the solid matrix exceeds this mass ratio, the crystallization of sucrose can be completely inhibited. These findings are in

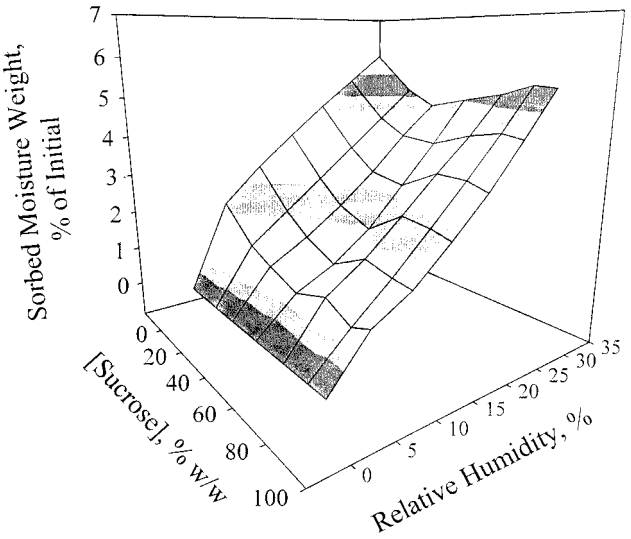

Figure 7—X-ray diffractograms of spray-dried trypsinogen formulations after equilibrium exposure to 74% RH for 10 days. Formulations illustrated are at sucrose-to-protein mass ratios of (a) 1:1, (b) 2:1, (c) 4:1, and (d) 8:1.

Table 4—Crystallinity of Spray-Dried Trypsinogen–Sucrose Formulations before and after Exposure to Controlled Relative Humidity Environments[a]

sucrose:trypsinogen mass ratio	no exposure	% crystallinity			
		12%	43%	75%	84%
1:1	0[a]	ND[b]	ND[b]	0[a]	0[a]
2:1	0[a]	0[a]	0[a]	51	0[a]
4:1	0[a]	0[a]	0[a]	71	44
8:1	0[a]	0[a]	76	85	71

[a] No crystalline peaks were detected. Samples are characterized as 100% amorphous. [b] Sample crystallinity was not determined.

agreement with literature studies which concluded that sucrose crystallization is entirely inhibited when the protein concentration in the spray-dried rConIFN and rhG-SCF formulations exceeded 50%.[37] In contrast, the sucrose in the 2:1 and 4:1 formulations underwent crystallization upon exposure to 75% RH, as indicated by the diffraction patterns shown in Figures 6b-c. These were identical to those observed for the 8:1 formulation at 43% RH. Again, these results conform well with those obtained from the dynamic sorption studies, which showed sucrose crystallization phenomena at 55 and 75% RH, respectively. However, the extent of crystallization varied, as indicated by the quantitative crystallinity estimates of 51%, 67%, and 82% for the 2:1, 4:1, and 8:1 formulations, respectively. These findings suggest that the amount of crystallizable sucrose increases with increasing concentration of the excipient in the solid matrix. No glass transitions were detected for the formulations exposed to 75% RH. This is probably due to the crystallization of most of the sucrose in the formulations, which renders the amount of the remaining amorphous material insufficient for detection of its T_g via DSC.

Finally, upon exposure of the formulations to 84% RH, the crystallinity patterns were partially disrupted, as indicated by the decreased intensity of the diffractogram peaks. As a consequence, the determined crystallinity percentages dropped to 44% and 71% for the 4:1 and 8:1 formulations, respectively, while the crystalline patterns completely disappeared for the 2:1 sample. These findings are in good agreement with the previous studies which demonstrated decreased crystallinity levels of sucrose on exposure to 84% RH, due to the crystal dissolution and the formation of saturated solutions at this vapor pressure.[39]

Discussion

It is well documented that pharmaceutical solids tend to adsorb significant amounts of water over a wide range of relative humidities. The presence of water can accelerate degradation phenomena in the solid state, such as deamidation, oxidation, disulfide cross-linking, and Maillard reactions.[41] In particular for proteins, water can affect a complex matrix of protein motions, ranging from oscillatory and rotational movement of individual amino acid groups, to segmental motions and internal fluctuations that increase their dynamic mobility and thereby decrease their conformational stability.[41,42] Moreover, the sorbed water may have a tremendous impact on both the physical properties of the processed material. In terms of the latter, water sorption plasticizes the solid matrix, reduces its T_g,[43] and may induce excipient crystallization and alter its morphology, physicochemical properties, and physical characteristics,[44] phenomena that can all deteriorate product stability or even diminish proper delivery.

In agreement with previous studies,[37,45] the X-ray diffraction results suggest that spray drying of trypsinogen, even in the presence of increasing amounts of sucrose, results in the formation of amorphous microparticles. In this state, proteins are devoid of long-range intermolecular interactions or orientation, although they maintain their specific short-range interactions.[41] Upon exposure to different relative humidity levels, the protein-based powders take up large amounts of water, illustrative of their amorphous nature. Water sorption confers increased mobility, which may be regarded as an increase in the dynamic fluctuations of the protein, as demonstrated for trypsin, a protein that has a significant degree of homology with trypsinogen.[46]

Similarly with amorphous polymers, water sorption in all spray-dried trypsinogen−sucrose formulations occurs via penetration into the disordered solid and is not limited to surface adsorption.[41] This was demonstrated by the large excess of moisture taken up by the solid at high vapor pressures and the lack of dependence of the water uptake on the specific surface area of the samples.[43] The absorption process is further elucidated by comparison of the surface areas obtained from the nitrogen adsorption studies with those calculated from fits of the BET equation to the moisture sorption isotherms; although the former are highly dependent on particle size and physical state of the solid, the latter are unaffected by these properties. The very large H_2O/N_2 surface area ratios obtained for all spray-dried formulations are consistent with the water penetration hypothesis.

This explanation is also consistent with the sorption hysteresis, observed for formulations at the low sucrose concentration regime. Hysteresis has been described for many amorphous systems.[27] Although it was first suggested to originate from capillary condensation, it was later thought to be caused by chemisorption in rigid materials, and by water−polymer interactions in nonrigid solids (such as proteins).[27] Specifically for proteins, hysteresis phenomena have also been attributed to conformational rearrangements that involve a structural relaxation or even a phase change, which can be facilitated by increasing free volume and mobility of the protein during sorption.[44,47] It has been previously hypothesized that it provides an indication of the existence of the protein in a kinetically metastable, dynamically constrained state, which arises from the macroscopic swelling due to the penetration of water in the solid matrix.[25,41,44,47] The extent of the hysteresis loop in our experiments, decreased with increasing sucrose concentration, indicating the decreased plasticization of the amorphous solid by water. Alternatively, the protein con-

formational changes should be less dramatic in the presence of sucrose; this is confirmed by our previous studies, which indicated that trypsinogen gradually maintains a more nativelike conformation in the presence of increasing amounts of sucrose.[1] Finally, since hysteresis is related to the glass transition of the solid at the specified RH,[44] it is possible that its decreased magnitude may also relate to variations of $\Delta T = T - T_g(\mathrm{RH})$ during the sorption process for the different trypsinogen−sucrose formulations. The disappearance of the hysteresis loop at a sucrose-to-protein mass ratio of 1:1, formulation at which the protein fully recovers its native structure and activity,[1] further underscores the utility of this parameter in correlating solid behavior with protein conformation and structural dynamics.

The hygroscopic nature of both trypsinogen and sucrose would forecast a cumulative water sorption capacity of their physical mixtures. However, comparison of the actual amounts of sorbed water at low (<35%) relative humidities indicated a concentration-dependent effect of sucrose. At low mass ratios of the disaccharide, the sorptive capacity of the powders actually decreased, in good agreement with literature studies.[26,48] This observation indicates that addition of sucrose contributes to the blockage of potential sorption sites in the binary solid matrix, providing evidence of specific hydrogen bonding interactions between the two components. This analysis further supports the expressed "water replacement" hypothesis.[3,4,12] The interaction is also confirmed by the decreased heat of sorption with increasing sucrose concentration. Moreover, the facility of the replacement of protein−sucrose interactions by water, as represented by the amount of sorbed water at low vapor pressures (<35%) can provide an estimate of the extent (and perhaps the strength) of their interactions. The latter is illustrated in the three-dimensional mesh plot of Figure 7 as a function of the sucrose concentration and vapor pressure. It becomes apparent that the extent of interaction increases with increasing sucrose concentration and becomes maximal at equal mass ratios; thereafter in decreases, as the sorptive capacity of the formulation increases, potentially implying the preferential replacement of the stabilizing protein−sugar contacts.

The existence of specific protein−sucrose interactions was further confirmed by examination of the estimated BET monolayer of water. The importance of this parameter stems from its correlation with the onset of internal protein flexibility.[49,50] Moreover, the water content at the monolayer has been directly linked to the free energy changes induced by water sorption and its concomitant changes in the protein structure,[43] while it can provide information on the relative affinity of the water for the substrate. The decreased value of W_m, upon sucrose addition, confirmed the specific protein−sucrose hydrogen bonding interactions. Similar to our previous observations, W_m became minimal at a sucrose-to-protein mass ratio of 1:1, while it increases at higher sucrose contents, reaching its value for the pure protein at the highest sucrose content.

This explanation is in agreement with our enzymatic activity results,[1] which indicated the sucrose-induced stabilization of trypsinogen up to a mass ratio of 1:1, with subsequent reduction of its protective effects at excess concentrations of the carbohydrate. Moreover, the profile of monolayer values closely follows that of the activity losses of the protein during spray drying, potentially indicating that sucrose−protein interactions in the solid matrix are responsible for both stabilizing and destabilizing effects of the disaccharide. Assuming that the relative values of W_m are proportional to the number of component−water interactions, a relative estimate of the sucrose-occupied sites on the protein surface could be obtained by

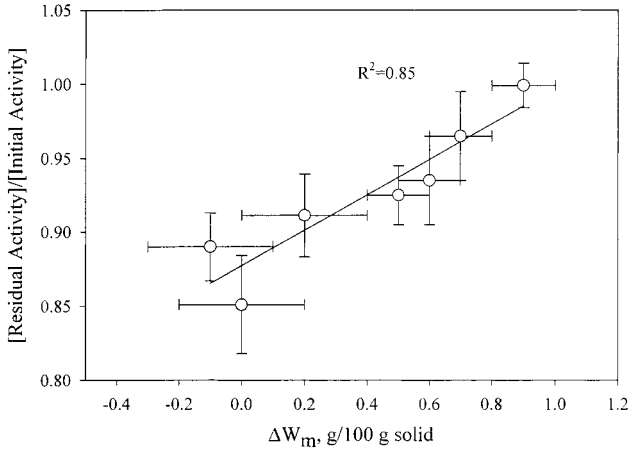

Figure 8—3-D mesh plot of the effect of sucrose and %RH of exposure on the moisture uptake by the spray-dried trypsinogen–sucrose powders.

subtracting the number of water-accessible hydrogen bonding sites of the protein/sucrose mixture ($W_m^{\text{protein/sucrose}}$) from the total number of water-accessible hydrogen bonding sites on the protein in the absence of sucrose (W_m^{protein}), $\Delta W_m = W_m^{\text{protein}} - W_m^{\text{protein/sucrose}}$. From the values of ΔW_m, which are given in Table 2, it follows that at conditions of excess sucrose, the hydrogen bonds between the two components actually decrease and finally reach depletion. This interpretation would support the finding of reduced stability of trypsinogen at the high sugar concentration regime.[1] Indeed, as illustrated in Figure 8, a good correlation ($R^2 = 0.85$) exists between ΔW_m and the residual activity of trypsinogen after spray drying, confirming this hypothesis and implying the replacement of the stabilizing protein−sugar interactions.

Sucrose Crystallization and Inhibition Phenomena—Our moisture sorption experiments indicated that pure, amorphous sucrose can undergo an amorphous-to-crystalline state change at a moisture level of 5.8% w/w. Sucrose crystallization was initiated presumably by sorption of sufficient moisture that reduced its T_g below the operating temperature of 37 °C; in the spray-dried particles crystallization is thought to start at the particle surface and rapidly propagate in the interior.[51] The crystals persisted until approximately 85% RH, which is close to the saturation water activity ($a_w = 0.86$) of sucrose.[27] It is interesting to consider the structure of sucrose in the crystals. In sufficiently diluted solutions, all eight available hydroxyl groups of sucrose form bonds with water molecules.[52−54] However, in concentrated solutions, the high flexibility of the bond joining the two glucose and fructose units promotes the formation of two intramolecular and several intermolecular hydrogen bonds.[53] At this concentration regime, aggregation phenomena occur between sucrose molecules, which now exist in clusters, and under the appropriate conditions will create the stable three-dimensional nucleus.

Although crystallization events were absent at sucrose-to-protein mass ratios lower than 1:1, they became apparent at higher mass ratios of the disaccharide, after exposure to intermediate or high relative humidities. The critical RH of crystallization of these formulations were higher than that observed for the pure compound, denoting the inhibitive role of the protein: increasing concentrations of the protein more effectively inhibit the state transition of the disaccharide, as also indicated by the increasing T_{cryst} with increasing trypsinogen content. From a different perspective, and as illustrated in Figure 3, increasing sucrose concentrations facilitate crystallization, approaching that of the pure compound. Despite the small differences in the

actual critical RH levels, similar results on the inhibitive role of protein in the growth of sucrose crystals were previously described for the rbST−sucrose lyophilized system.[38] It is well documented that impurities decrease the overall growth rate of crystals and change their morphology, as they can block the crystal faces, or even modify the solution characteristics and affect the supersaturation level of sucrose.[52,53] The inhibition of sucrose crystal growth in the presence of high amounts of trypsinogen could reflect the absence of nuclei or even their poisoning by the protein. At low relative protein concentrations, there is less protein available for growth inhibition, while the capacity of the protein phase to compete for water sorption is reduced. In this case, and when adequate water is sorbed to increase the mobility of the sucrose molecules, nuclei can form and grow in the absence of inhibiting interactions. Once nucleation takes place, crystallization occurs rapidly.[55]

For crystallization to proceed, the presence of significant sucrose−sucrose contacts in the solid matrix is imperative. It is therefore conceivable that these are responsible for replacing the stabilizing protein−sugar interactions and could account for the altered interactions of the solid with water. We further assessed the validity of this hypothesis to investigated the nature of this phenomenon.

Phase Separation Phenomena and Origin Hypothesis—Quantitative estimates of the maximum amount of crystallizable sucrose in the formulations can be obtained by the X-ray estimates at conditions of maximal crystal content, 75% RH. Even under these conditions, the X-ray-estimated fractions of crystalline material (within the 5−10% error of the method) cannot fully account for the total amount of sucrose in the formulations, indicating the simultaneous presence of amorphous sugar. Since sucrose crystallization would be inhibited by the presence of protein, it can be assumed that the crystallizable sugar matrix is devoid of protein. This provides evidence for the separation of the dried solid into two distinct phases: a protein-rich and a sugar-rich phase. In the former, amorphous phase, sucrose molecules are in contact with protein, which inhibits their crystallization. In contrast, the second, crystallizable phase, is devoid of protein, so when the system acquires sufficient mobility upon moisture sorption, crystallization is induced. This implies that in the spray-dried material, the phase-separated, crystallizable sucrose does not contribute to the stabilization of the protein, due to its exclusion from it. Assuming that the determined crystallinity fractions provide, within error, a representation of the mass fraction of the crystallized sucrose, we could then obtain via a mass balance an estimate of the actual amounts of amorphous sucrose in the formulations; the analysis is illustrated in Table 5. Using this approach, the amount of protein-interacting, amorphous sucrose was calculated at 15.7, 13.0, and 6.9% w/w for formulations 2:1, 4:1, and 8:1. The analysis indicates that as the mass fraction of sucrose in the formulation increases, there is less available carbohydrate to interact with the protein. The actual amounts of active, protein-interacting sucrose are smaller than expected, based on the formulated mass ratios, as indicated in Table 5. In fact, the effective mass ratios are below the maximally stabilizing mass ratio of 1:1, indicating the inadequate protection of the protein, in agreement with the decreased stability of trypsinogen at these sucrose mass ratios.[1] Moreover, despite the small variability of the observed effects, the phenomenon of partial dissipation of the protective effects of disaccharides has been observed with other proteins,[13,14] indicating a global phenomenon rather than an isolated, protein-specific event.

The onset of the phase separation and crystallization phenomena, with respect to the sucrose content, in the solid formulations coincides with that of the excluded volume effects of the sugar in the solutions before spray drying.[1] Excluded volume phenomena arise from the preferential separation of the carbohydrate from the protein surface; they represent by default phase-separation events at the molecular level. We hypothesize that this distribution of phase-separated formulation components in solution before spray drying is not significantly disturbed during the atomization step, resulting in the formation of protein-rich and sugar-rich phases in the formed particles. The low moisture contents achieved during spray drying prohibited sucrose crystallization in the formulations; however, when the viscosity of the solid matrix decreased upon water sorption, crystal formation was promoted. Further, as discussed above, the protein-excluded sucrose molecules in the solution phase may exist as aggregates, promoting nuclei formation. The presence of aggregate clusters is favored at high concentrations of the disaccharide, as reflected in the reduced hydration number of sucrose: it decreases from 10 to 12 (mol of water/mol of sugar) at sucrose concentrations < 2% w/w, to 5 (mol of water/mol of sugar) at concentrations between 10 and 50% w/w.[54] While the formulated solutions at low sucrose concentrations (mass ratios < 1:1) reside in the former, those prepared at high sucrose concentrations (mass ratios > 1:1) lie in the latter regime, indicating the possible presence of phase-separated, aggregated sucrose in the pre-spray drying solutions.

The proposed mechanisms are in agreement with previous studies on the destabilization of β-galactosidase during lyophilization in the presence of an excess amount of mannitol and inositol;[56,57] however, our results indicate that it is not crystallization per se, but the preceding phase separation event that is responsible for the destabilizing phenomena. It is important to note, however, that the initial protein concentration during spray drying may play an important role, as it may dramatically influence both the starting solution equilibria and the interactions with the excipient in the solid state. More work is required in this direction to understand the concentration dependence of the protein−excipient interactions in the solid state.

Our results suggest that utilization of high concentrations of excipients during preparation of solid state protein formulations may not always be desirable, as even ordinarily stabilizing excipients (such as the commonly utilized disaccharides) may not guarantee the expected stabilization. This becomes particularly important when excipients

Table 5—Nominal and Effective Sucrose Concentrations in the Spray-Dried Trypsinogen–Sucrose Powders

[sucrose: TGN]$_{nominal}$ mass ratio	sucrose[a] (% mass$_{total}$)	free sucrose[b] (% mass$_{total}$)	bound sucrose[c] (% mass$_{total}$)	[sucrose: TGN]$_{effective}$[d] mass ratio
no sucrose	0	0	0	no sucrose
0.25:1	20.0	0	20.0	0.25:1
0.5:1	33.3	0	33.3	0.5:1
1:1	50.0	0	50.0	1:1
2:1	66.7	51.0	15.7	0.47:1
4:1	80.0	71.0	9.0	0.45:1
8:1	88.9	85.0	3.9	0.35:1

[a] Nominal sucrose concentration (% w/w) on a percent total solids basis ($f^{sucrose}_{set}$). [b] Crystallizable sucrose, percent total solids basis. The value represents X-ray diffraction percent crystallinity estimates, under the assumption that sucrose is the only crystallizable formulation component ($f^{sucrose}_{free} = f^{XRD}_{crystalline}$). [c] Noncrystallizable sucrose, percent total solids basis. The value is extracted from a mass balance from the crystallizable sucrose X-ray diffraction estimates ($f^{sucrose}_{bound} = (f^{sucrose}_{set} - f^{sucrose}_{free})$. [d] The "effective" sucrose-to-protein mass ratio is calculated from the mass ratio of noncrystallizable (protein-bound) sucrose to total protein ($f^{sucrose}_{bound}/f^{protein}_{total}$).

that exert excluded volume effects are utilized. Formulation components that exhibit increased capacity for exclusion from the protein surface will have a high tendency to phase separate and will preferentially interact with themselves rather than the protein. Moreover, they may undergo undesirable phase transformations that may decrease product stability. This becomes of particular significance during the administration of pharmaceutical products with sustained release delivery systems, such as polymeric injectable depots or implantable micropumps, because of the exposure of the formulation to increased water levels at the physiologic temperature of 37 °C.

Accepted for publication December 7, 1998.

Abstract □ A method is described for quantifying the pattern of deformation within a matrix and is demonstrated by analyzing the expansion of polymer hydrophilic matrix tablets. The fundamental features of the method are the incorporation of nondiffusing markers into the matrix and the subsequent tracking of these markers during deformation. Since the markers are too large to diffuse, their individual movement reflects the translocation of the surrounding matrix, and the separation between pairs of markers reveals any perturbation in the intervening area. By tracking many markers, the pattern of deformation within a matrix can be ascertained. The method was demonstrated on hydrating hydrophilic matrix tablets, using fluorescent microspheres as nondiffusing markers which were observed with a confocal laser scanning microscope. Analysis of the tracks showed a wave of expansion moving from the exterior toward the core, with the greatest and earliest expansion found in the outer regions. The results also showed that even as deeper layers started to expand the outer layers continued to swell.

Introduction

Many materials undergo alterations in size during their production or use and while it is relatively easy to measure gross dimensional changes[1,2] it is much harder to establish the pattern of internal deformation. Deformation can vary from the isotropic expansion of an evenly heated metal bar to the contraction of drying gels or the hydration of hydrophilic matrix (HM) tablets, both of which are anisotropic, despite the homogeneity of the original material. The experimental difficulty lies in following and quantifying differential deformation, for which there appear to be no established methods.

Hydrophilic matrix tablets are used as controlled release formulations.[3] Their performance depends on the rapid formation of a coherent gel layer around the tablet on hydration. An intact gel layer restricts the further ingress of water and controls drug release by acting as a diffusional barrier and by limiting erosion. The gel layer is inhomogeneous,[4] varying between a water rich exterior and an initially dry core.[4] The common USP dissolution methods used to assess the performance of HM tablets measure only rates of drug release. However, the underlying processes are dynamic and complex, involving interactions between water, polymer, the drug, and ions, all in an expanding and eroding matrix. Similarly, in the food industry, syneresis of gels is estimated by reweighing[5] or from volume changes. These measures adequately describe overall performance but do not expose the underlying processes.

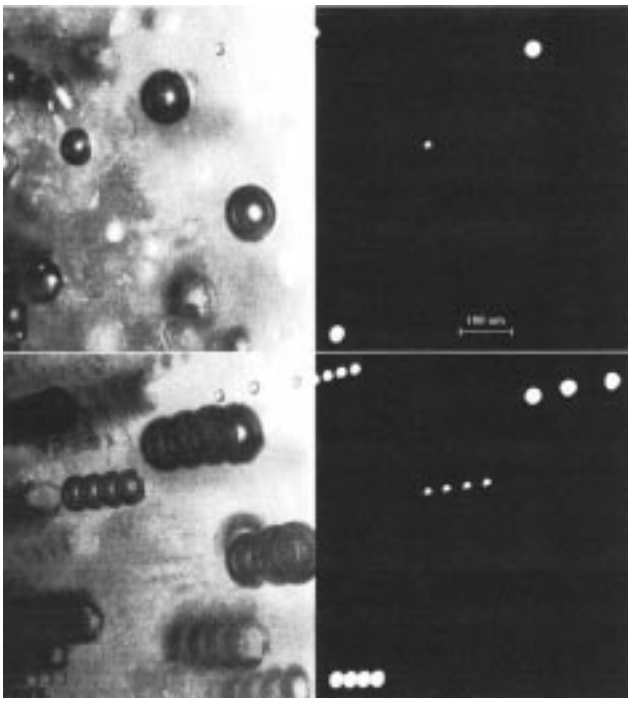

Figure 1—The left panels show (transmitted light image) air bubbles and microspheres, and the right panels (fluorescence image) microspheres only, in the gel layer of an HPMC tablet. The lower panels show a superimposed sequence of four images, showing movement. The bottom left image (transmitted light) is a minimum projection, and the bottom right (fluorescence) a maximum projection. Two sizes of fluorescent microspheres are apparent diameters of 2 μm and 22 μm.

In studying the performance of gel or tablet matrixes, the real goal is to expose the underlying mechanisms and advance from using experiments to observe the performance of specific formulations, to the experimental validation of predictive mathematical models. To confirm and validate such models, experimental methods are required that generate data which fully describes their properties and behavior. With this in mind we have been developing techniques to examine the internal performance of matrixes.[6−8]

We have reported on the presence of air bubbles[9] in HM tablet gel layers and have subsequently observed that these bubbles move as the gel layer continues to expand (Figure 1). Similarly undissolved particulates within a gel are also translocated (Figure 2). In this paper we consider how this observable movement can be used to map the internal performance of matrixes, and we describe a novel method in which nondiffusing markers are embedded within a tablet matrix and tracked during hydration. These tracks are then used to establish where and when expansion occurs. A fundamental assumption is that the influence of Brownian motion on our markers is minimal and that any

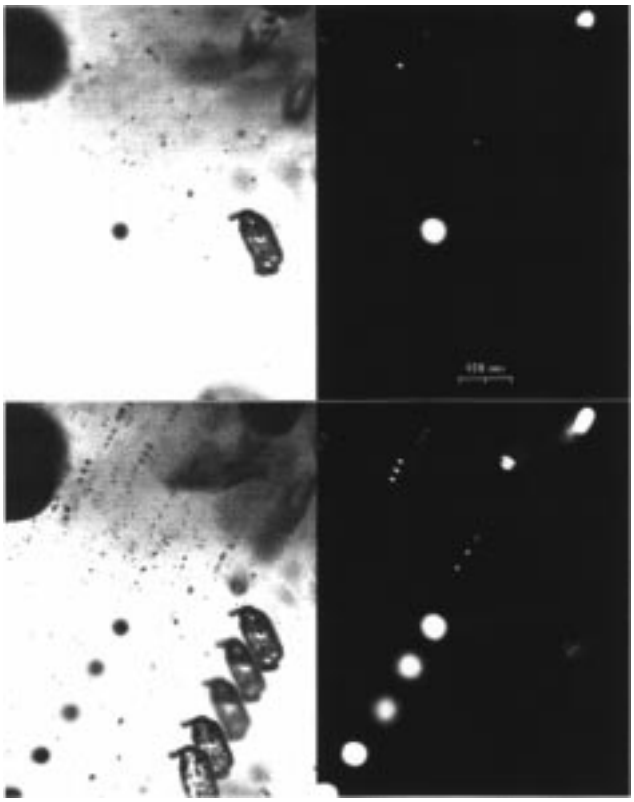

Figure 2—Left panels (transmitted light) show particulates and microspheres, and the right panels (fluorescence image) microspheres in the gel layer of a HPMC tablet. The lower two panels show a superimposed sequence of five images: the bottom left image is a minimum projection, and the bottom right image is a maximum projection. Two sizes of fluorescent microspheres are apparent, diameters of 22 μm and 2 μm.

movement of the markers therefore mirrors movement of the surrounding matrix.

Tracking the positions of individual embedded markers shows the changing location of these points within the matrix. However, their movement is not necessarily a consequence of a localized deformation: when a train moves, all the carriages also move but without any local or even overall deformation. Similarly a difference in velocity between markers does not necessarily reveal different degrees of local expansion: stretching a rubber band, with one fixed end, produces the greatest extension at the free end while the fixed end remains almost stationery, but the local expansion is nonetheless uniform. However, local expansion can be measured from the changing distance between a pair of markers, because their relative separation reflects any perturbation in the intervening zone, and it therefore becomes possible to move from measuring the translocation of markers to the measurement of localized deformation.

In summary, this study examines the use of nondiffusing markers to follow localized deformation within hydrating hydrophilic matrix tablets.

Experimental Section

Materials—Five millimeter diameter flat-faced circular tablets were prepared by direct compression of 40−63 μm sieve fractions of hydroxypropylmethylcellulose (HPMC) (Methocel K4M, Dow Europe, Germany) or xanthan gum (Satiaxane CX90, Sanofi Biopolymers France) containing 0.125% w/w latex microspheres, 2 μm and 22 μm average diameter, labeled with Nile red (Polymer Labs Ltd, UK). The microspheres, supplied in 10% w/v suspension in water, were dried by evaporation and then mixed with the dry polymer by trituration prior to tableting. Tablets were manufactured at a compression force of 1.2−1.5 kN using a Manesty F3 single-punch tablet press (Manesty machines, Speke, UK). Additional HPMC tablets were prepared containing different quantities of microspheres (0, 0.025, 0.05, 0.1, and 0.2% w/w).

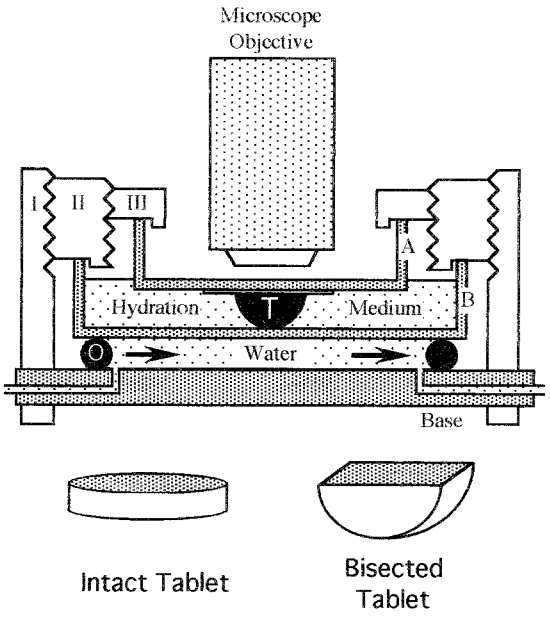

Figure 3—Tablet hydration cell: A bisected tablet (t) is shown placed between two Petri dishes (A and B) and held in place by three concentric brass rings (I, II, III). There is a silicon rubber membrane between Petri dish A and the tablet surface. The lower chamber, formed by compression of an O ring between the base and Petri dish B, can be perfused to maintain a constant temperature. Intact or bisected tablets were mounted in the cell, with a flat surface presented to the microscope objective.

Tablet Hydration Cell—Consisted of three interlocking brass rings (I, II, and III), two Petri dishes, and a transparent Perspex (poly(methyl methacrylate) base (Figure 3). Rotation of the upper two rings fixed a tablet between the two Petri dishes, enabling the observation of the upper surface of the tablet during hydration. The hydration medium was added to the chamber formed between the two Petri dishes. To prevent the hydration medium penetrating between the upper Petri dish (diameter 35 mm) and the upper surface of the tablet, a 200 μm transparent silicon rubber membrane was inserted between the tablet and the underside of the upper Petri dish. Temperature control was achieved by (i) preheating the hydration medium and (ii) circulating water through a bottom chamber formed by the compression of a silicon rubber O ring between the lower Petri dish and the Perspex base.

Tablets were hydrated at 37 °C in degassed distilled water. Two different orientations (Figure 3, bottom) of the tablets were used: (i) intact tablets face down for examination of radial expansion and (ii) bisected tablets with their exposed surface facing upward for both radial and axial expansion.

Confocal Laser Scanning Microscopy (CLSM)—Sequential images (768 × 512 pixels with 8-bit intensity) were generated using a MRC600 confocal microscope (Bio-Rad, Hemel Hempstead, UK) based on a Nikon Labophot upright microscope using the YHS filter with excitation at 565 nm and a ×1 microscope objective. Images were taken with the microscope focused 100 μm below the silicone/tablet interface.

The method relies on following individual microspheres through a series of images, but small movements in the *z* axis can take a microsphere outside the plane of focus, making tracking difficult. This problem was ameliorated by generating each image from a maximum projection of four almost synchronous images taken at increasing (20 μm step) depths. In a projection, homologous pixels from each image are compared and either the most intense (a maximum projection) or the least intense (a minimum projection) retained in the final image.

The confocal microscope was also used to generate transmitted light images which showed the initial edge of the dry tablet and the outer limit of the gel layer after hydration. These images were obtained using a light collector beneath the hydration cell. Changes in the extent of the gel layer were used to compare water uptake

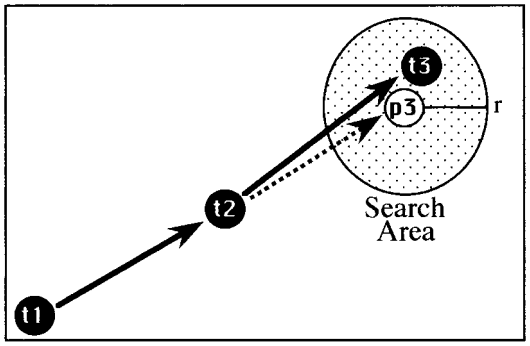

Figure 4—The tracking method: the two previous positions (t1 and t2) are used to predict the next location (p3), which is used as the center of a search area (radius r) for the actual subsequent location (t3).

in the series of tablets containing different fractions of microspheres.

Image Processing—In the CLSM images, the fluorescent microspheres appeared as areas of high intensity against a dark background, with each microsphere covering several pixels. Ideally each microsphere should be tracked from its center to the next center; however, it is possible that the brightest single pixel may not occur at the center. To ensure that the tracking was from center to center, a local averaging of the image preceded each search. For a bright object of a similar size to the distance used by the local area average, the brightest pixel is forced to center. The fluorescence image of the microsphere typically covered about 20 pixels and an equally weighted local average over a 5×5 pixel block was used. The centers were located to the nearest pixel.

Tracking Microspheres—Software was developed around a Semper 6.4 (Synoptics, Cambridge, UK) kernel operating on a Sprynt 40 processing board (Synoptics, Cambridge, UK). The objective was to determine the *x,y* coordinates of identified particles throughout a sequence of images. Figure 4 shows how the location of a microsphere in two preceding images (t1 and t2) was used to predict the next location (p3), and this predicted location then became the center for a local search (radius *r*) for the particle, producing the actual location (t3). Once the location of the microsphere had been established in several images, the predicted location was then based on the preceding three images, which proved to be more accurate. The initial location of each particle (t1) was input using a mouse from a prehydration image, and the second location (t2) was also input manually from either the first post-hydration image or from a maximum projection image, which sometimes made it easier to establish the direction of a track. After the first two locations had been established, the subsequent tracking was undertaken by the software alone. The search radius around the predicted location was either 8 pixels or half the length of the predicted movement, whichever was the greater. This choice of search radius depended upon the density of microspheres and was a compromise between checking a small enough area to exclude a second microsphere, and using a sufficiently large area to accommodate substantial changes in velocity.

Provision was made in the tracking software for automatically discontinuing the search for microspheres that exceeded the limits of the image (once part of the search area fell outside the image) and also for the rejection of manifestly incorrect tracks. These can occur when a second more intense microsphere appears in the search area and the search algorithm then latches onto an incorrect path.

Analysis—After tracking was completed, the initial location and subsequent path taken by each microsphere was stored as a sequential list of *x,y* coordinates from which the speed of each microsphere was obtained. However, our primary interest lies in determining where and when the matrix deforms. As discussed previously, the movement per se of a single microsphere does not reveal the local rate of expansion in the matrix, but this can be determined from the relative position of a pair of microspheres. However, when considering the radial expansion of flat-faced cylindrical tablets, which are radially symmetrical, the distance of each microsphere from the center of the tablet can replace the *x,y* coordinates. This then permits the grouping of microspheres into bands of similar radii. Within each band the radius of each microsphere was expressed as a ratio to its original radius, and the mean ratio multiplied by the nominal radius of the band then produced the average radius. The changes in the average radius of each band and difference in radii between adjacent bands were used to measure overall expansion and local expansion. The coordinates of the tablet center were derived from the curvature of the tablet edge. When bisected tablets were observed, the movements of individual microspheres were separated into radial and axial vectors.

Results

The images obtained showed that it was practical to incorporate and detect fluorescent microspheres in HM tablets. The compression used during tableting did not seem to fracture or fragment the microspheres, and their distribution appeared to be random. Sequential CLSM images of hydrating HM tablets showed that individual microspheres could be followed for long periods.

In Figures 1 and 2 individual fluorescent microspheres and their movement are apparent. The individual microspheres, polymer particles, and air bubbles appeared to move linearly and in concert. The speed (the distance between successive occurrences) of microspheres within a few hundred micrometers of each other differs, which we attribute to different rates of local expansion of the matrix. In the lower panels of Figure 2 a blurring of the polymer particle and the large microsphere is apparent, and in the maximum projected image (bottom, left) there are five occurrences of the large microsphere but only three occurrences of the smaller microspheres. We attributed these variations to small movements in the *z* axis that took smaller objects outside the focal plane and defocused the larger objects. Problems associated with small movements in the *z* axis were minimized by using only the larger 22 μm microspheres in subsequent experiments and by using a maximum projection of four images taken at different depths.

Figure 5 (upper) shows that individual microspheres can be clearly seen in a dry tablet. The maximum projections (Figure 5 center and Figure 9 upper) contain the combined sequence of images and revealed linear tracks, apparently radiating away from the center of the tablet. The tracks of individual microspheres, shown in the maximum projected images in Figures 5, 8, and 9 are either linear or gently curving and are in the direction of expansion. Their linearity shows that Brownian motion had minimal influence. The overall pattern of movement and the continuing proximity of microspheres to the edge of the gel layer indicate that the microspheres were carried along with the hydrating polymer.

Individual microspheres, shown by their paths in the maximum projected images in Figures 5, 8, and 9, cover markedly different distances depending on their initial position in the tablet. The actual distance covered is the path length minus the diameter of the microsphere, but this is an overall measure taken over the full duration of the experiment; a more detailed assessment requires tracking individual microspheres through the whole sequence of images.

The tracking software proved able to follow a substantial number of microspheres. However, some microspheres moved outside the plane of focus of the confocal images and were lost; others were not apparent in the first image and only appeared in subsequent images, either by moving into the plane of focus or becoming visible as a transparent gel layer replaced the relatively opaque dry polymer. The greatest problems occurred with microspheres on the edge of the tablet, which move very rapidly in the initial 2 min after hydration making them difficult to track, and with

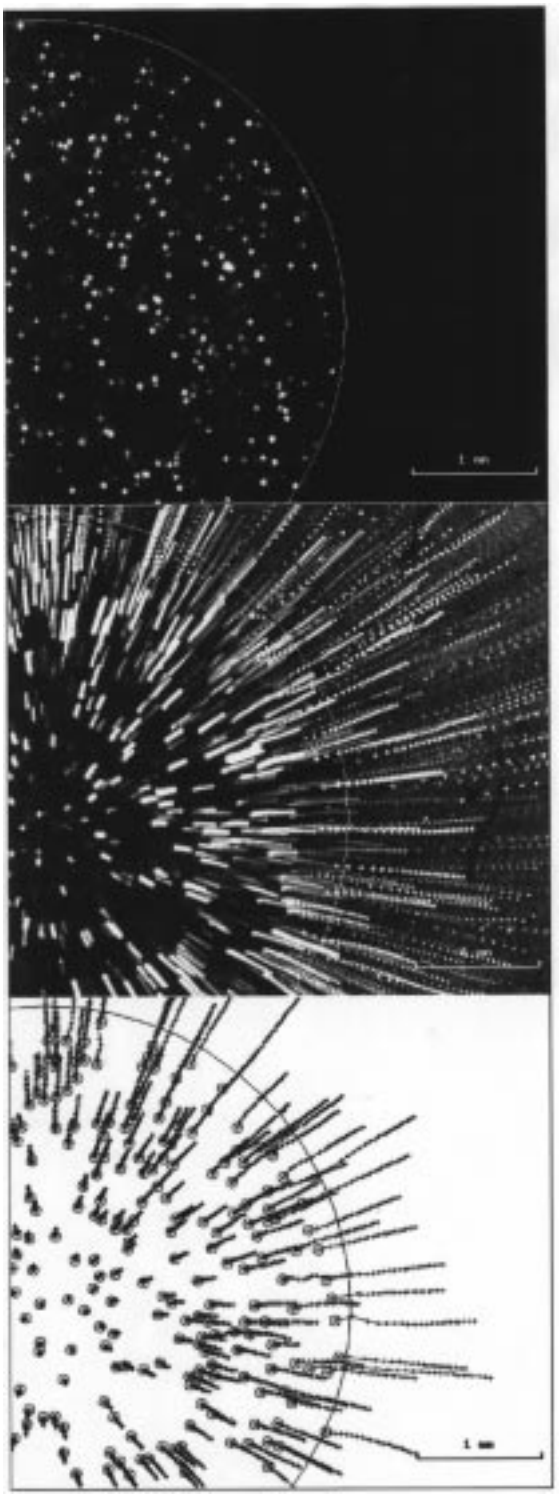

Figure 5—Radial expansion of a xanthan tablet. Upper panel: a confocal microscope image showing fluorescent microspheres within a dry tablet. Lower panel: the mapped tracks of identified microspheres starting from their original locations. The original edge of the tablet is superimposed on each image.

pairs of microspheres that were too close to be easily separated. The complete tracks of 211 microspheres that were followed from the first image appear in Figure 5 lower panel.

It is apparent that the movement of individual microspheres depends on their proximity to the initial edge of the tablet and declines further into the tablet. This is made clear in Figure 6 when the individual movements are

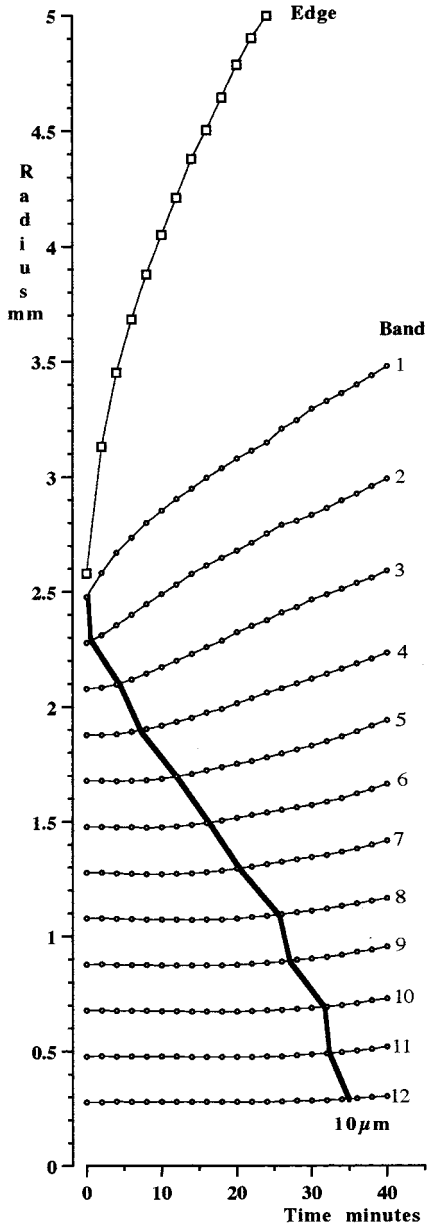

Figure 6—The expansion within a xanthan tablet undergoing hydration, shown as the growth of a series of 200 μm concentric bands radiating from the tablet center. Band 1 is the outermost and band 12 the innermost. $y = 0$ mm is the tablet center. The movement of the outermost edge of the tablet is also shown. The thick line links the time points when each band first moved by 10 μm.

pooled by assigning microspheres into a series of 200 μm wide bands at increasing distance from the tablet edge. The outer bands move earlier and faster, but even the deepest bands finally undergo some movement. An estimate of when each band began to move was obtained by marking the time when a 10 μm displacement first occurred. This reveals the ingress of a wave of expansion which reached the innermost band after 36 min. This was a surprising finding since the gelatinous layer formed around the tablet only extends over the first few bands.

The outer edge of the gel, shown in Figure 6, appears to expand much more dramatically than the microspheres in the outermost 200 μm band. This is a consequence of underestimating the expansion of the outer band due to difficulties in tracking microspheres that originate close to the tablet edge. The rapid expansion made following these microspheres difficult.

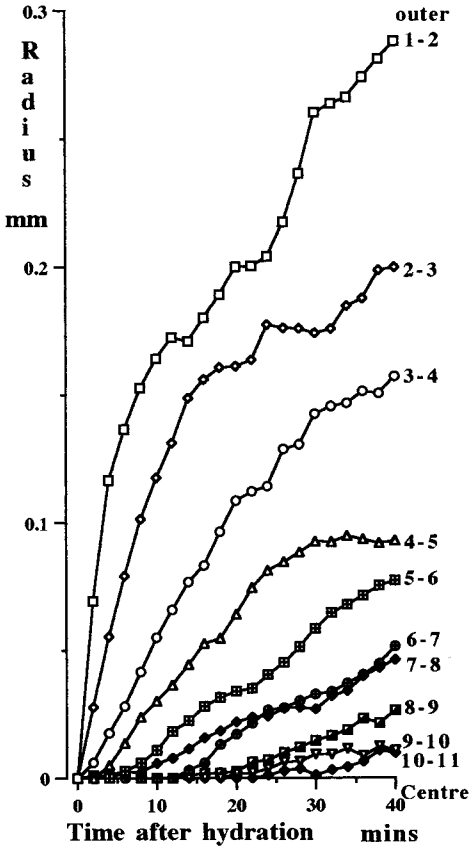

Figure 7—The differential expansion between adjacent concentric bands in a hydrating xanthan tablet, determined by subtracting the movement of the adjacent inner band. Each band is 200 μm thick and band 1-2 is the outermost.

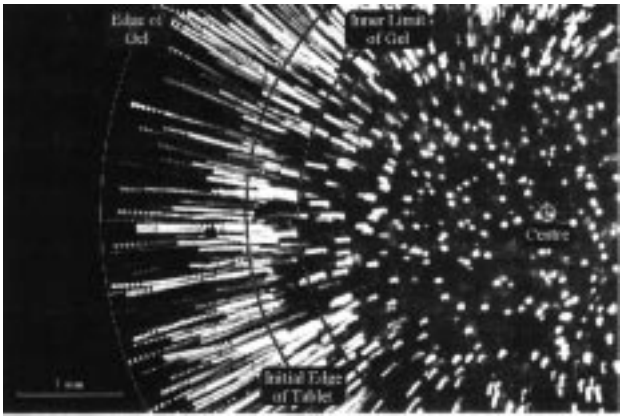

Figure 8—Tracks made by fluorescent microspheres in a xanthan tablet hydrating in 0.05 M NaCl over 80 min. The image is a maximum projection. Also marked is the initial location of the tablet edge and the final limits, inner and outer, of the gel layer.

The progressively increasing radius of each band could correspond to expansion within the band, to displacement following the expansion of deeper areas of the matrix, or to a combination of both mechanisms. In Figure 7 the analysis is extended by subtracting the radius of the adjacent inner band from each band, leaving the endogenous expansion. This shows that expansion progressively decreases deeper within the tablet and that the outer band is still expanding at the end of the experiment.

To determine the relative penetration of the gel layer into a tablet and the depths at which the movement of microspheres occurred, the gel layer of a hydrated tablet was gently removed with a small spatula and the size of the residual core measured. The core of the tablet was hard and appeared dry. In Figure 8 the initial tablet edge and the limits of the gel layer are superimposed on the tracks of the embedded microspheres. The extended tracks of microspheres beyond the inner limit of the gel layer shows that expansion had occurred deep in the core of the tablet though had not yet reached the center.

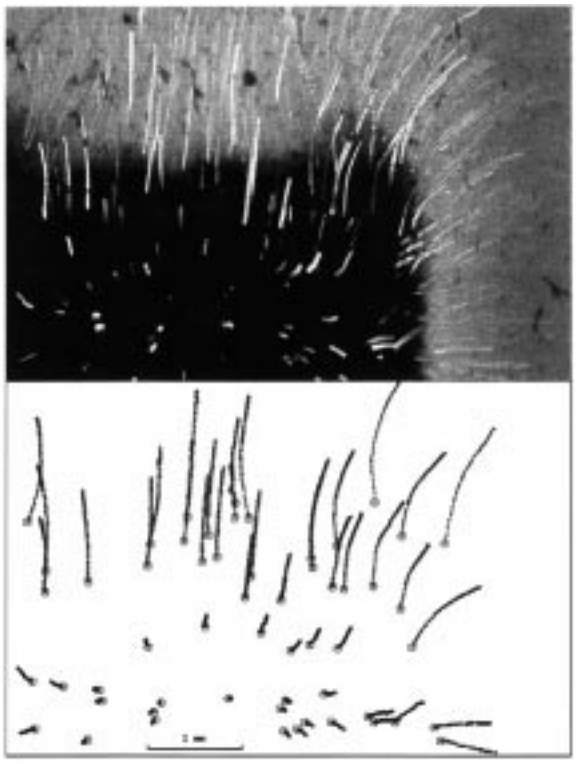

Figure 9—The expansion of a bisected hydroxypropylmethylcellulose tablet after hydration. Upper panel: a maximum projected image showing the paths followed by microspheres following hydration. The inclusion of the fluorophore Congo red in the hydration medium makes the gel layer apparent. Lower panel: the mapped tracks of identified microspheres, starting from their original locations. Axial movements are in the vertical plane and radial movements in the horizontal plane.

When a bisected hydroxypropylmethylcellulose (HPMC) tablet was examined (Figure 9), the pattern of microsphere movements was more complex, with some microspheres taking curved paths, rather than the linear trajectories seen with intact tablets. Curved tracks predominated at the corners of the tablet, reflecting the interplay between axial and radial expansion. More unexpected were the tracks of some microspheres that originated slightly away from the corners and, while predominantly moving axially, had an initial inward radial component that was later replaced by an outward component. We suspect that this pattern may be due to an inward pressure exerted by the more rapidly expanding corners of the tablet that cause a slight short-lived radial compression. The larger surface area at the corners increases their exposure to water and accordingly leads to a greater rate of expansion, which produces a dumbbell shape.[10]

Examination of tablets containing different amounts of microspheres (0−2.0% w/w) showed no discernible difference in their rates of expansion when recorded at 4 min intervals and followed over 60 min, with each performed in duplicate.

Discussion

We have demonstrated that it is possible to closely follow events within a hydrating tablet and to follow its expansion in the *x* and *y* axes but not concurrently in the *z* axis.

The hydration cell, by preventing direct access by water to the upper face of the tablet, effectively makes observation of only this face serve to cover a range of depths from the outer limit of gel layer to the center of the tablet. Prevention of direct hydration of the upper face is critical because (i) the formation of an overlying gel layer would quickly exceed the imaging depth of even a confocal microscope, (ii) the opacity of the unhydrated polymer would prevent imaging below the unhydrated surface, and (iii) the accurate measurement of depth[11] is especially difficult through layers of progressively changing refractive index. The prevention of direct hydration was achieved with a silicon rubber membrane between the upper surface of the tablet and the upper Petri dish and is further enhanced once a gel layer has formed around the edge of a tablet, which seals any residual gaps and prevents water flowing across the upper surface. By imaging 100 μm below the silicon rubber/tablet interface, we probably avoid any interference between the polymer and the membrane. However, an interaction can only be precluded either by imaging at much greater depths, which is unfortunately impractical, or by comparison of the experimental observations with similar observations from an unrelated technique, which is currently unavailable.

The use of intact tablets measures radial expansion while bisected tablets permit the measurement of both radial and axial expansion. Intact tablets, when confined in our hydration cell, model a tablet of infinite axial thickness in which only radial expansion can occur. The curved and faster trajectories seen with microspheres at the corners of bisected tablets is probably due to their exposure to external water from two surfaces and generates the dumbbell shape commonly observed with flat-faced circular tablets. The bisected tablet is a better model of in vivo hydration since it shows both axial and radial expansion; however, the analysis of the tracks is much more difficult, and this approach requires the physical cutting of tablets, which may alter their performance.

Our measurements of expansion were made in unstirred water, unlike the standard USP procedures for measuring drug release which place tablets in a rotating cage or a medium stirred by a paddle. Our experiment was therefore a simplification of a tablet undergoing drug release since erosion of the tablet was greatly reduced; however, it does demonstrate that complex measurements are possible within these tablets. The hydration cell could be modified to permit both agitation of the hydrating medium and also to allow fluid sampling to determine drug release rates, thereby providing a more complete picture of in vitro release.

A major assumption underlying the use of markers is that they remain trapped within the matrix and do not move independently. The linearity of their tracks, in contrast to the random walks seen with Brownian motion, confirms our expectation, based on their mass and the viscosity of the gel that diffusion does not contribute significantly to their movement. Also we found no evidence that the initial inrush of water carried microspheres deeper into the matrix. An additional assumption was that the presence of the microspheres does not alter the performance of the matrix; the small fraction of the matrix occupied by the chemically inert microspheres makes this assumption plausible, and experiments showed that the expansion of tablets was unaffected by the presence microspheres.

Early experiments tested silver granules, observed by reflection, as nondiffusing markers, but their lower intensity and irregular shape made tracking difficult and they proved less satisfactory than fluorescent microspheres. Undissolved particles of polymer and air bubbles could potentiallly be used as markers, but air bubbles are only found in hydrated regions of the gel layer and are unevenly distributed, while the irregular shape of undissolved polymer particles makes precise tracking difficult. Both air bubbles and polymer particles can only be observed with transmitted light which would preclude observation in the poorly hydrated tablet core which is opaque.

The tracking software combined with CLSM imaging was able to follow individual microspheres. Similar tracking of particulates has been employed to measure the motion of individual particles on cell surfaces,[12] sperm motility,[13] and rates of mucocillary clearance.[14] The use of a predictive tracking strategy is only appropriate because the random walks seen with simple diffusion are not seen. Our analysis requires that each microsphere is tracked from its initial location, prior to hydration, over the whole image sequence. This proved difficult for microspheres originating close to the tablet edge, because the dramatic initial swelling makes finding the subsequent location very difficult. Increasing the frequency of images over the first few minutes reduces this problem, though the changing time intervals need to be incorporated into the predictive part of tracking strategy.

To summarize the pattern of expansion, the tracks of individual microspheres were grouped into bands of similar depth and the normalized movements of each microsphere were combined to obtain the changing radius of each band (Figure 6). This treats each band as homogeneous, which is reasonable given the radial symmetry of the expansion and the relatively macroscopic level of investigation. Within each band microspheres appeared to be randomly distributed and each band contained many microspheres; however, it should be noted that the shrinking area covered by bands closer to the center of the tablet progressively reduces the number of associated microspheres and therefore the accuracy of the measurements. This could be ameliorated by calculating the location of each microsphere to subpixel accuracy.[15] In the outermost band the assumption of homogeneity of deformation is combined with the difficulty of tracking the outermost microspheres and produces an underestimate of the expansion. While this is lessened by the ability to follow the outer gel edge, it could be reduced by using thinner bands and by using more frequent imaging in the initial period after hydration.

Overall we are able to quantify deformation throughout a HM tablet and confirm that expansion reaches deep into the tablet, well in advance of the limits of gel layer. Expansion of the core, especially in HPMC matrix tablets has been reported previously,[16] but this is the first direct observation made of the internal dynamics of the process. The underlying mechanism is unclear, but we suspect either the effect of water vapor moving ahead of the gel front or that the gelation of the exterior reduces the mechanical integrity of the tablet, releasing stresses stored during compression. Prolonged exposure to water vapor alone has been reported to cause axial expansion of HM tablets[1] albeit over a longer time scale.

It is also apparent that the outer layers of the these tablets expanded dramatically and still continued to expand as deeper layers began to hydrate. In tablets made from HPMC we have observed how rapid water uptake of the constituent polymer particles then retards the total water uptake by the whole tablet,[17] but the time scale for this process may differ between polymers. In addition, we would anticipate finding, and being able to experimentally differentiate between, hydrated matrixes with similar gel layer thicknesses, but which have resulted from different patterns of internal expansion. This could result in different polymer distribution within the gel layer and altered controlled release properties.

Our method has similarities to studies of HM tablets with magnetic resonance imaging that were used to follow gross changes in the size of the gel layer[18] and map water mobility[19] but cannot establish the local expansion within the gel or dry core. At present, MRI imaging also has poorer temporal and spatial resolution than CLSM.

There is considerable scope for extending the use of embedded microspheres. We have used them to measure syneresis in gels,[20] and the technique would be suitable for examining dehydration shrinkage. The method could also be used to examine selected areas at much higher magnifications, to isolate localized inhomogeneities that undoubtedly exist. The development of techniques for imaging deep within matrixes would make it feasible to measure deformations in three dimensions.

Through measuring internal events within HM tablets we believe it will become possible to elucidate the complex events that underlie their performance. Although the suggestion that "I have yet to see any problem, however complicated, which when looked at in the right way, did not become still more complicated"[21] might be considered to apply, we submit that the dynamics of drug release from HM tablets are inherently complex and require models of similar complexity founded on similarly detailed experimental observations.

Abstract □ Halofantrine hydrochloride (Hf) is an orally active, highly lipophilic antimalarial indicated for the treatment of multi-drug resistant *Plasmodium falciparum.* In this study, we have examined the binding profile of Hf to the various classes of human and beagle plasma lipoproteins as such interactions have been implicated in a post-prandial plasma lipoprotein-induced decrease in the total clearance and volume of distribution of Hf. The distribution of Hf within plasma was dominated by interaction with the various classes of plasma lipoproteins, and the characteristics and extent of binding were markedly different between species and between pre- and post-prandial plasma. In an attempt to understand the basis for the differential binding of Hf to the various lipoprotein fractions, the relationship between the proportion of Hf associated with each lipoprotein fraction (as a function of the respective mass of protein, triglyceride, cholesterol, and phospholipid) was investigated. The data indicated that the distribution of Hf between plasma lipoproteins was highly correlated with the apolar lipid load of individual plasma lipoprotein fractions suggesting that the mechanism of association was primarily via solubilization in the lipoprotein apolar lipid core. These data suggest that acute changes in plasma lipoprotein profiles, such as encountered post-prandially or in disease states such as malaria, will likely have an impact on the plasma lipoprotein binding of Hf.

Introduction

Halofantrine hydrochloride (Hf) is an orally administered, highly lipophilic phenanthrenemethanol antimalarial indicated for the treatment of acute infections caused by multi-drug resistant *Plasmodium falciparum* and *Plasmodium vivax*.[1] Absorption of Hf after fasted oral administration is poor and highly variable, although the extent of absorption is markedly enhanced when administered post-prandially.[2,3] The primary biopharmaceutical consequence of post-prandial Hf administration is improved solubilization within the bile salt rich post-prandial intestinal environment leading to enhanced absorption.[2] An interesting secondary consequence of post-prandial administration is an apparent plasma lipoprotein-induced decrease in the clearance and volume of distribution of Hf.[4]

The distribution of Hf within beagle plasma is dominated by interaction with plasma lipoproteins, with the characteristics and extent of the binding reflecting the relative pre- and post-prandial lipoprotein profiles.[4,5] In beagles, a significant temporal relationship was noted between the association of Hf with lipoproteins and the post-prandial reduction in total clearance (15%) and volume of distribution (21%).[4] This effect was most likely mediated via a reduction in the free fraction of Hf in plasma which occurred secondarily to increased binding to plasma lipoproteins.[4]

The profile of plasma lipoproteins varies widely between and within individuals as a function of age, gender, co-administered drugs, diet, and disease states including alcoholism, diabetes, and acute malaria,[6,7] thereby raising the possible specter of altered therapeutic profiles of highly lipoprotein-bound drugs (such as Hf) under these circumstances.[8] For example, it was recently demonstrated that the IC_{50} of Hf determined in continuous in vitro culture of *P. falciparum* was significantly increased when incubated in the presence of 10% post-prandial serum.[9] From a drug targeting standpoint, as high-density lipoproteins (HDL) are a major phospholipid source which can support the intra-erythrocytic stage of parasite reproduction,[10] the possibility of HDL-associated uptake of Hf into infected erythrocytes has been suggested.[11] From a toxicological standpoint, there appears to be a linkage between excessively high plasma Hf concentrations and cardiac side effects (typically observed as a lengthening of the QTc interval) in patients with a preexisting cardiopathy.[12] As excessively high plasma concentrations of Hf are typically observed after post-prandial administration, elucidation of the distribution of Hf between post-prandial lipoproteins may contribute to a better understanding of the possible factors contributing to the changed QTc profiles.

In this study, we have extended our previous preliminary examination[5] of the in vivo lipoprotein binding of Hf in beagle plasma to pre- and post-prandial human plasma. In an attempt to understand the basis for the differential binding of Hf across lipoprotein fractions, the relationship between the proportion of Hf associated with each lipoprotein fraction (as a function of the respective mass of protein, triglyceride, cholesterol and phospholipid) was investigated between species in pre- and post-prandial states.

Materials and Methods

Chemicals—Halofantrine hydrochloride and Hf base were obtained from SmithKline Beecham Pharmaceuticals (Brentford, Middlesex, U.K.). Acetonitrile (Mallinckrodt, Paris, KY) and *tert*-butyl methyl ether (Fluka, Buchs, Switzerland) were HPLC grade, and sodium dodecyl sulfate (SDS, Eastman Kodak, Rochester, NY) was electrophoresis grade. All other chemicals were at least AR grade, and water was obtained from a Milli-Q (Millipore, Bedford, MA) water purification system.

Plasma Incubation Studies—Blank plasma was taken from healthy male beagle dogs after either an overnight fast or 4 h after ingestion of 400 g of standard canned dog food (average composition: 2.5% fat, 7.5% protein) supplemented with 50 mL of soybean oil (a representative long-chain triglyceride). Human plasma was obtained from a healthy male volunteer after either an overnight fast or 4 h after ingestion of a lipid rich meal (fat content greater than 50 g: MacDonalds Big Mac and french fries). Blood samples were collected into sterile tubes, anti-coagulated with 1.5 mg mL^{-1} Na_2EDTA, and centrifuged at 2000 rpm for 15 min, and the plasma stored at 4−8 °C. For incubation studies, fresh blank plasma (used within 3 h of collection) was prewarmed to 37 °C and spiked with drug dissolved in ethanol (10 μL of ethanol per mL of plasma) to provide a final drug concentration of 1000 ng mL^{-1} (Hf base equivalents). The addition of up to 50 μL of ethanol per mL of plasma does not have a discernible affect on plasma lipoprotein concentrations or their respective composition or integrity.[13] The spiked plasma samples were incubated at 37 °C for 60 min in a temperature-controlled water bath, and the samples were gently swirled manually at 5 min intervals. At the conclusion of the incubation period, samples were placed in an ice bath for at least 5 min prior to immediate density gradient ultracentrifugation.

The Hf distribution profiles from the in vitro spiking studies were compared with the distribution profile of Hf in a plasma sample taken from a fasted male beagle (3 yr, 18 kg) 30 min after intravenous administration of a 2 mg kg^{-1} dose of Hf base prepared in Intralipid.[14]

Lipoprotein Separation—After incubation of plasma with Hf, 1 mL plasma samples were fractionated by single spin density gradient ultracentrifugation as previously described.[5,15] Briefly, stock buffer for density gradient solutions contained 0.1% NaN_3, 0.2% Na_2EDTA, and 1.2% Tris base dissolved in distilled water adjusted to pH 7.4, which was stored at room temperature after filtration. Density gradient solutions were prepared by adding appropriate quantities of KBr to a plasma background solution, and the solution densities were confirmed using refractometry. The density gradient was formed in a 4 mL centrifuge tube (Seton Scientific, Sunnyvale, CA), and the samples were centrifuged at 15 °C for 19 h at 58 000 rpm (Sorvall OTD65B Ultracentrifuge, Newtown, CT) using a SW 60 rotor (Beckman, CA). Plasma samples were separated into the following fractions: triglyceride rich lipoproteins (TRL, which includes VLDL and chylomicrons), low-density lipoproteins (LDL), high-density lipoproteins (HDL), and lipoprotein deficient plasma (LPDP). In a minor modification to our previous technique,[4,5] the majority of TRL was first recovered from the top of the centrifuge tube by needle aspiration of 2 × 200 μL aliquots. This modification improved the separation of post-prandial TRL and minimized potential contamination of the more dense fractions with TRL. The LDL, HDL, and the LPDP fractions were then obtained using a fraction collection system (Beckman, CA) where a high-density solution (Fluorinert, Sigma Chemicals, St Louis, MO) was pumped into the bottom of each centrifuge tube at 24 mL h^{-1}, the eluent was collected from the top of the tube and passed through a UV detector set at 280 nm (to identify peak elution via monitoring of lipoprotein-associated protein), prior to the automated collection of 18 × 200 μL aliquots.

Each aliquot was analyzed for total protein (TP), total cholesterol (CH), free cholesterol (FC), triglyceride (TG), and phospholipid (PL) using commercial enzymatic colorimetric kits (Bohringer Mannheim, Germany) running on a Cobas BIO clinical analyzer (Roche, Basle, Switzerland). The analyzer was externally calibrated for each run and quality control samples were run on a weekly basis. In aliquots from beagle plasma, the amount of cholesteryl ester (CE) was calculated as the difference between the measured CH and FC values, whereas in aliquots from human plasma the mass of CE was calculated as a fixed percentage of the measured TC value for each individual lipoprotein fraction.[16]

The individual cholesterol and triglyceride concentration profiles in each aliquot were used to define the respective TRL, LDL, HDL, and LPDP fractions. Typically, the two aspirated aliquots were combined with the initial two aliquots obtained using the fraction recovery system (i.e., aliquots 3 and 4) and designated as the TRL fraction, aliquots 5−11 were combined for the LDL fraction, aliquots 12−17 were combined for the HDL fraction, and aliquots 18−20 were combined for the LPDP fraction.

Analysis of Hf in Lipoprotein Fractions—The concentration of Hf in plasma and individual lipoprotein fractions was determined using a validated assay.[17] Due to the logistical difficulty in obtaining sufficient quantities of blank lipoproteins to routinely prepare standard curves for each individual lipoprotein fraction, spiked blank plasma was used to prepare standard curves on a daily basis. The validity of this approach was confirmed by the similarity in the ratio of the peak area/concentration values (<5%) from standard curves prepared using either plasma or specifically isolated lipoprotein.

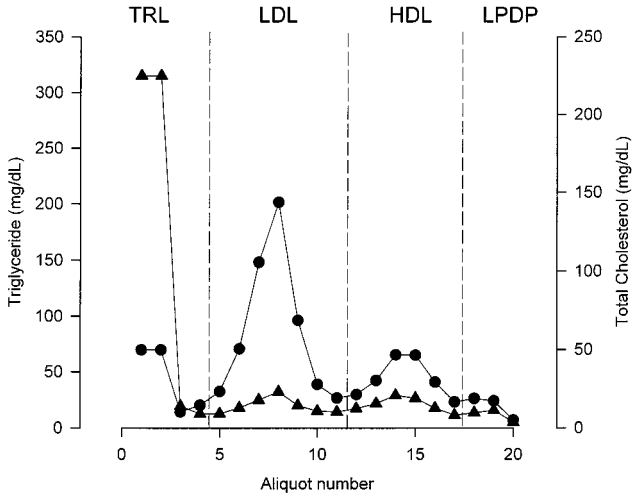

Figure 1—Representative profile of total cholesterol (●) and triglyceride (▲) concentrations as a function of fractionation aliquot obtained after density gradient ultracentrifugation of 1 mL of post-prandial human plasma. Aliquots 1–4 were combined for the TRL fraction, aliquots 5–11 for the LDL fraction, aliquots 12–17 for the HDL fraction, and aliquots 18–20 were designated as the LPDP fraction.

Compositional Analysis of LP Fractions—To explore the basis for the distribution of Hf between lipoprotein fractions, the compositional profile of individual lipoprotein fractions based on measured PL, CH, FC, CE, TG, and TP values were assessed in the following manner. The mass of apolar lipid, which effectively constitutes the hydrophobic core of lipoproteins, was calculated for each respective fraction as the sum of the CE and TG content. The volume of the hydrophobic core was calculated assuming individual lipoprotein particles to be spherical, with each lipoprotein fraction having a similar gross structure including a 20.5 Å thick surface monolayer as previously described.[18] The following average values[16] for the density (ρ) and average radius (r) of human lipoproteins were used to calculate the volume of the hydrophobic core and the surface area of individual human lipoprotein fractions: VLDL, r = 275 Å, ρ = 989 mg mL^{-1}; LDL, r = 100 Å, ρ = 1042 mg mL^{-1}; HDL, r = 37.7 Å, ρ = 1136.5 mg mL^{-1}. The volume and surface area values of lipoprotein fractions from beagle plasma could not be estimated as published density and radius data were not available.

Results

The lipoprotein fraction isolation procedure employed in the current study was modified to better separate the increased quantities of TRL present in post-prandial plasma compared with our previous technique designed for pre-prandial plasma.[4,5] Figure 1 depicts a typical separation profile of post-prandial human plasma when monitored using the TG and TC concentrations present in individual fractionation aliquots. Importantly, there was distinct separation of TG associated with the sequential TRL and LDL fractions indicating an excellent separation profile.

The distribution of Hf between lipoprotein fractions obtained after in vitro spiking of pre-prandial beagle plasma with an ethanolic Hf·HCl solution, or from a blood sample taken from a pre-prandial beagle after intravenous administration of Hf base (sample taken at 30 min post-dosing as this afforded a plasma Hf concentration of approximately 1000 ng mL^{-1}), are presented in Table 1.

Table 1—Percentage Distribution of Hf between Plasma Lipoprotein Fractions[a] (Mean ± SD, $n = 3$) Obtained after in Vitro Incubation of Fasted Beagle Plasma with Hf·HCl Dissolved in Ethanol (10 μL/mL Plasma) and from an in Vivo Plasma Sample Taken from a Fasted Beagle 30 min after Intravenous Administration of 2 mg kg^{-1} Hf Base

[c] Recovery is defined as the % mass of drug recovered after plasma fractionation divided by the mass of drug present in the original sample.

Greater than 90% of Hf present in either plasma sample was accounted for in the TRL, LDL, HDL, and LPDP fractions. The utility of the in vitro spiking procedure was confirmed by the similar distribution profiles of Hf between the various lipoprotein fractions isolated from either the in vitro or in vivo samples.

Table 2 describes the lipoprotein distribution of Hf in spiked pre- and post-prandial human and beagle plasma when incubated with Hf using the validated in vitro procedure. The distribution of Hf in beagle and human plasma was dominated by significant binding to lipoproteins as 54.8% of Hf was lipoprotein bound in fasted human plasma, and 64.6% was lipoprotein bound in fasted beagle plasma. Additionally, there were increases in the extent of Hf binding by lipoproteins in pre-prandial compared with the post-prandial state (an 18.2% increase in human plasma, and a 10.7% increase in beagle plasma).

Although the extent of lipoprotein binding of Hf was similar between man and dog, analysis of the distribution of Hf between individual lipoprotein fractions indicated substantial species differences. For example, a much larger proportion of the plasma concentration of Hf was carried in TRL and LDL fractions in human plasma compared with beagle plasma, whereas the proportion of Hf carried in HDL was 6−8-fold higher in beagle plasma compared with human plasma (Table 2).

Assessment of the distribution of Hf between pre- and post-prandial lipoprotein classes demonstrated increased amounts of drug associated with the lipid rich TRL fraction of post-prandial plasma with an average 2-fold increase observed in human plasma, and a 8-fold increase in beagle plasma. In contrast, there were decreases in the proportion of Hf associated with post-prandial LDL and LPDP fractions in human and beagle plasma, and HDL in beagle plasma. The proportion of Hf in human HDL was low (6%) and apparently unchanged in pre- and post-prandial human, whereas a much larger proportion of Hf was associated with HDL in pre-prandial beagle plasma (51%) which decreased in the post-prandial state.

The mass of TG, CH, FC, CE, PL, and TP determined in each lipoprotein fraction isolated from the Hf spiked pre- and post-prandial human and beagle plasma are presented in Table 3, with the values for human lipoproteins being similar to literature reports.[19] Data are also presented describing the individual quantities of apolar lipid (i.e. TG + CE) and total lipid (TC + TG + PL) present in the various isolated lipoprotein fractions.

Discussion

In a preliminary communication, we demonstrated that Hf was highly associated with lipoproteins in beagle plasma, and that the characteristics of association were altered when the concentration profile of plasma lipids increased post-prandially.[5] The primary change was an increased proportion of Hf associated with TRL in post-prandial plasma, and from a pharmacokinetic standpoint, this was accompanied by a reduction in drug clearance and volume of distribution which most likely arose through reduction in the plasma free fraction of drug.[4] In this study, we have examined the association of Hf with human plasma lipoproteins (as a possible indicator of similar effects in humans) and explored correlations between the association of Hf with lipoproteins and the mass of protein, triglyceride (TG), cholesterol (CH), and phospholipid (PL) within specific lipoprotein classes as a possible predictor of the basis for the interaction.

It was only possible to study the association of Hf with human plasma lipoproteins in an in vitro setting as an acceptable intravenous formulation for human administration was not available,[20] and potential toxicity concerns precluded post-prandial oral administration to healthy volunteers.[12] Consequently, it was necessary to demonstrate the equivalence of a plasma spiking methodology which afforded a Hf lipoprotein binding profile representative of the in vivo situation.

Employing beagles as a test species, the data in Table 1 indicates that the binding profile of Hf across lipoprotein fractions in plasma sampled after intravenous drug administration was essentially identical to that obtained after fractionation of plasma spiked with Hf, thereby indicating the equivalence of the spiking methodology. Similar in vivo and in vitro lipoprotein distribution profiles have been reported for cyclosporin when small volumes of ethanol were used as the plasma spiking solvent.[21]

Application of this spiking methodology to pre- and post-prandial human plasma, and subsequent fractionation of plasma into TRL, LDL, HDL, and LPDP subgroups, indicated that Hf was also significantly bound to pre- and post-prandial human plasma lipoproteins although the distribution profile was markedly different to that observed in beagles (Table 2). Broadly, the proportion of Hf associated with the TRL and LDL fractions was higher in humans compared with beagles, whereas the proportion of Hf associated with HDL was much higher in beagles. These findings reflect the broad species differences in lipoprotein profiles (Table 3) where a larger proportion of human plasma lipid is carried by TRL and LDL fractions,

whereas HDL are the major lipid carrier in dogs. The post-prandial state induced significant changes in the distribution of Hf between plasma lipoprotein fractions, with increased proportions of Hf in the TRL fractions in both human and beagle plasma at the expense of a species-dependent decrease in the proportion of Hf in LDL and HDL fractions (Table 2). Unfortunately, toxicity concerns and related ethical issues precluded our assessment of the post-prandial pharmacokinetics of Hf in human volunteers. However, as the in vitro studies identified increased post-prandial lipoprotein binding of Hf in human plasma, this suggests the possibility of a potential decrease in clearance and volume of distribution (as observed in the beagle studies).[4]

Historically, methods used to quantify drug–lipoprotein interactions have been modifications of classical protein binding experiments. Typically, individual association constants (K) and the number of binding sites (n) associated with drug–lipoprotein binding are generated from study of the interaction between a drug substrate and isolated fractions using Scatchard-type analyses. Subsequently, an indication of the overall lipoprotein binding profile is obtained from the product of the affinity constant, the apparent number of binding sites and the estimated concentration of each lipoprotein class in plasma.[22] The lipoprotein binding profile of drugs such as anthracycline,[23] ticlopidine and PCR2362,[24] nicardipine,[25] propranolol,[22] and etretinate and acitretin[26] have been assessed in this manner. In contrast to the majority of drug–plasma protein interactions, the nature of the lipoprotein association profiles for these compounds is nonsaturable, which only allows for calculation of the overall binding capacity from the product of the association constant and the number of binding sites. In each of the above examples, the order of the lipoprotein binding capacity (expressed per mole of lipoprotein) was VLDL > LDL > HDL, and the binding was seemingly related to the size and/or overall lipid content of the lipoprotein subclasses. In each case, it was suggested that the nonsaturable nature of the binding, and the apparent correlation of the binding capacity with the size and/or lipid content of the lipoproteins indicated that the binding interaction was solubilization-based rather than a specific binding phenomenon.

To investigate solubilization as the basis for the interaction of Hf with the various lipoprotein fractions, correlations were investigated between the amount of Hf present in individual fractions and the corresponding mass of total protein, phospholipid, triglyceride, and apolar lipid in human and beagle plasma lipoproteins (Figures 2 and 3, respectively). In beagle and human plasma, the Hf distribution profile was poorly correlated with individual lipoprotein surface constituents (protein and phospholipid), reasonably correlated with TG profiles in human compared with beagle lipoproteins, and better correlated with the mass of the apolar lipid core (TG + CE) in both human and beagle lipoprotein fractions.

As representative dimensions were available for the various lipoprotein fractions in human plasma,[16] this

enabled estimation of the surface area and hydrophobic core volume parameters for each lipoprotein fraction in human plasma. Figure 4 presents the relationship between the mass of Hf present in each fraction and these calculated parameters. There was a poor correlation with the respective surface area of individual fractions, but an improved correlation with the calculated volume of the hydrophobic core of the lipoprotein fractions.

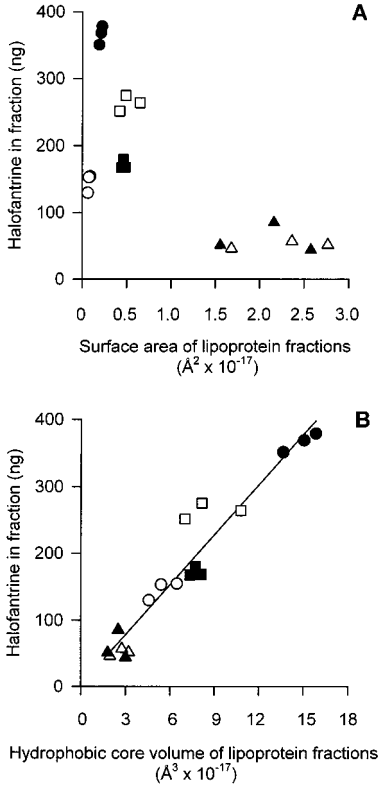

Figure 4—Correlation between the mass of Hf present in individual pre-prandial (open symbols) and post-prandial (closed symbols) HUMAN lipoprotein fractions (TRL (●), LDL (■), HDL (▲)) and the calculated surface area of the individual lipoprotein fractions ((A) $r^2 = 0.52$) and the calculated volume of the hydrophobic core of the individual lipoprotein fractions ((B) $r^2 = 0.93$).

The positive correlation between the mass of Hf in each lipoprotein fraction and the mass of apolar lipid as depicted in Figures 2 and 3, and the calculated volume of the hydrophobic core presented in Figure 4, was consistent with solubilization of Hf in the apolar lipid core and inconsistent with a specific interaction with surface groups or apolipoproteins. Furthermore, the correlation parameters were similar for all lipoprotein groups in human and beagle plasma (Figures 2 and 3), indicating that the binding/solubilization of Hf was independent of the lipoprotein fraction, relative lipid load, and species. These data indicated that the quantity of Hf solubilized per mg of lipoprotein apolar lipid was effectively constant regardless of the overall lipoprotein composition. On first inspection, these data were surprising as significant compositional differences exist between TRL, LDL, and HDL and across species. However, although the percentage composition of lipoproteins varies with the changing particle sizes (e.g. smaller lipoproteins such as HDL have proportionally more surface material such as PL and protein), the nature of the hydrophobic apolar core lipids is largely invariant such that their capacity to solubilize Hf was proportional to the respective mass of apolar lipid.

These data suggest that the trend governing the association of Hf with lipoprotein fractions was the quantity of apolar lipid in each of the respective fractions. Although the decreased proportion of Hf present in post-prandial LDL compared with pre-prandial LDL (despite the mass of LDL apolar lipid remaining relatively constant) (Tables 2 and 3) appears to contradict this scenario (Table 2), the actual driving force behind the lipoprotein distribution of Hf was the *proportional* distribution of lipids across the

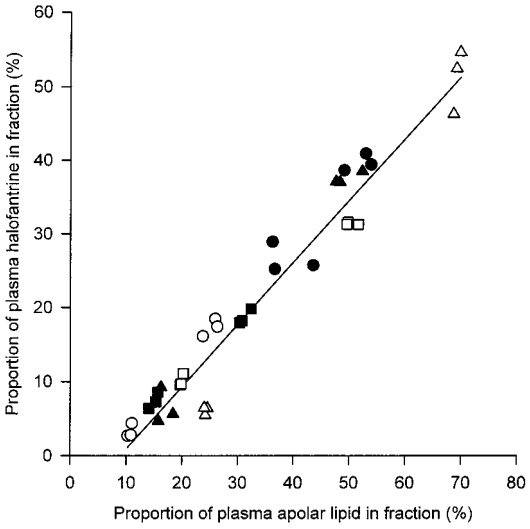

Figure 5—Combined correlation between the proportion of Hf distributed between lipoprotein fractions (TRL (●), LDL (■), HDL (▲)) in human and beagle plasma and the proportional distribution of apolar lipid (TG + CE) within the individual lipoprotein fractions from pre-prandial (open symbols) and post-prandial plasma (closed symbols). The correlation coefficient was 0.95.

lipoprotein fractions and not their absolute masses. Therefore, although the mass of apolar lipid in LDL was similar between pre- and post-prandial states, the proportion of apolar plasma lipid carried by LDL decreased due to the increased quantity of apolar lipid present in the TRL fraction. From consideration of the proportional distribution of apolar lipid, Figure 5 presents the combined correlation between the proportion of Hf between lipoprotein fractions from pre- and post-prandial beagle and human plasma and the proportional distribution of apolar lipid across the individual fractions. The significant correlation between these parameters across species, lipoprotein fractions, and pre- and post-prandial states supports the contention that the apolar lipid content of the individual lipoprotein fractions is the basis for the lipoprotein distribution of Hf.

For drugs with significant lipoprotein binding, the overall binding profile can be estimated from the product of the binding capacity per mole (nK) and the concentration of each individual lipoprotein fraction in plasma. Therefore, as the relative concentrations of plasma lipoprotein fractions are VLDL ($\approx$0.1 μM) < LDL ($\approx$1 μM) < HDL ($\approx$11 μM),[23,24,26] the distribution profile of lipophilic drugs often reflects the relative lipoprotein concentrations such that a larger proportion of the drug is carried by HDL or LDL as observed for ticlopidine,[24] nicardipine,[25] diclofenac,[27] and propranolol.[22] Employing this approach, Cenni and co-workers[28] recently determined the in vitro binding constants (nK) of Hf to human serum constituents (LDL and HDL, human serum albumin α_1-acid glycoprotein) and predicted that a significant proportion of Hf in plasma would be associated with lipoproteins. On the basis of the calculated binding constants, Cenni and co-workers predicted that approximately 67% of Hf in serum would be associated with LDL, about 25% with HDL and that the unbound fraction of Hf in blood would be as low as 0.4%. The marked differences between the data reported in this study and the predicted Hf distributions described by Cenni and co-workers[28] are likely to be (at least in part) a result of an erroneous assumption of minimal Hf binding to TRL. This assumption was based on results of preliminary gel filtration chromatography studies for Hf binding to serum constituents where the recovery of Hf was only 40%. Therefore, the low recovery of Hf from the preliminary gel filtration studies may have clouded the accuracy of the binding profile such that significant binding of Hf with constituents such as TRL was not observed. We believe that the direct method of estimating the plasma lipoprotein binding profile of Hf in plasma employed in the current study yields a more accurate estimate of the overall lipoprotein binding and plasma distribution of Hf.

In summary, the results from this study extends to human plasma the previously identified changes in the post-prandial distribution of Hf in beagle plasma, and raises the possibility of a decrease in Hf clearance and volume of distribution in post-prandial compared with pre-prandial human subjects. The data from this study indicate that the distribution of Hf among plasma lipoproteins was highly correlated with the apolar lipid load of individual plasma lipoprotein fractions thereby suggesting that the mechanism of Hf association with plasma lipoprotein was primarily via solubilization in the apolar lipid core. Furthermore, these findings suggest that acute changes in plasma lipoprotein distributions, such as encountered post-prandially or in disease states such as malaria, may markedly affect the plasma lipoprotein binding of Hf (and other highly lipophilic drugs).

Abstract □ Burger's two polymorphs of tolbutamide (TB), an oral hypoglycemic agent, were obtained by spray-drying the drug dissolved in a mixed solvent of ethanol/dichloromethane (Form IV) and allowing Form IV to stand at constant temperatures and humidities (Form II). These polymorphs were characterized by various physical methods [e.g., powder X-ray diffractometry, differential scanning calorimetry, infrared spectrometry, and solid-state carbon-13 nuclear magnetic resonance (^{13}C NMR) spectroscopy] and compared with two other TB polymorphs Forms I and III. The ^{13}C NMR spectra showed that the chemical shift and the peak shape of resonance associated with the toluene and *n*-butyl moieties of TB were different for each of the four polymorphs, whereas the carbonyl carbon was unchanged, indicating different conformations and molecular motions of the toluene and *n*-butyl moieties in the solid states. Form IV converted itself to Form II within 3 h when it was stored at 45 °C and 75% relative humidity (RH) and, in turn, Form II transformed to Form I at higher temperatures. The conversion of Form IV to Form II proceeded according to a zero-order equation (Polany–Winger equation), and that of Form II to Form I according to a first-order equation. The increase in RH accelerated the polymorphic transition of Form IV. Both the apparent dissolution rate and the solubility of Form IV were nearly identical with those of Form II, because the former changed to the latter during the dissolution, but their dissolution rates and solubility were higher than those of Forms I and III. These dissolution characteristics of TB polymorphs were reflected in the oral absorption behavior in dogs; that is, the bioavailability increased in the order Form I < Form III < Form II ≈ Form IV.

Introduction

Pharmaceutical solids can exist in different crystal forms, such as crystalline, amorphous, or glass, and also in solvated or hydrated states.[1−3] Because of the difference in molecular packing, polymorphic forms of solid drugs influence their dissolution rate, solubility, stability, bioavailability, pharmaceutical manufacturing, etc.[4−6] Therefore, some of the most important components of pharmaceutical solid formulation are the detection of as many polymorphs as possible, as well as their characterizations and selection of the desired ones. Tolbutamide [1-butyl-3-{4-methylphenylsulfonyl)urea, TB] is an oral hypoglycemic agent used clinically in the treatment of insulin-dependent diabetic patients.[7] Early studies have suggested that TB has several polymorphs in the solid states.[8−17] For example, Simmons et al.[8] reported the presence of two polymorphs, whereas Burger et al.[9] and Traue et al.[14] suggested the existence of four polymorphs. The Simmons's Forms A and B are identical with the Burger's Form I and III, respectively, and have been well characterized. However, Burger's Forms II and IV have been not fully characterized; for example, the diffraction pattern of the Georgarakis's Form II is different from that of the Al-Saieq's Form II but resembles that of Form IV.[11,15] In this study, two polymorphs (Forms II and IV) of TB were prepared and characterized by various physical methods [e.g., powder X-ray diffractometry (PXRD), differential scanning calorimetry (DSC), infrared (IR) spectrometry, and solid-state carbon-13 nuclear magnetic resonance (^{13}C NMR) spectroscopy] and compared with the TB polymorphs Forms I and III reported by Simmons et al.[8] Furthermore, the polymorphic transition behavior of Form IV was investigated. Because TB is a poorly water-soluble drug with several different polymorphs, its tablets are obligated to pass the dissolution test in Japanese Pharmacopoeia.[18] The dissolution and in vivo absorption behavior of Form IV in dogs were compared with those of Forms I, II, and III.

Experimental Section

Materials—TB (purity > 99%) and chlorpropamide were donated by Nippon Hoechst-Marion-Roussel Ltd. (Tokyo, Japan) and Ono Pharmaceutical Company (Osaka, Japan), respectively. Other chemicals and solvents were of analytical reagent grade, and deionized double-distilled water was used throughout the study.

Apparatus—The PXRD patterns were measured with a Rigaku Rint-2500 diffractometer (Tokyo, Japan) under the following conditions: Ni-filtered Cu−Kα radiation (1.542 Å), a voltage of 40 kV, a current of 40 mA, a divergent slit of 1.74 mm (1°), a scattering slit of 0.94 mm (1°), a receiving slit of 0.15 mm, and a goniometer angular increment of 1°/min. The theoretical diffraction profiles on the basis of single-crystal X-ray analysis data were drawn using the teXsan crystallographic software package of Molecular Structure Corporation[19] on a Silicone Graphics IRIS Indigo work station (U.S.A.). The DSC analyses were carried out using a Perkin-Elmer DSC-7 thermal analyzer (Norwalk, CT) with a data analysis system (DEC station 325C computer, U.S.A.), operated with sample weights of 5 mg and a scanning rate of 10 °C/min. The heat fusion was calibrated with indium (purity, 99.999%; melting point, 156.4 °C; ΔH 28.47 mJ/mg; heating rate, 10 °C/min). Fourier transform infrared (FT-IR) spectra were recorded using a JEOL JIR-6500 FT-IR spectrometer (Tokyo, Japan) on samples prepared with KBr. The solid-state ^{13}C NMR spectra were taken on a JEOL JNM EX-270 spectrometer with a cross polarization/magic angle spinning (CP/MAS) accessory (Tokyo, Japan). The operating conditions were 270 MHz (^1H) and 25 °C. The CP radio frequency field strength was about 56 kHz, the contact time was 5 ms and the MAS rate was 6 kHz. The ^{13}C NMR chemical shifts were measured with respect to the resonance of tetramethylbenzene (17.3 ppm downfield from the resonance of tetramethylsilane). The chemical shift of TB was assigned according to the report of Ueda et al.[20] Crystal appearance was observed with a scanning electron microscope (SEM) instrument (Hitachi-Akashi S-501, Tokyo, Japan), after crystals were mounted onto an SEM sample stub with double-sided sticky tape and coated with gold by a direct current sputter technique.

Preparation of TB Polymorphs—Form I of TB was prepared according to the method of Simmons;[8] that is, TB (5 g) was dissolved in benzene (10 mL) at 70 °C, and then hexane (5 mL) was slowly added. The resulting solution was allowed to stand at room temperature. Form III was prepared by dissolving TB (5 g) in ethanol (10 mL) at 60 °C, slowly adding warm water, and allowing the resulting solution to stand at room temperature.[8] Form II was prepared by storing Form IV at 60 °C, 75% RH for 10 min. Form IV was prepared by the spray-drying method; that is, TB was dissolved in the mixed solvent ethanol/dichloromethane (1.2:1 v/v, 150 mL) and subjected to spray-drying, using a Pulvis GA32 Yamato spray-drier (Tokyo, Japan) under the following conditions: an air flow rate of 0.4 m^3/min, an air pressure of 1.0 kgf/cm^3, and inlet and outlet temperatures of 85 and 55 °C, respectively.

Aging Studies—The test powder (about 300 mg, <100 mesh) was placed in glass containers in desiccators at constant humidity (saturated solutions of potassium acetate, sodium bromide dihydrate, and sodium chloride at 22%, 50% and 75% RH, respectively), and then stored in incubators at constant temperatures (35−70 °C).[21,22] The phase change of TB crystals was monitored by PXRD.

Dissolution Studies—The dissolution rate of TB polymorphs was measured according to the dispersed amount method.[23] A fixed amount (100 mg, <100 mesh) of TB polymorphs was put into 25 mL of Japanese Pharmacopoeia XIII (JP XIII) second fluid (pH 6.8) and stirred at 91 rpm at 37 °C. At appropriate intervals, an aliquot (1.0 mL) was withdrawn with a cotton plugged pipet and analyzed for TB spectrophotometrically at 230 nm. To monitor the polymorphic change of TB during the dissolution, DSC curves were made of the powder suspended in the medium after drying under reduced pressure for 1 day.

Absorption Studies—The absorption studies were carried out using male beagle dogs (9−11 kg) that were fasted for 24 h before drug administration. The sample (equivalent to 100 mg/body) was wrapped in a wafer and administered orally with water (50 mL), using a catheter. Blood samples (1 mL) were withdrawn from the cephalic vein with a heparinized injection syringe and centrifuged at 1100 × g for 10 min. The plasma (0.2 mL) was added to the solution containing an internal standard, chlorpropamide (1.0 mg/mL, 0.5 mL), and extracted with ethyl ether (4.0 mL). The organic phase (3.0 mL) was evaporated, the residue was dissolved in acetonitrile (0.1 mL), and TB was determined by high-performance liquid chromatography (HPLC) with an Hitachi L-600 pump and a 635A UV detector (Tokyo, Japan), a Yamamura YMC AQ-312 ODS column (5 μm, 6 × 150 mm, Kyoto, Japan), a mobile phase of acetonitrile/0.05 M NaH_2PO_4 solution (45:55 v/v), a flow rate of 1.6 mL/min, and detection at 230 nm.

Results and Discussion

Characterization of TB Polymorphs—Figure 1 shows PXRD patterns of the TB solids (Forms I, II, III, and IV). Form IV was prepared by spray-drying TB using the mixed solvent ethanol/dichloromethane (1.2:1 v/v) and Form II was prepared by storing Form IV at 60 °C, 75% RH (see *Experimental Section*). Form I of TB gave diffraction peaks at 8.7, 12.1, and 19.9°, and this pattern coincided in diffraction angle and with the computer-simulated pattern drawn on the basis of single-crystal data of Form I reported by Donaldson et al.[24] The difference in diffraction intensity at 2θ = about 20° may be ascribed to the difference in crystal habit of the two samples. Rowe and Anderson reported that Form III is less soluble than Form I in water at 37 °C; thus, Form III is a stable form at room temperature, although the difference in free energy of the two forms is small.[25] Form III gave diffraction peaks at 11.2, 15.4, and 18.2° and Form II at 10.3, 11.3 and 19.6°. The diffraction pattern of Form II was identical in diffraction angle to the computer-simulated pattern drawn on the

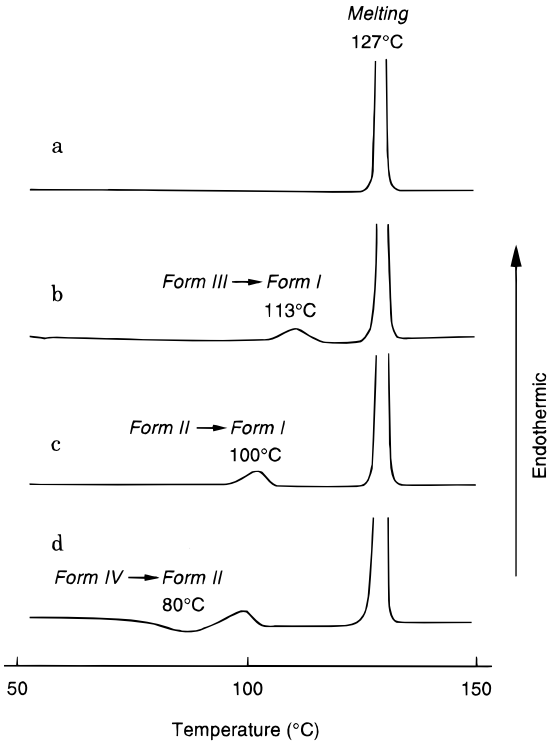

Figure 2—DSC thermograms of TB polymorphs: (a) Form I; (b) Form III; (c) Form II; (d) Form IV.

basis of single-crystal data of Form II, which was analyzed in our laboratory and will be reported elsewhere.[26] The difference in diffraction intensity may be also ascribed to the difference in crystal habit of the two samples. On the other hand, the spray-dried TB gave two strong diffraction peaks at 10.6 and 18.9° and a small peak at 18.0°, which were clearly different from those of Forms I, II, and III, although its diffraction pattern resembled that of Form II. These results suggest that the spray-dried TB is one of polymorphs of TB and its internal structure may resemble that of Form II. These polymorphs of TB, Forms II and IV, were further characterized by other physical methods.

Figure 2 shows DSC curves of Forms I, II, III, and IV. Form I showed an endothermic peak at 127 °C due to melting. Form III gave two peaks at 113 and 127 °C. The latter peak is due to the melting of Form I and the former peak is due to the melting of Form III followed by the crystallization of Form I, because the PXRD pattern of Form III heated to about 110 °C coincided with that of Form I. Form II showed a similar polymorphic transition behavior; that is, the melting of Form II and crystallization of Form I at 100 °C and the melting of Form I at 127 °C. On the other hand, Form IV showed an exothermic peak at 80 °C, followed by endothermic peaks at 100 and 127 °C. The PXRD pattern of Form IV heated to 80 °C was identical to that of Form II, indicating that the 80 °C peak is due to the transition of Form IV to Form II, the 100 °C peak is due to the melting of Form II and crystallization of Form I, and the 127 °C peak is due to the melting of Form I. The conversion of Form IV to Form II was apparently accompanied by no liquification, whereas that of Form II to Form I is a crystallization from the liquified Form II. The enthalpy changes (ΔH) for the conversion of Form IV to Form II and the melting of Form I were 1.2 and 27.2 kJ/mol, respectively. The apparent ΔH values for the conversion of Forms III and II to Form I were 1.9 and 1.5 kJ/mol, respectively, although they contain the combined ΔH changes of fusion and crystallization processes.

Figure 3 shows SEM pictures of the four TB polymorphs.

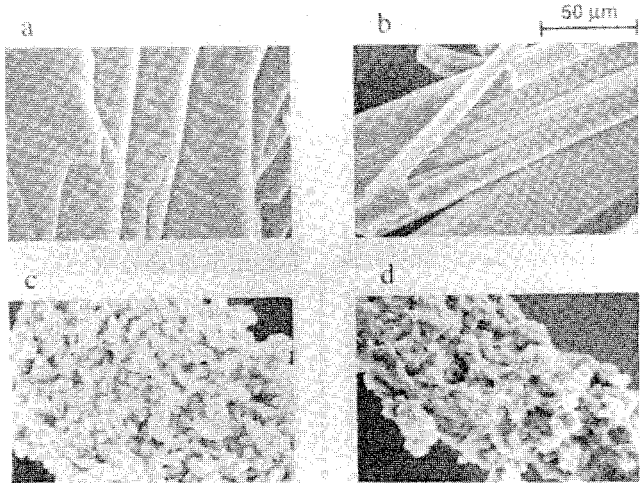

Figure 3—Scanning electron micrographs of TB polymorphs: (a) Form I; (b) Form III; (c) Form II; (d) Form IV.

Form I is in the form of plate crystals with a microscopically layered sheet structure and Form III consists of needlelike crystals, with both forms having smooth surfaces. Form II, an aggregate, consists of small solid particles, whereas Form IV has a rodlike structure, with many pores and clusters of small particles on the surface, and its appearance resembles that of Form II.

The solid-state ^{13}C NMR spectroscopic studies were employed to gain insight into the internal structure of TB polymorphs. Figure 4 shows ^{13}C NMR spectra of Forms I, II, III, and IV measured in a CP/MAS mode. The chemical shifts are listed in Table 1. These ^{13}C NMR signals were assigned according to the spectrum of TB in solution.[20] In Form I, the butyl and methyl carbons gave sharp peaks, suggesting a definite conformation[24] as described later, whereas the benzene carbons gave rather broad peaks with a shoulder, suggesting that each *ortho*- and *meta*-carbon is magnetically unequivalent and the broadening of the C2 carbon may arise from a magnetic fluctuation due to a rotation of the methyl group. Form III gave chemical shifts similar to those of Form I, although the signals of the *ortho*-(C4 and C6) and *meta*-(C3 and C7) carbons became sharp whereas those of the C10−C12 carbons split. These results suggest that the conformation of TB in Form III is very similar to that in Form I, but with different motional freedom as reflected by the observed NMR peak splitting. On the other hand, the chemical shifts of the butyl moiety in Forms II and IV were significantly different from those in Forms I and III, although the benzene ring had similar chemical shifts; that is, C10 carbon: 31.8 ppm (Form I), 30.9 and 31.9 ppm (Form III), 35.2 and 33.4 ppm (Form II), and 33.8 ppm (Form IV); C12 carbon: 13.6 ppm (Form I), 12.7 and 12.0 ppm (Form III), 15.8 and 13.7 ppm (Form II), and 16.1 ppm (Form IV). Our results on the single-crystal analysis of Form II[26] and the reported result of Form I[24] indicate that the butyl moiety of TB is in a trans conformation in Form II crystals (C9−C10−C11−C12 dihedral angle = 178.6°) but it is in a gauche conformation in Form I crystals (the dihedral angle = 101.3°). Therefore, the shift difference of the butyl moiety can be ascribed to this conformational alteration. The chemical shifts of TB in Form IV were very similar to those in Form II, although the signals of the *ortho*- and *meta*-carbons became sharp. These results indicate that the conformation of TB in Form IV is almost the same as that of Form II, but the environment around the benzene ring may differ; that is, there may be some vacant space that allows the ring to rotate due to the looser packing of crystals in Form IV. The FT-IR spectroscopic studies supported this conclusion; that

is IR absorption bands of the functional groups involving in the intermolecular hydrogen bonding of TB molecules, such as the imino (NH, 3328 cm^{-1}), carbonyl (CO, 1703 and 1660 cm^{-1}), and sulfonyl (SO_2, 1336 and 1159 cm^{-1}) groups, showed insignificant differences in the wavelength between the four TB polymorphs, suggesting the similar hydrogen bonding network.[24,26] On the other hand, the spectral shapes of the stretching absorption band of alkyl portion around 2950−3000 cm^{-1} and the aromatic CH stretching

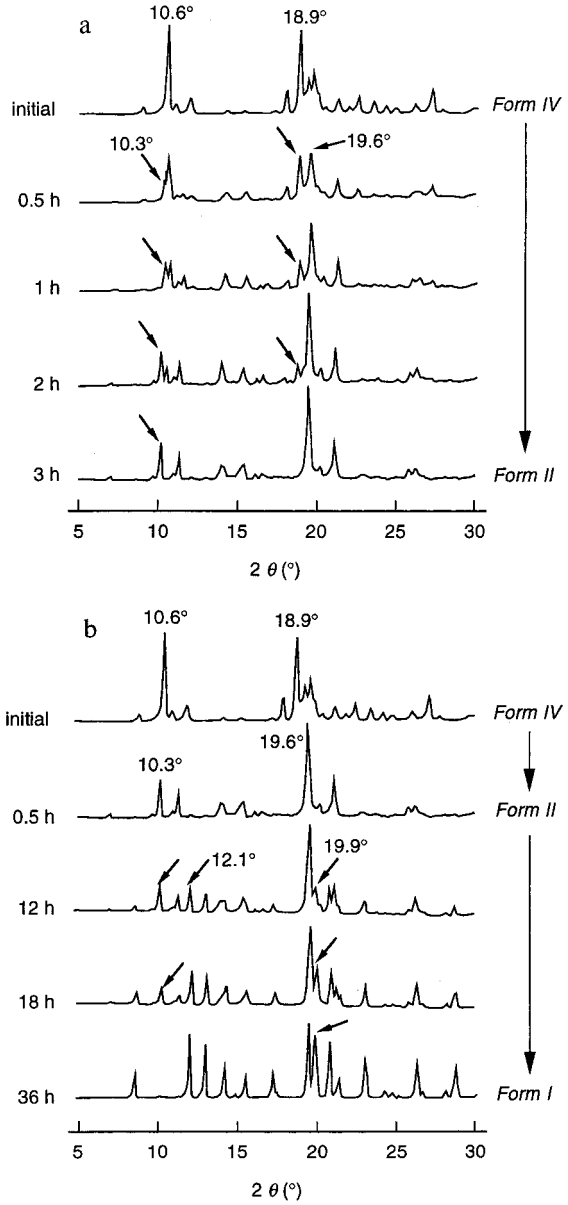

Figure 5—Changes of PXRD pattern of Form IV during storage at (a) 45 °C and 75% RH and (b) 60 °C and 75% RH.

band around 800−850 cm^{-1} were different between the four polymorphs. As judged by the peak intensities of 816 and 843 cm^{-1}, our Forms I, II, III, and IV are identical with Burger's Forms I, II, III, and IV, although it is difficult to completely identify the latter because no diffraction data are given in his paper.[9] However, it is apparent from the diffraction data, that Al-Saieq's[11] Form IV corresponds to our Form II and Georgarakis's[15] Form II corresponds to our Form IV.

Transition Behavior of Form IV—The isothermal transition behavior of Form IV was investigated because it may be easily converted to Form II, which has a similar crystal structure. Figure 5 shows changes in the PXRD pattern of Form IV during storage at 45 and 60 °C at 75% RH. During the storage at 45 °C (Figure 5a), the diffraction peaks characteristic of Form IV at 2θ = 10.6° and 18.9° decreased, whereas those of Form II at 10.3° and 19.6° increased. The longer storage at the higher temperature (Figure 5b) gave diffraction peaks characteristic of Form I at 12.1° and 19.9°, indicating the transition of Form IV to Form I via Form II. Figure 6 shows the time courses for the conversion of Form IV to Forms II and I on storage at

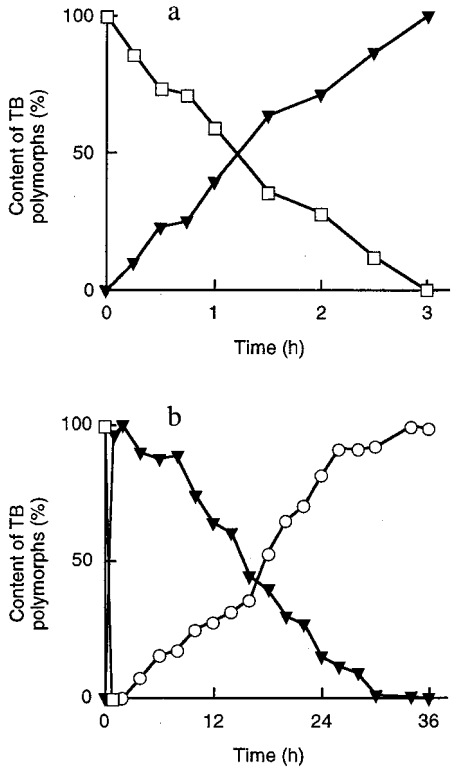

Figure 6—Time courses for conversion of Form IV to Form II and Form I during storage at (a) 45 °C and 75% RH and (b) 60 °C and 75% RH. Key: (○) Form I; (▼) Form II; (□) Form IV.

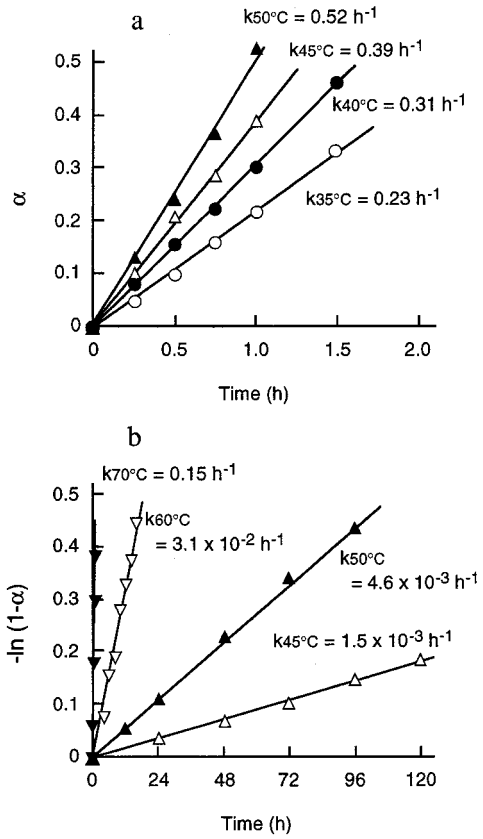

Figure 7—Plots of α and [–ln(1 – α)] for transitions of (a) Form IV to Form II and (b) Form II to Form I at 75% RH. Key: (○) 35 °C; (●) 40 °C; (△) 45 °C; (▲) 50 °C; (▽) 60 °C; (▼) 70 °C.

the conditions just stated. The contents of each polymorph were determined from the following diffraction intensity ($2\theta = 19.9°$ for Form I, 10.3° for Form II, and 18.9° for Form IV). Form IV was converted completely to Form II in 3 h with storage at 45 °C, 75% RH, whereas at 60 °C, Form IV rapidly changed to Form II within 30 min and Form II slowly changed to Form I in 30 h. These polymorphic transition−time profiles were analyzed according to the Hancock and Sharp equation (eq 1):[27]

$$\ln [-\ln(1 - \alpha)] = m \ln t + \ln B \qquad (1)$$

where m is the intrinsic value for various theoretical equations of solid-state decomposition, α is the fraction of the total sample converted to the other polymorph, based on the X-ray relative intensities, t is the storage time, and B is a constant. The plot of $\ln[-\ln(1 - \alpha)]$ versus $\ln t$ using the data of $\alpha = 0.1-0.5$ gave straight lines of $m = 1.23 \pm 0.06$ (mean ± SE, $n = 4$, correlation coefficient (r) = 0.998) for the conversion of Form IV to Form II at 45 °C and 75% RH, and $m = 0.99 \pm 0.04$ ($n = 4$, $r = 0.997$) for that of Form II to Form I at 60 °C and 75% RH. The m value of 1.23 indicates that the Form IV-to-II transition proceeds according to a zero-order mechanism (a criterion for zero-order transition: $m = 1.24$)[27] and its rate obeys the equation of $\alpha = kt$. On the other hand, the m value of 0.99 indicates that a random nucleation on each particle is a rate-determining step for the Form II-to-Form I transition (a criterion for this conversion is $m = 1.0$)[27] and its rate obeys the equation of $-\ln(1 - \alpha) = kt$. Therefore, the polymorphic transition rates of Form IV to Form II and Form II to Form I were analyzed, respectively according to the aforementioned equations, and the results at various temperatures are shown in Figure 7. The plots of α or $-\ln(1 - \alpha)$ versus t were confirmed to be linear, and the transition rate constants (k, see Figure 7) were obtained from the slopes. The Arrhenius plots of these rate constants gave straight lines ($r = 0.999$), from which the activation energies of 44 and 166 kJ/mol were obtained for the transitions of Form IV to II and Form II to I, respectively. These results indicate that the energy barrier of the transition of Form IV to Form II is very low, because the internal structure of Form IV, including the conformation of TB, is similar to that of Form II, whereas that of Form II to Form I is rather high because the crystal system and the conformation of TB are different between Form II (monoclinic, $P2_1/n$, $a = 11.815$ Å, $b = 9.069$ Å, $c = 13.981$ Å, $\beta = 104.50°$)[26] and Form I (orthorhombic, $Pna2_1$, $a = 20.223$ Å, $b = 7.831$ Å, $c = 9.090$ Å)[24] crystals. The transition behavior of Form IV at different humidity conditions (22, 50, and 75% RH) and 50 and 60 °C was investigated, and the rate constants were obtained from the linear plots of α and $-\ln(1 - \alpha)$ versus t for the Form IV-to-Form II transition and the Form II-to-Form I transition, respectively, as follows: $k = 0.16$, 0.52, and 1.01 h^{-1} for the Form IV-to-Form II transition at 50 °C, and $k = 0.0030$, 0.012, and 0.031 h^{-1} for the Form II-to-Form I transition at 60 °C. The transition rate increased as the humidity increased, presumably because TB dissolves in adsorbed water on the crystal surface, which may consequently promote the nucleation and growth of crystals.

Dissolution and Absorption Behavior of Polymorphs—Figure 8 shows dissolution profiles of TB polymorphs in the JP XIII second fluid (pH 6.8), measured by the dispersed amount method at 37 °C. The dissolution rate of Form III was slightly faster than that of Form I, whereas those of Forms IV and II were significantly faster than that of Form I. The dissolution rate of Form IV was almost the same as that of Form II. The Form IV powder in the dissolution medium was taken out, dried, and subjected to DSC measurements to gain insight into phase changes of Form IV during the dissolution. As is apparent from the change in DSC curves in Figure 9, Form IV transformed

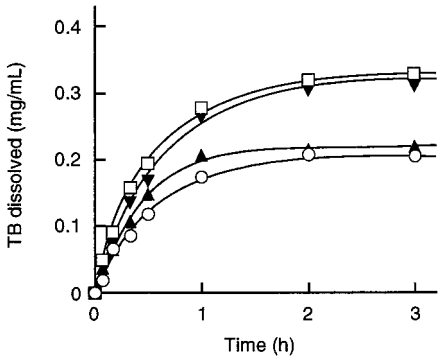

Figure 8—Dissolution profiles of TB polymorphs (equivalent to 100 mg TB) in JP XIII second fluid at 37 °C, measured by the dispersed amount method at 91 rpm. Key: (○) Form I; (▲) Form III; (▼) Form II; (□) Form IV. Each point represents the mean of 3 experiments.

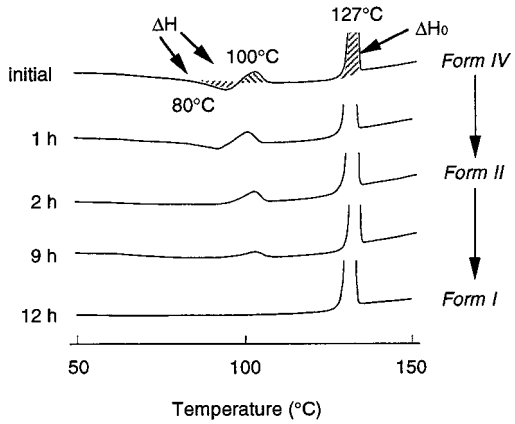

Figure 9—DSC thermograms of Form IV during dissolution in JP XIII second fluid at 37 °C, measured by the dispersed amount method at 91 rpm.

into Form I via Form II during the dissolution. The apparent first-order transition rate constants of Form IV to Form II and Form II to Form I under the dissolution test condition (dispersed amount method, JP XIII second fluid, powder size < 100 mesh, 37 °C, 91 rpm) were determined by plotting the data of $\ln(\Delta H/\Delta H_0)$ versus time, where ΔH_0 is the enthalpy change for fusion of total Form I at 127 °C. The enthalpy changes (ΔH) of the exothemic peak at about 80 °C during 0−2 h were used for calculation of the rate constant of the Form IV-to-Form II transition, and those of the adjacent endothermic peak (about 100 °C) after 2 h were used for the rate constant calculation of the Form II-to-Form I transition. The first-order plot of both transitions gave a straight line ($r = 0.998$), from which the rate constants of 0.45 and 0.087 h^{-1} for the transitions of Form IV to Form II and Form II to Form I, respectively, were obtained. Therefore, the insignificant difference in the dissolution rate between Forms IV and II can be attributed to the phase change of Form IV to Form II within about 2 h under experimental conditions. Figure 10 shows the plasma TB level−time profiles after oral administration of TB polymorphs in dogs. Their bioavailability parameters are summarized in Table 2. The oral bioavailability of TB increased in the order Form I ≪ Form III < Form II ≈ Form IV, and that of Forms IV and II was >2-fold higher than that of Form I, reflecting the in vitro dissolution behavior of the polymorphs.

Conclusion

In this study, we fully characterized polymorphs of TB (Burger's Forms I, II, III, and IV) by various physical methods such as XRPD, solid-state ^{13}C NMR, FT-IR, and thermal analysis. The results indicate that Form IV has an internal structure and conformation that resemble closely those of Form II. Because of this similarity, Form IV was easily converted to Form II under both isothermal and nonisothermal conditions. The dissolution rate of Form IV was almost identical to that of Form II because of the conversion to Form II during the dissolution. This dissolution property of Form IV was clearly reflected in the oral bioavailability of TB in dogs. The present systematic characterization of TB polymorphs will be useful for identification of solid TB and gives a rational basis for the design of solid TB formulations.

Transport of the δ-Opioid Receptor Agonist [D-Penicillamine^{2,5}] Enkephalin Across the Blood–Brain Barrier Involves Transcytosis[1]

RICHARD D. EGLETON AND THOMAS P. DAVIS*

Contribution from *Department of Pharmacology, The University of Arizona, College of Medicine, LSN 533, 1501 N. Campbell Avenue, Tucson, Arizona 85724.*

Received October 14, 1998. Accepted for publication January 6, 1999.

Abstract □ The delta opioid receptor antagonist [D-penicillamine^{2,5}]-enkephalin (DPDPE) is an enzymatically stable peptide analogue of Met-enkephalin. DPDPE uses a saturable transport mechanism to cross the blood-brain barrier (BBB), though the exact mechanism is not fully understood. The aim of the present study was to identify the mechanism by which DPDPE enters the brain. The effect of phenylarsine oxide (PAO), an endocytosis inhibitor, on the transport of [^{3}H]DPDPE was investigated using both in vitro and in situ transport studies. Two in vitro models of the BBB utilizing primary bovine brain microvascular endothelial cells (BBMEC) were studied. [^{3}H]DPDPE permeability across monolayers of BBMEC grown on polycarbonate filters was studied. PAO significantly reduced the permeability of [^{3}H]-DPDPE across the monolayer. PAO also reduced the uptake of [^{3}H]-DPDPE into BBMEC cells, without affecting binding to the cells. The in situ perfusion model of the BBB was also studied, PAO reduced DPDPE uptake by the brain in a dose-dependent manner. These studies indicate that DPDPE enters the brain via an energy-dependent transcytotic mechanism.

Introduction

The blood-brain barrier (BBB), consisting of the cerebral capillary endothelial cells, restricts the entry of solutes into the brain. There are, however, a number of transport mechanisms that peptide drugs can utilize to enter the brain.[2] For example biphalin ([Tyr-D-Ala-Gly-Phe]$_2$), an enkephalin analogue, uses the large neutral amino acid transporter to enter the brain.[3] The cyclic somatostatin analogue, CTAP (D-Phe-Cys-Tyr-D-Trp-Arg-Thr-Pen-Thr) enters the brain via a diffusional mechanism.[4]

[D-Penicillamine^{2,5}] enkephalin (DPDPE, Tyr-D-Pen-Gly-Phe-D-Pen) is a δ-opioid receptor agonist that is conformationally constrained by a disulfide bridge between the two D-Pen moieties.[5] Conformationally constraining the peptide results in a higher enzymatic stability in both brain and serum[6,7] compared with the endogenous enkephalins.[8] In the bovine brain microvascular endothelial cell (BBMEC) model of the BBB, DPDPE had a higher permeability than most other opioid peptides studied.[9]

In situ perfusion studies have shown that DPDPE accumulates in the brain significantly better than the BBB-impermeable marker sucrose.[10] This accumulation is partially saturable.[10] The saturable component follows Michaelis–Menten kinetics with a maximum velocity (V_{max}) of 51.1 ± 13.2 pmol·min^{-1}·g^{-1}, and a Michaelis–Menten constant (K_m) of 45.6 ± 27.6 μM, and the nonsaturable component has a K_d of 0.6 ± 0.3 μL·min^{-1}·g^{-1}.[11] Further studies show that DPDPE does not use a number of previously reported peptide transporters, including the enkephalin transporter and the insulin transporter.[11] DPDPE uptake is also not dependent on any δ-opioid receptor-mediated mechanism.[11] Recent studies have shown an important role for endocytosis in the transport of peptides and proteins across the BBB,[12] and phenylarsine oxide (PAO) has been shown to inhibit saturable endocytotic mechanisms.[13] In this study, we investigated the role of endocytosis in the transport of DPDPE in BBMEC monolayers and into the rat brain.

Experimental Procedures

In Vitro BBMEC Permeability Studies. BBMEC cells were isolated from the cerebral cortex gray matter as previously described.[14,15] Isolated BBMECs, suspended in culture media, were seeded onto 25-mm polycarbonate membrane filters (Costar Nucleopore 10 μm; Costar Corp., Cambridge, MA) that had previously been coated with rat-tail collagen and human fibronectin. After the cells had grown to confluence (10–12 days), the BBMEC monolayers were used for transendothelial transport studies of [^{3}H]DPDPE in the presence and absence of PAO. The PAO was administered to both chambers commencing at the preincubation period.

Polycarbonate filters with confluent BBMEC monolayers were placed in side-by-side diffusion chambers (Crown Glass Company, Somerville, NJ) kept at 37 °C. Both sides of the diffusion cell chamber contained phosphate buffered saline (PBS) (122 mM NaCl, 3 mM KCl, 25 mM Na_2PO_4, 1.3 mM K_2HPO_4, 1.4 mM $CaCl_2$, 1.2 mM $MgSO_4$, 10 mM glucose, 10 mM HEPES pH 7.4) that was continuously stirred. At 15, 30, 60, 90, and 120 min, after the addition of 1 mL of [^{3}H]DPDPE (0.33 μCi·mL^{-1}) to the donor chamber, 200 μL samples were removed from the receiver chamber. An equal volume of fresh PBS was added to the sampled chamber to maintain a constant volume during sampling. Four milliliters of Budget Solve Scintillation Cocktail (RPI, Mount Prospect, IL) was added to each sample, and the samples were counted for radioactivity using a Beckman Beta counter model LS 5000 TD (Fullerton, CA).

The effect of phenylarsine oxide on the basal permeability of the BBMEC membranes was studied using [^{14}C]sucrose. [^{14}C]-Sucrose has a very low permeability across BBMEC-coated membranes and is used to access basal permeability.

In Vitro BBMEC Uptake Studies. BBMEC cells were grown to confluence on 24 well plates (Falcon, Becton Dickinson, Lincoln Park, NJ) precoated with rat tail collagen and human fibronectin. Growth media was removed, and the cells were preincubated with assay buffer (122 mM NaCl, 3 mM KCl, 25 mM Na_2PO_4, 1.3 mM K_2HPO_4, 1.4 mM $CaCl_2$, 1.2 mM $MgSO_4$, 10 mM glucose, 10 mM HEPES pH 7.4). After 20 min, 0.33 μCi of [^{3}H]DPDPE was added to each well. The cells were then incubated for 5–30 min at 37 °C on a shaker table. After the set time, the radioactive buffer was removed and the cells were washed three times with ice cold assay buffer and then incubated for 4 min with an acid buffer (0.2 M acetic acid in 0.2 M NaCl[16]). The acid wash was performed to strip any of the DPDPE from the external surface of the cell. Therefore, any radioactivity that remains with the cell has been taken into the cell itself. After 4 min, the acid wash was removed and the cells were incubated with a 1% Triton-X-100 for 30 min. Samples (100 μL) from both the acid wash and the Triton-X-100 wash were prepared for radioactive sampling by adding 4 mL of Budget Solve

Scintillation Cocktail to each sample, and the samples were counted for radioactivity using a Beckman Beta counter model LS 5000 TD (Fullerton, CA). The remaining samples were assayed for protein using a Pierce BCA-protein kit.

The effect of PAO on [^{3}H]DPDPE uptake was studied at the 20-min time point. PAO (10−200 μM) was added to the cells during the preincubation and throughout the experimental time course. The experiment was repeated as already described.

In Situ Rat Brain Perfusion. The following experimental protocol was approved by the Institutional Animal Care and Use Committee at the University of Arizona. Adult Sprague−Dawley rats (weighing 250−350 g) were anesthetized with 1 mL·kg^{-1} of a cocktail of acepromazine (0.6 mg·mL^{-1}), ketamine (3.1 mg·mL^{-1}), and xylasine (78.3 mg·mL^{-1}), and then heparinized (10 000 U·Kg^{-1}). The neck vessels were exposed, and the right common carotid artery was cannulated with fine silicon tubing connected to a perfusion system. The perfusion fluid was a modified Krebs-Henseleit Ringers[17] [117.0 mM NaCl, 4.7 mM KCl, 0.8 mM $MgSO_4 \cdot 3H_2O$, 24.8 mM $NaHCO_3$, 1.2 mM KH_2PO_4, 2.5 mM $CaCl_2 \cdot 6H_2O$, 10 mM D-glucose, 39% dextran (MW 70 000), and 1% bovine serum albumin] that had been aerated with 5% CO_2, 95% O_2 and warmed to 37 °C. The right jugular vein was sectioned at the start of the perfusion. Once the correct perfusion pressure of 90.8 ± 5.3 mmHg and perfusion flow rate of 3.1 mL·min^{-1} were obtained, the contralateral carotid artery was cannulated and perfused in the same manner. The [^{3}H]DPDPE or [^{14}C]sucrose, along with various concentrations of PAO (10−200 μM), 100 μM DPDPE, or 100 μM DPDPE + 100 μM PAO, was then infused via a slow-drive syringe pump (model 22, Harvard Apparatus, South Natick, MA) into the inflowing mammalian Ringers solution. After 20 min, the perfusion was terminated and the animals were sacrificed by decapitation. The brain was removed, choroid plexi were excised, and brain samples taken and weighed. Perfusion fluid samples were taken from the carotid cannulae immediately at the termination of the perfusion.

Brain tissue samples and 100 μL of perfusion fluid were prepared for liquid scintillation counting by 12 h of solubilization in 1 mL of tissue solubilizer (TS-2; Research Products, Mount Pleasant, IL). After solubilization, 100 μL of 30% acetic acid was added to each sample to eliminate chemiluminescence, followed by 4 mL of Budget Solve Scintillation Cocktail (Research Products). The samples were counted for radioactivity (model LS 5000 TD counter; Beckman Instruments, Fullerton, CA).

Materials. *Radiolabeled Substances.* [^{3}H] Tyr^1 DPDPE (42 Ci·mmol^{-1}) was obtained from Chiron Mimotopes Peptide Systems (San Diego, CA), under the direction of the National Institute on Drug Abuse. [^{14}C]Sucrose (672 mCi·mmol^{-1}) was purchased from NEN Research Products (Boston, MA).

Nonradiolabeled Substances. DPDPE was provided by Chiron Mimotopes Peptide Systems under the direction of the National Institute on Drug Abuse. PAO was purchased from Sigma (St. Louis, MO). All other chemicals were supplied by Sigma (St. Louis, MO) unless otherwise stated.

Expression of Results. *In Vitro BBMEC Permeability.* The flux of peptide was determined by the linear regression of picomoles of DPDPE appearing in the receiver chamber versus time in minutes. The apparent permeability constant (*PC*) was then calculated as

$$PC = \text{flux}/(AC_{DO}) \quad (1)$$

where flux is the gradient of the linear regression, *A* is the surface area of the membrane (0.636 cm^2), and C_{DO} is the initial concentration in the donor chamber.

In Vitro BBMEC Uptake. The flux of peptide into the cells was determined by the linear regression of picomoles of DPDPE per milligram of protein associated with the cells versus time in minutes. The cell-associated radioactivity was composed of two components, the acid-sensitive (representing [^{3}H]DPDPE bound to the cell surface) and the acid-insensitive uptake (representing the radioactivity within the cell).

In Situ Perfusion. The amount of radioactivity in the whole brain was expressed as the percentage ratio of the tissue concentration (C_{Tissue}, in dpm/g) to the concentration in the perfusion fluid (C_{Perf}, in dpm/mL).

$$R_{Tissue}\,(\%) = C_{Tissue}/C_{Perf} \times 100$$

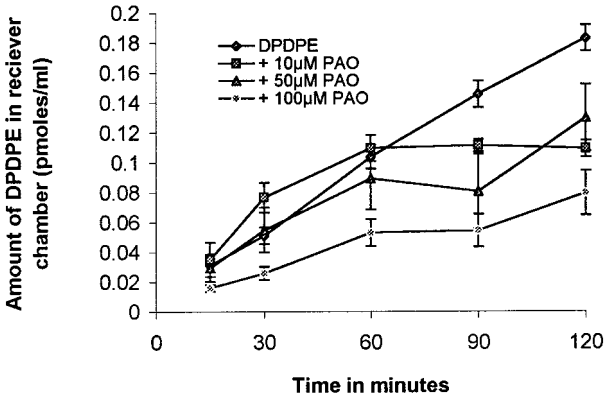

Figure 1—The permeability of [^{3}H]DPDPE across BBMEC monolayers. Each point represents the mean and SEM of 12 individual BBMEC confluent monolayers on filters. Concentrations of phenylarsine oxide (PAO) from 10 to 100 μM led to significant inhibition of [^{3}H]DPDPE permeability across the monolayers.

Table 1—Permeability Coefficient (*PC*) Values Calculated for [^{3}H]DPDPE in the Presence of 10–100 μM PAO[a]

PAO, μM	$PC \times 10^{-4}$ cm·min^{-1} (± SEM)	level of significance
0	9.31 (0.62)	—
10	3.73 (1.86)	$p < 0.05$
50	4.97 (1.24)	$p < 0.05$
100	3.54 (0.62)	$p < 0.01$

[a] *PC* values calculated from Figure 1 were compared using ANOVA and Newman–Keuls analysis; there was no significant difference between the concentrations of PAO used.

Unidirectional rate constants, K_{in} (μL·min^{-1}g^{-1}) were determined by single time point analysis as described previously,[18] where *T* is the time in minutes

$$K_{in} = C_{Tissue}\,(T)/C_{perf}T$$

The blood−brain unidirectional transfer constants determined in this manner were corrected for vascular space by subtracting the [^{14}C]sucrose R_{Brain} from the [^{3}H]DPDPE R_{Brain} values.

Statistical Analysis. For all experiments, the data were presented as the mean and SEM All concentration effects of PAO on the [^{3}H]DPDPE transport were compared by ANOVA, followed by Newman−Keuls using the Pharmacological Calculation System (PCS) statistical analysis program.[19] Linear regressions were carried out using the PCS statistical analysis program, and compared by the method of Bailey.[20]

Results

In Vitro BBMEC Permeability of [^{3}H]DPDPE. The effect of PAO on the basal permeability of BBMEC monolayers to [^{14}C]sucrose was studied. There was no effect on sucrose permeability across the membranes with 10, 50, or 100 μM PAO (data not shown). The permeability of [^{3}H]-DPDPE across BBMEC monolayers grown on collagen/fibronectin-coated polycarbonate filters and the effect of 10, 50, and 100 μM PAO were studied. Figure 1 shows the permeability of [^{3}H]DPDPE with time. The *PC* values calculated from Figure 1 (Table 1) show that all concentrations of PAO led to a significant decrease in the rate of [^{3}H]DPDPE permeability across the membrane. The amount of DPDPE in the receiver chamber was significantly lower at all time points in the presence of 100 μM PAO ($p < 0.01$ at all time points). Also, the values at 100 μM PAO were significantly lower than the values for 10 μM PAO for all but the 120-min time point ($p < 0.05$ for 10 and 90 min, $p < 0.01$ for 30 and 60 min). The 50 μM concentration of PAO significantly reduced DPDPE permeability at all time points studied ($p < 0.05$ at 15 and 60 min, $p < 0.01$ at 30,

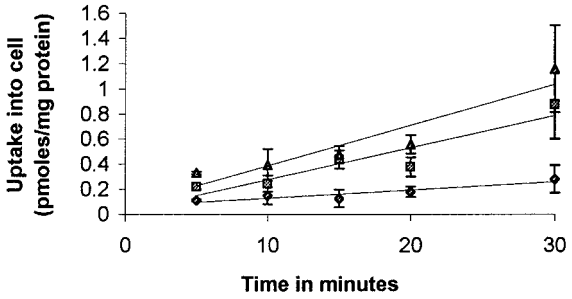

Figure 2—The time-dependent uptake of [^{3}H]DPDPE into BBMEC monolayer cells. Each point represents the mean and SEM of eight wells. Triangles represent the total amount of DPDPE associated with the cells, and diamonds represent the acid-sensitive and squares represent the acid-insensitive fractions of the binding.

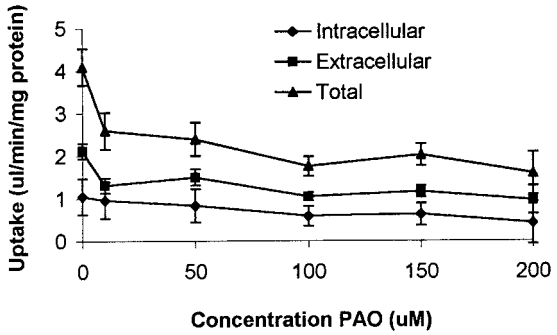

Figure 3—The effects of PAO (10–200 μM) on the total cell association of DPDPEs and acid-sensitive/acid-insensitive fractions at the 20-min time point. Each point represents the mean and SEM of eight wells.

60, and 90 min) and was significantly different from 10 μM PAO at the 30- and 60-min time points ($p < 0.01$ and $p < 0.05$, respectively). A solution 10 μM PAO reduced DPDPE permeability at the 90- and 120-min time point ($p < 0.05$ and $p < 0.01$, respectively).

In Vitro BBMEC Uptake of [^{3}H]DPDPE. In the in vitro BBMEC model of the BBB, [^{3}H]DPDPE uptake is linear with time with an uptake rate of 32.3 ± 0.7 fmol·min^{-1}·mg^{-1} protein (Figure 2). The total uptake could be split into two components, the binding of [^{3}H]DPDPE to the external membrane (acid sensitive), with a rate of 6.5 ± 0.15 fmol·min^{-1} ·mg^{-1} protein; and the internalized fraction (acid insensitive), with a rate of 25.6 ± 0.59 fmol·min^{-1}·mg^{-1} protein. The uptake of [^{3}H]DPDPE was significantly decreased at all concentrations of PAO (Figure 3). The acid-sensitive fraction showed no significant difference in [^{3}H]DPDPE binding to the cell except at the 200-μM PAO concentration ($p < 0.05$), whereas the acid-insensitive uptake fraction was significantly reduced.

In Situ Perfusion. The effects of phenylarsine oxide concentrations ranging from 10 to 200 μM on the basal permeability of the BBB to [^{14}C]sucrose were studied. PAO had no significant effect on the basal permeability of the BBB (Figure 4) at the concentrations used. All subsequent in situ figures have had the sucrose space subtracted.

The transport of [^{3}H]DPDPE across the BBB was studied during in situ brain perfusion with various (10−200 μM) concentrations of PAO. Addition of PAO decreased the uptake of [^{3}H]DPDPE into the rat brain in a dose-dependent manner (Figure 5, Table 2). The [^{3}H]DPDPE uptake was decreased by 27% ($p < 0.05$) at 10 μM, 43% ($p < 0.01$) at 50 μM, 73% ($p < 0.01$) at 100 μM, 80% ($p < 0.01$) at 150 μM, and 49% ($p < 0.01$) at 200 μM PAO. The effects at both 100 and 150 μM were significantly different from those at 10 μM ($p < 0.05$ for both).

Addition of 100 μM nonradioactive DPDPE led to a significant inhibition of [^{3}H]DPDPE uptake ($p < 0.01$)

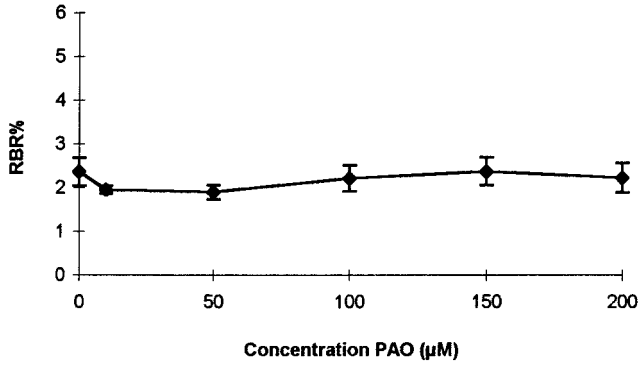

Figure 4—The effects of DPDPE and PAO on the permeability of the rat BBB to [^{14}C]sucrose. Each bar represents the mean and SEM of 4–6 animals. Concentrations of 100 μM DPDPE and 100 μM PAO had no significant effect on the permeability of the BBB to sucrose.

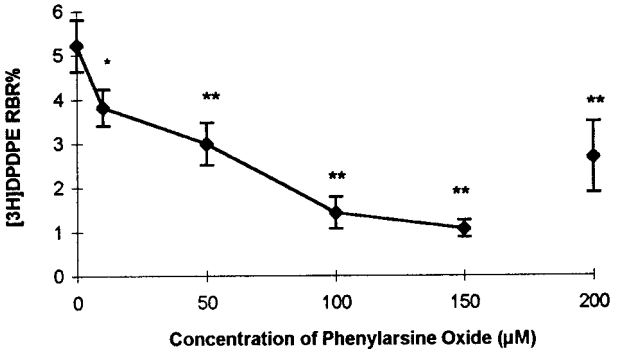

Figure 5—Dose-dependent inhibition of [^{3}H]DPDPE in situ uptake by rat brains of 10–200 μM PAO. Each point represents the mean and SEM of 4–6 animals. Statistical significance is indicated by (*) $p < 0.05$ and (**) $p < 0.01$ (using ANOVA followed by Newman–Keuls ad hoc test with the sucrose space subtracted).

Table 2—Unidirectional Transfer Constants (K_{in}) for [^{3}H]DPDPE in the Presence of Various Concentrations of PAO[a]

PAO, μM	K_{in} (μL·min^{-1}·g^{-1}) ± SEM	percent change (p value)
0	2.61 ± 0.29	—
10	1.91 ± 0.21	27% ($p < 0.05$)
50	1.49 ± 0.27	43% ($p < 0.01$)
100	0.71 ± 0.17	73% ($p < 0.01$)[b]
150	0.53 ± 0.10	80% ($p < 0.01$)[b]
200	1.30 ± 0.39	51% ($p < 0.05$)

[a] The unidirectional transport constants (K_{in}) for [^{3}H]DPDPE calculated from Figure 5 and the percent decrease in the constants with 10–200 μM PAO. Concentrations of PAO from 50 to 200 μM led to significant decreases in the K_{in} values (K_{in} values compared by ANOVA, followed by Newman–Keuls test). [b] This value is also significantly different from 10 μM PAO data at $p < 0.05$.

(Figure 6). Co-administration of both PAO and cold DPDPE led to no additive inhibition of [^{3}H]DPDPE uptake.

Discussion

In this study, we investigated the role of a saturable endocytotic mechanism in the transport of DPDPE (a cyclized opioid peptide) into the brain, using a three-model BBB paradigm. It is assumed with each of the three models that the receiver chamber, cells, or brain are acting as a sink (i.e., that the transport of DPDPE will be in one direction only). We also assume that the transport will be linear. The concentration of peptide that we used in this study is 7.6 pM. This concentration is considerably lower than the half-saturation constant of the peptide transporter, which is 45.5 μM.[11] Thus, the concentration we use

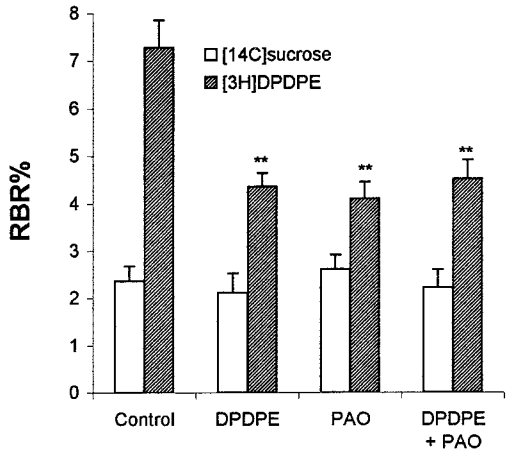

Figure 6—The effects of a combination of 100 μM PAO and 100 μM DPDPE on the uptake of [^{3}H]DPDPE by rat brain. Each bar represents the mean and SEM of 4–6 animals. Addition of PAO, DPDPE, and the combination to the perfusate led to a significant decrease in [^{3}H]DPDPE uptake. There was no significant difference between the three treatment groups.

is 10^{-6} lower than the concentration required to saturate the transport. This concentration is thus reasonable and we assume that the sink conditions will occur, if the amount of peptide in the donor solution remains higher than the amount of peptide in the receiver chamber. In this study, only a small percentage of the peptide actually crosses into the receiver chamber, cell, or brain. If the concentration of peptide used in a study is lower than the K_m value, it is likely that the process will remain linear.

The trivalent monosubstituted organoarsenic compound, PAO has been shown to inhibit endocytosis via clathrin coated pits[21] and has been used to study receptor-mediated endocytosis at concentrations of 0.1 to 100 μM.[16] The major toxic effect of PAO is the inhibition of cellular pyruvate dehydrogenase, which results in a decrease in ATP production via the citric acid cycle.[22] Viability of MDCK cells in the presence of PAO was maintained in the presence of 5 mM glucose.[22] In all of our models, of the BBB the concentration of glucose was 10 mM. Most of the other toxic effects of PAO are generally seen at longer time points than those used in this study and can be related to its long-term inhibition of endocytosis.

The first model of the BBB that was investigated in the present study was the in vitro permeability of [^{3}H]DPDPE across BBMEC monolayers. In general, this model of the BBB is used to study the transport of nonradioactive peptides across the BBB, and the typical concentrations used (i.e., 500 μM) will result in the predominant mode of transport being diffusion. In this report, we used [^{3}H]-DPDPE with a specific activity of 42 Ci·mM^{-1}, and 0.33 μCi was added to each of the donor chambers (i.e., approximately 7.6 pM compared with 500 μM of peptide added in cold experiments). This low pmolar concentration of [^{3}H]DPDPE is similar to that used in the in situ model and thus makes comparison easier. If we assume a cerebrovascular surface area of 100 cm^2·g^{-1},[23] the permeability surface area constant (*PC*) for the in situ [^{3}H]DPDPE is 1.46 ± 0.31 cm·min^{-1} $\times$ 10^{-5} compared with a cold 500 μM in vitro value of 49.24 ± 2.78 cm·min^{-1} $\times$ 10^{-4}.[9] This result is a 337-fold difference. In contrast, when the in vitro study is carried out with [^{3}H]DPDPE, the *PC* value is 9.31 ± 0.62 cm·min^{-1} $\times$ 10^{-4}, which is a 64-fold difference. From the previous in situ studies[10,11] it is known that the K_m for DPDPE is 45.6 ± 27.6 μM. Therefore, in the control DPDPE permeability studies, any transport system expressed by the cells would be thoroughly saturated at the 500 μM concentration. However, in the present study, the [^{3}H]-DPDPE is at a concentration of 7.6 pM, which would not saturate the transporters. Therefore, it is likely that a larger proportion of the permeability across the membranes is due to a transport mechanism other than diffusion. Previous studies have used this model to study the transport of insulin[24] and angiotensin II.[13] These peptides are biologically important and use receptor-mediated transcytosis to enter the brain. Furthermore, both of these previous studies used concentrations of PAO similar to those used in this study, and neither group reported any adverse affects of PAO on the membranes or cells studied. In the present study, PAO lead to a significant decrease in the permeability of DPDPE across BBMEC monolayers (Figure 1). The basal permeability of the monolayers to [^{14}C]sucrose was not effected by PAO (data not shown), indicating that the monolayer was not adversely affected by the PAO. In previous studies, it has been shown that the presence of high glucose will protect cell viability against PAO,[22] and 10 mM glucose was used in these experiments. The higher concentration of PAO (100 μM) led to an inhibition at all time points of DPDPE permeability. There was a dose-dependent effect on the inhibition between the 10 and 100 μM concentrations. The 10 μM concentration significantly inhibited the permeability of [^{3}H]DPDPE only at 90 and 120 min. The [^{3}H]DPDPE (7.6 pM) permeability in the presence of 100 μM PAO was significantly different from the 10 μM PAO concentration at all time points except the 120-min time point.

The uptake of [^{3}H]DPDPE into confluent monolayers of BBMEC cells was also studied. The uptake of DPDPE by the cells was linear with time (Figure 2). To assess the actual uptake into the cell, an acid wash was carried out. The peptide that was acid sensitive represented the amount of peptide bound to the outer membrane of the cells. The acid-sensitive fraction remained fairly consistent throughout the time-course of the uptake, with no significant difference in binding to the cells at any time point. PAO has been shown to cross-link vicinal sulfydryl groups to form stable ring structures, thus inhibiting the internalization of receptors.[25] However, it is also possible that PAO could be preventing DPDPE from binding to sites on the membrane responsible for its uptake. PAO (10−200 μM) significantly reduced the uptake of [^{3}H]DPDPE (Figure 3), without affecting the acid-sensitive portion (except at 200 μM). Thus it is evident that PAO was preventing internalization rather than cell surface binding of the DPDPE. Similar results have been seen with other peptides, such as angiotensin II in rat myometrial cells[26] and BBMEC.[13]

For both of the in vitro models of the BBB, the cells were grown without co-culture with astrocytes or astrocyte-conditioned media. A number of groups have reported improved BBB characteristics due to addition of either astrocytes or media from astrocytes.[27,28] However, in studies carried out in this laboratory, we have found no significant change in either trans-endothelial resistance or sucrose crossing of monolayers due to either astrocyte-conditioned media or co-culture.[29] In fact, our sucrose space and trans-endothelial resistance measurements indicate that we have a tighter in vitro BBB than those reported by other groups who use co-culture.[27,28]

The in situ perfusion model used in this study has been previously utilized to study the transport of a number of peptide neuropharmaceuticals across the BBB.[3,4,10,30] The basal permeability of the BBB has been extensively studied using inert nontransported substances such as sucrose. In this study, the sucrose space was measured to assess the effect of PAO on the basal permeability of the BBB. The values measured ranged from 0.12 ± 0.002 to 0.13 ± 0.002 μL·min^{-1}·g^{-1} for basal and PAO-treated rats, respectively. These values are well within the range of normal sucrose spaces reported previously in the literature.[31,17,10] It is thus

Table 3—Comparison of *PC* Values from Literature and Those Calculated from This Study for DPDPE

model of BBB	*PC*, cm·min^{-1}	reference
BBMEC permeability with 500 μM DPDPE	49.24×10^{-4}	Weber et al., 1993
BBMEC permeability with [^{3}H]DPDPE	9.31×10^{-4}	present study
in situ with [^{3}H]DPDPE	1.46×10^{-5}	Williams et al., 1996
	2.61×10^{-5}	present study
uptake studies with [^{3}H]DPDPE	9.56×10^{-5}	present study

clear that, within the experimental parameters studied, PAO has no significant effect on the basal permeability of the BBB for a 20-min exposure. Furthermore, 100 μM DPDPE did not significantly affect the vascular space under the current experimental conditions. The uptake of DPDPE was inhibited in a dose-dependent manner by 10−150 μM PAO (Figure 5.). The inhibition caused by 100 μM PAO was not significantly different from that caused by 100 μM DPDPE, and no additive effect was observed on co-administration (Figure 6). At the 200 μM concentration of PAO, there was a slight yet not statistically significant rise in the uptake of DPDPE into rat brains. This rise was obviously not due to an increased basal permeability of the BBB because at the same concentration there was no increase in the sucrose space of the brain. Furthermore, a similar effect was not seen in the cellular uptake model.

PAO has been shown to have similar effects on the uptake/transport of DPDPE in two in vitro and one in situ model of BBB transport. It is generally difficult to compare in vivo and in vitro studies of the BBB. However, in this study, all the chemicals used were similar and the isotope was from the same batch and equivalent concentrations of isotope were used in each experiment. To make comparison of the three models easier, the flux and K_{in} values were converted to a *PC* value that was already described for the in situ experiments. The *PC* values for the uptake were calculated on the assumption that the mean protein value was 59.6 μg of protein per well (based on 162 individual wells) and the surface area of the wells is fixed at 2 cm^2. The *PC* values from this study and others (Table 3.) show that the BBMEC uptake studies have *PC* values 3.6 times higher than the in situ studies.

PAO has been used at concentrations ranging from 1 to 100 μM in a number previous studies and has resulted in variable levels of inhibition on receptor-mediated endocytosis. For example, Bradley et al.[32] showed that the receptor-mediated endocytosis of low-density lipoprotein by human umbilical vein endothelial cells was reduced 66% by 1 μM PAO. Wiley et al.[16] used a range of PAO concentrations (10^{-4}−10^{-7} M) to inhibit receptor-mediated endocytosis of EGF by human fibroblast cells, finding that there was almost total inhibition at 10 μM. In contrast, angiotensin II receptor-mediated transcytosis across endothelial cells was significantly decreased by 25 μM PAO, though it required 100 μM PAO to significantly reduce uptake into the cell.[13] These differences in the required concentrations of PAO to cause an effect may be linked to the differences in the endocytotic rate constants for each receptor studied and to the number of receptors expressed in a given system. For example, EGF receptors have endocytotic rate constants ranging from 0.03 to 0.3 min^{-1}, depending on cell type.[33] Also, receptor distribution and density varies from cell type to cell type, for example, the transferrin receptor is constitently expressed at a high density on the BBB endothelial cells and relatively low in other capillary beds.[34] The fact that we were unable to totally inhibit the permeability across BBMEC cells on filters is not surprising. The *PC* value takes into account the diffusion across the membranes between cells (by calculating the *PC* value from linear regression), however, it does not divide the transport into saturable and nonsaturable mechanisms. The evidence that we present in this study is that the saturable component of DPDPE transport is inhibited by PAO, thus implicating clathrin-dependent receptor-mediated endocytosis. It has been shown that DPDPE also uses a nonsaturable diffusional mechanism to cross the BBB.[11] This mechanism would not be affected by PAO and thus should not be inhibited. Therefore, we would be more surprised if we totally inhibited all DPDPE transport.

Together with data from previous studies, we can now state that DPDPE crosses the BBB in part via an endocytotic (transport) mechanism. PAO has been shown to inhibit some fluid phase endocytosis[25] at higher concentrations. Although this form of endocytosis may explain some of the DPDPE transport, it would not explain the saturable component of the transport. Furthermore, if the PAO were indeed inhibiting the nonsaturable component of the transport, it would be reasonable to assume that addition of a high concentration of DPDPE to the in situ media would lead to an additive inhibition. This assumption is evidently not the case (Figure 6), and the likely saturable mechanism is endocytosis. The two saturable forms of endocytosis are adsorptive endocytosis and receptor-mediated endocytosis. In an earlier study, the competitive adsorptive endocytosis inhibitor poly-L-lysine failed to reduce DPDPE uptake into rat brain,[11] suggesting that DPDPE does not bind to the anion-rich sites in the cell membrane and thus does not use classical adsorptive endocytosis. DPDPE has been shown to have a K_m in the micromolar range,[11] which is indicative of a carrier-mediated rather than receptor-mediated process.[35] This result would indicate that the mechanism of DPDPE uptake is unlikely to be via a normal receptor-mediated endocytotic effect. However, DPDPE transport could be explained by DPDPE binding specifically to a protein/receptor in an area that has a high basal endocytotic rate (for example, clathrin-coated pits) and entering the cell via receptor turnover rather than stimulating its own endocytosis. PAO has previously been shown to reduce the basal endocytotic rate in 3T3 cells[25] and could inhibit DPDPE uptake in this manner. Furthermore, insulin, which binds to its receptor (in clathrin-coated pits) and is internalized, leads to an increase in the basal endocytotic rate and also increases DPDPE uptake.[11]

In conclusion, the present study demonstrates that DPDPE enters the brain via an endocytotic mechanism that is saturable and can be inhibited in a dose-dependent fashion by PAO. The understanding of the transport of DPDPE is important for several reasons. First, a number of opioid peptides based on the structure of DPDPE are currently being developed and studied for analgesia therapy. Second, the disulfide bridge between two D-amino acids has become a common strategy for stabilizing the peptide backbone of peptide pharmaceuticals. By studying the transport of DPDPE, we will be able to determine whether cyclization via disulfide bridges results in a common transport mechanism for peptide drugs.

Accepted for publication January 8, 1999.

Abstract □ Absorption rate constants (in situ rat gut technique) and in vitro antibacterial activities of twenty fluoroquinolones have been evaluated. A biophysical model that relates the absorption of the compounds with their lipophilicity was fitted. The model considers the absorption process from the intestinal lumen as the sum of two resistances in series: aqueous diffusional barrier and lipoidal membrane. Even if partitioning into the membrane and membrane diffusion are both enhanced for lipophilic compounds, the absorption rate constant is limited by the aqueous diffusion. To estimate the influence of structural modifications on each property and to establish the role of lipophilicity in controlling in situ absorption and in vitro antibacterial activity, the PATQSAR search system is used to construct structure–property relationships. The structural models, which explain 99% of the total variance of each physicochemical property and 96% of each in vitro biological activity, provide an explicit and precise interpretation of lipophilicity, absorption, and antimicrobial activity. The results confirm the important role of lipophilicity in controlling absorption, as pointed out by the biophysical model for the piperazinyl series, and suggest the introduction of electronic factors in order to extend the model to heterologues. They also justify the mechanism by which quinolones are assumed to induce antibacterial activity.

Introduction

Absorption−lipophilicity correlations can help to explain absorption mechanisms by passive diffusion. The Plá-Delfina and Moreno absorption model[1] considers that in the small intestine diffusion can occur by two parallel paths: the aqueous pores and the lipoidal membrane. The actual absorption rate represents the sum of the rate constants governing the penetration into the lipoidal membrane and across the aqueous pores. When the molecular weight of the compounds is above approximately 250 Da, diffusion by the aqueous pathway becomes impossible, and the absorption is reduced to membrane penetration. In this case, the Higuchi-Ho equation[2] is able to describe in more detail the two steps involved in absorption. This equation considers that there are two resistances in series associated with the stagnant aqueous layer and the lipoidal barrier. In the present study, a lipophilicity−absorption relationship for homologous series of compounds is established by means of a previously published[3] modification of the Higuchi-Ho equation, to check its utility and predictive potentialities.

In the field of computer-aided design, we have developed an interactive graphic system, PATQSAR (Population Analysis by Topology-based QSAR), based on the topological DARC/PELCO methodology,[4−6] for predicting physicochemical or biological properties of molecules, starting from their characteristic structural elements and the appropriate experimental data. With a view to validating the absorption−lipophilicity correlation established with the compartmental model and to gaining insight into the mechanism by which fluoroquinolones induce antimicrobial activity, we use our general QSAR search procedure to construct structure−absorption, structure−lipophilicity, and structure−activity correlations.

Materials and Methods

Test Compounds—Sixteen 6-fluoro-7-piperazinyl quinolones derived from norfloxacin and ciprofloxacin by progressive alkylation of *N′*-piperazinyl,[7] as well as four additional compounds, one homologue and three related heterologues, were provided by Cenavisa S. A. Laboratories (I+D Department, Reus, Spain).[8]

Each compound was identified by its infrared spectrum. Purity was checked by ion-pair reversed phase HPLC and shown to be above 99.9% in all cases. The names, structures, and molecular weights of the compounds are given in Table 1. The piperazinyl quinolones exhibited a pK_{a1} between 5.5 and 6.5, and a pK_{a2} between 7.5 and 8.5, and at the working pH (7.00) they were in their zwitterionic form. The heterologues have only one pK_a value between 6.0 and 7.0.

Absorption Studies—*Biological Technique*—The in situ rat gut technique, adapted as previously described,[9,10] was performed using the whole small intestine of male Wistar rats weighing 210−295 g (six animals per compound). To prevent enterohepatic recycling, the bile duct was cannulated before the perfusion. An isotonic saline solution was prepared and buffered to pH 7.00 by addition of 10% (v/v) of 0.066 M Sörensen phosphate solution. This concentration prevents the disturbing effects of phosphates on the intestinal membrane[11] while maintaining the ionization of the substances. Test solutions were prepared immediately before use by dissolving a fixed amount of each compound in the vehicle solution (w/v), depending on its solubility. The concentrations, shown in Table 1, are low enough to avoid precipitation in the lumen during the absorption tests. After dissolving the xenobiotic, the pH of the solution was checked and readjusted when necessary. The perfusate was sampled into silanized glass tubes at fixed times after 5 min, at intervals of 5 min. All samples were analyzed immediately.

Water Reabsorption Studies—The volume of the perfused solutions at the end of the experiments was significantly reduced (up to 20%), and a correction became necessary in order to calculate the absorption rate constants accurately. If this process is not considered, the disappearance from the gut is underestimated and the absorption rate constant is incorrectly calculated. Water reabsorption is an apparent zeroth-order process.[10,12] A method based on direct measurement of the remaining volume of the test solution was employed.[7] The volume V_0 at the beginning of the experiment for each compound was determined on groups of three animals, while the volume V_t at each time t was measured on every animal used. The corrected concentration C_t, which represents the concentration in the gut that would exist in the absence of the water reabsorption process, was deduced from the concentration C_e analyzed in the sample at the same time t, by the following equation:

$$C_t = C_e \frac{V_t}{V_0} \qquad \text{(eq 1)}$$

Absorption Rate Constants—The absorption rate constants k_a were determined by nonlinear regression analysis of the corrected concentrations C_t versus time, using Sigma Plot 2.0 (Jandel Scientific), as it had been previously established that the process follows first-order kinetics. To prevent adsorption on the intestinal mucosa and residual sample dilution effects,[10,13] only the calculated values after 5 min, listed in Table 2, were used for regression, as it was found that after that time adsorption equilibrium was generally reached.

Lipophilicity Indexes—*Partition Coefficients*—Bulk phase partition coefficients, *P*, between *n*-octanol (Merck analytical grade) and of 0.066 M Sörensen phosphate buffer, pH 7.00, were determined for each compound of the series. Six values per compound were used to establish the average value to be used in the correlations. These values are reported in previous papers.[3,14]

Number of Methylene Groups—This was used as a lipophilicity index free of the influence of solvent interactions. Provided that a perfect homologous series is studied, it has been demonstrated to be equivalent to other indexes such as partition coefficients, *P*,[1,15] or capacity factors, *K*.

Analysis of the Samples—An original HPLC procedure was used to quantify the solute concentration in both biological and partition samples. The analysis was carried out on a Novapak C18 column (3.9 × 150 mm), using as mobile phase a mixture of methanol and 15 mM phosphate buffer, adjusted to pH 2.4 with orthophosphoric acid. The percentage of each component of the mobile phase was selected for each compound of the series in order to obtain the best chromatographic resolution. The equipment consisted of a Series III Hewlett-Packard quaternary pump, a Rheodyne injector, a 1046 Hewlett-Packard fluorescence detector, and a 3395 Hewlett-Packard integrator. Quantification was done by fluorometry, with excitation and emission wavelengths of 338 and 425 nm, respectively. This technique offers a high degree of selectivity and specificity. The procedure was validated for inter- and intraday runs before use. Accuracy was estimated from the percentage error associated with measuring 5 to 8 standards, analyzed at least three times. Accuracy was demonstrated to be

better than 15%, regardless of the analyte concentration. Precision was calculated as the coefficient of variation of five determinations over the same standards, and it was shown to be better than 5%. Linearity was established over the range of concentrations present in the samples for every compound (correlation coefficients always over 0.999).

In Vitro Antibacterial Activity—The lowest concentration of the drug that inhibited the growth of 90% of the strains on agar was taken as the minimum inhibitory concentration, MIC_{90}. It was determined on 100 strains of *Escherichia coli*, using the agar plate dilution method. The procedure was validated by means of the following typified strains: *Pseudomonas aeruginosa* ATCC 27853, *E. coli* ATCC 25922, *Streptococcus faecalis* ATCC 29212, and *Staphilococcus aureus* ATCC 29213. The assay was carried out following the specifications of the National Committee for Clinical Laboratory Standards.[16] Mueller-Hinton agar plates were prepared with known concentrations of the quinolone tested, covering a suitable range. The bacterial suspension was then inoculated into the plates with a Steers replicator. The plates were cultured at 37 °C for 20 h and evaluated immediately thereafter.

Fitting of Models to the Data—To test the pertinence of the absorption rate constants for establishing correlations, their values were compared with each of those by means of ANOVA after the homogeneity of the variance had been tested using the Cochran test.

Absorption−Lipophilicity Relationship—A biophysical compartmental model, which considers the total resistance to passive absorption as the sum of two resistances in series, was fitted. As previously pointed out,[3] the partial resistances correspond to the aqueous resistance, produced by the stagnant aqueous layer and to the lipoidal resistance due to the membrane. The original equation[2,3,17] was adapted assuming that the permeability in the aqueous layer depends inversely on the square root of the molecular weight and that the permeability in the membrane lipoidal phase is related to lipophilicity. The equation can be written as follows:

$$k_a = \frac{CP^d}{1 + E\sqrt{M}P^d} \qquad \text{(eq 2)}$$

where *C*, *d*, and *E* are fitting parameters. Curve fitting was carried out only for perfectly homologous compounds. All fitting operations were run on a computer using the PCNONLIN 4.0 program. For more complicated fitting models, PCNONLIN was used instead of Sigma Plot because it is a more powerful software which uses several algorithms to optimize the objective function, provides more statistical information about the parameters obtained, and gives the standard deviation of the predicted values. To appreciate the goodness of fit, the correlation coefficients between the experimental and model-predicted k_a values were calculated. Precision in the estimation of the parameters, and the standard deviation, *s*, were also used as criteria for evaluating the results.

Structural Models—Four correlations were run on the compounds and the available data for each property. The experimental population consisted of 20 compounds for the absorption rate and partition coefficients, and 16 for in vitro antibacterial activity. The models were established by using PATQSAR,[18] a system for QSAR search based on the DARC/PELCO topological procedure.[4−6]

Data are encoded directly by an interactive procedure. The compounds are represented as ordered chromatic graphs. Their superposition generates the population trace, which contains all the elements required for constructing the initial structural variable automatically. Compounds are described by a vector of discrete structural variables, which have values of 0 or 1 depending on their absence from or presence in the molecule, respectively.

These primary variables can be further combined into more complex ones:

Interaction variables designate the simultaneous existence of two or more basic structural elements, each of which can exist without the other; they are written as $V_1{*}V_2$;

Exclusion variables designate the existence of a basic element in the absence of another one, which can exist simultaneously; they are represented as $V_1{*}\overline{V_2}$;

Equivalence variables make elements, which belong to homogeneous series and have closely similar effects on the property, equivalent; they are written as $V_1 = V_2$.

Optimal correlations were sought on the basis of the criterion of experimental precision (± 0.04 for log k_a and ± 0.02 for log *P*). For each model an exploratory correlation was run on the available data with all the topochromatic "sites" as parameters, i.e., atoms and bonds different from the common structure or "focus". Deviations from additivity were taken into account by introducing interaction sites. Regularities, which allow certain structural effects to be generalized, were detected by introducing equivalence sites. At each step the new SAR is set up by multiple linear regression analysis. A stepwise module is available to detect the most significant parameters.

Results and Discussion

Lipophilicity Indexes—The *n*-octanol/water partition coefficients listed in Table 2 undoubtedly constitute the most classic index. To study the effect of alkylation on lipophilicity, the relationships between log *P* and the number of methyl groups of homologous compounds were established for each series. Statistical comparison (*t* test) of their slopes demonstrated that they are the same. Therefore, the overall correlation is shown in Figure 1. In such a correlation the intercept should represent the log *P* value of the parent compounds of the series (i.e. norfloxacin and ciprofloxacin), but it does not. This can be interpreted as the result of specific interactions between these elements and the solvent, promoted by the absence of the methyl substituent. This effect has been reported for many parent

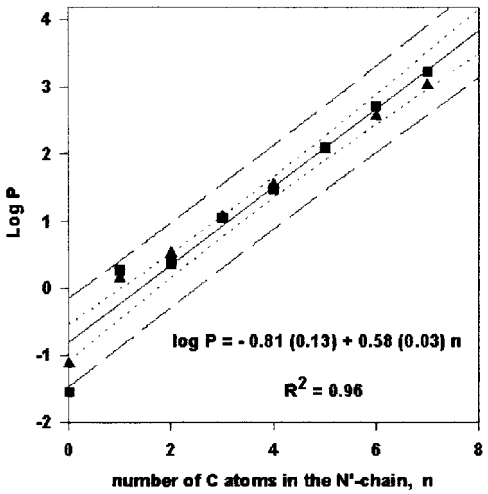

Figure 1—Relationship between partition coefficient and number of methylene groups for *N′*-alkylnorfloxacin (■) and *N′*-alkylciprofloxacin (▲). The dotted and dashed lines represent the 95% confidence (•••) and prediction (- - -) intervals, respectively.

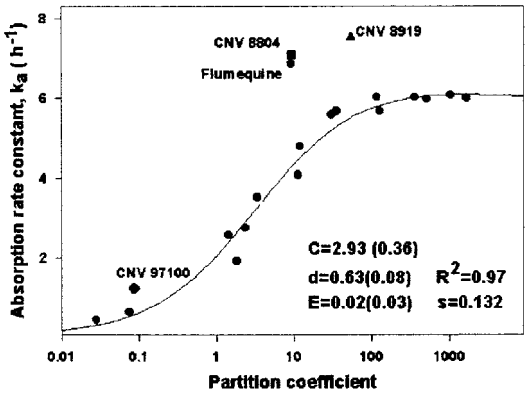

Figure 2—Relationship between absorption and partition coefficient for perfectly homologous compounds. The line represents the best fit of eq 2: $k_a = (2.60P^{0.72})/(1 + 0.02M^{1/2}P^{0.72})$. The points associated with the heterologues are superimposed: CNV 8804 (■); CNV 8919 (▲); flumequine (●).

compounds of very different homologous series. The methyl derivatives, on the contrary, show higher lipophilicity indexes than predicted. This effect, known as the "first element effect", can easily be explained if we consider the fact that the methyl group has a larger volume than the hydrogen of the parent ring. Therefore, the substituent significantly reduces the water to *n*-octanol transfer energy. Obviously, this substituent produces greater changes than subsequent alkylation. Finally, the slope of the correlation, which represents $\Delta\pi$ for the series, is in good agreement with Hansch's predictions.

Absorption–Lipophilicity Correlation—Applying the biophysical model to the 17 6-fluoro-7-piperazinylquinolones leads to a very significant absorption–lipophilicity correlation ($R^2 = 0.97$) represented in Figure 2 where the fitting parameters are listed along with the statistical data. As can be seen, the absorption rate constant increases with lipophilicity up to a certain value because of the limiting effect of water diffusion through the stagnant layer. Therefore, there is a practical limit to the lipophilicity that improves the intestinal absorption rate. The k_a and P values of the three heterologous compounds have also been plotted in Figure 2. Their absorption rate constants are higher than those predicted by the correlation from their lipophilicity index. This could be due to the electronic changes that the new substituents introduce into the molecule, which probably modify their interactions with the absorptive membrane. Nevertheless, the optimal values for lipophilicity that could be predicted reproduce the value obtained by the correlation for homologous compounds.

Structural Models—*Lipophilicity–Structure Model*—The results are displayed on the population trace diagram in Table 3. The relationship can be written:

$$\log P = 0.96(\pm 0.04) - 2.56(\pm 0.05)\ \text{N}\bigcirc\text{N} + 0.81(\pm 0.03)\ \text{S}\bigcirc\text{N}$$

$$+1.82(\pm 0.05)C_1 + 0.27(\pm 0.01)C_2 + 0.54(\pm 0.02)\sum_{i=3}^{7} C_i + 0.54(\pm 0.02)\ \text{CH}_2\!\curvearrowright\! {}^{*}\overline{C_1}$$

$R^2 = 0.99$ F = 2556 s = 0.07 df = 16 n = 20 (eq. 3)

where:

ΣC_i groups the chain-lengthening atoms; $\text{CH}_2\!\curvearrowright\! {}^{*}\overline{C_1}$ represents the methylene bridge in the absence of chain-lengthening on the piperazinyl ring: the contribution of the methylene bridge is zero when C_1 is present.

The structural elements, whose contributions are 0.27, 0.54, and 0.81, are grouped in an equivalence variable where they are weighted as indicated below:

$$C_2 = 1,\ C_3 = C_4 = C_5 = C_6 = C_7 = \text{CH}_2\!\curvearrowright\! {}^{*}\overline{C_1} = 2,\quad \text{S}\bigcirc\text{N} = 3$$

Contributions of the different heterocycles take into account the absence of the flumequine moiety represented by the dotted line in Table 3.

The lipophilicity, as expected, is markedly reduced by introducing a piperazinyl ring at position 7. Replacing the N′ nitrogen of this ring by a different heteroatom, oxygen or sulfur, produces a more lipophilic molecule. The lipophilicity is decreased by a higher electron-donating effect of the substituent which enhances its solvation by water. It is greatly increased upon methylation of the *N′*-piperazinyl nitrogen (+1.82) and regularly enhanced by lengthening or branching of the *N*-alkyl chains (+0.54) except in the β positions with respect to the N′ nitrogen. The contribution of the first methyl to total lipophilicity is about three times that of the chain-lengthening atoms. This can be explained by the fact that secondary amines have a higher polarity and affinity for the aqueous phase and interact with it more easily. Replacing the hydrogen by a donor substituent, such as the methyl group, reduces the transfer energy from water into *n*-octanol.[19] The small contribution of the β chain-lengthening atom (0.27) compensates the first element effect. Replacing the *N*-ethyl by a *N*-cyclopropyl in position 1 increases lipophilicity by the same 0.54 value but has no effect in the presence of a N′-chain. The influence of the methylene bridge is quantified by the interaction–exclusion variable. Surprisingly, introducing a methyl group on the piperazinyl ring at the β position with respect to the N′ nitrogen has no effect.

Absorption–Structure Model. The relationship presented in Table 4 can be expressed as:

$$\log k_a = 0.82(\pm 0.02) - 1.13(\pm 0.03)\ \text{N}\bigcirc\text{N} + 0.06(\pm 0.02)\ \text{CH}_2\!\curvearrowright$$

$$+0.35(\pm 0.04)\ C_0 + 0.64(\pm 0.03)\ C_1 + 0.14(\pm 0.01)\sum_{i=2}^{4} C_i$$

$R^2 = 0.99$ F = 387 s = 0.04 df = 14 n = 20 (eq. 4)

In this case the interaction variable is not necessary because the membrane behaves as a less discriminative partitioning system than *n*-octanol/water.

The 7-piperazinyl group reduces both lipophilicity and absorption, as this implies an increase in polarity.[19] Again, replacing the nitrogen of the piperazinyl ring by a different heteroatom, oxygen or sulfur, enhances both lipophilicity

Table 3—Structure–Lipophilicity Model

[a] Contributions of the heterocyclic rings take into account the absence of the flumequine moiety represented by the dashed line. [b] Contribution of the methylene bridge is zero when C_1 is present.

and absorption. However, the relative contributions are not the same. Starting from flumequine whose lipophilicity is a little higher than absorption, introducing the 7-piperazinyl group decreases lipophilicity (−2.56) much more than absorption (−1.13) while introducing a morpholinyl or a thiopiperidyl group either has no effect on both properties or increases lipophilicity (+0.81) markedly and does not influence absorption. Introducing a methylene bridge into the *N*-ethyl side chain strengthens this effect, leading to heterologues having a higher lipophilicity than absorption, in contrast to the first terms of the piperazinyl series. This could explain why they were found as outliers in the biophysical model. It suggests that absorption is an increasing function of lipophilicity which must be modulated by electronic factors.

In the piperazinylquinolones, each chain-lengthening atom that increases lipophilicity produces an increase in absorption up to four carbons. The relative contributions are also reproduced: the first methyl group produces a bigger increase than any other, as previously seen for log *P*, and further elongation produces a uniform absorption increase. However, in this case the scheme changes, the three last chain-lengthening atoms have no effect on absorption and can be ignored. This fact can be understood if we consider the biophysical model. As stated by Higuchi-Ho, adjacent to the intestinal membrane there is an aqueous diffusion barrier, whose thickness creates an aqueous resistance to solute diffusion which has to be overcome before partitioning into the membrane. This step represents the absorption rate-limiting process. Even if partitioning into the membrane and membrane diffusion are enhanced for lipophilic compounds, the absorption rate has a practical limit fixed by the aqueous diffusion,[3] as is clear from the zero contribution of the three last chain-lengthening elements.

Additionally, introducing a 3′-methyl group or a 1-cyclopropyl has a slightly different effect on absorption and lipophilicity: 3′-methyl, which has no influence on lipophilicity, increases absorption weakly; 1-cyclopropyl, which has no influence on absorption, increases lipophilicity but only for the first term.

Structure–Antibacterial Activity Models—The results are displayed on the population trace diagrams in Tables 5 and 6. The equations can be written:

$$\log(1/MIC)_{E.Coli} = 1.03\,(\pm 0.03) - 0.28\,(\pm 0.01)\sum_{\substack{i=2\\ i\neq 6}}^{7} C_i + 0.56\,(\pm 0.02)\ \ CH_2$$

$$R^2 = 0.96 \quad F = 371 \quad s = 0.11 \quad df = 14 \quad n = 16 \qquad \text{(eq.5)}$$

The two structural elements are grouped in an equivalence variable, where they are weighted as indicated:

$$C_2 = C_3 = C_4 = C_5 = C_7 = -1, \quad CH_2 = 2.$$

$$\log(1/MIC)_{Staph.} = 0.33\,(\pm 0.04) - 0.28\,(\pm 0.02)\sum_{i=3}^{7} C_i + 0.28\,(\pm 0.02)\ \ CH_2$$

$$R^2 = 0.96 \quad F = 323 \quad s = 0.12 \quad df = 14 \quad n = 16 \qquad \text{(eq. 6)}$$

In this case, the two structural elements grouped in the equivalence variable are weighted:

the cyclopropyl group and the DNA or bacterial girase binding site, was not clarified. On the other hand, it can be noted that the activity on both strains is decreased by lengthening the *N*′-alkyl chain. According to the structure–lipophilicity model, these structural effects are not related to cellular penetration, as the methylene bridge has no influence on lipophilicity, and chain-lengthening increases it. Thus, antibacterial activity is enhanced by a *N*-cyclopropyl which could help to bind the molecule to the DNA or to the bacterial girase. It is decreased by steric hindrance of the *N*′-alkyl chain which could hinder access of the molecule to the enzyme or its intercalation in the DNA.

Conclusion

Two strategies are used to identify the properties which influence in situ absorption. In the first, the influence is assessed quantitatively by searching for correlations between absorption and lipophilicity. Within the series of closely related piperazinyl fluoroquinolones, lipophilicity appears as a strong determinant factor, and the results validate our previous biophysical model. Although the three heterologues are found as outliers, the biophysical model is still able to predict the lowest value of lipophilicity for a maximum absorption. In the second strategy, we construct structural models by using the PATQSAR approach and deduce the influence, starting from a simultaneous analysis of absorption and lipophilicity. The results confirm that absorption is increased by higher lipophilicity up to a limit due to N′-chain lengthening which could hinder membrane penetration by steric hindrance. Moreover, they suggest that electronic factors could be introduced into the biophysical model in order to reflect the marginal behavior of the heterologues.

The PATQSAR approach confirms some of the hypotheses of the biophysical absorption model and suggests its extension, thus demonstrating that they are complementary. Moreover, its use to identify the properties which influence antibacterial activity suggests the role of steric factors. This system is therefore a powerful tool for interpreting physicochemical and biological data and for optimizing certain processes, such as in situ absorption and antibacterial activity.

Colloidal and Thermal Characteristics of Concentrated Dispersions of Polymethacrylate-Based Latices for Aqueous Enteric Coating

MATTIAS PAULSSON[†] AND SATISH K. SINGH[*,‡,§]

Contribution from *Department of Pharmacy, Division of Pharmaceutics, Uppsala University, Uppsala Biomedical Centre, Box 580, S-751 23 Uppsala, Sweden, and Department of Pharmaceutical Technology, Pharmacia & Upjohn AB, S-751 82 Uppsala, Sweden.*

Received August 31, 1998. Accepted for publication December 10, 1998.

Abstract □ We have used rheological and thermal methods to study the colloidal characteristics of a widely used technical latex. The dispersions of poly(methacrylic acid–ethyl acrylate) (Eudragit L100-55) were found to be stabilized by a combination of electrostatic and steric mechanisms termed as electrosteric stabilization. The electrosteric stabilization is considered to arise in part from dissolved polymer chains with charged carboxylic groups extending out into the continuous phase. The presence of dissolved polymer chains in the dispersion implies that coalescence and interpenetration will be facilitated during film formation, enabling a smooth continuous film to be formed. The extent of the stabilization layer and an effective hard-sphere volume was estimated to discuss the steady shear and viscoelastic properties in this context. The glass transition temperature (T_g) of the particles making up the dispersion has also been determined as a function of sorbed moisture and modeled by the Gordon–Taylor equation modified for specific interaction between water, surfactant, and polymer. This parameter at high moisture content can be used as a first approximation to the minimum film-forming temperature (MFT). Change in T_g (and thus MFT) with moisture content implies that the coating process must be controlled so as to produce a rate of drying slow enough to allow coalescence to occur.

Introduction

The release of drug from a solid dosage form is often tailored by applying a polymeric coating. Water-based rate-controlling polymer films are generally made by spraying an aqueous polymeric dispersion (latex) onto the dosage form (tablet or multiparticulates) and then evaporating the water, a process not unlike film formation from water-borne paints. Commonly used aqueous coating polymers within the pharmaceutical industry are cellulose derivatives and acrylic polymers. These latices are characterized by low viscosity, even at relatively high solid content.[1]

The mechanism of film formation from aqueous latex dispersions has been discussed for almost half a century. The evolution of the theories of film formation can be followed through a number of interesting papers.[2−5] Rheology,[4,6] scanning electron microscopy,[4,6] and lately atomic force microscopy[4,7] are primary techniques that have been employed for studying dispersions and film formation. Latex dispersions are subject to a range of shear rates during the coating process ranging from 10^5 s^{-1} during atomization to 10^{-2} s^{-1} during leveling. The process of deformation and coalescence is a function of polymer viscoelasticity.[2] In this work, we have applied rheology to study a commercial latex dispersion based on a methacrylic acid−ethyl acrylate (MAEA) copolymer and relate its characteristics to the first stages of film formation in pharmaceutical processing.

Film formation from polymer dispersions is correlated to the glass transition temperature (T_g) of the polymer and the temperature of operation in relation to the minimum film-forming temperature (MFT) of the latex.[8] The MFT is the minimum temperature above which a continuous and clear film is formed during drying.[2,8] While film formation does not imply that interdiffusion of polymer chains between adjacent particles must occur,[7,9] coalescence and interpenetration would be required for the formation of a strong film.[5] This flexibility is influenced by additives (plasticizers) as well as water (moisture) content of the polymer and can be detected as a reduction in both the T_g and the MFT. While both these parameters are apparently similar, T_g is a fundamental property of the material while MFT is an ill-defined parameter[10] reflecting latex morphology[11] and even particle size in some cases[2]. T_g can, however, be used as a first approximation for the MFT. (Data from Heuts et al.[8] gives the ratio of MFT to T_g as ranging between 0.8 and 1.1 for single stage acrylic dispersions, while data from Hoy[12] gives a ratio of 0.95). The T_g (and MFT) of the sprayed latex will change with moisture content, and a poor film will be formed if the MFT rises above operating temperature due to too rapid a drying. We have therefore determined the moisture adsorption isotherm for the dry commercial latex dispersion and measured the T_g of as a function of moisture content.

Materials and Methods

A spray-dried aqueous dispersion of methacrylic acid−ethyl acrylate (MAEA) copolymer (MW 250 000) with the commercial name Eudragit L100-55 was used (Röhm GmbH, Darmstadt, Germany). The as-received Eudragit L100-55 also contains 0.7% sodium lauryl sulfate (SLS) and 2.3% Polysorbate 80 based on solid substance, added to function as emulsifiers.

Dispersions were made by adding NaOH to the latex particle agglomerates in water and dispersing in accordance with Lehmann.[1] The dispersion is stable when 3−6% of the carboxylic groups of the copolymer are ionized; at greater than 20% ionization, the polymer particles would dissolve.[1] A suitable ratio of alkali and polymer was found to be 90 g of polymer/g of NaOH. This ratio was determined by measuring the viscosity and stability of the dispersions with constant polymer content but varying alkali concentration. Low pH gave an unstable dispersion while high pH's resulted in a rapid increase in viscosity due to dissolution of polymer. Dispersions were considered to be stable if no sedimentation could be detected in 24 h by visual inspection. The pH of the dispersions ranged between 5.1 and 5.3 (see Table 1). By keeping the NaOH−MAEA ratio constant, stable dispersions over a wide

range of solids content could be made. A suggested procedure for preparation of the dispersion requires a ratio of 71 g of polymer/g of NaOH along with 10% triethyl citrate at a final pH of ~5.[1] The ready-to-use commercial 30% dispersion Eudragit L30 D from Röhm has a pH of 2.5. At this pH, however, a 30% dispersion of the spray dried L100-55 is not stable and sediments immediately.

True polymer concentration of the latices was determined by "Loss on drying", method d (383 K, 3 h), in accordance with Ph. Eur. 1979. Taking into account the mass of compounds that did not evaporate and knowing the density of Eudragit L100-55, 1.18 g/cm^3 (data from manufacturer), the volume fraction of polymer, ϕ, was calculated.

The ζ potential of the particles was measured using a Malvern Zetasizer 4 (Malvern Instruments Ltd, Malvern, UK). Measurements were performed 24 h after preparation, on three samples from each dispersion. The latex dispersions were diluted 160-fold in an acetate buffer with similar pH and ionic strength (~10^{-2} M) prior to measurement due to their high turbidity. The used ionic strength is an estimate, since the exact degree of ionization of the carboxylic groups on the polymer is unknown.

Steady-state rheological measurements were carried out using a Bohlin VOR Rheometer (Bohlin Reologi, Lund, Sweden), a controlled strain instrument, with a double gap measuring system (DG 24/27) for dispersions of low viscosity or a concentric cylinder (C25) for dispersions of intermediate viscosity. A controlled stress instrument (Stresstech Rheometer, Reologica Instruments, Lund, Sweden) with a concentric cylinder (CC15) measuring system was used for all the dynamic viscoelastic measurements. The frequency range of 0.0001-90 Hz with a constant stress of 0.5 Pa was used. This stress is such that resulting deformation lies within the linear viscoelastic region of all dispersions measured. All measurements were performed at 298 K. Unwanted drying out and film formation at the surface of the sample were prevented by covering the measuring cups with a vapor trap. The intrinsic viscosity was determined using an Ostwald capillary viscometer at 298 K.

The glass transition temperature of the spray-dried Eudragit L100-55 was determined using modulated temperature differential scanning calorimetry (MTDSC) on a Seiko DSC220C instrument upgraded with a SSC5300 analysis system. Other operational conditions are described by Singh et al.;[13] the instrument operational parameters used were a heating rate of 3 K/min, an amplitude of 1 K, and a frequency of 0.02 Hz. The T_g of the MAEA copolymer in question here could not be detected using a conventional DSC.

To examine the effect of moisture on the glass transition temperature, samples were stored for 3−4 weeks in desiccators with constant humidity atmosphere at room temperature. The constant relative humidity atmospheres, in the range 31−95% RH, were created using saturated salt solutions.[14] Dried polymer samples were weighed (5−10 mg) into aluminum DSC pans and placed in these desiccators for equilibration. Prior to measurement, the pans were quickly sealed with crimping covers.

The water content of the MAEA powder equilibrated at the specified relative humidity was measured by Karl Fischer (coulometry) analysis (Metrohm 737 KF Coulometer, Metrohm AG, Herisau, Switzerland).

The glass transition temperature (at various moisture contents) can also be determined by an isothermal dynamic vapor sorption (DVS) method.[15] The sample is loaded onto a quartz pan of a microbalance located in a controlled gas flow environment, where the relative humidities (0−95%) can be accurately specified while the weight gain is continuously registered (DVS-1, Surface Measurement Systems, Marlow, UK). DVS was performed on the MAEA sample at one temperature (313 K) only to confirm the results of the MTDSC measurements.

Results and Discussion

The surface charge of particles in dispersions has a strong influence on both the stability and the flow behavior of the dispersion. Since the MAEA particles carry carboxylic groups, the particles will be negatively charged at the pH of the experiments (Table 1). This is confirmed by measuring the ζ potential of the particles. At $\phi = 0.25$ the ζ potential was -42 ± 1.9 mV, and at $\phi = 0.34$ the value was -43 ± 1 mV. There was a small tendency of the ζ potential to increase with increasing the polymer content. This was, however, within the uncertainty of the method. All the dispersions were therefore considered to have the same ζ potential. The ζ potential of the ready-to-use Eudragit L30D was -14 ± 3 mV in a dilution buffer of pH 2.5 and ionic strength 10^{-2} M.

In addition to the charges on the particles and the probable presence of dissolved polymer chains, the dried latex contains surface active substances that could in principle contribute to the steric stabilization of the dispersion.[16,17] Some simple experiments were performed in order to gain some insight into the interparticle repulsion/stabilization mechanism. Addition of small amounts of salt (e.g. KCl) instantaneously affected the stability causing the dispersion to flocculate irreversibly. The same effect was seen when the pH was lowered slightly. This is a typical feature of electrostatically stabilized dispersions. The freeze−thaw stability of the dispersion was good, however, which usually indicates steric stabilization.[18] Thus, a combination of electrostatic and steric stabilization is indicated for the dispersion.

From the above experiments it is also clear that the dispersion tested here cannot be described as hard spheres. The data also does not fit Einstein's law for hard spheres since the measured intrinsic viscosity, [η], is 4.7, compared to the expected hard-sphere intrinsic viscosity of 2.5. [For comparison, Raynaud et al.[19] report an intrinsic viscosity of 3.65 for a sterically stabilized dispersion of particle diameter 250 nm, while Krieger and Dougherty[20] report 3.44 for a dispersion with rigid uncharged particles with a diameter of 110 nm]. It is apparent that the effective hydrodynamic radius of the particles is increased by the adsorbed surfactants, dissolved polymer chains, and/or electroviscous effects from surface charges, forming a stabilization layer. An estimate of the effective hydrodynamic radius can be made using the expression

$$[\eta] = 2.5\left[\frac{a_H}{a}\right]^3 \quad (1)$$

where a is the core or true radius of the particles while a_H is the effective hydrodynamic radius. The (number) average particle radius of the dispersions, containing 10−40 wt % polymer is 100 nm although the particle size distribution is fairly broad ranging from 60 to 200 nm[1]. The thickness of the stabilization layer calculated from eq 1 is 23 nm.

Steady-State Shear Flow Behavior—The steady-state shear viscosity of various volume fractions of Eudragit L100-55 latex dispersions as a function of applied shear rate is plotted in Figure 1. The dispersion with lowest ϕ's showed Newtonian behavior. All dispersions above a volume fraction of $\phi = 0.4$ showed a more or less pronounced shear thinning behavior. The extent of shear thinning increased with increasing volume fraction. At very low shear rates a plateau is evident, which is an approximation of the zero shear viscosity. The experimental

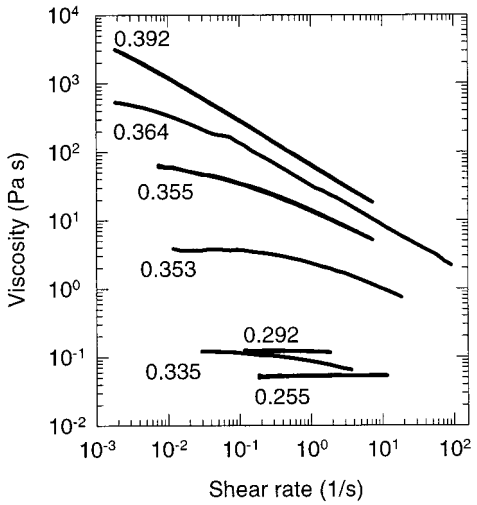

Figure 1—Steady-state shear flow curves of MAEA dispersions as a function of applied shear for increasing polymer volume fractions, ϕ ($n = 3$; see Table 1 for standard deviations). Data from controlled strain instrument.

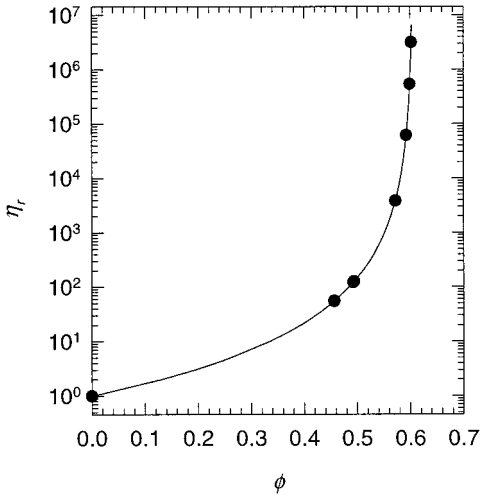

Figure 2—The low shear relative viscosity as a function of effective volume fraction for MAEA dispersions (●) fitted to the Krieger–Dougherty model, eq 3, with $[\eta] = 4.7$ and $\phi_{eff,m} = 0.605$. Data from controlled strain instrument.

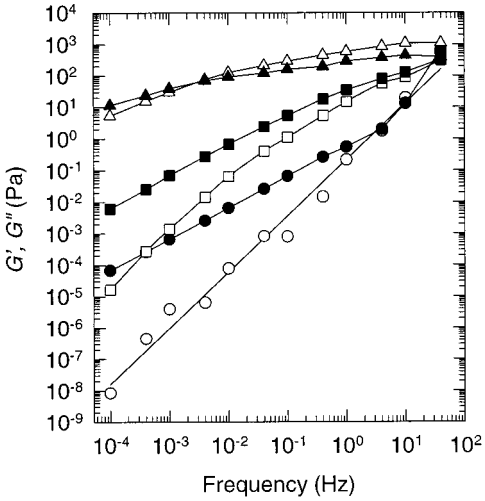

Figure 3—The storage (open symbols) and loss (closed symbols) moduli of $\phi = 0.33$ (○, ●), $\phi = 0.35$ (□, ■), and $\phi = 0.39$ (△, ▲) dispersions. Data from the controlled stress instrument.

set up could not detect the low-shear plateau for the dispersion with the highest solid content.

On the basis of previously discussed electrostatic and steric stabilization mechanism, an effective volume fraction, ϕ_{eff}, can be defined[6] such that

$$\phi_{eff} = \phi\left(1 + \frac{\Delta}{a}\right)^3 \quad (2)$$

where a is the particle radius (= 100 nm) and Δ is the increase of the effective particle radius due to contributions from the stabilization mechanisms (Debye length and/or adsorbed layer). With the above correction, the dispersion can be modeled as a hard-sphere system. The semiempirical Krieger−Dougherty equation[20] can then be used to correlate the relative viscosity, η_r, at low shear (approximation of the zero-shear viscosity from Figure 1) to the effective volume fraction

$$\eta_r = \left(1 - \frac{\phi_{eff}}{\phi_{eff,m}}\right)^{-[\eta]\phi_{eff,m}} \quad (3)$$

$[\eta]$ is the intrinsic viscosity and $\phi_{eff,m}$ is the maximum packing fraction. The value of $[\eta]$ from capillary viscometry = 4.7. The value used for $\phi_{eff,m} = 0.605$, corresponding to a hexagonally packed sphere structure (loose packing, coordination number 8). [The dispersion has a honeycomb-like structure in the last stages before the water layer disappears and the particles begin to deform and possibly coalesce.[21] Roulstone et al. propose a close-packed hexagonal structure for this stage with a maximum packing fraction of 0.74;[22] however, their conclusion is based on cast films where the particles have a longer time to achieve such a structure. Heterodispersity can also lower the packing efficiency[10]]. The value of Δ used to fit the experimental data points in Figure 2 to eq 3 are tabulated in Table 1, in accordance with Prestidge and Tadros.[23] At the low volume fractions, the effective thickness of the stabilization layer, Δ, is estimated to be 21 nm. The thickness of this stabilization layer decreases gradually with increasing volume fraction (Table 1). This is not surprising since the layer is compressed with increasing volume fractions as the particles approach each other closely. This compression causes the dispersion to display an increasingly elastic behavior as discussed below.

Viscoelastic Behavior—The viscoelastic response of the MAEA dispersion, in terms of the storage (G') and loss (G'') moduli, is shown in Figure 3 for three volume fractions. For $\phi = 0.33$ ($\phi_{eff} = 0.49$) which corresponds to a less-than-close packing fraction, G'' is considerably larger than G' at low frequencies. When the frequency is increased, the difference between the moduli decreases and at a critical value called the crossover frequency ~1 Hz, they are equal.

Increase in G' with frequency is a function of the relaxation time scale, τ_r, of the suspension in relation to the experimental time scale. At low frequencies, the experimental time of the order of $\tau \approx 1/\omega$ is longer than the relaxation time allowing the perturbed structure to relax during oscillation. The applied energy is thus dissipated, resulting in a large loss modulus or viscous behavior. With increasing frequency, τ becomes of the order of τ_r, resulting in a combined viscous and elastic response. Further increases in frequency will thus result in a predominantly elastic response i.e.,

$$G^* \approx G' = G_\infty$$

implying that the viscoelastic properties do not change at higher frequencies.[24]

With increasing volume fraction the average distance between the particles decreases causing increasing overlap of the stabilization layers surrounding the particles and

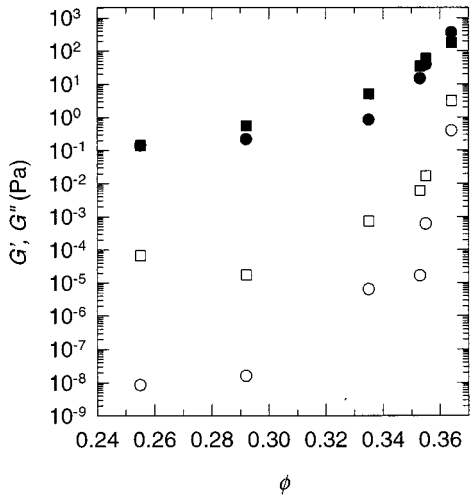

Figure 4—The storage (○, ●) and loss (□, ■) moduli at 10^{-4} Hz (open symbols) and 1 Hz (closed symbols) as a function of increasing volume fraction. Data from the controlled stress instrument.

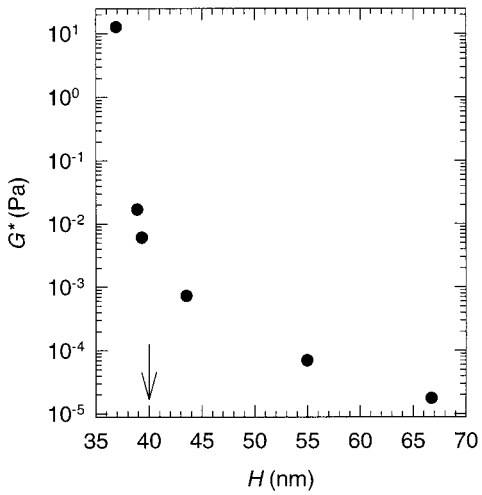

Figure 5—Complex modulus (at 10^{-4} Hz) as a function of the mean interparticle spacing from eq 5. The arrow shows the estimated point where the particles start overlapping. Data from the controlled stress instrument.

therefore increasing the elasticity (G'). This is apparent in Figure 3 for $\phi = 0.39$ ($\phi_{eff} = 0.60$). G' and G'' of this dispersion is almost frequency independent. A much lower crossover frequency is obtained, ≈0.002 Hz, since the dispersion is unable to scatter the applied energy due to its high solid content and begins to show elastic behavior at low levels of perturbation.

At low volume fractions ($\phi = 0.33$) the dispersion follows the Maxwell model, implying that one relaxation process dominates the dynamic properties of the latex in solution. The implication is that transient structures (stabilization layer) existing in the system at these concentrations are similar. [The slope of $G'(\omega)$ in Figure 3 is 1.8, and the slope of $G''(\omega)$ is 1.1, compared to 2 and 1, respectively, as required by the model]. The dispersions with higher volume fractions, however, do not fit the Maxwell model: for $\phi = 0.39$ ($\phi_{eff} = 0.60$), the slope for $G'(\omega)$ is 0.4 and for $G''(\omega)$ is 0.27 in Figure 3. This is not surprising since stabilization layer overlap and the resulting interactions introduce a new type of "cross-link" in the dispersion.

The variation of G' and G'' with volume fraction at two different frequencies of oscillation are shown in Figure 4, where an increase in solid content increases G'' and particularly G'. The phase angle shift is almost 90° for the lowest volume fractions but increases to approximately 45°, at $\phi = 0.36$ ($\phi_{eff} = 0.60$). Results from both frequencies confirm that the close-packing volume fraction for the present system occurs at $\phi_{eff} = 0.60$, above which the system behaves as a gel.[23]

The reciprocal crossover frequency (in rad/s) can be used to approximate the relaxation time, assuming that the material follows the Maxwell model of viscoelastic fluids. The relaxation time increases with the volume fraction and typical values of the relaxation time are 0.1 s for the low ($\phi_{eff} = 0.49$) concentration increasing to ~75 s for the high solid dispersions ($\phi_{eff} = 0.60$). To put these in perspective, characteristic process times for spraying are of the order of 10-5 s, while that for leveling of an applied film is 100 s. These times thus agree well with the characteristic relaxation times of the dispersions at the relevant concentrations. To further relate the viscoelastic properties to the deformation and possible coalescence processes, we resort to the modified viscoelastic model[9] for film formation by Eckersley and Rudin.[2] According to this model, film formation requires

$$G'(t) \leq \frac{34\sigma}{a} \tag{4}$$

where σ is the surface tension of water in the capillaries between particles, while $G'(t)$ is the time-dependent elastic shear modulus of the polymer. Using $\sigma = 30$ mN/m and 200 nm as the largest particle size in the dispersion gives a critical upper limit for elastic modulus of 5.1×10^6 Pa. Figure 4 shows that this criteria is satisfied by the present dispersion.

The mean interparticle spacing in a dispersion, H, is a measure of the closeness of approach of these particles and can be expressed as

$$H = 2a\left[\left(\frac{\phi_{eff,m}}{\phi_{eff}}\right)\right] \tag{5}$$

In Figure 5, we have plotted the complex modulus G^* (at 1 Hz) against H calculated from eq 5 using values of ϕ from Table 1 and $\phi_m = 0.605$ as indicated above. It is clearly apparent that as the interparticle spacing falls below 40 nm, G^* increases markedly due to the stabilization layers beginning to overlap. An estimate of the thickness of this layer is therefore = $^1/_2H$, i.e., approximately 20 nm. This value compares well to the Δ-value in Table 1 for the low volume fractions, as well as the estimate from intrinsic viscosity using eq 1.

The Debye double layer thickness, $1/\kappa$, in the present system (water at 298 K)

$$\kappa = 3.288\sqrt{I} \quad (\text{in nm}^{-1}) \tag{6}$$

gives a fairly thin double layer of the order of 3 nm, due to the ionic strength estimated as 10^{-2} M. The large value of κ_a (≈ 30) suggests that primary electroviscous effects would be small. Secondary electroviscous effects, while not significant at low volume fractions, may, however, play a role in increasing the viscosity at the high volume fractions considered here. In the literature, such effects have been attributed to the formation of (temporary) doublets of like-charged particles which allow energy to be dissipated when rotating in or when destroyed by shear.[25] Examining the possible steric contributions to the stabilization layer suggests that the surfactants added to the latex particles (Polysorbate 80 and SLS) cannot extend out 20 nm from the surface of the particles. This and the fairly high ζ potential imply that alternative explanations are needed to rationalize the extent of the stabilization layer (which is in agreement when calculated from the various methods). This layer must arise due to dissolved latex polymer chains

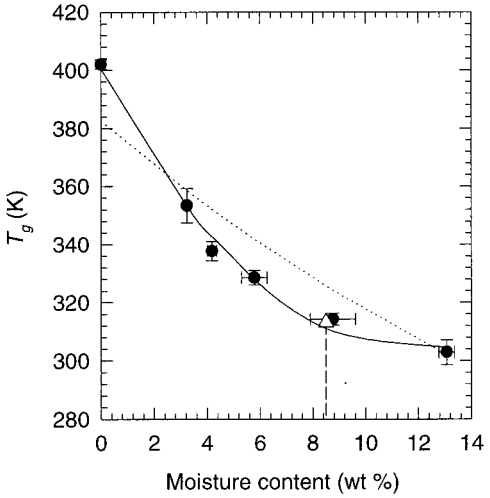

Figure 6—Influence of moisture content on T_g for spray-dried MAEA dispersion from MTDSC (●). The dotted line is calculated from eq 7 while the continuous line is a data fit using eq 9. Standard deviations are shown for both T_g and the moisture content. Results of T_g determination by DVS (Δ) at 40 °C (313 K) is marked with a line.

Table 2—Moisture Sorption Isotherm at 25 °C, and the Glass Transition Temperature (T_g) of Eudragit L 100-55 (Methacrylic Acid–Ethyl Acrylate Copolymer) ($n = 3$)

rel humidity (%)	equilibrium moisture content by KF (wt %)	equilibrium moisture content by DVS (wt %)	T_g by MTDSC (K)
0	0	0	402 ± 1.6
31	3.24 ± 0.05	3.68	353 ± 5.8
42	4.19 ± 0.17	4.70	338 ± 3.3
58	5.78 ± 0.48	6.70	329 ± 2.5
90	8.76 ± 0.86	10.9	314 ± 2.0
95	13.1 ± 0.29	13.8	303 ± 4.2

which allow the charged carboxyl groups to extend further out from the surface. The alkyl chain of anionic SLS can also adsorb to the surface of the latex as well as bind to the dissolved chains extending the charged headgroup into the surrounding phase, effectively increasing the (negative) surface charge. The picture we have of the latex is thus one with a charged "hairy" surface, electrosterically stabilized.[26] The presence of the adsorbed neutral surfactant (as well as dissolved polymer) can influence the adsorption characteristics of the ions in the diffuse layer as well as shifting the shear plane away from the surface. Contribution to the latter effect due to Polysorbate 80 will not be very strong since the amount added is small, allowing the adsorbed layer to be approximated as free draining; any contribution due to dissolved latex polymer is, however, difficult to estimate. Change in the ion distribution in the diffuse layer can be caused by excluded volume effect leading to an extension of the double layer and thereby an increase in the surface potential of the particle.[25]

Moisture Sorption and Thermal Analysis—MAEA is an amorphous polymer and takes up water in a humid environment. The moisture sorption isotherm at 298 K is tabulated in Table 2 and shows good agreement between the two (KF and DVS) techniques. The particles absorb up to 13% moisture when exposed to high relative humidity. The data seems to follow a typical Type II isotherm for multilayer physical adsorption on nonporous solids.

The corresponding T_g of the MAEA particles (measured by MTDSC) equilibrated at a range of relative humidities is also shown in Table 2 and plotted in Figure 6. The glass transition temperature of the particles is substantially lowered after exposure to moisture, as is to be expected. Lehmann[1] reports the MFT of redispersed MAEA latex is 291 K, the MFT of the ready-to-use Eudragit L30D dispersion is 300 K, and the T_g of the dry polymer is 380 K. We find that the T_g (at high moisture content; Figure 6) is a good first approximation of the MFT. The data also suggests that since the T_g (and thus MFT) rises rapidly with decreasing water content, the process of film formation should be complete before the sprayed material is dried to such an extent that the MFT rises above operating temperature. A balance is therefore required between spray rate, temperature, and drying air flow. It also implies that the MFT of (and T_g for hydrophilic) latex systems must be related to the moisture content, and determined by the humidity of the drying air in which it is measured.

The data from the Dynamic Vapor Sorption measurement performed at 313 K agrees well with the MTDSC data as shown in Figure 6. A glass transition event at this temperature is detected when the moisture content of the polymer is approximately 9%. However, no such event is observed when the experiment is performed at 298 K. The plasticizing effect of sorbed moisture is not sufficient to lower the T_g to 298 K.

Monotonic variations of the T_g with composition in mixtures/blends are often modeled by the modified Gordon−Taylor equation which is based on free volume effects under the assumption that there are no specific interactions between the components. For a three-component mixture, this can be written as

$$T_{gmix} = \frac{w_1 T_{g1} + K_{12} w_2 T_{g2} + K_{13} w_3 T_{g3}}{w_1 + K_{12} w_2 + K_{13} w_3} \quad (7)$$

where w_1, w_2, and w_3 are the weight fractions of the three components, and T_{g1}, T_{g2}, and T_{g3} are the corresponding pure component glass transition temperatures. Constants K_{12} and K_{13} are ratios of free volumes of components and can be estimated from

$$K_{ij} = \frac{\rho_i T_{gi}}{\rho_j T_{gj}} \quad (8)$$

where ρ_i represents density of component i.

We expect that the MAEA copolymer has specific interactions with water including deprotonation of the carboxylic groups. Similarly, hydrophobic portions of Polysorbate 80 will have an increased affinity for the latex surface. To account for these interactions, quadratic and third-power interaction terms are added to eq 7, giving

$$T_{gmix} = \frac{w_1 T_{g1} + K_{12} w_2 T_{g2} + K_{13} w_3 T_{g3}}{w_1 + K_{12} w_2 + K_{13} w_3} + Q_{12} w_1 w_2 + Q_{13} w_1 w_3 + Q_{123} w_1 w_2 w_3 \quad (9)$$

where Q_{12}, Q_{13}, and Q_{123} are empirical interaction parameters reflecting the strength and type of interactions.[27,28] We denote MAEA, water and Polysorbate 80 as components 1, 2, 3 with T_{g1}, T_{g2}, and T_{g3} as the glass transitions temperatures of pure MAEA, water (= 135 K),[29] and Polysorbate 80 (= 207 K), respectively. The T_g of Polysorbate 80 was measured in this work, but the same could not be done for pure MAEA since the MAEA available was preblended with surfactants. While an extensive dialysis procedure could in principle remove all added surfactant, we chose to estimate this parameter (T_{g1}) from the data at 0% RH. We have neglected any plasticizing effect of SLS because of the small amount added. Using a two-component version of eq 7 on T_g data at 0% RH gives T_{g1} = 412 K. (Specific gravity of Polysorbate 80 = 1.08 and of MAEA = 1.18). Utilizing this parameter in eq 7 to calculate the T_{gmix}

of the blend at various moisture contents gives a theoretical glass transition that does not agree with the experimental data (Figure 6). However, using eq 9 with Q_{12} and Q_{123} as curve-fitting parameters allows the data to be modeled well as shown in Figure 6. (It was found that the parameter Q_{13} could be dropped without any effect on the goodness of fit). The value obtained for parameter Q_{12} is positive while that for Q_{123} is negative. While Kwei et al. have presented arguments based on intermolecular force parameters to explain the negative values of such parameters,[30] we will simply ascribe these to be empirical parameters that enable the data to be modeled and underline the importance of specific interaction terms in our system.

Conclusions

In the first part of this study, we have used the techniques and methods of colloid science and applied them to a technical latex, widely used in the pharmaceutical industry. The dispersions are found to be electrostatically and sterically stabilized. The stabilization is considered to arise in part from dissolved polymer chains with charged groups that extend out into the bulk continuous phase. The extent of the stabilization layer was estimated to be around 20 nm, giving an effective hard-sphere volume that can be used to relate the steady shear and viscoelastic properties to the film formation phenomena. The presence of dissolved polymer chains in the dispersion implies that coalescence and interpenetration will be facilitated during film formation.

The results generated here provide a baseline to evaluate the effect of normal coating additives such as plasticizers, colorants, flavorants, buffering agents etc., on dispersion stability and film-forming ability. While such studies increase our understanding of the systems in question, they also point to the complexity and limitations in the strict application of techniques and models based on ideal and simplified systems. Technical dispersions present a challenge because of their heterodispersity and the combination of mechanisms involved.

The glass transition temperature of the particles making up the dispersion has then been determined as a function of sorbed moisture and modeled by the Gordon−Taylor equation modified for specific interaction between water, surfactant, and polymer. Our data and that in the literature suggests that the high-moisture content T_g can be used as a first approximation for the MFT. Change in T_g (and thus MFT) with moisture content implies that the process must be controlled so as to produce a rate of drying slow enough to allow coalescence to occur. A curing stage is generally added to assist in the coalescence and interpenetration of the sprayed polymer chains. Knowledge of the moisture sorption and T_g data can be used to determine the conditions of this stage especially for heat labile substances.

Accepted for publication January 8, 1999.

Abstract □ Insufficient intratumoral concentration of therapeutic agents and multidrug resistance are major factors responsible for failure of treatment of solid tumors. Simultaneous delivery of chemosensitizing and antineoplastic agents by microspheres could lead to enhanced chemotherapy of multidrug-resistant (MDR) tumors. Ionic polysaccharide microspheres derived from dextran were used to load chemosensitizers (e.g., verapamil) and anticancer drugs such as vinblastine. High drug loading was achieved for both a single agent and dual agents. The equilibrium drug loading was dependent on the ratio of the microspheres (MS) to the drug, as well as the relative affinity of the agents to the MS in the case of dual agents. The drug release from drug–MS involved hydration and swelling of the MS in addition to ion exchange. The effectiveness of MS-delivered chemosensitizers in the reversal of drug resistance was evaluated by measuring the uptake of [^{3}H]vinblastine by MDR cells (CH^{R}C5). The concomitant delivery of verapamil with vinblastine by the MS led to a 6–7-fold increase in the uptake of vinblastine, a level similar to the uptake obtained with free drug solutions. The results suggest that the antineoplastic and chemosensitizing agents were released effectively from the MS and the bioactivity of the chemosensitizer was preserved during the process.

Introduction

The efficacy of cancer chemotherapy may be limited by the drug toxicity, drug concentration achievable in the tumor, and the development of multidrug resistance (MDR). The maximum systemic drug concentration is set by the drug toxicity to the normal tissues (e.g., leukopenia of vinblastine, and cardiotoxicity and immunosuppressive activity of doxorubicin). In addition, it is difficult to obtain an effective therapeutic drug level in solid tumors because of higher intratumoral pressure and poor blood supply.[1] Therefore, targeted drug delivery has been extensively investigated to increase the drug exposure of the tumor relative to that of normal tissues. Of all the targeting approaches, the most direct one is the intratumoral or intra-arterial injection of drug solutions to the tumor site.[2−4] This technique, however, is often associated with significant systemic exposure due to rapid egress of the drug from the tumor mass. To maintain the intratumoral drug concentration and reduce the systemic exposure, slow-release formulations, especially in the form of microspheres (MS), have been utilized in the place of free drug solutions.[5−14]

To date, slow-release MS have been tested in regional cancer chemotherapy in over a thousand patients worldwide[6−9] as a potential, effective treatment of solid tumors in the liver, kidney, breast, lung, head, and neck. Pharmacokinetic and pharmacodynamic studies in animals and humans have shown enhanced drug exposure of tumors and diminished systemic toxicity as compared with organ perfusion with free drug solutions.[2−14] Moreover, there is little indication of increased local toxicity in most studies.[5,7,8] Despite these positive results, a considerable percentage of chemotherapy failure is still observed in animal tumor models and in clinical trials, which may be partly attributed to MDR to chemotherapy.[8,15−19]

It has been demonstrated that chronic exposure of cancer cells to sublethal concentrations of chemotherapeutic agents can lead to the outgrowth of the MDR phenotype.[15−19] MDR, characterized by diminished cellular drug accumulation, usually derives from an increased rate of drug efflux by specific membrane proteins [e.g., P-glycoprotein (P-gp)[16−19]]. Integration of MDR-reversing agents, such as verapamil and cyclosporins, in conventional chemotherapy has been used for treatment of MDR tumors.[18−22] However, there has been limited success in clinical trials, especially in the treatment of solid tumors, which is believed to be a consequence of insufficient drug concentration in the tumors.[23,24] We hypothesized that simultaneously delivery of both chemosensitizing and antineoplastic agents to the tumor sites by MS could increase local drug concentration and thus enhance the therapeutic efficacy while reducing the systemic side effects.

Among the numerous methods for incorporating drugs into MS, loading of ionic drugs into ion-exchange MS is of particular interest because of their high drug-loading capacity and ease of the loading process.[25−28] Furthermore, biocompatible and biodegradable materials, such as polysaccharides and albumin, can be used to prepare the MS.[5,25,29] The biodegradable MS drug carriers are more suitable for in vivo application than nonbiodegradable polystyrene MS, although the latter have also led to positive therapeutic results.[26−28]

Our group has initiated the development of microspherical delivery systems for enhanced therapy of MDR tumors via regional, simultaneous delivery of chemosensitizing and antineoplastic agents.[30,31] The purpose of this work was to undertake in vitro characterization and evaluation of MS for simultaneous delivery of the dual agents to MDR cells. Ionic polysaccharide MS derived from cross-linked dextran were chosen as the drug carriers because of their biocompatibility and biodegradability.[29,32−34] More importantly, the original material, dextran, has been applied in vivo as a blood expander for years. Although the cross-linked dextran MS have not been approved officially, they have been used clinically in cancer therapy[32,33] and wound treatment[34] without observed adverse effects. To achieve a sustained release of the therapeutic agents and retention of the MS in the tumor or the arteries leading to the tumor

while maintaining the ease of injection, MS with diameters ranging from 40 to 125 μm were selected. As our previous work suggested,[35,36] the therapeutic agents may interfere with each other or redistribute among the MS after having been released into a confined compartment in the tumor, thus altering their bioavailability. To elucidate the possible mutual effect of the dual agents on the release kinetics, the competitive loading and release of the dual agents were investigated. Moreover, because of the concern about loss of biological activity of the agents during the process of loading and release, in vitro efficacy of the agents in the reversal of MDR was evaluated using an MDR model cell line with high expression of P-gp.

Experimental Section

Characterization of the Microspheres. The morphology of the MS before and after drug loading was examined by microscopy. The diameters of the MS with or without a loaded drug were measured by a Wild M420 stereomicroscope equipped with a Wild MMS 235 digital optical accessory and an automated camera.[35] The swelling kinetics and swelling ratio were determined based on the diameter change measured by microscopy.

Drug Loading into the Microspheres. Cross-linked dextran MS containing sulfonic groups (Sephadex SP C-25, Pharmacia) were washed several times with deionized water prior to use. Vinblastine sulfate and verapamil hydrochloride (Sigma Chemical Company) were used in this study because the former is a P-gp substrate and broadly used anticancer drug and the latter is a well-known effective chemosensitizer for P-gp-mediated MDR. In a typical loading process, 0.05 g of the dry, ionic MS were added to 10 mL of 0.5% verapamil aqueous solution. After incubation at room temperature for predetermined time intervals, the MS were separated by centrifugation, and the drug concentration in the supernatant was analyzed by ultraviolet−visible (UV−VIS) spectrophotometry (Hewlett-Packard 8452A) at wavelengths of 270 nm for vinblastine and 278 nm for verapamil. When the drug absorption reached equilibrium (after ~30 h), the MS were harvested by centrifugation and washed extensively with deionized water. The amount of drug loaded was calculated from the difference between the initial drug concentration and the final one after incubation with the ion-exchange MS. Unbound drug in the washout was also determined by spectrophotometry for the calibration of the drug loading. The MS were then lyophilized. In the case of loading of dual agents (i.e., vinblastine and verapamil), the same procedures were applied except that the drug assay was carried out by high performance liquid chromatography (HPLC; see next section).

Analysis of Drug Mixture by HPLC. Because of the interference of UV absorbance of the two drugs, for the studies of competitive drug loading and dual-agent release, the concentration of vinblastine and verapamil in the solution was analyzed using a Waters HPLC system including a spectrophotometer (Model 481), an HPLC pump (Waters 501), and a System Interface Module. The mobile phase consisted of phosphate buffer (ionic strength, 0.1 M; pH 7.0), tetrahydrofuran, and methanol, with a volume ratio 0.43:0.41:0.16. Vinblastine and verapamil were separated in a reverse-phase column (Norva-pak C-18, Waters) by the mobile phase at a flow rate of 0.6 mL/min. The drug concentration in the solution was determined based on the standard curves by a UV detector at a wavelength of 270 nm.

In Vitro Drug Release. Release rate of vinblastine and verapamil from single-agent-loaded and dual-agent-loaded MS was determined at 37 °C with the addition of 1.4 mg of dry MS in 10 mL of pH 7.4 phosphate buffer with ionic strength of 0.05 M. At predetermined time intervals, the suspension was centrifuged and the supernatant was analyzed by spectrophotometry or by HPLC. The release kinetics of both agents from dual-agent-loaded MS was also studied at 37 °C in an Earle's Balanced Salt Solution (EBSS), a pH 7.4 buffer solution commonly used in studies of drug uptake by cultured cells. The solution consists of $CaCl_2$ (1.8 mM), KCl (5.3 mM), $MgS0_4$ (0.8 mM), NaCl (138 mM), Na_2HP0_4 (1.0 mM), D-glucose (5.5 mM), *N*-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid (HEPES; 20 mM), and Trizma base to bring the pH to 7.4. In this case, the concentration of the individual drugs in the dual-agent solution was monitored by spectrophotometry (for verapamil) and liquid scintillation counting (for [^{3}H]vinblastine).

Tissue Cell Culture and Drug Accumulation Studies. Parent (AUXB1) and MDR (CH^RC5) Chinese hamster ovary (CHO) cells were initially grown in Dr. V. Ling's laboratory.[37,38] The resistant cell line, CH^RC5, is chosen because it expresses high levels of P-gp and has been shown to be resistant to a variety of structurally unrelated drugs, such as vinblastine and doxorubicin. The cells were grown in plastic culture flasks containing alpha minimal essential medium (α-MEM), 10% fetal bovine serum, and 0.5% penicillin-streptomycin at 37 °C, under an atmosphere of 95% air and 5% CO_2. Subculture of the cells was undertaken by trypsinization with 0.05% trypsin-EDTA when a confluent monolayer was formed.

Drug accumulation tests were carried out using monolayer cells grown on 24-well plates.[39] Initially, the accumulation of vinblastine over time by the parent and resistant cells was determined in the absence (control) or presence of chemosensitizers. Cyclosporin A (20 μM, a gift from Sandoz Canada) and verapamil hydrochloride (50 μM) were used as the chemosensitizers to verify the MDR characteristic of the resistant cells. Drug uptake was initiated in the presence or absence of a chemosensitizer by the addition of 0.5 mL of an EBSS containing 21 nM [^{3}H]vinblastine sulfate (11.7 Ci/mmol, Moravek Biochemicals) with 1/3 ^{3}H-labeled and 2/3 cold drug. At various time intervals (e.g., 0.5, 1, and 2 h), drug accumulation by the monolayer cells was stopped by aspirating the medium and washing the cells twice with an excess of ice-cold 0.16 N NaCl. The cells were then lysed with 1 mL of 1 N NaOH for 30 min and then transferred to scintillation vials containing 0.5 mL of 2 N HCl. Radioactivity was measured by a standard liquid scintillation technique using a Beckman Scintillation Counter and the standard Beckman scintillation fluid cocktail "Ready Safe". The protein concentration of the cells was determined by a colorimetric method using bovine serum albumin as a standard.[40]

The effect of blank MS and MS-immobilized agent(s) on the cellular uptake of vinblastine was determined using the same method as already described. Typically, in the place of a free drug solution, 0.5 mL of EBSS containing 0.2 wt % MS were introduced to the monolayer cells followed by the addition of 0.5 mL EBSS containing 21 nM vinblastine. After the medium was aspirated, the MS were removed by washing with an excess of ice-cold 0.16 N NaCl.

Cell Viability Tests. Cell viability in the presence of blank MS was tested by the standard trypan blue method. This procedure monitors the integrity of the plasma membrane. An aliquot (100 μL) of CH^RC5 cells incubated with the blank MS at various times was rapidly added to an equal volume of 0.8% trypan blue solution in isotonic saline and examined by optical microscopy. The percentage of nonviable cells was evaluated from the percentage of cells taking up the stain.

Statistical Analysis. For the drug uptake studies, each experiment was performed using at least two different sets of cultured cells. Within each experiment, the experimental data points were determined in quadruplicate. The results are expressed as means ± SD from data obtained from at least two separate experiments. Two-way analysis of variance (ANOVA) was applied to compare the results from different experiments. A value of $p < 0.05$ is considered statistically significant.

Results and Discussion

Characterization of the Microspheres. *Morphology of the Microspheres.* Figure 1 shows the microscopic photographs of the unloaded (Figure 1a) and verapamil (VER)-loaded (Figure 1b) dry MS with the same magnification. As illustrated, the process of drug loading did not rupture the MS. Instead, the surface of the MS became smoother and the size of the MS became larger, indicating an increase in the volume of the MS due to the drug loading.

Swelling of the MS in Various Media. Equilibrium swelling and swelling rate are two important parameters associated with the release mechanism and kinetics of a solute from hydrogels. The MS used in this study are essentially polyelectrolyte hydrogels. Therefore, their swelling in various media, such as deionized water, 0.05 M pH

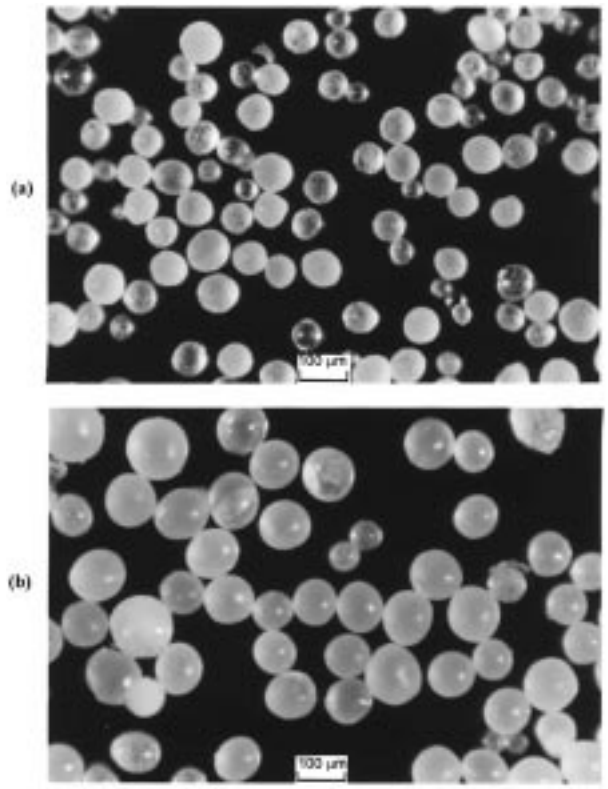

Figure 1—Microscopic photographs of (a) unloaded and (b) verapamil-loaded MS in dry state.

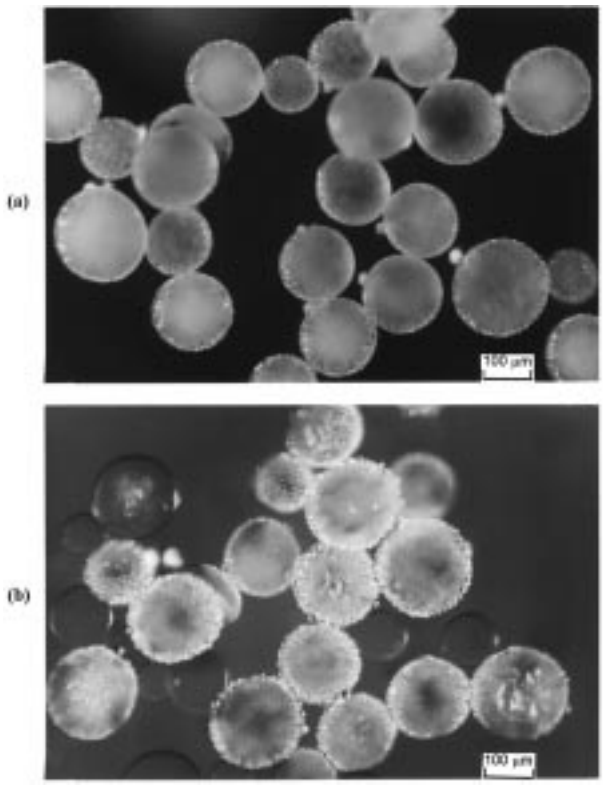

Figure 2—Microscopic photographs of verapamil-loaded MS in 0.05 M pH 7.4 buffer solution at room temperature for (a) 5 min and (b) 20 min.

7.4 phosphate buffer (Fisher Scientific), and 0.9% NaCl, was investigated microscopically. The MS without loaded drug swelled instantaneously like "pop corns" in all three media. Their swelling ratio, H, defined as the volume of the MS at the swollen state divided by the volume at the dry state, was 12−13. In contrast, the drug-loaded MS exhibited slower swelling and a much smaller swelling ratio, especially in deionized water. The VER-loaded MS reached the equilibrium swelling ($H \approx 3$) in deionized water in about 30 min, with a clear swelling or solvent penetration front, like the observation with hydrophobic gels.[41] In the isotonic saline and the buffer solution, the maximal size ($H \approx 6$) was observed within 3−10 min, followed by a size reduction. The peak size may be an indication of an initial swelling-dominated stage and thereafter solute depletion, which is typical in hydrophobic hydrogel loaded with high drug content.[42] The diminished swelling ratio and rate for drug-loaded MS suggest an increased hydrophobicity of the MS due to the bound drug molecules (i.e., VER) that are more hydrophobic than Na^+ present in the unloaded MS. In pH 7.4 buffer solution, the swelling or penetration front disappeared, probably as a result of quick ion exchange of the drug with the counterions (i.e., K^+ or Na^+), which converts the hydrophobic drug−MS complex into hydrophilic MS.

Microscopic photographs of the VER-loaded MS in the buffer solution for 5 and 20 min are shown in Figures 2a and 2b, respectively. It was observed that oily droplets accumulated on the surface of the MS at a later time. The droplets disappeared as more buffer solution was added and more vigorous shaking was applied. This result may be ascribed to small volume of the solution and insufficient mixing during the examination of microscopy. It implies that the rate of removal of the released drug from the MS surface is lower than the drug release from the MS, resulting in the drug accumulation on the surface. This accumulation may be the case in the body cavities, such as a solid tumor, where circulation of the body fluid is poor.[35,36]

Interestingly, the oily droplets were absent when 0.9% NaCl was used as a releasing medium. Moreover, the boundary of undissolved drug that was observed in the pH 7.4 buffer solution disappeared in the saline. These results agree with the observations of the dependence of the drug moving front on the drug solubility,[41] suggesting that the solubility of verapamil salts may vary with its salt form. In a NaCl solution, the released verapamil salt is in a chloride form, whereas in the phosphate buffer, it is in a phosphate form. The latter may exhibit lower solubility than the former. Based on this observation, it may be concluded that in the present system, ion exchange is a major mechanism of the drug release from the MS, but drug solubility and drug diffusion away from the surface of the MS into the bulk fluid may play important roles in the release kinetics.

Determinants of Drug Loading. To obtain optimal drug loading, several factors influencing the amount of drug bound to the MS were investigated, including incubation time, ratio of MS to drug (M/D), drug affinity to the MS, and initial drug concentration.

Effect of Incubation Time. Curve A in Figure 3 depicts the fraction of remaining verapamil in the solution as a function of time for the MS incubated in a 0.025-mg/mL verapamil solution. A rapid decrease in the remaining drug is seen in the initial 10 h, followed by a slower change in the subsequent 10 h. A plateau in the curve after 20 h indicates an equilibrium state. A similar trend was also observed for vinblastine. Therefore, incubation was carried out for 30 h for all the drug loading to ensure completion of the process. The fraction of the drug loaded into the MS, as shown by curve B in Figure 3, follows typical first-order sorption kinetics, suggesting that the drug loading is essentially a diffusion-controlled process like drug release.[43]

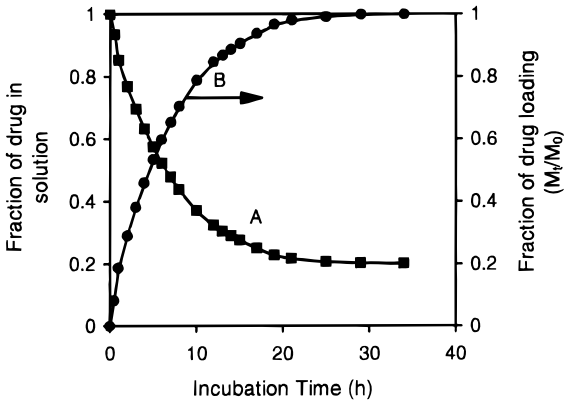

Figure 3—Dynamics of verapamil absorption into the MS through ion exchange. The initial concentration of verapamil is 0.025 mg/mL; curve A, Fraction of drug remains in the solution; curve B, fraction of drug loaded into the MS calculated using the amount of drug loaded at time *t* divided by the equilibrium amount of drug loaded. Experiments in Figures 3–6 were performed as described in the Experimental Section (SD < 10%).

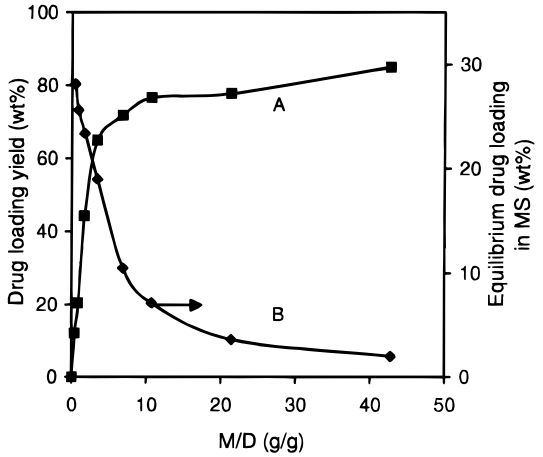

Figure 4—Effect of the MS/drug ratio (M/D) on the equilibrium level of verapamil loaded and the yield of the loading. The initial verapamil concentration is 0.05 mg/mL.

Although swelling of the dry MS is observed, the swelling in an aqueous medium is very quick compared with the drug absorption, as discussed previously.

Effect of Ratio of Microspheres to Drug. The amount of MS relative to drug is an important factor influencing the equilibrium drug content and the yield of drug loading. However, there has been little work in this area, though various conditions have been used by different researchers.[25−28] Using verapamil as a model drug, the effect of the M/D ratio was investigated. The yield of drug loading and the equilibrium level of verapamil loaded are plotted against the M/D ratio in Figure 4. As the M/D ratio increases, the yield of drug loading increases while the equilibrium level of drug loaded decreases (Curve A). This result indicates that to raise the equilibrium drug content in the MS, one has to sacrifice the loading efficiency. Therefore, a compromise approach is to control the M/D ratio between 1 and 3 and thus the drug content can reach ~30% and the yield of drug loading is in the range 40−60%.

Effect of Drug Concentration. The effect of drug concentration on the equilibrium drug content was investigated for initial verapamil concentrations ranging from 10 to 85 mg/mL at an M/D ratio of 1. In this wide range of verapamil concentrations, the equilibrium loading is only slightly reduced from 24 to 22%. This observation is not abnormal. At a fixed M/D ratio, the amount of drug bound to MS is determined by the competition between the drug and the counterions (e.g., Na^+). Addition of water to the mixture causes an equal dilution of both cations, but the equilibrium constant remains unchanged. Consequently, the amount of drug bound to the MS undergoes little change.

Relative Affinity of Vinblastine and Verapamil. The relative affinity of vinblastine (VIN) and verapamil (VER) was determined by the sorption method. The competitive sorption of VIN and VER was carried out using known amounts of MS (e.g., M/D ratio = 1.5) in the solution of dual agents with various VIN/VER ratios. The separation and assay of the dual agents were performed with HPLC. The dual agents were effectively separated with a retention time of 5.95 min for VIN and 6.82 min for VER.

When the MS are added to a solution containing a cationic drug, the drug competes with Na^+ to bind to the MS as illustrated by the following formula

$$\mathrm{Re{-}SO_3^-\ Na^+ + DRUG^+ \rightleftharpoons Re{-}SO_3^-\ DRUG^+ + Na^+}$$

The equilibrium of ion exchange determines the maximum of the drug loaded into the MS, which can be correlated with selective coefficients that are expressed by the following equations[44]

$$K_{VIN} = \frac{[VIN]_m[Na]_s}{[VIN]_s[Na]_m} \quad (1)$$

$$K_{VER} = \frac{[VER]_m[Na]_s}{[VER]_s[Na]_m} \quad (2)$$

where K_{VIN} and K_{VER} are the selectivity coefficients for the drug and the competing ions, Na^+; and the subscripts m and s denote the concentration in the microspheres and in the solution, respectively. In the process of absorption of dual agents, the Na^+ concentration in the solution and the MS should be the same in eqs 1 and 2. Therefore, the relative selectivity coefficient of VIN and VER, K_R, can then be obtained from eq 3

$$K_R = \frac{K_{VIN}}{K_{VER}} = \frac{[VIN]_m/[VER]_m}{[VIN]_s/[VER]_s} \quad (3)$$

By plotting the [VIN]/[VER] ratio in the MS against that in the solution at the equilibrium as illustrated by Figure 5, the value of K_R was estimated from the slope of the straight line to be 1.25. The K_R value greater than unity reflects slightly higher affinity of VIN to the MS than that of VER.

Kinetics of Drug Release. Figure 6a shows the release profiles of verapamil and vinblastine from single-agent-loaded MS in 0.05 M pH 7.4 buffer at 37 °C. It appears that verapamil is released completely within 2 h and vinblastine by 3 h. Similarly, Figure 6b illustrates a higher release rate of verapamil than vinblastine from the dual-agent-loaded MS. In EBBS, the same trend was also observed. The lower release rate of vinblastine may be a reflection of its higher affinity to the MS in addition to its larger molecular size. When the MS loaded with the drugs without drying were added to the release medium, the release rate was increased significantly. This result suggests that hydration of the MS or the polymer relaxation may play some role in the kinetics of drug release. Microscopic studies revealed a short period time of swelling of the MS, as discussed previously. The completion of the swelling was within 10 min which was relatively short compared with other hydrogel beads[41,42] because of their much smaller diameter and higher hydrophilicity. Never-

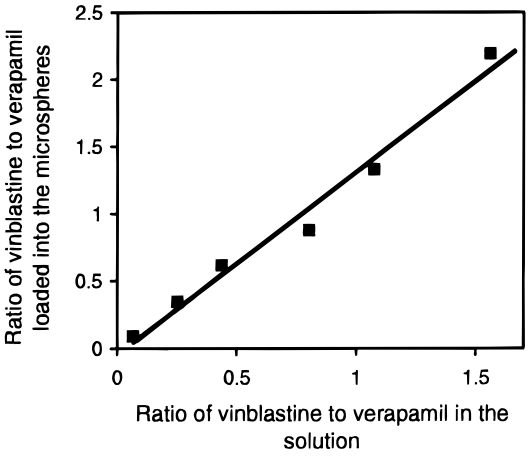

Figure 5—A plot of [VIN]/[VER] ratio in the MS against that in the solution at the equilibrium (M/D = 1.5, the total drug loading is ~20 wt %). The relative selective coefficient of vinblastine is evaluated from the slope of the straight line (K_R = 1.25).

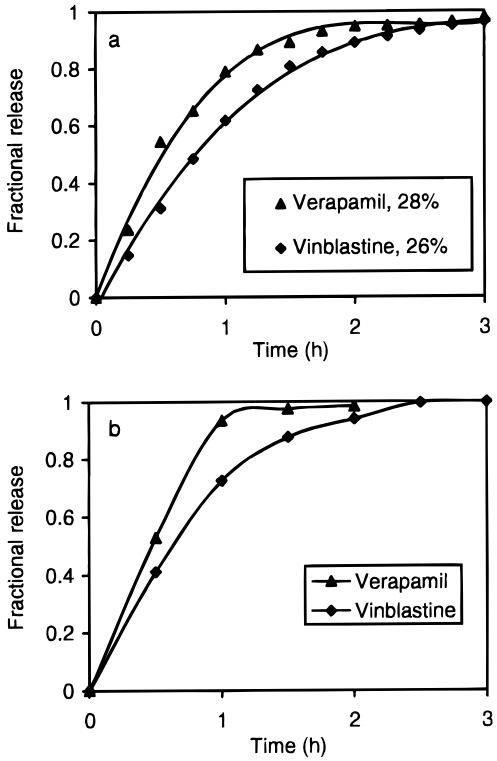

Figure 6—Fractional release of vinblastine and verapamil in 0.05 M pH 7.4 buffer at 37 °C as a function of time from (a) single-agent-loaded MS (drug loading for verapamil is 28 wt % and for vinblastine is 26 wt %); and (b) dual-agent-loaded MS (the total drug loading is ~20 wt %).

theless, this time span is about 10% of the total release time of the drug (i.e., VER). Therefore, the hydration of the MS is not negligible in the present system.

In Vitro Evaluation of the MS Delivery System. *Drug Resistance of CH^{R}C5 Monolayer Cells.* The effectiveness of CH^{R}C5 monolayer cells as a MDR cell model was investigated by measuring drug uptake by the cells in the absence (control) and presence of a chemosensitizer, either verapamil (50 μM) or cyclosporin A (20 μM). Figure 7a shows that in the presence of verapamil or cyclosporin A, the cellular uptake of vinblastine by CH^{R}C5 cells significantly ($p < 0.01$) increases 7 and 9 times, respectively. In contrast, only up to 3-fold ($p < 0.01$) increase in drug uptake by nonresistant cells, AUXB1, is observed in the

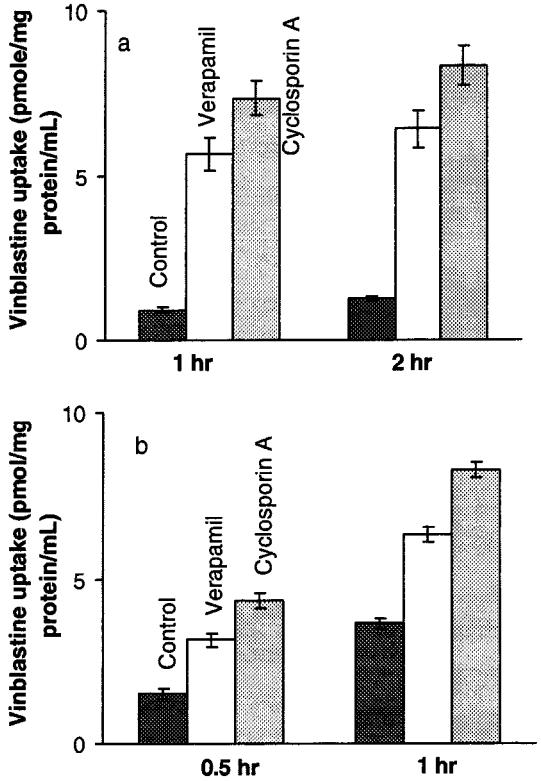

Figure 7—Vinblastine uptake by (a) MDR (CH^{R}C5) monolayer cells and (b) parent cells (AuxB1) after incubation for 1 h and 2 h. The bars represent control (i.e., without a chemosensitizer), with addition of verapamil (50 μM), and with addition of cyclosporin A (20 μM). The concentration of vinblastine used in the uptake is 21 nM with 1/3 radiolabeled and 2/3 cold drug. Results are expressed as mean ± SD from at least two different experiments. A statistically significant difference between the control and the uptake in the presence of chemosensitizers was found ($p < 0.01$) for Figure 7a and 7b.

presence of chemosensitizers (Figure 7b). These results confirm that CH^{R}C5 cell line grown as a monolayer is an effective model for the in vitro evaluation of chemosensitization.

Effect of Blank Microspheres on Cell Viability and Cellular Drug Uptake. Cell viability in the presence of blank MS was comparable to the control (data not shown), suggesting that the blank MS did not cause cell toxicity. As shown in Figure 8a, in the presence of the blank MS and absence of chemosensitizers, the cellular drug uptake (bar 2) does not statistically differ from the control (bar 1; $p > 0.05$). In the presence of chemosensitizers (bar 3: 50 μM verapamil, and bar 4: 20 μM cyclosporin A), the blank MS do not have any significant effect on the drug uptake as evidenced by the equivalent efficacy of MDR reversal in the absence (Figure 7a, bars 2 & 3) and presence of the MS (Figure 8a, bars 3 & 4). As presented in Section 2, the relative equilibrium loading of vinblastine to verapamil is 1.25; that is, the amount of vinblastine loaded in the MS can reach 1.25 times of that of verapamil if both are of the same concentration in the solution. However, the concentration of vinblastine used in the uptake studies is 21 nM, which is about or less than the one-thousandth of the concentration of the chemosensitizers (20 and 50 μM). Therefore, the competitive binding of vinblastine with verapamil to the MS is expected to be negligible.

Effectiveness of the Chemosensitizer Delivered by the Microspheres. Two different approaches of delivering chemosensitizers and anticancer drugs to MDR cells were evaluated: (1) verapamil-loaded MS plus free vinblastine (bar 2 in Figure 8b), and (2) vinblastine- and-verapamil-

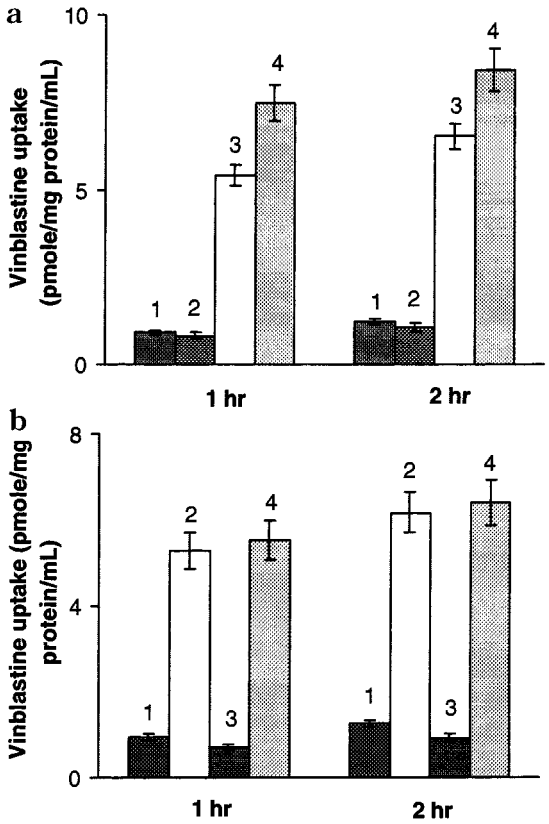

Figure 8—(a) Effect of blank MS on vinblastine uptake by MDR (CH^RC5) monolayer cells at 1 and 2 h. The bars represent (1) control; (2) blank MS; (3) free verapamil plus the blank MS; and (4) free cyclosporin A plus the blank MS. The concentration of vinblastine used is the same as in Figure 7. Results are expressed as mean ± SD from at least two different experiments. A statistically significant difference between the control and the uptake in the presence of chemosensitizers/blank MS was found for bar 3 and bar 4 ($p < 0.01$). (b) Effect of different microspherical formulations on vinblastine uptake by MDR (CH^RC5) monolayer cells. The bars represent (1) control; (2) verapamil-loaded MS plus free vinblastine (21 nM); (3) vinblastine-loaded MS; and (4) vinblastine- and-verapamil-loaded MS. Results are expressed as mean ± SD from at least two different experiments. A statistically significant difference between the control and the uptake in the presence of chemosensitizer-loaded MS was found for bar 2 and bar 4 ($p < 0.01$).

loaded MS (bar 4 in Figure 8b). For comparison, a control (bar 1) and vinblastine-loaded MS (bar 3) are also presented in the figure. In the absence of verapamil, the drug uptake in the presence of vinblastine-loaded MS (bar 3) is almost the same ($p > 0.05$) as the control. In contrast, the verapamil-loaded MS (Figure 8b, bar 2) exhibit a comparable efficacy in the reversal of MDR as free verapamil (Figure 7a, bar 2), suggesting that the bioactivity of the chemosensitizer has been preserved. Moreover, the MS loaded with both verapamil and vinblastine display a significant ($p < 0.01$) enhancement of drug uptake up to 7-fold, a level achieved with free drug solutions.

The diameter of the MS ranges from 40 to 125 μm in dry form (even larger in wet form), much bigger than the size of CHO cells, so it is unlikely that the increase in drug uptake is due to the phagocytosis of the particles by the cells. On the other hand, the blank MS have no effect on drug uptake. Therefore, the enhancement of the drug uptake is likely a reflection of the effect of the chemosensitizer released from the MS. These results demonstrate that the bioactivity of the MS-loaded verapamil in reversing MDR remains unchanged in both formulations of single-agent and dual-agent loading. The results also suggest that both antineoplastic and chemosensitizing agents are released from the MS effectively.

Conclusion

The ionic polysaccharide MS possess a fairly good loading capacity for ionic chemosensitizer and anticancer drug. The loading of a single agent or dual agents could readily reach 28 wt %. The amount of drug loaded was influenced by the M/D ratio and drug affinity to the MS. Release rate of the loaded drugs was likely controlled by ion exchange; that is, the counterions diffuse in and the ionic drugs diffuse out of the MS. However, hydration of the MS, solubility of the drug, as well as the rate of drug leaving the surface of the MS each might play an important role in release kinetics. The delivery system appeared effective at releasing both antineoplastic and chemosensitizing agents in vitro. More importantly, similar enhancement of anticancer drug uptake was achieved with the MS-delivered chemosensitizer as that with the free drug, suggesting that the biological activity of the chemosensitizer was preserved. To further evaluate the therapeutic efficacy of the new formulation, in vivo investigation is presently being undertaken using an animal tumor model.

Abstract □ The present study aimed to investigate new pore induction as a flux-enhancing mechanism in human epidermal membrane (HEM) with low to moderate voltage electric fields. The extent of pore induction and the effective pore sizes of these induced pores were to be assessed using a low frequency (12.5 Hz) low to moderate voltage (2.0 to 4.0 V) square-wave alternating current (ac) "passive" permeation method (ac iontophoresis). This ac approach was to allow for inducing and sustaining a state of pore induction in HEM while permitting no significant transport enhancement via electroosmosis; thus, transport enhancement entirely due to new pore induction (enhanced passive permeation) was to be assessed without any contributions from electroosmosis. Good proportionality between the increase in HEM permeability and its electrical conductance was found with the "passive" transport data obtained during square-wave ac iontophoresis using urea as the model permeant. Typically, at 3.0 to 4.0 V, HEM conductance increases (and permeability increases) ranged from around 3- to 30-fold. These results appear to be the first *direct* evidence that new pore induction in HEM is a significant flux enhancing mechanism under moderate voltage conditions. The extents of pore induction in HEM under low frequency moderate voltage (2.0 to 3.0 V) ac, pulsed direct current (dc), and continuous dc were also compared. The extents of pore induction from square-wave ac and pulsed dc were generally of the same order of magnitude but somewhat less than that observed during continuous dc iontophoresis at the same applied voltage and duration, suggesting less extent of pore induction with reversing polarity or when a brief delay is provided between pulses to allow for membrane depolarization. The average effective pore sizes calculated for the induced pores from the experimental data with urea and mannitol as probe permeants and the hindered transport theory were 12 ± 2 Å, which are of the same order of magnitude as those of preexisting pores determined from conventional passive diffusion experiments.

Introduction

Previous studies have provided insights regarding iontophoretic transdermal transport mechanisms of ionic and polar compounds with human epidermal membrane (HEM). It has been shown that the alteration of HEM barrier properties during low to moderate voltage iontophoresis is consistent with the induction of new pores (or new pathways) with the observed increase in HEM electrical conductance correlating with the increase in HEM permeability.[1] The occurrence of pore induction during low to moderate voltage iontophoresis was hypothesized in even earlier studies,[2−5] but other explanations for the decrease in electrical resistance and the increase in permeability during iontophoresis could not be justifiably excluded.[5−9] Also, some recent reports have continued to take the view that significant new pore induction in HEM can occur only at high voltages and that (at conventional voltages employed in iontophoresis) "iontophoresis primarily involves electrically driven transport through *fixed* pathways across the stratum corneum".[10−12]

In a recent study with HEM, the size of the pores induced during low to moderate voltage iontophoresis was estimated with neutral permeants in electroosmosis experiments.[13] However, because electroosmosis depends on the sign and magnitude of the pore surface charge density, pore size estimation based on these data are considered to be compromised by possible variable pore surface charge density in HEM.

As will be shown, square-wave ac iontophoresis can be used as a tool in characterizing the barrier properties of human skin during iontophoresis and pore induction. A method based on ac iontophoresis may be employed to study the state of pore induction in the absence of flux enhancement from electroosmosis and from electrophoresis. Particularly, the characteristics of the pores induced in HEM during iontophoresis (pulsed dc, square-wave ac, and/or continuous dc) may be investigated with this ac iontophoresis strategy regardless of possible pore surface charge distributions because transport enhancement due to pore induction can be isolated from the additional enhancement due to electroosmosis and electrophoresis.

The present study aimed to investigate pore induction as a flux-enhancing mechanism during low to moderate applied voltage iontophoresis with HEM. An ac "passive" permeation method (i.e., square-wave ac iontophoresis) was to be developed and used to quantify the extent of pore induction and the effective size of the pores induced. The effects of square-wave ac and pulsed dc on the barrier properties of HEM were also to be compared with continuous dc iontophoresis.

Experimental Section

Materials—Radiolabeled [^{14}C]urea and [^{3}H]mannitol were purchased from New England Nuclear (Boston, MA) and American Radiolabeled Chemicals (St. Louis, MO). Human epidermal membrane (HEM) was supplied by TheraTech Inc. (Salt Lake City, UT). HEM was prepared by heat separation[14] with human skin (from the back, abdomen, or thigh) obtained from Ohio Valley Tissue and Skin Bank (Cincinnati, OH) and was frozen immediately for later used. Millipore GVWP filters (0.22 μm pore diameter) were purchased from Millipore Corporation (Bedford, MA). Phosphate-buffered saline (PBS) at 0.1 M ionic strength and pH 7.4 containing 0.02% sodium azide was prepared by reagent grade chemicals and distilled deionized water.

General Experimental Setup—Iontophoresis studies were carried out in a side-by-side two-chamber diffusion cell (diffusional surface area of around 0.8 cm^2 and chamber volume of 2 or 4 mL) using a four-electrode potentiostat system (JAS Instrumental Systems, Inc., Salt Lake City, UT) as described previously[15] and a waveform programmer (JJ 1276, JAS Instrument Systems, Inc., Belmont, NC) at 37 °C. The counter electrodes were Ag−AgCl. Unless otherwise specified, dc iontophoresis was conducted with

the anode in the donor chamber and cathode in the receiver chamber. The electrical conductance of the membrane was monitored by an oscilloscope (Model 2211, Tektronix Inc., Beaverton, OR). Initial electrical conductance was determined by applying a 100 mV potential drop across the membrane. In each transport experiment, the receiver and donor chambers were filled with PBS and PBS premixed with tracer levels of radiolabeled permeants. An appropriate amount of receiver solution sample (1 mL sample for the 2 mL diffusion cells and 1 or 2 mL for the 4 mL diffusion cells) was withdrawn at predetermined time intervals and replaced with fresh PBS, and a 10 μL donor sample was also withdrawn at the same time. These samples were mixed with 10 mL of scintillation cocktail (Ultima Gold, Packard, Meriden, CT) and assayed in a liquid scintillation counter. The apparent permeability coefficients (P) in each experiment were calculated by:

$$P = \frac{1}{C_D A}\frac{dQ}{dt} \quad (1)$$

where A is the membrane surface area, t is time, Q is the amount of permeant transported into the receiver chamber, and C_D is the concentration of permeant in the donor chamber. The pH of the solutions in the donor and receiver chambers was checked after each iontophoresis run.

Nuclepore Membrane Studies—Nuclepore membranes (polycarbonate membrane, 7.5 nm pore radius, 0.001 porosity) were used (the control) to examine the "passive" permeation technique (i.e., square-wave ac iontophoresis) before applying the method to HEM. An assembly of 50 Nuclepore membranes (Nuclepore Corp., Pleasanton, CA) was mounted between the two side-by-side diffusion half-cells. These studies were divided into two stages with mannitol as the permeant. Stage I was passive permeation. In stage II, one of the following protocols was carried out: square-wave ac iontophoresis (amplitude of 1.0 or 2.0 V and frequency ranging from 1.25 to 50 Hz), continuous 0.5 V dc iontophoresis, or a protocol of superposition of 12.5 Hz 2.0 V ac and 0.5 V continuous dc iontophoresis. The duration of the ac transport experiments was around 3 to 5 h. Representative waveforms are shown in Figure 1. Radiolabeled [^{3}H]mannitol was the model permeant in the experiments.

HEM Electrical Resistance Studies—Prior to carrying out the HEM permeant transport studies, a set of experiments were conducted to assess the extent of pore induction in HEM under the low frequency (12.5 Hz) ac voltage regimens and to compare the results to continuous dc and pulsed dc regimens. See General Experimental Setup. HEM supported with a Millipore filter[16] was mounted between the two half-cells of the diffusion cell. HEM was allowed to equilibrate in PBS at 37 °C for 12 to 40 h until its conductance became essentially constant with time before the experiments. The purpose of incubating HEM in PBS was to establish a steady baseline (an essentially constant HEM conductance with time, determined with 100 mV) for comparison studies; changes in HEM electrical conductance are generally observed in the first 10 h (sometimes up to 20 h) of the incubation even though HEM conductance usually does not change by more than a factor of 2 (usually decreases and sometimes increases) during this period. It has been shown that after this equilibration phase, the barrier properties of HEM can remain stable for up to 5–7 days.[16] After this equilibration phase, the following protocol of consecutive runs with a given HEM was employed: 2.0 V 12.5 Hz square-wave ac (which is alternating 40 ms pulses) for 10 s; 2.0 V 40 ms square-wave dc pulses with 1, 2, or 3 ms delay between pulses for 10 s; continuous 2.0 V dc for 10 s; then returning back to 2.0 V 12.5 Hz ac for 10 s. Other similar protocols were also employed with the first and last runs always the same to ensure reversibility/reproducibility in a given set of consecutive runs with a single HEM. Similar experiments were carried out with 3.0 V instead of 2.0 V. HEM electrical resistance was monitored by measuring the current[17] with the oscilloscope throughout the sequence of runs.

HEM Transport Studies—For the iontophoresis/transport studies with HEM, the same experimental setup was used (as above). The receiver and donor chambers were filled with PBS and PBS premixed with trace amounts of the radiolabeled [^{3}H]mannitol

and/or [^{14}C]urea. Mannitol and urea were chosen as the model permeants in the present study because they have well-characterized diffusion properties and are polar nonelectrolytes that essentially transport across the stratum corneum via the pore pathways.[14,18] The apparent permeability coefficients for HEM were calculated with eq 1. The present HEM investigation was divided into three levels of analyses (studies A, B, and C). In study A, the effective radii of the pores induced during square-wave ac iontophoresis were deduced and compared with those of the preexisting pores. In study B, a 1 min 4.0 V prepulse was provided before the square-wave ac run to better match the extent of pore induction to that with continuous dc iontophoresis because the extent of pore induction under continuous dc iontophoresis was generally found to be somewhat higher than that under the same voltage ac iontophoresis (see HEM Electrical Resistance Studies in the Results section and Pulsed and Continuous Iontophoresis in the Discussion section). The objective of study C was to examine whether the pores induced under square-wave ac iontophoresis are similar to those induced under continuous dc iontophoresis.

As part of study A, some preliminary experiments were performed with urea as the only probe permeant. These experiments with urea alone were aimed to establish a HEM permeability vs resistance correlation for square-wave ac iontophoresis. The main experiments in study A were done using urea and mannitol as dual permeants to permit estimating the effective radii of the induced pores. Study A involved three stages. Stage I was a passive permeation run. Stage II was 2.0 V 12.5 Hz square-wave ac and 3.0 V 12.5 Hz square-wave ac iontophoresis when urea was involved alone and when urea and mannitol were the dual permeants, respectively. The duration of stage II ranged from 2 to 5 h depending on the electrical resistance of HEM (around 2 h for the lower resistance and around 5 h for the higher resistance HEM samples). Stage III was a passive permeation run carried out again after the iontophoresis run when the electrical resistance of HEM became constant with time.

Study B also involved three stages. Stage I was passive transport run. Stage II was 4.0 V dc iontophoresis for 1 min (prepulse) followed by a square-wave ac iontophoresis run (3.0 or 4.0 V at 12.5 Hz) for a duration ranging from 1.5 to 6 h. Again, stage III was a passive permeation experiment after iontophoresis when the electrical resistance of HEM became constant with time.

Study C involved five stages. Stage I was a passive permeation run. Stage II was continuous dc iontophoresis (2.0 or 3.0 V; duration of around 0.5 to 1.5 h). Immediately after the continuous dc iontophoresis, stage III was square-wave ac iontophoresis (3.0 or 4.0 V at 12.5 Hz; around 2 to 6 h) following a 4.0 V dc 1 min prepulse. In stage IV, square-wave ac iontophoresis (3.0 or 4.0 V at 12.5 Hz) was superimposed over 1.0 V continuous dc for a duration ranging from around 1.5 to 3 h. The various waveforms used in stages II, III, and IV are illustrated in Figure 1. Stage V was a passive permeation run after the electrical resistance of HEM became constant with time.

Theory and Effective Pore Radius Calculation—Methods of estimating the effective pore radii for the pore pathway in HEM have been described previously for passive permeation[18] and iontophoresis[13] using the hindered transport theory. Briefly, the steady-state iontophoretic flux ($J_{\Delta\psi}$) for a nonionic permeant through HEM can be described by a convective transport model derived from the modified Nernst–Planck theory:[13]

$$J_{\Delta\psi} = \frac{C_D \epsilon W v}{1 - \exp[-Wv(\Delta x)/(HD)]} \quad (2)$$

where ϵ is the combined porosity and tortuosity factor for the membrane, v is the average velocity of the convective solvent flow, H and W are the hindered transport factors for passive diffusion and for transport due to the convective solvent flow induced by electroosmosis, Δx is the effective membrane thickness, C_D has been previously defined in eq 1, and D is the permeant diffusion coefficient taken from the literature.[18] Assuming a single pore size (radius, R_p) and a cylindrical pore geometry in the membrane, the hindrance factor for Brownian diffusion (H) and the hindrance factor for pressure-induced parabolic convective solvent flow (W) can be expressed by:[19]

$$H(\lambda) = (1 - \lambda)^2(1 - 2.104\lambda + 2.09\lambda^3 - 0.948\lambda^5) \quad (3)$$

$$W(\lambda) = (1 - \lambda)^2(2 - (1 - \lambda)^2)\left(1 - \frac{2}{3}\lambda^2 - 0.163\lambda^3\right) \quad (4)$$

when the ratio of solute radius to pore radius (r/R_p) is small (i.e. $\lambda = r/R_p < 0.4$). The hydration radii (Stokes–Einstein radii, r) of the permeants can be obtained from the literature.[18]

At the convection limit (convective flow transport ≫ passive diffusion), eq 2 reduces to:

$$J_{\Delta\psi} = \epsilon W v C_D \quad (5)$$

In the case of passive diffusion, the appropriate relation is:

$$J_{\text{passive}} = \frac{DC_D\epsilon H}{\Delta x} \quad (6)$$

Fluxes for nonionic permeants with square-wave ac iontophoresis in the present study are expected to be well approximated by eq 6, because the electroosmosis contribution to the flux is expected to be negligible at the ac frequencies used (see Nuclepore Membrane Studies in the Results section and the last paragraph in HEM Transport Studies in the Discussion section). In this situation, the effective pore radii for HEM can be estimated from the ratio of urea and mannitol fluxes with eq 6 as in the passive diffusion experiments:

$$\frac{J_m}{J_u} = \frac{H_m}{H_u}\frac{D_m}{D_u} \quad (7)$$

where the subscripts m and u represent the probe permeants mannitol and urea, respectively. The limitations of eqs 5–7 and the uncertainties of estimating the effective pore radii have been previously discussed.[13,18]

The electrical resistance of HEM (R) in PBS is expected to be proportional to its thickness and inversely proportional to its effective porosity:

$$R \propto \frac{\Delta x}{\epsilon H} \quad (8)$$

From eqs 6 and 8 and taking logarithms,

$$\log P = -\log R + c \quad (9)$$

where c is a constant. Equation 9 shows that the electrical resistance of HEM can be expressed as a function of its permeability for the conducting ions. A plot of the logarithm of the permeant permeability coefficient of a membrane vs the logarithm of membrane electrical resistance yielding a slope of − 1.0 would therefore suggest similar transport pathways for the permeant and the conducting ions across the membrane under the specified experimental conditions.

Results

Nuclepore Membrane Studies—The studies with Nuclepore membrane (Figure 2) served to validate the instrumentation (i.e., the four electrode potentiostat system and the waveform programmer) and provided a baseline for the transport studies with HEM. The resistance of an assembly of 50 Nuclepore membranes was found to be essentially the same over the range of applied voltage conditions and the frequency range in the present study (data not shown). The plateau value of the current observed on the oscilloscope display after a brief (within 1 ms) transient period was used to calculate the electrical resistance (the resistance portion of a parallel capacitance and resistance model circuit[20]). Results for mannitol transport with square-wave ac iontophoresis (ranging from 1.25 to 50 Hz), continuous dc iontophoresis (0.5 V), and square-wave ac (2.0 V at 12.5 Hz) superimposed with continuous dc iontophoresis (0.5 V) are summarized in Figure 2. As can be seen, the mannitol

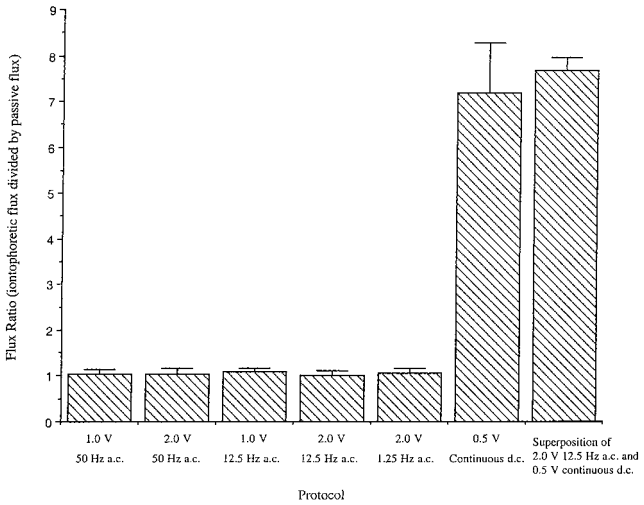

Figure 2—Mannitol flux ratios (iontophoretic flux divided by passive flux) during square-wave ac iontophoresis, continuous dc iontophoresis, and superposition of 12.5 Hz square-wave ac and continuous dc iontophoresis for an assembly of 50 Nuclepore membranes are plotted against the respective experimental protocols. Each bar represents the mean and standard deviation of $n \geq 3$.

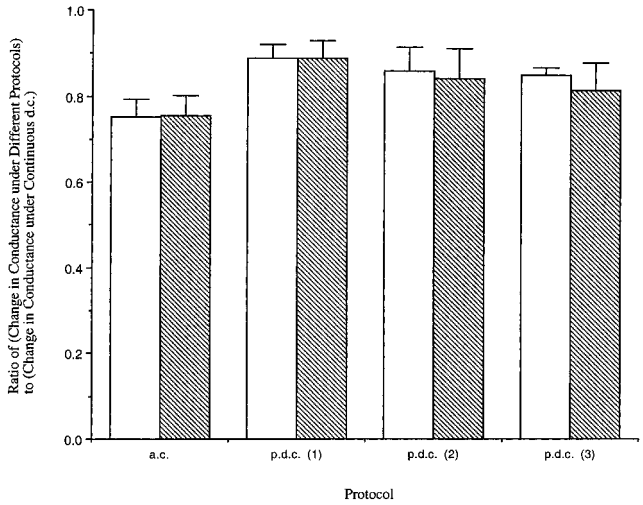

Figure 3—Effects of square-wave ac and pulsed dc iontophoresis on the barrier properties of HEM relative to those of continuous dc at 2.0 V (open bar) and 3.0 V (striped bar). The changes in HEM conductance under different protocols divided by the changes in conductance during continuous dc iontophoresis (for individual HEM samples) were plotted against different protocols. Changes in conductance were determined by conductance (i.e., $1/R$ ($1/k\Omega$)) at 10 s into the iontophoresis run minus the conductance before the iontophoresis run. Abbreviations: ac, 12.5 Hz square-wave ac iontophoresis; pdc, 40 ms square-wave pulsed dc iontophoresis with a brief delay (numbers, ms, in brackets) between each pulse. Each data bar represents the mean ± 95% confidence interval ($n \geq 3$).

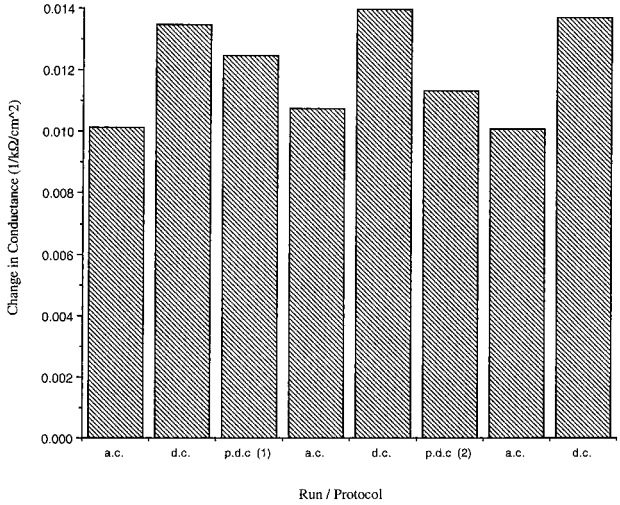

Figure 4—Representative data from a 2.0 V HEM resistance study with a single HEM. The initial electrical resistance of this HEM sample was 71 kΩ cm^2. The HEM electrical resistance just before an iontophoresis run (original or after recovery from the preceding run) was 72 ± 3 kΩ cm^2 (mean ± SD, ranging from 68 to 75 kΩ cm^2). The changes in HEM electrical conductance (changes in $1/R$ from before to the end of the iontophoresis run) are plotted against the different iontophoresis protocols from left to right in the order in which they were carried out. Abbreviations: ac, 12.5 Hz square-wave ac iontophoresis; dc, continuous dc iontophoresis; pdc, 40 ms square-wave pulsed dc iontophoresis with a brief delay (numbers, ms, in brackets) between each pulse.

fluxes with square-wave ac iontophoresis at the voltage conditions in the present study and at frequency ranging from 1.25 to 50 Hz were essentially the same as the fluxes in passive diffusion, in good agreement with predictions based on eq 6 as discussed earlier. This demonstrates that, at sufficiently high frequencies (≥1.25 Hz in the case of the present Nuclepore membrane) under the applied voltage conditions and duration studied, ac iontophoresis does not enhance the transport of permeants across membranes. The results in Figure 2 represent the concept underpinning the HEM studies in the next section.

The flux enhancement with 0.5 V continuous dc superimposed with square-wave ac (2.0 V at 12.5 Hz) was essentially the same as that with 0.5 V continuous dc iontophoresis. The fluxes with 0.5 V continuous dc iontophoresis were more than 7 times higher than those with square-wave ac iontophoresis and passive diffusion; the enhancement factor determined in the present 0.5 V continuous dc iontophoresis experiments is consistent with previous results.[21]

HEM Electrical Resistance Studies—Figure 3 summarizes the results of the experiments designed to compare the extent of pore induction in HEM during 12.5 Hz ac and pulsed dc iontophoresis with continuous dc iontophoresis. A total of 19 HEM samples were involved in this study, with each sample taken successively through several 10 s runs as described in the Experimental section. Figure 4 shows representative results of consecutive experimental runs with a HEM sample. As can be seen in Figure 3, the increases in the electrical conductance with 12.5 Hz ac and with pulsed dc were generally less than (Student's *t*-test of 95% confidence level), but of the same order of magnitude of that observed with continuous dc at the same applied voltages (2.0 or 3.0 V). In general, the increase in the electrical conductance with 12.5 Hz ac was around 75% of that with continuous dc. In these experiments, as the delay time between pulses was increased, the pore induction approached that found with 12.5 Hz ac.

HEM Transport Studies—Typical examples of transport enhancement results of studies A and C are presented in Figures 5 and 6, respectively. Figure 5 gives data of urea flux and electrical conductance for stage II of study A, where 3.0 V 12.5 Hz square-wave ac was applied for approximately 250 min. As can be seen here, both the electrical resistance and the corresponding flux generally attained near plateau values within 1 h, the plateaus representing around an 8-fold increase in conductance relative to the initial value. Results similar to those in study A were observed in study B. In the example presented in Figure 6 (an example of study C), stage II was 2.0 V dc iontophoresis for around 50 min; stage III was 4.0 V dc for 1 min followed by 3.0 V square-wave ac iontophoresis for 2 h; stage IV was superposition of 1.0 V dc over 3.0 V 12.5 Hz ac iontophoresis. It is seen in this example that there was significant pore induction during stage II but little or no further change in the state of pore induction during stages III and IV. Also can be noted in

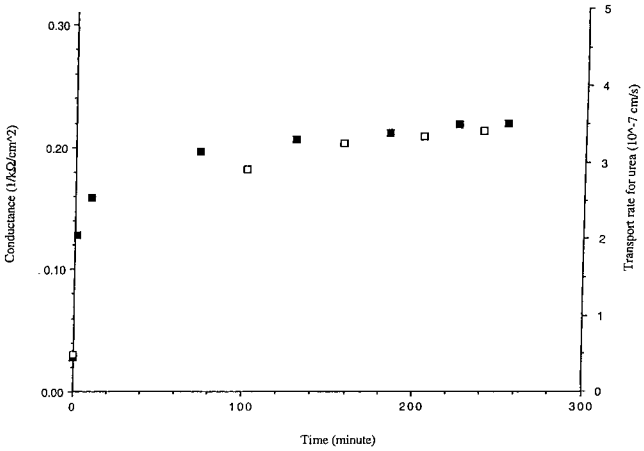

Figure 5—Representative HEM conductivity data ((kΩ cm^2)$^{-1}$), closed symbols, and HEM transport data for urea, open symbols, in study A (stage II: 3.0 V 12.5 Hz square-wave ac iontophoresis). Data are from skin sample 9.

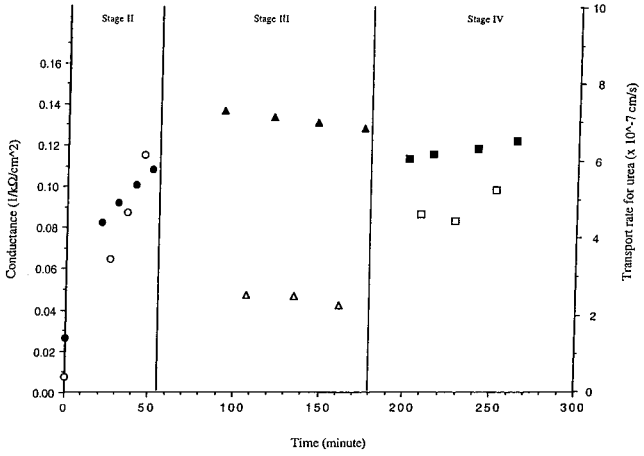

Figure 6—Representative HEM conductivity data ((kΩ cm^2)$^{-1}$), closed symbols, and HEM transport data for urea, open symbols, in study C (stage II: 2.0 V dc iontophoresis; stage III: 4.0 V 1 min followed by around 2 h 3.0 V square-wave ac iontophoresis; stage IV: superposition of 1.0 V dc and 3.0 V 12.5 Hz square-wave ac iontophoresis). Symbols: stage II, circles; stage III, triangles; stage IV, squares. Data are from skin sample 17.

Figure 6 are the relatively constant electrical resistance values and the corresponding fluxes in stages III and IV. In stage II, a lag between the increase in transport rate and the increase in conductance can be seen; this lag was noted in four of the six HEM samples of study C.

Table 1 shows the HEM electrical resistance decreases and HEM permeability increases that occurred with the modest applied 12.5 Hz square-wave ac voltages (stage II of studies A and B and stage III of study C). HEM electrical resistance and HEM permeability generally did not change by more than 25% during the conventional passive diffusion runs (stage I of studies A, B, and C). During square-wave ac iontophoresis of 2.0 to 4.0 V (stage II of studies A and B and stage III of study C), both the HEM permeability and the HEM conductance increased by up to around 30-fold relative to conventional passive diffusion runs (stage I of studies A, B, and C). Figure 7 is a plot of the Table 1 data, and it clearly reveals the relationship between the increase in HEM urea permeability and the increase in HEM electrical conductance during square-wave ac iontophoresis.

The effective pore radii estimated using the urea and mannitol flux data and the hindered transport theory in studies A and B are summarized in Table 2, and those for study C are in Table 3. The effective pore radii for HEM deduced in the passive transport experiments are consis-

[a] Data taken from near the plateau region after the initial decrease (see Figures 5 and 6).

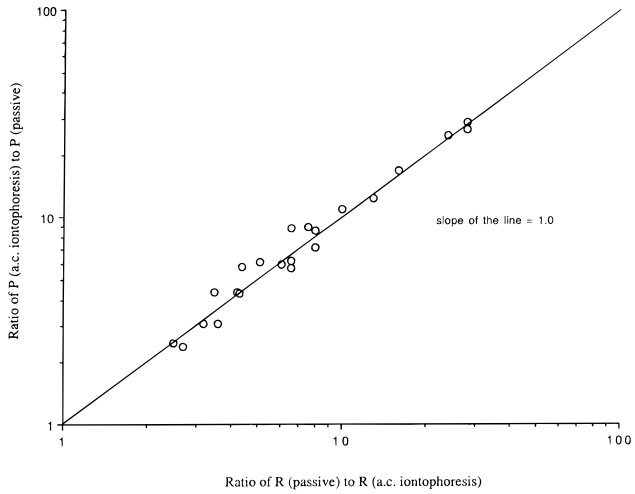

Figure 7—A correlation between the increase in HEM permeability for urea and the increase in HEM conductance in studies A, B, and C. The ratios of passive permeability to permeability during the 12.5 Hz square-wave ac iontophoresis ("passive" permeation) are plotted against the ratios of electrical conductance in passive diffusion study to the conductance in the square-wave ac iontophoresis study.

tent with those determined previously by Peck et al.[18] In Tables 2 and 3, the effective pore radii deduced for the induced pores under the electric field are seen to be of the same order of magnitude as those of the preexisting pores involved in passive diffusion. Results obtained in study B in which the extent of pore induction was expected to be increased by a 1 min dc prepulse before the square-wave ac transport run are similar to those from study A. Also seen in Table 3 are the generally somewhat smaller effective pore sizes calculated from the electroosmotic transport data obtained with continuous dc iontophoresis (stage II of study C; mean ± SD = 8.5 ± 1.4 Å, $n = 6$) when compared to those of the preexisting pores deduced from passive transport runs (stage I of studies A, B, and C; mean

[a] Stages I and III were passive diffusion experiments. [b] Equation 3 was used.

$\pm$ SD $= 14 \pm 4$ Å, $n = 16$) and those deduced from the square-wave ac iontophoresis runs (stage II of studies A and B, stage III of study C; mean $\pm$ SD $= 12 \pm 2$ Å, $n = 16$). The effective radii of the pores induced by an ac electric field during square-wave ac iontophoresis (stage II of studies A and B and stage III of study C) seem to be smaller, but only marginally, than those of the preexisting pores determined in the passive diffusion runs (stage I of studies A, B, and C). The results (mean $\pm$ SD $= 8 \pm 1$ Å, $n = 6$) from stage IV of study C involving the superposition of square-wave ac (3.0 or 4.0 V) for pore induction with 1 V continuous dc as the driving force for transport (i.e., electroosmosis) were essentially the same as those from continuous dc iontophoresis alone (stage II of study C). No significant differences were observed between the effective pore radii obtained in the passive permeation runs before (stage I of studies A to C; mean $\pm$ SD $= 14 \pm 4$ Å, $n = 16$) and after the application of the electric fields (stage III of studies A and B and stage V of study C; mean $\pm$ SD $= 13 \pm 2$ Å, $n = 16$). It should be noted that the effective pore radii deduced with continuous dc iontophoresis (stage II of study C) are consistent with the results obtained in a previous study.[13] Finally, the recovery of HEM barrier properties after the application of the electric field in the ac protocol was observed to be generally faster and more complete than those after continuous dc iontophoresis (see Table 4).

Discussion

HEM Transport Studies—The effective pore sizes of HEM have important implications on the delivery of large molecules (such as oligonucleotides and polypeptides), and this has been discussed previously.[13,18] Recent findings in the effective pore sizes during low to moderate voltage iontophoresis with continuous dc electroosmotic transport may be complicated by possible variable pore surface charge density in HEM.[13] Because HEM transport enhancement with ac iontophoresis in the present experiments is basically due to the induction of new pores and not due to electroosmosis (see *Nuclepore Membrane Studies* in the *Results* section and the last paragraph in this section), possible pore charge density distributions in HEM would not affect the deduced effective pore radii with the ac protocol. Also, the same equation (eq 3) has been used in the pore radii determination with the ac iontophoresis data as in the case of the passive transport data; hence, any uncertainties arising from the use of eq 3 would likely be essentially the same for the passive and the ac situations, especially when the pore sizes are essentially the same. Thus, it is rather safe to conclude that the effective pore sizes of the pores induced in the ac experiments are close to those deduced for the preexisting pores. The situation is more complicated when the effective pore sizes deduced from the electroosmotic transport data obtained during continuous dc iontophoresis (stage II of study C) are compared to either those deduced from ac iontophoresis (stage II of studies A and B and stage III of study C) or those deduced from passive diffusion (stage I of studies A, B, and C). The smaller effective pore sizes deduced from the electroosmosis data presented in Table 3 (stages II and IV of study C) are likely the result of one or both of two possible explanations: (a) because of the directionality of the convective solvent flow during HEM electroosmosis, clearly negatively charged pores must dominate. However, there can exist a distribution of negative, positive, and neutral pores,[22] and, conceivably, negatively charged induced pores may possess smaller effective pore sizes than the neutral and/or positively charged pores; (b) the alternative explanation is that eq 4 likely has different limitations (than eq 3) in the calculation of effective pore sizes. These limitations in the region of $\lambda \geq 0.4$ have not been well investigated from the experimental standpoint[19] and raise the question of the magnitude of the actual uncertainty in the effective pore sizes presented in Tables 3 and 4 where λ values range from around 0.1 to 0.6. Only further independent studies on the quantitative applicability of eqs 3 and 4 can provide a more quantitative assessment of this issue. In the meantime, eqs 3 and 4 may be employed as a first approximation in the range of $\lambda \geq 0.4$. It is of interest to note that calculations carried out based on a mathematically more rigorous approximation of the centerline theory for $0 \leq \lambda \leq 1.0$[19] show differences of only 10 to 20% from those of eqs 3 and 4 at $\lambda \approx 0.6$.

It is noteworthy that the pore size estimates from stage II of study C are essentially the same as those from stage IV. This together with the resistance data (initial, stage II, stage III, and stage IV in Tables 1 and 3) suggest that pores induced by dc alone (stage II of study C) have characteristics similar to those induced by 12.5 Hz ac (stage IV of study C, where the 3.0 or 4.0 V ac component prevails over the 1.0 V dc component with regard to pore induction).

The correlation in Figure 7 is consistent with the results obtained in a previous study[1] and demonstrates the appropriateness of using the changes in HEM electrical resistance to represent the increase in accessible porosity/tortuosity during iontophoresis. The results in Figure 7 accordingly provide the first direct quantitative evidence of pore induction under the modest voltage conditions. Also, because the average effective pore sizes of the transport pathways during ac iontophoresis and the effective sizes of the preexisting pores are essentially the same (Tables 3 and 4), the increase in HEM permeability and the corresponding increase in HEM conductance (up to around a 30-fold increase) shown in Table 1 and Figure 7 under the ac conditions can best be interpreted as electric field induction of new pores in HEM rather than the enlargement of the preexisting pores.

Another important result of the present study is revealed in Figure 8. Here, the permeability coefficient (P) for the 12.5 Hz ac iontophoresis runs (square symbols) are plotted against electrical resistance (R) together with the corresponding conventional passive permeation data obtained before (circle symbols) and after (triangle symbols) ac iontophoresis. What is significant is that the passive permeation data fall upon the same line (slope $= -1.0$). This, together with the results in Figure 7, is further support that HEM transport enhancement under the present ac conditions is entirely due to enhanced "passive" permeation resulting from pore induction with negligible contribution from electroosmosis. The slope of -1.0 is what

[a] Duration of iontophoresis was around 2–5 h. [b] Data obtained from Li et al.;[13] duration of iontophoresis was 50 min. [c] As percent of initial electrical resistance (data from the close to plateau region after the initial decrease). [d] As percent of initial electrical resistance after the iontophoresis run when resistance became constant with time (after more than 10 h). [e] First value is the dc voltage of the 1 min prepulse and the second value is the ac voltage (in 12.5 Hz ac iontophoresis) in the present study or dc voltage (in continuous dc iontophoresis) from a previous study.[13]

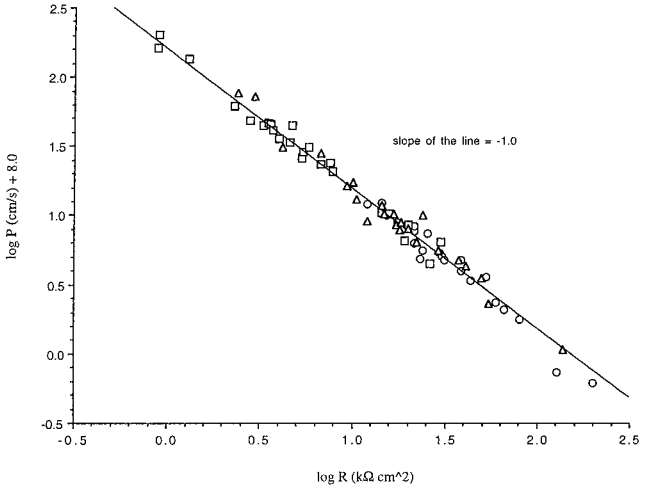

Figure 8—A correlation between HEM electrical resistance and its permeability for urea in studies A, B, and C. Symbols: passive permeation before iontophoresis, circles; 12.5 Hz square-wave ac iontophoresis ("passive" permeation), squares; passive permeation after iontophoresis, triangles.

would be expected when the transport pathways for the conducting ions in PBS during iontophoresis correlate with both the preexisting and the induced pathways for urea passive transport in HEM (see eq 9 and ref 13). The results in Figure 8 are evidence that the electrical current increases that take place during moderate voltage low-frequency ac iontophoresis is the direct result of pore induction in the stratum corneum and not due to some other transient electrical effects[5–8] such as a complex potential-dependent energy barrier for transport at the membrane–solution interface or effects arising from time dependent membrane polarization, the latter being likely important only for much shorter time frames (e.g., in the order of a millisecond[7]) than that of the present situation. These findings support the pore induction hypothesis made in previous studies with applied voltages ≥ 1 V.[1–5]

Electroporation of HEM at Low to Moderate Voltages (2 to 4 V), Yes or No—Although the issue of the sites of pore induction in human skin at low to moderate voltages is beyond the scope of the present investigation, possible mechanisms and skin morphology proposed in the literature[1,4,23–24] for the increase in skin electrical conductance observed in the present study may be discussed. Previously, Inada et al.[1] hypothesized that the increase in HEM electrical conductance at 1 to 4 V is similar to the reversible electrical breakdown found with lipid bilayer membranes and that pore formation may occur transepidermally or via the cells lining the appendageal ducts. For transepidermal electrical breakdown, the electric field across HEM under an applied potential of 2 V for an average of 15 to 20 corneocyte layers in the stratum corneum was estimated to be in the order of 40 kV/cm when the voltage drop was assumed to be concentrated across the intercellular lipid bilayers rather than the conductive corneocytes. Thinner portions of the stratum corneum may experience a higher field strength and thus may disproportionally contribute to electroporation. This calculated electric field strength (40 kV/cm) is in the order of the magnitude of, but probably at the lower end of the range of, field strengths needed to induce electrical breakdown of lipid bilayer membranes, estimated to be around 50 to 200 kV/cm based on a bilayer thickness of around 10 nm and a "threshold voltage" of around 50 to 200 mV over periods of seconds[25,26] to minutes.[27] The "threshold" voltage used in the above estimation for membrane electroporation is strongly dependent on the duration of the applied electric field and the particular type of the membrane. The view of reversible breakdown of the epithelial cell bilayers lining the appendages was offered earlier by Kasting and Bow-

man[5] as a possible explanation for the time-dependent, nonlinear, current−voltage relationship observed in their skin electrical resistance study. The number of bilayers involved in this case is much smaller than that of full thickness stratum corneum, and accordingly the electric field strengths attainable in the bilayers lining the appendages could be much greater and much more than sufficient to induce electroporation. Chizmadzhev et al.[23] has come to a similar conclusion in a recent quantitative examination of this problem. Under applied potentials of a few volts, Chizmadzhev et al. state that the "time-dependent, nonlinear current−voltage characteristics of the skin can be attributed to electroporation" associated with the epithelial cells lining skin appendages. Their analysis "confirms skin electroporation at low voltages", which is in agreement with the views of Kasting and Bowman[5,6] and Inada et al.[1] The results in Figures 7 and 8 of the present study clearly support electroporation at these low to moderate voltage conditions.

Pulsed and Continuous Iontophoresis—Although pulsed dc iontophoresis transport experiments were not conducted in the present investigation, the results of the present HEM electrical resistance study impact upon the understanding of pulsed dc iontophoresis, and some discussion here is instructive. Pulsed dc iontophoresis has been an aspect of interest in transdermal iontophoresis partly because of the possible advantage of less skin irritation than that with continuous dc iontophoresis[28,29] and the belief by some researchers that it may provide greater transport enhancement than conventional continuous dc iontophoresis via mechanisms that are unique in pulsed iontophoresis.[30] Some previous studies have reported that higher or equal fluxes are observed under continuous dc iontophoresis relative to pulsed dc iontophoresis,[7,29,31−32] but other studies have suggested higher transport rates or greater pharmacological effects under pulsed dc iontophoresis.[33,34] These differing results demonstrate the need for more systematic mechanistic studies to compare the effects of pulsed dc and continuous dc upon the barrier properties of skin.

Results from the present electrical resistance study can provide a better understanding of the mechanism(s) of pore induction in human skin during pulsed and/or continuous dc iontophoretic enhanced transdermal delivery. A particular advantage of the protocols used in the present study has been that of minimizing the influence of skin-to-skin variabilities. By utilizing the same HEM sample for successive experiments, the influence of the variabilities has been reduced and more meaningful results were obtainable. The merit of this approach is illustrated by the relatively small data scatter in Figure 3 (contrast this with the large variations seen in Table 4 for the effects of pulsed dc and continuous dc on the barrier properties of HEM).

Because HEM conductance was shown to be directly proportional to the "passive" permeability of HEM (Figures 7 and 8), the electrical conductance results presented in Figure 3 suggest that continuous dc iontophoresis generally induces a greater extent of pore induction than those observed during pulsed dc and ac iontophoresis at the same level of applied voltage (2.0 to 3.0 V) and duration. The present electrical conductance data are consistent with the study by Yamamoto and Yamamoto.[35] The generally larger extent of pore induction in HEM observed during continuous dc iontophoresis than in pulsed and ac iontophoresis under the applied voltage conditions in the present study is believed to be at least in part due to the depolarization/recovery of the membrane allowed between each ac square-wave pulse and is consistent with the hypothesis of pore induction at the bilayer level in HEM. The dc square-wave pulsed iontophoresis (with a 1, 2, or 3 ms delay between each pulse) induced a lesser extent of pore induction than those by continuous dc (Figure 3) and approached those by 12.5 Hz square-wave ac; this also supports the hypothesis that depolarization between the pulses (ac or dc) allows for depolarization/recovery of the membrane during iontophoresis, and hence, lessen the extent of pore induction. This depolarization/recovery between pulses may also lead to the observed faster (data not shown) and more complete (Table 4) recovery of HEM barrier properties after ac and pulsed dc iontophoresis than those after continuous dc iontophoresis. It should be noted that the results presented in Figure 3 are for the particular case of consecutive 10 s runs, and the differences between continuous dc and pulsed dc are rather modest. For longer duration and at higher applied voltages, there may be greater differences between continuous dc and pulsed dc and/or ac. More work is needed in this area.

Abstract □ DMP 754 is an ester prodrug of a glycoprotein IIb/IIIa receptor antagonist that undergoes ester and amidine hydrolysis in the presence of excipients. A means for the stabilization of DMP 754 was needed for the formulation of a stable drug product. Incorporation of a pH modifier in the formulation was used to control the microenvironment pH to coincide with that of maximum stability for DMP 754. Stability of tablets and capsules manufactured by (a) trituration process, (b) dry granulation process, and (c) wet granulation process was evaluated in HDPE bottles. Formulations manufactured by the dry and wet granulation processes contained disodium citrate as the pH modifier. Although aqueous wet granulation of a hydrolyzable drug is usually avoided, tablets and capsules manufactured by wet granulation were more stable in this case than those manufactured by the dry granulation process. This was attributed to the more uniform distribution of the pH modifier. Although the compression process resulted in enhanced degradation of the binary blend of DMP 754 and anhydrous lactose, tablets manufactured by the wet granulation process were more stable than capsules manufactured by the same process. Decreasing excipient-to-drug ratio enhanced the stability of tablets manufactured by the wet granulation process.

Introduction

DMP 754, the acetate salt of (*R*)-methyl 3-[[[3-[4-(aminoiminomethyl)phenyl]-4,5-dihydro-5-isoxazolyl]acetyl]amino]-*N*-(butoxycarbonyl)-L-alanine, is an ester prodrug of platelet IIb/IIIa glycoprotein receptor antagonist.[1,2] DMP 754 drug substance is crystalline and was found to exhibit good stability in the solid state. DMP 754 degradation in the solid state was significantly enhanced in the presence of different excipients, and the rate of degradation was proportional to the excipient:drug ratio. Among all the fillers tested, anhydrous lactose showed the lowest rate of DMP 754 degradation. However, DMP 754 showed significant degradation in the presence of anhydrous lactose at high excipient-to-drug ratios. A means for the stabilization of DMP 754 in solid dosage forms was needed since it is a potent drug that is present at low concentration in the drug product. The two main degradation products isolated in the solid state (Figure 1) were the ester hydrolysis product (XV459) and the amidine hydrolysis product (SJ459). Enhanced hydrolysis of DMP 754 in the presence of lactose was attributed, at least partly, to lactose catalysis, since lactose was shown to provide concentration-dependent catalysis of ester and amidine degradation in solution.[3] While catalysis of esters by sugars and polyhydric alcohols in aqueous solutions was reported,[4] this effect was not previously shown for the amidine group.

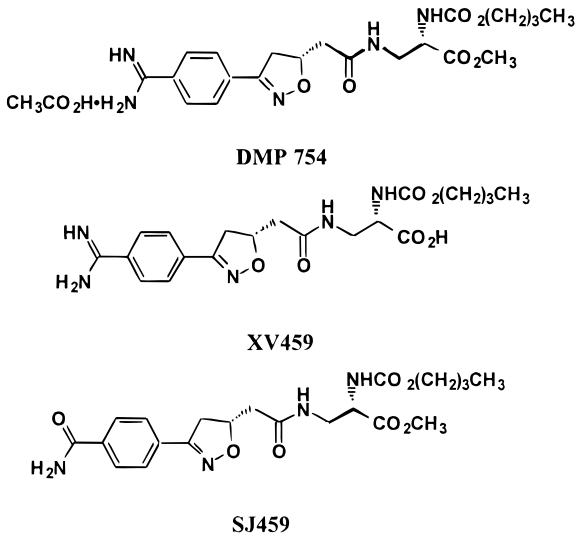

Figure 1—Structure of DMP 754 and degradation products, XV459 and SJ459.

Hydrolysis rate of DMP 754 in the presence of lactose was found to be dependent on the microenvironment pH. The hydrolysis rates of the ester and amidine groups of DMP 754 in lactose blends were altered by incorporation of acidic components in the blend. The use of pH modifiers to decrease the degradation rate in the solid state was previously reported.[5,6] However, the rationale for the choice of particular pH modifier was generally lacking. The effect of an acid on the microenvironment pH of DMP 754 was predicted by the saturated solution pH of the acid.[3] The ester group attained maximum stability with acids having saturated solution pH of approximately 4. On the other hand, the amidine group showed increased stability with the more acidic modifiers having saturated solution pH values as low as 0.4. Hydrolysis rate of amidines was reported to decrease as the acidity of the reaction medium increased.[7] Disodium citrate (saturated solution pH of 4.6) was the only acid tested that improved the stability of both groups. Stability of DMP 754 in the solid state can, therefore, be improved by the use of an appropriate acid that adjusts the microenvironmental pH to approximately 4.

The purpose of this study was to develop a stable oral solid dosage form for DMP 754. The formulation and manufacturing process were selected to maximize DMP 754 stability. Disodium citrate was included in the formulation as a pH modifying agent, in an attempt to control the microenvironment pH to that of maximum stability for DMP 754 as mentioned earlier. The effect of the manufacturing process on DMP 754 stability was also evaluated. Although aqueous wet granulation is usually avoided for a hydrolyzable drug,[8] both dry and wet processes were evaluated for the manufacture of DMP 754 drug product. Method of incorporation of a pH modifier can affect the

stability of the drug product.[6] Initially, the effect of compression and encapsulation on DMP 754 stability was examined for binary blends with anhydrous lactose. The effect of processing on the stability of drug product containing disodium citrate was then evaluated. Thus, stability of DMP 754 tablets and capsules containing disodium citrate and manufactured by a dry granulation (slugging) process or a wet granulation process was assessed.

Materials and Methods

Materials—DMP 754 was obtained from the Chemical Processing Research and Development Department of DuPont Pharmaceuticals Company and used as received. Mean particle size of DMP 754 was 11.5 μm. Anhydrous lactose, NF (Quest International Inc., Norwich, NY), was used as the filler. Disodium citrate sesquihydrate was supplied by Aldrich Chemical Co. (Milwaukee, WI). Other excipients used were magnesium stearate, NF (Mallinckrodt, St. Louis, MO), and povidone, USP (ISP, Wayne, NJ). HPLC grade trifluoroacetic acid (TFA) and glacial acetic acid were obtained from J. T. Baker, Phillipsburgh, NJ. HPLC grade acetonitrile (ACN) was obtained from EM Science (Gibbstown, NJ).

Equipment—Turbula T2C mixer (Willy A. Bachofen AG, Basel, Switzerland); Carver press (Fred S. Carver Inc., Menomonee Falls, WI); V-blender (Patterson-Kelley, East Stroudsburg, PA); Stokes single station press (Pennwalt Corporation, Warminster, PA); Key KG-5 high shear granulator (Key International, Englishtown, NJ); Zanasi AZ5 capsule filling machine (IMA, Fairfield, CT).

Methods—Table 1 summarizes the different DMP 754 formulations. Figure 2 shows a summary of the different manufacturing processes. Strength (or concentration) of DMP 754 in the various formulations represents that of the free base. Potency of DMP 754 was corrected for the assay value of the free base in the drug substance (use as value).

1. Preparation of Blends—A blend containing DMP 754 (0.33% w/w), disodium citrate (2.5% w/w), and anhydrous lactose (97.17% w/w), was prepared by a trituration process. DMP 754 was triturated with anhydrous lactose/disodium citrate preblend in a mortar and pestle using a geometric dilution technique. Another blend of DMP 754 (0.33% w/w) and anhydrous lactose (99.67% w/w) without disodium citrate was also prepared by a similar trituration process.

2. Preparation of Capsules and Tablets from the Binary Blend with Anhydrous Lactose—A binary blend of DMP 754 and anhydrous lactose, prepared by the above-mentioned method, was hand-filled into size 1 hard gelatin capsules (Capsugel, Greenwood, SC). Tablets were also manufactured by direct compression of the binary blend (no magnesium stearate) using the Carver press.

3. Preparation of Capsules and Tablets by the Dry Granulation Process—Capsules and tablets, 0.2 mg strength, containing 2.5% disodium citrate were prepared by a dry granulation process. Disodium citrate, DMP 754, and anhydrous lactose were blended with three-fourths the quantity of magnesium stearate using a V-blender with I-bar. The discharged blend from the V-blender was compressed into tablets (slugs) with a target weight of 200 mg on a Stokes single station press. The slugs were hand-screened through a 25-mesh screen and blended with the remaining amount of magnesium stearate in the V-blender. The resulting granulation was filled into size 3 hard gelatin capsules on the Zanasi capsule filling machine, or compressed into tablets on the Stokes single station press.

4. Preparation of Capsules and Tablets by the Wet Granulation Process—A formulation containing 2.5% disodium citrate was also manufactured by a wet granulation process. DMP 754 was blended with anhydrous lactose in the bowl of the high shear granulator. The blend was then granulated with an aqueous solution containing disodium citrate and povidone (pH of granulating solution was adjusted to 4 with 1 N hydrochloric acid). The wet granulation was screened through 8-mesh screen and dried in a vacuum oven at 40 °C to a moisture NMT 1.0% (determined by loss on drying at 105 °C). The dried granulation was screened through a 25-mesh screen and blended with magnesium stearate in a V-blender. The granulation was filled into hard gelatin capsules, or compressed into tablets similar to the dry granulation formulation. Various tablet strengths (0.2, 0.5, and 1.0 mg) were manufactured by the wet granulation process. Tablet weight was kept constant and the different strengths were obtained by changing the excipient-to-drug ratio.

In addition, DMP 754 tablets were manufactured by the above wet granulation process without disodium citrate. The formulation contained 0.0083% lactic acid added to the granulating solution. The pH of granulating solution was adjusted to 4 with 0.1 N sodium hydroxide. The formulation was similar to that mentioned above for the 0.2 mg tablets except for the substitution of lactic acid for disodium citrate.

5. Stability of Blends, Tablets and Capsules—Blends, tablets, and capsules were packaged into 40-cc high density polyethylene (HDPE) bottles capped with child-resistant caps. A 180 mg amount of the blend was accurately weighed into a bottle without desiccant, and the bottle was capped, torqued, and induction sealed. Capsules and tablets were packaged into the HDPE bottle in counts of ten or six, respectively, with or without desiccant (0.6 g silica gel). The packaged HDPE bottles were stored in stability chambers at 30 °C/60% RH and/or 40 °C/75% RH. The bottles were pulled at different time intervals, and the contents were analyzed for DMP 754 and degradation products by the HPLC method described below.

6. Analytical Method—An HPLC system equipped with automatic sampler, heated column compartment, gradient elution pump, and variable wavelength UV detector set at 280 nm (Model 1050/Hewlett Packard) was used for analysis of the blend, capsule, and tablet samples. The reverse phase HPLC assay method utilized a Waters Symmetry C-18 column (15 × 0.4 cm, 5 μm packing) with a mobile phase of 18:82 ACN/0.05% TFA in water

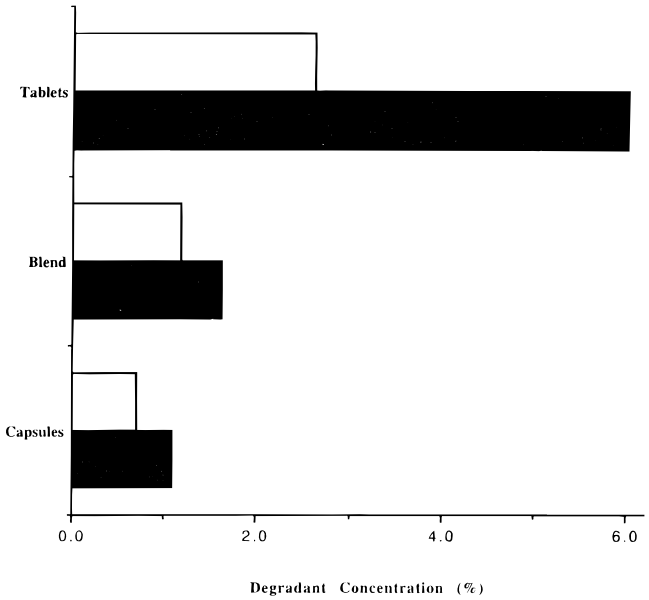

Figure 3—Percent degradation products of DMP 754 in binary blends (without magnesium stearate) after four weeks at 40 °C/75% RH. SJ459, (□); XV459, (■).

delivered at a flow rate of 1.5 mL/min and column temperature of 35 °C. The degradation products method also used a Waters Symmetry C-18 column with gradient elution of the mobile phase from 10:90 to 60:40 ACN/0.05% TFA in water over 30 min at a flow rate of 1.5 mL/min and a column temperature of 35 °C.

The blend samples were prepared by adding 30 mL of 14:86 ACN/0.05% glacial acetic acid in water to the HDPE bottles containing the blends and shaking for 30 min. The solution was then filtered as needed through 0.45 μm syringeless filter (Whatman, Clifton, NJ). In the case of tablets and capsules, 10 dosage units were dissolved in 14:86 ACN/0.05% glacial acetic acid in water, and the solution was filtered through the 0.45 μm syringeless filter. An external standard method was used for the assay and degradation products analysis.

The HPLC method was validated for linearity, accuracy, precision, limit of quantitation, and specificity. Studies with spiked placebo samples showed recoveries of 99.5% with method repeatability of 0.6% RSD. Specificity was determined by stressing samples with heat and light and by chromatographing known impurities; no peaks were found to coelute with the known degradants. Studies with degraded samples showed mass balance of drug substance and degradation products. Methods were linear over the range of study, and limit of quantitation of degradants was measured to be 4 ng/mL which was equivalent to 0.02% of drug substance in blends. Samples showed no degradation in the extraction solvent for up to 4 days.

7. X-ray Microanalysis—Citrate distribution in the tablets manufactured by the dry and wet granulation processes was evaluated by determining the sodium distribution on the tablet surface using X-ray analysis in the electron microscope. Citrate exists as sodium salt in the formulation, and therefore sodium distribution is expected to reflect the extent of citrate distribution in the sample. Intact tablet samples were mounted on aluminum stubs, carbon-coated, and examined using a Cameca electron microprobe fitted with a Wavelegth Dispersive Spectrometry (WDS) detector.

8. Moisture Uptake Studies—Moisture uptake by the granulation was determined at 25 °C using VTI MB 300G Integrated Microbalance System (VTI Corporation) from 40% RH to 90% RH with desorption to 10% RH. All transitions were in incremental steps of 10% RH.

Results and Discussion

1. Stability of DMP 754 Binary Blends with Anhydrous Lactose—Encapsulation and compression affected the stability of DMP 754 in the binary blend with anhydrous lactose. The encapsulation of the lactose/DMP 754 blend into hard gelatin capsules decreased drug degradation. The stabilizing effect of encapsulation was comparable for the ester and the amidine groups. The encapsulation of the blend reduces the surface area of the blend exposed to the environment and can decrease the rate of penetration of water vapor into the powder bed. The capsule shell can also act as a barrier that water vapor has to penetrate before it reaches the blend. This is particularly true if the gelatin shell is more hygroscopic than the blend and can consequently act as a "desiccant". Thus, encapsulation can prolong the time that it takes the moisture content of powder bed to equilibrate with water vapor pressure at 75% RH, which may be the reason for the improved stability of blends encapsulated into hard gelatin shells. To the contrary, tableting of the DMP 754/lactose blend enhanced drug degradation (Figure 3). Tableting increases the number of contact points between lactose and DMP 754. This would possibly enhance lactose catalysis and also increase the rate of moisture transfer between lactose and the drug, thus resulting in an increased rate of drug degradation in the tablets as compared to the blends. Despite the low concentration of moisture associated with anhydrous lactose (approximately 0.5% at 75% RH), this moisture corresponds to high water:drug molar ratio due to the small amount of DMP 754 in the blend and the low

molecular weight of water. The destabilizing effect of tableting appeared to be more pronounced for ester hydrolysis than amidine hydrolysis. Thus, processing influences the stability of DMP 754.

2. Stability of DMP 754 Drug Product Manufactured by Dry Granulation Process—Capsules containing disodium citrate manufactured by dry granulation showed enhanced ester hydrolysis compared to the corresponding blend with disodium citrate in the same packaging configuration at 40 °C/75% RH. On the other hand, the dry granulation process resulted in diminished amidine hydrolysis compared to the blend (Figure 4). The dry granulation process for capsules involves the destabilizing effect of slugging (compression) and the stabilizing effect of encapsulation as mentioned above. On the basis of results from the binary blends, capsules manufactured by the dry granulation process would be expected to have higher ester and amidine degradation rates since the destabilizing effect of tableting was shown to be more pronounced than the stabilizing effect of encapsulation for both groups. The same effect of the dry granulation process on stability was also observed for a similar formulation without disodium citrate. Thus, the effect of the dry granulation process on amidine hydrolysis was not predicted by the blend studies. It is possible that this discrepancy may be due to magnesium stearate, which is not present in the binary blend. Magnesium stearate is known to have the ability to coat individual particles in a pharmaceutical formulation.[9] This can act as a barrier that protects DMP 754 from lactose catalysis, which is an important factor in the solid-state hydrolysis of the amidine group.[3]

Tablets manufactured by the dry granulation process showed comparable ester stability to the corresponding capsule formulation manufactured by the same process in the same packaging configuration at 40 °C/75% RH. However, the amidine group appeared to be even less stable in the tablet formulation (Figure 5).

3. Stability of DMP 754 Drug Product Manufactured by the Wet Granulation Process—DMP 754 capsules, 0.2 mg, manufactured by wet granulation process were more stable when stored at 40 °C/75% RH compared to capsules manufactured by the dry granulation process in the same packaging configuration (Figure 5). A similar trend was also observed at 30 °C/60% RH. The rates of

degradation of the ester and amidine groups were lower for the wet granulation capsules than for the dry granulation capsules. The higher stability of capsules manufactured by wet granulation may be explained by the more uniform distribution of the citrate in this formulation. Adding the citrate to the granulating solution leads to intimate contact of this acidic component with the drug and other formulation components, resulting in a better control of the microenvironment pH. The granulating solution wets the particles, and when the water evaporates, the citrate is in close contact with the formulation constituents. Sodium distribution was found to be more diffuse in the wet granulation sample compared to localized distribution in the dry granulation sample, thus suggesting a more uniform distribution of the citrate in the former formulation (Figure 6).

Moisture content of capsules manufactured by the wet granulation process was higher than those manufactured by the dry granulation process. Capsule moisture content at time zero, determined by a Karl-Fisher titration, was found to be 0.6% and 2.0% for the dry and wet formulations, respectively. The moisture content of capsules manufactured by wet granulation was also higher than those manufactured by dry granulation after 3 months of storage at 40 °C/75% RH (Table 2). The higher moisture content of the wet granulation formulation is attributed to two reasons. First, partial conversion to lactose monohydrate during the wet granulation process was observed by X-ray diffraction of the granulation manufactured by the wet process. Second, the formulation manufactured by the wet granulation process was found to be more hygroscopic than the dry granulation formulation as determined by moisture sorption−desorption isotherms for the two formulations. Percent weight gain of the granulation upon the increase of relative humidity from 40% to 90% was 1.7% and 6.5% for the dry and wet formulations, respectively. Although the increased hygroscopicity of a formulation is generally expected to increase the degradation rate of a moisture sensitive drug, the effective microenvironment pH control in the case of the wet granulation formulation was a key factor for the stability of this formulation. The microenvironment pH control in the case of the wet granulation formulation was probably able to compensate for the increased hygroscopicity, resulting in a more stable dosage form than the less hygroscopic dry granulation formulation, which lacked effective pH control.

DMP 754 tablets, 0.2 mg, compressed from the granulation manufactured by the wet process were more stable than the capsules filled with the same granulation at 40 °C/75% RH (Figure 5). DMP 754 degradation was more pronounced at 40 °C/75% RH than at 30 °C/60% RH. At both conditions, ester and amidine hydrolysis rates were lower in the tablet dosage form. The higher degradation rate in the case of capsules may be due to the moisture associated with capsule shell. Due to the hygroscopic nature of the formulation manufactured by wet granulation, moisture may be transferred from the capsule shell to the granulation, which is in direct contact with the gelatin shell. Capsules manufactured by wet granulation showed higher moisture content than tablets (Table 2). In the case of the wet granulation formulation, compression did not demonstrate the destabilizing effect observed for the dry blends. Increasing the number of contact points in the case of granulation manufactured by the wet process did not result in enhanced degradation, probably due to the control of microenvironment pH. Stability of tablets manufactured by the wet granulation process increased with the decrease of the excipient-to-drug ratio. Thus, the

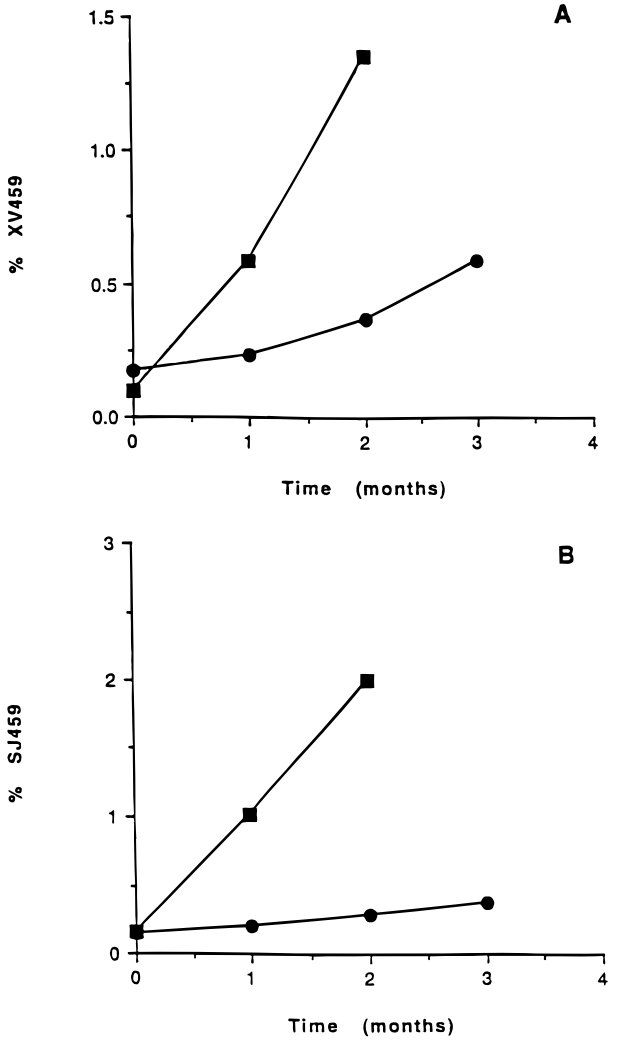

Figure 7—Percent degradation products of DMP 754: (a) XV459 and (b) SJ459 in tablets manufactured by the wet granulation process. Tablets are packaged in HDPE bottles with desiccant and stored at 40 °C/75% RH. Tablets containing 2.5% disodium citrate, (●); tablets without disodium citrate, (■).

1.0 mg tablet showed the least degradation among the three strengths followed by the 0.5 mg tablet, while the 0.2 mg tablet demonstrated the highest rate of degradation (Table 2).

The stabilizing effect of disodium citrate was further demonstrated by the instability of tablets without disodium citrate. Although this formulation was manufactured using a granulating solution buffered to pH 4 with lactate, these tablets showed a higher degradation rate than for the tablets with disodium citrate (Figure 7). The very low concentration of lactate (0.0083% of the total weight of the formulation) was probably insufficient to control the microenvironment pH in the tablets. This was shown by measuring the pH of a slurry prepared by mixing 0.5 g of the granulation with 0.5 g of water. The pH values of the slurries prepared from the granulations with disodium citrate and lactate were found to be 4.4 and 7.7, respectively.

Conclusions

A stable solid dosage form containing a pH modifying agent was developed for DMP 754. The choice of the manufacturing process was critical to the stability of the drug product. The stability of DMP 754 in the dosage form was maximized by the inclusion of the pH modifying agent and the selection of the appropriate manufacturing process. Method of incorporation of an acidic ingredient affects its ability to control the microenvironment pH of a hydrolyzable drug such as DMP 754 and, hence, the stability of the drug product. Depending on the nature of the moisture-sensitive drug and the formulation, the dry granulation process may not be the process of choice. The wet granulation process can yield a more stable drug product for a hydrolyzable drug if the formulation contains a pH modifying agent that controls the pH of the microenvironment. Excipient-to-drug ratio can also be modified in order to maximize drug product stability.

Dissolution Specifications Based on Release Rates

ZEEV ELKOSHI*

Contribution from *Teva Pharmaceutical Industries Ltd., P.O. Box 353, Kfar-Sava 44102, Israel.*

Received August 6, 1998. Accepted for publication January 4, 1999.

Abstract □ A procedure based on release rates is proposed for the establishment of dissolution specifications that ensure the bioequivalence of a test and a reference product. This procedure, which confines C_{max} (the maximum concentration of the drug in vivo) and AUC_∞ (the area under the time–concentration curve, extrapolated to infinity) values within any desired range (relative to a reference product), can be used as an alternative to the methods presented in the FDA guidance[1] or the USP.[2] The method is appropriate for zero-order or first-order release products with linear Level A in vitro/in vivo correlations (IVIVC). Based on the result that the relative difference in C_{max} must always be smaller than the relative difference in the absorption rate constants (for any test and reference products of a given drug), the "minimum range" specifications are set. These specifications, which are identical for both zero-order and first-order release products, are of general validity. They depend only on the relative extents of release, but are otherwise drug or formulation independent. For certain extended release products demonstrating a constant release rate that is unaffected by dissolution conditions (thus allowing the assumption of Level A IVIVC), the "minimum range" dissolution limits are applicable even when in vivo data is not available. If the reference product in vivo data is available, wider limits (which are product specific) may be set. If the drug disposition is monoexponential, the specifications generated are the widest possible. They are termed the "ideal" specifications. In the case of a multiexponential disposition, the limits set by the procedure will (generally) not be the widest possible. Although the method is based on one-compartment models, it is essentially model independent in the sense that microscopic modeling is redundant for its application.

Introduction

In the presence of in vitro/in vivo correlations (IVIVC), dissolution specifications are important as a means of controlling drug bioavailability and thus can be used as a substitute for human bioequivalence studies. A recently published FDA guidance deals with the application of IVIVC for the setting of dissolution specifications for extended release (ER) products.[1] This guidance includes a section concerning specifications based on the release rate of the product. The section, however, is very brief and refers only to products presenting a zero-order release rate. No method for the establishment of the specifications is included.

The present work proposes a procedure for the determination of rate specifications that ensures the bioequivalence of a tested product and a reference product. This procedure presents an alternative approach to the methods proposed by the USP[2] and FDA guidance.[1] The procedure assumes zero- or first-order release rates and linear Level A IVIVC. Generally, IVIVC are established with in vivo data. Under certain conditions, however, when the rate and extent of release of an ER product are unaffected by dissolution conditions (such as, pH, stirring rate, etc.), linear Level A IVIVC are anticipated (assuming that drug release is the rate-limiting step in the process of in vivo drug absorption).[3] In these cases the procedure is applicable, even in the absence of in vivo data. If the reference product in vivo data are available, the dissolution specifications can be widened.

Although this method is based on monoexponential disposition models, it is also applicable when a multiexponential disposition is involved. The method is essentially model independent in the sense that microscopic modeling is not needed.

The bioequivalence metrics required today by most regulatory agencies are AUC_∞ (the area under the time−concentration curve, extrapolated to infinity) and C_{max} (the maximum concentration of drug in vivo). The specifications produced by the proposed procedure may bound both metrics of a tested product, within any desired range, relative to a reference product, thus ensuring their bioequivalence. In this text, a range of ±20% for both metrics is used.

Setting Dissolution Specifications

Dissolution limits are used as a batch-to-batch quality control means. If in vitro dissolution data are related to in vivo data, these in vitro limits can then be used to control the bioavailability of a tested product, relative to that of a reference product (with a known bioavailability). In this way, the bioequivalence of the two products can be guaranteed in vitro.

Bioavailability and bioequivalence are usually assessed in terms of the C_{max} and AUC_∞ metrics. Most regulatory agencies consider two drugs as bioequivalent when they differ by no more than ±20% with respect to each of these metrics. Hence, dissolution limits that control a ±20% difference between the test metrics and the reference metrics will ensure the bioequivalence of the products. Under these circumstances, quality control is meaningful in terms of the in vivo performance of the drug. Dissolution limits that are set in this way may also be used for a selection of a generic substitute or for the approval of manufacturing changes (drug formulation, drug substance, manufacturing site, etc.).

Dissolution limits that are too wide may allow the approval of batches that are bioinequivalent to a reference product. Limits that are too tight, on the other hand, may lead to the rejection of a large number of production batches. It is desired, therefore, to use the widest possible dissolution specifications that are also consistent with the allowed differences between the test and reference metrics of bioequivalence.

Two sets of dissolution specifications are presented: the "minimum range" and the "ideal" specifications. These two sets are first investigated under the constraint of equal extents of release (between the test and reference products).

Then, dissolution specifications for test and reference drugs with different extents of release are considered.

It is assumed throughout this text that linear level A IVIVC are present.

The "Minimum Range" Specifications—The "minimum range" specifications are the widest (relative) dissolution limits that are common to all reference products with IVIVC. Being common to all reference products, the "minimum range" limits must be tighter than the widest feasible dissolution limits for any individual product. Hence, the origin of the name.

It is useful to introduce, at this point, two dimensionless variables, x and y.

For a one-compartment model with zero-order absorption (Appendix A):

$$x = k_{el}D/k_o = k_{el}T \quad (1)$$

where D is the dose absorbed, k_o is the zero-order absorption rate constant, k_{el} is a first-order elimination constant, and T is the duration of the absorption process. Then

$$C_{max} = \frac{D}{Vx}(1 - e^{-x}) \quad (2)$$

where V is the compartment volume.

For a one-compartment model with a first-order absorption (Appendix B):

$$y = k_{el}/k_a \quad (3)$$

where k_a is a first-order absorption constant. Then, by eq B6:

$$C_{max} = \frac{D}{V}y^{y/(1-y)} \quad (4)$$

It is proved in Appendixes A and B that the sensitivity of C_{max} to changes in the rate constant value grows as x or y increase. This result was previously noticed numerically, for the first-order case.[5] The sensitivity reaches a maximum value as $\{x \text{ or } y\} \rightarrow \infty$, where a change in k_o or k_a leads to a change in C_{max} of exactly the same relative value. This, in turn, leads to the conclusion that the in vivo limits $\{\Delta k_o/k_{o(r)} \text{ or } \Delta k_a/k_{a(r)}\} = \pm 0.2$ ensure the condition $|\Delta C_{max}|/C_{max(r)} < 0.2$, where Δ is the test to reference difference and the subscript "r" stands for a reference product. This conclusion is based on the assumption that the test and the reference products are absorbed to the same extent.

If linear level A IVIVC are present, the in vivo absorption rate constants must be linearly related to the in vitro dissolution rate constants. Similarly the (in vivo) extent of absorption must be linearly related to the in vitro extent of release. Therefore, the in vitro condition:

$$-0.2 < \frac{\Delta k_{do}}{k_{do(r)}} \text{ or } \frac{\Delta k_{da}}{k_{da(r)}} < +0.2 \quad (5)$$

where k_{do} or k_{da} are the zero- or first-order dissolution rate constants, respectively, will generally confine the C_{max} value of the test product within ±20% of the reference product value. As before, the Δ sign stands for the test-to-reference difference.

Equation 5 presents the "minimum range" rate specifications when the test and reference products are released to the same extent. The "minimum range" specifications are of general validity because they are not product specific. They are valid even when the drug disposition is multiexponential, as demonstrated in Appendixes C and D. The "minimum range" specifications may be applied for any drug product with established IVIVC. They are particularly useful for certain ER products, where drug release is slow enough and well controlled (see the Discussion). With these products, IVIVC are *expected*. Hence, in these particular cases (and in these cases only), the "minimum range" specifications may be used even when in vivo data are not available.

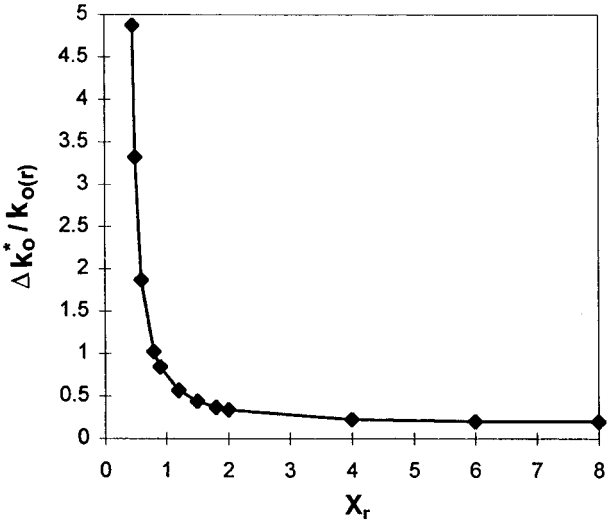

Figure 1—The relative difference in the (zero-order) absorption rate constant values correlating to a standard +20% difference in the C_{max} values, as a function of x_r. The line presents $\Delta k_o^*/k_{o(r)}$ values estimated by the use of eq A11. In the presence of linear IVIVC, the same line defines the upper limit of the "ideal" specifications.

The "Ideal" Specifications—The "ideal" specifications are the widest possible specific dissolution limits that ensure the bioequivalence of any test drug relative to a specific reference product. Similar to the "minimum range" specifications, the "ideal" specification may be applied for any drug product with established IVIVC. However, the "ideal" specifications are dependent on x_r or y_r, which renders the "ideal" specifications product specific.

The widest specific limits of the in vivo absorption rate constants are set in Appendix A (eqs A11 and A12) and Appendix B (eqs B14 and B15) by a test-fitting procedure, assuming one-compartment models with zero- or first-order absorption, respectively. The test and reference products are assumed to be absorbed to the same extent. If linear level A IVIVC are present, the in vivo absorption rate constant (k_o or k_a) is linearly related to the in vitro dissolution rate constant (k_{do} or k_{da}). Similarly, the extent of in vivo absorption is linearly related to the extent of in vitro release.

Hence, when absorption is *zero-order*, the "ideal" dissolution limits are as follows:

Upper limit ($\Delta C_{max}/C_{max(r)} = +0.2$):

$$\Delta k_{do}^*/k_{do(r)} = 0.0018722x_r^{-9.097} + 0.52492x_r^{-2.003} + 0.2 \quad (6)$$

Lower limit ($\Delta C_{max}/C_{max(r)} = -0.2$):

$$\Delta k_{do}^*/k_{do(r)} = -0.35753e^{-4.4507x_r} - 0.44063e^{-1.0255x_r} - 0.2 \quad (7)$$

These limits are presented by the lines in Figures 1 and 2.

When absorption is *first-order*, the "ideal" dissolution limits are as follows:

Upper limit ($\Delta C_{max}/C_{max} = +0.2$):

$$\Delta k_{da}^*/k_{da(r)} = 0.277y_r^{-0.767} + 0.0271y_r^{-3.005} + 0.2 \quad (8)$$

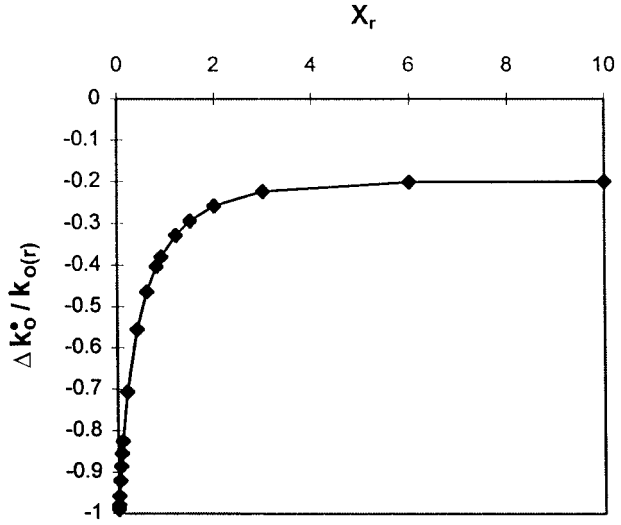

Figure 2—The relative difference in the (zero-order) absorption rate constant values correlating to a standard –20% difference in the C_{max} values, as a function of x_r. The line presents $\Delta k_0^*/k_{0(r)}$ values estimated by the use of eq A12. In the presence of linear IVIVC, the same line defines the lower limit of the "ideal" specifications.

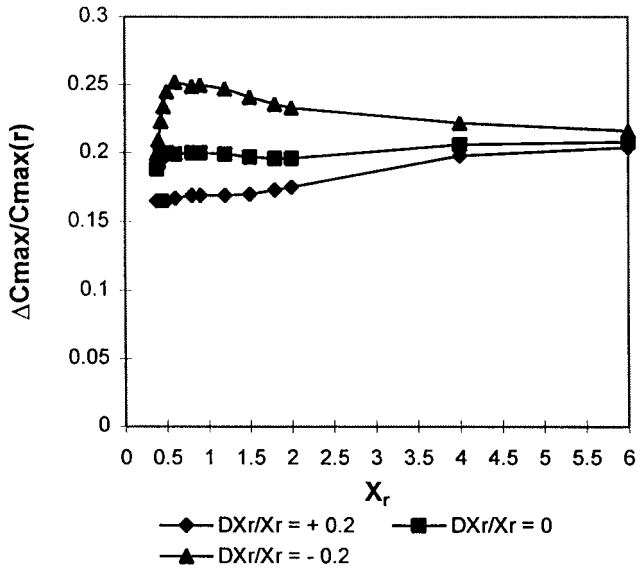

Figure 3—$\Delta C_{max}/C_{max(r)}$ values generated for the zero-order case by using $\Delta k_0^*/k_{0(r)}$ values (defined by eq. A11) in eqs. A5 and A6. The effects of +20% or –20% errors in the estimation of x_r ($Dx_r/x_r = +0.2$ or $Dx_r/x_r = -0.2$) are also included.

Lower limit ($\Delta C_{max}/C_{max(r)} = -0.2$):

$$\Delta k_{da}^{\bullet}/k_{da(r)} = -0.299e^{-26.4y_r} - 0.348e^{-3.128y_r} - 0.146e^{-0.165y_r} - 0.2 \quad (9)$$

These limits are presented by the lines in Figures 3 and 4. Again, Δ is the test-to-reference difference. The (*) and (•) superscripts are reminders that +20% and −20% differences in C_{max}, respectively, are involved.

The use of eqs 6−9 ensures a difference of exactly +20% or −20% between the C_{max} values of the test and reference products. Thus, the range of the rate specifications is the widest possible for each reference product, which renders the "ideal" specifications product specific.

Equations 6 and 8 diverge for $x_r < 0.38$ and $y_r < 0.07$ respectively, indicating that an increase of >20% in C_{max} is *impossible* for x or y values low enough to satisfy these conditions. This leads to the conclusion that a rate-related

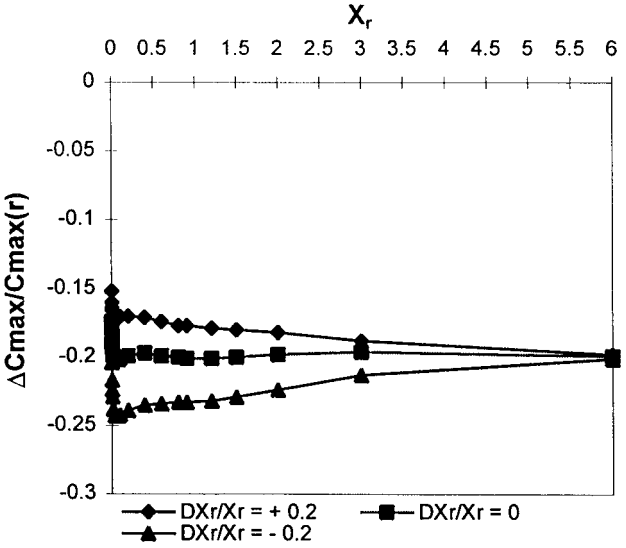

Figure 4—$\Delta C_{max}/C_{max(r)}$ values generated for the zero-order case by using $\Delta k_0^*/k_{0(r)}$ values (defined by eq A12) in eqs. A5 and A6. The effects of +20% or –20% errors in the estimation of x_r ($Dx_r/x_r = +0.2$ or $Dx_r/x_r = -0.2$) are also included.

dose-dumping is impossible when $x < 0.38$ in the zero-order case, or $y < 0.07$ in the first-order case (see Appendixes A and B).

Like the "minimum range" specifications, the "ideal" specifications are particularly useful for ER products with a well-controlled drug release. In these cases, the "ideal" limits may be applied when the reference product in vivo data are the only in vivo data available (see the Discussion).

Equations 6−9 are useful, even when the disposition of the drug is multiexponential. In this case (as described in Appendixes C and D), k_e in x_r or y_r should be replaced by α_1, the largest macroscopic disposition rate constant. The specifications defined this way are, in general, tighter than the "ideal" specifications (which are not feasible when disposition is multiexponential) and wider than the "minimum range" specifications.

Dissolution Specifications when Products are Absorbed to a Different Extent. It has been postulated so far that both the test and the reference products are released (and hence absorbed) to the same extent. The equations used for the dissolution specifications may be generalized to include the effect of a difference in the extent of release (Appendix E). The "minimum range" specifications in this case are

$$\left.\begin{aligned} -0.2 < \frac{\Delta A}{A_r} < 0.2 \\ -0.2 - \frac{\Delta A}{A_r} < \frac{\Delta k_{do}}{k_{do(r)}} \text{ or } \frac{\Delta k_{da}}{k_{da(r)}} < 0.2 - \frac{\Delta A}{A_r} \end{aligned}\right\} \quad (10)$$

where A is the extent of in vitro release and Δ is the test-to-reference difference.

The "ideal" specifications are generalized by the use of eqs E6 and E7. One of the following two equations should be solved (numerically) to estimate Q, depending on whether the absorption is zero- or first-order:

When absorption is zero-order

$$\frac{1 - e^{-Qx_r}}{Q(1 - e^{-x_r})} - 1 + \frac{\Delta A}{A_r} = \pm 0.2 \quad (11)$$

When absorption is first-order

$$\frac{Qy_r^{Qy_r/(1-Qy_r)}}{y_r^{y_r/(1-y_r)}} - 1 + \frac{\Delta A}{A_r} = \pm 0.2 \qquad (12)$$

where the (+) sign is related to the upper dissolution limit and the (−) sign to the lower dissolution limit.

The "ideal" dissolution limits are then defined by

$$\{\Delta k_{do}/k_{do(r)} \text{ or } \Delta k_{da}/k_{da(r)}\} = 1/Q - 1 \qquad (13)$$

If multiexponential disposition is involved, k_{el} in x_r or y_r (eq 11 or 12) should be replaced by α_1, the largest macroscopic disposition rate constant. In that case, as before, the generated limits are, in general, tighter than the "ideal" limits (which are not feasible, when disposition is multiexponential) and wider than the "minimum range" limits.

Discussion

The conclusion that a 20% change in the value of the in vivo rate constant cannot lead to more than a 20% change in the value of C_{max} is a fundamental result of this work. In the presence of linear IVIVC, this result enables the setting of in vitro "minimum range" dissolution limits that are unspecific to the product and hence are of a general validity. If in vivo data related to the reference product are available, x_r or y_r can be estimated, and the dissolution limits may be widened (by the use of eqs 6−9). The dissolution limits in this case are product specific. The generated limits widen as the x_r or y_r values decrease.

The determination of the in vitro/in vivo correlation coefficients is not required for any of the proposed sets of specifications but in vivo data are generally needed to verify IVIVC. However, when IVIVC are *expected*, the "minimum range" specifications may be set even in the absence of in vivo data. Similarly, when IVIVC are expected, the "ideal" specifications may be set even when only the reference product in vivo data are available. IVIVC are highly probable when the drug release is sufficiently slow and well controlled (i.e., when it is unaffected by dissolution conditions such as pH, stirring rate, ionic strength, surfactant concentration, etc.) Roxatidine controlled/modified-release capsules[3] and the nifedipine push−pull osmotic pump[6,7] are examples. Thus, the proposed specifications, which are valid for any drug product with established IVIVC, are particularly useful when IVIVC are expected. This is not true for methods of setting release specifications based on convolution/deconvolution or modeling techniques where the particular in vitro/in vivo correlation coefficients are required.

It should be emphasized that the availability of in vivo data is always desired, even when linear IVIVC are expected. If in vivo data are available, the validity of the linear IVIVC assumption may be assessed. In addition, wider dissolution limits can be set because x_r or y_r may be evaluated.

Once linear IVIVC have been established (or assumed), dissolution limits are easily set. The "minimum range" limits may always be set with the help of a simple desk calculator. This simplicity is true also with the "ideal" limits when both the test and the reference products are released to the same extent. However, a best-fit procedure is needed to set the "ideal" specifications when the products are released to a different extent.

An interesting and practical result of this work is the observation that for $x < 0.38$ in the zero-order case, or $y < 0.07$ in the first-order case, a rate-dependent dose-dumping (an increase of >20% in C_{max}) is impossible (Appendixes A and B). In other words, formulations with $x < 0.38$ or $y < 0.07$ are dose-dumping proof.

The methods just described do not deal with any microscopic rate constants. The only values derived from the in vivo data are the largest disposition rate constant and either the first-order absorption rate constant or the duration of the zero-order "infusion". All of these are macroscopic constants that do not require any microscopic modeling. In this respect, the procedure is model independent.

For products with a first-order release, it is extremely important to correctly identify the absorption exponential term. A wrong identification (in a "flip-flop" situation) may lead to an underestimation of $y_1(=\alpha_1/k_a)$. The generated dissolution limits, in this case, will allow deviations of the C_{max} value from the ±20% range.

Only when IVIVC prevail can dissolution data be used as a surrogate for the in vivo performance of the drug. From practical experience, the majority of dissolution profiles can be closely approximated by zero- or first-order rates of release. To demonstrate linear Level A IVIVC, the patterns of in vitro release and in vivo absorption profiles must be similar, which means that mainly zero- or first-order in vivo absorption profiles can linearly be correlated with the in vitro data. The more complex absorption curves originating due to the changing physiological environment along the gastrointestinal tract, (usually) cannot be linearly correlated with the (simple) in vitro release curves. Hence, a procedure for the establishment of dissolution specifications, that deals with zero-or first-order release rates (like the one proposed in this work) covers most cases with linear Level A IVIVC.

Appendix A: One-Compartment Model with Zero-Order Absorption

Consider a one-compartment open model with a zero-order absorption. Define the dimensionless variable x

$$x = k_{el}\, T \qquad (A1)$$

where T is the duration of the absorption process (the

"infusion" time) and k_{el} is a first-order elimination constant. Then

$$C_{max} = \frac{D}{Vx}(1 - e^{-x}) \quad \text{(A2)}$$

where D is the dose absorbed and V is the compartment volume.[4]

The following question is addressed: How is a (macroscopic) difference between the (zero-order) absorption rate constants of two products related to the difference in their C_{max} values? Equation A1 may be rewritten as

$$x = \frac{k_{el}\, D}{k_o} \quad \text{(A3)}$$

where k_o is the zero-order absorption rate constant. Consider test and reference products with equal D, V, and k_{el} values.

The absorption rate constant of the test product, $k_{o(t)}$, has a different value from that of the reference product, $k_{o(r)}$.

Define

$$Q = \frac{x_t}{x_r} = \frac{k_{o(r)}}{k_{o(t)}} \quad \text{(A4)}$$

Then

$$\frac{\Delta k_o}{k_{o(r)}} = \frac{k_{o(t)} - k_{o(r)}}{k_{o(r)}} = \frac{1}{Q} - 1 \quad \text{(A5)}$$

By eqs A2 and A4

$$\frac{\Delta C_{max}}{C_{max(r)}} = \frac{C_{max(t)} - C_{max(r)}}{C_{max(r)}} = \frac{1 - e^{-Qx_r}}{Q(1 - e^{-x_r})} - 1 \quad \text{(A6)}$$

At the limit, as $x_r \to \infty$

$$\lim_{x_r \to \infty} \frac{\Delta C_{max}}{C_{max(r)}} = \frac{1}{Q} - 1 = \frac{\Delta k_o}{k_{o(r)}} \quad \text{(A7)}$$

Hence, as $x_r \to \infty$, the relative difference in C_{max} is equal to the relative difference in k_o.

Derive x with respect to k_o

$$\frac{dx}{dk_o} = -\frac{k_{el} D}{k_o^{\,2}} = -\frac{x}{k_o} \quad \text{(A8)}$$

The infinitesimal relative difference in C_{max} is defined by

$$\frac{dC_{max}}{C_{max}} = \frac{C'_{max}}{C_{max}} dx = -\frac{C'_{max}\, x}{C_{max}} \frac{dk_o}{k_o} = \left[\frac{1 - e^{-x}(x+1)}{1 - e^{-x}}\right] \frac{dk_o}{k_o} \quad \text{(A9)}$$

where eq A8 was used, and C'_{max} is the derivative of C_{max} with respect to x.

Define

$$F(x) = \frac{1 - e^{-x}(x+1)}{1 - e^{-x}} \quad \text{(A10)}$$

It may be proven (Appendix F) that $F(x)$ is a positive and monotone increasing function of x for $x > 0$.

As $x \to \infty$, $F(x)$ assumes its maximal value and therefore, for a constant value of dC_{max}/C_{max}, dk_o/k_o is minimal (by its absolute value) at that limit.

It is demonstrated in Appendix G that the macroscopic quantity $|\Delta k_o|/k_{o(r)}$ corresponding to a constant value of $|\Delta C_{max(r)}|/C_{max}$, assumes a minimum value as $x_r \to \infty$.

This value, which is equal (by eq A7) to $|\Delta C_{max}|/C_{max(r)}$ is a lower boundary to $|\Delta k_o|/k_{o(r)}$ (at any x_r) that corresponds to a constant relative difference between the C_{max} values. In other words, a relative difference of $\pm q$ in k_o corresponds to a relative difference in C_{max}, which is less than q by its absolute value. When $x_r \to \infty$, this relative difference in C_{max} approaches q (by its absolute value).

Hence, the in vivo limits $\Delta k_o/k_{o(r)} = \pm 0.2$ ensure the condition: $|\Delta C_{max}|/C_{max(r)} < 0.2$. These limits will be termed the "minimum range" limits. The "minimum range" limits are the widest (relative) rate constant limits common to all reference products. Being common to all reference products, the "minimum range" limits must be tighter than the widest feasible rate constant limits for any individual product. Hence the origin of the name.

Using eqs A5 and A6 it is possible to estimate (numerically) the value of $\Delta k_o/k_{o(r)}$ correlating to a certain relative difference in $C_{max,}$ as a function of x_r. Figure 1 depicts the best fitted $\Delta k_o/k_{o(r)}$ values related to $\Delta C_{max}/C_{max(r)}$ value of $+0.2$. An asterisk was added as a reminder that a standard $+20\%$ difference in C_{max} is involved.

For $x_r < 0.38$, $\Delta k_o^*/k_{o(r)}$ values diverge. This result means that an infinite relative increase in the $k_{o(r)}$ value is needed when $x_r < 0.38$ to observe a $+20\%$ change in C_{max}. Therefore, dose-dumping (due to a difference in the drug release rate) is not expected when $x_r < 0.38$. This is a consequence of the fact that for $x_r < 0.38$, C_{max} is closer to its maximal value (at $x \sim 0$) by $<20\%$.

The data presented in Figure 1 fit the equation

$$\Delta k_o^*/k_{o(r)} = 0.0018722 x_r^{-9.097} + 0.52492 x_r^{-2.003} + 0.2 \quad \text{(A11)}$$

The $\Delta k_o^*/k_{o(r)}$ values estimated with eq A11 are presented by the line in Figure 1. The accuracy of eq A11 was tested by using $\Delta k_o^*/k_{o(r)}$ values estimated by eq A11 in eqs A5 and A6 to evaluate $\Delta C_{max}/C_{max(r)}$. With 20 x_r values in the range $\{0.38 < x_r < 100\}$ the relative difference in C_{max} was close to 0.2 (ranging from 0.189 to 0.209), as presented in Figure 3. Figure 2 depicts the best fitted $\Delta k_o/k_{o(r)}$ values related to a $\Delta C_{max}/C_{max(r)}$ value of -0.2. The $(\bullet)$ superscript is a reminder that a standard -20% difference in C_{max} is involved. The data presented in Figure 2 fit the equation

$$\Delta k_o^\bullet/k_{o(r)} = -0.35753 e^{-4.4507 x_r} - 0.44063 e^{-1.0255 x_r} - 0.2 \quad \text{(A12)}$$

The fit is presented by the line in Figure 2. The accuracy of eq A12 was examined by using the values generated by this equation in eqs A5 and A6 to evaluate $\Delta C_{max}/C_{max(r)}$. The relative difference between the C_{max} values was close to -0.2 [from (-0.190) to (-0.202)] for 20 x_r values in the range $\{0.008 < x_r < 100\}$, as presented in Figure 4.

Equations A11 and A12 define the relative differences in the absorption rate constant values that are consistent with exactly $+20\%$ or -20% difference between the C_{max} values. Therefore, these equations constitute *the widest* possible absorption rate constant limits that ensure the bioequivalence of test and reference products. Hence, they will be termed the zero-order absorption "ideal" limits. The "ideal" limits are specific to each reference product.

An error in the estimation of $\Delta k_o^*/k_{o(r)}$ or $\Delta k_o^\bullet/k_{o(r)}$ by eqs A11 or A12 may result from a misevaluation of x_r. This misevaluation will lead to $\Delta C_{max}/C_{max(r)}$ values different from the expected values of $\sim +0.2$ or ~ -0.2, respectively. Figure 3 includes the effects of $+20\%$ or -20% errors in the estimation of x_r on the value of $\Delta C_{max}/C_{max(r)}$, when its

expected value is $\sim +0.2$ (i.e. when eq. A11 is used for an estimation of $\Delta k_o^*/k_{o(r)}$). In a similar way, Figure 4 includes the effect of +20% or −20% errors in the estimation of x_r on the value of $\Delta C_{max}/C_{max(r)}$ when its expected value is ~ -0.2 (i.e., when eq A12 is used for an estimation of $\Delta k_o^\bullet/k_{o(r)}$). An overestimation of x_r will lead to $|\Delta C_{max}|/C_{max(r)} < 0.2$. In this case, the $\Delta k_o^*/k_{o(r)}$ and $\Delta k_o^\bullet/k_{o(r)}$ values estimated with eqs A11 and A12 will lead to $\Delta C_{max}/C_{max(r)}$ values within the assumed boundary. However, when x_r is underestimated, $|\Delta C_{max}|/C_{max(r)} > 0.2$. The effect of an error in the estimation of x_r is especially pronounced for low values of x_r. Therefore, when the precise value of x_r is uncertain, it is good practice to use its highest estimated value to evaluate $\Delta k_o^*/k_{o(r)}$ or $\Delta k_o^\bullet/k_{o(r)}$. The resultant $\Delta C_{max}/C_{max(r)}$ value will then probably be confined within the ± 0.2 limits.

If the x_r value is unknown, using the "minimum range" rate limits: $\Delta k_o/k_{o(r)} = \pm 0.2$ will ensure the condition: $|\Delta C_{max}|/C_{max} < 0.2$.

Generally, it is desired to set the widest limits (on a variable) that are consistent with a certain constraint. The "ideal" limits are always wider than the "minimum range" limits. On the other hand, the "ideal" limits may be used only when the reference in vivo rate constants are known.

Appendix B: One-Compartment Model with First-Order Absorption

Consider a one-compartment open model with first-order absorption. The parameter C_{max} is given by[4]

$$C_{max} = \frac{k_a D}{V(k_a - k_{el})}(e^{-k_{el}t_{max}} - e^{-k_a t_{max}}) \qquad (B1)$$

where k_a is a first-order absorption constant. The parameter t_{max} is given by

$$t_{max} = \frac{1}{k_a - k_{el}}\ln[k_a/k_{el}] \qquad (B2)$$

Define the dimensionless variable y

$$y = k_{el}/k_a \qquad (B3)$$

Then, by eq B2,

$$e^{-k_{el}t_{max}} = y^{y/(1-y)} \qquad (B4)$$

$$e^{-k_a t_{max}} = y^{1/(1-y)} \qquad (B5)$$

Using eqs B4 and B5 in eq B1 produces

$$C_{max} = \frac{D}{V} y^{y/(1-y)} \qquad (B6)$$

It is of interest to investigate the effect of a (macroscopic) difference between the (first-order) absorption rate constants of two products on their relative C_{max} values. Consider test and reference products with equal D, V, and k_{el} values. The first-order rate constant of the test product, $k_{a(t)}$ has a different value from that of the reference product, $k_{a(r)}$.

Define

$$Q = \frac{y_t}{y_r} = \frac{k_{a(r)}}{k_{a(t)}} \qquad (B7)$$

Then

$$\frac{\Delta k_a}{k_{a(r)}} = \frac{k_{a(t)} - k_{a(r)}}{k_{a(r)}} = \frac{1}{Q} - 1 \qquad (B8)$$

Equation B8 is identical to eq A5 except that here first-order constants are involved. By the use of eq B6,

$$\frac{\Delta C_{max}}{C_{max(r)}} = \frac{C_{max(t)} - C_{max(r)}}{C_{max(r)}} = \frac{y_t^{y_t/(1-y_t)} - y_r^{y_r/(1-y_r)}}{y_r^{y_r/(1-y_r)}} = \frac{(Qy_r)^{Qy_r/(1-Qy_r)} - y_r^{y_r/(1-y_r)}}{y_r^{y_r/(1-y_r)}} = \frac{(Qy_r)^{Qy_r/(1-Qy_r)}}{y_r^{y_r/(1-y_r)}} - 1 \qquad (B9)$$

At the limit as $y_r \to \infty$,

$$\lim_{y_r \to \infty} \frac{\Delta C_{max}}{C_{max(r)}} = \frac{1}{Q} - 1 = \frac{\Delta k_a}{k_{a(r)}} \qquad (B10)$$

Equation B10 is identical to eq A7. By eq B10, as $y_r \to \infty$, the relative difference in C_{max} is equal to the relative difference in k_a.

Derive y with respect to k_a

$$\frac{dy}{dk_a} = -\frac{k_{el}}{k_a^2} = -\frac{y}{k_a} \qquad (B11)$$

The infinitesimal relative difference in C_{max} is defined by

$$\frac{dC_{max}}{C_{max}} = \frac{C'_{max}}{C_{max}}\,dy = -\frac{C'_{max}}{C_{max}}\,y\,\frac{dk_a}{k_a} = \left[\frac{(y - 1 - \ln y)y}{(1-y)^2}\right]\frac{dk_a}{k_a} \qquad (B12)$$

where eq B11 was used and C'_{max} is the derivative of C_{max} with respect to y (derivation of eq B6).

Define

$$G(y) = \frac{(y - 1 - \ln y)y}{(1-y)^2} \qquad (B13)$$

It may be proven (see Appendix H) that $G(y)$ is a positive and monotone increasing function of y, for $y > 0$ ($y \neq 1$). Therefore, as $y \to \infty$, $G(y)$ assumes a maximal value. Hence, by eq B12, for a constant value of dC_{max}/C_{max}, dk_a/k_a is minimal (by its absolute value) as $y \to \infty$, exactly as in the zero-order model when $x \to \infty$.

By replacing x with y and k_o with k_a in Appendix G, it is demonstrated that the macroscopic quantity $|\Delta k_a|/k_{a(r)}$, corresponding to a constant value of $|\Delta C_{max}|/C_{max(r)}$ assumes a minimum value as $y_r \to \infty$, just as in the zero-order model when $x_r \to \infty$. This value, which is equal (by eq B10) to $|\Delta C_{max}|/C_{max(r)}$, is a lower boundary of the absolute value of $|\Delta k_a|/k_{a(r)}$ (at any y_r) that corresponds to a constant relative difference in C_{max}. In other words, a relative difference of $\pm q$ in k_a corresponds to a relative difference in C_{max} that is less than q by its absolute value. When $y_r \to \infty$, this relative change in C_{max} approaches q (by its absolute value). Hence the in vivo "minimum range" limits $\Delta k_a/k_{a(r)} = \pm 0.2$, ensure the condition $\Delta C_{max}/C_{max(r)} < 0.2$, just as in the zero-order case.

Using eqs B8 and B9, it is possible to estimate (numerically) the value of $\Delta k_a/k_{a(r)}$ corresponding to a certain relative difference in C_{max} as a function of y_r. Figure 5 depicts the best fitted $\Delta k_a/k_{a(r)}$ values related to a $\Delta C_{max}/C_{max(r)}$ value of ± 0.2. Like before, the asterisk stands for a standard +20% difference in C_{max}. For $y_r < 0.07$, the $\Delta k_a/k_{a(r)}$ values diverge, indicating that under this condition, a

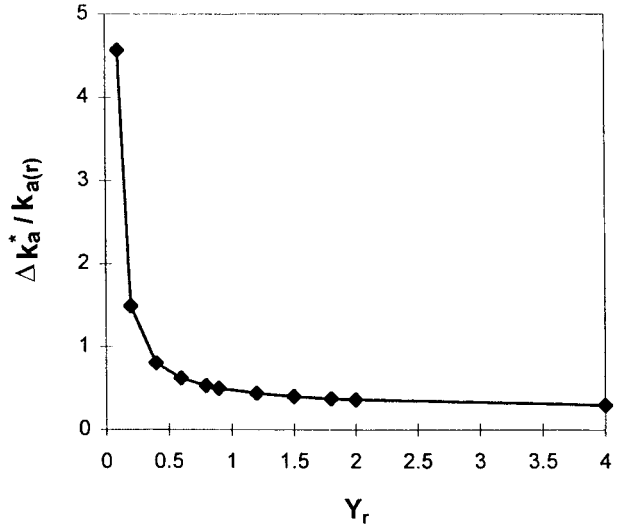

Figure 5—The relative difference in the (first-order) absorption rate constant values correlating to a standard +20% difference in the C_{max} values, as a function of y_r. The line presents $\Delta k_a^*/k_{a(r)}$ values estimated by the use of eq B14. In the presence of linear IVIVC, the same line defines the upper limit of the "ideal" specifications.

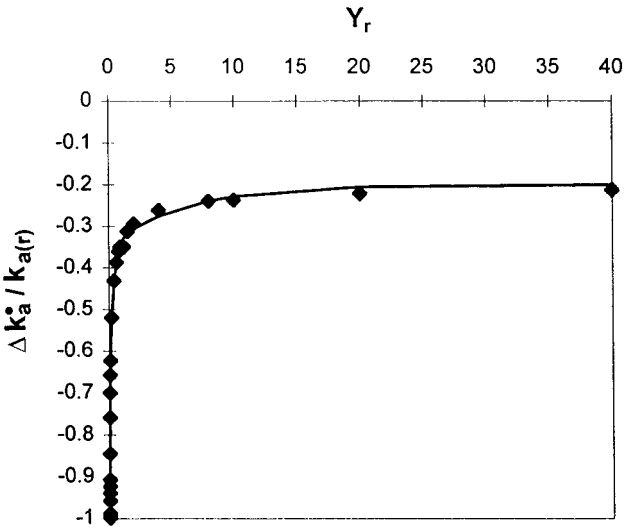

Figure 6—The relative difference in the (first-order) absorption rate constant values correlating to a standard –20% difference in the C_{max} values, as a function of y_r. The line presents $\Delta k_a^\bullet/k_{a(r)}$ values estimated by the use of eq B15. In the presence of linear IVIVC, the same line defines the lower limit of the "ideal" specifications.

+20% difference in C_{max} (a dose-dumping due to a difference in the release rates) is impossible. This is a consequence of the fact that, for $y_r < 0.07$, C_{max} is closer to its maximal value (at $y \sim 0$) by <20%.

The data presented in Figure 5 fit the equation

$$\Delta k_a^*/k_{a(r)} = 0.277 y_r^{-0.767} + 0.0271 y_r^{-3.005} + 0.2 \qquad \text{(B14)}$$

The $\Delta k_a^*/k_{a(r)}$ values estimated with eq B14 are presented by the line in Figure 5. The accuracy of eq B14 was tested by using the estimated $\Delta k_a^*/k_{a(r)}$ values in eqs B8 and B9 to evaluate $\Delta C_{max}/C_{max(r)}$. Twenty y_r values in the range $\{0.07 < y_r < 100\}$ were examined. The relative difference in C_{max} was close to 0.2 (from 0.184 to 0.201), as presented in Figure 7.

Figure 6 depicts the best fitted $\Delta k_a/k_{a(r)}$ value related to a $\Delta C_{max}/C_{max(r)}$ value of −0.2. The (•) superscript, as in the zero-order model, stands for a standard −20% difference

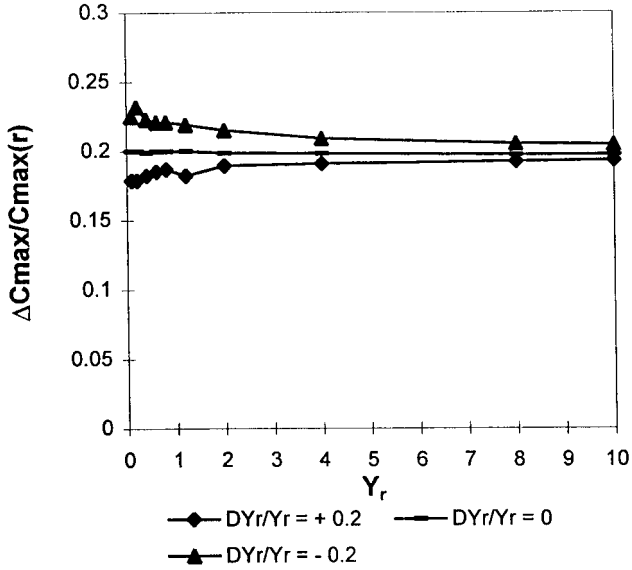

Figure 7—$\Delta C_{max}/C_{max(r)}$ values generated for the first-order case by using $\Delta k_a^*/k_{a(r)}$ values (defined by eq B14) in eqs. B8 and B9. The effects of +20% or −20% errors in the estimation of y_r ($Dy_r/y_r = +0.2$ or $Dy_r/y_r = -0.2$) are also included.

in C_{max}. The data presented in Figure 6 fit the equation

$$\Delta k_a^\bullet/k_{a(r)} = -0.299\, e^{-26.4 y_r} - 0.348\, e^{-3.128 y_r} - 0.146\, e^{-0.165 y_r} - 0.2 \qquad \text{(B15)}$$

The fit is presented by the line in Figure 6. The accuracy of eq B15 was examined, like before, by using the values generated by this equation in eqs B8 and B9 to evaluate $\Delta C_{max}/C_{max(r)}$. With 20 y_r values examined in the range $\{0.004 < y_r < 100\}$, the $\Delta C_{max}/C_{max(r)}$ values were between −0.186 and −0.212, as presented in Figure 8.

Like eqs A11 and A12, eqs B14 and B15 define the relative differences in the absorption rate constant values, consistent with exactly +20% or −20% differences between the C_{max} values. Therefore, these equations provide *the widest* possible rate constant limits that ensure the bioequivalence of the test and reference products. They will be termed the first-order absorption "ideal" limits. These limits are specific to each reference product.

An error in the estimation of $\Delta k_a^*/k_{a(r)}$ or $\Delta k_a^\bullet/k_{a(r)}$ by eqs B14 or B15 may result from a misevaluation of y_r. This misevaluation will lead to $\Delta C_{max}/C_{max(r)}$ values different from the expected values of $\sim +0.2$ or ~ -0.2, respectively. Figure 7 presents the effects of +20% or −20% errors in the estimation of y_r on the value of $\Delta C_{max}/C_{max(r)}$, when its expected (standard) value is $\sim +0.2$ (i.e., when eq B14 is used for the estimation of $\Delta k_a^*/k_{a(r)}$). In a similar way, Figure 8 presents the effect of +20% or −20% errors in y_r on the value of $\Delta C_{max}/C_{max(r)}$ when its expected (standard) value is ~ -0.2 (i.e., when eq B15 is used for an estimation of $\Delta k_a^\bullet/k_{a(r)}$). As in the zero-order case, an overestimation of y_r will lead to $\Delta C_{max}/C_{max(r)}$ values within the boundaries assumed. However, when y_r is underestimated, $\Delta C_{max}/C_{max(r)} > 0.2$. As before, the effect of an error in y_r is especially pronounced for low y_r values.

When the precise value of y_r is uncertain, it is a good practice to use its highest estimated value in eqs B14 and B15. If the y_r value is unknown, the "minimum range" limits $\Delta k_a/k_{a(r)} = \pm 0.2$ should be used. The "ideal" limits are always wider. They are, however, feasible only when the reference in vivo data are available.

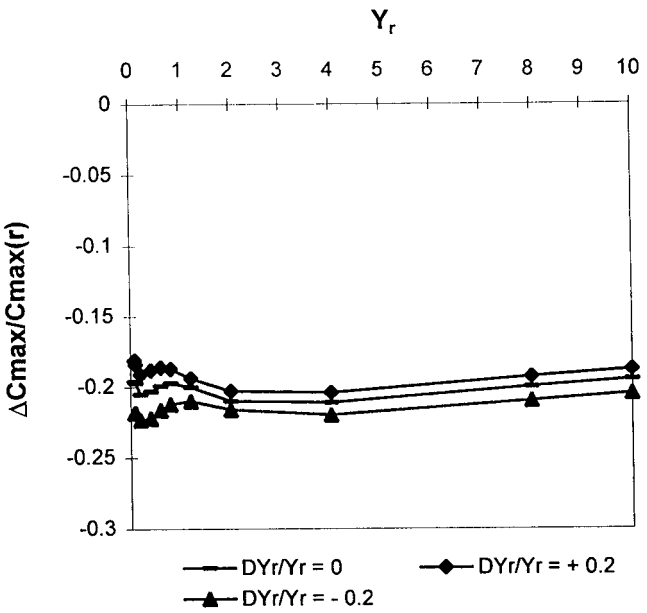

Figure 8—$\Delta C_{max}/C_{max(r)}$ values generated for the first-order case by using $\Delta k_a^{\bullet}/k_{a(r)}$ values (defined by eq. B15) in eqs B8 and B9. The effects of +20% or –20% errors in the estimation of y_r ($Dy_r/y_r = +0.2$ or $Dy_r/y_r = -0.2$) are also included.

Appendix C: Multicompartment Model with Zero-Order Absorption

When the disposition phase of a drug with a zero-order absorption is appropriately described by n exponential terms, with n first-order rate constants: $\alpha_1 > \alpha_2 > \ldots > \alpha_n$, the dependence of C_{max} on the zero-order rate constant is specific to the kinetic model involved. Consider an n-compartment model with a zero-order absorption and m (microscopic) first-order disposition rate constants k_j (j = 1, ... m). When elimination occurs from the central compartment, the concentration in this compartment (while absorption is continuing) is given by[4]

$$C(t) = \frac{D/T}{V_c}\sum_{l=1}^{n}\frac{(1-e^{-\alpha_l t})\prod_{i=2}^{n}(E_i-\alpha_l)e^{-\alpha_l t}}{-\alpha_l\prod_{\substack{i=1\\ i\neq l}}^{n}(\alpha_i-\alpha_l)} \qquad (C1)$$

where V_c is the volume of the central compartment and E_i is the sum of the exit rate constants from the i^{th} compartment. The parameter α_l can be expressed in terms of the k_j values (it is not dependent on other physical constants). Because α_l has the same dimensions as k_j (time^{-1}), α_l is a homogeneous function of the first degree with respect to the k_j values. That is, α_l (k_1, ..., k_m) satisfies the identity

$$\alpha_l(qk_1,....qk_m) = q\alpha_l(k_1,....k_m) \qquad (C2)$$

where q is any number.

Equations C1 and C2 imply

$$C(D/V_cT,k_1,....,k_m,t) = C(qD/V_cT,qk_1,...,qk_m,t/q) \qquad (C3)$$

When $t = T$, we have

$$C_{max} = C(D/V_cT,k_1,...k_m,T) = C(qD/V_cT,qk_1,...,qk_m,T/q) \qquad (C4)$$

Using $q = T$ in eq (C4) provides

$$C_{max} = C(D/V_c, k_1T,,...k_mT) \qquad (C5)$$

Therefore, C_{max} is dependent on the m dimensionless variables: k_1T, ... k_mT and on D/V_c. The same conclusion may be reached when the elimination is not from the central compartment or when the concentration involved is that of a peripheral compartment.

The one-compartment model discussed in Appendix A is a special case with $m = 1$ and $k_1 = k_{el}$. As demonstrated

$$C_{max}\text{ (one compartment)} = C(D/V_c, x) \qquad (C6)$$

where $x = k_{el}\ T$.

If a one-compartment model is used (as an approximation) to describe the kinetics of a drug with n exponential disposition terms, the best-fitted disposition rate constant must be smaller than α_1 (and larger than α_n).

Define

$$x_1 = \frac{\alpha_1 D}{k_o}(=\alpha_1 T) \qquad (C7)$$

If $x_{1(r)}$ is used instead of x_r in eq A6, it is reasonable to believe that

$$\frac{|\Delta C_{max}|}{C_{max(r)}} < \frac{1-e^{-Qx_{1(r)}}}{Q(1-e^{x_{1(r)}})} - 1 \qquad (C8)$$

because the $x_{1(r)}$ is an upper boundary of x_r. For the same reason, using $x_{1(r)}$ values as defined by eq C7 in eqs A11 or A12 will generate $|\Delta C_{max}|/C_{max(r)} < 0.2$.

Four different compartment models (with a zero-order absorption) were used to assess this assumption: a classical two-compartment model, a classical three-compartment model, a two-compartment model with a central absorption and a peripheral elimination, and a three-compartment model with a central absorption and a peripheral elimination. Values between 0 and 1 were randomly assigned to the disposition rate constants of each model. For this purpose, a computerized random number generator was used. Ten sets of disposition rate constants were thus produced for each model. For the two-compartment models, the values of the three microscopic disposition rate constants were assigned in this same way. For the three-compartment models, the values of the three macroscopic rate constants and of two of the microscopic rate constants were similarly assigned.

Five absorption rate constant values were defined such that

$$x_{1(r)} = 0.1,\ 0.5,\ 1.5,\ 5,\ 30 \qquad (C9)$$

where eq C7 was used to define $x_{1(r)}$. In this way, a total of 50 different sets of constants were generated for each model.

Equations A11 and A12 with $x_{1(r)}$ substituted for x_r, were utilized to produce $k^*_{o(t)}$ (the upper boundary of $k_{o(t)}$) or $k^{\bullet}_{o(t)}$ (the lower boundary of $k_{o(t)}$). These values were introduced into the model to estimate $C_{max(t)}$.

In each of the four models examined, the inequality

$$|\Delta C_{max}|/C_{max(r)} < 20\% \qquad (C10)$$

was verified for all 50 data sets. The values for $|\Delta C_{max}|/C_{max(r)}$ were in the range of ~ 1% to 19%. Hence, eqs A11 and A12 (the zero-order "ideal" limits) may be used to assess the absorption rate limits for products with a zero-order absorption and a multiexponential disposition.

The relative rate limits defined by eqs A11 and A12 are wider than ±20% for any finite value of $x_{r(1)}$. Because eq C10 holds when the limits are wider than 20%, it will certainly hold when the relative rate is limited to ±20% (in each of the four models used, for each of the sets of data examined). Thus, the validity of the "minimum range" rate limits is verified for products with a zero-order absorption and a multiexponential disposition.

Appendix D: Multicompartment Model with First-Order Absorption

For the case of multiexponential disposition, consider an *n*-compartment model with a first-order absorption (k_a) and m(microscopic) first-order disposition rate constants k_j ($j = 1,...m$). When the elimination occurs from the central compartment, the concentration in the central compartment is given by[4]

$$C = \frac{k_a D}{V_c} \frac{\prod_{i=2}^{n}(E_i - k_a)}{\prod_{i=1}^{n}(\alpha_i - k_a)} e^{-k_a t} + \frac{k_a D}{V_c} \sum_{l=1}^{n} \frac{\prod_{i=2}^{n}(E_i - \alpha_l)}{(k_a - \alpha_l)\prod_{\substack{i=1 \\ i \neq l}}^{n}(\alpha_i - \alpha_l)} e^{-\alpha_l t} \quad \text{(D1)}$$

where α_l is a first-order macroscopic disposition constant, V_c is the volume of the central compartment, and E_i is the sum of the exit rate constants from the i^{th} compartment.

By eqs C2 and D1, the following identity is satisfied

$$C(D/V_c, k_a, k_1,...,k_m, t) = C(D/V_c, qk_a, qk_1,...,qk_m, t/q) \quad \text{(D2)}$$

where q can be any number.

Therefore, under the transformations

$$k_a \rightarrow qk_a$$

$$k_1 \rightarrow qk_1$$

$$\vdots$$

$$k_m \rightarrow qk_m$$

The value of the untransformed function (at any time point t) is equal to the value of the transformed function (at time point t/q). In particular, the maximum value of the untransformed function (at t_{max}) is equal to the maximum value of the transformed function (at t_{max}/q). Hence

$$C(D/V_c, k_a, k_1,...k_m, t_{max}) = C(D/V_c, qk_a, qk_1,...qk_m, \hat{t}_{max}) \quad \text{(D3)}$$

where $\hat{t}_{max}$ is the time correlating to maximum value of the transformed function.

Therefore, C_{max} is a function of the following variable

$$C_{max} = C(D/V_c, qk_a, qk_1,...,qk_m) \quad \text{(D4)}$$

However, its value is independent of the value of q. The parameter t_{max} is not included among the variables in eq D4 because C_{max} is defined at $t = t_{max}$ (C_{max} is not a function of t_{max}).

Using $q = 1/k_a$ in eq D4 provides

$$C_{max} = C(D/V_c, k_1/k_a,...,k_m/k_a) \quad \text{(D5)}$$

C_{max} is therefore dependent on the m dimensionless variables ($k_1/k_a,...k_m/k_a$) and on D/V_c. The same conclusion may be reached when the elimination is not limited to the central compartment, or when the concentration involved is that of a peripheral compartment.

In the one-compartment case

$$C_{max} = C(D/V_c, k_1/k_a) \quad \text{(D6)}$$

This is demonstrated by eq B6 (with $k_1 = k_{el}$).

Define

$$y_1 = \frac{\alpha_1}{k_a} \quad \text{(D7)}$$

where α_1 is the largest first-order (macroscopic) disposition rate constant. If $y_{1(r)}$ is used instead of y_r in eq B9, it is reasonable to believe that

$$\frac{|\Delta C_{max}|}{C_{max}} < \frac{Qy_{1(r)}^{Qy_{1(r)}/(1-Qy_{1(r)})}}{y_{1(r)}^{y_{1(r)}/(1-y_{1(r)})}} - 1 \quad \text{(D8)}$$

because y_1 is an upper boundary of y. For the same reason, using $y_{1(r)}$ values as defined by eq D7 in eqs B14 or B15 will generate $|\Delta C_{max}|/C_{max} < 0.2$.

For assessing this assumption, the four compartment models used in Appendix C, were utilized with a first-order absorption. The procedure of assigning values to the disposition rate constants was identical to that previously used. The five absorption rate constant values were defined such that

$$y_{1(r)} = 0.1,\ 0.5,\ 1.5,\ 5,\ 30 \quad \text{(D9)}$$

where eq D7 was used to define $y_{1(r)}$. Equations B14 and B15 with $y_{1(r)}$ substituted for y_r were used to produce $k^*_{a(t)}$ (the upper boundary of $k_{a(t)}$) or $\Delta k^{\bullet}_{a(t)}$ (the lower boundary of $k_{a(t)}$). These values were introduced into the model to estimate $C_{max(t)}$.

As in the zero-order models, with each of the four models examined, the inequality

$$|\Delta C_{max}|/C_{max} < 20\% \quad \text{(D10)}$$

was verified for all 50 data sets. Hence, eqs B14 and B15 (the first-order "ideal" limits) may be used to evaluate the absorption rate limit for products with a first-order absorption and a multiexponential disposition.

The relative rate limits defined by eqs B14 and B15 are wider than ±20% for any finite value of $y_{1(r)}$. Hence, it is clear that limiting the relative rate to ±20% will also lead to eq D10 in each of the four models used and for each of the data sets examined. Thus, the "minimum range" limits are applicable for products with a first-order absorption and a multiexponential disposition.

Appendix E: The Effect of a Difference in the Extent of Absorption

It has been postulated, so far, that both test and reference products are absorbed to the same extent. Suppose that each product is absorbed to a different extent.

By the zero-order or the first-order models (mono- or multiexponential disposition), C_{max} may be presented as

$$C_{max} = D \cdot E(z) \tag{E1}$$

where D is the dose absorbed and z stands for either x or y, depending on the model used. The function E depends on the particular model.

Therefore

$$dC_{max} = \frac{\partial C_{max}}{\partial D} dD + \frac{\partial C_{max}}{\partial z} dz \tag{E2}$$

Using eq E1 in eq E2, we get

$$\frac{dC_{max}}{C_{max}} = \frac{dD}{D} + \left[\frac{dC_{max}}{C_{max}}\right]_D \tag{E3}$$

By eq E3, the total relative difference in C_{max} is the sum of the relative difference in D and the "partial" relative difference in C_{max} (when D = constant).

Hence, when the test and reference products are absorbed to a different extent, eq A6 for the zero-order case is generalized as

$$\frac{\Delta C_{max}}{C_{max(r)}} = \frac{1 - e^{-Qx_r}}{Q(1 - e^{-x_r})} - 1 + \frac{\Delta D}{D_r} \tag{E4}$$

Similarly, eq B9 for the first-order case is replaced by

$$\frac{\Delta C_{max}}{C_{max(r)}} = \frac{(Qy_r)^{Qy_r/(1-Qy_r)}}{y_r^{y_r/(1-y_r)}} - 1 + \frac{\Delta D}{D_r} \tag{E5}$$

For the zero-order model, at the limit as $x_r \to \infty$

$$\lim_{x_r \to \infty} \frac{\Delta C_{max}}{C_{max(r)}} = \frac{1}{Q} + 1 + \frac{\Delta D}{D_r} = \frac{\Delta k_o}{k_{o(r)}} + \frac{\Delta D}{D_r} \tag{E6}$$

Similarly, for the first-order model when $y_r \to \infty$

$$\lim_{y_r \to \infty} \frac{\Delta C_{max}}{C_{max(r)}} = \frac{1}{Q} + 1 + \frac{\Delta D}{D_r} = \frac{\Delta k_a}{k_{a(r)}} + \frac{\Delta D}{D_r} \tag{E7}$$

Equations E6 and E7 are generalizations of eqs A7 and B10, respectively.

Appendix F: The Function *F(x)*

By eq A10

$$F(x) = \frac{1 - e^{-x}(x + 1)}{1 - e^{-x}}$$

Define

$$f(x) = 1 - e^{-x}(x + 1) \tag{F1}$$

Then

$$f'(x) = xe^{-x} > 0 \text{ for } x > 0 \tag{F2}$$

By eq F1

$$f(0) = 0 \tag{F3}$$

Hence, eq F2 implies

$$f(x) > 0 \text{ for } x > 0 \tag{F4}$$

It is also true that

$$1 - e^{-x} > 0 \quad \text{when} \quad x > 0 \tag{F5}$$

Therefore

$$F(x) = \frac{f(x)}{1 - e^{-x}} > 0 \quad \text{when} \quad x > 0 \tag{F6}$$

Derive $F(x)$ with respect to x

$$F'(x) = \frac{e^{-x}(e^{-x} + x - 1)}{(1 - e^{-x})^2} \tag{F7}$$

Define

$$p(x) = e^{-x} + x - 1 \tag{F8}$$

Then

$$p'(x) = 1 - e^{-x} > 0 \quad \text{when} \quad x > 0 \tag{F9}$$

By eq F8, $p(0) = 0$. Therefore eq F9 implies

$$p(x) > 0 \quad \text{when} \quad x > 0 \tag{F10}$$

It is also true that

$$\frac{e^{-x}}{(1 - e^{-x})^2} > 0 \quad \text{for any } x \tag{F11}$$

Therefore

$$F'(x) = \frac{e^{-x}p(x)}{(1 - e^{-x})^2} > 0 \quad \text{when} \quad x > 0$$

Hence $F(x)$ is a positive monotone increasing function of x for $x > 0$.

Appendix G: The Asymptotic Behavior of $\Delta k_o/k_{o(r)}$

$$\int_r^t \frac{dC_{max}}{C_{max}} = \ln \frac{C_{max(t)}}{C_{max(r)}} = \ln\left(\frac{\Delta C_{max}}{C_{max(r)}} + 1\right) \tag{G1}$$

A constant value of the integral on the left-hand side of eq G1 corresponds to a constant value of $\Delta C_{max}/C_{max(r)}$.

It was proven that the infinitesimal quantity dk_o/k_o, corresponding to a constant infinitesimal relative difference in C_{max} (dC_{max}/C_{max}), is minimal (by its absolute value) as $x \to \infty$. Therefore, the integrated form $\int_r^t dk_o/k_o$ corresponding to a constant value of $\int_r^t dC_{max}/C_{max}$ must also assume a minimum value as $x_r \to \infty$.

Because

$$\int_r^t \frac{dk_o}{k_o} = \ln \frac{k_{o(t)}}{k_{o(r)}} \tag{G2}$$

$|\ln(k_{o(t)}/k_{o(r)})|$, corresponding to a constant value of $\Delta C_{max}/C_{max(r)}$, has a minimum value as $x_r \to \infty$.

When $k_{o(t)}/k_{o(r)} > 1$, both $k_{o(t)}/k_{o(r)}$ and $|k_{o(t)}/k_{o(r)} - 1|$ attain a minimum value as $x_r \to \infty$. When $k_{o(t)}/k_{o(r)} < 1$, $k_{o(t)}/k_{o(r)}$ is maximal as $x_r \to \infty$, whereas $|k_{o(t)}/k_{o(r)} - 1|$ is minimal at this limit.

Hence $|k_{o(t)}/k_{o(r)} - 1|$ $(=|\Delta k_o|/k_{o(r)})$ corresponding to a constant value of $|\Delta C_{max}|/C_{max(r)}$, is minimal as $x_r \rightarrow \infty$.

Appendix H: The Function *G(y)*

By eq B13

$$G(y) = \frac{(y - 1 - \ln y)y}{(1 - y)^2}$$

Define

$$g(y) = y - 1 - \ln y \tag{H1}$$

Then

$$g'(y) = \frac{y - 1}{y} \tag{H2}$$

By eq H2

$$g'(y) > 0 \quad \text{for} \quad y > 1 \tag{H3}$$

$$g'(y) < 0 \quad \text{for} \quad 0 < y < 1 \tag{H4}$$

By eq H1 $g(y = 1) = 0$; hence, eq H3 implies

$$g(y) > 0 \quad \text{for} \quad y > 1 \tag{H5}$$

For the same reason, eq H4 implies

$$g(y) > 0 \quad \text{for} \quad 0 < y < 1 \tag{H6}$$

Therefore

$$G(y) = \frac{g(y)}{(1 - y)^2} y > 0 \quad \text{for} \quad y > 0 \tag{H7}$$

Derive $G(y)$ with respect to y

$$G'(y) = \frac{(y - 1 - \ln y)(1 + y) - (1 - y)^2}{(1 - y)^3} \tag{H8}$$

Define

$$h(y) = (y - 1 - \ln y)(1 + y) - (1 - y)^2 \tag{H9}$$

Then

$$h'(y) = 1 - \ln y - y^{-1} \tag{H10}$$

Suppose $h'(y) = 0$, then by eq H10

$$\ln y = \frac{y - 1}{y} \tag{H11}$$

Equation H11 is satisfied when $y = 1$. Therefore, $y = 1$ is a solution for $h'(y) = 0$. We shall prove that $y = 1$ is the only solution for $h'(y) = 0$ $(0 < y < \infty)$:

When $y > 0$, both $\ln y$ and $(y - 1)/y$ are monotone increasing functions of y, as demonstrated by eqs H12 and H13

$$[\ln y]' = \frac{1}{y} \tag{H12}$$

$$\left[\frac{y - 1}{y}\right]' = \frac{1}{y^2} \tag{H13}$$

By eqs H12 and H13

$$[\ln y]' > \left[\frac{y - 1}{y}\right] \quad \text{for} \quad y > 1 \tag{H14}$$

$$[\ln y]' < \left[\frac{y - 1}{y}\right] \quad \text{for} \quad 0 < y < 1 \tag{H15}$$

Therefore, for $y > 1$, $\ln y$ increases (with y) faster than $(y - 1)/y$, and the functions do not cross each other. For $0 < y < 1$, $\ln y$ decreases (when y decreases) slower than $(y - 1)/y$ and again, both functions do not cross. Therefore, $y = 1$ is the only solution for $h'(y) = 0$ $(0 < y < \infty)$.

A second differentiation of $h(y)$ with respect to y, provides

$$h''(y) = \frac{1}{y} + \frac{1}{y^2} \tag{H16}$$

At $y = 1$

$$h''(y = 1) = 0 \tag{H17}$$

Therefore $y = 1$ is an inflection point of $h(y)$. Because $y = 1$ is the only point where eq H11 holds, $h(y)$ is monotone for $0 < y < \infty$. By substituting any positive value $(\neq 1)$ for y in eq H10, it is found that

$$h'(y) < 0 \tag{H18}$$

Therefore, $h(y)$ is a monotone decreasing function of y for $0 < y < \infty$.

By eq H9

$$h(y = 1) = 0 \tag{H19}$$

Hence

$$h(y < 1) > 0 \tag{H20}$$

$$h(y > 1) < 0 \tag{H21}$$

Therefore

$$G'(y) = \frac{h(y)}{(1 - y)^3} > 0 \quad \text{for} \quad 0 < y < \infty \ (y \neq 1)$$

It may be concluded that $G(y)$ is a positive and monotone increasing function of y for $0 < y < \infty$ $(y \neq 1)$ and it is undefined at $y = 1$.

Accepted for publication December 10, 1998.

Abstract □ We present a model for perfusion of the isolated perfused neonatal sheep liver which allows examination of drug disposition by the intact organ. We studied the disposition of sodium taurocholate (TC) in seven neonatal lambs (ages 2–11 days) and compared the results with earlier data from the perfused fetal sheep liver (Ring, J. A. et al. *Biochem. Pharmacol*. **1994**, *48*, 667–674). Measurements of perfusion pressure, oxygen consumption, lactate:pyruvate ratio, bile flow, and liver histology indicated that the preparation was both viable and stable over a 2 h period. [^{14}C]-labeled TC was added to the reservoir by constant infusion (30 μmol/h) and the ductus venosus shunt quantitated by injection of [^{153}Gd]-labeled microspheres. Shunt-corrected hepatic extraction ratio of TC was 0.56 ± 0.14 (fetal 0.23 ± 0.16, $p < 0.005$) and clearance of TC was 0.92 ± 0.35 mL/min/g liver (fetal 0.44 ± 0.23 mL/min/g, $p < 0.01$). We conclude that the isolated perfused neonatal sheep liver is a useful experimental model which will facilitate the study of the developmental physiology and pharmacology of the liver. There is considerable maturation of the biliary excretion of TC between the late fetal and early neonatal periods in the lamb.

Introduction

Sodium taurocholate (TC) is a principal bile salt in many mammalian species, including humans.[1] In the adult, TC undergoes an efficient enterohepatic circulation from bile to small intestine, active reabsorption from the terminal ileum, and then hepatic uptake and re-excretion into bile. TC is highly cleared from portal plasma by the liver cell and concentratively excreted into bile.[2] In contrast to many highly cleared drugs, TC is taken up by the liver by an active or facilitated transport process[3] and is then actively secreted into bile.[2]

Several studies have examined TC transport in the developing liver, both in late fetal and neonatal life.[4−7] In general they have shown, in several species, that hepatic transport processes of TC appear to be immature in the fetus and neonate. The same can also be said of many drug metabolic processes.[8,9] One of the difficulties encountered in studying fetal hepatic function in vivo is the inability to obtain samples consistently from, for example, hepatic outflow vessels or the bile duct. This leads to difficulties in defining fetal hepatic clearance and differentiating this from placental transfer and subsequent clearance by maternal organs. To overcome these problems we have recently developed the in-situ isolated, perfused fetal sheep liver model.[4] This has allowed detailed study of TC transport and the metabolism of a number of drugs by the fetal liver near term.[10,11]

The present study details the development of an analogous model in the neonatal sheep. This allows direct comparison of a variety of hepatic functions at various times before and after birth, a period of dramatic physiological change. We present here the findings on neonatal TC transport and compare them with our earlier data from late fetal life.

Experimental Section

Materials and Reagents—[^{14}C]TC (99% pure by TLC, 1.7 GBq/mmol) and [^{153}Gd] microspheres (37-185 MBq/g) were purchased from NEN (Boston, MA). D-Glucose and unlabeled TC (sodium salt) were obtained from Sigma Chemical Co. (St. Louis, MO), and bovine serum albumin (fraction V) from the Commonwealth Serum Laboratories (Melbourne, Victoria, Australia). Hartman's solution and sodium heparin were purchased from David Bull laboratories (Melbourne, Victoria, Australia).

Animals and Surgical Procedure—The experiments were approved by the Austin and Repatriation Medical Centre (ARMC) Animal Welfare Ethics Committee. Experiments were conducted in seven neonatal sheep between 2 and 11 days of age (2, 2, 3, 6, 8, 10, and 11 days). Pregnant ewes were supplied by a contracted local farmer and delivered to the animal house at least 2 weeks before the scheduled parturition date. All lambs were born by natural delivery at the ARMC and fed naturally by their mothers.

Anaesthesia was induced with intravenous sodium thiopental, a tracheostomy performed, and the lamb intubated and ventilated. Anaesthesia was maintained with halothane. A midline abdominal incision was performed and the remnant of the umbilical vein ligated. The portal vein, hepatic artery, bile duct, and superior mesenteric vein were located, and the gall bladder was isolated by ligating the cystic duct. The bile duct was cannulated (internal diameter (i.d.) 1.0 mm, external diameter (o.d.) 1.5 mm) and left to drain externally into a collection tube. Loose ties were applied around the portal vein, hepatic artery, and superior mesenteric vein. The inferior vena cava above the renal veins was located and a loose tie applied. A midline thoracotomy was performed to expose the suprahepatic inferior vena cava, and a loose tie was applied. A silastic inflow cannula (o.d. 6 mm, i.d. 4.5 mm, with an in-line small preliver bubble trap) primed with Hartman's solution at 37 °C, containing sodium heparin (5 units/mL), was then prepared for portal vein cannulation.

The superior mesenteric vein was ligated distally and cannulated with the inflow cannula via a proximal incision. The cannula was passed down the superior mesenteric vein to the portal vein, visually confirmed to be in the correct position and then secured. The supra-hepatic inferior vena cava was cannulated (o.d. 8 mm, i.d. 6 mm) and left to drain externally. The loose ties around the hepatic artery and inferior vena cava above the renal veins were secured, isolating the liver, which was flushed with heparinized Hartman's solution until it had uniformly blanched. Perfusion was commenced by connecting the primed perfusion circuit to the

silastic inflow cannula, and the distal end of the outflow catheter was connected to the reservoir to complete the recirculating system. The liver was perfused in situ and covered with saline-soaked gauze. The lamb was sacrificed by an overdose of sodium thiopental injected into the left ventricle.

Perfusion Circuit—The perfusate volume was 1000 mL and comprised Krebs-Henseleit buffer pH 7.4, bovine serum albumin 1% w/v, D-glucose 0.1% w/v, washed human red blood cells 20% v/v, and Hepes 5 mM. The perfusion circuit (Figure 1) was based on our perfused fetal liver preparation.[4] Modifications were made as follows to improve and simplify the method of perfusate oxygenation and perfusate sampling. The reservoir was a 3 L spherical glass flask with a ground glass neck. To this was connected a hollow glass stalk 30 cm long (i.d. 25.4 mm, o.d. 31.75 mm) with a ground glass connector to the reservoir. The reservoir with stalk was mounted at a 60° angle using a Corning model 349/2 rotary evaporator apparatus which constantly rotated at 40 rpm to mix the perfusate and form a thin perfusate film on the inside of the reservoir for oxygenation. Entering the stalk were three stiff, nonrotating Teflon tubes; one tube was immersed into the perfusate as the liver portal supply, another tube as the venous return from the liver, and the third tube positioned so as to constantly oxygenate the reservoir air space.

A peristaltic pump (Masterflex No. 7521-25 Cole-Palmer Instrument Co., Chicago, IL) provided a flow rate of approximately 200 mL/min, and flow was accurately quantitated at the conclusion of each experiment. The perfusate was kept at a temperature of 37 °C by recirculating water through a glass heat exchanger from a 15 L water bath. Perfusate pH was maintained at 7.40 by mixing humidified carbogen (95% oxygen, 5% carbon dioxide) in addition to the delivered oxygen via a T-piece, as required. TC was delivered into the reservoir at 30 μmol/h (4 mL/h of 7.5 mM TC solution) by a syringe pump (Sage Instruments No. 355, Cambridge, MA).

Viability and Stability—An initial equilibration time of 15 min was followed by a perfusion time of 120 min. The perfusion pressure of the liver was determined by subtracting the circuit pressure obtained before connection of the circuit to the liver from the pressure reading with the liver in place. Oxygen delivery and consumption were calculated using an AVL 995 blood gas analyzer (AVL Medical Instruments, Switzerland) every 30 min by sampling perfusate inflow to and outflow from the liver. At the conclusion of each experiment, samples of the left and right lobes of the liver were taken and fixed in 10% formalin solution for later histological examination. The perfusate lactate:pyruvate ratio was measured spectrophotometrically in samples collected at 0, 30, 60, 90 and 120 min using a commercially available kit (kit nos. 826-A and 726, Sigma Chemical Co, St Louis, MO).

Experimental Design—After the initial 15 min equilibration, a bolus loading dose of 30 μmol (4 mL of 7.5 mM solution, specific activity 111Bq/mmol) [^{14}C]TC was injected into the reservoir, followed by a constant infusion of 30 μmol/h of [^{14}C]TC (4 mL/h of 7.5 mM solution) for 120 min. Samples (5 mL) from the inflow and outflow cannulae were then taken every 15 min for the duration of the experiment. Reservoir volume was maintained by replacing sampled perfusate with an equal volume of blank perfusate. All bile was collected via the common bile duct cannula into preweighed tubes in 30 min aliquots. Volume of bile was calculated by weight, assuming a specific gravity of 1.0 g/mL. Perfusate (whole blood perfusate including red blood cells) and bile radioactivity was determined by liquid scintillation counting on a Packard 1900CA liquid scintillation analyzer as described previously.[12]

Hepatic Distribution of Perfusate Flow—Latex microspheres 15 μm in diameter labeled with [^{153}Gd] were used to determine the ductus venosus flow shunting through the liver, the proportion of flow to left and right lobes, and the evenness of liver perfusion as previously described.[13] Briefly, 200 μL [^{153}Gd] of the microsphere preparation (approximately 2 million microspheres) were injected into the inflow cannula, and the outflow perfusate was collected in 10 s aliquots for 60 s, by which time all microspheres not distributed to the liver had eluted. The liver was then removed from the carcass and divided into left and right lobes (via Cantlie's line, a line joining the middle of the gallbladder fossa to the left of the inferior vena cava posteriorly), and the lobes were individually weighed. The lobes were then divided further into 2−4 g sections which were subjected to γ counting using a Packard Cobra 5005C γ counter at an energy window of 85−115 keV. The proportion of perfusate shunted through the ductus venosus was taken as the ratio of total counts in outflow perfusate to the sum of total counts in outflow perfusate and liver tissue.

Calculations and Statistics—The hepatic extraction ratio (E) at steady state (using the 60−90 min interval, Figure 2) was calculated as:

$$E = C_{in} - C_{out}/C_{in}$$

where C_{in} is TC concentration in the inflow cannula, and C_{out} is TC concentration in the outflow cannula from the liver. Where a ductus venosus shunt was present, a corrected hepatic extraction ratio (E^*) was calculated to take into account the fraction of perfusate shunting through the ductus venosus:

$$E^* = E/(1 - S)$$

where S is the fraction of the perfusate shunted, calculated from the portal injection of microspheres. Total clearance of TC from perfusate (CL) was calculated as:

$$CL = EQ$$

where Q is perfusate flow rate. Biliary clearance of TC at steady state (using the 60−90 min interval, CL_{bile}) was calculated as:

$$CL_{bile} = v/C_{ss}$$

where v is the mean excretion rate of TC into bile at steady state,

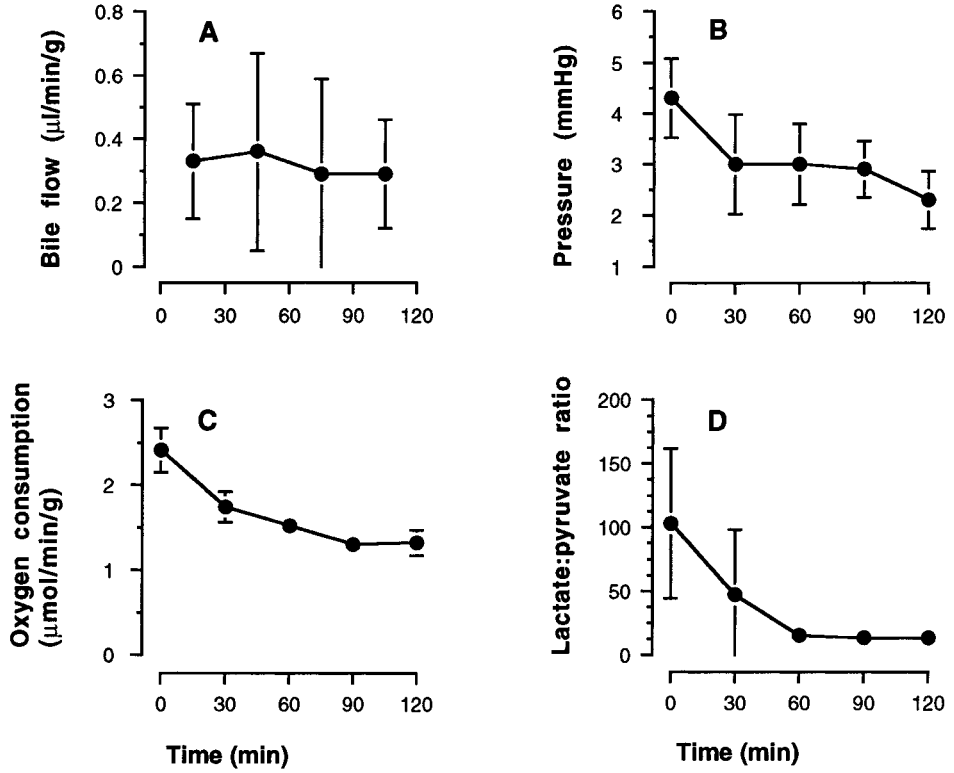

Figure 3—Physiological parameters (mean and standard deviation) versus time: (A) bile flow, (B) perfusion pressure, (C) oxygen consumption, (D) perfusate lactate:pyruvate ratio.

Table 1—Distribution of Perfusate Flow in Neonatal Liver

		liver weight (g)			perfusate flow (mL/g/min)	
neonatalage (days)	shunt (%)	left lobe	right lobe	total	left lobe	right lobe
2	15.2	45.8	52.8	96.6	1.67	2.96
2	18.2	41.3	52.2	91.5	1.83	2.92
3	1.6	72.8	90.3	163.1	1.17	1.37
6	1.4	73.8	62.9	136.7	1.31	1.53
8	2.0	41.3	50.2	91.5	1.83	2.92
10	0	71.2	67.1	138.4	0.84	2.21
11	3.0	56.3	52.6	108.9	1.58	2.72
Mean ± SD	5.9 ± 7.5	62.6 ± 14.7	66.4 ± 17.7	129.0 ± 30.8	1.39 ± 0.33	2.11 ± 0.79

and C_{ss} is the mean steady-state perfusate concentration in the inflow cannula.

Data are expressed as mean ± standard deviation. Correlations between variables were examined by linear regression analysis, and differences between groups of data were examined by unpaired *t*-test. A p value less than 0.05 was considered statistically significant.

Results

Liver Viability and Stability—Liver appearance was satisfactory in that the liver remained a uniform red color throughout the perfusion and there were no areas of hepatic capsular distension or exudation. Light microscopy of liver tissue showed no evidence of hypoxic damage or sinusoidal congestion. The whole liver was shown to have been grossly perfused by the presence of microspheres in all liver samples. Bile flow throughout the experiment was stable at 0.32 ± 0.24 µL/min/g of liver (as shown by linear regression) (Figure 3 A). Mean perfusion pressure was 3 mmHg and did not change significantly (as shown by linear regression) throughout the experimental period (Figure 3B). Overall mean oxygen consumption was 1.67 ± 0.44 µmol/min/g, falling from an initial rate of 2.41 ± 0.68 µmol/min/g liver to be stable over the latter 90 min of the perfusion at a rate of 1.48 ± 0.40 µmol/min/g liver (Figure 3C). The lactate:pyruvate ratio did not rise during the experiment, indicating that hepatic oxygenation did not deteriorate (Figure 3D).

Hepatic Distribution of Perfusate Flow—Ductus venosus flow as a proportion of total perfusate flow is shown in Table 1. The two neonates aged 2 days had ductus venosus shunts of 15.2 and 18.2%, and the five older lambs had shunts of less than 3% of perfusate flow (Table 1). Perfusate flow was 39.5 ± 8.5% to the left lobe of the liver and 60.5 ± 8.5% to the right lobe. The right lobe received a somewhat greater flow per gram of tissue (2.11 ± 0.79 mL/g/min) than the left lobe (1.39 ± 0.33 mL/g/min, $p < 0.05$).

Taurocholate Elimination—Mean C_{in} and C_{out} concentrations are depicted in Figure 2. Data for steady-state calculations were taken from the time period 60–90 min. Mean steady-state hepatic extraction of TC, calculated after taking into account shunted perfusate flow, was 0.56 ± 0.14; TC was concentratively secreted into bile (bile:plasma concentration ratio up to 5000). The total clearance of TC at steady state was 0.92 ± 0.35 mL/min/g liver (Table 2),

Table 2—Kinetics of Taurocholate Elimination

neonatal age (Days)	TC extraction	shunt-corrected TC extraction	bile/perfusate TC ratio	total TC clearance (mL/min/g)	biliary clearance of TC (mL/min/g)
2	0.43	0.51	785	1.01	0.65
2	0.46	0.56	1787	1.12	0.80
3	0.44	0.45	5241	0.56	0.60
6	0.32	0.33	2308	0.45	0.34
8	0.70	0.71	5828	0.85	0.53
10	0.61	0.61	3906	0.92	0.55
11	0.71	0.73	5529	1.51	1.49
Mean ± SD	0.52 ± 0.15	0.56 ± 0.14	3626 ± 2014	0.92 ± 0.35	0.71 ± 0.37

which was significantly higher than biliary clearance of TC (0.71 ± 0.37 mL/min/g liver, $p < 0.05$, Table 2). There was no significant correlation between hepatic extraction ratio, total clearance or biliary clearance of TC, and neonatal age over the age range studied.

Discussion

The isolated perfused liver (IPL) has proved a valuable experimental model in enhancing our understanding of the pharmacology and physiology of the liver.[14] Studies with this model complement those using isolated organelles or hepatocytes, and studies in whole animals. The IPL preserves the structural and functional integrity of the liver, while eliminating the confounding elements of metabolism and elimination by other organs.[14] Moreover, it allows ready access to hepatic inflow and outflow vessels and to the biliary tree.

The IPL model which we recently established to examine hepatic function in the fetal sheep[4] has proved particularly valuable in facilitating access to fetal hepatic blood vessels and bile ducts and in eliminating placental transport and maternal metabolism as confounding factors. The development of the neonatal IPL model described in the present study represents a modification of the approach used to establish the fetal model. The neonatal IPL is equally robust and stable over a 2 h experimental period, and the two preparations allow direct comparison of fetal and neonatal hepatic function.

The neonatal IPL has a stable bile flow comparable to other perfused liver models,[4,15] and maintains a low perfusion pressure,[16] a low lactate:pyruvate ratio, and a steady oxygen consumption after an early fall from a high initial level (Figure 3). The high initial reading was probably occasioned by increased tissue oxygen extraction consequent upon a transient acidosis after flushing the system with Hartman's solution. The absence of any later increase in lactate:pyruvate ratio, and normal histology, indicate that there has been no significant tissue hypoxia.[17] Moreover the mean level of oxygen consumption was significantly greater than that in the fetus (1.67 ± 0.44 versus 0.86 ± 0.07 μmol/min/g liver $p < 0.005$)[4] and approximates that previously reported in the neonatal and adult sheep liver in vivo.[18]

In the early neonatal period there was still appreciable shunting of blood through the ductus venosus (Table 1), although the degree of shunting was considerably less than in the near-term fetus (35 ± 18%[4]). By 6 days the ductus venosus had all but closed. This accords with previous observations in the sheep in vivo.[16,19] Nonetheless, it will be important in using this neonatal model, as in the fetal IPL, to measure and correct for the degree of ductus venosus shunting.

It is of interest that, on a weight basis, the right lobe of the liver appeared to be more generously perfused than the left (Table 1) whereas in the fetus, perfusion rates are similar.[4] This may reflect increasing resistance to flow in the portal sinus, and one consequence may be the disproportionate growth of the right lobe that is seen in the neonatal period.[16]

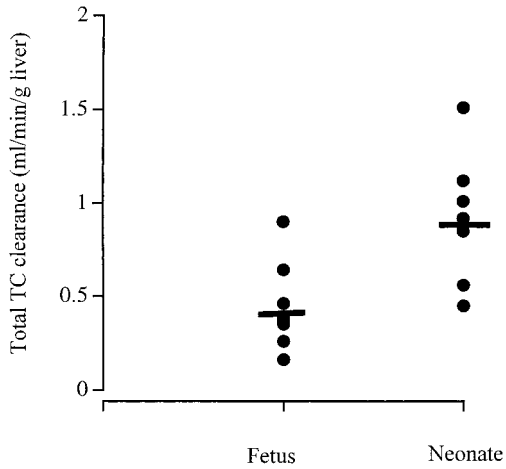

Figure 4—Total clearance of TC in neonatal liver (this study) and fetal liver (data from: Ring, J. A. et al. *Biochem. Pharmacol*. **1994**, *48*, 667–674).

In the adult human and rat, TC extraction approaches unity,[20,21] but no data are available in the adult sheep. In late fetal life, the hepatic extraction ratio (E^*) of 0.23 ± 0.16[4] indicates that at this stage of the liver's development TC is a low clearance compound. Within days of birth, TC extraction ratio had risen 2-fold to 0.56 ± 0.14 ($p < 0.005$), which represents an intermediate level of clearance. This increase in hepatic extraction ratio around the time of birth was accompanied by an increase in mean total TC clearance from 0.44 to 0.92 mL/min/g liver ($p < 0.01$, Figure 4). These results indicate a substantial change in the efficiency of hepatic TC transport, although there is further development in TC uptake and biliary excretion before the functions are fully mature.[21]

Values for total TC clearance were significantly greater than biliary clearance of TC in this study. The likely explanation is that although TC levels had reached steady state in perfusate (Figure 4), transport of TC into bile may not have reached steady state.

We conclude that the sheep neonatal IPL is a useful experimental model which will facilitate the study of the developmental physiology and pharmacology of the liver. Our study shows that there is considerable maturation of the biliary excretion of TC between the late fetal and early neonatal period in the lamb.

Abstract □ Poly(lactic-*co*-glycolic)-D,L-85/15 (PLAGA) nanocapsules and poly(epsilon caprolactone) (PCL) nanocapsules were labeled with a relatively long half-life compound that is usually used in humans; that is, ^{111}In-labelled oxine (^{111}In oxine). This labeling technique led to a high ^{111}In oxine entrapment efficiency and good stability during dialysis against phosphate buffer and phosphate buffered albumin solution. Because of these characteristics, the nanocapsules biodistribution was followed up after intravenous administration for up to 96 h by determining the gamma activity in the tissues after sampling. The administration of the PCL-encapsulated ^{111}In oxine led to a decrease in the blood radioactivity and an increase in the liver radioactivity compared with the solution. This effect was even more pronounced with the PLAGA nanocapsules. Finally, the activity level in other tissues, such as the kidneys, the lungs, and the spleen, appeared to be rather low and only slightly affected by the encapsulation into one or the other polymer.

Introduction

Most research in the field of drug targeting is being carried out with either liposomes or polymeric micro- or nanoparticles. However, it has been demonstrated that submicron vesicular structures, the so-called nanocapsules, are of great interest for the delivery of lipophilic drug substances. The ability of nanocapsules to improve the biopharmaceutical properties of lipophilic drug substances has been studied using different routes of administration; namely, the intravenous (iv), oral, and ophthalmic routes.[1,2] Follow-up studies with nanocapsules made of different polymers after iv administration are useful to characterize the influence of physicochemical parameters on the ability of the carriers to escape the mononuclear phagocyte system (MPS). Nevertheless, the biodistribution of poly(lactic-*co*-glycolic)-D,L-85/15 (PLAGA) and poly(epsilon caprolactone) (PCL) nanocapsules in mice after iv administration has still not been described.

Biodistribution studies of colloidal carriers are usually performed with either liposomal lipids, polymers, or encapsulated drug labeled with beta emitters[3] or carbon-14.[4,5] For example, the biodistribution of radiolabeled cyclosporine incorporated into poly(isobutyl cyanoacrylate) nanocapsules has been described.[6] However, mainly because of safety reasons, preliminary phases of clinical trials can hardly be performed with such labeled dosage forms.

Therefore, colloidal carriers incorporating gamma emitters have been prepared and injected in humans by different routes of administration, such as the iv or the pulmonary route. Although most of these colloids are found in the MPS after iv administration,[7−9] the potential of gamma scintigraphy study techniques has been outlined by Rolland et al.[8] and by Gahnem et al. in humans[9] using poly(cyanoacrylate) nanoparticles labeled with Indium-111 and technetium-99m, as well as by Thanoo et al.[10] using ^{111}In oxine-labeled microspheres. In these studies, the particle distribution in the body was followed as a function of time.

Nevertheless, the labeling technique appears to be critical. Indeed, binding efficiency and radioactive half-life have a great impact onto the feasibility of the experiments, whereas stability of the labeling greatly influences the reliability of the data. For example, the binding efficiency of technetium-99m or iodide-125 to cyanoacrylates nanoparticles or to cellulose derivative microparticles, respectively, is poor; moreover, the technetium-99m gamma emitter has a relatively short half-life (6 h), which implies the use of highly radioactive preparations for a distribution follow-up of ≈12 h. Finally, noncovalent gamma emitter−carrier binding is susceptible to desorption due to dilution or particle degradation, especially in a blood protein environnement. Poly(butylcyanoacrylate) nanoparticles have been successfully labeled with ^{111}In by an adsorption process by Kreuter et al.,[11] but the stability of the binding has not been demonstrated. Discrimination between particles and the released free emitter biodistribution then appears to be difficult.

The objectives of the present work were to directly label polymeric nanocapsules with a relatively long half-life compound usually used in humans i.e., ^{111}In oxine (half-life, 2.8 days). Additionally, the labeling was to be done by an easy, fast, and reproducible method and the binding was to be stable in a blood environment. The potential of the labeling technique to follow up the distribution of the nanocapsules in the body after iv administration was evaluated in mice. Finally, the biodistribution of two different types of nanocapsules (PLAGA and PCL) were compared.

Experimental Section

Chemicals—Copolymer of lactic and glycolic acid (PLAGA MW 40 000) was kindly furnished by Medisorb (Cincinnati, OH). Polyepsilon caprolactone (MW 60 000) was purchased from Aldrich Chemical (Saint Quentin Fallavier, France), olive oil and ^{111}In

PLAGA	340 ± 12	–25 ± 1.1	94
PCL	454 ± 8	–29 ± 1.1	95

oxine (^{111}In oxine, 1 mCi/mL) were purchased from Cooper (Melun, France) and Oris Industrie (Saclay, France), respectively. Pluronic F68 was a gift from BASF (Paris, France). All reagents were analytical grade and used as received.

Preparation of Labeled Nanocapsules—the commercial indium oxine is an aqueous solution containing <0.1 μg of radioactive indium atoms complexed by 50 mg of hydroxy-8-quinoleine (i.e., oxine). According to the first step of the preparation process, the lipophilic marker was partioned upon shaking for 20 min between the aqueous radioactive phase (0.25 mL) and olive oil (0.7 mL). Up to 80% of the radioactive compound transferred into the olive oil. After separation by centrifugation, 0.5 mL of olive oil was used for further processing.

PLAGA and PCL nanocapsules were prepared according to the method of Fessi et al.[12] Briefly, 0.125 g of polymer was dissolved in 20 mL of acetone. After dissolution of the polymer, the radioactive oily phase was mixed with the acetonic phase. This radioactive organic solution was mixed with 50 mL of an aqueous solution containing 0.25 g of Pluronic F68 as a stabilizer. Acetone was evaporated under reduced pressure, and the final volume of the suspension was adjusted to 15 mL. The final polymer concentration in the suspension was 0.83% (w/v).

Indium Oxine Incorporation Ratio—Gel permeation chromatography was performed to assess the incorporation ratio of the radioactive compound in the nanocapsules. Briefly, an aliquot (0.1 mL) of the suspension was passed through a Sephadex G75 column (3 × 16 cm). The suspension was eluted with a 0.9% NaCl solution at a rate of 1 mL/min. Samples were collected at the bottom of the column, and the radioactive content of each sample was counted with a gamma counter. An aliquot of 0.1 mL of pure indium oxine solution was also eluted at the same conditions and served as a reference. The activity of each sample was expressed as a percentage of the total activity of the suspension counted before the sample was passed through the column.

Characterization of the Nanocapsules—The particle diameter was determined by photon correlation spectroscopy (Malvern 4600, Malvern, France) and the zeta-potential by LASER doppler velocimetry (Zetamaster, Malvern, France). All suspensions were diluted with a 10^{-6} M NaCl, pH 6.5 aqueous solution to maintain a constant ionic strength and an adequate concentration of particles.

Biodistribution Studies of the Indium Oxine Formulations—Studies were carried out in Swiss male mice weighing ≈20 g. A 0.1 mL volume of ^{111}In-labelled nanocapsules was injected by iv bolus into the tail vein. After various time intervals up to 96 h after administration, five mice per time point were sacrified by cervical fracture. The blood, liver, spleen, lungs, and kidneys were removed, washed with 0.9% NaCl solution, and accurately weighed. A group of five mice also received a 0.1 mL bolus dose of ^{111}In oxine aqueous solution by the same administration route. Along with standards prepared from the injected materials, the total radioactivity in the blood and the organs was measured on an auto-gamma well counter (Beckman Gamma 4000, Munich, Germany). The raw radioactive data were corrected for the half-life of the marker and presented as the percentage of the administered dose per gram of tissue. Statistical analysis was performed using the ANOVA test (Fischer, $p < 0.05$). The ^{111}In oxine half-life in the blood was calculated with a noncompartmental model.

Results and Discussion

Preparation and Labeling of the Nanocapsules—as shown in Table 1, the preparation method led to the production of PLAGA and PCL nanocapsules of 340 ± 12 and 454 ± 8 nm, respectively, as well as a high gamma emitter encapsulation efficiency. Both PLAGA and PCL nanocapsules gel permeation elution profiles show that >90% of the total ^{111}In oxine radioactivity was associated with the combined fractions of nanocapsules. Thus, the manufacturing process of labeled nanocapsules appears to be fairly independent of the polymer used. Although the gamma emitter is water soluble at this low concentration, most of it did not diffuse from the oil into the acetone/water phase during the manufacturing process, nor during the elution of the nanocapsules from the gel permeation column. The release of ^{111}In oxine upon high dilution in aqueous medium is fairly low. These results are not in favor of a diffusion process driven by Fick's Law but rather by the partition effect. The partitioning effect has also been considered as one of the driving force of the release process of drugs from the oily core of nanocapsules into outer phases, such as blood or intestinal fluids.[13] Moreover, it has been proposed that the intraocular penetration of drugs encapsulated in PCL nanocapsules after topical application is partly related to the partition of the drug between the oily inner phase of the capsules and the lipophilic corneal epithelium.[2]

The in vitro stability of the labeling of PCL nanocapsules in an albumin or buffer environment was investigated, earlier in our laboratory[14] and was shown to be high. The release kinetics of ^{111}In oxine from PCL nanocapsules during dialysis against albumin aqueous solution or phosphate buffer were compared with the free ^{111}In oxine solution, and the results showed that ^{111}In oxine diffuses very slowly out of the capsules into the albumin solution or the buffered outer phase. After 4 h, <5% of the aqueous (i.e., nonencapsulated) solution of the gamma emitter is still present into the dialysis bag compared with 100% of the encapsulated gamma emitter. This labeling technique, therefore, leads to high ^{111}In oxine entrapment efficiency and good stability against dilution and partitionning. The method is easy, fast, and reproducible. Because of these characteristics, the nanocapsules biodistribution can be followed-up after iv administration either by gamma scintigraphy imaging or by determining the gamma activity in the tissues after sampling. Moreover, the study can be performed for up to 96 h because of the relative long half-life of indium oxine. Finally, the gamma dose used under these conditions is relatively safe because the same low dose is used for diagnosis purposes in humans.

Biodistribution of Indium Oxine after Intravenous Administration—Depending on the drug dosage form (solution or nanocapsules), the distribution of the ^{111}In oxine appears to be very different. A comparison of the radioactivity detected in the blood and the other tissues at the earlier sampling time shows that most of the ^{111}In oxine solution was distributed into the blood and the liver (Figures 1 and 2). However, the administration of the PCL-encapsulated ^{111}In oxine led to a decrease in the blood activity and an increase in the liver activity compared with the solution (Figures 1 and 2). This effect was even more pronounced after administration of the PLAGA nanocapsules. In that latter case, 60−70% of the administered dose reached the liver. The activity level in other tissues, such as kidneys, lungs, and spleen, appeared to be unaffected by the encapsulation into one or the other polymer (Tables 2, 3, 4). These results are in good agreement with results obtained with ^{14}C-labeled colloidal carriers. Indeed, it was previously shown that a high proportion of the nanoparticles were quickly taken up by the liver after iv administration.[1,7−10,15] The plasma half-life of such carriers usually ranges from 1 to 10 min,[15] but could be extended up to >10 h if nanoparticles are precoated with Pluronic F108.[16]

In addition, it appears that the ^{111}In oxine radioactivity kinetics in the blood as well as in the liver are, quite similarly, independent of the dosage form. Indeed, the blood

radioactivity after administration of the solution, the PCL nanocapsules, and the PLAGA nanocapsules followed a monoexponential decline with a half-lives of 23, 25, and 28 h, respectively. In the kidneys, the marker radioactivity declined slowly after administration of either the solution or the encapsulated forms. It has been previously demonstrated that after iv administration of an indium oxine solution, the indium oxine is quickly bound to the plasma transferin. After adsorption, the marker is taken up by the liver cells through the transferin receptor, and a progressive elimination of the marker from the blood occurs. Indeed, the elimination of the marker from the blood is driven by the availability of free transferin receptors. The

marker is continuously internalized and released into the liver cells where the complex is disrupted and the hydrophilic indium molecule is eliminated. However, the biodistribution process of encapsulated indium oxine appears to be very different. It seems that it mainly proceeds through a rapid liver uptake. The uptake of nanocapsules by the liver is nonspecific, mediated by the opsonization of the particles after contact with the plasma proteins, and leads to a higher uptake of the marker compared to the solution. After internalization of the nanocapsules, the indium oxine is released and reduced to its hydrophilic form. This form is then eliminated, as demonstrated by the activity in the kidneys.

Although a high proportion of both PLAGA and PCL nanocapsules were quickly taken up by the liver after iv administration, the biodistribution profiles of the two carriers were different. These differences are apparent in the blood and the liver distribution, whereas the distribution of the carriers in the other tissues does not seem to depend on the polymer used. Both the proportion of the carrier that was detected in the tissues as well as the elimination rate of the carrier from the tissues have to be considered. Indeed, until 20 h after administration of the nanocapsules, a higher gamma activity was detected in the blood after administration of PCL nanocapsules compared with PLAGA nanocapsules. However, the gamma emittor encapsulated either in PLAGA or in PCL nanocapsules was eliminated at a similar rate from the blood (25 and 28 h, respectively). In the liver, we found a higher proportion of ^{111}In oxine after administration of PLAGA nanocapsules than after administration of PCL nanocapsules but, again, both were eliminated at a slow and similar rate. Previously, it was demonstrated that particle size, zeta potential, and surface hydrophilicity greatly influence the kinetics of the elimination of particles from the blood.[4,5,13,15–18] Because following internalization into the liver the release rate from the two types of nanocapsules are similar, one can assume that the longer residence time of PCL nanocapsules in blood compared with that of the PLAGA nanocapsules

results from the lower liver uptake mediated by the adsorption of opsonins onto the carriers. Budhi et al.[5] have shown that larger polystyrene particles were eliminated from the blood faster than smaller ones. In our study, the size as well as the zeta potential of the two types of nanocapsules are similar. In addition, both polymers are considered to be hydrophobic. However, the glass transition temperature of the PCL is far lower that of the PLAGA (−53 and +42 °C, respectively). The PCL nanocapsules surface is therefore less rigid than the PLAGA nanocapsules surface at temperatures <42 °C (e.g., 37 °C, body temperature). Both types of nanocapsules have been prepared in the presence of Pluronic F68 as stabilizer, but the interaction of the stabilizer with the polymer during the formation of the polymeric wall could be influenced by the physical state of the polymer. The rubbery state of PCL at room temperature (≈20 °C, manufacturing temperature) could facilitate the anchor of the stabilizer into the polymeric wall. As already demonstrated,[19−21] the presence of block copolymers, such as Pluronic F68, promotes a decrease in the interaction with liver-specific opsonins, which in turn leads to a slower blood clearance and a lower liver uptake. Because the uptake of the two types of nanocapsules is similar in the spleen, it seems that the difference in the interaction with spleen-specific opsonins is less pronounced. The preferential adsorption of liver- and spleen-specific opsonins onto polymeric colloidal carriers has nevertheless not been demonstrated. Polymers with a glass transition temperature lower than the manufacturing temperature and/or 37 °C, like PCL, appear therefore to be a potential interesting polymer in the development of colloidal carriers. Because of its rubbery state at 37 °C, this polymer could be an alternative to PLAGA. In particular, higher plasma drug level could be achieved for a prolonged period of time after administration of PCL colloidal carriers prepared only with hydrophilic surfactant. This procedure could be an alternative to stealth PLAGA colloidal carriers, at least for the first 24 h, during which the hydrophilic part is covalently bound onto the polymer.

Accepted for publication February 1, 1999.

Abstract □ Intravenous lipid emulsions are used for total parenteral nutrition and as carriers for lipophilic drugs. Exposure to the high temperature (121 °C) required for steam sterilization may cause coalescence and an increase in droplet size. The purpose of this study was to investigate whether an increase in the electrostatic repulsive force between oil droplets produced by formulation modification improves the thermal stability of lipid emulsions during autoclaving. The addition of a small amount, 0.66 or 1.32 mmol/kg (mm), of purified anionic phospholipid fractions (phosphatidic acid, phosphatidylglycerol, or phosphatidylinositol) to the standard formula increased the ζ potential from its normal value of –11 mV to –39 mV. Emulsions with the larger negative ζ potential did not exhibit any change in oil droplet size or distribution during steam sterilization at 121 °C for 15 min. The autoclaved emulsions having the larger negative ζ potential did not exhibit any evidence of coalescence when samples were stored for 1 month at 4 °C, room temperature, or 40 °C. Reduction of the negative surface charge of the oil droplets by the addition of stearylamine confirmed that the surface charge was an important factor, as emulsions having a reduced negative surface charge separated into two phases during autoclaving.

Introduction

Lipid emulsions have a long history of safe use as a source of intravenous nutrition. They have been used more recently for the intravenous administration of lipid-soluble drugs. Intravenous lipid emulsions must be sterile. The preferred sterilization process is steam sterilization. Exposure to the high temperature, 121 °C, required for steam sterilization may cause an increase in the mean droplet size.[1] The droplet size is important for the safe use of intravenous lipid emulsions, as the smallest capillaries have a diameter of 5 μm.[2−5] The desirable size range of oil droplets administered intravenously is approximately 0.4 to 1 μm,[2−5] which is approximately the same size as naturally occurring chylomicron in the blood.

Intravenous lipid emulsions are stabilized by a combination of forces such as electrostatic, hydration, and steric repulsive forces. Egg phospholipid, the emulsifier in most intravenous lipid emulsions, is a mixture of nonionic and anionic phospholipids. The anionic components have apparent pK_a values between 3 and 4[6] and contribute an electrostatic repulsive force within the pH range of intravenous lipid emulsions, i.e., pH 8.0−9.0. It has been proposed that phospholipids form a liquid crystal interfacial film structure at the oil−water interface by adsorption of water.[7] The phospholipid molecule can attach to itself up to 39 water molecules, resulting in a great increase in molecular volume.

The hydration and steric repulsive forces, which depend on adsorption, are inversely related to temperature. Thus, these stabilizing forces are less effective during exposure to 121 °C during steam sterilization. On the other hand, the electrostatic repulsive force is inversely related to the dielectric constant of the medium.[8] In the case of lipid emulsions, the medium is water and its dielectric constant decreases as temperature increases. Therefore, the electrostatic repulsive force is larger at elevated temperatures than at room temperature.

The electrostatic repulsive force has been increased in phospholipid-stabilized o/w emulsions by the addition of oleic acid, phosphatidylserine, phosphatidylglycerol, or phosphatidic acid.[9−13] Most of the studies focused on reducing the rate of coalescence when the lipid emulsion was mixed with electrolytes in an admixture for total parenteral nutrition. In general, the stability of emulsions to the addition of electrolytes was directly related to the magnitude of the negative surface charge. Yamaguchi et al.[13] reported that when the ζ potential of a lipid emulsion was increased from −8 to −18 mV by the addition of 17.5 mM oleic acid, the emulsion exhibited no change in mean particle size after autoclaving at 121 ° C for 20 min. The mean particle size of the control emulsion (without the added oleic acid) increased from 0.20 to 0.32 μm during autoclaving. No information was presented regarding the particle size distribution. Thus, although the mean droplet size (as measured by photon correlation spectroscopy) did not change during autoclaving, coalescence may have occurred. A second technique capable of monitoring droplets larger than 1 μm, such as single-particle optical sensing, was needed to determine if coalescence occurred during autoclaving.

This study was undertaken to determine if the formulation of o/w emulsions can be modified by the addition of purified anionic phospholipid fractions to increase the naturally occurring negative surface charge and if emulsions having a larger negative surface charge will undergo less coalescence during steam sterilization.

Experimental Section

Miglyol 812 is a neutral oil composed of caprylic and capric triglyceride (Huls, Hillside, NJ). Olive oil was obtained from ICN Biomedical, Aurora, OH. Egg phospholipid was a gift of Pharmacia & Upjohn, Clayton, NC. Phosphatidic acid, phosphatidylcholine, phosphatidylglycerol, and phosphatidylinositol were obtained from Avanti Polar Lipid, Alabaster, AL. Stearylamine was obtained from Sigma Chemical Co., St. Louis, MO.

Table 1—Effect of Autoclaving on the Properties of the Standard Emulsion

	before autoclaving	after autoclaving
acid value, mg KOH/g emulsion	0.247 ± 0.003	0.348 ± 0.009
pH	8.0 ± 0.0	7.2 ± 0.0
ζ potential, mV	−10.5 ± 2.4	−23.6 ± 0.8
Mean diameter, μm	0.28 ± 0.01	0.40 ± 0.00
Volume of oil present as droplets larger than 1 μm, % v/v	0.060 ± 0.005	0.473 ± 0.046

The following formula was the standard emulsion used in this study: Miglyol 812 10 g olive oil 10.0 g; butylated hydroxytoluene 0.2 g; egg phospholipid 1.2 g; glycerol 2.4 g; doubly distilled water, qs 100.0 g.

The emulsion was produced by preparing the aqueous phase by dispersing the egg phospholipid in a solution of glycerol and water using a constant speed stirrer at 1500 rpm. Nitrogen was bubbled into the glycerol and water solution for 15 min before the egg phospholipid was added. The oil phase was prepared by combining Miglyol 812 and olive oil and bubbling nitrogen into the solution for 15 min. Butylated hydroxytoluene was dissolved in the oil phase. A primary emulsion was prepared by mixing the oil and aqueous phases for 10 min using a high speed mixer with a propeller blade (Multimix 4642, Braun). The primary emulsion was passed through a microfluidizer (Model 110 Y, Microfluidics Corp., Newton, MA) five times at 20000 psi. The cooling coil and interaction chamber were packed with ice. The final pH of the emulsion was adjusted to 8.0 by the addition of 0.5 to 1.0 mL of 0.1 N NaOH per 300 g of emulsion.

The temperature of emulsions produced by the microfluidizer has been reported to increase by 5 °C for each pass when no cooling is used.[14,15] The use of ice on the cooling coil and interaction chamber in this study controlled the temperature of the discharged emulsion in the range of 16 to 22 °C.

The emulsion was packaged in 10 mL vials (Type 1 glass) and sealed with a pulp and plastic screw cap. The emulsion was purged with nitrogen before sealing. Samples of the emulsion in the 10 mL vials were autoclaved for 15 min at 121 °C, 15 psi.

The pH of the emulsion and the results of all of the other tests were reported as the mean of four measurements from two sample vials. The acid value was determined by a standard procedure and is expressed as the milligrams of potassium hydroxide required to neutralize the free acids in 1 g of emulsion.[16] The mean droplet diameter was determined by dynamic light scattering (Nicomp 370, Particle Sizing Systems, Santa Barbara, CA) and was based upon volume weighting. The emulsion was diluted 1:100 immediately before measurement with doubly distilled water that had been passed through a 0.22 μm membrane filter. This dilution procedure was selected after a preliminary experiment indicated that the mean droplet diameter remained the same when measured immediately after dilution or 10, 15, or 30 min after dilution. The percentage of oil present as droplets larger than 1 μm was determined using a single-particle optical sensing system (Accusizer 770, Particle Sizing Systems, Santa Barbara, CA). The emulsion was diluted immediately before measurement with doubly distilled water that had been passed through a 0.22 μm membrane filter. The dilution ratio was adjusted to obtain a droplet count between 3000 and 8000 droplets/mL. The ζ potential was determined by Doppler electrophoretic light scattering analysis (DELSA 440, Coulter, Hialeh, FL). The emulsion was diluted with 0.01 M HEPES buffer at pH 7.5 (Fisher, Fairlawn, NJ) which contained 5 mM NaCl.

Results and Discussion

The effect of autoclaving at 121 °C for 15 min on the properties of the standard emulsion is presented in Table 1. The acid value increased following autoclaving, indicating the formation of free fatty acids. It is likely that the elevated temperature accelerated the hydrolysis of the oil phase and the egg phospholipid used as the emulsifier. The rate of hydrolysis of phospholipids has been found to follow the Arrhenius equation in the temperature range of 5 to 90 °C.[17] The fatty acids formed by the hydrolysis of egg phospholipid are probably also responsible for the decrease in pH observed after autoclaving. The ζ potential became more negative following autoclaving. This may be the result of the increased fatty acid concentration and/or the redistribution of the egg phospholipid from the aqueous phase where it is present as liposomes to the interface during autoclaving.[18]

Table 2—Effect of Adding Egg Phospholipid Fractions (0.66 or 1.32 mm) on the ζ Potential

egg phospholipid fraction added	ζ potential ± SD, mV	
	0.66 mm	1.32 mm
none	−10.5 ± 2.4	−10.5 ± 2.4
phosphatidylcholine	−12.2 ± 3.4	
phosphatidic acid	−35.1 ± 1.7	−38.4 ± 1.4
phosphatidylglycerol	−39.4 ± 1.2	−40.0 ± 1.8
phosphatidylinositol	−32.7 ± 0.3	−37.3 ± 0.4

Autoclaving caused an increase in the mean droplet size from 0.28 to 0.40 μm. It is likely that coalescence occurred during exposure to 121 °C which resulted in an increased mean droplet size. Further evidence that coalescence occurred is the increase in the percentage of oil present as droplets larger than 1 μm. This parameter is more critical for safety than the mean droplet size, as the smallest capillary has a diameter of 5 μm.[2–5] Some oil droplets which formed during autoclaving became large enough to rise to the surface of the emulsion and were seen without magnification as oil droplets on the surface.

Egg phospholipid is a mixture of many components.[19] The major components are phosphatidylcholine (PC) and phosphatidylethanolamine which exhibit no net charge at physiological pH. The minor components, which comprise 2−5% of the total lipid, are phosphatidylserine, phosphatidic acid (PA), phosphatidylglycerol (PG), phosphatidylinositol (PI), sphingomyelin, cholesterol, and lysophosphatidylcholine. Phosphatidylserine, PA, PG, and PI are negatively charged at pH 7.0. Along with free fatty acids, these anionic fractions are probably responsible for the negative ζ potential of the standard emulsion (Table 1).

The effect of increased negative ζ potential on the physical stability of the standard emulsion during autoclaving was tested by adding approximately 0.05% w/w (0.66 millimolal (mm)) of purified egg phospholipid fractions which are anionic (PA, PG, or PI). The nonionic fraction, PC, was included at the same concentration as a control. As seen in Table 2, the addition of 0.66 mm of the anionic fractions caused the ζ potential to increase from −11 mV to approximately −39 mV. The nonionic egg phospholipid fraction, PC, did not cause a statistically significant change in the ζ potential. The formula modification did not affect the production of the emulsion as the mean droplet diameter of the emulsions containing an additional 0.66 mm of nonionic or anionic egg phospholipid fractions was the same as the standard formulation (Figure 1).

The effect of increased electrostatic repulsive force was seen when the emulsions containing 0.66 mm egg phospholipid fractions were autoclaved. The mean droplet size of the emulsions having a larger negative ζ potential (PA, PG, PI) were unchanged during autoclaving (Figure 1). In contrast, the mean droplet size increased during autoclaving in the standard emulsion and the emulsion containing additional nonionic fraction, PC. The change in mean droplet diameter during autoclaving for the standard emulsion and the emulsion containing additional PC was statistically significant at *p*-values of 0.001 and 0.003, respectively.

Table 3—Effect of Adding 0.66 mm Egg Phospholipid Fractions on the Free Fatty Acid Content, pH, and ζ Potential Following Autoclaving at 121 °C for 15 min

[a] The standard deviation was ± 0.0.

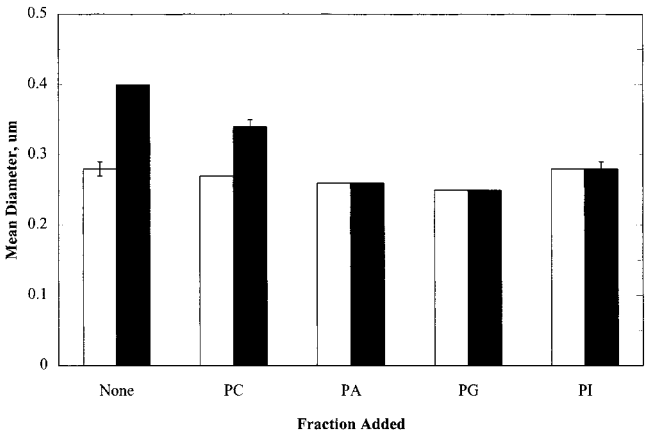

Figure 1—Effect of adding 0.66 mm egg phospholipid fractions on the mean droplet size following autoclaving at 121 °C for 15 min. The standard deviation is indicated on each bar when its value was greater than 0.00. Key: open bar, before autoclaving; hatched bar, after autoclaving; PC, phosphatidylcholine; PA, phosphatidic acid; PG, phosphatidylglycerol; PI, phosphatidylinositol.

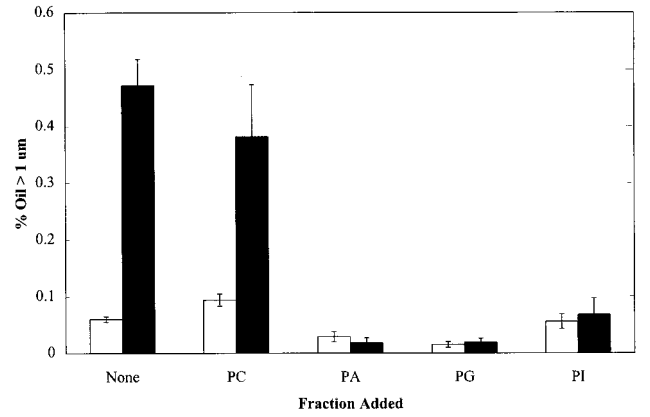

Figure 2—Effect of adding 0.66 mm egg phospholipid fractions on the percentage of oil present as droplets larger than 1 μm following autoclaving at 121 °C for 15 min. The standard deviation is indicated on each bar. Key: open bar, before autoclaving; hatched bar, after autoclaving; PC, phosphatidylcholine; PA, phosphatidic acid; PG, phosphatidylglycerol; PI, phosphatidylinositol.

The enhanced physical stability of the emulsions having an increased negative ζ potential was also seen when the percentage of oil present as droplets larger than 1 μm was determined (Figure 2). The three emulsions containing 0.66 mm anionic egg phospholipid fractions and having an increased negative ζ potential exhibited no change in the percentage of oil present as droplets larger than 1 μm as a result of autoclaving. This behavior is in sharp contrast to the standard formulation and the formulation containing an additional 0.66 mm PC. The percentage of oil present as droplets larger than 1 μm in these emulsions increased from less than 0.1 to 0.4 during autoclaving. Oil droplets were also visible on the surface of the standard emulsion and the emulsion containing additional PC. The three emulsions having a larger negative ζ potential did not have any visible oil droplets on the surface after autoclaving. Thus, the hypothesis that additional electrostatic repulsive force would inhibit coalescence during autoclaving was supported.

Table 4—Mean Droplet Size[a] of Autoclaved Emulsions Containing 0.66 mm Egg Phospholipid Fractions during Storage at 4 °C, Room Temperature (rt), and 40 °C

egg phospholipid fraction added	mean diameter, μm			
	initial	1 mo, 4 °C	1 mo, RT	1 mo, 40 °C
none	0.40	0.41	0.40	0.41
phosphatidylcholine	0.34	0.33	0.33	0.34
phosphatidic acid	0.26	0.26	0.26	0.26
phosphatidylglycerol	0.25	0.25	0.25	0.25
phosphatidylinositol	0.28	0.28	0.28	0.28

[a] All standard deviations were ± 0.01 or less.

Exposure to the elevated temperature of autoclaving caused hydrolysis of the egg phospholipid in the standard emulsion which was seen as an increase in the acid value, a decrease in the pH, and an increase in the negative ζ potential (Table 1). These parameters changed in a similar way during autoclaving of the emulsions containing additional egg phospholipid fractions (Table 3).

The effect of a higher concentration of added anionic egg phospholipid fractions was studied by repeating the experiments using 1.32 mm (approximately 0.10%) egg phospholipid fractions. The ζ potentials of the emulsions containing 1.32 mm PA, PG, and PI (Table 2) were −38.4, −40.0, and −37.3 mV, respectively. These values are only slightly increased in comparison to the values obtained when half that amount was added (Table 2). The mean droplet size of emulsions containing 1.32 mm PA, PG, or PI did not change during autoclaving. The percentage of oil present as droplets greater than 1 μm also did not change in these emulsions during autoclaving. Thus, increasing the concentration of added anionic egg phospholipid fractions above 0.66 mm (approximately 0.05%) did not significantly increase the surface charge or improve the physical or chemical stability of the emulsion to autoclaving.

The autoclaved standard emulsion and emulsions containing an additional 0.66 mm egg phospholipid fractions were stored at 4 °C, room temperature, and 40 °C for 1 month. As seen in Table 4, the mean droplet size of all of the emulsions was stable at all three temperatures. Likewise, the percentage of oil present as droplets larger than 1 μm did not significantly change during the storage period (Table 5). Thus, the addition of small amounts of anionic egg phospholipid fractions to reduce the rate of coalescence during autoclaving did not adversely affect the rate of coalescence during storage.

The preceding experiments demonstrate that the thermal stability of o/w emulsions can be improved by increasing the electrostatic repulsive forces between oil droplets.

2	11.1	0.28 ± 0.00	0.27 ± 0.00

[a] The emulsion had separated into two phases.

To verify that the surface charge plays an important role in the stability of o/w emulsions, emulsions were prepared which had reduced negative ζ potentials as well as positive ζ potentials. The ζ potential of the standard emulsion containing 1.2% egg phospholipid was modified by incorporating concentrations of stearylamine ranging from 0.371 to 11.1 mm. The emulsions were prepared and autoclaved as two experiments. The first experiment consisted of the standard emulsion and emulsions containing 0.371, 0.925, and 1.85 mm stearylamine. The second experiment consisted of the standard emulsion and emulsions containing 3.71 and 11.1 mm stearylamine.

The ζ potential of the standard emulsion in the first experiment was −20.3 ± 0.8 mV and −19.0 ± 1.4 mV in the second experiment (Figure 3). Addition of 0.371 mm (approximately 0.01%) stearylamine reduced the negative ζ potential to −6.6 mV. This result indicates that the interface contains both anionic egg phospholipid fractions and stearylamine. The mean droplet diameter of this emulsion (Table 6) prior to autoclaving was larger (0.75 μm) than the standard emulsion. The mean droplet diameter prior to autoclaving was also larger than the standard emulsion when 0.925 and 1.85 mm stearylamine was included in the formulation. However, emulsions containing 3.71 or 11.1 mm of stearylamine exhibited initial mean droplet diameters which were virtually identical to the standard emulsion. This behavior suggests that coalescence occurred prior to autoclaving in the emulsions containing 0.371, 0.925, and 1.85 mm stearylamine.

Table 7—Effect of Autoclaving at 121 °C for 15 min on the Percent of Oil Present as Droplets Larger than 1 μm in Emulsions Containing Stearylamine

1	1.85	0.201 ± 0.030	cracked[a]
2	0	0.051 ± 0.008	0.486 ± 0.067
2	3.71	0.099 ± 0.024	0.103 ± 0.038
2	11.1	0.019 ± 0.001	0.029 ± 0.10

[a] The emulsion had separated into two phases.

The standard emulsions without added stearylamine (Table 6) exhibited the same increase in mean droplet size during autoclaving as was reported in Table 1. The emulsion with a reduced negative ζ potential (0.371 mm stearylamine) coalesced to such a degree during autoclaving that it completely separated into two phases. The surface charge of the emulsions became positive (+2.8 mV) when the concentration of stearylamine was 0.925 mm or higher (Figure 3). The ζ potential was +64.9 mV at the highest stearylamine concentration (11.1 mm). Only the two emulsions having the highest positive ζ potentials failed to exhibit an increase in mean droplet size during autoclaving (Table 6). These two emulsions were also the only ones which did not exhibit an increase in the percent oil present as droplets larger than 1 μm (Table 7). Although there was no significant change following autoclaving in the mean droplet size or percentage of oil present as droplets greater than 1 μm in the emulsions containing 3.71 or 11.1 mm stearylamine, examination of the surface of the emulsions after autoclaving revealed that the emulsion containing 11.1 mm stearylamine was more stable. No oil droplets were observed on the surface of the emulsion containing 11.1 mm stearylamine after autoclaving. In contrast, oil droplets were visible on the surface of the emulsion containing 3.71 mm stearylamine after autoclaving.

The thermal instability of the emulsions containing 0.371 or 0.925 mm stearylamine may be attributed to the small surface charge, −6.6 or + 2.8 mV, respectively. The electrostatic repulsive forces present in these emulsions may be insufficient to prevent coalescence during autoclaving. The emulsion containing 1.85 mm stearylamine had a ζ potential of +21.3 mV. The absolute value of the ζ potential was similar to the standard emulsions (−20.3 and −19.0 mV). Since the standard emulsion never separated into two phases during autoclaving (Tables 1 and 6), it was

surprising that the emulsion containing 1.85 mm stearylamine cracked during autoclaving. Previous experiments showed that autoclaving the standard emulsion caused the formation of free fatty acids and increased the negative ζ potential (Table 1). Thus, it is likely that the positive ζ potential of the emulsion containing 1.85 mm stearylamine became less positive during autoclaving. It is believed that the reduced positive ζ potential did not provide enough electrostatic repulsive force to prevent coalescence. Unfortunately, the ζ potential of this emulsion after autoclaving could not be measured because the emulsion separated into two phases during autoclaving.

The emulsions containing 3.71 and 11.1 mm stearylamine did not separate during autoclaving. Measurement of the ζ potential after autoclaving yielded reduced positive ζ potentials of $+7.5 \pm 0.9$ and $+31.5 \pm 1.5$ mV, respectively. The formation of free fatty acids may explain why the emulsion containing 11.1 mm stearylamine exhibited better thermal stability than the emulsion containing 3.71 mm stearylamine. The ζ potential of the emulsion containing 11.1 mm stearylamine was always greater than +31.5 mV during autoclaving while the ζ potential of the emulsion containing 3.71 mm stearylamine decreased to a minimum ζ potential of +7.5 mV during autoclaving.

Conclusions

This study demonstrates the important role of the electrostatic repulsive force in the thermal stability of o/w emulsions. We have shown that positively charged egg phospholipid emulsions are not desirable, as the positive ζ potential is neutralized during autoclaving. In commerce, o/w emulsions stabilized by egg phospholipid are autoclaved at an alkaline pH (pH 8−9) in order to maintain an adequate negative ζ potential for thermal stability.

Formulation modification by the addition of small amounts of anionic phospholipid fractions is a convenient means of increasing the ζ potential. This approach may be an attractive alternative to alterations of the autoclaving process when coalescence occurs during steam sterilization. The results of this study may also be relevant to observed batch-to-batch differences in the stability of egg phospholipid to autoclaving. As a natural product, the composition of egg phospholipid may vary in terms of nonionic and anionic components. All other factors being equal, one lot of egg phospholipid having a larger fraction of anionic components may produce a more stable emulsion at elevated temperatures than another lot having a smaller fraction.

The mechanical properties of the interfacial film may also be an important factor in the thermal stability of o/w emulsions. This factor will be investigated in a subsequent study.

Abstract □ The effect of alcohol coadministration on cocaine pharmacokinetics and pharmacodynamics was investigated in awake, freely moving rats. Cocaine plasma and brain extracellular fluid (ECF) concentration–time profiles were characterized after intraperitoneal (ip) administration of 30 mg/kg cocaine to rats that were pretreated with either normal saline or alcohol at 5 g/kg in a balanced crossover experimental design. The neurochemical response to cocaine administration, measured as the change in dopamine concentration in the nucleus accumbens (N ACC) and the change in the mean arterial blood pressure were monitored simultaneously. Intragastric alcohol administration significantly increased cocaine systemic bioavailability after ip administration from 0.550 ± 0.044 to 0.754 ± 0.071. Also, the absorption rate constant increased from 0.199 ± 0.045 to 0.276 ± 0.059 min^{-1} due to alcohol coadministration; however, this increase was not significant. Alcohol inhibition of cocaine metabolism caused an increase in cocaine elimination half-life from 26.3 ± 3.6 to 40.0 ± 8.1 min. Also, cocaine tissue distribution was enhanced by alcohol, resulting in a significant increase in cocaine volume of distribution. Analysis of the brain cocaine concentration–neurochemical effect relationship by the sigmoid-E_{max} pharmacodynamic model showed that E_{max} increased from 850 ± 200 to 1550 ± 640% of baseline due to alcohol coadministration, whereas EC_{50} decreased from 3400 ± 580 to 2000 ± 650 ng/mL, indicating higher cocaine potency in the presence of alcohol. The estimates of the indirect inhibitory pharmacodynamic model used to examine the plasma cocaine concentration–change in blood pressure relationship were not significantly different after the two treatments. These results indicate that alcohol significantly alters cocaine absorption, distribution, and elimination, resulting in higher and prolonged cocaine plasma concentration. Alcohol coadministration also potentiates the neurochemical response to cocaine administration.

Introduction

The pharmacological activities of cocaine include central nervous system (CNS), cardiovascular, and local anesthetic effects.[1] Cocaine inhibits catecholamine reuptake in the brain, leading to higher catecholamine concentration and producing cocaine stimulant effects.[2] Cocaine can also inhibit peripheral catecholamine reuptake leading to higher peripheral catecholamine concentrations that are primarily responsible for cocaine sympathomimetic effects.[3] It is also believed that cocaine may produce its sympathomimetic effect by a central mechanism.[4] The local anesthetic effect of cocaine results from blocking the sodium channel in sensory neurons, a mechanism that can affect the cardiac action potential leading to slower heart rate and slower cardiac conduction at high cocaine concentrations.[5] The sympathomimetic and the local anesthetic effects of cocaine can lead to opposite effects on the cardiovascular functions, which is responsible for the large variability in the cardiovascular effects of cocaine.[6,7]

Concurrent cocaine and alcohol use is one of the most frequently abused drug combinations.[8] The popularity of this drug combination arises primarily from the fact that abusers of this drug combination experience more intense and longer lasting euphoric effects, while the unpleasant disphoria experienced with cessation of cocaine use is reduced.[9] However, concurrent cocaine and alcohol abuse is associated with serious medical problems. This drug combination was identified as the most frequent substance abuse pattern found among individuals presented to emergency rooms with substance abuse-related problems (Drug Abuse Warning Network, 1991). Also, epidemiological studies of cocaine fatalities have indicated that combined cocaine and alcohol abuse results in 18-fold increase in the risk of sudden death compared with cocaine abuse alone.[10] Although the observed effects of this drug combination may result from the pharmacological effects of cocaine in addition to those of alcohol, several investigations have shown that alcohol can significantly alter the pharmacokinetics of cocaine.[11−14]

Alcohol coadministration with cocaine in experimental animals and humans has been shown to inhibit the metabolism of cocaine,[15,16] increase the plasma and brain cocaine concentrations,[14] and lead to the formation of the pharmacologically active metabolite cocaethylene.[11−14] In controlled human studies, concurrent cocaine and alcohol administration have been shown to increase the plasma cocaine concentrations in addition to the formation of cocaethylene.[17,18] Cocaine area under the plasma concentration−time curve (AUC_p) and the maximum cocaine plasma concentration ($C_{p\ max}$) after administration of alcohol and cocaine were significantly higher than those after administration of cocaine only.[11−13,17] Because good correlation between the pharmacokinetics and pharmacological effects of cocaine has been reported,[19−21] alteration in cocaine pharmacokinetics has been implicated, at least in part, for the increased incidence of cocaine-related toxicities after combined abuse of cocaine and alcohol.

The primary objective of this study was to investigate the effect of alcohol coadministration on the pharmacokinetics and the pharmacological effects of cocaine in the rat. This objective was achieved by comparing cocaine absorption, distribution, and elimination when administered alone and in combination with alcohol. Both the neurochemical response measured as the change in dopamine concentration in the nucleus accumbens (N ACC) and the change in mean arterial blood pressure after the two treatments were

monitored simultaneously. This is the first investigation that examined the effect of alcohol coadministration on cocaine pharmacokinetics and pharmacological activities simultaneously in the same group of experimental animals.

Materials and Methods

Chemicals and Reagents—Cocaine hydrochloride, bupivacaine, 1-heptanesulfonic acid, and sodium fluoride were purchased from Sigma Chemical (St. Louis, MO). Acetonitrile and chloroform were supplied by Burdick and Jackson Laboratory (Muskegon, MI). The dehydrated-200 proof ethyl alcohol (USP) was purchased from McCormick Distilling (Weston, MO). Methanol, citric acid, EDTA, monobasic sodium phosphate, sodium hydroxide, and monobasic ammonium phosphate were obtained from J. T. Baker (Phillipsburg, NJ). All solvents were of high-performance liquid chromatographic (HPLC) grade, and all chemicals were of analytical reagent (AR) grade.

Animal Care and Preparation. Male Wistar rats (250−350 g, Simonsen Laboratories, Gilroy, CA) were maintained on a 12 h light/dark cycle and were given Purina chow pellets and water ad libitum for at least 7 days before use in the experiments. All operating procedures on animals were in accordance with the Guide for the Care and Use of Laboratory Animals (National Institutes of Health Publication No. 85-23, revised 1985) and were approved by the institutional animal care and use committee. The details of the animal preparation procedures were described previously.[22] Briefly, for the cocaine ip experiment, rats were prepared under aseptic condition while fully anesthetized by implanting a microdialysis cranial probe, cannulating the femoral arteries, and inserting abdominal and gastric catheters. For the cocaine iv experiment, all the procedures were similar except that the abdominal catheter was not implanted and only one femoral artery and one femoral vein were cannulated.

Cocaine and Alcohol Administration—A stock solution of cocaine (10 mg/mL) in normal saline was used for cocaine administration. For the ip cocaine experiment, the administered dose was 30 mg/kg, and for the iv cocaine experiment, the dose was 6.8 mg/kg. These doses were chosen because they are well below the cocaine dose that is lethal in 50% of the tested rats (LD_{50} 17 mg/kg for iv, and 75 mg/kg for ip, Material Safety Data Sheet, University of Washington, Seattle, 1995). Also, these doses should achieve measurable plasma and brain concentrations of cocaine and its metabolites over the period of the experiment. The alcohol dose (5 g/kg) was chosen to achieve an alcohol plasma concentration in the range of concentrations observed in humans after moderate drinking based on the reported alcohol pharmacokinetic parameters in rats.[23] Cocaine was administered ip via the abdominal catheter and iv via the femoral vein cannula, whereas alcohol was administered through the gastric catheter. This animal model allows cocaine and alcohol administration and collection of samples without the need to hold the rat, thereby avoiding the effect of animal handling on the monitored pharmacodynamic parameters.

Cocaine Pharmacokinetic and Pharmacodynamic Studies—*Cocaine ip Treatment*—Eight male Wistar rats were randomly chosen and were prepared following the surgical procedures just outlined. After the recovery period, each rat was treated with cocaine+normal saline and cocaine+alcohol in a balanced crossover experimental design with 48-h washout period between treatments. Four of the rats received cocaine+normal saline first followed by cocaine+alcohol after the washout period and the other four received cocaine+alcohol then cocaine+normal saline. In all the experiments, rats were pretreated with normal saline or alcohol 20 min before cocaine administration.

On the day of the experiment, one of the femoral artery cannulae was connected to a pressure transducer linked to a portable physiological monitor (Model VSM1, Physio-control, Redmond, WA) for monitoring the mean arterial blood pressure. Meanwhile, the effluent of the microdialysis probe (1 μL/min) was collected every 20 min into an HPLC autosampler vial spiked with 20 μL of dopamine mobile phase, and 5 μL was injected immediately into an HPLC with electrochemical detection (HPLC−EC) for dopamine analysis. This procedure was repeated until a stable basal dopamine concentration was detected (<10% difference in dopamine concentration in three consecutive collections). Once a stable dopamine baseline was achieved, the rat received either 10 g/kg of normal saline or 5 g/kg of alcohol (50% v/v in normal saline) through the gastric catheter. Twenty minutes later, 30 mg/kg of cocaine was administered ip through the abdominal catheter. This lag time was necessary to allow alcohol absorption into the systemic circulation before cocaine administration.[23] After cocaine administration, 10 blood samples, each of 0.2 mL, were collected through the femoral artery cannula at 2, 5, 10, 15, 30, 60, 90, 120, 180, and 240 min into vacutainers pretreated with heparin and sodium fluoride to avoid cocaine hydrolysis by the plasma esterases. Plasma samples were obtained by centrifugation and were stored at −20 °C until analysis for cocaine and its metabolites by HPLC with ultraviolet detection (HPLC−UV). The effluent of the microdialysis probe was continuously collected every 20 min throughout the experiment in HPLC autosampler vials containing 20 μL of the mobile phase for dopamine analysis (pH 4). This mobile phase was added to increase the stability of dopamine, cocaine, and cocaine metabolites in the collected samples. After mixing the vial content, 5 μL was injected immediately into the HPLC-EC system for dopamine analysis, and the remainder was analyzed for cocaine and its metabolites by HPLC−UV. The concentrations of cocaine and cocaine metabolites in the brain ECF were determined from the microdialysis probe effluent concentrations after correcting for the probe recovery, which was determined from an in vitro experiment.[24] The mean arterial blood pressure was continuously monitored during the entire experiment.

After the two treatments just described, four of these eight rats received a third treatment that consisted of alcohol (5 g/kg, 50% v/v in normal saline) through the gastric catheter. The purpose of this alcohol treatment was to determine the range of alcohol plasma concentrations achieved after alcohol administration during the pharmacokinetic experiment. Serial blood samples were obtained after alcohol administrations, and the plasma samples, each of 100 μL, were analyzed immediately for their alcohol content utilizing the Abbott ADx Analyzer (Abbott Diagnostic, Chicago, IL) as described previously.[13]

Cocaine iv Treatment. This experiment was performed to estimate the absolute bioavailability of cocaine after ip cocaine administration with and without alcohol pretreatment. Also, the results of this experiment were used to validate the pharmacokinetic model used in the analysis of the effect of alcohol pretreatment on cocaine pharmacokinetics. In this experiment, 12 male Wistar rats were randomly chosen and were prepared as already outlined.[22] After the recovery period, each rat received cocaine+normal saline and cocaine+alcohol in a balanced crossover design with a 48-h washout period between treatments. The rats received either normal saline (10 g/kg) or alcohol (5 g/kg, 50% v/v in normal saline) through the gastric catheter followed 20 min later by iv cocaine (6.8 mg/kg) via the femoral vein cannula. After cocaine administration, 10 blood samples, each of 0.2 mL, were collected through the femoral artery cannula at 2, 5, 10, 15, 30, 60, 90, 120, 180, and 240 min into vacutainers pretreated with heparin and sodium fluoride. Plasma samples were obtained by centrifugation and were stored at −20 °C until analysis for cocaine and its metabolites by HPLC−UV. The effluent of the microdialysis probe was continuously collected every 20 min and was analyzed for cocaine and its metabolites by HPLC−UV immediately after each collection.

Analytical Methods—*Cocaine and its Metabolites*—Plasma and microdialysis probe effluent were analyzed for cocaine and its metabolites by the method developed in our laboratory.[25] This is an isocratic HPLC method that involves extraction of cocaine and its metabolites from plasma samples with chloroform and utilizes bupivacaine as an internal standard. This method is sensitive enough to quantitate cocaine and its metabolites in concentrations as low as 25 ng/mL in 100-μL plasma samples, with a coefficient of variation of <10%. The brain ECF concentrations of cocaine and its metabolites were determined by the same method, except that the probe effluent was injected directly into the HPLC−UV system without any pretreatment.

Dopamine—The effluent of the microdialysis probe was injected directly into an HPLC system equipped with an electrochemical detector for dopamine analysis (Coulochem detector Model 5100A, guard cell Model 5020, and analytical cell Model 5014A, ESA, Bedford, MA). The mobile phase consisted of 0.1 M citrate, 0.075 M monobasic sodium phosphate, 36 mg/L of EDTA, 303 mg/L of 1-heptanesulfonic acid, and 5.5% methanol (v/v). The pH of the

mobile phase was adjusted to pH 4 with sodium hydroxide pellets. On the coulochem detector, the potential for the guard cell was set at −0.20 V, whereas those for detectors 1 and 2 were set at +0.30 and −0.15 V, respectively. Quantitation of dopamine was achieved on a Supelcosil LC-18-DB column (250 × 2.1 mm i.d., 5 μm), and the flow rate was 0.3 mL/min. The signal from detector 2 was analyzed with an electronic integrator (Hewlett-Packard, Model 3390, Palo Alto, CA). Because the change in dopamine ECF concentration after cocaine administration was expressed as percentage of baseline, dopamine probe recovery, which was necessary to calculate the actual concentration of dopamine in the brain ECF, was not determined.

Pharmacokinetic Analysis—A two-compartment pharmacokinetic model with elimination from the central compartment was used to analyze the effect of alcohol on cocaine absorption, distribution, and elimination after ip administration. This model assumes that cocaine absorption, distribution, and elimination follow first-order kinetics, and that the brain is part of the peripheral tissue compartment. The following equations were used to describe cocaine concentrations in the central (eqs 1 and 2) and the peripheral (eqs 3 and 4) compartments after a single ip (eqs 1 and 3) and iv administration (eqs 2 and 4):[26]

$$C_p = \frac{FD_{ip}k_a}{V_c}\left[\frac{(k_{21}-k_a)}{(\alpha-k_a)(\beta-k_a)}e^{-k_a t} + \frac{(k_{21}-\alpha)}{(k_a-\alpha)(\beta-\alpha)}e^{-\alpha t} + \frac{(k_{21}-\beta)}{(k_a-\beta)(\alpha-\beta)}e^{-\beta t}\right] \quad (1)$$

$$C_p = \frac{D_{iv}}{V_c(\alpha-\beta)}[(\alpha-k_{21})e^{-\alpha t} + (k_{21}-\beta)e^{-\beta t}] \quad (2)$$

$$C_b = \frac{FD_{ip}k_a k_{21}}{V_t}\left[\frac{e^{-k_a t}}{(\alpha-k_a)(\beta-k_a)} + \frac{e^{-\alpha t}}{(k_a-\alpha)(\beta-\alpha)} + \frac{e^{-\beta t}}{(k_a-\beta)(\alpha-\beta)}\right] \quad (3)$$

$$C_b = \frac{D_{iv}k_{12}}{V_t(\beta-\alpha)}(e^{-\alpha t} - e^{-\beta t}) \quad (4)$$

where D_{ip} and D_{iv} are cocaine doses for ip and iv administrations, F is cocaine bioavailability after ip administration, C_p and C_b are cocaine concentrations in the central (plasma) and tissue (brain ECF) compartments, respectively, V_c and V_t are volumes of distribution of the central and tissue compartments, k_a is cocaine first-order absorption rate constant after ip administration, k_{12} is the first-order transfer rate constant from the central to the tissue compartment, k_{21} is the first-order transfer rate constant from the tissue to the central compartment, k_{10} is the first-order elimination rate constant from the central compartment, and α and β are the hybrid first-order rate constants for the distribution and elimination processes, respectively.[26,27]

Plasma and brain ECF cocaine concentrations for each rat after ip cocaine with or without alcohol coadministration were fitted simultaneously to the two integrated equations that describe the plasma and brain ECF concentration−time profiles (eq 1 and 3). The pharmacokinetic model parameters were estimated by nonlinear regression analysis utilizing PCNONLIN (Version 4.0, SCI Software, Lexington, KY). Other pharmacokinetic parameters such as the total body clearance (*TBC*), the volumes of distribution at steady state and during the elimination phase (V_{dss} and $V_{d\beta}$), and the areas under cocaine plasma (AUC_p) and brain ECF (AUC_b) concentration−time curves were calculated from the estimated parameters.[27] The systemic bioavailability of cocaine after ip administration with and without alcohol pretreatment was calculated by comparing the corresponding AUC_p after iv and ip cocaine administrations.

Pharmacodynamic Analysis—*Neurochemical Response*—The sigmoid-E_{max} pharmacodynamic model was used to describe the relationship between the brain ECF cocaine concentration and the percent change in the brain ECF dopamine concentration.[22] The mathematical expression that describes the concentration−effect relationship for the sigmoid-E_{max} model is the following:

$$E = E_0 + \frac{E_{max}C_b^n}{EC_{50}^n + C_b^n} \quad (5)$$

where E is the effect measured as the percent change in dopamine basal concentration, E_0 is the baseline effect measured as the basal dopamine concentration, E_{max} is the maximum effect measured as the maximum change in dopamine concentration, EC_{50} is the brain ECF cocaine concentration when the observed effect is 50% of E_{max}, C_b is the brain ECF cocaine concentration, and n is the sigmoidicity factor. The pharmacodynamic model parameters were estimated by fitting the percent change in dopamine level and the cocaine concentration in the brain ECF at different time points to eq 5. The basal dopamine concentration was kept constant (100%) during the analysis. Nonlinear regression analysis was performed utilizing PCNONLIN.

Mean Arterial Blood Pressure Response—The relationship between the plasma cocaine concentration and the change in mean arterial blood pressure after ip cocaine administration followed counterclockwise hysteresis loop. The mean arterial blood pressure did not return to its baseline value at the end of the 4-h experiment.[21,22] This result indicates that under the condition of our investigation, there was no direct relationship between cocaine plasma concentration and the change in mean arterial blood pressure. Therefore, the indirect pharmacodynamic response model was utilized to characterize this relationship.[28,29] We chose the model that can describe indirect drug response resulting from inhibition of a mediator because cocaine effect on blood pressure results primarily from inhibition of catecholamine reuptake at the peripheral nerve endings leading to higher peripheral catecholamine concentration, which is responsible for the vasopressor effect of cocaine. The mathematical expression that describes the model for the change in the pharmacological response and the drug concentration is:

$$\frac{dR}{dt} = k_{in} - k_{out}\left(1 - \frac{I_{max}C_p^n}{IC_{50}^n + C_p^n}\right)R \quad (6)$$

where R is the observed response (percent change in mean arterial blood pressure), k_{in} is the apparent zero-order rate constant for response production, k_{out} is the first-order rate constant for response dissipation, I_{max} is the maximum inhibition of the factor that produces the effect, IC_{50} is the plasma cocaine concentration that leads to 50% inhibition of the factor that produces the effect, C_p is the plasma cocaine concentration at the time of the observed response, and n is the sigmoidicity factor.[28,29] The maximum response that will be achieved when D_{ip} is very large or IC_{50} approaches zero is the following:

$$R_{max} = \frac{R_0}{1 - I_{max}} \quad (7)$$

where R_{max} is the maximum response and R_0 is the basal response (100%).

The indirect pharmacodynamic model parameters were estimated by fitting the percent change in mean arterial blood pressure and the plasma cocaine concentration at different time points to eq 6. Nonlinear regression analysis was performed utilizing PCNONLIN.

Statistical Analysis—The pharmacokinetic and pharmacodynamic parameters obtained after cocaine+normal saline and cocaine+alcohol treatments were analyzed using the Statistical Analysis System (SAS Institute Inc., Cary, NC). The balanced crossover design of our investigation is equivalent to the two-way factorial experiment (2 × 2) with repeated measures on the cocaine treatment factor. The plasma and brain ECF cocaine concentration−time profiles, the percent change in dopamine brain ECF concentration−time profiles, and the percent change in mean arterial blood pressure−time profiles after the two treatments were analyzed with two-way analysis of variance with repeated measures on both factors using SAS. Treatments (cocaine+normal saline or cocaine+alcohol) and time were considered as the between subject-variability. Multiple comparison with Bonferroni correction was conducted to examine the difference between

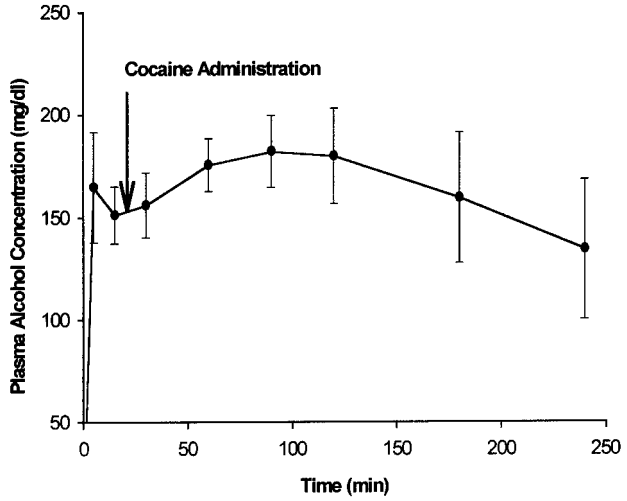

Figure 1—Plasma alcohol concentration–time profile after 5 g/kg of alcohol po ($n = 4$, data are presented as mean ± SE).

treatments at each time point. Differences of $P < 0.05$ were considered significant.

Results

Alcohol was rapidly absorbed after intragastric administration and its plasma concentration declined very slowly because alcohol elimination has been shown to follow zero-order kinetics in rodents.[13] The average plasma alcohol concentrations in the four rats that received 5 g/kg of alcohol intragastrically ranged from 140 to 180 mg/dL (0.14−0.18%) during the 4-h sampling period (Figure 1). This range of alcohol concentrations is similar to that observed in humans after moderate alcohol drinking.

The plasma concentration−time profile of cocaine after a single iv administration declined biexponentially with an average elimination half-life of 28.6 ± 3.5 min. After ip administration, cocaine was absorbed rapidly from the abdominal cavity, reaching the maximum plasma concentration within 10−15 min, and then the concentration declined, with an average elimination half-life of 26.3 ± 3.6 min. Meanwhile, the brain ECF cocaine concentration increased rapidly, reaching its maximum value within 10−20 min after iv administration and within 20−40 min after ip administration, and then declined parallel to the concentration in plasma (Figures 2A and 2B). Cocaethylene was detected in plasma and brain ECF only when cocaine was given with alcohol. Although other cocaine metabolites, including benzoylecgonine and norcocaine, were measured in both plasma and brain ECF in this study, the effect of alcohol on cocaine metabolic profile will be discussed in detail in a separate publication.

Pharmacokinetic studies that involved administered cocaine doses similar to those used in our investigation have shown that cocaine follows linear pharmacokinetics, which validates the first assumption of our proposed model.[13,14,30] The assumption that the brain is part of the peripheral compartment was validated by comparing the estimates for the pharmacokinetic parameters obtained from fitting the plasma concentrations to eq 2 with those obtained from fitting the plasma and brain concentrations simultaneously to eqs 2 and 4. Agreement between the estimated parameters using the two fitting procedures should indicate that the brain is indeed part of the peripheral compartment. The plasma and brain ECF concentrations obtained after iv cocaine administration were used in this validation. The average estimates for k_{12}, k_{21}, k_{10}, and V_c in 12 rats obtained from fitting eq 2 only

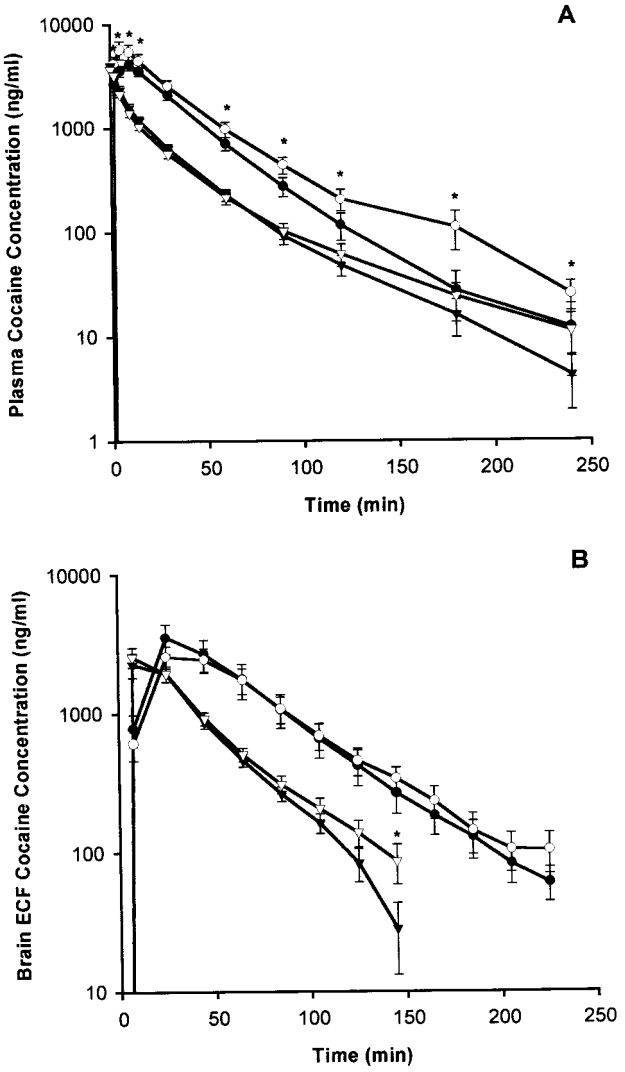

Figure 2—Plasma concentration–time profile of cocaine in plasma (A) and brain (B) after administration of 6.8 mg/kg cocaine iv (▼), 6.8 mg/kg of cocaine iv plus 5 g/kg alcohol po (▽), 30 mg/kg of cocaine ip (●), and 30 mg/kg of cocaine ip plus 5 g/kg alcohol po (○). Each point represents the mean ± SE from 12 rats (iv) and 8 rats (ip). Key: (*) significantly different from the cocaine+ normal saline treatment ($p < 0.05$).

were 0.094 min^{-1}, 0.097 min^{-1}, 0.075 min^{-1}, and 1.63 L/kg, respectively. The average estimates for k_{12}, k_{21}, k_{10}, and V_c in the same 12 rats obtained from fitting eq 2 and 4 simultaneously were 0.082 min^{-1}, 0.093 min^{-1}, 0.073 min^{-1}, and 1.76 L/kg, respectively. Statistical analysis showed that the estimated pharmacokinetic parameters from the two fitting procedures were not different. However, the precision of the parameter estimates was better when the plasma and brain concentrations were used simultaneously. These findings indicate that the brain is a representative part of the peripheral compartment in the proposed pharmacokinetic model and that fitting the plasma and brain data simultaneously improves the precision of the parameter estimation. The fact that the brain is part of the peripheral compartment in the pharmacokinetic model indicates that cocaine distribution to the brain is not instantaneous. As a result, the proposed pharmacokinetic model should adequately describe cocaine absorption, distribution, and elimination after ip administration. A representative example of the simultaneous fitting of the measured plasma and brain ECF cocaine concentrations after ip cocaine administration to eqs 1 and 3 is shown in Figure 3.

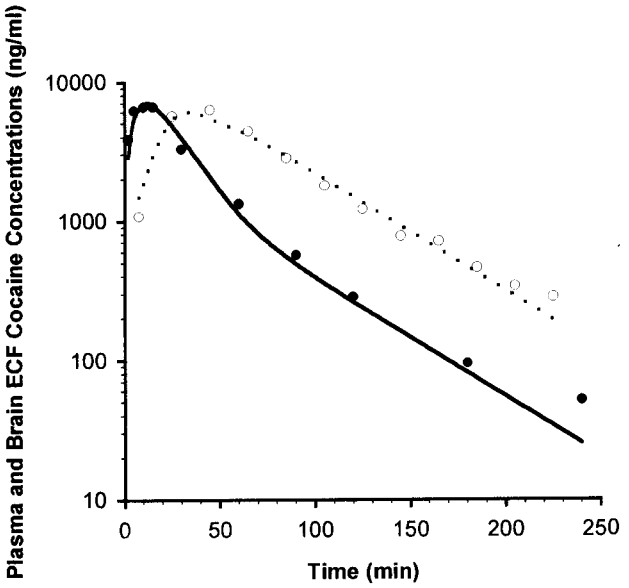

Figure 3—A representative example of the simultaneous fitting of the observed plasma (●) and brain ECF (○) cocaine concentration–time profiles after administration of 30 mg/kg of cocaine ip. The symbols represent the actual experimental data and the line represent the model-fitted curve.

Table 1—Pharmacokinetic Parameters for Cocaine after ip Administration in Wistar Rats (Mean ± SE, $n = 8$)

pharmacokinetic parameter	cocaine treatment: cocaine (ip)[a] + normal saline (po)	cocaine treatment: cocaine (ip)[a] + alcohol (po)
AUC_p (μg-min/mL)	154 ± 12	219 ± 34[c]

[a] Cocaine dose, 30 mg/kg, ip; alcohol dose, 5 g/kg, po. [b] Presented as *TBC/F*. [c] Significantly different from the cocaine+normal saline treatment ($P < 0.05$).

The proposed pharmacokinetic model was used to examine the effect of alcohol coadministration on cocaine pharmacokinetics by comparing the pharmacokinetic parameters estimated after cocaine+normal saline and cocaine+alcohol. The estimated cocaine pharmacokinetic parameters after ip administration with and without alcohol pretreatment are summarized in Table 1. Alcohol pretreatment significantly affected the extent of cocaine absorption after ip cocaine administration. The absolute bioavailability of cocaine significantly increased from 0.550 ± 0.044 after cocaine+normal saline to 0.754 ± 0.071 after cocaine+alcohol. Although cocaine absorption rate, measured as the first-order absorption rate constant, was not significantly faster after alcohol pretreatment, the time to achieve the maximum plasma cocaine concentration was significantly shorter than that after administration of cocaine+normal saline. This result is an indication of a faster rate of cocaine absorption after alcohol pretreatment.

Table 2—Pharmacodynamic Parameters of Cocaine in Wistar Rats (Mean ± SE, $n = 8$)

pharmacodynamic parameter	cocaine treatment: cocaine (ip)[a] + normal saline (po)	cocaine treatment: cocaine (ip)[a] + alcohol (po)
A. neurochemical		
E_{max} (% of baseline)	850 ± 200	1550 ± 640

[a] Cocaine dose, 30 mg/kg; alcohol dose, 5 g/kg. [b] Significantly different from the cocaine+normal saline treatment group ($p < 0.05$).

Alcohol pretreatment also resulted in a significant prolongation of cocaine elimination half-life from 26.3 ± 3.6 min after cocaine+normal saline to 40.0 ± 8.1 min after cocaine+alcohol treatment. Similarly, the estimated cocaine elimination half-life after iv administration significantly increased from 28.6 ± 3.5 min after cocaine+normal saline to 37.3 ± 4.7 min after cocaine+alcohol. The estimated apparent *TBC* of cocaine decreased from 203 ± 16 mL/min/kg after cocaine+normal saline to 158 ± 21 mL/min/kg after cocaine+alcohol; however, this difference was not significant. Another interesting finding of this study is that the brain-to-plasma distribution ratio, measured as the ratio of the cocaine AUC in the brain ECF to the cocaine AUC in plasma, decreased significantly from 1.35 ± 0.28 after cocaine+normal saline to 0.98 ± 0.17 after cocaine+alcohol. Also, alcohol pretreatment resulted in a significant increase in the volume of distribution of cocaine.

After cocaine administration, the brain ECF dopamine concentration increased and reached its maximum value within 20−40 min, then it gradually declined to its baseline value at the end of the 4-h experiment period. Dopamine concentration−time profile followed closely the cocaine concentration−time profile in the N ACC. Alcohol coadministration with cocaine caused significantly higher dopamine concentrations in the N ACC, and the rate of decline of dopamine concentration to its baseline level was slower compared with that after cocaine+normal saline (Figure 4A). The relationship between the brain ECF cocaine concentration and the percent change in dopamine concentration was described using the sigmoid-E_{max} pharmacodynamic model. A representative example of the sigmoid-E_{max} model-fitted curve is shown in Figure 4B. The average estimate for E_{max} increased by ≈80% when alcohol was administered with cocaine, however, this difference was not statistically significant. Also, after cocaine+alcohol, the estimated EC_{50} was significantly smaller and the sigmoidicity factor *n* was significantly larger than those after cocaine+normal saline. A summary of the pharmacodynamic parameters is shown in Table 2.

The mean arterial blood pressure increased rapidly after cocaine administration and then declined slowly and did not return to its baseline value at the end of the 4-h experiment (Figure 5A). Because alcohol alone caused, on average, a 5−10% decrease in blood pressure, we partitioned this effect from the combined effect of cocaine+alcohol when these drugs were administered together (Figure 5A). The corrected percent change in mean arterial blood pressure−time profile was used for pharmacodynamic

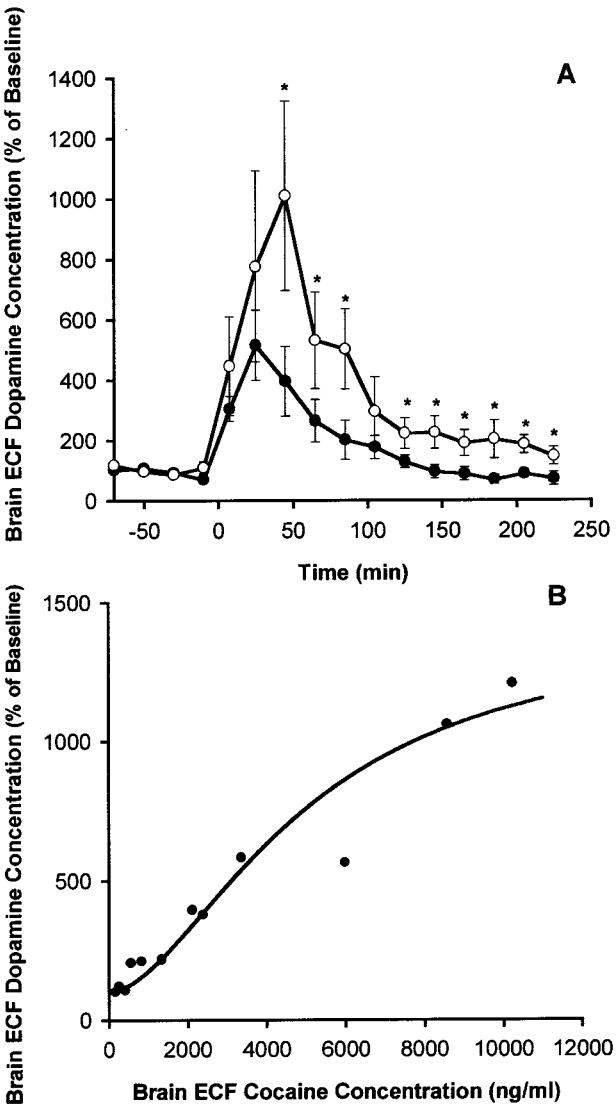

Figure 4—(A) Brain ECF dopamine concentration–time profiles after administration of 30 mg/kg of cocaine ip (●) and 30 mg/kg of cocaine ip plus 5 g/kg of alcohol po (○). Each point represents the mean ± SE from 8 rats. modeling. A representative example of the observed values and the indirect inhibitory pharmacodynamic response model-fitted curve is shown in Figure 5B. Table 2 shows that the estimated parameters for the proposed pharmacodynamic model were not different after cocaine+normal saline and cocaine+alcohol.

Discussion

The pharmacokinetic model used to describe cocaine disposition in our investigation is a two-compartment model with first-order absorption, distribution, and elimination. The proposed two-compartment pharmacokinetic model used in our investigation was adequate in describing cocaine pharmacokinetics as indicated by the good agreement between the experimental data points and the model predicted curves. Examination of the cocaine plasma concentration−time profile and the brain ECF concentration−time profile showed the existence of a short delay in the appearance of cocaine in the brain. This delay represents the distribution of cocaine to the brain, which has been shown to be part of the peripheral compartment in the proposed model. The experimental design in the current investigation involved serial sampling of both plasma and brain ECF that represent the central and the peripheral compartments, respectively. This design allowed characterization of the absorption, distribution, and elimination of cocaine after ip administration, and examination of the effect of alcohol pretreatment on these processes.

Cocaine undergoes significant presystemic elimination, which is the main cause of its incomplete bioavailability after ip administration. Alcohol coadministration significantly increased the systemic bioavailability of cocaine due to the inhibition of cocaine presystemic metabolism. This conclusion is indicated because the maximum concentration of benzoylecgonine, one of the major cocaine metabolites, was lower after cocaine+alcohol administration in the

current study (data not shown) and in pervious investigations.[13,17] Similar inhibition of the presystemic metabolism by alcohol has been reported for drugs that undergo significant first-pass effect.[31,32] This increase in cocaine bioavailability was reflected by the significant increase in its *AUC* and $C_{p\ max}$ after cocaine+alcohol compared with those values after cocaine+normal saline. Although the increase in cocaine first-order absorption rate constant was not significant after cocaine+alcohol, the time to achieve maximum cocaine plasma concentration was significantly shorter. This result indicates that alcohol may enhance the rate of cocaine absorption, which is consistent with what we have reported previously.[13]

Alcohol coadministration significantly increased the volume of distribution of cocaine. The results of our investigation showed that V_c did not change due alcohol administration with cocaine, however both V_{dss} and $V_{d\beta}$ increased significantly. Cocaine has been shown to bind primarily to albumin and alpha-1-acid glycoprotein in serum.[33] Also, cocaine is extensively distributed to tissues such as kidney, brain, liver, heart, and placenta.[34] The significant increase in cocaine volume of distribution due to alcohol coadministration is caused by increased cocaine tissue distribution, which may have resulted from altering the binding of cocaine in plasma and tissues.[35] These results are not contradictory to the decreased brain-to-plasma *AUC* ratio when cocaine was administered with alcohol. Because the microdialysis technique used for the determination of cocaine brain ECF concentration measures only the free (unbound) cocaine concentration in the brain ECF. This free concentration is dependent on the total cocaine concentration and the cocaine bound fraction in the brain, which may be altered due to alcohol coadministration. We have previously reported that alcohol coadministration with cocaine increased the brain ECF concentration of cocaine.[14] However, alcohol was administered by a constant-rate iv infusion in that study, and the plasma alcohol concentration achieved at the end of the 4-h experiment period was on average 365 mg/dL. This result may suggest that more severe alcohol intoxication can lead to higher brain and plasma cocaine concentrations that may augment cocaine pharmacological effects and toxicity.

Alcohol coadministration has been shown to inhibit cocaine metabolism in vivo and in mouse and human liver preparations in vitro.[15−17] The decrease in *TBC* due to alcohol coadministration in our investigation was barely insignificant. However, cocaine elimination half-life was significantly prolonged due to alcohol coadministration. The increase in cocaine volume of distribution in addition to the insignificant reduction of the cocaine TBC contributed to the significantly prolonged cocaine half-life. These findings suggest that the enhanced cocaine systemic bioavailability and the prolonged cocaine elimination half-life are the major factors responsible for the significantly higher and prolonged cocaine plasma concentrations after cocaine+alcohol.

It has been reported previously that drug abusers often experience more intense and longer lasting euphoric effect after simultaneous use of cocaine and alcohol.[9] Controlled human studies have shown that, compared with either cocaine or alcohol administration alone, the combination of cocaine and alcohol seemed to produce more marked subjective effects especially in the feelings related to well-being.[17,18] Results from the current investigation also showed that the increase in dopamine concentration in the N ACC after cocaine+alcohol was significantly higher and its rate of decline to the baseline was slower than that after cocaine+normal saline. Several factors may contribute to the higher dopamine concentration in the N ACC. Cocaethylene, a pharmacologically active metabolite formed only when both cocaine and alcohol are administered, has been shown to possess cocaine-like effects and can increase dopamine concentration after administration in experimental animals.[34−38] Another contributing factor may be related to alcohol administration because alcohol has been shown to increase dopamine brain concentrations after acute or chronic administrations in experimental animals.[39] It is also possible that the increased tissue distribution of cocaine due to alcohol pretreatment may result in higher (bound + free) brain tissue concentration of cocaine, which can lead to higher dopamine concentrations.

The relationship between cocaine brain ECF concentration and the change in N ACC dopamine level can be described by the sigmoid-E_{max} pharmacodynamic model.[22] Our pharmacodynamic analysis showed that the estimated E_{max} was higher after cocaine+alcohol compared with after cocaine+normal saline, however, this difference was not significant. On the other hand, EC_{50} was significantly lower after cocaine+alcohol compared with after cocaine+normal saline. This result means that the same brain ECF cocaine concentration will produce higher neurochemical response after coadministration of alcohol, which is consistent with the more intense and longer lasting euphoric effects experienced by subjects after combined abuse of cocaine and alcohol.[9] This higher response may be caused by the pharmacologically active metabolite cocaethylene, which is formed only when cocaine is administered with alcohol. The contribution of cocaine metabolites to the observed pharmacological activities after administration of cocaine and alcohol will be discussed in detail in a separate publication. Other possibilities for the enhanced neurochemical responses when cocaine is administered with alcohol may include the effect of alcohol and the increased cocaine brain tissue distribution as was discussed previously.

The cardiovascular activities of cocaine are mainly due to its sympathomimetic effects. These include an increase in blood pressure, QRS duration, and heart rate.[1] However, at higher cocaine concentrations, the sodium channel blocking effect of cocaine can slow the cardiac conduction and result in slower heart rate.[5] In this study, the immediate increase in mean arterial blood pressure achieved after cocaine administration is mainly due to the sympathomimetic vasopressor effect of cocaine. Alcohol coadministration did not have any significant effect on the change in the mean arterial blood pressure after cocaine administration. Studies conducted in humans also showed that the change in arterial systolic and diastolic blood pressures after administration of cocaine and alcohol was similar to that of cocaine only.[17] The lack of difference in the vasopressor response after the two treatments despite the higher cocaine plasma concentrations after cocaine+alcohol may be attributed to the effect of alcohol on the cardiovascular system. Alcohol caused an average 5−10% reduction in the mean arterial blood pressure in the rats that received alcohol only. This reduction means that the change in the mean arterial blood pressure in response to cocaine administration was larger after cocaine+alcohol (if the effect of alcohol is partitioned) compared with that after cocaine+normal saline. The higher and the prolonged cocaine plasma concentration in addition to the formation of cocaethylene after cocaine+alcohol treatment may be responsible for the higher response to cocaine after cocaine+alcohol.

Several previous studies reported that the relationship between plasma cocaine concentration and the change in the mean arterial blood pressure showed a counterclockwise hysteresis.[21,22,40] This hysteresis indicates that there is no direct relationship between cocaine plasma concentration and the change in the mean arterial blood pressure.

When direct concentration−effect relationship does not exist, indirect pharmacodynamic response models,[28,29] or the use of an effect compartment may be useful in the pharmacodynamic analysis.[41] The indirect pharmacodynamic response model used to describe the relationship between cocaine plasma concentration and the change in blood pressure adequately characterized this relationship. This adequacy is evident from the agreement between the observed results and the model-fitted curve. Table 2 shows that the maximum inhibitory effect of cocaine on neurotransmitter reuptake was increased by 2.30% when alcohol was administered with cocaine. Also, alcohol coadministration increases the potency of cocaine as reflected by the 20% reduction in IC_{50}. This difference in the blood pressure response to cocaine after the two treatments may have clinical and biological significance despite the fact that the difference is statistically insignificant.[6] This difference may also explain the increased incidence of cardiovascular toxicity after abusing this drug combination.

The cocaine dose used in the ip administration experiment (30 mg/kg) is in the range of doses used frequently in the pharmacological investigations of cocaine. The plasma cocaine concentrations achieved after administration of this dose was higher than the plasma cocaine concentration observed in human studies. However, this dose was well tolerated by the rats and there was no visible evidence of acute adverse effects. The choice of this dose was necessary to precisely determine the pharmacokinetic behavior of cocaine in plasma and brain ECF and to characterize the cocaine concentration−pharmacological effects relationship over a wide range of cocaine concentrations. It will be important to determine if the outcome of the interactions between cocaine and alcohol is dependent on the dose of cocaine and/or alcohol.

In conclusion, alcohol coadministration increases the rate and extent of cocaine absorption after ip administration and increases the tissue distribution of cocaine as manifested by the increase in cocaine volume of distribution. Meanwhile, cocaine elimination is inhibited resulting in longer cocaine half-life. The combined effect of these pharmacokinetic changes produces higher and prolonged cocaine plasma concentrations. The pharmacologically active metabolite cocaethylene is detected in both plasma and brain ECF only when cocaine and alcohol are administered together. Alcohol coadministration also augments the pharmacological activities of cocaine, especially its CNS effects. Because of the existence of good relationships between cocaine brain and plasma concentrations and the neurochemical and cardiovascular responses to cocaine administration, the changes in cocaine pharmacokinetics are, at least partially, responsible for the changes in cocaine effects after administration of this drug combination.

Abstract □ The pharmacokinetics and pharmacodynamics of cocaine and its three metabolites, benzoylecgonine, norcocaine, and cocaethylene, were investigated in awake, freely moving rats. This work was performed to examine the effect of alcohol coadministration on the metabolic profile of cocaine and to determine the contribution of cocaine metabolites to the pharmacological responses observed after cocaine administration. The plasma and brain extracellular fluid concentration–time profiles were characterized after intravenous (iv) administration of cocaine and the three metabolites in a crossover experimental design. The neurochemical response, measured as the change in dopamine concentration in the nucleus accumbens, and the cardiovascular responses, measured as the change in the mean arterial blood pressure, heart rate, and QRS interval, were monitored simultaneously. Cocaethylene had the highest brain-to-plasma distribution ratio, followed by cocaine, norcocaine, and benzoylecgonine. The estimated total body clearances for cocaine, benzoylecgonine, norcocaine, and cocaethylene were 140 ± 19, 14.7 ± 1.2, 130 ± 19, and 111 ± 16 mL/min/kg, respectively. Alcohol coadministration increased the formation of norcocaine, decreased the formation of benzoylecgonine, and resulted in the formation of the pharmacologically active metabolite cocaethylene. When cocaine was administered with alcohol, 12.9 ± 3.1% to 15.3 ± 2.9% of the cocaine dose was converted to cocaethylene. Benzoylecgonine did not have any central nervous system or cardiovascular activities after iv administration. Compared with cocaine, norcocaine and cocaethylene had more potent and prolonged effects on the neurochemical, heart rate, and QRS interval responses, and were equipotent in increasing the mean arterial blood pressure. These results indicate that changes in the cocaine metabolic profile and the formation of the pharmacologically active metabolite cocaethylene are, at least partially, responsible for the more intense and longer lasting effects reported after using this drug in combination with alcohol.

Introduction

Cocaine metabolism involves both hydrolysis and oxidation pathways. Benzoylecgonine is formed by spontaneous hydrolysis or as a result of enzymatic hydrolysis by serum and liver microsomal carboxylesterases.[1,2] When both cocaine and alcohol are present, the same enzymes are responsible for the formation of cocaethylene via ethyl transesterification.[2] Ecgonine methyl ester is formed via hydrolysis of the cocaine phenyl ester group by serum and liver cholinesterases.[1,2] Formation of norcocaine is catalyzed by either cytochrome P-450 enzymes or flavin adenine dinucleotide (FAD)-containing monooxygenases.[3−5] Further oxidative metabolism of norcocaine by cytochrome P-450 enzymes yields reactive metabolites that are implicated in the norcocaine-mediated hepatotoxicity of cocaine.[5]

Cocaine is a short-term sympathomimetic psychostimulant that produces marked physiological and behavioral effects in both humans and experimental animals. The pharmacological consequences of cocaine consumption include central nervous system (CNS) stimulant effects manifested by euphoria, increase in locomotor activity, and stereotypy.[6] The cardiovascular activities of cocaine are mainly due to its sympathomimetic effects, which include an increase in blood pressure, QRS duration, and heart rate. However, at higher cocaine concentrations, the sodium channel blocking effect of cocaine can slow the cardiac conduction and result in slower heart rate. The mechanism of the effects of cocaine is believed to be the binding of cocaine to the neurotransmitter reuptake sites, leading to accumulation of the neurotransmitters in the synaptic cleft.[7] The locomotor activity and the reinforcement effects of cocaine are believed to be mediated by the increased brain extracellular (ECF) dopamine concentrations.[8] The major toxicities of cocaine abuse include addiction, cardiac arrhythmia, myocardial ischemia, myocarditis, aortic dissection, cerebral vasoconstriction, seizure, and trauma that leads to death.[9] The proposed mechanism for the cardiac arrhythmia and conduction disturbances associated with cocaine overdose is the blockage of cardiac sodium channels by cocaine.[10,11]

The two major metabolites of cocaine, benzoylecgonine and ecgonine methyl ester, do not have any cocaine-like stimulant activity when administered to experimental animals. However continuous intravenous (iv) infusion of benzoylecgonine and ecgonine methyl ester in doses of 0.45 and 1.5 mg/kg/min, respectively, for 30 min to anesthetized rats have been shown to significantly increase the blood pressure without affecting either the heart rate or the QRS duration.[11] Norcocaine can cause a CNS stimulant effect in rats after intracerebroventricular administration and has higher affinity for inactivated cardiac sodium channels than cocaine in guinea pig cardiac myocytes.[10,12] Norcocaine is also hepatotoxic in both animals and humans.[5,13] Cocaethylene is a CNS stimulant and has cardiovascular effects comparable to those of cocaine in rats and rabbits.[11,14]

Alcohol coadministration with cocaine has been shown to alter the metabolic profile of cocaine, leading to the formation of cocaethylene and increasing the fraction of cocaine dose converted to norcocaine.[15] The changes in cocaine pharmacokinetics and metabolic profile has been implicated in the more intense and longer-lasting cocaine pharmacological effects observed after abusing this drug combination.[16] The primary objective of this study was to investigate the pharmacokinetics and pharmacodynamics of cocaine and its three metabolites, benzoylecgonine,

norcocaine, and cocaethylene, in the rat. This work was important to determine the effect of alcohol coadministration on the metabolic profile of cocaine and to evaluate the contribution of cocaine metabolites to the pharmacological effects of cocaine. In this study, the pharmacokinetics of cocaine and its metabolites were characterized after iv administration of the four compounds to the rat in a crossover experimental design. Meanwhile, the neurochemical response, measured as the change in dopamine concentration in the nucleus accumbens (N ACC), and the cardiovascular responses, measured as changes in mean arterial blood pressure, heart rate, and QRS interval, were monitored simultaneously after each drug administration. This is the first study that examined the pharmacokinetics and pharmacodynamics of cocaine metabolites and compared the effect of cocaine and its metabolites on the pharmacological activities in the same group of experimental animals.

Materials and Methods

Chemicals and Reagents—Benzoylecgonine, norcocaine hydrochloride, and cocaethylene hydrochloride were obtained from Research Biochemicals International (Natick, MA). Cocaine hydrochloride was purchased from Sigma Chemical (St. Louis, MO).

Animal Care and Preparation—Male Wistar rats (250−350 g, Simonsen Laboratories, Gilroy, CA) were used in this investigation. All animal preparation procedures were in accordance with the *Guide for the Care and Use of Laboratory Animals* (National Institutes of Health Publication No. 85-23, revised 1985) and were approved by the institutional animal care and use committee at Washington State University. The details of the animal preparation procedures were described previously.[17,18]

Administration of Cocaine and its Metabolites—Stock solutions of cocaine (10 mg/mL), benzoylecgonine (5 mg/mL), norcocaine (1.5 mg/mL), and cocaethylene (3 mg/mL) in normal saline were prepared and used for the experiment. Drugs were administered iv through the femoral vein cannula at doses of 0.02 mmol/kg (for cocaine) and 0.01 mmol/kg (for benzoylecgonine, norcocaine, and cocaethylene) in a crossover experimental design. The cocaine dose was chosen because it is well below the dose of cocaine that is lethal in 50% of the tested rats (LD_{50}) after iv administration (0.05 mmol/kg, Material Safety Data Sheet, University of Washington, Seattle, 1995). The dose of 0.01 mmol/kg for benzoylecgonine, norcocaine, and cocaethylene was chosen based on the preliminary studies conducted in our laboratory to determine the tolerable doses of these metabolites in the rat. The doses of cocaine and its metabolites used in this experiment should achieve measurable plasma and brain concentrations of these compounds for at least 2 h after drug administration.

Pharmacokinetic and Pharmacodynamic Studies—Nine male Wistar rats were randomly chosen and were prepared following the surgical procedures described previously.[17,18] After the recovery period, the rats were treated with cocaine, benzoylecgonine, norcocaine, and cocaethylene in a crossover experimental design, with a 24-h washout period between treatments.

On the day of the experiment, one of the femoral artery cannulae was connected to a pressure transducer linked to a blood pressure analyzer (Digi-Med model 190, Micro-Med, Louisville, KY) for monitoring the mean arterial blood pressure and heart rate. The three exposed tips of the insulated wires of the 3-electrode EKG cable were connected to the sinus rhythm analyzer (Digi-Med model 200, Micro-Med, Louisville, KY) in Lead-II setting for monitoring the cardiac electrical activity. The signals from the two analyzers were collected, updated, and averaged every 1 min by a system integrator (Digi-Med model 200, Micro-Med, Louisville, KY) and were stored in a computer for subsequent analysis. Meanwhile, the brain microdialysis effluent was collected every 20 min (at 1 μL/min) in HPLC autosampler vials containing 20 μL of dopamine mobile phase. After mixing the vial content, 5 μL was injected immediately into an HPLC equipped with an electrochemical (EC) detector for dopamine analysis. This procedure was repeated until a stable basal dopamine concentration was detected (<10% difference in dopamine concentration in three consecutive samples). Once a stable dopamine baseline was achieved, the rat received iv cocaine (or one of the three metabolites) through the femoral vein cannula. After drug administration, 10 blood samples each of 0.2 mL were collected through the femoral artery cannula at 2, 5, 10, 15, 30, 60, 90, 120, 180, and 240 min in heparin- and sodium fluoride-pretreated vacutainers to avoid cocaine and cocaethylene hydrolysis by plasma carboxylesterases. Plasma samples were obtained by centrifugation and were stored at −20 °C until analysis for cocaine and its metabolites by HPLC with ultraviolet (UV) detection. The effluent of the microdialysis probe was continuously collected every 20 min throughout the experiment in HPLC autosampler vials containing 20 μL of dopamine mobile phase (pH 4). This procedure was to maintain dopamine, cocaine, and its metabolites under acidic condition so as to reduce their spontaneous oxidation and hydrolysis. After mixing the vial content, 5 μL was injected immediately into the HPLC−EC system for dopamine analysis, and the remainder was analyzed for cocaine and its metabolites by HPLC−UV. The mean arterial blood pressure, the heart rate, and the QRS interval were continuously monitored during the entire experiment. Nine rats received all three metabolites in a crossover experimental design, whereas only six of these rats received cocaine in addition to the three metabolites.

The pharmacokinetic parameters for each of the cocaine metabolites estimated in the current study were utilized to investigate the effect of alcohol on cocaine metabolic profile. This was achieved by estimating the fraction of the cocaine dose converted to each of the metabolites when cocaine was administered alone and in combination with alcohol. The results obtained from a previous pharmacokinetic experiment, which involved iv and intraperitoneal (ip) cocaine administrations, were used in this analysis.[18] The pharmacological effects observed after the administration of benzoylecgonine, norcocaine, and cocaethylene were used to determine the contribution of these metabolites to the overall cocaine pharmacological effects when cocaine was administered alone and in combination with alcohol.

Analytical Methods—*Cocaine and Its Metabolites*—Plasma and microdialysis probe effluents were analyzed for cocaine and its metabolites by the method developed in our laboratory.[19] This method is sensitive enough to quantitate cocaine and its metabolites in concentrations as low as 0.075 nmol/mL in 100-μL plasma samples, with coefficient of variation of <10%. The brain ECF concentrations of cocaine and its metabolites were determined by the same method, except that the probe effluent was injected directly into the HPLC−UV system without any pretreatment. The actual concentrations of cocaine and its metabolites in the brain ECF were determined from the probe effluent concentration after correcting for the probe recovery, which was determined from an in vitro calibration experiment.

Dopamine—The microdialysis probe effluent was injected directly into an HPLC system equipped with an EC detector for dopamine analysis immediately after collection. The details of the analytical procedures used for dopamine determination in the microdialysis probe effluent were described previously.[18]

Pharmacokinetic Analysis—A two-compartment pharmacokinetic model with elimination from the central compartment was used to analyze the distribution and elimination of cocaine and its metabolites after iv administration.[18] This model assumes that the distribution and elimination of these compounds follow first-order kinetics, and that the brain is part of the peripheral tissue compartment. The plasma and brain ECF drug concentrations for each rat after administrations of each compound were fitted simultaneously to the equations that describe the plasma and brain ECF concentration−time profiles.[18] The pharmacokinetic model parameters were estimated by nonlinear regression analysis utilizing PCNONLIN (Version 4.0, SCI Software, Lexington, KY). Other pharmacokinetic parameters such as the total body clearance (TBC), the volumes of distribution at steady state and during the elimination phase (Vd_{ss} and Vd_{β}), and the area under the drug plasma (AUC_p) and brain ECF (AUC_b) concentration−time curves were calculated from the estimated parameters.[20]

The fraction of the cocaine iv dose converted to each metabolite (f_m) was calculated using eq 1:[21]

$$f_m = \frac{AUC_{\text{iv cocaine}}(m)TBC(m)}{D_{iv}} \quad (1)$$

where $AUC_{\text{iv cocaine}}(m)$ is the area under the plasma metabolite

concentration−time curve after iv administration of cocaine, D_{iv}, is cocaine dose, and TBC(m) is the total body clearance of the metabolite after iv administration of cocaine, which is assumed to be equal to the estimated metabolite TBC after administration of the preformed metabolite. For ip cocaine administration, the fraction of the cocaine dose converted to the metabolite (f_m) was also calculated using eq 1 after substituting $AUC_{iv\ cocaine}(m)$ and D_{iv} by $AUC_{ip\ cocaine}(m)$ and D_{ip}.

Pharmacodynamic Analysis—*Neurochemical Response*—The linear pharmacodynamic model was used to describe the relationship between the brain ECF drug concentration and the change in the brain ECF dopamine concentration. The mathematical expression that describes the concentration−effect relationship for the model is the following:

$$E = E_o + \text{slope}\ C_b \tag{2}$$

where E is the effect measured as the percent change in dopamine concentration, E_0 is the baseline effect measured as the basal dopamine concentration, Slope is the percent increase in the measured dopamine concentration caused by every unit increase in the brain ECF drug concentration (C_b). In this model, the slope is a measure of the potency of the drug. The pharmacodynamic model parameters were estimated by fitting the percent change in dopamine level and the drug concentration in the brain ECF at different time points to eq 2. The basal dopamine concentration was kept constant (100%) during the linear regression analysis.

Cardiovascular Responses—The relationship between the plasma drug concentration and the change in the mean arterial blood pressure, heart rate, and QRS interval after iv administration of the four compounds was characterized by the mechanism-based pharmacodynamic response model as described previously.[22,23] The mathematical expression that describes the model for the change in the pharmacological response and the drug concentration is the following:

$$\frac{dR}{dt} = k_{in} - k_{out}\left(1 - \frac{I_{max}C_p^{\,n}}{IC_{50}^{\,n} + C_p^{\,n}}\right)R \tag{3}$$

where R is the observed response (for example the percent change in mean arterial blood pressure), k_{in} is the apparent zero-order rate constant for response production, k_{out} is the first-order rate constant for response dissipation, I_{max} is the maximum inhibition of the factor that produces the effect, IC_{50} is the plasma drug concentration that leads to 50% inhibition of the factor that produces the effect, C_p is the plasma drug concentration at the time of the observed response, and n is the sigmoidicity factor. At very high drug concentration or at the maximum inhibition, the maximum response can be estimated as follows[22,23]

$$R_{max} = \frac{R_0}{1 - I_{max}} \tag{4}$$

where R_{max} is the maximum response and R_0 is the basal response (100%).

The pharmacodynamic model parameters were estimated by fitting the percent change in each of the monitored cardiovascular functions and the plasma concentrations of cocaine and its metabolites at different time points to eq 3. Nonlinear regression analysis was performed utilizing PCNONLIN.

Statistical Analysis—Cocaine and its metabolites were administered to the rats in a crossover experimental design. The estimated pharmacodynamic parameters for the neurochemical and the cardiovascular effects of each compound were compared by the paired t test. Also, the effect of alcohol coadministration with cocaine on the pharmacokinetic parameters of each metabolite were compared by the paired t test. Differences of $p < 0.05$ were considered significant.

Results

The plasma and the brain concentration−time profiles of cocaine, benzoylecgonine, norcocaine, and cocaethylene after a single iv bolus administration are illustrated in Figure 1. For these four compounds, the plasma concentration declined biexponentially and the brain ECF concentration increased rapidly and then declined parallel to the concentration in plasma during the elimination phase. The distribution half-lives of cocaine and its metabolites were not significantly different from each other and they ranged from 4.48 ± 0.51 to 6.4 ± 1.1 min. On the other hand, benzoylecgonine had the longest elimination half-life, followed by norcocaine, cocaethylene, and cocaine. Benzoylecgonine had the smallest TBC, followed by cocaethylene, norcocaine, and then cocaine. The brain-to-plasma distribution ratio, measured as AUC_b/AUC_p, was the highest for cocaethylene, followed by cocaine, norcocaine, and benzoylecgonine. A summary of the model-estimated pharmacokinetic parameters of cocaine, benzoylecgonine, norcocaine, and cocaethylene is listed in Table 1.

After iv administration of cocaine, norcocaine, and cocaethylene, the brain ECF dopamine concentration increased and reached its maximum value within 20−40 min, then it gradually declined to its baseline value after 2 h when the brain ECF drug concentration approached zero. The dopamine concentration−time profile followed the drug concentration−time profile in the N ACC. Benzoylecgonine, however, did not cause any significant change in N ACC dopamine concentration (Figure 2A). The relationship between the brain ECF drug concentration and the percent change in dopamine concentration was determined with the linear pharmacodynamic model. Representative examples of the linear model-fitted lines in one rat after iv administration of cocaine, norcocaine, and cocaethylene are shown in Figure 2B. Norcocaine and cocaethylene were more potent than cocaine with respect to the neurochemical effect, and the average model-estimated slopes for these two compounds were 3.7 and 2.5 times larger than that of cocaine (Table 2).

The mean arterial blood pressure increased rapidly after cocaine administration and then declined slowly and did not return to its baseline value when plasma drug concentration approached zero (Figure 3A). The effect of cocaine on the mean arterial blood pressure was higher than that of norcocaine and cocaethylene, however, this difference was due to the higher cocaine dose. The pharmacodynamic analysis showed that there was no difference in the estimated IC_{50} and R_{max} for the effect of cocaine, norcocaine, and cocaethylene on the mean arterial blood pressure, which indicates that there is no differences in the potency and the maximum intrinsic activity of these three compounds (Table 2). Norcocaine and cocaethylene caused larger reductions in heart rate even though their doses were 50% lower than that of cocaine (Figure 3B). The higher potency of these two cocaine metabolites was reflected in their significantly lower IC_{50} compared with that of cocaine (Table 2). For the QRS response, norcocaine and cocaethylene were more potent than cocaine, as indicated by their lower IC_{50} (Table 2). Benzoylecgonine did not have any significant effect on the mean arterial blood pressure, heart rate, or QRS interval (Figures 3A−C). Representative examples of the observed cardiovascular response values and the indirect pharmacodynamic response model-fitted curves for one rat after administration of cocaine and its metabolites in a crossover experimental design are shown in Figures 4A−C. All estimated parameters of cocaine and its metabolites for the pharmacodynamic model are summarized in Table 2.

In one of our previous cocaine pharmacokinetic studies, we administered cocaine iv and ip to rats with and without alcohol.[18] The plasma and brain ECF concentration−time profiles of cocaine and its metabolites after ip cocaine with and without the coadministration of alcohol are shown in Figure 5. After ip cocaine alone, both benzoylecgonine and norcocaine were detected in the plasma and the brain (Figures 5A & B). In the presence of alcohol, the pharma-

cologically active metabolite cocaethylene was formed and it was detected in both plasma and the brain (Figures 5C & D). The effect of alcohol coadministration on the metabolic profile of cocaine was determined utilizing the pharmacokinetic parameters of cocaine metabolites determined in the current study, and the results are summarized in Table 3.

Compared with iv cocaine alone, alcohol coadministration caused significant inhibition of cocaine metabolism to benzoylecgonine. This effect is shown in the significant reduction in benzoylecgonine AUC_p and $C_{p\ max}$. Also, the fraction of the administered cocaine dose converted to benzoylecgonine was significantly reduced from 0.432 ± 0.047 to 0.237 ± 0.038, and the formation clearance of this cocaine metabolite was decreased from 47.2 ± 4.0 to 27.2 ± 4.0 mL/min/kg. Alcohol coadministration also led to a slight increase in the formation of norcocaine, and cocaethylene was formed only when alcohol was administered

with cocaine. The fraction of cocaine iv dose converted to cocaethylene was 0.129 ± 0.031. When cocaine was given ip, alcohol coadministration caused significant reduction in benzoylecgonine $C_{p\ max}$. However, no changes were found in the fraction of the cocaine dose converted to benzoylecgonine. There was about a 40% increase in the formation of norcocaine, and 15.3 ± 2.9% of the cocaine dose was metabolized to cocaethylene.

Discussion

In the present study, we investigated the pharmacokinetics and pharmacodynamics of cocaine and its three metabolites simultaneously after iv bolus administration of these compounds to awake, freely moving rats. Our results showed that the highly hydrophilic cocaine metabolite benzoylecgonine had the highest AUC_p, whereas its AUC_b was the lowest. The brain-to-plasma distribution ratio of benzoylecgonine was the lowest among the four

benzoylecgonine may be explained by the low brain distribution of this hydrophilic metabolite because intracerebroventricular administration of benzoylecgonine has been shown to produce stimulant effect in awake Sprague-Dawley rats.[12] A previous investigation has shown that benzoylecgonine can increase the blood pressure after iv infusion of 0.45 mg/kg/min for 30 min to anesthetized rats; however, the dose of benzoylecgonine used in that investigation was much higher than the dose used in our experiment.[11]

Cocaethylene has the highest brain-to-plasma distribution ratio, followed by cocaine, norcocaine, and then benzoylecgonine, which is the same rank order of the lipophilicity of these four compounds. This result indicates that the brain distribution of these compounds is probably via passive diffusion across the blood–brain barrier. Norcocaine and cocaethylene administration resulted in higher dopamine concentration in the N ACC compared with after cocaine administration. The brain ECF concentration–neurochemical effect relationships for cocaine, norcocaine, and cocaethylene after iv administration were best described by the linear pharmacodynamic model, even though we used the sigmoid-E_{max} pharmacodynamic model to describe the brain ECF concentration–neurochemical effect relationship after ip cocaine administration.[17] The reason for this discrepancy is that the iv dose used in the current investigation was much lower than the ip dose that resulted in lower brain ECF concentration of cocaine and its metabolites. It was not possible to characterize the sigmoid-E_{max} relationship because all the observed brain ECF concentrations were in the lower linear portion of this relationship. The linear pharmacodynamic model showed that norcocaine and cocaethylene were more potent than cocaine in dopamine reuptake inhibition. This result was consistent with the higher dopamine concentrations observed after norcocaine and cocaethylene administration despite the fact that cocaine dose was twice that of norcocaine and cocaethylene. This finding indicates that after cocaine administration with alcohol, despite the lower concentrations of norcocaine and cocaethylene, these metabolites may be significantly contributing to the observed neurochemical response to cocaine administration due to

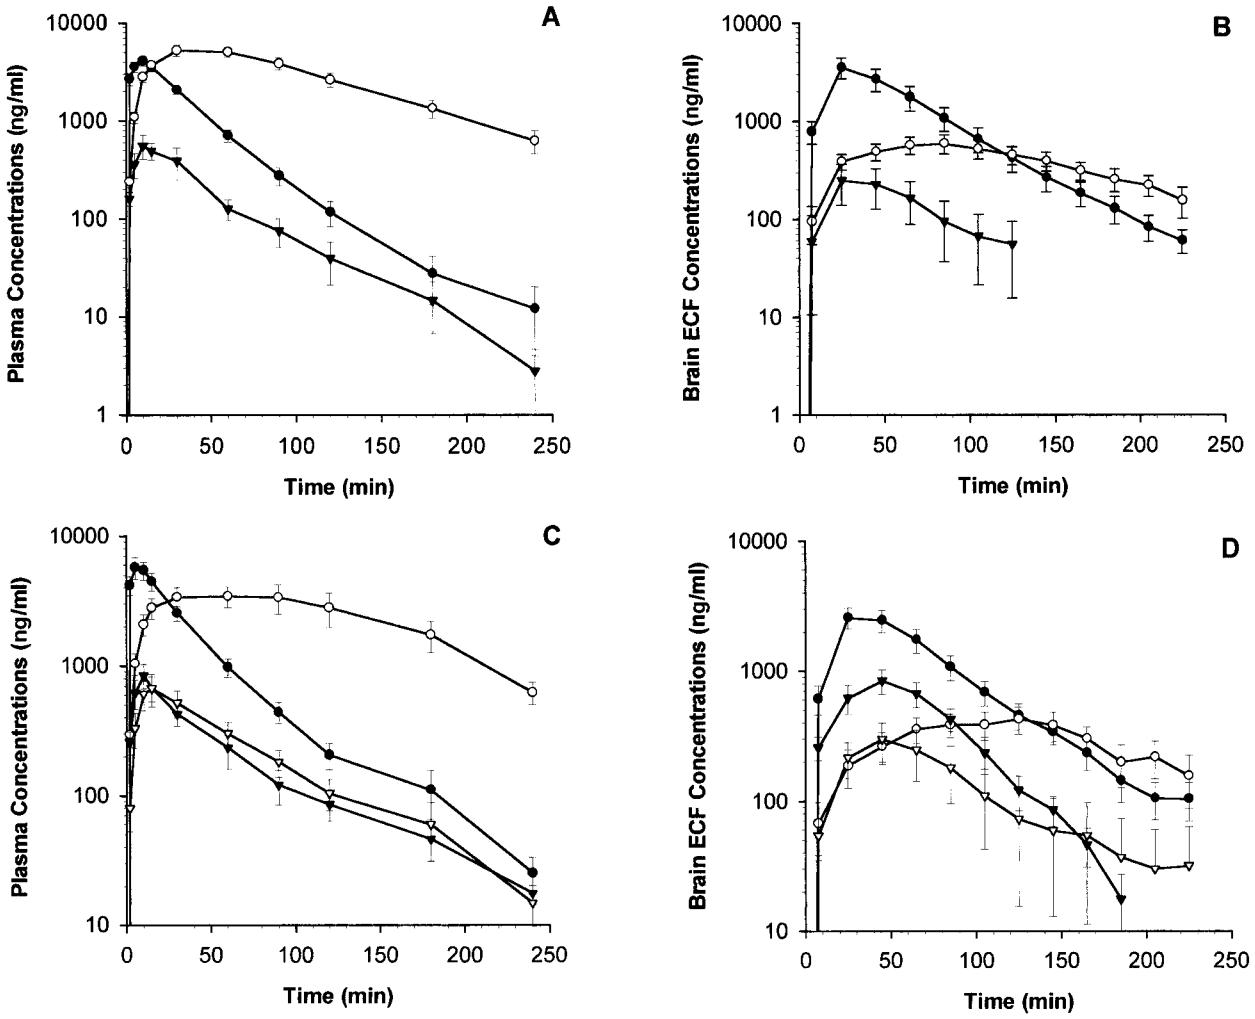

Figure 5—Plasma (A, C) and the brain (B, D) ECF concentration–time profiles of cocaine (●), benzoylecgonine (○), norcocaine (▼), and cocaethylene (▽) after administration of 0.088 mmol/kg cocaine ip (A, B) and 0.088 mmol/kg cocaine ip plus 5 g/kg alcohol po (C, D) to the rat in a balanced crossover experimental design. their higher potency. Also, factors that can alter the formation of these two metabolites, such as genetic polymorphism and drug-drug interactions, may change the overall neurochemical response to cocaine administration.

Analysis of the cardiovascular effects observed after administration of cocaine and its metabolites showed that cocaine, norcocaine, and cocaethylene have similar potency and maximum intrinsic activity on the mean arterial blood pressure. Both norcocaine and cocaethylene were more potent than cocaine in reducing the heart rate and prolonging the QRS interval. This result is consistent with the previous experimental results obtained in vitro using cardiac myocytes.[10,24] Meanwhile, k_{out} was the smallest for norcocaine, so that the dissipation of the heart rate response was the slowest when rats were treated with norcocaine. Norcocaine and cocaethylene also had smaller k_{out} values compared with cocaine, which means slower dissipation of the QRS response after administration of these two compounds. These pharmacodynamic results were consistent with the pharmacokinetic findings because norcocaine and cocaethylene have longer elimination half-lives and lower TBCs when compared with cocaine. The pharmacodynamic model-predicted higher potency of cocaethylene and norcocaine with respect to their effect on heart rate is consistent with the higher responses observed after administration of these two metabolites. These findings indicate that norcocaine and cocaethylene should be contributing to the cardiovascular responses to cocaine administration because of their higher potency.

The fraction of the cocaine iv dose converted to benzoylecgonine was reduced by >50% when iv cocaine was administered with alcohol. However, the formation of benzoylecgonine was not reduced after ip administration of cocaine with alcohol. The difference in the fraction of the iv and the ip doses of cocaine metabolized to benzoylecgonine (0.43 for iv versus 0.33 for ip) indicates that less benzoylecgonine is formed during the presystemic metabolism of cocaine compared with the systemic metabolism of cocaine. Coadministration of alcohol results in increased cocaine bioavailability after ip administration, which will lead to the formation of more benzoylecgonine and may mask the effect of alcohol coadministration on benzoylecgonine formation. This result may explain the small difference in the fraction of cocaine dose metabolized to benzoylecgonine after cocaine ip alone and after cocaine ip and alcohol.

Norcocaine formation after ip cocaine administration was ≈8 times more than that after iv cocaine administration. This difference may be caused by more norcocaine formation during the presystemic metabolism when cocaine was given ip. The reason for this result is that the formation of norcocaine is catalyzed by either cytochrome P-450 enzymes (CYP2B and CYP3A subfamilies) or FAD-containing monooxygenase.[3] These enzymes, especially the CYP3A subfamily, have different expressions and activities in the gut and liver isoforms.[25] Norcocaine formation increased by 10 and 40% due to alcohol coadministration with iv and ip cocaine administration, respectively. Our pharmacodynamic analysis showed that norcocaine is more potent than cocaine in its neurochemical, heart rate, and QRS interval effects. Norcocaine AUC in plasma was ≈1−2% as large as cocaine AUC after iv cocaine administration and was ≈17% as large as cocaine AUC after ip cocaine administration. Because of the higher potency of norcocaine this metabolite significantly contributes to the observed neurochamical and cardiovascular effects after ip cocaine administration because 11−16% of cocaine dose is converted to norcocaine. However, after iv cocaine administration, which is the route of administration relevent to human cocaine abuse, the contribution of norcocaine to the neurochamical and cardiovascular effects may not be significant because only 1−2% of the administered iv cocaine dose is converted to norcocaine.

The hepatotoxicity of norcocaine is believed to be the result of its further oxidative metabolism by CYP2Bs, either through redox cycling between *N*-hydroxynorcocaine and norcocaine nitroxide or the production of an unidentified reactive metabolite.[5,26] The hepatic toxicity of norcocaine may be synergized by alcohol because both of these drugs act on the central lobular area of the liver.[27] In addition to potentiation of cocaine-induced hepatocellular toxicity through CYP2E1-dependent oxidative stress, alcohol could also enhance cocaine bioactivation through induction of other P-450 enzymes, such as the CYP2B and 3A subfamilies.[26,28] In our investigation, the increase in norcocaine formation due to a single dose of alcohol was ≈10% after iv cocaine administration and 40% after ip cocaine administration. This difference may indicate that the increase in cocaine hepatotoxicity when given in combination with alcohol is not exclusively dependent on the increased norcocaine formation especially after iv cocaine administration.

Approximately 13 to 15% of the cocaine doses were converted to cocaethylene when cocaine was administered iv or ip in combination with alcohol. Presystemic and systemic metabolism led to similar fractional conversion of cocaine to cocaethylene. Our pharmacodynamic analysis showed that cocaethylene is ≈2−3 times more potent than cocaine in its neurochemical, heart rate, and QRS interval effects. The pharmacokinetic analysis showed that cocaethylene AUC in plasma and brain were ≈15−20% as large as those of cocaine after administration of cocaine and alcohol. Because of its higher potency, cocaethylene should be significantly contributing to the pharmacological effects observed in response to combined cocaine and alcohol administration even if cocaethylene concentration in brain and plasma is much lower than that of cocaine.

In conclusion, benzoylecgonine does not possess any significant CNS or cardiovascular activities after iv administration with the dose used in our investigation. Norcocaine and cocaethylene are more potent than cocaine with respect to their neurochemical, heart rate, and QRS interval effects. However, cocaine, norcocaine, and cocaethylene are equipotent with respect to their effect on the mean arterial blood pressure. Alcohol coadministration causes the formation of the pharmacologically active metabolite cocaethylene, reduces the formation of the inactive metabolite benzoylecgonine, and increases the formation of norcocaine. Because of its higher potency, cocaethylene should have significant contribution to the observed pharmacological effects after administration of cocaine and alcohol. Also, modification of the cocaine metabolic profile, such as that due to drug−drug interactions, can lead to significant modification of the observed cocaine pharmacological effects. Because our investigation has been performed in rodents and differences in cocaine pharmacokinetics and pharmacodynamics in different species have been reported, the clinical significance of these finding warrants further investigation.

Abstract □ The effect of calcium ions on the structure and stability of recombinant human DNase I (rhDNase) in the aqueous and solid (lyophilized) states was investigated. Fourier transform infrared (FTIR) spectroscopy was used to examine the overall secondary structure, while chemical stability was monitored in terms of deamidation and soluble aggregate formation at 40 °C. The exogenous calcium was removed by EGTA. This process can remove all but approximately one calcium ion per protein molecule. Analysis of the FTIR spectra in the amide III region in either the aqueous or lyophilized state demonstrated that removal of exogenous Ca^{2+} by EGTA-treatment had little effect on the secondary structure (and lyophilization-induced rearrangement thereof). For the aqueous solution, circular dichroism was used as an independent technique and confirmed that there was no large overall change in the secondary or tertiary structure upon the removal of calcium. The primary degradation route for the aqueous protein was deamidation. For the EGTA-treated protein, there was also severe covalent aggregation, e.g., formation of intermolecular disulfides facilitated by the cleavage of Cys173-Cys209. The aggregates exhibited a markedly different secondary structure compared to the native protein. For instance, the β-sheet band observed at ca. 1620 cm^{-1} wavenumber in the amide I second derivative spectra was increased. Enzymatic activity was completely lost upon aggregation, consistent with the cleavage of the aforementioned native disulfide. For the protein lyophilized in the presence of Ca^{2+}, there was no increase in deamidated species during solid-state storage; however, some aggregation was observed. For the lyophilized EGTA-treated protein, aggregation was even more pronounced, and there was some loss in enzymatic activity upon reconstitution. Thus, the removal of calcium ions by EGTA-treatment decreased the stability of rhDNase in both the aqueous and solid states even though no large overall calcium-induced structural changes could be observed by the techniques used in this study.

Introduction

It has been established that divalent metal cations, particularly Ca^{2+}, play an important role in the structure and function of deoxyribonuclease I (DNase).[1] For the bovine-derived molecule (bDNase), it was shown that the removal of Ca^{2+} from aqueous solution induced changes in the secondary structure, as evidenced in the far-UV circular dichroism spectrum, although no change was seen by sedimentation velocity analysis.[2] In addition, the presence of Ca^{2+} has been shown to increase bDNase's resistance to proteolysis (e.g., by trypsin),[2,3] play a role in refolding the reduced protein,[4] and impart stability toward pH-induced structural alterations.[5] The biological activity of bDNase is lost upon the removal of calcium ions.[1,6] According to Price,[7] bDNase has two strongly binding Ca^{2+} sites and several weakly binding ones. Similar results have demonstrated the importance of Ca^{2+} for the structure and function of the homologous recombinant human form of DNase (rhDNase).[8]

Suck and co-workers[9−11] have examined the structure of bDNase by X-ray crystallography. The protein has a mixed α/β composition, with a hydrophobic core of two, six-stranded β-pleated sheets flanked by α-helices and extensive loop regions. The electron density map also revealed two Ca^{2+} bound to the native protein, one located in a flexible loop formed by residues Gly100 to Gly105, and another in the loop formed by residues Asp201 to Cys209. Both sites are located in proximity to cystine bridges, one between Cys101 and Cys104 and the other between Cys173 and Cys209. The latter disulfide bridge, which is essential for enzymatic activity, is protected against reduction in the presence of Ca^{2+}.[4] It was hypothesized that the stabilizing effects of Ca^{2+} were due to configurational restraints imposed by binding of the cation in the flexible loop regions.[9,10] The putative catalytic Ca^{2+} binding site is located in the proximity of residues Glu78 and His134 at the active center.[11] The X-ray crystal structure of rhDNase has also been determined and is very similar to the bovine form.[8,12]

In the present investigation, we have focused on the effect of removal of exogenous Ca^{2+} on rhDNase structure and biochemical stability, in particular, aggregation and deamidation. The protein was studied both in aqueous solution and the freeze-dried form. The latter is often considered as a common dosage for biopharmaceuticals since many deleterious processes are retarded upon the removal of water (and thus shelf life can be extended).[13] The data reveal that the influence of Ca^{2+} on the rhDNase molecule observed for the aqueous solution also persists following lyophilization and storage in the solid state.

Materials and Methods

Materials—rhDNase (a glycosylated protein with MW ~ 32.7 kDa) was produced at Genentech, Inc. (South San Francisco). Deamidation is the major route of degradation of the protein in aqueous solution. The degradation happens during the manufacturing process, resulting in the starting material with ~60% deamidation. All other chemicals were of reagent grade and purchased from commercial suppliers.

Protein Lyophilization—rhDNase was provided in an aqueous solution consisting of ~18 mg/mL protein, 150 mM NaCl, and 1 mM $CaCl_2$ at pH ~ 6.5 ± 0.5. To remove calcium ions, this solution was exhaustively dialyzed against 1 mM EGTA (pH ~ 6.5 ± 0.5) at 5 °C. It should be noted that it is difficult to completely remove bound Ca^{2+}, and even after exhaustive dialysis against the chelating agent, there is approximately one calcium ion bound per rhDNase molecule.[8] Samples were filtered (0.22 μm, Millipore-

GV) and filled (2 mL) in 3-cc glass vials. The lyophilization cycle consisted of freezing for 4 h at −55 °C, followed by drying at a chamber pressure of 50 μm Hg and a shelf temperature which was ramped at a rate of 10 °C/h to a maximum of 25 °C and held for 50 h. A Leybold (Germany) model GT20 freeze-dryer was used. The moisture content of lyophilized samples was 6 ± 3%. There was no observed moisture transfer from the stoppers during storage (7 ± 2% after incubation for 24 months at 15 °C).

Determination of rhDNase Aggregation—Size exclusion chromatography (SEC) was used to monitor protein monomer, fragments, and soluble aggregates. A Hewlett-Packard 1090L system was used with a silica-based TSK Gel2000SWxl column (Tosohaas, Japan). Sample loadings were approximately 50 μg, and the flow rate for the mobile phase (phosphate-buffered saline; 5 mM sodium phosphate, pH 7.3, and 150 mM NaCl) was 0.5 mL/min. Molecular weight standards (BioRad) consisting of thyroglobulin (670 kDa), γ-globulin (158 kDa), ovalbumin (44 kDa), myoglobulin (17 kDa), and cyanocobalamin (1.35 kDa) were used to calibrate the column. Silver-stained SDS−PAGE, under both reducing and nonreducing conditions, was employed to further examine protein fragments, monomer, and aggregates.

Determination of rhDNase Deamidation—The extent of deamidation of rhDNase was measured using tentacle ion-exchange chromatography.[14] Samples (~50 μg) were loaded on a LiChrosphere column (EM Separations) equilibrated with 1 mM $CaCl_2$, 0.1% acetate buffer, pH 4.7, and eluted with a linear gradient of 0−50% of 1 M sodium chloride in the same buffer. The flow rate was 0.8 mL/min.

Enzymatic Activity Assay—Measurement of rhDNase enzymatic activity was accomplished via a colorimetric method (using DNA complexed with methyl green as a substrate).[15] The activity of experimental samples was determined (in triplicate) relative to a rhDNase standard. Data are expressed as % specific activity, i.e., concentration of rhDNase determined by activity assay divided by that based on UV absorption of the sample.

Circular Dichroism (CD)—CD spectra were measured and analyzed as described previously.[8] All spectra were taken at a concentration of ~0.6 mg/mL rhDNase at room temperature using an Aviv 60DS spectropolarimeter. A 1-cm cylindrical cell was used for CD measurement above 250 nm with a 5-s averaging time for each data point taken at 0.5 nm interval and bandwidth of 0.2 nm. A 0.01-cm cell was used for CD measurement below 250 nm with a 5-s averaging time for each data point taken at 0.5 nm interval and bandwidth of 1.5 nm. Ellipticity values were converted to mean residue weight ellipticity using a mean weight of 112.8 for the protein.

Fourier transform Infrared (FTIR) Spectroscopy and Estimation of Secondary Structure—FTIR spectra were measured using an ATI-Mattson Galaxy 5022 IR spectrophotometer as described previously.[16] A total of 256 scans at 4 cm^{-1} resolution using Happ-Ganzel apodization were averaged to obtain each spectrum. Aqueous samples were measured using a 15-μm spacer between CaF_2 windows in a liquid cell (Spectra-Tech). The spectrum of pure water was subtracted out using Nicolet OMNIC 3.1 software in order to obtain the pure aqueous protein spectrum. Lyophilized samples were measured as KBr pellets (~1 mg of protein per 200 mg of KBr, pressure into a pellet at 5 kpsi compaction pressure); these conditions were shown not to induce any artifactual alterations in rhDNase secondary structure.[16] Spectra were analyzed by second derivatization (with smoothing equivalent to an approximate 10 cm^{-1} span) to determine the number of spectral bands and their approximate locations (OMNIC 3.1 software). Using this information as a starting point, the original spectra in the amide III region (1320−1220 cm^{-1}) were Gaussian curve-fitted using GRAMS/32 software (Galactic Industries), following the strategy detailed by Griebenow and Klibanov.[17] The secondary structure contents were calculated from the areas of the individual assigned bands and their fraction of the total area in the amide III region.[16,17] Data are presented as the average and deviation of at least three determinations. Secondary structure was also assessed and confirmed by qualitative examination of the second derivative amide I spectra (1700−1620 cm^{-1}).[18]

Results and Discussion

Effect of Ca^{2+} on Secondary Structure of rhDNase by Fourier transform Infrared (FTIR) Spectroscopy—

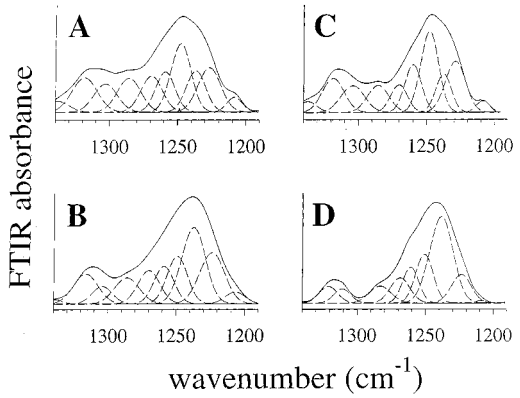

Figure 1—IR spectra for rhDNase I in the amide III region and their Gaussian curve-fitting: (A) in aqueous solution (EGTA-treated, no incubation); (B) in the lyophilized powder (EGTA-treated, no incubation); (C) deamidated form (aqueous protein incubated in 1 mM $CaCl_2$ for 120 days at 40 °C); (D) aggregated form (aqueous EGTA-treated protein incubated in the absence of exogenous calcium ions for 120 days at 40 °C). The solid and dotted curves represent the superimposed original spectra and curve-fit, and the dashed curves are individual Gaussian bands.

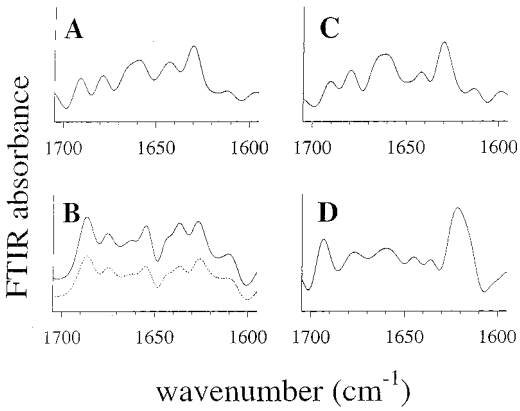

Figure 2—Inverted second derivative of the amide I IR spectra of rhDNase I: (A) in aqueous solution (EGTA-treated, no incubation); (B) lyophilized untreated power (solid line), and lyophilized EGTA-treated power (dotted line) (no incubation for either sample); (C) deamidated form (aqueous protein incubated in 1 mM $CaCl_2$ for 120 days at 40 °C); (D) aggregated form (aqueous EGTA-treated protein incubated in the absence of exogenous calcium ions for 120 days at 40 °C).

Recently, we examined the structure of rhDNase employing Fourier transform infrared (FTIR) spectroscopy, which allows for estimation of protein secondary structure in both aqueous and solid states.[16] It was seen that there was a dehydration-induced structural change, specifically a loss in α-helix and increase in β-sheet structures. Such alterations may be a common occurrence for proteins upon the removal of water.[17,18] In the present investigation, we have further extended FTIR spectroscopy to examine the effect of removing exogenous calcium ions on the protein structure in aqueous solution and also upon drying.

The FTIR spectrum, in the conformationally sensitive amide III region,[17] was measured for rhDNase in aqueous solution following EGTA-treatment to remove exogenous calcium ions (Figure 1A). The spectrum appears very similar to the protein in aqueous solution containing calcium ions, as presented earlier.[16] The amide I second derivative spectrum (Figure 2A) shows similar numbers of peaks and peak positions, but slightly different peak intensities, as for the spectrum for rhDNase with calcium reported previously.[16] To quantitate the structure in terms of the overall secondary structure, Gaussian curve-fitting of the original amide III spectra was employed.[17] A summary of the data is presented in Table 1 and shows that

Table 1—FTIR Analyses of Various rhDNase I Samples[a]

sample	secondary structure (%)		
	α-helix	β-sheet	other[b]
aqueous solution, with Ca^{2+}[c,d]	21 ± 2	23 ± 3	56 ± 6
aqueous solution, EGTA-treated	20 ± 2	26 ± 2	54 ± 3
lyophilized, with Ca^{2+}[d]	13 ± 2	41 ± 3	46 ± 2
lyophilized, EGTA-treated	14 ± 2	45 ± 3	41 ± 3
deamidated form[e]	21 ± 1	25 ± 2	54 ± 2
aggregated form[f]	10 ± 1	44 ± 4	46 ± 3

[a] The secondary structure of rhDNase was calculated by Gaussian curve-fitting the original amide III spectra. [b] Other secondary structure includes random coil and turns, and extended chains. [c] The aqueous solution contained 1 mM calcium chloride. [d] Data from ref 16. [e] Aqueous protein incubated in 1 mM $CaCl_2$ for 120 days at 40 °C. [f] Aqueous EGTA-treated protein incubated in the absence of exogenous calcium ions for 120 days at 40 °C.

removal of exogenous calcium had little effect on the overall secondary structure. The mixed α/β secondary structure estimated from the amide III FTIR spectra is in agreement with that predicted from consideration of the X-ray crystal structure of native rhDNase,[8,12] which is similar to bDNase.[9–11] As an independent method, we also employed circular dichroism (CD) to examine the structure of rhDNase in aqueous solution (data not shown). The secondary structure of rhDNase in the presence and absence of calcium as revealed by the far-UV CD were the same. Furthermore, the near-UV CD indicated that there was no change in the tertiary structure for the protein in the presence and absence of calcium ions. Therefore, data from two independent techniques, FTIR spectroscopy and CD, indicate that the removal of calcium does not affect the solution structure of rhDNase.

It is intriguing that a previous study on bDNase concluded that there was some change in the protein conformation upon addition of calcium based on circular dichroism (CD) data.[2] It was found that the addition of calcium (10^{-4} to 10^{-2} M) to bDNase resulted in an intensification of the CD bands with major peaks centered at 275 and 284 nm. It was also found that as the pH was decreased (from pH 8 to pH 3), the change in the CD spectrum (change in ellipticity at 215 nm) induced by 10^{-3} M $CaCl_2$ was eliminated. It was hypothesized that the affinity of bDNase for binding calcium was greatly decreased due to protonation of the amino acid side chains involved in binding calcium.[2] The explanation for the difference in the effect of calcium observed for rhDNase herein compared to the earlier bDNase study is uncertain. The two protein forms have a high structural homology, including the ability to bind calcium ions.[1,8–12] In our current study, we started with rhDNase in the presence of 1 mM $CaCl_2$. Even after exhaustive dialysis in the presence of the chelating agent EGTA, there is still approximately one calcium ion bound per rhDNase molecule.[8] In the bDNase study, no information was provided regarding the calcium level of the starting material. It is possible that the binding of calcium is less strong for bDNase, leading toward a more complete removal. A direct comparison of rhDNase and bDNase starting from the same, known level of calcium on the protein is necessary to shed light on this issue.

Chan et al.[20] have studied the thermal denaturation of rhDNase as a function of calcium ion concentration by solution differential scanning calorimetry (DSC). It was found that there was a significant increase in T_m and H_m (putative "melting" temperature and enthalpy corresponding to an endothermic event associated with protein denaturation) as the exogenous calcium ion concentration was increased. Furthermore, this event was associated with unfolding and irreversible aggregation of rhDNase. It was hypothesized that the effect was due to stabilization of rhDNase structure in its native state and protection of disulfides near calcium binding sites (which may be involved in aggregation via intermolecular disulfide formation). The latter effect has been well-established for bDNase and is also likely to play a role in the thermal denaturation of rhDNase. The former effect, if true, may be minor since there was quantitatively a similar percentage of ordered secondary structures found for the protein in the presence of calcium and following EGTA-treatment. It should be noted that such solution DSC studies, while valuable in obtaining information regarding denaturation at elevated temperatures, cannot necessarily be used as an indication of stability in aqueous solution at lower temperatures, or upon freeze-drying. The binding of calcium may stabilize rhDNase via mediation of the free energy of denaturation. For the classic, native-to-denatured state transition, the native state would be favored (lowered free energy) if it binds calcium more strongly than the denatured state. This view is consistent with an increase in T_m, without calcium-induced changes in protein conformation at lower (e.g., ambient) temperatures.

Next, we examined the secondary structure of solid (lyophilized) rhDNase. The amide III spectra (Figure 1B depicts data for the protein that was EGTA-treated prior to freeze-drying) clearly indicate that some structural perturbations occurred upon drying. These alterations were quantified by curve-fitting of the original spectra, as summarized in Table 1. It can be seen that there was a significant decrease in α-helical structures and increase in β-sheets for the EGTA-treated protein. To further confirm this change, we also examined the second-derivative amide I spectra for the aqueous (Figure 2A) and lyophilized (dashed line in Figure 2B) EGTA-treated protein. These data also reveal alterations upon lyophilization, in particular, augmentation of the band centered at approximately 1691 cm^{-1}, which likely indicates increased β-sheets in the solid state as a result of increased protein−protein interactions.[18] The nature and extent of the drying-induced structural alterations for the lyophilized EGTA-treated protein were similar to that for rhDNase freeze-dried from aqueous solution containing 1 mM calcium chloride (Figure 2).[16]

Therefore, although calcium ions increase rhDNase structural stability with respect to thermal unfolding, there was little effect on the stability toward dehydration-induced structural perturbation. This result is similar to that presented in a previous investigation of the enzyme lysozyme.[21] In that study, the protein lyophilized from a series of pHs from 1.9 to 5.1, corresponding to a wide range in T_m values from 45 °C to 75 °C (determined by solution DSC), exhibited very similar structural rearrangements upon lyophilization (estimated from FTIR spectra in the amide III region).[21]

Effect of Ca^{2+} on Protein Stability in the Aqueous and Lyophilized States—As described by Shire,[8] the dominant degradation pathway for rhDNase in current liquid formulation is deamidation of Asn74. The pseudo-first-order rate constants are not affected by the starting levels of deamidation of the protein (data not shown). Furthermore, deamidation, which results in partial loss of the enzymatic activity, does not significantly alter the protein's structure, as evidenced in the far- and near-UV CD.[8]

Figure 3A depicts data for the deamidation of rhDNase in aqueous solution at the accelerated stability condition of 40 °C. This condition is well below the T_m for rhDNase, even in the absence of calcium ions.[20] As expected, based on previous data,[8] the molecule readily deamidated. The starting material was already largely deamidated (about 60%), and complete deamidation was observed after 120

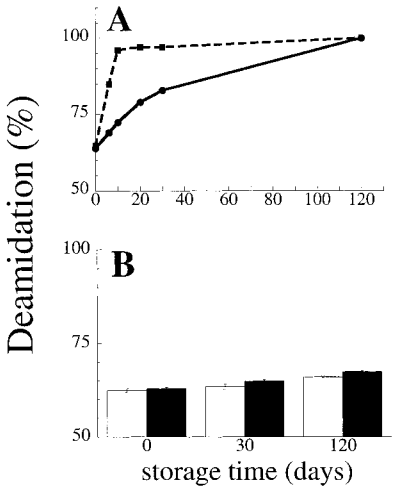

Figure 3—Deamidation of rhDNase at 40 °C: (A) in aqueous solution: solid line depicts data for untreated protein in the presence of 1 mM $CaCl_2$ and dashed line represents EGTA-treated protein in the absence of exogenous calcium ions (note that all error bars are too small to be seen); and (B) in the lyophilized untreated powder (open symbols) and lyophilized EGTA-treated powder (filled symbols).

days at 40 °C for the protein in the presence of 1 mM $CaCl_2$ (dashed line in Figure 3A). For this latter sample, which was fully deamidated (and did not exhibit any significant aggregate formation as discussed below), we measured the amide III FTIR spectra (Figure 1C) and estimated the secondary structure (Table 1), in addition to qualitative inspection of the amide I second derivative spectra (Figure 2C). Despite the conversion of asparagine to isoaspartate (i.e., the placement of an extra methylene group in the peptide backbone), there was no difference in the secondary structure, consistent with previous data obtained by CD.[8]

Deamidation was then monitored for the EGTA-treated protein which was incubated in aqueous solution without calcium ions (solid line in Figure 3A). In the absence of calcium, the degradation occurred even more rapidly compared to the protein in the presence of calcium ions. There was nearly complete deamidation seen after only a 10-day incubation at 40 °C. This result is different from that observed previously under a milder condition.[8] In that investigation, rhDNase was treated with EDTA to remove calcium and reformulated in isotonic 10 mM phosphate buffer. Deamidation of rhDNase under this condition did not increase significantly compared to untreated samples over ~0.5 year stored at 25 °C.[8]

We also examined the protein by size-exclusion chromatography (SEC), which was useful in detecting soluble aggregate formation. For the protein in the aqueous solution of 1 mM $CaCl_2$, there was virtually no aggregation observed by SEC, even after 120 days at 40 °C (filled symbols in Figure 4A). However, for the case of the protein in aqueous solution in the absence of calcium, there was rapid deterioration, with nearly complete aggregation following only 30 days of incubation (open symbols in Figure 4A).

Therefore, the data show that the removal of calcium ions results in increased rates of both deamidation and soluble aggregate formation in aqueous solution. These findings are consistent with results of bDNase, demonstrating that the removal of calcium was associated with increased rates of proteolysis (e.g., by trypsin),[2,3] susceptibility toward pH-induced structural alterations,[5] and reduction of the Cys173-Cys209 disulfide.[4] The latter may play a role in covalent aggregation via intermolecular disulfide formation. Majority of aggregates as observed by SDS−PAGE were dissociable in the presence of free thiol

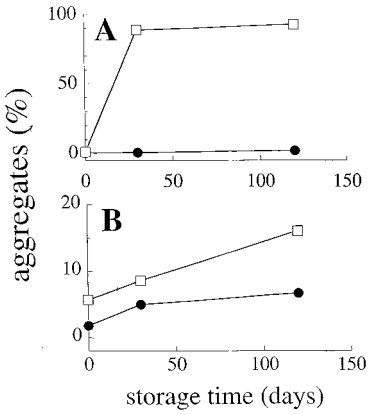

Figure 4—Aggregation of rhDNase at 40 °C: (A) in aqueous solution; (B) in the lyophilized powder. Filled symbols depict data for untreated protein in the presence of 1 mM $CaCl_2$, and open symbols represent EGTA-treated protein in the absence of exogenous calcium ions (note that all error bars are too small to be seen).

Table 2—Enzymatic Activities of Various rhDNase I Samples[a]

sample	enzymatic activity after incubation at 40 °C for[b] 0 days	30 days	120 days
aqueous solution, with Ca^{2+}[c]	100 ± 12	67 ± 5	58 ± 2
aqueous solution, EGTA-treated	90 ± 9	<9	<6
lyophilized, with Ca^{2+}	100 ± 13	89 ± 4	89 ± 2
lyophilized, EGTA-treated	92 ± 6	75 ± 6	53 ± 5

[a] Enzymatic activity was determined by the methyl green assay. [b] Data are expressed as % specific activity, or the amount of protein determined by the activity assay divided by that based on UV absorption of the sample. [c] The aqueous solution contained 1 mM calcium chloride.

agent (data not shown). Therefore, these aggregates were linked by disulfides.

Since reduction of the Cys173-Cys209 disulfide is known to affect the enzymatic activity, we used the methyl green assay[15] to probe the integrity of the active site of the molecule. For the protein in aqueous solution containing 1 mM calcium chloride, there was a substantial drop in activity, up to about 40% loss after 120 days at 40 °C (Table 2), even though there was no significant aggregation observed (Figure 4A). In this case, the drop in activity is a result of increased deamidation (Figure 3A), which is known to result in decreased activity.[8]

If the disulfide bridge Cys173-Cys209 had been cleaved for aqueous rhDNase in the absence of calcium ions, then it follows that the enzymatic activity would be lost, based on observations for the bovine-derived protein.[4] Thus, we measured the enzymatic activity of the EGTA-treated protein in aqueous solution without calcium ions. As predicted, there was over 90% loss of enzymatic activity after only 30 days of incubation (Table 2), concomitant with the aggregation of the molecule (Figure 4A). These data, along with the confirmation of the presence of disulfides in the rhDNase aggregates, strongly support the view that removal of calcium from binding sites near native disulfides made these areas more susceptible to cleavage and ultimately intermolecular bond formation. The increased susceptibility toward deamidation in the absence of calcium may be linked to increased configurational freedom as a result of the disulfide cleavage and/or exchange.

It was interesting to also examine the secondary structure of the rhDNase aggregates (generated by incubation of EGTA-treated protein for 120 days in aqueous solution). To this end, we measured the amide III FTIR spectra for the rhDNase aggregates (Figure 1D) which showed sig-

nificant perturbation compared to the protein prior to incubation, particularly an increase in the β-sheet band centered at approximately 1238 cm^{-1} (Figure 1D). Estimation of the secondary structure (Table 2) confirmed that there was an increase in the overall β-sheet content in the aggregates. Protein aggregates tend to have increased β-sheet contents, largely intermolecular in nature.[18] This was also confirmed in the amide I second derivative spectra (Figure 2D) which exhibited a band at $\sim$1620 cm^{-1}. It has been reported that this band indicates the presence of intermolecular aggregates, and has been correlated with protein aggregation.[18]

Having established the influence of calcium ions on the solution structure/stability of rhDNase, we then next examined the lyophilized form of the protein. Generally, proteins exhibit superior stability in the dehydrated state due to several factors, such as the increase in molecular rigidity upon dehydration, which should retard deleterious reactions.[22,23] The level of deamidation (Figure 3B) shows that there was no significant increase in the extent of deamidation, regardless of the absence of calcium. This result may stem from the fact that deamidation is a hydrolytic process, i.e., requires water;[24] it is logical then, that removal of water would coincide with reduction of deamidation.

Figure 4B depicts the formation of aggregates for rhDNase in the solid state. It can be seen that for the protein lyophilized from the aqueous solution containing Ca^{2+}, there was slight aggregation ($\sim$7% after 120 days at 40 °C). Note that under this condition in aqueous solution, there was essentially no aggregation observed. Therefore, from the standpoint of intermolecular processes, i.e., aggregation, the protein exhibited inferior stability in the solid compared to the aqueous state; the reverse was true for the intramolecular process of deamidation. This finding is consistent with the view that the proximity of protein molecules in the dried state facilitates intermolecular pathways over intramolecular ones.[25]

For the EGTA-treated protein, the extent of solid-state aggregation was more substantial (Figure 4B), although not as severe as observed for the aqueous solution (Figure 4A). Thus, in this case (EGTA-treated), superior stability was observed for the lyophilized protein. As expected, there was also significant loss in rhDNase enzymatic activity for the EGTA-treated protein (Table 2), whereas there was little change for the protein lyophilized from 1 mM $CaCl_2$. From the data it is clear that the activity loss does not directly correspond to the loss of monomer, suggesting that some monomers have become inactivated (e.g., cleavage of Cys173-Cys209). As was the case for the protein aggregates in aqueous solution, the aggregates generated in the solid-state had over 50% disulfide-bonded character, as revealed by reducing and nonreducing SDS−PAGE.

The data clearly demonstrate that the removal of calcium destabilizes rhDNase in the solid state. This result is intriguing considering the conjecture that protein biochemical stability is linked to the glass transition temperature (T_g) of the formulation.[24] Although it is difficult to measure the T_g for pure proteins,[26] it is expected that the T_g for rhDNase is much higher than that of calcium. Therefore, removal of calcium should raise the T_g, yet the data show that rhDNase stability was decreased. The other component present in our system, namely water, also has a very low T_g and is known to destabilize proteins.[22,23] Another possibility to explain the effect of calcium is that its removal results in increase in residual moisture level and/or increase in moisture over storage (e.g., moisture transfer from the lyophilization stopper). To check this, we measured the moisture levels of lyophilized rhDNase in the presence and absence of calcium after a storage period of 24 months at 15 °C. We found there was no significant difference in moisture levels between the samples in the presence and absence of calcium. In addition, the average moisture level ($n = 10$) was found the same as previous data,[16] suggesting that no moisture transferred from the stopper over time. These data strongly suggest that for the case of rhDNase the stabilizing influence of calcium is due to some specific effect (e.g., binding) rather than mediated by influence on the T_g of the system.

In addition to the formulation, the reconstitution medium may also affect protein stability. For instance, Zhang et al.[27] have studied the effect of additives in the reconstitution medium on aggregation and activity of lyophilized recombinant interleukin-2 and ribonuclease A. It was found that additives such as 0.05% sodium polyphosphate or 0.5% sulfated β-cyclodextrin increased recovery of activity of RNase (from 62% to 97% and 77%, respectively) after storage of the lyophilized proteins for three weeks at 45 °C. In the current investigation, we tested whether the addition of calcium in the reconstitution medium (but not the dried formulation) could influence rhDNase stability. EGTA-treated samples were stored for 2 years at 40 °C and then reconstituted in the absence and presence of calcium (1 mM $CaCl_2$). The data revealed the same activity loss, 60 $\pm$ 2% vs 55 $\pm$ 5%, and increase in aggregates, 17 $\pm$ 1% vs 15 $\pm$ 2% for the protein reconstituted in the absence and presence of calcium, respectively. This excludes the possibility that rhDNase is stabilized solely by calcium binding during the reconstitution step.

Both EGTA-treated and nontreated rhDNase exhibited similar alterations in their structure upon lyophilization as determined by FTIR spectroscopy, yet the two had different stability. This suggests that the predominant mechanism of solid-state instability, aggregation, did not depend on the overall secondary structure. If similar mechanisms hold for the aqueous and solid states, then it is likely that the local structure near a labile site, for instance, Cys173-Cys209, is influenced by calcium ions (such an effect is not detectable by examination of overall secondary structure by FTIR spectroscopy).

In summary, this investigation reports the effect of calcium ions on the structure and stability of rhDNase in the aqueous and solid (lyophilized) states. The data reveal that the removal of calcium ions by EGTA-treatment had little effect on the secondary structure (and lyophilization-induced rearrangement thereof) as determined by FTIR spectroscopy. The CD spectra also confirmed that the removal of calcium did not alter the secondary or tertiary structure for the aqueous protein. The primary degradation route for the aqueous protein at 40 °C was deamidation. There was also rapid aggregation observed for the aqueous EGTA-treated protein, presumably via a mechanism not related to the overall structure, but rather a labile site, e.g., reduction of Cys173-Cys209. For the protein lyophilized in the presence of calcium, there was some aggregation observed at 40 °C; thus the solid-state stability was actually worse than that in aqueous solution. For the EGTA-treated protein lyophilized in the absence of calcium, solid-state aggregation was much more pronounced compared to protein in the presence of calcium. Thus, the removal of calcium ions by EGTA-treatment has a similar effect on the structure and stability of rhDNase in both the aqueous and solid states.

Abstract □ Ethoxylated alcohols are widely used as surfactants. In the present study we have continued our investigations on the degradation with time upon air exposure of the ethoxylated alcohols at normal storage and handling. As a result, a new group of ethoxylated formates with the general formula $C_{12}H_{25}(OCH_2CH_2)_nOCHO$ ($n = 0–4$) was identified in $C_{12}H_{25}(OCH_2CH_2)_5OH$ stored and handled at room temperature. To facilitate the identification work, reference compounds were synthesized. The formates showed no allergenic activity in the sensitization studies performed. In previous investigations on the same ethoxylated alcohol, we have identified formaldehyde and ethoxylated aldehydes among the oxidation products formed. Formaldehyde is a common contact allergen, and the ethoxylated aldehydes were shown to have a sensitizing capacity of the same magnitude as formaldehyde. The instability of the ethoxylated alcohols and formation of oxidation products may give an allergenic contribution to hand eczema caused by work with water and surfactants. To investigate the clinical significance in man an appropriate diagnostic patch testing in exposed humans is required.

Introduction

The ethoxylated surfactants have wide applications and are used in, for example, household cleaners, laundry products, pharmaceuticals, and industrial and institutional cleaners. In 1993 the total consumption of ethoxylated alcohols was estimated to about 313000 tons in Western Europe.[1] The number of oxyethylene groups in nonionic ethoxylated surfactants determines application behavior, e.g. detergency, emulsification, and wetting, at a given temperature in all formulation work.

In recent studies[2−4] we have shown that oxidation products were rapidly formed from ethoxylated nonionic surfactants during storage and handling at room temperature in daylight and also during storage in dark. We detected peroxides,[2,4] formaldehyde,[2,4] and a series of ethoxylated aldehydes[3] among the oxidation products in our studies on Tween 80 (sorbitan monooleate)[2] and ethoxylated fatty alcohols.[3,4] The ethoxylated surfactants have so far been considered to be stable products at normal storage and handling.[5] The products are usually stored at room temperature, since they become semisolid at lower temperatures. However, ethoxylated surfactants are polyethers and as such susceptible to oxidation at air exposure. This autoxidation is theoretically discussed in the surfactant literature.[6] The proposed mechanism for autoxidation is a free radical mechanism initiated by minor amounts of free radicals present or catalyzed by metal salts, e.g. copper sulfate.[6] Peroxides and hydroperoxides are the primary oxidation products followed by formation of carbonyl compounds as secondary oxidation products.[7]

The prevalence of contact allergy in the general population in Europe is about 10%. Of those sensitized, about 2−4% have ongoing allergic contact dermatitis, which is the consequence of exposure to environmental chemicals.[8] About 90% of occupational contact dermatitis is located on the hands, and half of all work-related hand eczemas are caused by work with surfactants and water.[9] Most diagnoses of contact dermatitis from wet work are considered to be irritant dermatitis.[10] The diagnosis of allergy is difficult to exclude from irritancy in cases of chronic dermatitis. Surfactants are irritants, partially due to their ability to solubilize lipid membranes, since they possess both lipophilic and hydrophilic regions in their structures.[10] In our recent studies we found that the oxidation products identified after air exposure of ethoxylated surfactants had allergenic properties. Formaldehyde is a well-known contact allergen, and the ethoxylated aldehydes (Figure 1) were shown to be contact allergens in experimental sensitization studies.[3] In the literature some cases are reported of allergic contact dermatitis due to ethoxylated nonionic surfactants and emulsifiers.[11,12] Formaldehyde is described to be a significant allergen in women with hand eczema caused by occupational and domestic exposure.[13] Thus, allergenic oxidation products in ethoxylated surfactants may cause hand eczema or aggravate an ongoing irritant dermatitis in wet work.

In our previous studies on the identification of oxidation products formed from ethoxylated alcohols we have for the first time shown the formation of ethoxylated aldehydes with allergenic properties.[3] In the present study we have further investigated the autoxidation of the pure ethoxylated dodecyl alcohol, $C_{12}H_{25}(OCH_2CH_2)_5OH$ (below referred to as $C_{12}E_5$) by gas chromatography (GC) analysis during one year. We have identified a new group of oxidation products formed, the ethoxylated formates, and studied their allergenic activity.

Experimental Section

Chemicals—Tetraethylene glycol (99%) was obtained from Aldrich (Steinheim, Germany). Triethylene glycol (99%), formic acid (98−100%), 1-dodecanol (98%), 1-bromododecane, *p*-toluenesulfonic acid (99%), and dimethyl sulfoxide (DMSO) were obtained from Kebo Lab AB (Stockholm, Sweden). Sodium hydride (60% dispersion in mineral oil, toluene-soluble bags) was obtained from Acros Chimica N.V. (Geel, Belgium). Triethylene glycol mono *n*-dodecyl ether $C_{12}H_{25}(OCH_2CH_2)_3OH$ (CAS Reg. no. 3055-94-5) (referred to as $C_{12}E_3$) and pentaethylene glycol mono *n*-dodecyl

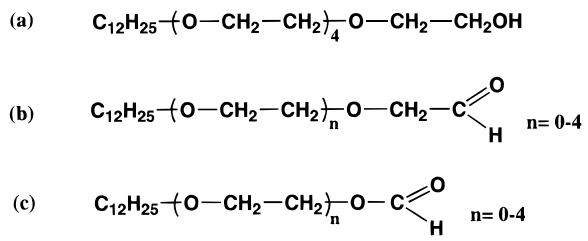

Figure 1—(a) Ethoxylated alcohol (pentaethylene glycol mono *n*-dodecyl ether) $C_{12}E_5$. (b) The earlier identified ethoxylated aldehydes in air exposed $C_{12}E_5$. (c) In the present study the identification and sensitizing capacity of the ethoxylated formates are presented.

ether $C_{12}H_{25}(OCH_2CH_2)_5OH$ (CAS Reg. no. 3055-95-6) (referred to as $C_{12}E_5$) were purchased from Nikko Chemicals CO., Ltd. (Tokyo, Japan). The purity was stated to be 98% by the producer, which was confirmed with GC analysis. The other ethoxylated alcohols were synthesized as described below. Standard chemicals were of p.a. quality.

Instrumentation and Mode of Analysis—FT-IR spectra were recorded with a Perkin-Elmer 16 PC FT-IR instrument using a sealed liquid cell with KBr windows. NMR spectroscopy was performed on a JEOL EX 270 instrument in $CDCl_3$ using tetramethylsilane as internal standard. GC analyses were carried out on a Hewlett-Packard HP 5890 gas chromatograph with a flame ionization detector (FID). The gas chromatograph was equipped with a fused silica capillary column (25 m × 0.22 mm i.d) coated with 0.2 μm CP-sil 8 CB (Chrompack, Middelburg, The Netherlands). Nitrogen was used as carrier gas at a linear gas velocity of 22 cm/s. An ELDS laboratory data system from Chromatography Data System Inc. (Svartsjö, Sweden) was used for registration and processing of the detector signal.

Mass spectrometric (MS) analyses were performed on a Finnigan Incos 50 quadrapole instrument equipped with a Varian 3400 gas chromatograph with an on-column injector. The MS analyses were carried out in electron impact (EI) and positive ion chemical ionization (PCI) modes. Introduction of the sample into the ion source was made via GC using on-column technique. The gas chromatograph was equipped with a fused silica capillary column (25 m × 0.25 mm i.d.) coated with 0.2 μm CP-sil 8 CB (Chrompack, Middelburg, The Netherlands), and helium was used as carrier gas. The temperature programming of the gas chromatograph oven was as follows: 35 °C for 1.0 min followed by a temperature increase of 10 °C/min up to 295 °C. The GC-MS transferline was held at 310 °C. The ion source was held at a temperature of 150 °C and the electron energy was 70 eV in the EI mode. In PCI mode the ion source was held at 80 °C, the electron energy was 110 eV, and the ion source pressure was about 1 Torr. At chemical ionization, methane of >99.995% purity was used as reagent gas, and the instrument was tuned by optimizing the reactant ions (CH_5^+, $C_2H_5^+$, and $C_3H_5^+$) to an approximate ratio of 5:4:1. The MS scan range in all analyses was *m*/*z* 50−600, and the scan cycle time was 0.6 s.

Synthesis—*Preparation of Dodecylethoxylated Alcohols **1**−**3***—Sodium hydride (0.80 g, 5.5 mmol) was stirred in DMSO (dry, 8 mL) at room temperature for 30 min. The appropriate glycol $H(OCH_2CH_2)_nOH$ (n = 1, 2, or 4) (77 mmol) was added slowly, and the mixture was stirred at room temperature under nitrogen for 2 h. 1-Bromododecane (5.0 g, 20 mmol) was added dropwise, and the mixture was heated at 90 °C overnight under nitrogen. The reaction mixture was dissolved in ethyl acetate and washed with water. The organic phase was dried over $MgSO_4$ and evaporated. The crude product was chromatographed on a silica gel column eluted with an increasing content of ethyl acetate 4−6% in hexane, followed by 20% methanol in ethyl acetate. The products **1**−**3** were obtained as clear oils in 57−66% yield and identified with FT-IR, NMR, and MS.

$C_{12}H_{25}OCH_2CH_2OH$ (1). Yield: 66%. FT-IR (neat): 3370 (O−H), 2850 and 2950 cm^{-1} (C−H). ^{1}H NMR ($CDCl_3$): δ 3.72 (tr, 2H, CH_2O), 3.53 (tr, 2H, CH_2O), 3.42 (tr, 2H, $CH_2CH_2CH_2O$), 2.11 (s, 1H, O**H**), 1.58 (m, 2H, $CH_2CH_2CH_2O$), 1.26 (m, 18H, (CH_2)$_9$) 0.85 (tr, 3H, CH_3). ^{13}C NMR ($CDCl_3$): δ 71.68, 71.43 ((CH_2O)$_2$), 61.85 (*C*H_2OH), 31.90 ($CH_3CH_2CH_2$), 29.63 (5 C:s), 29.47, 29.33 ((CH_2)$_7$), 26.09 (*C*H_2CH_2O), 22.66 (CH_3CH_2), 14.05 (*C*H_3). *Preparation of Ethoxylated Formates **4**−**8***—Samples of the appropriate alcohol **1**−**3** and $C_{12}E_3$(4 mmol) were heated at 85 °C in formic acid (10 mL) with *p*-toluenesulfonic acid as catalyst for 4 h.[14−16] The reaction mixture was neutralized with a saturated (10 M) sodium hydroxide solution and washed with water, dried over $MgSO_4$, and concentrated in a vacuum. The crude product was chromatographed on a silica gel column eluted with an increasing content of ethyl acetate 30−70% in dichloromethane to give the pure ethoxylated formates **4**−**8** as clear oils in 80−100% yield. Identification was performed with FT-IR, NMR, and MS.

$C_{12}H_{25}OCHO$ (4). Yield 100%. FT-IR (neat): 2924 and 2854 (C−H aliphatic), 1732 (C=O), 1180 cm^{-1} (C−O). ^{1}H NMR ($CDCl_3$): δ 8.03 (s, 1H, OC*H*O), 4.14 (tr, 2H, CH_2OCHO), 1.63 (m, 2H, CH_2CH$_2$O), 1.29 (m, 18H, (CH_2)$_9$), 0.85 (tr, 3H, CH_3). ^{13}C NMR ($CDCl_3$): δ 161.35 (O*C*HO), 64.26 (*C*H_2O), 32.04 ($CH_2CH_2CH_3$), 29.67 (5C:s), 29.47 29.31 ((*C*H_2)$_7$), 25.93 (*C*H_2CH_2O), 22.80 (*C*H_2-CH_3), 14.24 (*C*H_3). $C_{12}H_{25}(OCH_2CH_2)_4OCHO$ (8). Yield 80% FT-IR (neat): 2942 and 2845 (C−H), 1732 (C=O), 1178 cm^{-1} (C−O). ^{1}H NMR ($CDCl_3$): δ 8.10 (s, 1H, OC*H*O), 4.33 (tr, 2H, CH_2OCHO), 3.76−3.60 (m, 14 H, (CH_2O)$_7$), 3.45 (tr, 2H, CH$_2$CH_2O), 1.58 (m, 2H, CH_2CH$_2$O), 1.26

(m, 18H, $(CH_2)_9$), 0.89 (tr, 3H, CH_3). ^{13}C NMR ($CDCl_3$): δ 160.94 (OCHO), 71.52, 70.58 (5C, s), 70.10, 68.81, 63.00 $(CH_2O)_9$, 31.88 ($CH_2CH_2CH_3$), 29.55 (5C:s), 29.45, 29.31 $(CH_2)_7$, 26.04 (CH_2CH_2O), 22.64 (CH_2CH_3), 14.07 (CH_3). GC-MS-PCI *m/z* (% rel inten): 391 $[M + 1]^+$ (8.12), 390 M^+ (1.63), 389 $[M - 1]^+$ (11.8), 363 $[M + 1 - 28]^+$ (90.2), 223 $[H(OCH_2CH_2)_4OCHO]^+$ (36.3), 166 $[C_{12}H_{22}]^+$ (24.0), 133 $[(CH_2CH_2O)_2H]^+$ (17.8), 73 $[CH_2CH_2OCHO]^+$ (100).

Storage and Handling of Ethoxylated Alcohols—Two samples of undiluted $C_{12}E_5$ (98%) were used in the experiment. Sample 1 (5 g) was stored in a closed 10 mL vessel in darkness at room temperature (20−22 °C) for 12 months. Sample 2 (5 g) was stirred gently in an open 10 mL Erlenmeyer flask in daylight at room temperature (20−22 °C) for 1 h, 4 times a day, during 12 months, mimicking what we considered normal handling in laboratories and industries. The top of the flask was covered with aluminum foil to prevent contamination and to diminish the evaporation.

Detection of Oxidation Products in Ethoxylated Alcohols—Samples 1 and 2 were analyzed with GC-MS analysis using the synthesized references.

Samples 1 and 2 were also analyzed with GC every fourth week after start of the exposure. The content of the ethoxylated formates in samples 1 and 2 was quantified using the synthesized reference compounds. Aliquots of 2 × 10 mg were taken out from each sample. Two sample preparations (1.0 mg/mL) from each sample were prepared and dissolved in dichloromethane, methyl stearate was added as internal standard, and a duplicate analysis on each sample was performed. On-column injections (1 μL) were made at an injector temperature of 35 °C. The column oven was kept at 35 °C for 2 min whereafter the temperature of the column was raised with a rate of 10 °C/min to 210 °C. The column temperature was then raised with a rate of 5 °C/min to a final value of 240 °C which was kept for 10 min.

Studies on the Sensitizing Capacity of 5—The sensitization experiment was performed using female Dunkin-Hartley guinea pigs (weight 250−300 g) from AB Sahlins Försöksdjursfarm, Malmö, Sweden. The animals were kept on a standard diet from Beekey, North Humberside, England, and water *ad libitum*. The animals were randomly assigned to one exposed, group 1 ($n = 15$), and one control group, group 2 ($n = 15$).

The sensitization study was performed according to the Cumulative Contact Enhancement Test (CCET) method[17] in a modified form with closed epidermal challenge testing.[18,19] At induction the animals received an occlusive epidermal application on the shaved upper back on days 0, 2, 7, and 9. About 200 mg of the test material was applied on pieces of filter paper (4 × 2 cm) at each of the four inductions. The FCA injections at the third induction were omitted according to our earlier experience of sensitization studies on surfactants.[3] Challenge testing was performed on day 21 on the shaved left flank using Finn Chambers (aluminum chambers, 8 mm i.d from Epitest, Helsinki, Finland) with approximately 15 mg of the test material applied in each chamber.

The exposed group was induced with **5** 10% w/w (2.6×10^{-4} mol/g) in water, while the animals in the control group received water alone. Both groups were challenged with 10, 5, and 1% w/w (2.6×10^{-4}, 1.3×10^{-4}, and 2.6×10^{-5} mol/g) of **5** in water, with $C_{12}E_5$ 5% (1.3×10^{-4} mol/g) in water, and $C_{12}E_4OCH_2CHO$ 1% w/w (2.5×10^{-5} mol/g) in water (Table 1). Water was applied as a vehicle control. The chambers were removed after 24 h, and the reactions were assessed at 48, 72, and 96 h after start of the exposure. The minimum criterion for a positive reaction was a confluent erythema.

The experiment was performed with the equimolar concentrations for induction and challenge as used in the experiments with the ethoxylated aldehyde, $C_{12}H_{25}(OCH_2CH_2)_4OCH_2CHO$.[3] The challenge concentrations of **5** were in pretests shown to be nonirritating in three untreated guinea pigs. Patch testing with concentrations 20−1% of **5** in water gave no skin reactions after 48 and 72 h. The experiment was approved by the local ethics committee.

Statistical Analyses—The result from the animal experiment was analyzed with Fisher's exact test. The number of reactions to each applied test substance in the exposed animals was compared with the number of reactions in the control group. A p value <0.05 was statistically significant.

Table 1—Sensitizing Potential of Compound 5 and Cross-Reactivity Studies with $C_{12}E_5$ and an Ethoxylated Aldehyde in Guinea Pigs Using the Modified CCET Method without Adjuvant

	no. of animals with positive reaction after exposure[a]					
	5 (% w/w in water)			C12E5[b]	aldehyde[c]	
guinea pigs	10	5	1	5	1	water
	Group 1[d]					
exposed ($n = 15$)						
48 h	0	0	0	1[a]	1	0
72 h	0	0	0	2	2	0
96 h	0	0	0	1	1	0
	Group 2					
controls ($n = 15$)						
48 h	0	0	0	0	1	1
72 h	0	1	0	1	1	1
96 h	0	0	0	1	0	1

[a] The figures are the number of animals with confluent erythema 48, 72, and 96 h after application of the test material. [b] Ethoxylated alcohol, $C_{12}E_5$, 5% (w/w in water). [c] Ethoxylated aldehyde with four ethylenoxide groups, $C_{12}H_{25}(OCH_2CH_2)_4OCH_2OCHO$, 1% (w/w in water). [d] Induction: 10% (w/w in water) of **5** in water.

Results

Spectral Characteristics—In FT-IR the specific hydroxyl resonance of the synthesized alcohols **1**−**3** was observed at 3370−3467 cm^{-1}. The FT-IR spectra of the synthesized ethoxylated formates **4**−**8** had a specific carbonyl resonance at 1724−1732 cm^{-1} and the C−O resonance at 1180 cm^{-1} from the ester group.[15] The NMR signals were compared with literature data for poly(oxyethylene) alcohols[20,21] and formates[16] and accorded with structures **1**−**3** and **4**−**8**. MS analyses in the GC-EI mode yielded no molecular ions of the ethoxylated alcohols and formates. Aliphatic ethers normally exhibit weak molecular ion peaks.[22] In the GC-MS-PCI analyses of the synthesized alcohol ethoxylates, **1**−**3**, the molecular ion M^+ and $[M + 1]^+$ and $[M - 1]^+$ ions were observed. Cleavage of the ethoxylated chain led to fragments of the general formula $[(CH_2CH_2O)_nH]^+$. These data, together with the FT-IR and NMR data are consistent with the structures **1**−**3**. In the GC-MS-PCI analyses of the synthesized formates **4**−**8** the molecular ion M^+ and $[M + 1]^+$ and $[M - 1]^+$ ions were observed together with specific fragments with the general formula $[(CH_2CH_2O)_nH]^+$ and $[CH_2CH_2O)_nOCHO]^+$. The $[M - 1]^+$ ion fragment corresponded to α-cleavage. No adducts with methane, $[(M + C_2H_5)^+]$ and $[(M + C_3H_5)^+]$ were seen. These data, together with the FT-IR and NMR data are consistent with the structures **4**−**8**, $C_{12}H_{25}(OCH_2CH_2)_n$-OCHO, $n = 1-4$.

Detection of Oxidation Products in Ethoxylated Alcohols—The ethoxylated formates, $C_{12}H_{25}(OCH_2CH_2)_n$-OCHO, $n = 1-4$, were all detected in samples 1 and 2 of $C_{12}E_5$ with GC-MS-PCI analyses using **4**−**8** as reference compounds. The alcohols, $C_{12}H_{25}(OCH_2CH_2)_nOH$ ($n = 1-4$), were identified in samples 1 and 2 of $C_{12}E_5$ with GC-MS-PCI analyses using $C_{12}E_3$ and the synthesized alcohols **1**−**3** as reference compounds.

The amount of the identified formates increased continuously with time. The formates seem to be rapidly formed since they were detected in small amounts in the GC analysis already in a newly opened bottle of the pure ethoxylated alcohol. The limits of detection for the substances **1**−**5** in the GC-analysis were estimated to be in the range 0.001−0.05 ng/μL using a signal-to-noise ratio 3:1 (S/N = 3). The total content of formates in $C_{12}E_5$ was 3.3% in the sample stored in a closed vessel in darkness (sample 1) and 4.0% in the sample handled in daylight (sample 2) after 12 months. The content of the individual

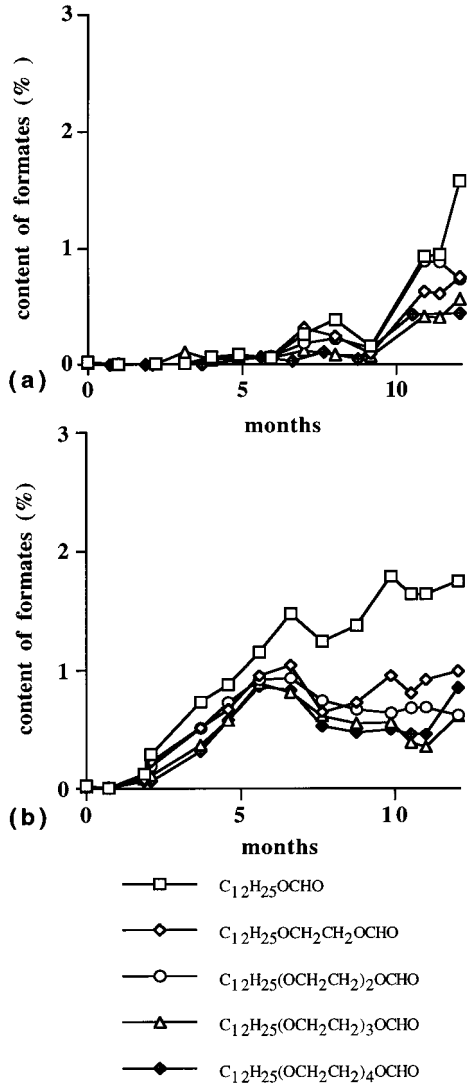

Figure 2—The content (%) of the individual ethoxylated formates **4**–**8** at different time points in $C_{12}E_5$: (a) sample 1 stored in a closed vessel in darkness at room temperature; (b) sample 2 stored and handled in daylight at room temperature.

formates in samples 1 and 2 is shown in Figure 2. Formate **4**, $C_{12}H_{25}OCHO$, was formed in the highest concentration. All calculations were performed relative to the internal standard. The coefficient of variation (CV) was below 10% at repeated measurements ($n = 10$). Duplicate analyses were performed of each sample. Approximately 5% of the total sample volume (5 g) was used for analysis, which was not regarded to contribute to the degradation. Figure 3 shows the GC separation of oxidation products in sample 2 air exposed for 12 months. The oxidation products that we have identified are assigned in the chromatogram with retention times corresponding to homologue retention characteristics accordning to boiling point.

Sensitizing Capacity of 5—No sensitizing response was observed to **5** in the animal experiment (Table 1). No cross-reactivity was observed to the corresponding alcohol, $C_{12}E_5$, or to the ethoxylated aldehyde, $C_{12}H_{25}(OCH_2CH_2)_4OCH_2CHO$. Some irritation was seen when the animals were tested with the alcohol and the aldehyde.

Discussion

Air exposure during storage and handling of the pure ethoxylated alcohol $C_{12}E_5$ at room temperature results in

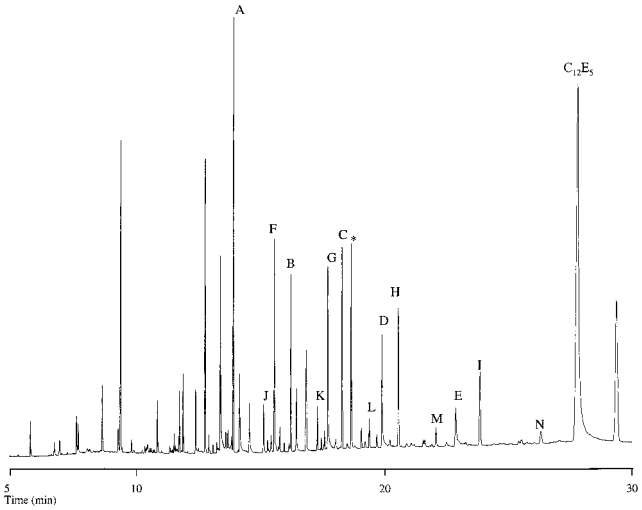

Figure 3—GC chromatogram showing the separation of different degradation products formed at air exposure of $C_{12}E_5$. The peak from the original ethoxylated alcohol is assigned $C_{12}E_5$, peaks A–E are the homologue series of ethoxylated formates, $C_{12}H_{25}(OCH_2CH_2)_nOCHO$ $n = 0$–4, eluting in the order of boiling point; peaks F–I are the homologue series of ethoxylated alcohols, $C_{12}H_{25}(OCH_2CH_2)_nOH$ $n = 1$–4, eluting in the order of boiling point; peaks J–N are the homologue series of ethoxylated aldehydes, $C_{12}H_{25}(OCH_2CH_2)_nOCH_2CHO$ ($n = 0$–4), eluting in the order of boiling point. The peak assigned * is the internal standard, methyl stearate, with a retention time of 18.63 min.

a number of degradation products as illustrated by the gas chromatogram in Figure 3. Among the oxidation products identified, some have significant allergenic properties. So far, nonionic ethoxylated surfactants have been regarded as stable products and are normally stored at room temperature, since they become semisolid at lower temperatures.[5] The practical consequence will be that a product containing ethoxylated alcohols can have quite a different chemical composition after storage and handling compared to the original product. In addition to an increase of their harmful effects on skin[3] with time, there might also be a change in their surface active properties.[25] To avoid significant decomposition, the pure ethoxylated alcohols must be stored in the refrigerator (8 °C), which was demonstrated in a previous study.[4]

To the best of our knowledge, ethoxylated formates are described here for the first time. The formates, $C_{12}H_{25}(OCH_2CH_2)_nOCHO$, $n = 0-4$, were identified and their structures elucidated in the oxidation mixture of $C_{12}E_5$. Prior to the identification work, the dodecyl poly(oxyethylene) formates that theoretically might be formed were synthesized and used as reference compounds in the analyses. The major formate, $C_{12}H_{25}OCHO$ (**4**), is apparently formed due to cleavage between the poly(oxyethylene) groups and the alkyl chain. The ethoxylated aldehydes earlier identified[3] are formed by cleavage of the poly(oxyethylene) chain resulting in loss of oxyethylene units and also by oxidation of the terminal hydroxyl group yielding the dominant ethoxylated aldehyde, $C_{12}H_{25}(OCH_2CH_2)_4OCH_2CHO$. This indicates that the autoxidation proceeds with parallel and different mechanisms.

The amount of ethoxylated formates increased with time of air exposure as determined with GC analysis. Different compounds are predominant in the degradation mixture depending on the time of air exposure. In our previous studies[2–4] the formation of peroxides, formaldehyde and ethoxylated aldehydes was shown. The amount of peroxides was determined with the unspecific iodometric titration method[23] whereas the aldehydes were quantified using GC- and LC methods. Peroxides were initially formed followed by formation of formaldehyde and the ethoxylated alde-

hydes as secondary oxidation products. There was a decrease in the content of peroxides after a certain time during the oxidation process, while the content of aldehydes steadily increased.[2−4] The ethoxylated alcohols, $C_{12}H_{25}(OCH_2CH_2)_nOH$, ($n = 1-4$) that we identified in the oxidation mixture with GC-MS may be formed by decomposition of the corresponding peroxides or hydroperoxides, since alkyl hydroperoxides are reported to decompose to alcohols at temperatures above 90 °C.[24] The boiling point of $C_{12}E_5$ is in the range of 202−216 °C. Therefore, the commonly used GC technique involves injection via a split/splitless injector at a temperature of 280 °C. Despite the use of on-column injection technique in this study to avoid degradation of thermally unstable compounds at injection, the hydroperoxides were not detected with GC-MS. The hydroperoxides could have decomposed in the column when the column temperature increased during the analysis. To identify ethoxylated hydroperoxides alternative methods have to be employed.

In the predictive sensitization studies, Freund's complete adjuvant (FCA) is often used. FCA consists of Arlacel (mannide mono-oleate), a sorbitan emulsifier to promote a stable water-in-oil emulsion, and dried heat-killed *Mycobacterium tuberculosis* organisms to enhance the nonspecific immune response and raise the sensitivity of the method.[26] However, also an increased irritability of the skin may be seen. Determination of the sensitizing potential of chemicals, such as surfactants, with irritating properties is difficult. The challenge testing should be performed with the chemical in nonirritating concentrations which might then be too low to detect an allergenic effect. In our investigation of the sensitizing capacity of the ethoxylated aldehydes[3] two parallel CCET protocols were used, one with intradermal FCA injections and one without. No increased allergenic activity was observed when FCA was administered, but an increased irritation was initially seen in the FCA-treated controls compared to the non-FCA-treated. A dose−response relationship was seen in both experiments. Thus, in our subsequent experiments with ethoxylated alcohols[4] and formates no FCA treatment was performed. In these experiments the compounds showed no significant allergenic activity (Table 1). Some irritation was seen showing the difficulties when testing with irritants. However, irritation in some of the control animals can also be observed in sensitization studies of other substances.[17]

Since alcohols and esters are rare sensitizers, the absence of a sensitizing capacity for the ethoxylated formate was not surprising.[27] To cause sensitization, a compound (hapten) has to penetrate the skin and react with macromolecules in the skin to form a complete antigen that is recognized as foreign. Molecules which can function as haptens in allergic contact dermatitis are either electrophilic or have structures that can easily form radicals.[27] Such molecules are able to react with the nucleophilic skin proteins forming stable covalent bonds. In our studies, three ethoxylated compounds have so far been tested for their contact allergenic properties, i.e., $C_{12}E_5$,[4] $C_{12}H_{25}(OCH_2CH_2)_4OCH_2CHO$[3] and $C_{12}H_{25}(OCH_2CH_2)_4OCHO$. The alcohol has no electrophilic properties, and contact allergenic activity could not be observed.[4] The formate has a very low reactivity as electrophile, whereas the aldehyde is an apparent electrophilic group. In our tests, only the aldehyde[3] showed contact allergenic activity which is in accordance with its electrophilic properties.

In a sample of $C_{12}E_5$ stored at room temperature only 70% of the original product remained after 6 months. Similar analysis after 12 months storage was not performed. The results in this study together with earlier investigations of the autoxidation of $C_{12}E_5$ show that the content of the identified oxidation products constitutes less than 10% of the total content in the product after 6 months. This indicates that a major part of the oxidation and degradation products from $C_{12}E_5$ still remains to be identified in the complex oxidation mixture. Our data indicates that the composition of ethoxylated alcohols may change rather rapidly upon storage. It has not been a topic of this study to investigate this in detail, but our data support that a stability study is requested.

It is important to further investigate the skin effects of the widely used ethoxylated surfactants, since a majority of the cases of occupational dermatits is caused by work with water and surfactants. Various types of ethoxylated surfactants are also used as emulsifiers in creams and lotions used on the skin. The clinical significance to man will require an appropriate diagnostic patch testing in exposed humans. The sensitizing capacity of other oxidation/degradation products will be studied and also the influence of oxidation on the skin-irritating properties.

Accepted for publication March 11, 1999.

Abstract ☐ Peptide and protein drugs are often formulated in the solid-state to provide stabilization during storage. However, reactions can occur in the solid-state, leading to degradation and inactivation of these agents. This review summarizes the major chemical reactions affecting proteins and peptides in the solid-state: deamidation, peptide bond cleavage, oxidation, the Maillard reaction, β-elimination, and dimerization/aggregation. Physical and chemical factors influencing these reactions are also discussed. These include temperature, moisture content, excipients, and the physical state of the formulation (amorphous vs crystalline). The review is intended to serve as an aid for those involved in formulation, and to stimulate further research on the determinants of peptide and protein reactivity in the solid-state.

Introduction

In the last two decades, proteins and peptides have become an important class of potent therapeutic drugs. However, their susceptibility to chemical degradation in solution presents a challenge in the development of stable protein pharmaceuticals.[1] As a result, many polypeptide drugs are formulated as lyophilized or freeze-dried products to prolong their shelf life.[2−4] While a "dry" formulation is generally more stable than the corresponding aqueous formulation, chemical degradation reactions can still occur.[2−4] In some cases, protein stability in the solid state is less than or comparable to that in solution.[5,6]

Factors that may impact the chemical stability of proteins and peptides in the solid-state include residual moisture and the excipient(s) used in a formulation. Excipients, such as polymers, are often included in protein and peptide formulations to protect the drug from degradation during processing and/or storage or to act as a matrix for controlled release. This review presents an overview of the chemical degradation reactions common to proteins and peptides in the solid state, and of our current knowledge regarding the effects of formulation and storage factors on peptide and protein stability in these systems.

The degradation pathways of proteins in the solid state can be classified into two types: chemical and physical. Chemical instability involves covalent modification of a protein or amino acid residue to produce a new molecule via bond cleavage, bond formation, rearrangement, or substitution. These chemical processes include such reactions as deamidation at asparagine (Asn) and glutamine (Glu) residues,[7] oxidation of sulfur atoms at cysteine (Cys) and methionine (Met) residues, disulfide exchange at Cys, and hydrolysis of aspartate (Asp) and glutamate (Glu) residues.[8] Physical instability refers to changes in the three-dimensional conformational integrity of the protein and does not necessarily involve covalent modification. These physical processes include denaturation, aggregation, precipitation, and adsorption to surfaces.[1] Chemical instabilities, such as deamidation and disulfide bond cleavage, may lead to physical instabilities, and vice versa. The physical instabilities of proteins will not be discussed in detail here, since the focus is chemical instability. The reader may refer to a recent article on the physical instability of proteins for further discussion.[9] Instead, this review will discuss reactions and factors that contribute to the chemical instability of proteins and peptides in the solid-state.

The different types of chemical reactions that contribute

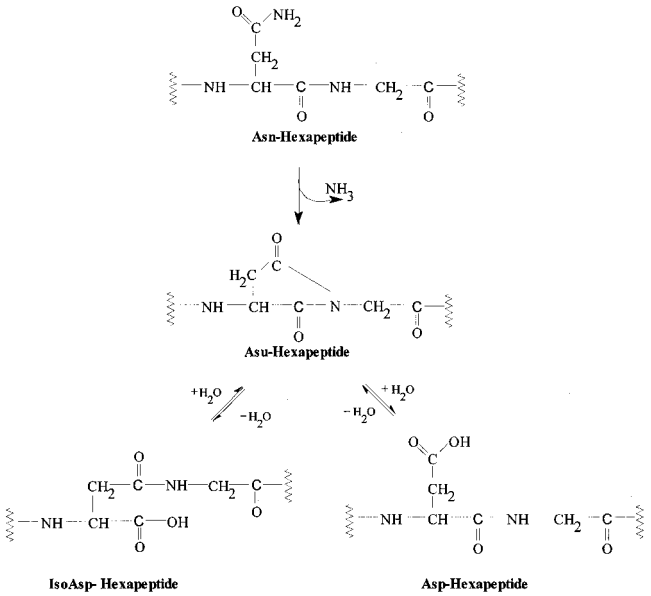


Scheme 1—Deamidation.

to protein and peptide instability in the solid-state are first presented. These include deamidation, peptide bond cleavage, oxidation, the Maillard reaction, β-elimination, and covalent dimerization or aggregation. In the next section, formulation factors that affect chemical stability, such as temperature, moisture, and excipients, are discussed. The review concludes with a summary and a discussion of the implications for future research.

Solid-State Reactions of Peptides and Proteins

Deamidation—Chemical instability in the solid state due to deamidation has been observed for human growth hormone (hGH),[4,10] recombinant human interleukin-1 receptor antagonist,[11] recombinant bovine somatotropin (growth hormone),[12] and insulin.[13,14] While there have been numerous mechanistic studies of protein and peptide deamidation in solution,[7,15–19] few such studies have been reported for deamidation in the solid state. Two studies which provide a mechanistic perspective on deamidation in solids are summarized below.

The stability and mechanism of degradation of the Asn-hexapeptide (Val-Tyr-Pro-Asn-Gly-Ala) were studied in solid formulations lyophilized from acidic solutions ranging from pH 3–5. The main degradation pathway for Asn-hexapeptide in the pH 3 formulation is deamidation via hydrolysis of the Asn side chain to produce the Asp-hexapeptide, which is further hydrolyzed at the Asp-Gly amide bond to generate a small quantity of tetrapeptide (Scheme 1).[18] As the pH of the solution prior to lyophilization increases from 3 to 5, intramolecular attack of the carbonyl center of the Asn side chain by the amide nitrogen of the succeeding amino acid to form a cyclic imide intermediate becomes more prominent, as evidenced by an increase in the cyclic imide in the product distribution (Scheme 1).[18] In solution at pH 5, the cyclic imide is hydrolyzed to form the isoAsp-hexapeptide, which is the dominant degradation product;[15] however, the isoAsp-hexapeptide was not observed in the solid state.[18] The absence of the isoAsp-hexapeptide in the product distribution may be due to the low level of water available for hydrolysis in the solid state. The mechanism of deamidation for the Asn-hexapeptide in the solid state was found to be similar to that in solution.[18] In an extension of this work, we have recently investigated the deamidation of this peptide in solid poly(vinyl alcohol) and poly(vinyl pyrrolidone) matrixes.[20–22] As in the lyophilized peptide, the mechanism of deamidation appears to be similar to that in solution, but the kinetics and product distribution are altered, particularly in matrices of low water content.

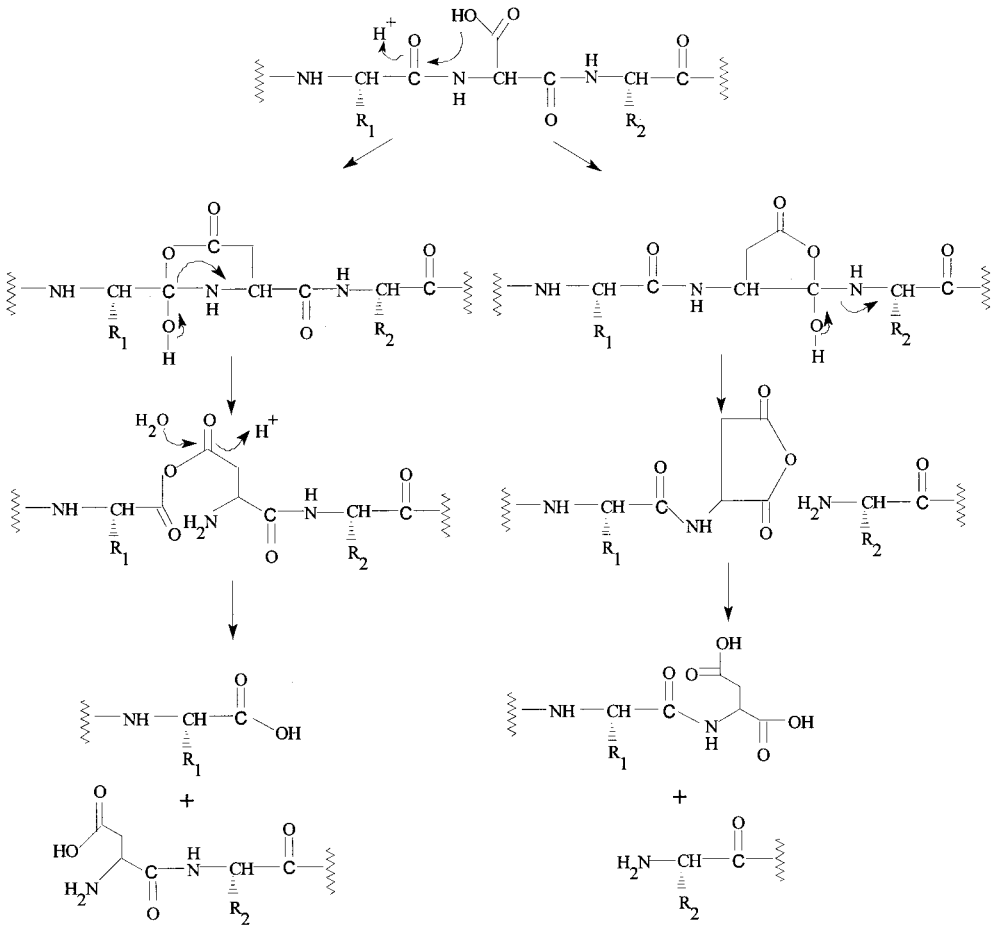
Human insulin has also been observed to undergo deamidation in the solid-state via a mechanism similar to that in solution.[13] In insulin formulations lyophilized from acidic solutions (pH 3–5), the rate-determining first step involves intramolecular nucleophilic attack of the C-terminal Asn_{A21} carboxylic acid onto the side-chain amide carbonyl to release ammonium and to form a reactive cyclic anhydride intermediate, which can further react with various nucleophiles.[13] The cyclic anhydride intermediate may react with water to form [desamido$_{A21}$] insulin,[13] and may also react with another molecule of insulin to form covalent dimers.[13] While the cyclic imide intermediates formed during Asn-hexapeptide deamidation in the solid state were observed to accumulate,[23] the cyclic anhydride intermediate formed during insulin deamidation did not.[13] Strickley and Anderson were able to verify that insulin deamidation proceeds via formation of a cyclic anhydride by using aniline trapping of the intermediate.[13] Consistent with these findings, Pikal and Rigsbee observed that the deamidation of human insulin occurs predominantly at Asn_{A21}, except at high relative humidity when deamidation at Asn_{B3} is more prevalent.[14]

Similar to the degradation of the Asn-hexapeptide discussed previously, the solid-state degradation of a model Asp-hexapeptide (Val-Tyr-Pro-Asp-Gly-Ala) is dependent on the pH of the bulk solution prior to lyophilization. This value is often referred to as the "pH" of the solid, since the true hydrogen ion activity is difficult to measure and pH is technically undefined in the solid-state. Under acidic conditions ("pH" 3.5 and 5.0), the Asp-hexapeptide mainly decomposes to produce a cyclic imide intermediate via base-catalyzed intramolecular cyclization.[23] Hydrolysis of the Asp-Gly amide bond also occurs but to a lesser extent. Under neutral and basic conditions ("pH" 6.5 and 8.0), the Asp-hexapeptide degrades exclusively via intramolecular cyclization to produce the Asu-hexapeptide, which is further hydrolyzed to form the isoAsp-hexapeptide.[23] At "pH" 8, the isoAsp-hexapeptide is the dominant degradation product,[23] similar to that observed in solution.[24]

Peptide Bond Cleavage—A second common degradation pathway for peptides and proteins involves cleavage of the peptide bond. Representative pathways of peptide bond cleavage are shown in Scheme 2. Lyophilized human relaxin formulated with glucose can undergo hydrolytic cleavage of the C-terminal serine (Ser) residue on the B-chain (Trp_{28}-Ser_{29}-COOH) upon storage at 40 °C.[25] This observation was supported by a reduction in molecular mass corresponding to the loss of Ser from fragment T5-T9 of relaxin, as verified by liquid chromatography/mass spectroscopy (LC/MS) and tryptic digest.[25] Li et al. proposed that this cleavage involved an initial reaction of the Ser hydroxyl group with glucose followed by subsequent hydrolysis of the Trp-Ser bond via a cyclic intermediate.[25]

In the solid state, the major degradation pathway of aspartame (α-aspartylphenylalanine methyl ester, APM) is intermolecular cyclization to form exclusively diketopiperazine (DKP) with the elimination of methanol.[26] In solution, the degradation of aspartame at neutral and basic pH also occurs mainly via cyclization to form diketopiperazine (DKP) or hydrolysis at the ester linkage to form α-aspartylphenylalanine (AP) and methanol.[27] Since water was absent in the aspartame solid-state study, no hydrolysis products were observed.[26]

The instability of the undecapeptide substance P (SP) in the solid state also proceeds through diketopiperzine



Scheme 2—Proteolysis.

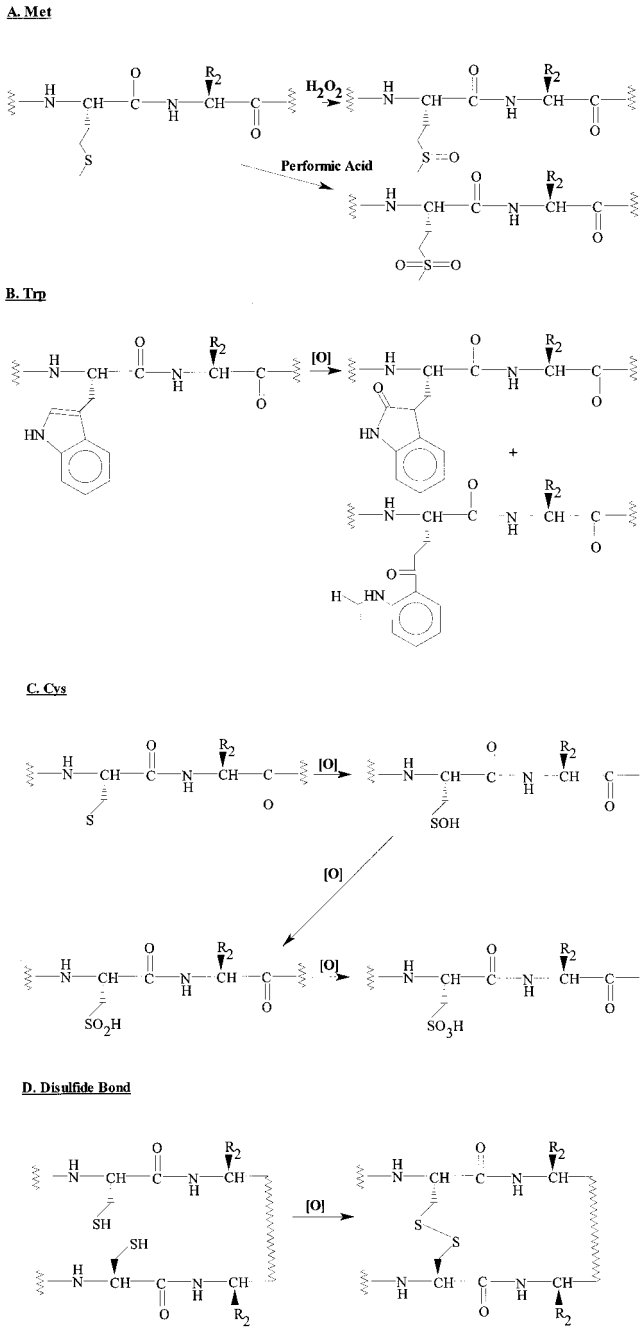
formation. The main pathway of decomposition consists of the sequential release of N-terminal dipeptides via their diketopiperazines, cyclo(Arg-Pro) and cyclo(Lys-Pro).[28] Under the conditions studied, the release of N-terminal dipeptides dominates over other possible routes of spontaneous modification, such as oxidation and deamidation.[28]

Oxidation—The side chains of His, Met, Cys, Trp, and Tyr residues in proteins are potential sites for oxidation (Scheme 3).[1] A major chemical decomposition pathway for human growth hormone (hGH) in the solid state is methionine oxidation at Met_{14} to form the sulfoxide.[10] Even with minimal oxygen (~0.05%) in the vial headspace, decomposition via oxidation is comparable to or greater than that due to the alternative reaction of deamidation.[4] Storage of lyophilized hGH in an oxygen atmosphere results in greater decomposition than storage in a nitrogen atmosphere.[29] As in solution, atmospheric oxygen can easily oxidize Met residues in the solid state, leading to chemical instability and loss of biological activity.

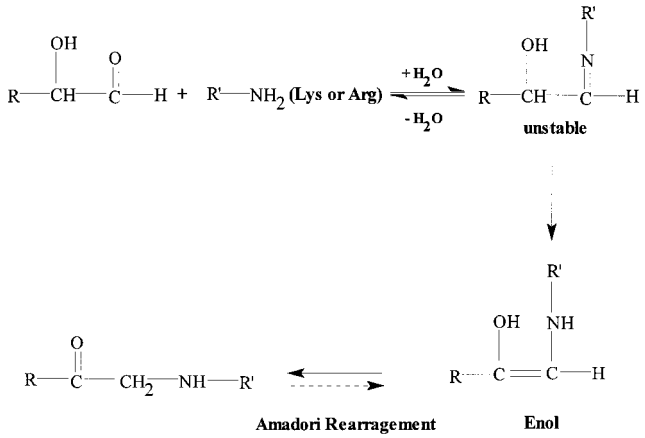
Human insulin-like growth factor I (hIGF-I), lyophilized from phosphate buffer, also undergoes oxidation at its Met residue.[30] There were no significant differences in reaction rates (second-order kinetics) between solution and solid states.[30] However, Met oxidation in the solid-state constitutes a greater fraction of the total protein modification than in solution.[30] Both oxygen content and light exposure affect the oxidation rate.[30] Exposure to light increases the oxidation rate by a factor of 30.[30] This increase in oxidation rate with exposure to light and oxygen suggests that photooxidation and molecular oxygen may be involved in the generation of radicals. However, no further experiments were conducted to determine the nature of the radicals involved or the mechanism of Met oxidation in the solid state.

The oxidative deamidation of a cyclic hexapeptide, acetylcysteine-asparagine-(5,5-dimethyl-4-thiazolidinecarbonyl)-(4-(aminomethyl)phenylalanine)-glycine-aspartic acid-cysteine cyclic disulfide, in a lyophilized mannitol formulation does not appear to depend on molecular oxygen as a reactive species.[31] The oxidation reaction occurs at the aminomethyl phenylalanine moiety to form a benzaldehyde derivative.[31] This oxidative degradant is not detected in the neat solid drug stored under atmospheric oxygen, suggesting that oxygen is not involved in the reaction.[31] Instead, the decomposition of the heptapeptide may be due to a reaction with reducing sugar impurities in the mannitol excipient.[31] The proposed mechanism involves (1) formation of a Schiff base from the peptide primary amine reacting with the carbonyl of the aldehydic group on the reducing sugar, (2) tautomerization to a more stable configuration, conjugated with the phenyl group, and (3) hydrolytic cleavage of the new Schiff base to generate the observed aldehyde derivative.[31] The first part of this proposed reaction, the formation of the Schiff base, proceeds via a mechanism similar to the Maillard reaction, discussed below.

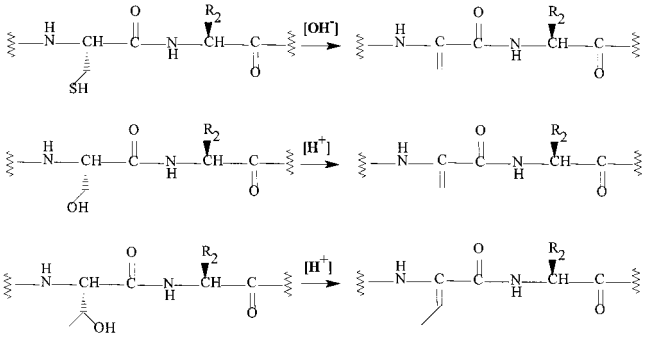
Maillard Reaction—The food industry has studied extensively the nonenzymatic browning of food due to the Maillard reaction, which results from reducing sugars reacting with either amino or free amine groups in proteins, leading to changes in both the chemical and physiological properties of the proteins (Scheme 4).[32] The first phase of the Maillard reaction involves a condensation reaction between the carbonyl of a reducing sugar and an amino group to form an N-substituted glycosylamine, which then converts to a Schiff base and a molecule of water.[33] Subsequent cyclization and isomerization (Amadori rearrangement) result in derivatives which cause discoloration



Scheme 3—Oxidation.



Scheme 4—Maillard Reaction.



Scheme 5—β Elimination.

(nonenzymatic browning) of the formulation.[33] This type of covalent modification is a problem in the solid state because the initial aminocarbonyl condensation reaction to form the Schiff base is accelerated in the low moisture range.[25,34]

Lyophilized human relaxin (Rlx) formulated with glucose was observed to degrade via the Maillard reaction to form adducts with glucose.[25] The resulting adducts were shown by liquid chromatography/mass spectroscopy (LC/MS) to contain up to four glucose molecules covalently attached to Rlx.[25] With tryptic digestion, the individual reaction sites on Rlx were identified as including Lys_{A9}, Lys_{B9}, and Arg_{B17}.[25] The fourth reaction site was hypothesized to be either Lys_{A17} or Arg_{B13} on the T2-T7 fragment, which showed a broadened peak on the tryptic map, but positive identification was not possible using mass spectroscopy.[25]

A review of the food literature prior to 1966 by Goldblith and Tannenbaum revealed that lysine loss in foods is primarily due to the Maillard reaction.[35] Lysine is usually lost more rapidly than the other amino acids because of its free ϵ-amino group, which will react easily with the carbonyl of reducing sugars.[33] However, other residues, such as arginine, asparagine, and glutamine, have been observed to react with reducing sugars also.[25,34]

***β*-Elimination**—Lyophilized bovine insulin has been observed to degrade rapidly with increased water content to produce both covalent and noncovalent aggregates after incubation at 50 °C at various relative humidities.[36] Costantino et al. hypothesized that the reducible covalent interactions were due to thiol-catalyzed disulfide exchange.[36] They speculated that these free thiol groups resulted from the β-elimination of intact disulfide bonds in insulin.[36] The proposed mechanism for β-elimination involves hydroxide ion catalyzed cleavage of a carbon–sulfur bond (cysteine) (Scheme 5A), resulting in two new residues, dehydroalanine and thiocysteine.[36] Dehydroalanine can then react with lysine to form a lysinoalanine cross-link, while thiocysteine can undergo further decomposition to form thiol-containing products, such as hydrosulfide ions (free thiols).[36] A 5-fold increase in the level of free thiols was measured in lyophilized insulin after incubation at 50 °C and 96% relative humidity.[36] The free thiols formed during solid state aggregation were predominantly low molecular weight (<3000 Da), perhaps hydrosulfide ions.[36]

Covalent Dimerization and Aggregation—Dimerization and aggregation differ from the other types of degradation reactions discussed in this review in that they are not the result of a single chemical change. In fact, many different types of chemical or physical changes can induce the formation of dimers or aggregates. A brief description of chemically induced dimerization and aggregation is included here because of its importance in the pharmaceutical industry, and because much of the published literature on protein stability uses aggregate formation as

a key stability indicator. Dimerization or aggregation via covalent cross-linkage can be categorized into two types: reducible (via disulfide exchange) and nonreducible.

Reducible Dimerization and Aggregation—Lyophilized bovine serum albumin, ovalbumin, glucose oxidase, and β-lactoglobulin were observed to form covalent intermolecular disulfide linkages via a thiol−disulfide interchange reaction (Scheme 3D).[37,38] Liu et al. postulated that the intermolecular thiol−disulfide interchange results from the ionized thiol on one albumin molecule attacking the disulfide linkage of another albumin molecule:

$$P_1{-}S^- + P_2{-}S{-}S{-}P_2 \rightarrow P_1{-}S{-}S{-}P_2 + P_2{-}S^-$$

where P1 and P2 are the first and second protein molecules.[37] Thiolate ions rather than thiols are the reactive species in this reaction, since a decrease in the initial solution pH resulted in a slower aggregation rate while an increase in pH led to a more rapid reaction.[37] Free thiols are both necessary and sufficient for the moisture-induced aggregation to occur, since S-alkylated BSA (no free sulfhydryl groups) does not undergo aggregation.[37]

Moisture-induced aggregation of bovine insulin occurred via both noncovalent and covalent interactions. The covalent interactions were reportedly due to intermolecular disulfide bonds as evidenced by the dissolution of 21% of the aggregates upon treatment with a reducing agent, 10 mM dithioerythritol, and 1 mM EDTA to prevent its autoxidation.[36] Costantino et al. postulated that β-elimination produced free thiols which can subsequently catalyze the reshuffling of intact protein disulfides and lead to intermolecular disulfide cross-linkage.[36]

Chemical instability in the solid state can also occur after proteins first experience physical instability, such as denaturation or unfolding. Lyophilized recombinant human keratinocyte growth factor (rhKGF) is prone to aggregation at elevated temperatures.[39] Its aggregation pathway is proposed to proceed initially with unfolding of the protein, leading to formation of large soluble aggregates, which can form disulfide bonds.[39] Finally, these precipitates are converted to scrambled disulfides and/or nondisulfide cross-linked oligomers. Recombinant human albumin (rHA) also undergoes intermolecular thiol−disulfide interchange.[40] The unfolding or loss of tertiary structure in lyophilized rHA is suspected to have initiated the covalent thiol−disulfide exchange.[40] The covalent aggregation of ovalbumin, glucose oxidase, and β-lactoglobulin have also been linked to initial protein physical instability, such as protein unfolding.[37]

Nonreducible Dimerization and Aggregation—Lyophilized human insulin can undergo covalent dimerization at the Asn_{A21} site to form [Asp_{A21}-Phe_{B1}] and [Asp_{A21}-Gly_{A1}] insulin dimers.[13] This dimerization occurs after deamidation of the C-terminal Asn_{A21} forms a reactive cyclic anhydride intermediate that further reacts with the free N-terminal amine of another insulin molecule to yield dimers.[13] Lyophilized tumor necrosis factor (TNF) is also susceptible to the formation of cross-linked aggregates consisting of dimers, trimers, and higher oligomers, which were nonreducible when treated with β-mercaptoethanol.[41]

Another protein that forms nonreducible dimers in the solid state is recombinant bovine somatotropin (rbSt). When lyophilized rbSt was stored at 30 °C and 96% RH, the rate of loss of monomeric rbSt was greater than or equal to the rate of loss in solution.[12] Covalent dimers accounted for 80−90% of the total degradation products observed, with the remaining 20−10% attributed to deamidation/cleavage. The fractional amount of nonreducible dimers was only 23−26% in solution.[12] Most of the covalent dimers were not reducible with β-mercaptoethanol, indicating that the covalent bonds were not disulfide bonds.[12] Hageman et al. hypothesized that such covalent interaction could be due to the condensation of a lysine ϵ-amine and a carbonyl side chain of either Asp or Glu.[12]

A similar mechanism was proposed for the degradation of lyophilized ribonuclease A due to the formation of soluble and insoluble aggregates during storage at 45 °C. These aggregates were not dissociable using an anionic detergent (sodium dodecyl sulfate) and a reducing agent (2-mercaptoethanol), indicating that the aggregates were covalently attached but not through disulfide bonds.[42] Originally, protein oxidation was believed to be the cause of the aggregation since exposure to oxygen and light increased the solid-state aggregation rate of ribonuclease A.[43] Upon further investigation, Townsend et al. postulated that these covalent linkages did not result from an oxidation reaction but from the lysine residues reacting with asparagine or glutamine in a manner similar to the mechanism proposed by Hageman et al. for rbSt.[44] The loss of free lysine residues in the insoluble aggregates, as determined by amino acid analysis, is consistent with this mechanism.[44]

A loss of lysine and histidine residues also was observed by Schwendeman et al. in studies of the moisture-induced aggregation of tetanus and diphtheria toxoids.[45] In this case, however, aggregation was thought to be caused by formaldehyde-induced cross-linking of the proteins, since the aggregates were not soluble under either reducing (10 mM dithiothreitol, 1 mM EDTA) or denaturing (6 M urea) conditions, and since the toxoids had been treated with formaldehyde ("formalinized") during production.[45] The authors proposed a mechanism for the formation of stable intermolecular cross-links in this system and established methods for stabilizing the toxoid formulation against this reaction. Effective stabilization methods included succinylation, treatment with sodium borohydride, and addition of sorbitol.[45]

Factors Influencing Protein and Peptide Chemical Instability in Solids

The importance of temperature, moisture, and formulation excipients in determining the solid-state stability of small molecule drugs has been widely reported and accepted.[45−47] However, the effects of these factors on the solid state chemical stability of proteins and peptides are not as widely reported or understood. In addition to these factors, there is a growing literature that suggests that the hydrogen ion activity in the solid-state may have a significant influence on peptide and protein stability, paralleling the influence of pH in the solution state. The physical state of the solid (e.g., glassy vs rubbery) also has been shown to affect protein reactivity in the solid state. This section reviews published reports of the effects of these factors on peptide and protein stability in the solid state: temperature, moisture, excipients, hydrogen ion activity, and the physical state of the solid.

Temperature—The exposure of solid protein and peptide formulations to elevated temperatures generally decreases chemical stability by accelerating almost all chemical degradation reactions. For example, the deamidation of the Asn-hexapeptide increases with increasing temperature in the solid-state, with the formation of the cyclic imide intermediate becoming more favored over the direct hydrolysis of the Asn side chain.[18] In general, the increase in degradation rates with temperature did not follow an Arrhenius relationship within the temperature range studied (40−70 °C).[18] This suggests that acceleration of chemical reaction kinetics due to temperature is not solely responsible for the rate increase.

High-temperature inactivation of proteins often results from the destruction of disulfide bonds in cystine via β-elimination.[1] Consistent with this, the aggregation of insulin, in which β-elimination is the first step, was observed to increase with increasing temperature.[36] Increases in temperature have been observed to increase the rate of covalent cross-linking in the solid state for rbSt,[12] bovine insulin,[36] and tumor necrosis factor.[41] Most degradation reactions, such as deamidation,[18] peptide bond cleavage,[23,26] the Maillard reaction,[33] and oxidation[49] are accelerated by increasing temperature.

The increases in chemical instability with temperature may be due to increased mobility in the system or lowering of the activation barrier for reaction. In particular, significant changes in mobility may occur when the temperature range of interest includes the glass transition temperature (T_g) of an amorphous solid. In this case, changes in temperature affect not only the intrinsic reactivity of the degrading species, as observed in the solution state, but also the medium in which the reaction occurs. The relationship between the glass transition temperature (T_g) and reactivity is discussed below, under "Physical State of the Solid".

Moisture—Residual moisture is often thought to be responsible for protein and peptide chemical instability in the solid-state. In general, lyophilized protein formulations are more stable at lower water contents.[2] For example, the rate of degradation of the Asp-hexapeptide increases as the formulation vial moisture content increases.[23] Likewise, the deamidation of the Asn-hexapeptide increases as water content increases from 0.5% to 2%.[18] However, further increases in water content of up 3% do not significantly affect the rate of degradation.[18]

A similar effect of water on the deamidation of insulin was observed. The rate of degradation of lyophilized human insulin increases steeply with water content at low levels of hydration, approaching apparent plateaus at water contents greater than 20%.[13] The rate constants in the plateau region are comparable to those in solution.[13] The rate of rbSt loss due to deamidation and dimerization also increased with increased water content.[12] Increasing the relative humidity from 75% to 96% doubled the rate of rbSt loss.[12] However, the fractional amount of nonreducible dimers formed remained constant at around 80% and was independent of water content over the range studied.[12]

The covalent aggregation of bovine serum albumin (BSA) in the solid state greatly depends on water content.[38] Freeze-dried BSA was more prone to aggregation in the moistened solid state than in solution and exhibited a maximum at a very low moisture level.[38] The aggregation of BSA in solution increased with increasing ratio of water to protein.[38] Jordan et al. proposed that the increase in aggregation rate is related to the increase in water mobility with increasing ratios of water to protein.[38] Lyophilized recombinant human interleukin-1 receptor antagonist (rhIL-1ra) formulated with 2% glycine, 1% glycerol, and 10 mM citrate buffer at pH 6.5 exhibited maximum relative instability at a moisture content of around 0.8% (w/w) and the least stability at water contents less than 0.5% or around 3.2% (w/w).[11] A similar bell-shaped relationship between covalent aggregation and water content has been observed for ovalbumin, glucose oxidase, and β-lactoglobulin.[37]

A few other types of chemical instabilities appear to exhibit this bell-shaped relationship between degradation kinetics and moisture content. A bell-shaped dependence on moisture content also was observed for the aggregation of rHA via thiol-disulfide exchange, with maximum aggregation corresponding to 47 g water/100 g dry protein (96% RH).[40] The Maillard reactions usually have maximum rates in the low-moisture range.[34] Insulin,[50] casein,[51] and blood plasma proteins[52] in "dry" systems containing glucose show a maximum in the range of 40−80% RH (10−20% water content).[2]

This bell-shaped relationship between water content and reaction rate is often attributed to the effect of water on molecular mobility and reactant concentration. At low moisture levels, the Maillard reaction is less rapid because the diffusion and mobility of reactants are restricted.[2,34,52] As water content increases, molecular mobility increases, leading to enhanced reactant mobility which should facilitate the reaction.[37] At higher water contents, the reaction rates decrease due to dilution of the reactants by water.[37,53] Liu et al. observed that the addition of various types of polymers (carboxymethyl-cellulose, dextran, poly(ethylene glycol)) as diluents also appeared to hinder the aggregation of BSA.[37]

While residual water can often increase chemical degradation rates, under some conditions it can suppress a chemical reaction. Pikal et al. observed that the oxidation of a lyophilized hGH formulation was affected by increases in headspace oxygen at low moisture levels but not at higher moisture contents.[29] This may be due to water's possible antioxidant properties. Water may be either an antioxidant or an oxidant depending on the system.[32] Generally, oxidation in foods reaches a maximum at low water content and decreases as water content increases.[2]

In addition to having an effect on solid-state degradation rates, water may also affect the reaction pathways. For example, the formation of the cyclic imide intermediate during deamidation of the Asn-hexapeptide at pH 5 was favored over direct hydrolysis as water content increased.[18] The low moisture environment of the solid-state can generate product distributions which differ from those of the solution state.[18] The main product in the degradation of the Asp-hexapeptide in solids lyophilized from pH 3.5 and 5 solutions is the cyclic imide hexapeptide.[23] In contrast, the dominant degradation product in solution at pH 3.5 is the tetrapeptide and at pH 5.0 is the isoAsp-hexapeptide.[24] Thus, the reduced moisture in the lyophilized solids appears to suppress the hydrolysis of the Asu-hexapeptide intermediate to form the isoAsp-hexapeptide and that of the Asp-Gly peptide bond to form the tetrapeptide.

We have observed similar shifts in the product distribution in our recent studies of Asn-hexapeptide deamidation in poly(vinyl pyrrolidone) and poly(vinyl alcohol) matrices.[21] In addition, the order of the reaction with respect to water content differs in these two polymers: it is first-order in poly(vinyl pyrrolidone), but second order in poly(vinyl alcohol).[21] Since it is unlikely that the molecular deamidation mechanism differs significantly in the two systems, the results suggest that the role of water extends beyond that of reactant and may involve plasticization of the polymer matrices.

So, while the importance of water in chemical reactions is well recognized, the exact relationship between solid-state chemical instability and water content is often difficult to delineate and is dependent on the type of degradation reaction(s). This difficulty in determining the mechanism by which water affects the chemical stability of proteins and peptides in the solid state is in part due to the various roles water can play in promoting chemical reactivity. Water can act as (1) a reactant, (2) a medium or solvent, and (3) a plasticizer to increase molecular mobility.[2,47,54] Discriminating among these possible effects is difficult, particularly since more than one effect may be important in a given system.

Excipients—Proteins are often formulated with excipients, such as sugars and polymers, to protect them during

Table 1—Types of Polyalcohols Used as Pharmaceutical Excipients

polyhydric alcohols	nonreducing sugars	reducing sugars
mannitol	dextran	fructose
sorbitol	sucrose	glucose (dextrose)
	trehalose	lactose
		maltodextrin
		maltose

freeze-drying and storage. Polymeric "excipients" may also be used to form a matrix for controlled release. The types of excipients used and their effects on the chemical stability of proteins and peptides are varied. For example, a wide range of excipients, such as heparin, sulfated polysaccharides, anionic polymers, and citrate, decreased the rate of covalent aggregation in recombinant human keratinocyte growth factor (rhKGF) at elevated temperatures.[39] On the other hand, while EDTA inhibited disulfide formation in aggregates, it was not as effective in stabilizing rhKGF.[39] In this section, three categories of excipients will be discussed since they comprise the majority used in solid formulations: polyalcohols, polymers, and buffer salts.

Polyalcohols—Sugars and polyols are the most commonly used excipients in lyophilized protein and peptide formulations.[55] Table 1 lists the different types of polyalcohols used as pharmaceutical excipients. These sugars and polyols are often added to lyophilized formulations to protect and stabilize the proteins against decomposition during processing and storage. TNF formulated with dextran, sucrose, trehalose, or 2-hydroxypropyl-β-cyclodextrin, which are amorphous, formed fewer nonreducible dimers than TNF formulated without an excipient.[41] The covalent dimerization of human insulin was markedly decreased by incorporation into a glassy matrix of trehalose.[56] The stability of lyophilized recombinant human interleukin-1 receptor antagonist (rhIL-1ra) was greatly improved by increasing the concentration of sucrose in the formulation.[11] Sucrose stabilized rhIL-1ra against chemical degradation better than trehalose.[11] Examination of a series of polyalcohols in this system showed the following order of decreasing ability to stabilize the protein: sucrose > trehalose > sorbitol > no excipient > maltose.[11] In a recent study of Asp-Pro bond cleavage in Physalaemin and Hamburger peptides, stabilization was provided by glassy polyols in the order: sucrose > Ficoll (low mw) > Byco A, Ficoll (high mw) > dextran.[57] The authors attributed the stabilizing ability of the polyols to the density of the matrix, with greater packing density leading to improved stability.

Some of these excipients, such as maltose in the rhIL-1ra example above, may have a destabilizing effect. For example, the oxidative deamidation of a cyclic heptapeptide was observed in formulations containing mannitol, but not in solution or in the neat solid (no excipient).[31] The extent of oxidative degradation increases with increasing mannitol content after 12 weeks of storage at 40 and 60 °C.[31] These researchers postulated that the cyclic heptapeptide was reacting with a reducing sugar impurity in the mannitol.[31] Thus, the lower stability of the rHIL-1ra maltose formulation may have been due to the rhIL-1ra reacting with maltose, a reducing sugar.

Reducing sugars are known to react with proteins and peptides via the Maillard reaction (formation of Schiff base) as well as other side reactions.[2,25,55] Rapid covalent modification of lyophilized human relaxin was observed in the presence of glucose.[25] The glucose appeared to have reacted with lysine and arginine residues via the Maillard reaction to form covalent adducts.[25] A significant amount of serine cleavage from the C-terminal of the B-chain of relaxin was also identified.[25] A high glucose content may be necessary for cleavage to occur, since the hydrolytic cleavage of relaxin stored in concentrated glucose solutions occurred to a lesser extent than in the solid state.[25] In contrast, formulating relaxin with nonreducing sugars such as mannitol and trehalose produced stable, lyophilized formulations.[25]

In addition to oxidation and deamidation products, human growth hormone formulated with lactose produced an additional product not observed in either the freshly freeze-dried lactose formulation or in any of the other formulations studied. The researchers postulated that the product was due to an adduct of lactose and hGH, either the glycosylamine or the corresponding Schiff base.[4] As stated above, the use of reducing sugars in lyophilized formulations is problematic due to their propensity to react with proteins via the Maillard reaction, especially at lysine and arginine residues.

Polymers—Polymeric excipients may influence the reactivity of peptides and proteins through direct chemical interactions or by altering the physical state (e.g., glassy vs rubbery) of the system. This section addresses chemical interactions between polymeric excipients and incorporated proteins. The effects of polymers on the physical state of the matrix are discussed below.

Many of the published studies on the chemical effects of polymers on peptides and proteins involve the lactide/glycolide copolymers. These polymers are of particular interest because they are biocompatible and biodegradable and are therefore used commonly in implantable devices.

The stability of atriopeptin III (APIII) encapsulated in poly(D,L-lactide-*co*-glycolide) (PLG) microspheres was studied and compared to that of APIII alone at 40 °C.[58] When microspheres were shaken in neutral buffer solution, APIII was completely degraded in 5 days. In neutral buffer alone, APIII degraded with a half-life of 8.7 days.[58] After 8 days at 95% relative humidity, 20% of APIII in the microspheres had degraded.[58] Concentrated APIII showed no degradation after 2 weeks, and dilute APIII in water showed no loss after one month.[58] Different degradation peaks were observed for APIII in microspheres and APIII alone.[58] It was concluded that PLG catalyzes the degradation of APIII, and the mechanism of this degradation appears to be different from that seen for APIII alone in buffer.[58] This suggests that the polymer environment has a significant effect on the chemical stability of this protein.

Park and co-workers also found this to be the case for the stability of carbonic anhydrase and bovine serum albumin during release from a polymer matrix immersed in buffered medium at 37 °C.[59] Carbonic anhydrase encapsulated in poly(D,L-lactic acid-*co*-glycolic acid) (PLGA) microspheres was released in an inactive form.[59] Severe hydrolysis of unreleased and released proteins was observed.[59] It was postulated that the hydrolysis was due to an acidified medium created by the degradation of the PLGA microspheres.[59] The degradation of the PLGA microspheres occurs via random chain scission of an ester linkage in the polymer backbone, which produces water soluble oligomers with carboxylic acid end groups that affect medium pH.[59] As the microspheres degraded, the pH of the medium decreased from 7 to 3 over 40 days.[59] Park et al. also suggest that the protonated carboxylic acid end group of the lactic and glycolic acid fragments may react with the carbonyl group of the amide linkage in the proteins, leading to cleavage of the peptide backbone.[59] So, in addition to having an environmental effect, polymers may also have a direct catalytic effect on the chemical stability of proteins in solids.

In contrast to these reports of a detrimental effect of lactide-glycolide polymers on protein stability, there have been several reports of successful protein formulation in

these polymers.[60−62] Cleland et al. describe the stability of recombinant human growth hormone (rhGH) during release from PLGA microspheres into isotonic buffer.[60] Rates of oxidation, diketopiperazine formulation, and deamidation in the microspheres were comparable to those in solution controls, and rates of aggregation were only slightly greater than in solution.[60] The authors infer that the pH within the microspheres is comparable to that in the surrounding buffer, and that rapid buffer equilibration may prevent a pH decrease in this system.[60] In related studies, rhGH was stabilized in a PLGA microsphere formulation by the formation of an insoluble complex with zinc.[61] In vitro studies showed that microsphere encapsulation did not alter rhGH activity in this system, and in vivo studies in rats and monkeys showed sustained delivery of rhGH for up to one month.[61] The discrepancies in protein stability in PLGA systems suggest that factors other than the polymer choice will influence drug stability. These may include the properties of the protein drug itself, other formulation variables, and the interaction of the formulation with the release matrix (e.g., buffer, tissue).

Limited information is available on the chemical effects of other polymeric excipients on peptide and protein stability. Recent studies in our laboratories suggest that the Asn-hexapeptide forms a reversible complex with poly(vinyl pyrrolidone) when stored in matrixes of this polymer at elevated temperature and low matrix moisture content.[63] Formation of the complex results in a reduction in Asn-hexapeptide degradation to the cyclic imide, but release of the Asn-hexapeptide from the complex requires more than 1 week in dialysis studies at neutral pH.[63] The chemical nature of this complex is under investigation. Protein binding to dextrans in lyophilized proteins has also been suspected.[64] After exposure to aqueous media for more than 2 weeks, recombinant bovine somatotropin (rbSt) and zinc insulin were released intact and active from microspheres composed of sucrose and poly[1,3-bis(*p*-carboxyhydroxy)-hexane anhydride], which is a very hydrophobic polymer.[65] Ron et al. postulated that the hydrophobic polymer prevented the entry of water into the microspheres[65] and thus protected rbSt from moisture induced decomposition, such as covalent dimerization and deamidation.[12]

Buffer Salts—Buffer salts are often included in solid formulations of peptides and proteins in an attempt to control the hydrogen ion activity, or the protonation state of the functional groups on the protein. In solution, buffer salts may have a catalytic effect on many protein degradation reactions, apart from their effect on pH. In this section, we review the limited evidence for specific chemical effects of buffers in the solid state. The effects of solid-state hydrogen ion activity on reactivity are discussed in the next section.

There is some evidence that phosphate buffers have a catalytic effect on protein degradation. In a study on lyophilized RNase, Townsend and DeLuca prepared lyophilized formulations from solutions containing varying concentrations of sodium phosphate buffer.[66] While a buffer-free formulation showed a 10% loss in activity over 120 days of storage at 45 °C, a formulation lyophilized from a 0.2 M buffer solution showed a nearly 40% loss in activity during the same period.[66] Similarly, Pikal et al. showed an effect of sodium phosphate buffer concentration on the chemical degradation and aggregation of lyophilized human growth hormone.[4] Mechanisms suggested for this effect include the catalysis of oxidation reactions by heavy metal contaminants in the buffer salts,[66] and the preferential crystallization of phosphate buffer components during freeze-drying, leading to pH shifts.[4] It should be noted that sodium phosphate buffers are thought to be particularly prone to preferential crystallization, and often are avoided in lyophilized protein formulations for this reason.[67] Acetate buffers are also avoided in lyophilized formulations, since volatilization of acetate species during freeze-drying may alter the buffer composition in the solid.

Buffer species themselves may be chemically unstable in solid formulations, producing degradation products that interact with peptides and proteins. Recent studies in our laboratories examined the deamidation of the Asn-hexapeptide in lyophilized matrixes containing PVP and Tris buffer.[68] We observed the formation of a new peak in HPLC chromatograms, which mass spectral analysis showed to be a formaldehyde adduct of the tyrosine residue on the aspartate or isoaspartate deamidation product. The presence of formaldehyde was shown to be associated with the inclusion of Tris buffer in the formulation, since no formaldehyde was detected when Tris was omitted or replaced with other buffers.[68] We hypothesize that degradation of Tris [tris(hydroxymethyl)aminomethane] occurs on storage of this formulation, liberating formaldehyde, which then reacts with the tyrosine residue on the peptide.[68]

Hydrogen Ion Activity—In the solution state, pH is used as a simple indicator of hydrogen ion activity. While pH is not defined in the solid state, there is a strong correlation between the chemical stability of proteins and peptides in the solid state and the pH of the solution prior to lyophilization. This value is often termed the "apparent pH" of the solid and is often given the abbreviated designation, "pH", with the quotation marks signifying that the value is apparent.

The deamidation rate of the Asn-hexapeptide increases as the solution pH prior to freeze-drying increases from 5 to 8.[18] The "pH" of the Asn-hexapeptide formulation solution also appears to dictate the extent to which the peptide stability depends on other variables, such as moisture level and temperature.[18] The deamidation of lyophilized human insulin is also quite sensitive to "pH".[13,14] Increases in the oxidation of hGH,[4,29] the β-elimination of cysteine in bovine insulin,[36] and the formation of nonreducible dimers of tumor necrosis factor[41] in the solid state all increase with formulation "pH". Interestingly, while no dimers were observed at "pH" 4, the biological activity of TNF at "pH" 4 was significantly lower than at higher "pH's".[41]

The increase in the rate of covalent dimerization of rbSt with increasing "pH" is attributed to the deprotonation of the lysine residues, which are more nucleophilic when deprotonated. Interestingly, the fractional amount of nonreducible dimers formed during rbSt degradation remained constant at around 80%, independent of "pH" over the range studied (pH 5−10).[2,69] Lyophilized recombinant human interleukin-1 receptor antagonist (rhIL-1ra) formulations containing citrate were less likely to form noncovalent aggregates than those with phosphate.[11] The researchers postulated that the destabilizing effect of phosphate buffer may be due to the selective crystallization of the dibasic salt, which would expose the protein to a low "pH".[11]

To avoid drastic pH shifts, the weight ratio of buffer to other solutes should remain low.[3] The addition of ionic agents such as NaCl should also be kept at a minimum or avoided. While NaCl does not affect "pH", the chemical stability of hGH in freeze-dried formulations was decreased by the presence of NaCl.[4] The researchers attributed the destabilizing effect of NaCl on hGH to a specific ion effect, due primarily to the chloride ion.[4] The effect of NaCl on hGH may also be due to a salt effect on "pK_a".

The Physical State of the Solid—The state of a pharmaceutical solid depends on the temperature, composition (drug and excipient), moisture, and on the time allotted to the experiment. While the effects of tempera-

ture, moisture, and formulation composition on chemical instability were presented independently above, their influences on the solid-state chemical stability of proteins and peptides are often synergistic. These variables combined determine the physical bulk state of solid protein and peptide formulations. The bulk state of a formulation (crystalline versus amorphous) has been linked to various cases of protein and peptide chemical instability in the solid-state.[4,13,18]

Crystalline—Crystalline solids possess long range molecular order with the molecules structured in fixed geometric units. In contrast, amorphous solids have irregular packing and lack long range order. For small molecule drugs in the solid-state, the crystalline drug is generally less prone to chemical decomposition than the amorphous form.[14,70] However, the crystalline state may not be more stable for protein and peptide formulations. Oliyai et al. found that the Asp-hexapeptide was more stable in a lactose matrix (amorphous) than in mannitol (crystalline).[23] Interestingly, the lactose formulation had a greater affinity for water (a higher water content) than the mannitol formulation, yet the peptide was significantly more stable in the lactose matrix than in mannitol.[23] Excipients that were more hygroscopic were generally better at stabilizing rHA against aggregation, suggesting that the stabilization arises primarily from interactions between the excipient and water rather than between the excipient and the protein.[40]

The stability of crystalline and amorphous insulin (neat solid) was also investigated at various water contents. For crystalline insulin, deamidation at the Asn_{A21} site increases rapidly with increases in water content.[14] In contrast, the deamidation of amorphous insulin was nearly independent of moisture content (up to 15%).[14] Crystalline human insulin was less stable than amorphous insulin, independent of the water content over the range studied.[14]

Solid formulations which are at least partially amorphous appear to best protect proteins and peptides against chemical instability.[4] Lyophilized human growth hormone (hGH) formulated in a partially amorphous excipient system (glycine:mannitol) was less susceptible to chemical degradation and aggregation than hGH formulated in either totally amorphous (dextran) or crystalline (mannitol) systems.[4] So, while a partially amorphous system is necessary to stabilize hGH, an amorphous system is not a sufficient condition for stability.[4] Pikal et al. postulated that a partially amorphous system allows molecular interaction with the protein and/or acts as "sink" for residual water.[4]

While residual moisture generally leads to chemical instability, the relative stability of proteins and peptides in solid formulations cannot be judged solely on the basis of the amount of water present, as seen in the above cases. The nature of the excipient, such as its crystallinity and affinity for water, appears to be important as well.

Amorphous—Depending on temperature, structure, and composition, amorphous solids such as polymers exhibit widely different physical and mechanical properties.[71] At low temperature and moisture, amorphous solids are brittle, hard, and highly viscous, and are said to be in the "glassy" state. In the glassy state, molecular motion is largely restricted to vibrations and short-range rotational motion.[71] As the temperature and/or moisture content increases, the solids undergo a transition from a glassy state to the so-called "rubbery" state, which is characterized by decreased viscosity and increased elasticity. The glass transition temperature (T_g) is defined as the temperature at which the solid softens because of the onset of long-range coordinated molecular motion.[71] The T_g varies greatly among different amorphous pharmaceutical solids and is dictated by such factors as composition and moisture content, since water may act as a plasticizer to increase bulk mobility and decrease T_g.

Researchers have speculated that chemical reactions which involve molecular mobility, such as bimolecular reactions, are unlikely to occur in the glassy state due to the limited mobility.[72] As the solid system becomes more rubbery ($T > T_g$) and mobility increases, the reaction rates would then greatly increase.[72] Lyophilized rhIL-1ra formulations with T_g's ranging from 20 to 56 °C were stored for several weeks at temperatures above and below their T_g's.[73] The decomposition of rhIL-1ra, both via deamidation and aggregation, was greatly accelerated at temperatures above T_g (rubbery state).[73] However, the rate of degradation also increased in some formulations whose T_g's were above the storage temperature (glassy state).[73]

Other instances of protein and peptide degradation in the glassy state have been documented. The aggregation of hGH has been found to occur in formulations stored at temperatures well below their glass transition temperature.[4] The dimerization and deamidation of insulin have been observed in the glassy state;[13] however, the actual formulation T_g was not measured in this study. Recently, the fission of the Asp-Pro bond in Physalaemin and Hamburger peptides has been detected in water soluble glasses (e.g., dextrose, Ficoll, sucrose) below their T_g.[57] Thus, while proteins and peptides are generally more stable in the glassy state, chemical degradation reactions can still occur. Although mobility is limited in the glassy state, glassy pharmaceutical solids may experience significant molecular mobility at temperatures up to 50 °C below their glass transition temperature.[74] Furthermore, significant rotational and translational mobility was shown to exist for water in solid poly(vinyl pyrrolidone), even at very low water contents (glassy state).[75]

The increase in reactivity with water content is often attributed to water's ability to plasticize or increase the molecular mobility of the bulk structure and thus the reactants. The decomposition of a freeze-dried monoclonal antibody–vinca conjugate has been correlated with formulation T_g.[76] However, since water activity and content were not kept constant, other factors which may contribute to this instability cannot be ruled out. In contrast, the degradation of aspartame in the solid-state correlates better with water activity and content than with T_g.[77] In recent studies of Asn-hexapeptide deamidation in poly(vinyl pyrrolidone) matrices, we have attempted to discriminate between water's effects on T_g (i.e., as a plasticizer) and its solvent effects by adding glycerol to the matrix as a secondary plasticizer.[22] This enabled us to generate systems with constant T_g and varying water activity, or with constant water activity and varying T_g. Interestingly, the deamidation rate showed a single log-linear correlation with T_g for matrices in the rubbery state, while in the glassy state this correlation resulted in multiple parallel lines with intercepts dependent on matrix water activity.[22] These results suggest that for this system, water acts primarily as a plasticizer in the rubbery state, but acts both as a plasticizer and a solvent or reaction medium in the glassy state. Taken together, these conflicting reports on water's role as a plasticizer demonstrate the complexity of these systems and the attendant difficulty in gaining a mechanistic understanding of the chemical reactivity of incorporated proteins and peptides.

Summary and Commentary

The results discussed above highlight the difficulty in determining the mechanisms of protein chemical instability in the solid-state. Protein decomposition in the solid state

can occur through multiple degradation pathways, involving both physical and chemical instabilities, as observed for rbSt and insulin. Since chemical instability can also lead to physical instability and vice versa, it can be difficult to determine the mechanism of chemical degradation in proteins. Furthermore, non-peptide/protein components of these solid-state formulations may have multiple effects. Residual moisture and polymeric excipients, for example, may influence matrix mobility (T_g), may participate directly or indirectly in degradation reactions, and may influence the "pH" or other properties of the reaction medium. Multiple effects caused by a single additive make mechanistic definition difficult.

Consideration of the available literature in this area suggests several avenues for additional research. Most notably, it is clear that the determinants of protein and peptide reactivity in the solid-state have not been fully characterized. While pH, temperature, and buffer composition are known to be critical in solution, different or additional factors may be important in the solid-state. These may include mobility in the matrix, hydrogen ion activity, and protein secondary and tertiary structure. Additional research relating to each of these factors is warranted.

For example, while mobility in a solid polymer matrix is often characterized using the glass transition temperature (T_g), this measurement describes the mobility of the matrix as a whole and not its specific components. Ultimately, the degradation of peptides and proteins in these systems is more likely to depend on the mobility of the drug molecules themselves or of specific amino acid residues within them, rather than on the "bulk" mobility described by T_g, particularly when the drug loading is low. Recent research has begun to address this question,[78,79] but continued effort will be required to establish a measure of solid-state mobility that is predictive of reactivity. In addition, mobility is likely to be more important for bimolecular reactions involving large molecules (e.g., protein aggregation) than for unimolecular reactions (e.g., succinimide formation) or bimolecular reactions involving relatively small, mobile reactants (e.g., oxidation). An understanding of the factors that produce a "mobility-limited reaction" in the solid state would aid in formulation, since stabilization strategies that reduce mobility (e.g., inclusion of glass-forming excipients) are most likely to be effective for these reactions. Reaction mechanism and reactant molecular weight are likely to be among these factors.

Hydrogen ion activity (i.e., pH) is important in the solution state degradation of many peptides and proteins, but its role in the solid-state remains unclear. At present, there is no convenient measure of hydrogen ion activity in these solid systems, so examination of its effects has relied on correlation with "effective" pH. These studies have suggested that the "pH" dependency in the solid state parallels its solution state counterpart. However, it is reasonable to expect that a reaction that is pH-driven in solution may be controlled by other factors, such as mobility, in a glassy solid. Examination of the dependence of solid-state "pH" rate profiles on other matrix properties would be useful, as would the development of methods to measure hydrogen ion activity in solid formulations.

Finally, the effects of protein secondary and tertiary structure on reactivity and reaction mechanism should be examined. In solution, secondary structure has been shown to affect deamidation rate,[80] and protein aggregation in the solid state has been attributed to adsorption-induced unfolding.[62] In addition, a recent study has demonstrated the utility of infrared spectroscopy to determine protein secondary structure in PLGA matrixes.[81] However, there is a lack of information on the effects of protein structure on chemical reactivity in solids. Such information is important not only for chemical routes of protein degradation, but also because physical modes of degradation, such as aggregation, are often associated with chemical changes. Information on the interaction of protein structural domains with matrix properties (such as mobility and water content) to produce degradation would help to identify labile residues in solid protein formulations a priori. Stabilization strategies could then be directed in a rational way toward the modification of protein structure and/or formulation variables.

Freeze-Drying above Room Temperature

MARC S. TESCONI, KIARESH SEPASSI, AND SAMUEL H. YALKOWSKY*

Contribution from *Department of Pharmaceutical Science, College of Pharmacy, University of Arizona, Tucson, Arizona 85721.*

Received December 10, 1998. Accepted for publication February 22, 1999.

Abstract □ This study investigates the use of solid, organic compounds to lyophilize drugs without conventional freeze-drying equipment. The aim of the investigation is to find a pharmaceutically acceptable solvent or solvent combination that is appropriate for freeze-drying on the basis of its ability to (1) solubilize hydrophobic drugs, (2) provide a stable environment for water-sensitive compounds, (3) be rapidly and completely removed from the product under vacuum, and (4) produce cakes that are readily reconstituted. A eutectic formed from 1,1,1-trichloro-2-methyl-2-propanol (chlorobutanol) hemihydrate and dimethyl sulfone ($DMSO_2$) is determined to be a suitable medium.

Introduction

The formulation of certain parenteral drugs as reconstitutable freeze-dried products offers the advantages of improved stability, dissolution rate, dosing accuracy, and sterility. However, freeze-drying is generally restricted to drugs that are water soluble and/or stable to hydrolysis for at least the time required for freezing. Compounds that hydrolyze rapidly are poor candidates because the amount of drug that remains in the dried product is likely to depend on the time required to freeze the sample. Hydrophobic nonelectrolytes are poor candidates because they require either large volumes of water or significant amounts of cosolvent to yield the desired quantity of drug in a reasonably sized container. Although cosolvents usually improve both stability and solubility, they can cause incomplete freezing and a drying stage that involves the simultaneous sublimation of ice and evaporation of liquid residue.[1] The resultant dried product is often very dense and difficult to reconstitute. Furthermore, since a surface skin is often produced when an incompletely frozen medium evaporates, drying times can be extended beyond the point of practicality.

It is also important to consider that if sublimation temperatures are significantly lower than normal to keep the medium frozen, then the condensing temperature required to recover the solvents may be lower than the −55 °C minimum of the lyophilizer.

The current study investigates the feasibility of using organic solvents that are solids at room temperature to lyophilize hydrophobic and water-sensitive compounds without conventional freeze-drying equipment. The aim of this investigation is to find a solvent or solvent combination that is suitable for freeze-drying on the basis of its ability to (1) solubilize hydrophobic drugs, (2) provide a stable environment for water-sensitive compounds, (3) be rapidly and completely removed from the product under vacuum, and (4) produce cakes that are easily reconstituted using pharmaceutically acceptable cosolvents.

Materials

Solvents were selected from the *Handbook of Pharmaceutical Excipients*[2] and *The Merck Index*[3] on the basis of their having low toxicity, melting points between 35 and 120 °C, and relatively low molecular weights. The compounds chosen for the study are listed in Table 1.

All compounds were >98% pure and were used as received from their respective suppliers except for anhydrous chlorobutanol, which was prepared by dehydration of a chlorobutanol hemihydrate melt.

Approach

The individual solvents in Table 1 were experimentally determined to be either too high melting to ensure solute stability or too nonpolar to solubilize semipolar compounds. Solvent combinations that formed eutectics were sought for their intermediate polarities and lower melting temperatures. The selection of a eutectic medium for freeze-drying involved seven steps: (1) screening solvent combinations for eutectic formation; (2) determination of the eutectic compositions; (3) measurement of sublimation rates; (4) assessment of solubilizing ability; (5) selection of an optimal medium; (6) freeze-drying sample compounds; and (7) analysis of freeze-dried products. Each of these steps is described below.

Experimental and Results

1. Eutectic Formation—The solvents in Table 1 were combined in a 1:1 mole ratio in quantities sufficient to yield approximately 2 g of material. The mixtures were melted, and those systems that exhibited solvent miscibility and stability were allowed to cool at room temperature for 2 h. These were refrigerated for 24 h at 4 °C to ensure complete solidification and then brought to room temperature. Samples that appeared "wet" were deleted from the study. Core samples of approximately 5 mg were taken from the remaining solids and analyzed with a DuPont Instruments model 910 differential scanning calorimeter using closed sample pans and a heating rate of 10 °C/min. Solvent combinations that exhibited a single, well-defined eutectic melt between 35 and 75 °C were considered further.

2. Eutectic Composition—The eutectic compositions were estimated using the van't Hoff equation

Table 1—Compounds Used in This Study

compds used as solvents	T_m (°C)	compds used as solvents	T_m (°C)
coumarin	69	chlorobutanol (hemihydrate)	78
imidazole	90	chlorobutanol (anhydrous)[a]	97
2-amino-4-picolene	100	vanillin	82
2-aminopyridine	58	ethyl vanillin	77
salicylamide	140	ethyl paraben	116
tiglic acid	64	2-furoic acid	133
2-amino-5-nitrothiazole	187	other compounds	
menthol	35	anthracene	219
dimethyl sulfone	109	caffeine	238
camphene	51	fluasterone	175
thymol	52	progesterone	130
urea	133	coronene	438
salicylic acid	158	phenytoin	297
camphor	180	1,1-dicyano-3-nitrobenzyl-1-propene	161

[a] Prepared by dehydration of chlorobutanol hemihydrate.

$$\ln X_A = \frac{\Delta_{fus}H_A}{R}\left(\frac{1}{T_m} - \frac{1}{T_{eut}}\right) \quad (1)$$

with the molar heat of fusion, $\Delta_{fus}H_A$, determined by differential scanning calorimetry (DSC). In eq 1, X_A represents the mole fraction of component A, T_m is the melting point of pure component A, and T_{eut} is the eutectic melting temperature. Once the calculated mole fractions were determined (with $X_B = 1 - X_A$), solvent ratios slightly above and below the estimated value were prepared and a closer approximation of the eutectic composition was made experimentally using DSC. The eutectic composition was obtained as the mole ratio that produced a single melting endotherm. Hot stage microscopy was used to confirm the DSC results.

3. Sublimation Rates—Samples of the eutectics weighing ~50 mg were sublimed at 10 °C below their eutectic melting points at ~0.3 mmHg pressure. Evaporation rates were measured using a DuPont Instruments model 951 thermogravimetric analyzer. Two evaporation rates were observed in most cases. The greater first rate is due to the sublimation of both solvents. The second rate is due to the sublimation of the less volatile component after the more volatile solvent has been removed. The results for the most readily sublimed solvent combinations are given in Table 2.

4. Solubilizing Ability—To test the ability of the binary systems to solubilize both semipolar and nonpolar compounds, 20 mg of anthracene, caffeine, coronene, phenytoin, progesterone, and urea were added separately to 1 mL volumes of the eutectic melts at temperatures within 5 °C above their respective melting temperatures. All of the solvent systems were able to solubilize this quantity of the solutes. Solubility parameters were also calculated for the eutectic melts using the method of Adjel et al.[4] for combined solvent systems with group contribution values of cohesive energy density and molar volume from Fedors.[5] The solubility parameters shown in Table 3 are in the range of most drugs, which suggests that the melts are good solvents for drugs.

5. Premier Eutectic for Freeze-Drying—The chlorobutanol hemihydrate–dimethyl sulfone ($DMSO_2$) eutectic was found to be the most suitable media for freeze-drying on the basis of nontoxicity, solubilizing ability, and rate of solvent removal. As shown in Table 2, the eutectic is formed at a mole ratio of 60% chlorobutanol hemihydrate and 40% dimethyl sulfone, and it has a melting temperature of 50 °C. Figure 1 shows a phase diagram constructed from DSC analysis of several solvent ratios.

6. Freeze-Drying—The five compounds shown in Figure 2, progesterone, coronene, Fluasterone, phenytoin, and 1,1-dicyano-3-nitrobenzyl-1-propene, were lyophilized from the chlorobutanol hemihydrate–$DMSO_2$ eutectic. Samples were prepared in 10 mL freeze-drying vials with orifices of ~2 cm^2 by dissolving 30 mg of solute in 5 g of the eutectic melt at 60 °C. These were allowed to solidify for 2 h at 25 °C. The samples were then placed in a large Erlenmeyer flask that was connected to a vacuum pump. The base of the flask was submerged in a water bath that was heated by a hot plate. The solvents were sublimed at approximately 0.3 mmHg pressure using two drying stages:

stage 1: 40 °C, 6.5 h (−450 mg/cm^2-h: primarily chlorobutanol hemihydrate)

stage 2: 60 °C, 6.5 h (−150 mg/cm^2-h: $DMSO_2$)

The stage times were roughly equal in this study because both the mass and evaporation rate ratios are 3:1. However, the evaporation rate ratio is likely to vary with the temperatures and pressures used.

7. Freeze-Dried Product Analysis—*Residual Solvent*—Thermogravimetric (TG) analysis was used to measure the amount of residual solvent remaining in the cakes. Samples of ~10 mg were placed under vacuum and heated at a rate of 10 °C/min. The TG scans of the cakes and the solvents are shown in Figure 3. The analysis indicates that the cakes contain less than 1% residual solvent. The profiles for pure chlorobutanol–hemihydrate (-×-) and pure $DMSO_2$ (-+-) in Figure 3 indicate the temperatures at which weight loss due to residual solvent would be expected.

Solute Stability—The investigational compound 1,1-dicyano-3-nitrobenzyl-1-propene has a half-life in water of approximately 20 min, which precludes its freeze-drying by conventional methods. High-performance liquid chromatography was used to analyze the product immediately following lyophilization from the eutectic and after 15 months of storage at room temperature. Assays were performed using a Beckman System Gold HPLC with a Pinnacle ODS amine column (5 μm, 250 mm × 4.6 mm i.d., Restek, Bellefonte, PA) and a mobile phase consisting of 500 parts water, 500 parts acetonitrile, and 3 parts acetic acid at a pH of 3.45. A Beckman model 110A pump was used to maintain a flow rate of 1.0 mL/min. Ultraviolet detection was made using a Kratos Analytical Spectroflow model 757 detector at a wavelength of 300 nm. Quantification of drug in the effluent was made using a Hewlett-Packard model 3394 integrator. The relative retention times of 1,1-dicyano-3-nitrobenzyl-1-propene and its major degradation product are 3.4 and 2.8 min, respectively. No

Table 2—Compositions, Melting Temperatures, and Relative Evaporation Rates (at 10 °C below the Melting Temperatures) of the Eutectics

	solvents			sublimation rate[a] × 10^{-3}

chlorobutanol (hemihydrate)	dimethyl sulfone	10.0

degradation was detected in the freeze-dried cake immediately after lyophilization or after 15 months of storage at room temperature.

Cake Structure and Particle Size—Figure 4a,b contains photomicrographs of the freeze-dried cakes of phenytoin and coronene, respectively, that were taken using a SPOT camera and a Leica DMLP polarizing microscope. The fiberlike structures in the phenytoin cake are loose aggregates of crystals that are approximately 1−2 μm long. The coronene cake is composed of bundles of roughly 5−10 crystals. The coronene crystals are the largest in the test set, having an average length of approximately 50 μm. The cakes of the other three compounds are similar in overall appearance and contain particles that range from 5 to 15 μm.

Reconstitution—The phenytoin cake was reconstituted using Millipore water adjusted to pH 12. Dissolution was complete with a single shake of the vial. With the exception of coronene, the other compounds were reconstituted using ethanolic solutions in which they were soluble. The progesterone cake was reconstituted using 8 mL of a 60% ethanol, 10% dimethylacetamide, and 30% water solution. The 1,1-dicyano-3-nitrobenzyl-1-propene and Fluasterone cakes were reconstituted using 8 mL of a nonaqueous 50% ethanol and 50% poly(ethylene glycol) 400 solution due to their low water solubilities, which are on the order of 1 μg/mL. For hydrophobic drugs such as these, the composition of the vehicles that are used for reconstitution, whether aqueous solutions or cosolvent concentrates, will depend on the solubilities of the drugs.

In all of the above cases, dissolution of the cakes was complete with 1−2 s of shaking. Note that coronene, which is not a therapeutic agent, was not soluble in pharmaceutical cosolvents.

Discussion

Solid organic solvents were successfully used to lyophilize hydrophobic and water-sensitive compounds. Because the solvents used for the freeze-drying medium were solids at room temperature, the process could be conducted without refrigeration and without conventional freeze-drying equipment. This also facilitated solvent collection, which was accomplished without using a cooled condenser.

A eutectic comprised of two solvents was used in order to achieve good solubilization of drugs in a medium with a moderate melting temperature. The latter property is required because drugs must be dissolved in a medium above its melting temperature and drug stability is compromised if that temperature is high. Since a eutectic is composed of two pure solid phases, these solvents are removed relatively independently of one another according to their vapor pressures. Consequently, two drying stages were used: one at 40 °C to remove (primarily) the more volatile chlorobutanol−hemihydrate and one at 60 °C to remove the $DMSO_2$. Note that these stages do not cor-

respond to the drying stages used for ice in which the first removes frozen water and the second removes bound water.

Thermogravimetric analysis showed that the freeze-dried products did not contain significant amounts of residual solvent. This indicates that the 60 °C used to sublime the bulk $DMSO_2$ was sufficient to remove bound solvent. However, 60 °C is a relatively high temperature compared to what is normally used in freeze-drying, and care must be taken to avoid drug loss. It may be necessary to use lower temperatures and longer drying times when freeze-drying volatile compounds.

One of the major concerns in this study was that the structure of the eutectic should not be significantly altered by the presence of solute. The eutectic contains ~3.6% water that is believed to exist primarily in the form of chlorobutanol−hemihydrate crystals. If a dissolved drug caused the anhydrous form of chlorobutanol to crystallize on cooling, it could lead to incomplete freezing or variable solvent sublimation rates. Analysis of a eutectic containing 5% phenytoin indicated that the eutectic structure is largely unaffected by the presence of this solute. Figure 5a,b shows the DSC traces of the eutectic and the eutectic with 5% phenytoin, respectively. The similarity of the DSC traces suggests that the eutectic microstructures are the same.

The likeness of the photomicrographs of the eutectic and the eutectic with 5% phenytoin in Figure 6a,b, respectively, provides additional evidence for a stable eutectic structure. Hot-stage microscopy indicated that the apparent coarseness in the eutectic with phenytoin is due to presence of drug crystals in the solid. After fusion of the solvents at 50 °C, small, needlelike phenytoin crystals remain in the melt. These dissolved by 70 °C on heating the melt at a rate of 10 °C/min.

Evidence that a hydrated form of chlorobutanol exists in the eutectic is provided by the different thermal properties of the solid formed from the anhydrous chlorobutanol−$DMSO_2$ mixture at a 60:40 mole ratio. DSC and hot-stage microscopic analysis of the anhydrous chlorobutanol−$DMSO_2$ solid indicate a fusion event at 35 °C that is not exhibited by the solid formed from the hemihydrate. However, when 3.6% water is added to the anhydrous melt, the solid that is produced on cooling exhibits the same thermal properties as the solid prepared from the hemihydrate, i.e., a melting point of 50 °C without a 35 °C transition. Physically, the anhydrous solid is much softer than the hydrous form. The former also appears translucent, whereas the hydrous form (the eutectic) is a white

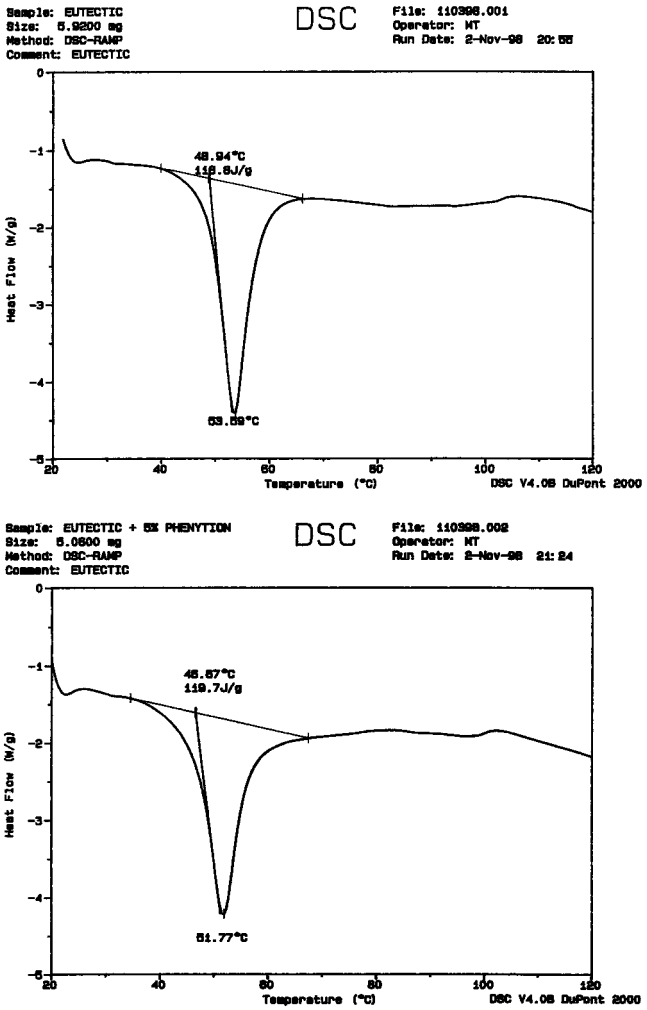

Figure 5—(a) DSC scan of the eutectic. (b) DSC scan of the eutectic + 5% phenytoin.

solid. Both properties may be due to the anhydrous form being incompletely frozen at room temperature. The physical properties of the hydrous eutectic also return with the addition of water to the anhydrous melt.

Thermogravimetric analysis indicated that the cakes produced in this study contained less than 1% residual solvent. Although human toxicity data are scarce, the available data suggest that trace amounts of the solvents which may remain in the freeze-dried products are well below harmful levels. Borody[6] found that plasma concentrations of chlorobutanol as high as 100 μg/mL produced sluggishness and slowed speech, but did not produce liver disease or abnormal electrolyte levels. Others have reported adverse reactions to high doses such as cardiovascular effects following the intravenous administration of heparin preserved with chlorobutanol, neurological effects following the administration of large doses of morphine with the preservative, and hypersensitivity reactions.[2] However, chlorobutanol is currently used in the U.S. as a parenteral preservative in concentrations of up to 0.5% in injectable (e.g., methadone, epinephrine, oxytocin, thiamine), opthalmic (e.g., pilocarpine, epinephrine, phospholine iodide), otic (e.g., Cresylate, Cerumenex), and cosmetic products. It is also the active ingredient in a nonprescription sleep aid (Seducaps: chlorobutanol 150 mg, salicylamide 300 mg) that is available in several countries outside of the United States.[2,7] The lethal dose of chlorobutanol is estimated to be 500 mg/kg[2].

Dimethyl sulfone is an oxidation product of dimethyl sulfoxide (DMSO) and is its major metabolite in all species

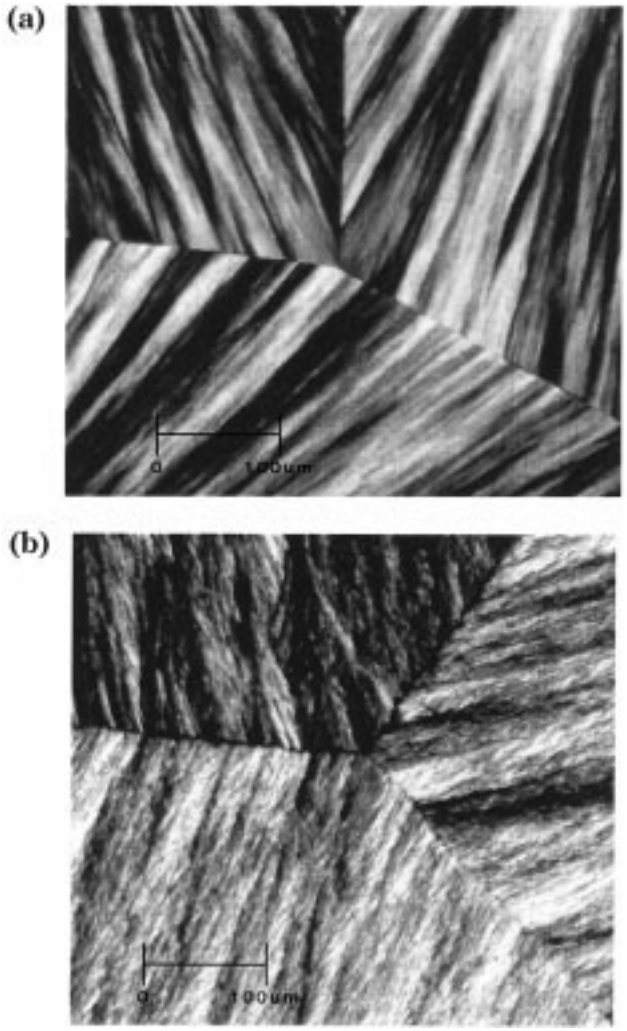

Figure 6—(a) Eutectic viewed with polarized light after crystallization between a glass slide and coverslip. (b) Eutectic with 5% phenytoin.

studied.[8] $DMSO_2$ was first identified as a natural constituent of biological systems in 1934 when Pfiffner and Vars isolated it from beef adrenals.[9] It was later isolated from beef blood and milk, and it has been indicated that human intake from these sources may be as high as a few milligrams daily.[8] The latter figure is consistent with Williams et al.'s finding of 4−11 mg of $DMSO_2$ in 24-h samples of human urine[10] and a reported circulating blood concentration of 0.2−0.5 ppm in the adult male.[11]

$DMSO_2$ has recently been tested for efficacy in the treatment of interstitial cystitis[11] without findings of any adverse effects. Bertken[8] also reported that a man who ingested approximately 4 g of $DMSO_2$ daily for 3 months suffered no ill effects. The only (related) report of toxicity that was found in the literature, other than the detrimental effects of $DMSO_2$ on nematode gamete production,[12] implicated dimethyl sulfate ($DMSO_4$) in a 1994 death.[13] However, as indicated by the authors of that paper, there is no established precedent for the direct conversion of $DMSO_2$ to $DMSO_4$.

Conclusion

The chlorobutanol hemihydrate−dimethyl sulfone ($DMSO_2$) eutectic was determined to be a suitable medium for lyophilizing drugs that are poorly water soluble and/or highly water sensitive. The eutectic is formed at a 60:40 mole ratio (75:25 weight ratio) and has a melting point of

50 °C. Lyophilization can be accomplished without refrigeration, and thus, without conventional freeze-drying equipment, because the melting point is above room temperature. The solvents are rapidly and thoroughly removed under vacuum with moderate heating. Two drying stages were used in the current study, both at a pressure of 0.3 mmHg. The first stage was at 40 °C to primarily remove the chlorobutanol hemihydrate, and the second was at 60 °C to remove the bulk of the $DMSO_2$. Each drying stage required approximately 6.5 h using standard 10 mL freeze-drying vials and solvent volumes of ~5 mL. The cakes produced from the eutectic contain <1% residual solvent and are rapidly reconstituted. Trace amounts of residual solvent are below harmful levels.

Abstract □ Because the ionized species is more polar than its un-ionized counterpart, it is often assumed that the ionized species of the drug does not make a meaningful contribution to solubilization by either cosolvents or surfactants. This report extends previous studies on solubilization of the ionic species by a combination of pH control and complexation to pH control and micellization and to pH control and cosolvency. The total aqueous solubility is expressed as the addition of the concentration of all contributing species: free un-ionized drug [D_u], free ionized drug [D_i], un-ionized drug micelle [D_uM], and ionized drug micelle [D_iM] for surfactant, and free un-ionized drug [D^c_u] and free ionized drug [D^c_i] for cosolvent. The equations indicate that under certain conditions the ionized species can be more important in determining the drug total solubility than the un-ionized species. Flavopiridol, a weak base, is used to test these newly generated equations. As expected, the micellar partition coefficient and solubilization power for ionized flavopiridol are both less than those of the un-ionized species. However, at acidic pH, the solubilities of the ionized drug in surfactant micelles [D_iM] and in cosolvent–water [D^c_i] are both much greater than that of the un-ionized drug. This difference is because the solubilization of the ionized drug is proportional to its aqueous solubility, and its solubility [D_i] can be as much as 24-fold greater than that of the free un-ionized species [D_u].

Introduction

The control of pH with either a cosolvent, a surfactant, or a complexant is often used to improve the aqueous solubility of drugs.[1] It is commonly believed that the un-ionized species makes the major contribution to the improvement of the total aqueous drug solubility.[2] In a recent study we found that a change of pH favoring ionization of the drug significantly increased not only the solubility of the drug in water but also the amount of the drug solubilized by the complexant.[3] In fact, the ionized species were shown to be solubilized to a greater extent than the un-ionized species.[3−6]

In this report, we extend our studies on the role of the ionized species in improving aqueous solubility to pH control combined with either cosolvency or micellization. The newly developed equations are verified using flavopiridol [5,7-dihydroxy-8-(4-*N*-methyl-2-hydroxy-pyridyl)-6′-choloroflavone hydrochloride], a derivative of rohitukine that has been developed for the treatment of breast cancer, as a model drug. The drug is weakly basic with an apparent pK_a of 5.68 and a low intrinsic solubility of 0.025 mg/mL for its zwitterionic form.[7]

Background

Solubilization by Surfactant—A surfactant or surface-active agent has two distinct regions: one polar and one nonpolar. When it is added to aqueous media, the surfactant molecules orient themselves to form micellar aggregates, provided their concentration exceeds the critical micellar concentration (cmc).[1] Because the interiors of these micelles are much less polar than water, they can more effectively dissolve the nonpolar drug molecules. As a result, the apparent aqueous solubility is increased.

For a given surfactant solution there is an equilibrium among four species: un-ionized drug [D_u], ionized drug [D_i], un-ionized drug in the micelle [D_uM], and ionized drug in the micelle [D_iM]. The total concentration of the drug [D^{tot}] is

$$[D^{tot}] = [D_u] + [D_i] + [D_uM] + [D_iM] \quad (1)$$

For a basic drug, the concentrations of the ionized drug and the un-ionized drug are related by the Henderson−Hasselbalch equation

$$[D_i] = [D_u]10^{(pK_a - pH)} \quad (2)$$

The value of [D_uM] is related to the micellar partition coefficient for the un-ionized species κ_u and the micellar concentration [C_m] by[1]

$$[D_uM] = \kappa_u[D_u][C_m] \quad (3)$$

Note that [C_m] is equal to the total surfactant concentration when the cmc is small enough to be ignored. Similarly, the value of [D_iM] is related to the micellar partition coefficient for the ionized species κ_i by

$$[D_iM] = \kappa_i[D_i][C_m] \quad (4)$$

Therefore eq 1 can be expanded to

$$[D^{tot}] = [D_u] + [D_u]10^{(pK_a - pH)} + \kappa_u[D_u][C_m] + \kappa_i[D_u]10^{(pK_a - pH)}[C_m] \quad (5)$$

Equation 5 indicates that the total drug aqueous solubility is a function of [D_u], pK_a, κ_u, κ_i, [C_m], and solution pH. The ionized species will be solubilized to a greater extent than the un-ionized species (i.e., [D_iM] > [D_uM]) if $\kappa_i[D_i] > \kappa_u[D_u]$. This condition will be met if $\kappa_i 10^{(pK_a - pH)} > \kappa_u$ (i.e., if pK_a − pH > log κ_u − log κ_i). This equation is similar to a previously developed equation that describes solubilization by pH control and complexation.[3]

Solubilization by Cosolvent—Unlike surfactants, cosolvents form homogeneous solutions with water. These solutions act as new solvents that have polarities between

10.1021/js980433o CCC: $18.00 Published on Web 04/02/1999

that of water and the pure cosolvents. In any cosolvent–water mixture, the concentrations of the un-ionized species $[D^c_u]$ and the ionized species $[D^c_i]$ are in equilibrium as described by eq 2. The total solubility in the mixed solvent $[D^{tot}]$ is

$$[D^{tot}] = [D^c_u] + [D^c_i] \quad (6)$$

The value of $[D^c_u]$ is related to the volume fraction of cosolvent f in the mixture and the solubilizing power for the un-ionized drug σ_u by[1,2]

$$[D^c_u] = [D_u]10^{\sigma_u f} \quad (7)$$

Similarly, the value of $[D^c_i]$ is related to the solubilizing power for the ionized drug σ_i by

$$[D^c_i] = [D_i]10^{\sigma_i f} \quad (8)$$

Equation 8 can be expressed as

$$[D^c_i] = [D_u]10^{(pK_a - pH)}10^{\sigma_i f} \quad (9)$$

Substituting eqs 7 and 9 into eq 6 gives

$$[D^{tot}] = [D_u]10^{\sigma_u f} + [D_u]10^{(pK_a - pH)}10^{\sigma_i f} \quad (10)$$

The total drug solubility in a mixed solvent can therefore be described in terms of $[D_u]$, σ_u, σ_i, pK_a, f, and solution pH. In general, the solubilizing power of the cosolvent for the ionized species (σ_i) is smaller than that of the un-ionized species (σ_u). As a result, the un-ionized species is often assumed to be primarily responsible for the improvement of the total drug solubility. However, eq 10 indicates that the solubilization of the ionized species can be more important than that of the un-ionized species in determining the total drug solubility. In fact, the concentration of the ionized species will exceed that of the un-ionized species if the difference between the pK_a of the drug and the solution pH is greater than the difference between the solubilization powers of the cosolvent for the un-ionized species and that of the cosolvent for the ionized species (i.e., $pK_a - pH > \sigma_u - \sigma_i$).

In this report, the effect of the ionized species on the total drug solubility by either micellization or cosolvency (as predicted by eqs 5 and 10, respectively) is confirmed using a weakly basic drug, flavopiridol.

Materials and Methods

Materials—Flavopiridol was provided by the National Cancer Institute and used as received. All other chemicals were reagent grade and purchased from Sigma (St. Louis, MO) or Aldrich (St. Louis, MO) and used without further purification. Citrate-phosphate buffers were prepared according to Scientific Tables.[8] Samples for the solubilization studies were prepared in a series of either polysorbate 20 or ethanol solutions at concentrations of 0, 1.25, 2.5, 5, 10, and 20% in citrate-phosphate buffers at pH 4.3, 5.0, and 8.4.

Methods—*Solubility Determination*—An excess amount of flavopiridol was added to vials containing 0.5 mL of an aqueous solution of either polysorbate 20 or ethanol. The sample vials were then rotated at 20 rpm using an end-over-end mechanical rotator (Glas-Col Laboratory Rotator, Terre Haute, IN) at 25 °C for 6 days. Samples with drug crystals present were considered to have reached their equilibrium solubility and were removed from the rotator. The samples were filtered through a 0.45-μm filter and the pH at equilibrium was measured before performing the HPLC analysis.

HPLC Analysis—The HPLC assay used an EPS C18 column (100 cm × 4.6 mm, Alltech, Deerfield, IL) with a mobile phase composed of acetonitrile and 50 mM phosphate buffer at pH 3.0 (ratio, 35:65). The flow rate was controlled at 1 mL/min (125 Solvent Module, Beckman), and the effluent was detected at 263 nm (168 detector, Beckman). All experimental data are the average of duplicate values, with a relative standard deviation of <3%.

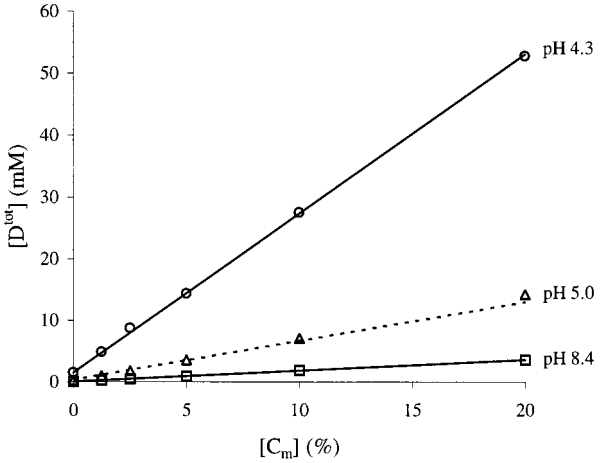

Figure 1—Experimentally determined total aqueous flavopiridol solubilities $[D^{tot}]$ (symbols) in polysorbate 20 solutions $[C_m]$ at different pHs.

Table 1—Results Determined with Equations 2, 3, and 4

pH	total $[D^{tot}]$	free un-ionized $[D_u]$	micelled un-ionized $[D_uM]$	free ionized $[D_i]$	micelled ionized $[D_iM]$
8.4	1.85	0.06	1.79	0.00	0.00
5.0	6.92	0.06	1.79	0.29	4.78
4.3	27.3	0.06	1.79	1.44	24.0

Results and Discussions

Solubilization by Surfactant—In Figure 1, the experimental total aqueous solubility is plotted against the concentration of polysorbate 20 at pH 4.3 (open circles) and pH 8.4 (open squares). Although linearity between the drug aqueous solubility and the surfactant concentration is observed at both pHs, the solubilization slopes are quite different. The solubilization slope at pH 4.3 is ≈15-fold higher than the slope at pH 8.4.

These solubilization slopes can be used to calculate polysorbate 20 micellar partition coefficients for un-ionized and ionized flavopiridol via eq 5. The calculated values are $\kappa_u = 333.3\ M^{-1}$ and $\kappa_i = 185.4\ M^{-1}$, respectively. The lower micellar partition coefficient for the ionized drug is obviously due to its greater affinity for water.

With $[D_u]$, pK_a, κ_u, and κ_i, we can calculate $[D_i]$, $[D_uM]$, and $[D_iM]$ at any given combination of surfactant concentration and solution pH by using eqs 2, 3, and 4, respectively. Table 1 lists these values and the experimental total drug solubility for a 10% surfactant concentration at pH 8.4, 5.0, and 4.3. The highest total drug solubility is achieved at pH 4.3 where most of the drug is ionized. At this pH $[D_i]$ accounts for 5% of total solubility and $[D_iM]$ accounts for ≈88%. The high concentration of the $[D_iM]$ is primarily responsible for the higher total solubility in the acidic solution than in the neutral solution. Note that $[D_uM]$ remains constant at all pH conditions because it is only determined by $[D_u]$ and κ_u, both of which are pH independent.

Solubilization by Cosolvent—Figure 2a shows the experimental aqueous solubility of flavopiridol versus the concentration of ethanol at pH 4.3 (open circles) and pH 8.4 (open squares). Unlike the linear surfactant solubilization curves, the drug solubility increases exponentially

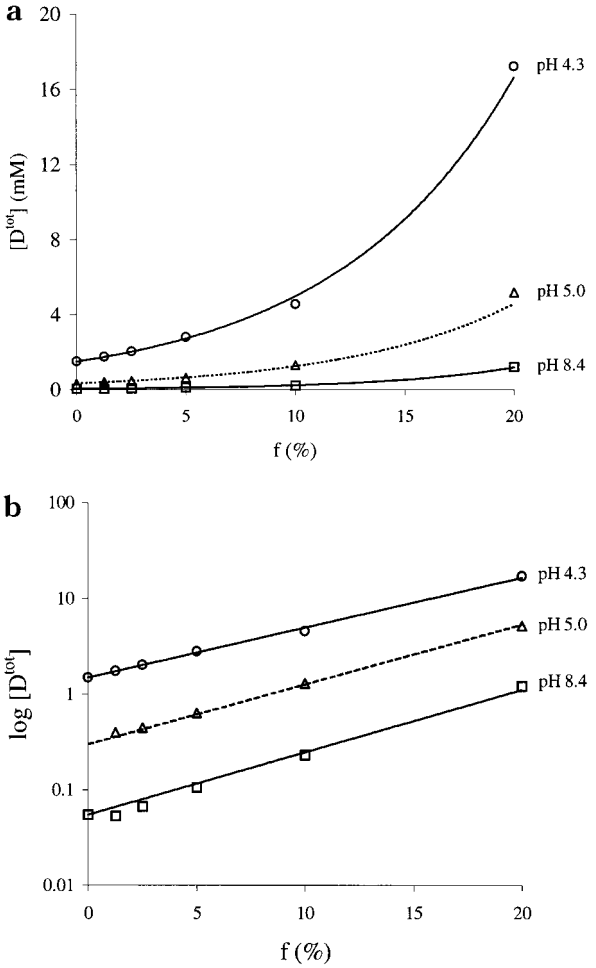

Figure 2—(a) Experimentally determined total aqueous flavopiridol solubilities [D^{tot}] (symbols) in ethanol solutions [*f*] at different pHs. (b) Schematic plot of the semilogarithmical total aqueous solubility of flavopiridol log[D^{tot}] against ethanol volume fraction *f*.

Table 2—Results Determined with Equations 7 and 9

pH	total [D^{tot}]	un-ionized [D^c_u]	ionized [D^c_i]
8.4	0.25	0.25	0.00
5.0	1.19	0.25	0.94
4.2	4.98	0.25	4.73

as the cosolvent concentration increases. Again, the solubilization curves are different at different solution pHs. The drug solubilities in both water and 10% ethanol solution at pH 4.3 are ≈20-fold greater than that at pH 8.4.

Figure 2a can be re-plotted semilogarithmically, as is seen in Figure 2b, where nearly parallel linear relationships between log[D^{tot}] and cosolvent volume fraction are evident at both pHs. This linearity persists up to 20% cosolvent. The slopes at pH 4.3 and 8.4 show that σ_u and σ_i are quite similar, with values of 0.06 and 0.05% $^{-1}$, respectively.

Table 2 lists the experimental total drug solubility [D^{tot}] in 10% cosolvent and the values of [D^c_u] and [D^c_i] calculated with eqs 7 and 9. As in surfactant solubilization, the total drug solubility in cosolvent is much higher at pH 4.3 than that at pH 8.4. Although the solubility of flavopiridol increases by nearly the same factor at both pH values, the amount of drug solubilized is much greater at the lower pH. This difference occurs because the concentration of ionized drug [D^c_i] far exceeds the concentration of the un-ionized drug [D^c_u] in the solution at pH 4.3. It is also noted that the value of [D^c_u] is pH independent.

Validation of Equations—The solubilities (dotted lines), calculated with eq 5 for polysorbate 20 solution and with eq 10 for ethanol solution, are compared with the experimental solubility data (open triangles) at pH 5.0 in Figures 1 and 2, respectively. The strong agreement between the predicted and the observed solubility data supports the validity of both eq 5 and eq 10.

Conclusion

A pH change that favors the ionization of the drug not only increases the solubility of the ionized species in water, but also increases the solubility of the ionized species in both micelles and cosolvent. This result is independent of the values of the micellar partition coefficient and the solubilization power. Furthermore, the solubilities of the ionized species in the micelles and cosolvent can exceed those of the un-ionized species.

For micellization:

$$[D_iM] > [D_uM], \text{ if } (pK_a - pH) > (\log \kappa_u - \log \kappa_i)$$

For cosolvency:

$$[D^c_i] > [D^c_u], \text{ if } (pK_a - pH) > (\sigma_u - \sigma_i)$$

Note that these relationships are similar to the following relationship, which was previously derived for complexation

$$[D_iL] > [D_uL], \text{ if } (pK_a - pH) > (\log K_u - \log K_i)$$

where K_u and K_i are complexation constants for the un-ionized and ionized solutes, respectively, and [D_uL] and [D_iL] are the concentrations of the corresponding complexes.

Abstract □ The aim of this study was to construct a novel drug delivery system suitable for controlled release of antibiotics. There is a need for devices that release antibiotics only during microbial infection, because prophylactic or prolonged use of antibiotics leads to serious problems, such as renal and liver toxicity and the emergence of drug-resistant bacteria (e.g., meticillin-resistant *Staphylococcus aureus*). We found previously that *Staphylococcus aureus*-infected wound fluid showed high thrombin-like activity; therefore, in this study we designed an antibiotic release system triggered by thrombin activity. We synthesized an insoluble polymer–drug conjugate in which gentamicin was bound to poly(vinyl alcohol) hydrogel through a newly developed thrombin-sensitive peptide linker. The conjugate released gentamicin when it was incubated with *Staphylococcus aureus*-infected wound fluid, with thrombin and leucine aminopeptidase, or with human plasma and Ca^{2+}, whereas no biologically active gentamicin was released when the conjugate was incubated with noninfected wound fluid, with leucine aminopeptidase alone, with thrombin alone, or with plasma. Furthermore, the conjugate reduced the bacterial number in an animal model of *Staphylococcus aureus* infection. These results demonstrated that the conjugate has sufficient specificity and excellent potential as a stimulus-responsive, controlled drug release system.

Introduction

Improper usage of antibiotics is very serious because of the appearance of renal and liver toxicity and the emergence of drug-resistant bacteria (e.g., meticillin-resistant *Staphylococcus aureus*).[1−4] In the ideal case, the proper amount of antibiotics is used at the site and during the period of the infection. For this purpose, many kinds of drug delivery systems have been investigated, including several antibiotic-impregnated polymer systems;[5−11] however, these systems are not appropriate for controlled release of antibiotics. Therefore, a system that detects the occurrence of bacterial infection and releases the proper amount of antibiotics relative to the degree of infection is needed. In this study, we constructed a system in which antibiotics are bound to an insoluble polymer matrix through a linker that acts as an infection sensor.

First, we investigated biological signals, such as enzyme activities, which appeared in infected wound fluid and found a remarkable increase of thrombin-like activity in *Staphylococcus aureus* (SA)-infected wounds.[12] This enzyme activity was thought to be mainly attributed to staphylocoagulase produced by SA, which forms an enzymatically active complex with prothrombin named staphylothrombin.[13] Second, we developed a novel peptide linker, Gly-(D)-Phe-Pro-Arg-Gly-Phe-Pro-Ala-Gly-Gly, which could connect insoluble polymer matrix and drug, and was specifically cleaved by thrombin.[14] The ideal insoluble polymer matrix should be biocompatible, noninflammative, and nontoxic, and should have good mechanical properties. A new hydrogel made of a poly(vinyl alcohol) derivative was synthesized in this study. Introduction of carboxyl groups to partially saponified polyvinyl pivalate gave a transparent, soft, and high-water-content hydrogel that is cross-linked by hydrophobic bonds between tertiary butyl groups in pivalate.[15]

Our preliminary study revealed that gentamicin was selectively released from the device when it was incubated with infected wound fluid and that the device showed bacteriocidal effect in vitro.[12] In this report, we describe the synthesis of the device combining these components to attain a suitable polymer−drug conjugate system, and the specificity of drug release properties in vitro and bacteriocidal effect in vivo. The results showed that the device is sufficiently potent and specific for treating SA-infected wounds.

Methods

Materials—Gentamicin sulfate, thrombin (human plasma, EC 3.4.21.5), and leucine aminopeptidase (cytosol, Type V: Porcine kidney, EC 3.4.11.1) were purchased from Sigma Chemical Company, St. Louis, MO. Fluorogenic peptide substrates, WSCD (1-ethyl-3-(3-dimethyl-aminopropyl)-carbodiimide hydrochloride), and HOSu (*N*-hydroxysuccinimide) were from Peptide Institute Inc., Minoh, Osaka, Japan. Other reagents were from Wako Pure Chemicals, Doshomachi, Osaka, Japan. Peptide linker (Gly-(D)-Phe-Pro-Arg-Gly-Phe-Pro-Ala-Gly-Gly) was synthesized by Peptide Institute Inc.; purity: 95.0%, as determined by reversed-phase HPLC [column: YMC PACK ODS-A (4.6 mm i. d. × 150 mm) + (4.0 mm i. d. × 10 mm); eluent: 10− 60% acetonitrile gradient (25 min) in 0.1% trifluoroacetic acid−water, flow rate: 1 mL/min, detection: 220 nm OD). Amino acids analyzed (calcd): Arg 1.00 (1), Pro 1.99 (2), Gly 4.01 (4), Ala 1.01 (1), Phe 1.99 (2). Mass analysis: 962.8 $[M + H]^+$ (calcd for $[M + H]$: 962.5).

Synthesis of PVA−Linker−Gentamicin (Scheme 1)—*Polyvinyl Pivalate* (***1***)—Freshly distilled vinyl pivalate (200 g, 1.56 mol) was dissolved in 70 g of methanol in a reaction vessel, and purged with nitrogen gas with stirring. The mixture was heated to 60 °C, and 2, 2′-azobis(isobutylonitrile) (0.04 g, 0.24 mmol) in 5 g of methanol was added to start the polymerization. When the polymerization ratio reached 40%, about 5 h after starting of the polymerization, the reaction mixture was cooled to 20 °C. Several volumes of *tert*-butyl alcohol were added to the reaction mixture, and residual vinyl pivalate was distilled off under reduced pressure. Then several volumes of tetrahydrofuran were added and *tert*-butyl alcohol was distilled off under reduced pressure. Finally the solution of polyvinyl vivalate in tetrahydrofuran (concentration: 45.7 wt %) was obtained. Yield: 78 g (39%).

*Partially Saponified Poly(vinyl alcohol) (**2**)*—Fifty grams of the solution of polyvinyl vivalate in tetrahydrofuran was heated to 60 °C with stirring in a reaction vessel equipped with a reflux condenser. The vessel was purged with nitrogen gas, and 20 g of a 25% solution of KOH was added. After the reaction mixture was kept at 60 °C for 6 h, it was neutralized by adding 5.5 g of acetic acid and 5.5 g of methanol. The solidified product, partially saponified poly(vinyl alcohol), was washed with methanol using a Soxhlet extractor and dried under reduced pressure. Yield: 10.7 g (46.8%), P = 1650, determined by [η] of the polyvinyl acetate at 30 °C, which was acetylated after full saponification of the partially saponified poly(vinyl alcohol), according to the following equation:

$$P = \{[\eta] \times (1000/7.94)\}^{(1/0.62)} \quad (1)$$

The saponified ratio was 0.811, determined from 500 MHz ^{1}H NMR (d_6-dimethyl sulfoxide): δ (ppm) 1.11 (s, 9H, $C(CH_3)_3$, integration: 89 au), 1.4−1.77 (complex, 2H, CH_2, integration: 106 au).

*Carboxylated Poly(vinyl alcohol) Hydrogel (PVA−COOH) (**3**)*—Ten grams of partially saponified poly(vinyl alcohol) was dissolved in 300 g of dimethyl sulfoxide at 70 °C, followed by the addition of succinic anhydride (1.64 g, 16.4 mmol) and pyridine (0.64 g, 8.1 mmol). After the reaction mixture was kept at 70 °C for 4 h, it was cast in a glass tray, followed by hydration in a humidified chamber. After 1 or 2 days of incubation in a humidified chamber, a sheet of transparent hydrogel (PVA−COOH) was obtained. This hydrogel was thoroughly washed with water to remove the residual reagents. The water content of the hydrogel was 91 wt % and the carboxyl group content was 12 μmol/g-hydrogel (= 1.3×10^{-4} mol/g-dry weight).

*Poly(vinyl alcohol) Hydrogel−Peptide Linker Conjugate (PVA−Linker) (**4**)*—PVA−COOH (10 g, 0.12 mmol carboxyl group) was washed several times with dimethylformamide, and to the resultant dimethylformamide-swollen gel, HOSu (46 mg, 0.4 mmol) and WSCD (81 mg, 0.42 mmol) in 10 mL of dimethylformamide were added, followed by shaking overnight. The gel was washed several times each with dimethylformamide and water, followed by the addition of the peptide linker, Gly-(D)-Phe-Pro-Arg-Gly-Phe-Pro-Ala-Gly-Gly (116 mg, 0.12 mmol), in 10 mL of 20 mM phosphate buffer (pH 7.0). After shaking the reaction mixture overnight, the resultant PVA−linker was washed several times with phosphate buffered saline (PBS, 10 mM phosphate, 150 mM NaCl, pH 7.4) and Gly-HCl buffer (0.1 M, pH 2.5), and then washed several times with 20 mM phosphate buffer (pH 7.0). The yield of this coupling reaction was ~80%, as determined by HPLC analysis of the residual peptide linker in the reaction mixture.

*Poly(vinyl alcohol) Hydrogel−Peptide Linker−Gentamicin Conjugate (PVA−Linker−Gentamicin) (**5**)*—PVA−linker (10 g) was immersed in 10 mL of 20 mM phosphate buffer (pH 7.0), and gentamicin (1.28 g, 1.68 mmol) and WSCD (46 mg, 0.24 mmol) were added, followed by overnight shaking. The resultant product, PVA−linker−gentamicin, was thoroughly washed with phosphate buffered saline (PBS) and water until the concentration of total organic carbon of the supernatant decreased below 10 ppm.

Bacterial Culture—*Staphylococcus aureus* (FDA209P, Institute of Fermentation Osaka, Osaka, Japan) was used. This strain was stored in trypticase soy broth with glycerol (20%) at −70 °C. Before the experiments, the strain was grown in Brain-Heart Infusion (BHI) broth overnight at 37 °C on a rotary shaker. The concentration of cells was measured by turbidity at 600 nm, and adjusted to the desired concentration by diluting with PBS.

SA-Infected Wounds—Male Wistar rats weighing 150 to 200 g were acclimatized to laboratory conditions for 7 days prior to use. The animals were fed a standard commercial rat chow ad libitum and housed individually in facilities that complied with the requirements of the Kyoto University Animal Experiment Committee, with controlled temperature (22−23 °C) and light (12 h light/12 h darkness). Each rat was anesthetized with an intraperitoneal injection of sodium pentobarbital (65 mg/kg). The dorsal paravertebral fur was then removed with electric clippers and a depilatory agent. The skin was cleansed with an iodophor solution followed by a 70% alcohol rinse. Air was sucked into a syringe through a sterile cotton filter, and 10 mL of air was injected into the loose subcutaneous tissue between the shoulders of the rat. One day after creation of the air pouch, 3 g of PVA−linker−gentamicin (n = 8) or PVA−COOH (n = 8) was inserted into the pouch with 5 mL of a suspension of 10^5 SA per milliliter in PBS. After 4 h, the bacterial number in the fluid from each pouch was estimated by limiting dilution methods using BHI agar plates.

Sampling of wound fluids was done by almost the same method just described except for the following points. One day after creation of the air pouch, animals were randomly assigned to the infected wound group or the noninfected wound group, and 10 mg of Montmorillonite clay soil fraction, a well-known infection-potentiating factor,[16] was inserted into each air pouch instead of PVA−COOH or PVA−linker−gentamicin as already described. Five days after creation of the infected air pouch, the animals were anesthetized as already described, and the wounds were opened. The pus was removed and the inner surface of the pouch was gently wiped with wet gauze to expose the fresh wound bed. Freeze-dried agarose sponges were inserted into the pouch to absorb the wound fluid, and the incision was closed. After 20 min, the pouch was reopened. The wound fluid contained in the agarose sponges was weighed and the amount of fluid obtained from the pouch during 20 min was calculated. The fluid contained in the agarose sponges was stored at −150 °C until assay. Simultaneously, the wound tissues were removed, weighed, and used to count the bacterial number by limiting dilution methods using BHI agar plates. Then, all the animals were sacrificed with an overdose of pentobarbital.

Assay for Enzymatic Activity of Infected Wound Fluid and Plasma—The wound fluid contained in the agarose sponges was extracted by addition of 9 volumes of PBS and filtered by centrifugation. Plasma was also diluted by addition of 9 volumes of PBS with or without 10 mM Ca^{2+}. Thrombin-like activity and aminopeptidase activity were measured using the fluorogenic peptide substrates (0.2 mM) Boc-Val-Pro-Arg-MCA[17,18] (MCA = 4-methylcoumaryl-7-amide) and Ala-MCA,[19] respectively. Enzymatic activity was calculated from the fraction of each substrate hydrolyzed after incubation for 30 min at 25 °C.

Assay of Gentamicin Release—The wound fluid in the agarose sponges was extracted by addition of two volumes of PBS and filtered by centrifugation. After incubation of 0.05 g of PVA−linker−gentamicin with 250 μL of the wound fluid, Ca^{2+}-supplemented plasma, plasma, or enzyme solution for 24 h at 37 °C, the supernatant was used to measure the concentration of gentamicin by the following two methods.

Width of Zone of Inhibition of SA Growth on BHI Agar Plates—Seventy-five microliters of the supernatant was adsorbed onto a paper disk, the disk was placed on a BHI agar plate inoculated with SA, and the plate was incubated overnight at 37 °C. The concentration of gentamicin was calculated from the width of the zone of inhibition around the disk compared with the widths of zones around standard gentamicin solutions with concentrations from 0 to 30 μg/mL of solution.

2. Fluorescence Polarization Immunoassay (FPIA)—A fully automatic FPIA apparatus (TDX analyzer, DAINABOT, Tokyo, Japan) and the corresponding reagents kit for gentamicin were used.

Statistical Analysis—All statistical evaluations were performed by unpaired t test and analysis of variance (ANOVA). All values were expressed as mean ± standard deviation.

Results

Enzymatic Activity in SA-Infected Wound Fluid—We found significantly elevated thrombin-like activity in SA-infected wound fluid compared with the level in noninfected wound fluid (Table 1). On the other hand, SA-infected wound fluid did not differ from noninfected wound fluid in aminopeptidase activity. Therefore, the thrombin-like activity in wound fluid seemed to be a specific signal of SA-infection. The amount of wound fluid also increased significantly in SA-infected wounds compared with noninfected wounds. The elevated thrombin-like activity in SA-infected wound fluid may be attributable to both α-thrombin and staphylothrombin.[12] Furthermore, high levels of aminopeptidase activity existed in both noninfected and SA-infected wound fluid.

Table 1—Enzymatic Activities and Weight of Exudate From Infected Wounds[a]

variable	digested substrate (nmol/30 min) non-infected ($n = 16$)	SA-infected ($n = 12$)
thrombin-like activity	0.376 ± 0.104	0.518 ± 0.084**
alanine amino peptidase activity	0.938 ± 0.372	1.402 ± 0.206*
amount of exudate (g/wound)	0.190 ± 0.051	0.449 ± 0.116***
bacterial number (CFU/mL)	0	5900***

[a] Key to statistical significance: (*) $p > 0.05$, not significant compared with non-infected control; (**) $p < 0.01$, significant compared with non-infected control; (***) $p < 0.001$, significant compared with non-infected control.

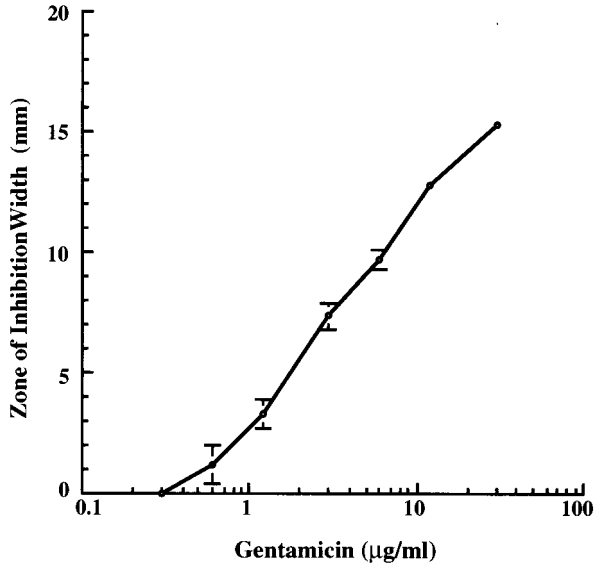

Figure 1—A representative standard curve showing the relationship between the width of the zone of inhibition and concentration of gentamicin. Each value represents mean ± SD of two or three experiments.

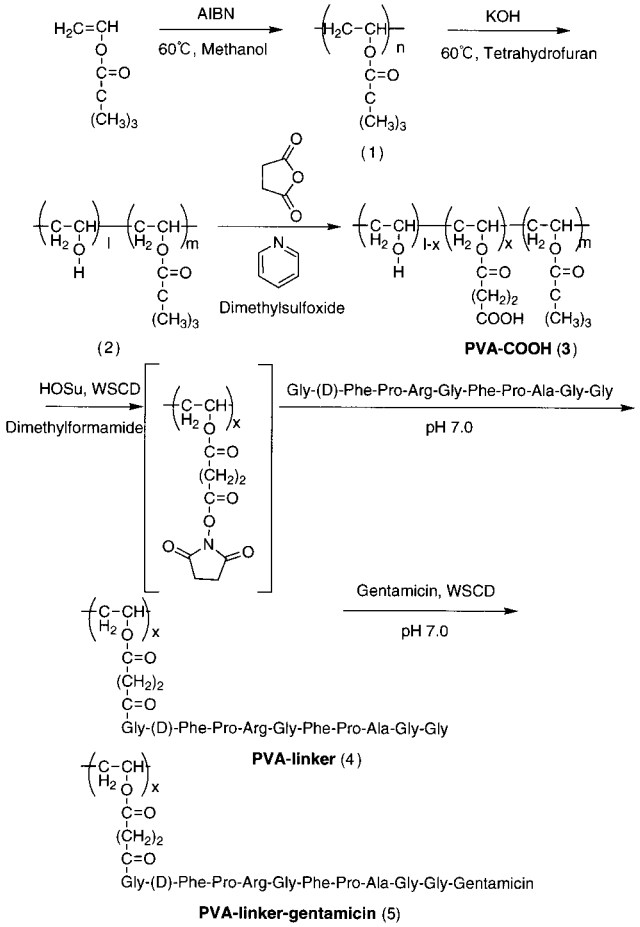
Gentamicin Release from PVA–Linker–Gentamicin—one representative standard curve showing the relationship between the width of the zone of inhibition and gentamicin concentration is shown in Figure 1. Because such curves showed a linear relation in the concentration range from 1 to 30 μg/mL, the concentration of released gentamicin was calculated from the width of the zone of inhibition using the standard curve obtained in each experiment.

As shown in Scheme 2, at least two enzyme activities were needed for gentamicin release from PVA–linker–gentamicin. That is, the Arg–Gly bond in the peptide linker was cleaved, and the resultant Gly-Phe-Pro-Ala-Gly-Gly gentamicin was released and digested by aminopeptidase to produce free gentamicin. Figure 2 shows the dose dependence of gentamicin release on thrombin concentration in the presence of leucine aminopeptidase (LAP). Almost no gentamicin was released without thrombin, as measured by both the zone of inhibition and FPIA methods. The amount of gentamicin released increased with increasing thrombin concentration, and seemed to reach a maximum at a thrombin concentration of 2 U/mL. At concentrations of thrombin >4 U/mL, gentamicin release measured by zone of inhibition decreased. LAP may be deactivated by excess thrombin.

The effects of LAP on gentamicin release in the presence of thrombin at 8 U/mL are shown in Figure 3. Gentamicin release was nearly undetectable in the absence of LAP when measured by the zone of inhibition method; however, a considerable amount of gentamicin released was detected by FPIA. This discrepancy seemed to arise from the difference of the specificity of the two methods. Because Gly-Phe-Pro-Ala-Gly-Gly-gentamicin is not biologically active, it was not detected by the zone inhibition method. In contrast, the anti-gentamicin antibody used in FPIA could bind with Gly-Phe-Pro-Ala-Gly-Gly-gentamicin; therefore, it was detected as gentamicin by FPIA.



Scheme 1—Synthesis of PVA-linker-gentamicin.

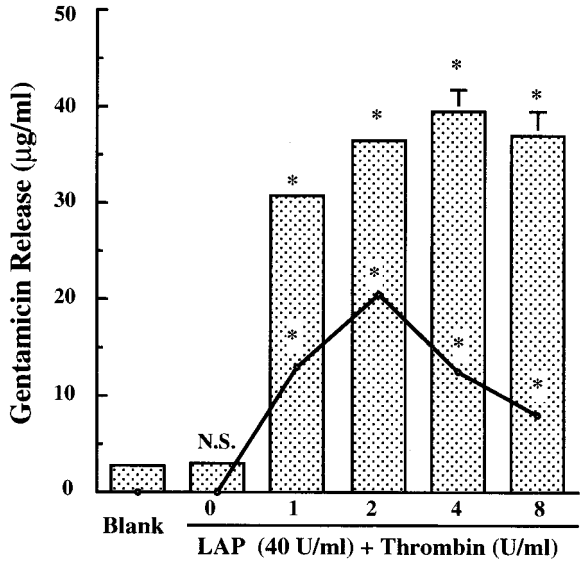


Figure 2—Dose dependence of gentamicin release on thrombin concentration in the presence of LAP: FPIA (bar); zone of inhibition (–○–). Each value represents mean ± SD of triplicate experiments. The data marked with * are significantly high values compared with blank ($p < 0.001$), calculated by ANOVA. N. S. denotes no significant difference compared with blank ($p > 0.05$), calculated by ANOVA.

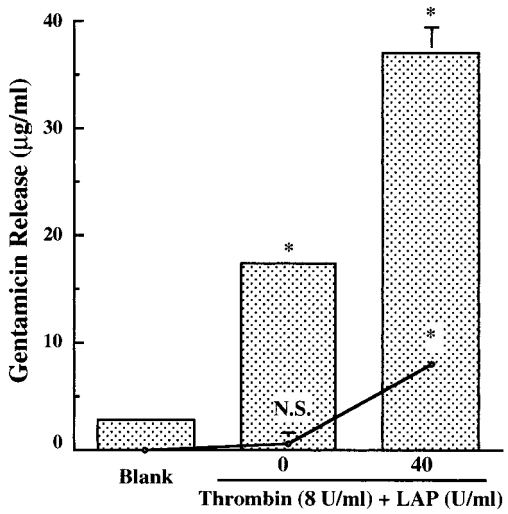

Figure 3—Effects of LAP on gentamicin release in the presence of thrombin: FPIA (bar); zone of inhibition (–○–). Each value represents mean ± SD of triplicate experiments. The data marked with * are significantly high values compared with blank ($p < 0.001$), calculated by ANOVA. N. S. denotes no significant difference compared with blank ($p > 0.05$) calculated by ANOVA.

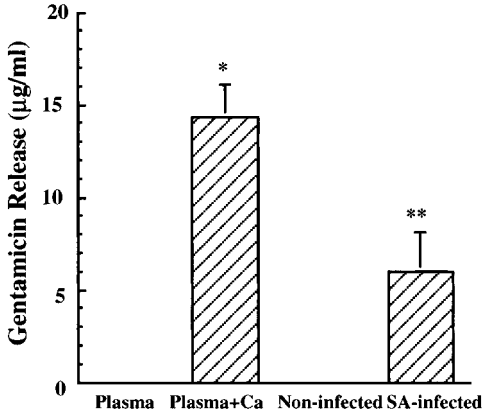

Figure 4—Gentamicin release detected by the zone of inhibition assay when PVA–linker–gentamicin was incubated with Ca^{2+}-supplemented human plasma ($n = 3$) or plasma alone ($n = 3$) in glass tubes, and SA-infected ($n = 13$) or noninfected wound fluid ($n = 3$). Key: (*) plasma + Ca shows a significantly higher value than plasma ($p < 0.001$), by the unpaired t test. (**) SA-infected wound fluid shows a significantly higher value than noninfected wound fluid ($p < 0.001$), calculated by the unpaired t test.

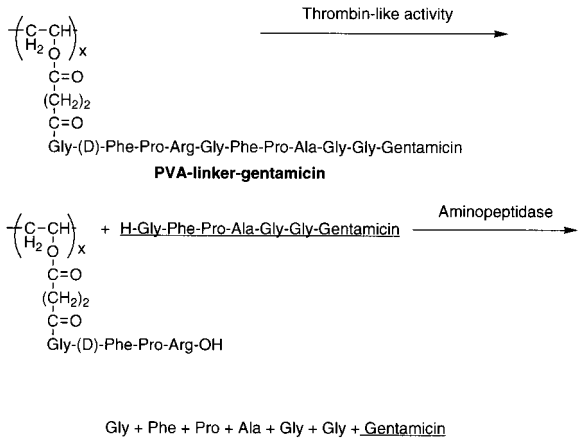
Figure 4 shows the release of biologically active gentamicin when PVA−linker−gentamicin was incubated with Ca^{2+}-supplemented human plasma and plasma alone in glass tubes. Because Ca^{2+} addition to human plasma in glass tubes causes thrombin activation, biologically active gentamicin was released. In plasma alone there was no thrombin activity; therefore, gentamicin release was not detected. Figure 4 also shows that PVA−linker−gentamicin could release biologically active gentamicin when it was incubated with SA-infected wound fluid, however, it could not release a detectable amount of gentamicin when incubated with noninfected wound fluid.

In Vivo Bacteriocidal Effect—The logarithm of the bacterial number (1.96 ± 0.79 CFU/mL, $n = 8$, $p < 0.001$) in an animal model of SA-infection in rats in which PVA−linker−gentamicin was applied was significantly lower than that in rats in which PVA−COOH was applied (5.74 ± 0.29 CFU/mL, $n = 8$) or that in rats in which no treatment was administered (3.76 ± 0.37 CFU/mL, $n = 9$). This result showed that PVA−linker−gentamicin was effective in vivo.



Scheme 2—Gentamicin release from PVA-linker-gentamicin by enzymes.

Discussion

LAP is a typical aminopeptidase present in human serum at a concentration of 8−12 mU/mL.[20] It is thought that LAP is also contained at about the same concentration in wound fluid. Actually, aminopeptidase activity was present in wound fluid and its activity was not changed by SA infection. Therefore, Gly-Phe-Pro-Ala-Gly-Gly-gentamicin produced from PVA−linker−gentamicin by the thrombin-like activity in SA-infected wound fluid was rapidly digested by aminopeptidase, and biologically active free gentamicin was generated. It was also shown that active gentamicin was released from PVA−linker−gentamicin in Ca^{2+}-supplemented human plasma; however, no active gentamicin was released by incubation in human plasma alone (Figure 4). When PVA−linker−gentamicin was incubated with only PBS, human plasma, or LAP, gentamicin release was not detected by either the zone of inhibition or FPIA methods (Figures 2 and 4). These results clearly show that significant contaminations of free gentamicin and peptide linker−gentamicin were not present in the PVA−linker−gentamicin.

Because the amount of released gentamicin was dependent on the thrombin concentration (Figure 2) and thrombin-like activity increases with SA-infection,[12] PVA−linker−gentamicin was expected to release an amount of active gentamicin proportional to the degree of SA-infection. In fact, PVA−linker−gentamicin did release biologically active gentamicin in SA-infected wound fluid (Figure 4), and showed a bacteriocidal effect in the animal model of SA infection. A considerable amount of thrombin-like activity was detected in noninfected wound fluid (Table 1); however, no gentamicin release was detected (Figure 4). This result might be because of failure to reach the threshold of the concentration of thrombin-like activity that could digest the macromolecular substrate, PVA−linker−gentamicin, and/or the threshold of gentamicin concentration that could be detected by the zone of inhibition assay (Figure 1).

The zone of inhibition method depends on the biological activity of intact gentamicin. In contrast, the FPIA method uses antibody that binds immunologically active gentamicin and therefore detects molecules that retain the required antigenic properties of gentamicin, such as, peptide-attached gentamicin, amino acid-attached gentamicin, and damaged gentamicin, as well as intact gentamicin. This point is very important in the study of drug delivery systems because there is a considerable chance that released drug may be damaged by the modification. In our synthesis of PVA−linker−gentamicin, shown in Scheme 1, the possibility of damaging the drug is minimized. According to the reaction shown in Scheme 2, PVA−linker−gentamicin can release intact gentamicin (Figures 2−4) in

the presence of thrombin and LAP. These results demonstrated that PVA−linker−gentamicin is an ideal system for the controlled release of this antimicrobial drug.

Systemic and local administration of antibiotics for wound infection is well established. The efficacy of antibiotics, however, depends on factors such as the pharmacokinetics, the timing of infusion, tissue concentrations, and the antibacterial spectrum of the drug. Because systemic administration of antibiotics is associated with certain drawbacks, such as systemic toxicity and poor penetration into severely infected or necrotic tissues, many physicians favor the use of local antibiotics and other topical measures. Controlled local delivery of antibiotics has been shown to reduce the number of microorganisms with minimal side effects compared with systemic administration. Thus, we have developed a new local, controlled-release system of an antibiotic stimulated by bacterial infection. PVA−linker−gentamicin showed specific release of gentamicin in SA-infected wound fluid and caused a significant reduction in SA number in vivo. These results show that this system allows gentamicin to be released at specific times and locations, namely, when and where SA infection occurs. Because PVA−COOH is a potential occlusive dressing material, it is expected that PVA−linker−gentamicin would inhibit bacteria from colonizing the dressing surface when applied to wounds infected with SA. In addition, if proteinases specific to each bacterium could be used for the triggering signal, different spectra of antibiotics could be released from the same material, depending on the strain of bacterium. That is, for bacterium X, use of bacterium-specific proteinase Y and proteinase Y-sensitive linker Z, would result in release of bacterium X-specific antibiotic. Furthermore, it may also be possible to make tumor-specific devices by utilizing peptide linkers sensitive to tumor-producing enzymes, such as some collagenases.[21,22]

Accepted for publication March 1, 1999.

Abstract □ The Potts and Guy equation that has been used to predict permeability coefficients for molecules being delivered from aqueous vehicles has been transformed to accommodate lipid vehicles that are less polar than skin, and polar vehicles that are less polar than water. Solubilities in pH 4.0 aqueous buffer (S_{AQ}), solubilities in isopropyl myristate (S_{IPM}), and molecular weights (MW) of prodrugs of 5-fluorouracil (5-FU), theophylline (Th), and 6-mercaptopurine (6-MP) have been regressed against their fluxes from suspensions in IPM (J_M). Seven series ($n = 39$) of alkylcarbonyloxymethyl (ACOM), alkyloxycarbonyl (AOC), alkylcarbonyl (AC), and alkylaminocarbonyl (AAC) prodrugs were used to determine the best fit to the transformed Potts and Guy equation (eq 6): $\log J_M = x + y \log S_{IPM} + (1 - y)\log S_{AQ} - z$ MW. The estimated values for x, y, and z were –0.193, +0.525, and +0.00364, respectively, with $r^2 = 0.945$ for $n = 39$. Inclusion of a miscellaneous series comprised of the parent drugs and a branched alkyl chain prodrug gave an equally good fit only if 6-MP was excluded from the analysis. The best performer (largest J_M) in each series was usually correctly identified. The values for x, y, and z were consistent with values obtained by Potts and Guy, but the inclusion of the $(1 - y)\log S_{AQ}$ term in eq 6 and the value for y, shows that water solubility is almost as important as lipid solubility in predicting flux. There were no significant changes in predicted $\log J_M$ or x_i for each series if their $\log J_M$ or x_i were calculated using y and z coefficients obtained for solutions to eq 6 from which the data for the series had been excluded. This suggests that the data from all the series is homogeneous. Data from Kasting, Smith, and Cooper for S_{IPM}, S_{PG}, and MW of unrelated molecules were regressed against their fluxes from propylene glycol (PG) using eq 7: $\log J_M = x + y \log S_{IPM} + (1 - y) \log S_{PG} - z$ MW. The estimated values for x, y, and z were –1.673, +0.599, and +0.00595, respectively, with $r^2 = 0.852$ for $n = 28$. These values for x, y, and z are also consistent with those previously reported by Potts and Guy, and, together with the results for fluxes from IPM, show the general utility of the transformed Potts and Guy equation in predicting flux from vehicles other than water and in showing the importance of solubility in a polar solvent as well as a nonpolar solvent in predicting flux.

Introduction

It has become obvious that the water as well as the lipid solubility of a permeant plays an important role in determining the rate of diffusion through biological membranes. Nowhere is this fact more obvious than in the results from diffusion cell experiments where prodrugs designed to enhance topical delivery—or flux—of a parent drug have been evaluated.[1] Examples where different types of promoieties have been used with one parent drug,[2–5] or where one type of promoiety has been used with a number of different parent drugs,[5–8] show that, for an homologous series of more lipid soluble prodrugs, the more water soluble member or members of the series are the more efficient at delivering the parent drug topically. Although the greatest accumulation of data supporting this axiom exists for prodrugs of heterocycles such as a fluorouracil (5-FU),[2–5] theophylline (Th),[8] 6-mercaptopurine (6-MP),[6,7] and arabinofuranosyladenine,[9,10] ample supporting data can also be found from experiments using prodrugs of lipophilic drugs such as levonorgestrel[11] and indomethacin.[12] In one comparison of variables affecting flux, the axiom holds regardless of the polarity of the vehicle used to deliver the prodrug,[6,7] while in another comparison, the axiom holds regardless of the type of skin that is used in the experiments—mouse[2–8] or human skin.[11]

It would be useful to develop a model that could predict the effect of changes in water and lipid solubilities of prodrugs on the topical delivery of their parent drugs. A large portion of the published data on the delivery of parent drugs by prodrugs has been obtained using suspensions of the prodrugs in isopropyl myristate (IPM) as the donor phase where the IPM and aqueous (AQ) solubilities of the prodrugs were variables and flux was measured.[1] On the other hand, many models that have been developed to predict flux actually use measurements of permeability coefficients of drugs obtained using concentrations of drugs in vehicles (usually water) significantly less than saturation as the donor phase, and where the partition coefficient and size of the drug were the variables.[13] In this paper we transform a model that had been developed previously for predicting permeability coefficients of drugs into a model where the aqueous as well as lipid solubilities of prodrugs are variables for predicting the flux of their parent drugs and vehicles other than water can be accommodated.

Development of the Model

Most models used to predict flux or solubility normalized flux—permeability coefficient (P)—have focused on the effects of lipid solubility [either directly as S_{LIPID} or in the form of partition coefficient ($K_{LIPID:AQ}$)] and size [as it affects diffusivity] on flux. Typical of these treatments is eq 1 derived by Kasting, Smith, and Cooper from data developed in their laboratories and published in 1987[14] where J_M is the maximum flux obtained by applying saturated propylene glycol solutions of permeants to the membrane (human skin), S_{MEM} is the solubility of the permeant in the membrane, $D°$ is the diffusivity in the membrane of a

$$\log J_M = \log(D°/L) + \log S_{MEM} - (\beta/2.303)V \quad (1)$$

hypothetical molecule having zero molecular volume, h (we will use L) is the diffusion path length, V is the van der Waals volume, and β is a constant that is characteristic of the skin.

Since it is very difficult to measure the solubility of the permeant in the membrane, the authors[14] examined several S_{LIPID} substitutes for S_{MEM} and suggested that S_{OCT} (measured solubility in octanol) gave a better correlation with J_M than S_{IPM} (measured solubility in isopropyl myristate) or S_i (calculated ideal solubility). The assumption was that some sort of lipid solubility alone was sufficient to characterize solubility of permeants in and their flux through the membrane. The other assumption was that J_M was independent of the vehicle because saturated solutions were used as donor phases where the thermodynamic activities of the permeants were the same. This assumed there was no effect of the vehicle on the barrier properties of the skin. Analysis of their unique data set of 36 compounds fitted to eq 1 gave $r^2 = 0.74$ for the correlation of J_M with the model. This data set was unique because propylene glycol, not water, was used as the vehicle or donor phase. Substitution of molecular weight for the molecular volume gave a similar fit.

Subsequently, several groups developed models that were based on permeability coefficients obtained from data from combinations of series from different laboratories[15–17] where water was used as the vehicle. One model frequently referenced is that represented by eq 2 developed by Potts and Guy and published in 1992.[13] In eq 2 K_P (we will use P) is permeability coefficient, $K_{OCT:AQ}$ is the partition coefficient between octanol and water, MW is the molecular weight, $\beta°$ is a constant similar to β in eq 1 but which

$$\log P = \log(D°/L) + f \log K_{OCT:AQ} - \beta° MW \qquad (2)$$

includes a conversion factor for the substitution of MW for molecular volume, and f accounts for the difference between K_m (partitioning between membrane and vehicle) and $K_{OCT:AQ}$ (partitioning between octanol and water): i.e., $K_m = (K_{OCT:AQ})^f$. From the data sets analyzed using eq 2, the values for $D°/L$ and $\beta°$ that were obtained were consistent with physical properties of the skin, and $r^2 = 0.83$ was obtained for the correlation of P with this model for $n = 42$. A somewhat poorer correlation ($r^2 = 0.67$) was obtained using the larger data set ($n = 93$) of Flynn.[18]

Although no positive dependence of log P on S_{AQ} was discussed, an inverse dependence derives from the definition of $K_{OCT:AQ} = C_{OCT}/C_{AQ}$ (where C_{OCT} and C_{AQ} are the equilibrium concentrations of the permeant in octanol and water, respectively), if it is assumed that $K_{OCT:AQ}$ for the permeant is approximately equal to its solubility ratio ($SR_{OCT:AQ}$) in the same solvents (S_{OCT}/S_{AQ}). On the other hand, Potts and Guy[13] discuss that one interpretation of skin transport for molecules of very high lipophilicites (low S_{AQ}) is that the rate-determining step becomes the slow transfer from the lipophilic stratum corneum to the aqueous, viable epidermis and upper dermis, i.e., low water solubility can become rate-determining. Significant conclusions from this analysis were that the limiting barrier, the stratum corneum, could be adequately characterized as a lipid-like barrier alone, and that an aqueous-polar (pore) pathway across the barrier was not necessary to explain the flux of the more water soluble members of the data set.

Improvements in eq 2 have been obtained by a number of groups[19–22] by defining permeant partitioning between membrane/water or organic phase/water from a transfer free energy model where R_2 is molar refractivity, MV is the molar volume, π is the dipolarity/polarizability, and H_d and H_a are the hydrogen bond donor and hydrogen bond acceptor activity, respectively, of the solute. Substitution of eq 3 for $K_{OCT:AQ}$ in eq 2 gives log P values that are independent of the organic phase/water partition coefficients and dependent on the physicochemical properties of the permeant alone. For a monofunctional group subset of their previous data set, Potts and Guy in 1995[20] showed that R_2 and π could be omitted from the analysis giving eq 4 to predict log P with $r^2 = 0.94$. Negative values were

$$\log K_{ORG} = a_1 MV + a_2 \pi + a_3 H_d = a_4 H_a + a_5 R_2 \qquad (3)$$

$$P = (a_1 - \beta)MV + a_3 H_d + a_4 H_a + \log(D°/L) \qquad (4)$$

found for a_3 and a_4 suggesting, for permeants delivered from water, that hydrogen bond donating or accepting abilities exhibited by the permeant were inversely related to stratum corneum (SC) permeation. Hence, water solubility was also inversely related to SC permeation.

Equation 4 or similar models give the best correlation with experimental results but do not offer a mechanism for incorporating water solubility (S_{AQ}) directly as a variable. Similarly, although all of the data in the Kasting, Smith, and Cooper permeation set[14] were from experiments where J_M values were measured, eq 1 does not have S_{AQ} as a variable. On the other hand, eq 2 offers the opportunity to substitute other K values for K_m besides $K_{OCT:AQ}$ and to include the effect of vehicle on flux in the model. Since[23]

$$K_{MEM:IPM} = K_{MEM:AQ}/K_{IPM:AQ}$$

and[24]

$$K_{MEM:AQ} = (K_{IPM:AQ})^f$$

then

$$K_{MEM:IPM} = (K_{IPM:AQ})^f/K_{IPM:AQ} \qquad (5)$$

Substitution of eq 5 into eq 2 for $K_{OCT:AQ}$ gives

$$\log P = \log(D°/L) + f \log S_{IPM} - f \log S_{AQ} - \log S_{IPM} + \log S_{AQ} - \beta° MW$$

or

$$\log P = \log(D°/L) + f \log S_{IPM} - \log S_{IPM} + (1 - f)\log S_{AQ} - \beta° MW$$

Addition of log S_{IPM} to both sides gives

$$\log J = \log(D°/L) + f \log S_{IPM} + (1 - f)\log S_{AQ} - \beta° MW$$

Substitution of x for log $D°/L$, y for f, z for $\beta°$, and assuming that saturated IPM donor phases are used in the diffusion experiments gives

$$\log J_M = x + y \log S_{IPM} + (1 - y) \log S_{AQ} - z\ MW \qquad (6)$$

which is the transformation of the Potts and Guy model, given in eq 2, that will be used in this analysis.

To fit the Kasting, Smith, and Cooper[14] data to the same type of equation, two different substitutions were made. Instead of using the identity $K_{MEM:AQ} = (K_{IPM:AQ})^y$ where IPM has been substituted for MEM, the identity $K_{MEM:AQ} = (K_{IPM:PG})^y$ has been used where PG has been substituted for AQ, and IPM has been substituted for MEM. Then, instead of adding log S_{IPM} to both sides of eq 2, log S_{PG} has been added to both sides of eq 2 to give eq 7 using the same

substitutions as in eq 6. $(K_{OCT:PG})^y$ can also be substituted for $(K_{IPM:PG})^y$ to give a similar equation.

$$\log J_M = x + y \log S_{IPM} + (1 - y) \log S_{PG} - z\,MW \qquad (7)$$

Experimental Section

The methods used to determine the values for flux (J_M), solubilities (S_{IPM}, S_{AQ}), and partition coefficients between IPM and water ($K_{IPM:AQ}$) are described in the original papers for each series of prodrugs: 1-alkylcarbonyloxymethyl-5-FU (ACOM-5-FU),[5] 1-alkyloxycarbonyl-5-FU (AOC-5-FU),[3] 1-alkylcarbonyl-5-FU (AC-5-FU),[4] 1-alkylaminocarbonyl-5-FU (AAC-5-FU),[2] 7-alkylcarbonyloxymethyltheophylline (ACOM-Th),[8] 6-alkylcarbonyloxymethyl-6-MP (6ACOM-6-MP),[7] and 6,9-bis(alkylcarbonyloxymethyl)-6-MP (6,9ACOM-6-MP).[6] In each series only straight chain homologues were completely characterized and evaluated except for the ACOM-5-FU series where one branched chain homologue was characterized and evaluated: 1-pivaloyloxymethyl-5-FU (pivACOM-5-FU). Solubilities (S_{IPM}, S_{AQ}) and partition coefficients ($K_{IPM:AQ}$) are listed in Table 1. S_{AQ} values were calculated from $S_{IPM}/K_{IPM:AQ}$ values where available. Where $K_{IPM:AQ}$ values were not available, directly measured S_{AQ} values were used. In one case where the reported $K_{IPM:AQ}$ value for one member of a series, octylaminocarbonyl-5-FU, was inconsistent with other literature values and did not fit the trend in the remaining data for that series; the literature value,[25] which did fit the trend, was used as well as the corresponding calculated S_{AQ}. The J_M values listed in Table 1 were obtained using female hairless mice (SKH-hr-1) obtained from Temple University Skin and Cancer Hospital or from Charles River. The mice were sacrificed by cervical dislocation. Their skins were removed by blunt dissection and then placed epidermal side up in Franz type diffusion cells thermostated to 32 °C in contact with pH 7.1 phosphate buffer receptor phase. The buffer contained 0.11% formaldehyde as a preservative to prevent microbial growth and maintain the integrity of the skins during the course of the experiment.[8] The surface area of the diffusion cells was 4.9 cm^2, and the receptor phase volume was 20 mL. After contact with the receptor phase for 48 h to condition the skins, aliquots of a suspension of the prodrug in IPM (usually 0.5 mL) were applied to the epidermal side of three skins ($n = 3$) for 48 h. The receptor phases were continuously stirred during the entire experiment and were changed every 3 h during the time when steady-state fluxes were measured which was usually from 19 to 33 h. Variation in flux values was less than 30% except from the 6ACOM-6-MP series where the variation was less than 50%.

The solubilities, partition coefficients, and flux values for the parent drugs (5-FU,[2] Th,[8] 6-MP[6]) and the one branched alkyl chain prodrug (pivACOM-5-FU)[5] are also listed in Table 1 as a separate, miscellaneous series.

The multiple linear regression model depicted in eq 6 was fit to various combinations of the sets of data in Table 1 using the SPSS 7.5 statistical software package.

The J_M values in $\mu g\ cm^{-2}\ h^{-1}$ from Kasting, Smith, and Cooper[14] were converted to $\mu mol\ cm^{-2}\ h^{-1}$ values and the S_{IPM} and S_{PG} (solubilities in propylene glycol) values were converted to millimolar values before converting them to their respective log values and analyzing them using eq 7. The multiple linear regression model depicted in eq 7 was fit to the Kasting, Smith, and Cooper data using the SPSS 7.5 statistical software package. The data for salt forms of amines and for benzyl alcohol were omitted from the analysis to give $n = 28$ instead of $n = 36$.

Results

The log J_M, MW, log S_{IPM}, and log S_{AQ} data for the 39 straight chain alkyl prodrugs from Table 1 comprising seven series of prodrugs ($n = 39$ set) were fit to eq 6 using the SPSS nonlinear function. The parameter estimates for the $n = 39$ set (solution 1) were $x = -0.193$ (± 0.199), $y = +0.525$ (± 0.029), and $z = +0.00364$ (± 0.00084) with $r^2 = 0.945$ (Table 2). Using these estimated values for x, y, and z from solution 1, predicted log J_M values were calculated and are listed in Table 3. The average error or residual for predicting log J_M (experimental log J_M − predicted log J_M = Δ log J_M, data not shown) was 0.126 log units for all log J_M values. The average Δ log J_M value for each series is listed in boldface in the predicted log J_M column in Table 3 and quantitates the variation in Δ log J_M among members of each series and among the different series. The largest Δ log J_M values for members within a series were obtained for the longer alkyl chain members of the ACOM-, AOC-, AC-, and AAC-5-FU series. The largest average error in predicting log J_M values for a series was obtained for the AAC-5-FU series while the smallest was for the 6,9ACOM-6-MP series. The best performing member in each series (highest value for log J_M) was correctly identified in each series except for the 6ACOM-6-MP series, but in that series

the top four performers were not statistically different from each other.[7] Solution 1 identified the C_2 member of the 6ACOM-6-MP series as the best performer while the C_3 member was actually the best performer experimentally. Using the estimated values for *y* and *z* from solution 1, the values of x_i for the members of each series that were required to give the experimental log J_M values were calculated and are given in Table 3. The average x_i for all members of all series was −0.193 with a standard deviation of ±0.155 log units. The average x_i value and SD for each series of prodrugs are also given in Table 3 and quantitate variations in x_i among the members of each series and among the different series. The largest SD of x_i was seen in the AAC-5-FU series, followed by that in the AOC- and AC-5-FU series. Figure 1 shows a plot of experimental log J_M values versus predicted log J_M values (eq 6) using all 39 prodrugs (solution 1).

Predicted log J_M values and calculated x_i values for the parent drugs and pivACOM-5-FU (miscellaneous series) were determined using the solution 1 fit to eq 6 as above for the $n = 39$ set. Those predicted log J_M and calculated x_i values are given in Table 3. The Δ log J_M value for 6-MP was over twice as large as the next largest Δ log J_M value and almost six times larger than the average for all Δ log J_M values: average Δ log $J_M = 0.146$ log units for all log J_M values, $n = 43$. Similarly, the calculated x_i value for 6-MP was twice as large as any other calculated x_i value. Figure 1 also shows the fit of the members of the miscellaneous series to the solution 1 fit to eq 6. When the log J_M, MW, log S_{IPM}, and log S_{AQ} data for the miscellaneous series were added to the $n = 39$ set to give an $n = 43$ set (solution 2, Table 2) and eq 6 was fit to that data, the correlation coefficient decreased to $r^2 = 0.924$ from $r^2 = 0.945$, and the estimated values for *x*, *y*, and *z* changed to −0.401, +0.530, and +0.00293, respectively. If the data for 6-MP was removed from the set (solution 3, Table 2) the values for *x* and *z* returned to approximately their solution 1 values, and the value for *y* stayed reasonably constant.

Equation 6 was then fit to the log J_M, MW, log S_{IPM}, and log S_{AQ} data for the seven series of straight chain alkyl prodrugs using the SPSS nonlinear function, but using only six of the series in each fitting. This systematically excluded a different series each time to give a total of seven sets of parameter estimates for eq 6 (solutions 4−10). This was done to correct for overly optimistic measures of fit which result from using the same data to both calibrate the model (estimate its parameters) and assess the error of prediction. The estimates for *x*, *y*, *z*, and associated r^2 values for these seven sets are given in Table 2. Using these estimated values for *x*, *y*, and *z* for solutions 4−10, predicted log J_M values were calculated for each member of the series that had been excluded from determining that solution to eq 6. Those predicted log J_M values for solutions 4−10 are given in Table 3. The average error for predicting log J_M (Δ log J_M, data not shown) was 0.132 log units for all log J_M values, $n = 39$. The average Δ log J_M value for each series is listed in boldface in the predicted log J_M column in Table 3. The largest average error in predicting log J_M values for the series excluded from obtaining the solution to eq 6 was for the AAC-5-FU series. Using the estimated values for *y* and *z* for each of the seven solutions to eq 6 generated by excluding the data from one series of prodrugs, values for x_i which were required to give the experimental log J_M values were calculated for each member of the series that had been excluded. These calculated x_i values for solutions 4−10 are given in Table 3. The average x_i for all members of all series was −0.193 with a standard deviation of ±0.173 which was essentially identical with the average x_i value and standard deviation from solution 1. The results in Table 2 show that the estimated *x*, *y*, and *z* values from solution 7 (exclusion of the AAC-5-FU series) exhibited the largest differences from the estimated *x*, *y*, and *z* values from solution 1. The estimated value for *z* from solutions 4−10 are all quite close to the estimated values of *z* from solution 1 and to several of those reported by Potts and Guy[13] for fits to data from combinations of series from different laboratories (+0.0042 ± 0.0001, $n = 19$; +0.0050 ± 0.0003, $n = 42$; +0.0061 ± 0.0006, $n = 93$).

Using the Potts and Guy value that is most frequently quoted for *z* of +0.0061, a solution to eq 6 was obtained using the $n = 39$ set: solution 11 Table 2, $x = +0.388$, $y = +0.590$. Using the estimated values for *x* and *y* from solution 11 and *z* fixed at 0.0061, predicted log J_M values were calculated and are listed in Table 3. The average error for predicting log J_M (Δ log J_M, data not shown) was 0.141 log units for all log J_M values, $n = 39$. The average Δ log J_M value for each series is listed in boldface in the predicted log J_M column in Table 3. The predicted log J_M values for the miscellaneous series were also calculated using the coefficients from solution 11. Figure 2 shows the fit of the $n = 39$ prodrug set and the members of the miscellaneous series to a plot of experimental log J_M versus predicted log J_M based on solution 11. Using the estimated value for *y* and the fixed value for *z*, values for x_i which were required to give the experimental log J_M values were calculated for all the members of all the series. Those x_i values are given in Table 3. The average x_i for all members of all series was +0.413 with a standard deviation of ±0.187 log units. Excluding the data for the AC- and AAC-5-FU series, the solution 12 fit to eq 6 gave estimated values for *x*, *y*, and *z* (no longer fixed) which are given in Table 2.

Equation 7 was fit to the log J_M, MW, log S_{IPM}, and log S_{PG} data for the 28 molecules comprising the Kasting, Smith, and Cooper[14] data set (with the amine salts and

Discussion

Transformation of the Potts and Guy model[13] was done not only to include S_{AQ} as a variable in predicting flux but

also to accommodate donor phases other than water in the model. One of the key features of the Potts and Guy model is the substitution of $(K_{OCT:AQ})^f$ for K_m where K_m is the partition coefficient between the biological membrane, skin, and water. A more specific representation of K_m would be $K_{MEM:AQ} = (K_{LIPID:AQ})^f$ where water (AQ) is defined as the polar phase, and lipids, which can be different from octanol, are defined as appropriate nonpolar phase substitutes for skin (MEM). However, since $K_m D°/L$ is equal to the permeability coefficient (P), in the Potts and Guy model the polar phase is also the donor phase in the diffusion cell experiments which measure flux. This presents a significant limitation to the extension of the Potts and Guy model to predict P (or J) where the donor phase is a lipid or a polar phase other than water. The key substitution cannot be made if the donor phase is also a lipid such as isopropyl myristate (IPM) or even octanol. Taking the example where IPM is used as the donor phase, K_m is the partition coefficient between skin and IPM and a lipid/aqueous partition coefficient cannot be substituted for K_m.

There are three important features of the transformation of the Potts and Guy model into the model represented by eq 6. The first feature is the use of the identity of $K_{MEM:IPM}$ with $K_{MEM:AQ}/K_{IPM:AQ}$ which had previously been established by Surber et al.[23] Use of this identity allows substitution of the experimental partition coefficient, $K_{MEM:IPM}$, by the partition coefficient used by Potts and Guy in developing their model, $K_{MEM:AQ}$, and by a partition coefficient, $K_{IPM:AQ}$, containing two variables available from the published data on the prodrugs: S_{AQ} and S_{IPM}. This assumes that the solubility ratio, $SR_{IPM:AQ} = S_{IPM}/S_{AQ}$, can be substituted for partition coefficient, K. The second feature is the use of the identity of $K_{MEM:AQ}$ with $(K_{LIPID:AQ})^f$ where the membrane phase cannot only be replaced by another lipid phase such as octanol, which is similar in polarity, but also by lipids such as ether,[17] or in this case IPM, which are much less polar than skin or octanol. In this case $K_{MEM:AQ} = (K_{IPM:AQ})^f$. The coefficient f is used to account for the difference between the partitioning domain presented by IPM and that presented by the permeation limiting barrier in the skin: the stratum corneum. The third feature is the use of saturated solutions of the permeants in the donor phases. This allows all of the prodrugs to be evaluated at the same thermodynamic activity.

The estimated values for x, y, and z obtained for solution 1 to eq 6 using data from the seven series of straight chain alkyl prodrugs are consistent with the values obtained by Potts and Guy.[13] The value for y is 0.525 ± 0.029 which is consistent with the f value of 0.48 ± 0.05 obtained by Potts and Guy when they performed multiple linear regression of log P (K_P) values upon log $K_{ETHER:AQ}$ and MW from the data of Ackerman et al.[17] A y value of 1.0 would indicate that IPM is a good substitute for the partitioning domain of the stratum corneum (SC) lipids. On the other hand, the y values when IPM or ether is used are significantly less than 1.0, which suggests that they are both much less polar than the partitioning domain of the SC and in fact are less polar than octanol for which y (f) values of from 0.82 to 0.70 were obtained.[13] This order of polarity follows from the solubility parameters of ether, IPM, skin, and octanol: 7.4,[26] 8.5,[26] 10.0,[27] and 10.3[26] $(cal/cm^3)^{1/2}$, respectively. Since ether and IPM exhibit similar solubility parameter values, one would expect them to behave similarly and to be significantly less polar than octanol or skin.

Cohen and co-workers[27] have estimated a macroscopic value of $\delta = 9.7-10.0$ $(cal/cm^3)^{1/2}$ for the solubility parameter of porcine skin. However, the fact that the y value for octanol as the SC substitute is less than 1.0 suggests that the SC is more polar than $\delta = 9.7-10.0$ $(cal/cm^3)^{1/2}$ and may be as large as 12 $(cal/cm^3)^{1/2}$.

The value for z of $+0.00364 \pm 0.00084$ is also consistent with the $\beta°$ value of $+0.0019 \pm 0.0008$ obtained by Potts and Guy[13] in their analysis of the Ackerman et al. data,[17] where mouse skin was used as the diffusion cell membrane and $K_{ETHER:AQ}$ was used instead of $K_{OCT:AQ}$. It is also consistent with the $\beta°$ value of $+0.0050 \pm 0.0003$ obtained by Potts and Guy for the $n = 42$ combined data from Schuplein and Blank[15] and Roberts et al.[16] Although the value for z most often quoted from the paper of Potts and Guy is the value of $+0.0061 \pm 0.0006$ obtained using the data collected by Flynn,[18] it was obtained from a regression analysis that only yielded an $r^2 = 0.67$.

Although the estimated values for y and z from the prodrug data set are consistent with those previously obtained by Potts and Guy data from combinations of series from different laboratories, the value for x obtained here is different from that obtained by Potts and Guy by a factor of approximately 10^6. This difference can be attributed to differences in the way the flux data was obtained and the units used to present the data. The prodrug J_M data has been presented in units of μmol cm^{-2} h^{-1} instead of units of μmol cm^{-2} s^{-1}. This introduces a factor of 3.6×10^3. In addition, since x defines D, any experimental difference that affects D will result in differences in x. The prodrug J_M data were obtained using hairless mouse skin instead of using human skin. Hairless mouse skin may be as much as 10 times more permeable than human skin,[28] using experimental conditions similar to the ones used to collect the prodrug flux data. Finally, isopropyl myristate (IPM) was used as the vehicle (donor phase) in the diffusion cell experiments used to obtain the prodrug J_M values. IPM has been shown[29−31] to irreversibly change hairless mouse skin so that it is 50 to 100 times more permeable than it would be if there were no interactions between the skin and vehicle. Taking all three factors into account gives an x value of the same order of magnitude as that obtained by Potts and Guy. Considering all the differences in the experimental details between the way the data in the two data sets were obtained, this is a good agreement.

A plot of experimental log J_M values versus predicted log J_M values from solution 1 for the prodrug series is shown in Figure 1. The largest differences between experimental and calculated values for log J_M (Δ log J_M) were found for the C_9 member of the ACOM-5-FU, the C_8 member of AOC-5-FU, and the C_4 member of AAC-5-FU series: Δ log $J_M = 0.31$ to 0.38 log units. Inclusion of the fit of the data from the miscellaneous series to solution 1 in Figure 1 shows that 6-MP is an obvious outlier (Δ log $J_M = 0.83$) to solution 1 and that pivACOM-5-FU (Δ log $J_M = 0.33$) is only predicted as well as the worst predicted members of the straight chain alkyl series. When the data from the miscellaneous series was included in the data used to determine a solution (solution 2, Table 2) to eq 6 the fit was worse ($r^2 = 0.924$) and x and z changed substantially from their solution 1 values. Exclusion of the data for 6-MP from the solution to eq 6 gave estimated values for x, y, and z (solution 3, Table 2) which were consistent with those from solution 1. Thus, there is no reason to exclude parent drugs (except for 6-MP) or branched alkyl chain prodrugs from analysis of the data for the straight alkyl chain prodrugs using eq 6.

To determine if any of the data from individual series were inconsistent with the remaining data set, solutions 4−10 to eq 6 were obtained in which each series was individually excluded from the entire data set one series at a time. Using solutions 4−10 from Table 2, predicted log J_M and x_i values were calculated for the excluded series and compared with the predicted log J_M and x_i values calculated from solution 1 for the excluded series (Table 3). There was no substantial change in the differences

between the experimental log J_M and predicted log J_M values calculated from solution 1 and predicted log J_M calculated from solutions 4−10. Also there were no significant differences between the average x_i values calculated for each of the individual series using solution 1 compared to the average x_i values calculated using solutions 4−10. Thus, the data from each of the series is consistent with the remaining series.

When the Potts and Guy value for z was used to obtain a solution (solution 11, Table 2) for the $n = 39$ data set fit to eq 6, there were significant changes in the average x_i value for all the series and the AC- and AAC-5-FU series together gave average x_i values that were significantly different ($p < 0.01$) from the average of all the other series (Table 3). If the data from AC- and AAC-5-FU series were excluded from the $n = 39$ data set and a solution (solution 12, Table 2) was obtained for the fit of that $n = 28$ data set to eq 6, the estimated values for x, y, and z were consistent with those from solution 11. The value for z remained the same even though it was not fixed in solution 12 and was free to optimize. Solution 12 gave the best fit to the data ($r^2 = 0.961$) but at the expense of excluding the AC- and AAC-5-FU data and possibly biasing estimation of x, y, and z to give values that are not representative of all the prodrugs. Thus, the best solution to eq 6 for all the data is solution 1 or 3.

To determine if the data from diffusion cell experiments where donor phases other than IPM and membranes other than hairless mouse skin were used could be analyzed by a transformation of the Potts and Guy model, eq 7 was fit to the data from Kasting, Smith, and Cooper to give solution 13 in Table 2. The value for z obtained (+0.00595) is consistent with the previous values obtained when water or IPM were the donor phases. Thus, the dependency (z) of diffusivity on molecular weight (size) of the solute is not changed by properties of the vehicle or the membrane used. The value for y obtained by substitution of $(K_{IPM:PG})^y$ for $K_{MEM:AQ}$ is consistent with the value of y obtained when $(K_{IPM:AQ})^y$ was substituted for $K_{MEM:AQ}$. Thus PG does not behave significantly differently from AQ as a donor phase. Finally, the value for x estimated from the Kasting, Smith, and Cooper data is about 2 orders of magnitude more negative than that from the IPM data. Since human skin was used in the Kasting, Smith, and Cooper diffusion cell experiments and PG, which does not irreversibly change the skin, was used as the donor phase, there could be as much as 3 orders of magnitude difference between the IPM and PG data. Thus, the x value from solution 13, where PG was the donor phase, is also consistent with those where IPM or AQ were the donor phases.

It is probable that some error is introduced into the model as a result of hydrolysis of the prodrugs to parent drug during their diffusion through the skin. Partial hydrolysis would tend to give increased values of experimental total flux compared to predicted values of flux because two species (parent drug and intact prodrug) would be diffusing independently. In this analysis no attempt was made to account for hydrolysis since rates for the hydrolyses of the prodrugs in skin homogenates were not available. However, neglect of hydrolysis has resulted in a good fit and a simple equation with good predictive value.

The results presented here show for the first time that S_{AQ} is an important variable to incorporate into a model that is to be used to predict the topical delivery of drugs and prodrugs. In addition, the importance of S_{AQ} in determining the best correlation between permeation of 5-FU and its prodrugs in Caco-2 cells and various physicochemical parameters has also recently been identified.[32] Thus, S_{AQ} is an important physicochemical parameter for predicting flux not only through skin but also membrane models for intestinal absorption.

Conclusion

Transformation of the Potts and Guy equation gives an eq 6 that can accommodate vehicles as donor phases that are less polar than skin and that can predict maximum flux values from aqueous and lipid solubilities (instead of partition coefficients) and molecular weights. The values for the coefficients estimated by fitting eq 6 to the values of fluxes from IPM through hairless mouse skin, solubilities in IPM and AQ and molecular weights from the prodrug literature were consistent with the values previously reported by Potts and Guy. In addition, the value for the coefficient defining the contribution of IPM and AQ solubilities to predictions of flux showed that water solubility was almost as important as IPM or lipid solubility. The Potts and Guy equation was also transformed into eq 7 to accommodate a vehicle that was more polar than skin but not as polar as water and a membrane other than hairless mouse skin, i.e., human skin. The values for the coefficients estimated by fitting eq 7 to the values of fluxes from PG through human skin, solubilities in IPM and PG and molecular weights from the data set of Kasting, Smith, and Cooper were also consistent with the values previously reported by Potts and Guy. These results support the conclusion that the coefficients have physical meaning in the diffusion process and that equations of the type developed by Potts and Guy have general utility in predicting flux when suitably transformed.

Abstract □ Lepirudin has a short half-life, and only 50–60% of the intravenously administered dose is excreted by the kidneys. The fate of the remainder is unknown. We designed a study to determine the fate of this lepirudin. In each of six baboons, [^{131}I]lepirudin was given intravenously as a bolus or infused over 30 min, 24 h apart. The in vivo redistribution of [^{131}I]lepirudin was determined and quantified by scintillation camera imaging. In all studies, the half-life of [^{131}I]lepirudin, as determined from the disappearance of radioactivity, was 21 ± 3 min. The half-life determined from the disappearance of lepirudin, measured by the Ecarin Clotting Time (ECT) method, was similar at 23 ± 8 min. Results obtained with the labeled lepirudin are therefore comparable with those obtained using the plasma concentration of lepirudin. When lepirudin was administered as a bolus, the half-life was 18 ± 4 min, and lepirudin was cleared from the plasma at a rate of 42 ± 12 mL/min and by the kidneys at 23 ± 2 mL/min. Following infusion over 30 min, the half-life and total and renal clearances were not significantly different. In both studies, between 50 and 60% of the administered lepirudin was excreted by the kidney. Studies on sacrificed baboons showed that appreciable amounts of lepirudin were present in the bile, indicating the liver as a contributor to the elimination of lepirudin.

Introduction

Hirudin is regarded as the most potent direct inhibitor of thrombin and its recombinant form, lepirudin ([leu^1, Thr^2]-63-disulfatohirudin), has the same physiochemical characteristics and biochemical properties as the native protein.[1,2] Lepirudin is a 65 amino acid polypeptide (7 kDa) produced by transfected yeast cells.[1] The interaction between hirudin and thrombin results in the formation of a stable, noncovalent stoichiometric 1:1 complex that inhibits all functions of thrombin.[1,2] Apart from its inhibition of coagulation, it also inhibits platelet-dependent arterial-type thrombosis when given in high enough dosages.[3−5] Although the pharmacokinetics of lepirudin is well-known, there are still some unresolved issues. It is generally accepted that lepirudin is mainly excreted in an unchanged form by the kidneys.[1,6] However, approximately 40 to 50% of injected protein cannot be accounted for in the urine. The sites of metabolism and/or uptake of this lepirudin are unknown. We designed this study to investigate the metabolism and fate of lepirudin in baboons.

Subjects and Methods

Experimental Animals—Eight male baboons (Papio ursinus) supporting permanent femoral arteriovenous shunts (A-V shunts) of silicone rubber tubing[7,8] were used. The animals were sedated with intramuscular ketamine hydrochloride (10 mg/kg body mass, Centaur Laboratories, South Africa) to enable handling. Anesthesia was maintained with subsequent administrations when necessary. One hundred milliliters of saline were given intravenously (iv) to each baboon 30 min before the start of a study to ensure that they were normovolaemic.

Experimental Protocol—Six baboons received [^{131}I]lepirudin as an iv bolus of 0.3 mg/kg as well as an infusion at a rate of 0.01 mg/kg/min for 30 min on separate days. The treatment requirements were such that an equal number of baboons received the bolus or infusion on each day. The lepirudin (HBW 023, Hoechst AG, Frankfurt and Behringwerke AG, Marburg, Germany) was labeled with 131-iodine (^{131}I; Radiochemical Centre, Amersham, UK) using the IODO-GEN method.[9] Labeling efficiency was 98 ± 1%. It is important to note that only labeled lepirudin was infused and that we determined the plasma concentration of the labeled lepirudin (see later). Therefore, when reference is made to lepirudin, it refers to the results obtained from the plasma concentration as determined using the ECT method.[10] Similarly, reference to labeled lepirudin refers to results obtained from radioactive count rates of [^{131}I]lepirudin.

Scintillation Camera Imaging—Imaging of the in vivo distribution of labeled lepirudin was done with a Large Field of View Scintillation Camera fitted with a high-energy collimator. Image analysis was done with an A^3-MDS data processing system that was interfaced with the camera. Imaging was done in two phases; they are, a dynamic image acquisition phase and a static acquisition phase.

Dynamic Image Acquisition—The baboons were positioned in front of the detector of the camera so as to include the kidneys, bladder, liver, and spleen in the field of view. Dynamic image acquisition, consisting of 3-min images (64 × 64 word mode) for 120 min (infusion study) and 90 min (bolus study), started simultaneously with the infusion of [^{131}I]lepirudin. For analysis, a region of interest was selected for the kidneys, the bladder, the spleen, and the liver, and the radioactivity in each region was expressed as a percentage of injected [^{131}I]labeled lepirudin, which was estimated by the geometrical mean method of quantification (see Static Image Acquisition). The radioactive count rates of the left and right kidneys were summed to obtain total kidney radioactivity.

Static Image Acquisition and Quantification of In Vivo Distribution of [^{131}I]Lepirudin—After the dynamic image acquisition, static anterior and posterior images of 3 min (64 × 64 word mode) were acquired of the head, thorax and abdomen, and legs. A background image was also acquired to correct whole body and region of interest (organ) radioactivity for background radioactivity. Before treatment on the second day, anterior and posterior images of the thorax and abdomen were acquired to determine and correct for residual ^{131}I radioactivity as a result of infusion of [^{131}I]lepirudin on the previous day.

To obtain anterior and posterior whole body radioactivity, the radioactivity in the head, thorax and abdomen, and legs was

10.1021/js980407q CCC: $18.00
Published on Web 04/15/1999

corrected for background radioactivity and/or residual radioactivity and summed. Regions of interest for the kidneys, bladder, spleen, and liver were selected to determine organ radioactivity. On the first day of the experiment, these radioactivities were corrected for background radioactivity. On the second day, organ radioactivity was corrected for background radioactivity and residual radioactivity, measured before the infusion of [^{131}I]lepirudin. The in vivo organ distribution of [^{131}I]lepirudin was quantified by the geometric mean method.[11]

Blood Collection and Analysis—Blood, 4.5 mL in 0.5 mL of a 3.2% sodiumcitrate solution, was collected before a study was started and then every 15 min thereafter. The radioactivity in 1 mL of plasma was determined in a gamma counter. Plasma levels of lepirudin were determined by the ECT method, which was specifically developed to measure hirudin levels in plasma and body fluids.[10] The activated partial thromboplastin time (aPTT) was measured with a fibrinometer (Clotex II, Hyland Division, Travenol Laboratories, Costa Mesa, CA), and reagents were supplied by the same company. The aPTT was measured to give an indication of the level of anticoagulation achieved and to show that the labeled lepirudin was functional.

To determine if the labeling procedure affected the function of [^{131}I]lepirudin, unlabeled and labeled lepirudin were added to plasma obtained from 4 baboons. Plasma concentrations were 2.5 and 5.0 μg/mL of lepirudin. In addition, a 50/50 mixture of labeled and unlabeled protein was also used. The aPTT was determined on all samples.

Urine Collection and Analysis—Urine was collected into a urine-collecting bag with a Teflon-coated latex Foley catheter (GRS Medicals, Kelvin, SA) for up to 24 h and analyzed for lepirudin by the ECT method.[10] The total amount of lepirudin was calculated from the total urine volume and the concentration in urine.

Urine was also analyzed by sodium dodecylsulfate polyacrylamide gel electrophoresis (SDS-PAGE). Samples analyzed were [^{131}I]lepirudin, urine without [^{131}I]lepirudin (native urine), [^{131}I]-lepirudin added to native urine, and urine collected from the treated baboons. The results strongly suggest that [^{131}I]lepirudin was excreted in an unchanged form. The results are not given.

Calculations—*Plasma Half-Lives of Lepirudin and [^{131}I]-Lepirudin*—The elimination half-lives of lepirudin and [^{131}I]-lepirudin were calculated by adjusting a one-phase exponential function to the appropriate phases of the log−linear plasma concentration−time and radioactive count rate−time profiles by the method of least-squares analysis. The value k, in the function $C_{max} \times e^{-kt}$, was thus found, where C_{max} is the maximum lepirudin concentration or maximum radioactive count rate in plasma. The half-lives were calculated as $t_{1/2} = 0.693/k$.

Total Clearance of Lepirudin and [^{131}I]Lepirudin—For the constant *infusion*, total clearance (CL_{total}) was calculated by dividing the rate of infusion (mg/min or radioactive count rate/min) by the maximum concentration of lepirudin or radioactive count rate in the plasma. To estimate the maximum plasma concentration or plasma radioactive count rate, an exponential association function was fitted to the data points obtained during the infusion period and extrapolated to maximum (i.e., an estimate of steady-state levels).[12]

For the *bolus* injection, CL_{total} was calculated by dividing the total dose, or the total counts injected, by the area under the curve ($AUC_{0-\infty}$) of the plasma lepirudin concentration (μg/mL)−time or plasma radioactivity (radioactive count rate/ml)−time profiles. The area under the plasma concentration−time and plasma radioactive counts rate−time curves up to 90 min (AUC_{0-90}) were calculated using the trapezoid rule. The curves were extrapolated to ∞ using the formula $AUC_{0-\infty} = AUC_{0-90} + C_p^*/k_e$, where C_p^* is the plasma lepirudin concentration or plasma radioactive count rate at the last sampling time (90 min). The terminal rate constant (k_e) was determined from the slope of the terminal portion of the log-linear C_p versus time curve.

Renal Clearance of [^{131}I]Lepirudin—For the constant *infusion*, renal clearance (CL_{renal}) was calculated by dividing the rate of appearance of [^{131}I]lepirudin in the bladder (radioactive count rate/min) by the maximum counts in the plasma. The latter was estimated by fitting an exponential association function to the available radioactive count rate/mL−time profiles and extrapolated to estimate the maximum value where a steady state was reached.

For the *bolus* injection, CL_{renal} was calculated by dividing the maximum radioactive count rate in the bladder by $AUC_{0-\infty}$ of the plasma radioactivity (radioactive count rate/mL)−time profiles.

Extravascular Clearance—The plasma clearance of lepirudin by the extravascular compartment was estimated by calculating the difference between the total clearance and the renal clearance.

Determination of Sites of Lepirudin Accumulation in Sacrificed Baboons—Two baboons were used. The one baboon was sacrificed after 30 min of infusion of [^{131}I]lepirudin. The other one received no lepirudin and was sacrificed to obtain organs and body fluids that served as controls for immunohistochemistry and lepirudin determinations, respectively. The baboons were deeply anesthetized. The test baboon was exsanguinated through the arterial side of the A-V shunt. About 2 L of saline at 37 °C were simultaneously infused under pressure (140 mmHg) into the venous side of the shunt to replace the blood that was lost.

Ex Vivo Quantification of the Distribution of [^{131}I]Lepirudin—The liver, spleen, kidneys, and bladder of the sacrificed baboons were immediately excised by careful dissection. Residual radioactivity in the body and that present in the liver, spleen, kidneys, and bladder were determined by scintillation camera imaging.[11] Images of 3 min (64 × 64 word mode) were acquired. Organ radioactivity was then expressed as a percentage of total body radioactivity, obtained by summation of residual and organ radioactivities.

Organ Biopsies—Biopsies of the kidneys (cortex and medulla), spleen, and liver were collected to establish the location of the lepirudin by using immunohistochemistry techniques. A primary antibody, rabbit anti-hirudin antibody (diluted 1:100 in PBS; Celsus Laboratories, Cincinnati, OH) was added to thin processed sections of the tissues and incubated for 60 min. A secondary goat anti-rabbit antibody (Signet kit, Johnson & Johnson, Johannesburg, Republic of South Africa) was added to bind to the primary antibody and a third antibody complex, a peroxidase−antiperoxidase immune complex, was used as the marker complex. These antibody complexes become visible when the tissues are exposed to the substrate diaminobenzidine. By adding hydrogen peroxide to the diaminobenzidine solution, a brown precipitate forms where lepirudin is present. Light microscopy was used to interpret the stains. Lightmicrographs of all tissues were enlarged 200 times and examined for the presence of lepirudin in cells.

Biopsies of the kidneys, liver, and spleen were also homogenized in saline and centrifuged at 8000 g for 24 h. The ECT method[10] was used to test for the presence of lepirudin in the supernatant of the homogenates.

Collection and Analysis of Duodenal and Gastric Juices and Bile—Duodenal and gastric juices and bile were collected from the sacrificed baboons to test for the presence of lepirudin by the ECT method.[10]

Statistics—Statistical comparison was done using Student's t test for paired data. Values of $p < 0.05$ were considered significant. The results are expressed as mean ± 1 standard deviation (SD).

Results

Changes in aPTT and Pharmacokinetics of Lepirudin—In the in vitro studies, concentrations of 2.5 and 5.0 μg/mL lepirudin lengthened the aPTT to 87 ± 4 and 174 ± 5 s. [^{131}I]Lepirudin, at the same concentrations, lengthened the aPTT to 92 ± 4 and 180 ± 6 s. When labeled and unlabeled lepirudin were mixed, the aPTT lengthened to 90 ± 3 and 178 ± 4 s. The difference in measurements was not significant. The labeling process therefore does not affect the function of lepirudin.

The in vivo changes in aPTT are summarized in Table 1. The labeled hirudin was biologically active because it caused a 2−3-fold lengthening in the aPTT. When lepirudin infusion was stopped and following the bolus injection, the aPTT rapidly shortened to reach near pre-infusion values after 90 min.

The changes in circulating lepirudin and labeled lepirudin are summarized in Figure 1. Following infusion or the bolus injection, the plasma levels of lepirudin and [^{131}I]-lepirudin decreased rapidly. In all studies, the plasma half-life of lepirudin was 24 ± 9 min. When calculated from the

Table 1—Changes in APTT[a]

time (min)	infusion	bolus
–30	40 ± 4	–
–10	–	–
0	131± 20	42 ± 6

Table 2—Total, Renal, and Extravascular Clearance of Lepirudin and [^{131}I]Lepirudin

route	clearance	r-Lepirudin	[^{131}I]Lepirudin
infusion	total	49 ± 16	52 ± 10
	renal	–	32 ± 10
	extravascular	–	20 ± 8
bolus	total	42 ± 12	45 ± 12
	renal	–	23 ± 2[b]
	extravascular	–	22 ± 12

[a] Values are given in mL/min and are expressed as mean ± 1 SD. [b] $p < 0.05$, infusion versus bolus (Student's *t* test for paired data).

disappearance of radioactivity from the blood, it was 21 ± 6 min. The difference was not statistically significant ($p > 0.05$). After infusion of [^{131}I]lepirudin was stopped, lepirudin was eliminated from the plasma with a half-life of 23 ± 8 min ([^{131}I]lepirudin = 21 ± 3 min). When the same amount of [^{131}I]lepirudin was given as a bolus, the half-life was 18 ± 4 min ([^{131}I]lepirudin = 19 ± 8 min). The mean difference in the half-lives between infused and bolus injected lepirudin was 5 ± 10 min. The 95% confidence interval of between −5 and 16 min indicates that the difference was not statistically significant.

Total, renal, and extravascular clearance of lepirudin is summarized in Table 2. Total clearance was ≈45 mL/min, whether it was calculated from the data obtained from the concentration of lepirudin or from labeled lepirudin. Between 51 and 61% of this lepirudin was cleared by the kidneys.

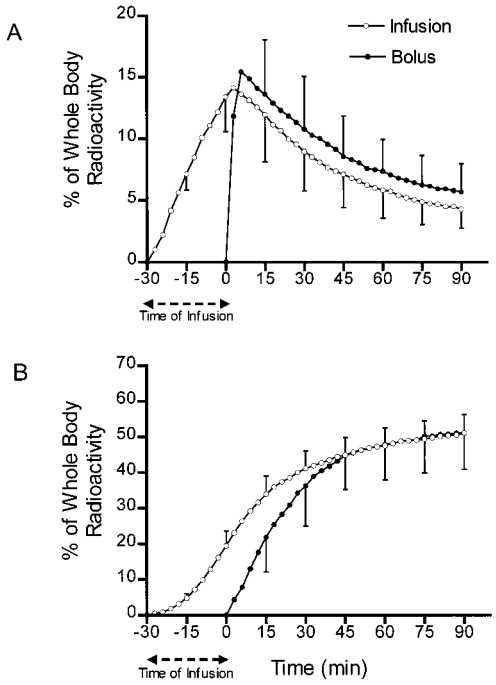

Figure 2—Dynamic changes of [^{131}I]lepirudin in the (A) kidneys and (B) bladder following infusion (open circles) and bolus administration (black circles). The radioactivity is expressed as a mean percentage ± 1 SD of whole body radioactivity at the end of each study.

Table 3—Organ Distribution of [^{131}I]Lepirudin at the End of Treatment

organ	infusion	bolus
kidneys	4.3 ± 1.5	5.7 ± 2.3
bladder	51.2 ± 5.2	51.2 ± 10.3
liver	1.7 ± 0.8	1.8 ± 0.9
spleen	3.6 ± 2.4	3.0 ± 2.7

[a] Percent of whole body radioactivity at the end of each study. Values are given as mean ± 1 SD.

Table 4—ECT of Bile and Duodenal and Gastric Juices, and of the Supernatant of Homogenized Kidney, Liver, and Spleen Tissue[a]

sample	ECT, s
bile	229
gastric juice	49
duodenal juice	39
kidney	77
liver	44
spleen	49

[a] Control values for the ECT method are between 38 and 40 s.

In Vivo Distribution of [^{131}I]Lepirudin—The changes in radioactivity in the kidneys and bladder are summarized in Figure 2, and the in vivo organ distribution at the end of the study in Table 3. Only ≈5% of total injected [^{131}I]-lepirudin was quantified in the liver and the spleen. The results obtained in the sacrificed baboon, 0.1% of the injected radioactivity in the spleen and 1.5% in the liver, also showed that the liver and spleen contained little [^{131}I]-lepirudin. Between 50 and 60% of the injected labeled lepirudin could be accounted for in the bladder. At the end of infusion or shortly after the bolus was injected, the kidneys contained ≈15% of the injected radioactivity (Figure 2A).

The presence of lepirudin in the bile and gastric and duodenal juices of the sacrificed baboon was measured by the ECT method, and the results are shown in Table 4. Of these, only the bile contained appreciable amounts as indicated by the markedly longer than normal ECT results.

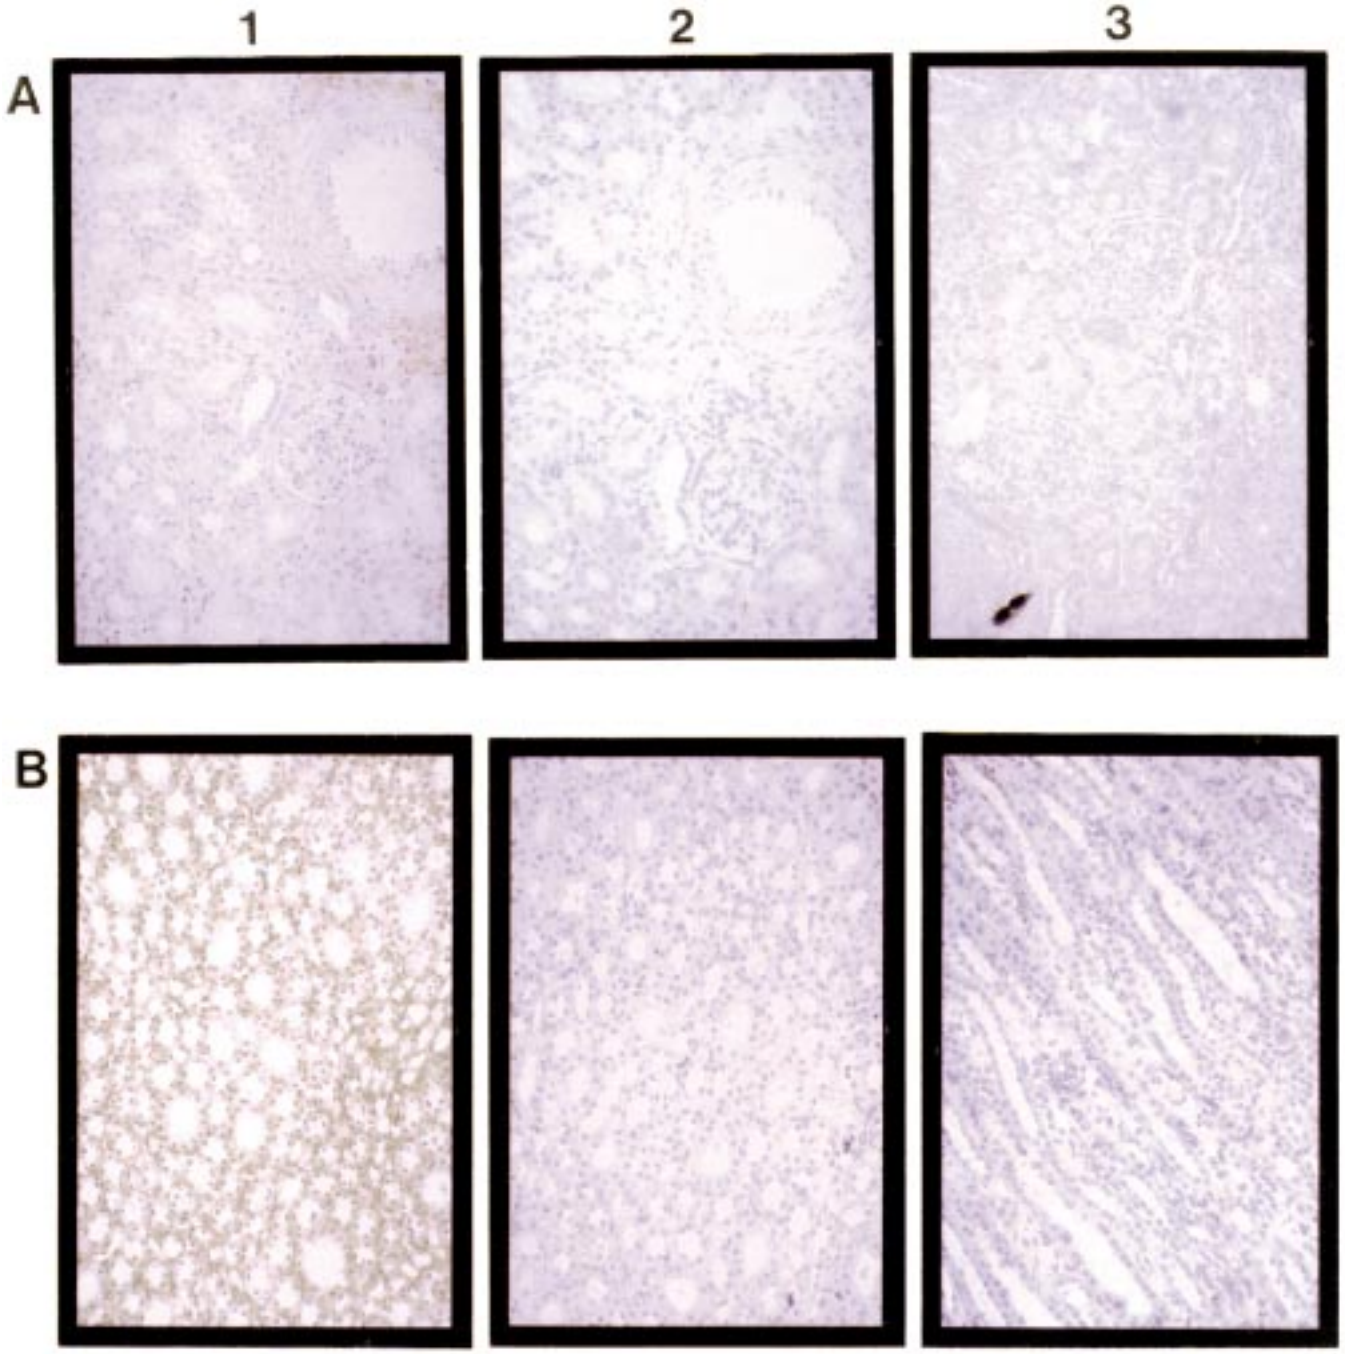

Figure 3—Light micrographs (enlarged 200X) of the (A) renal cortex and (B) medulla. A1 and B1 are from baboons that received lepirudin. A2 and B2 are negative controls where no anti-hirudin antibody was used. A3 and B3 show the renal cortex and medulla of the control baboon that did not receive lepirudin but was treated with anti-hirudin antibody.

The amount of lepirudin excreted by the kidneys was calculated from the total urine volume and the concentration of r-hirudin in urine. In two cases (1 × bolus study and 1 × infusion study), very little urine could be collected. The results are nevertheless given. After infusion of labeled lepirudin, 2.2 ± 1.9 mg of lepirudin was excreted, after the bolus 2.2 ± 1.5 mg was excreted. This amount was ≈54% of the total dose of lepirudin given.

Immunohistochemisty—The results are presented in Figures 3 and 4. The kidney, liver, and spleen of the baboon that was not treated with lepirudin stained negative when the tissues were incubated with the anti-hirudin antibody (Figure 3, A3 and B3, and Figure 4, A3 and B3). This result indicates that these tissues did not contain proteins that interact with the antibody. Kidney, spleen, and liver tissue from baboons treated with lepirudin also stained negative when the tissues were not incubated with the antibody (Figure 3, A2 and B2, and Figure 4, A2 and B2), indicating that the positive staining obtained in the test samples was not a result of the staining procedure.

In the renal cortex, the cytoplasm of the epithelial cells of the convoluted tubules, the cytoplasm of the endothelial cells of the blood vessels, and the connective tissue stained for lepirudin. The glomeruli stained negative (Figure 3, A1). The renal medulla stained intensely. It is likely that lepirudin was present in the epithelium of the thick and thin segments of the loop of Henly and the collecting tubes. The cytoplasm of the endothelial cells of the vas recta and the connective tissues between the cells stained strongly (Figure 3, B1).

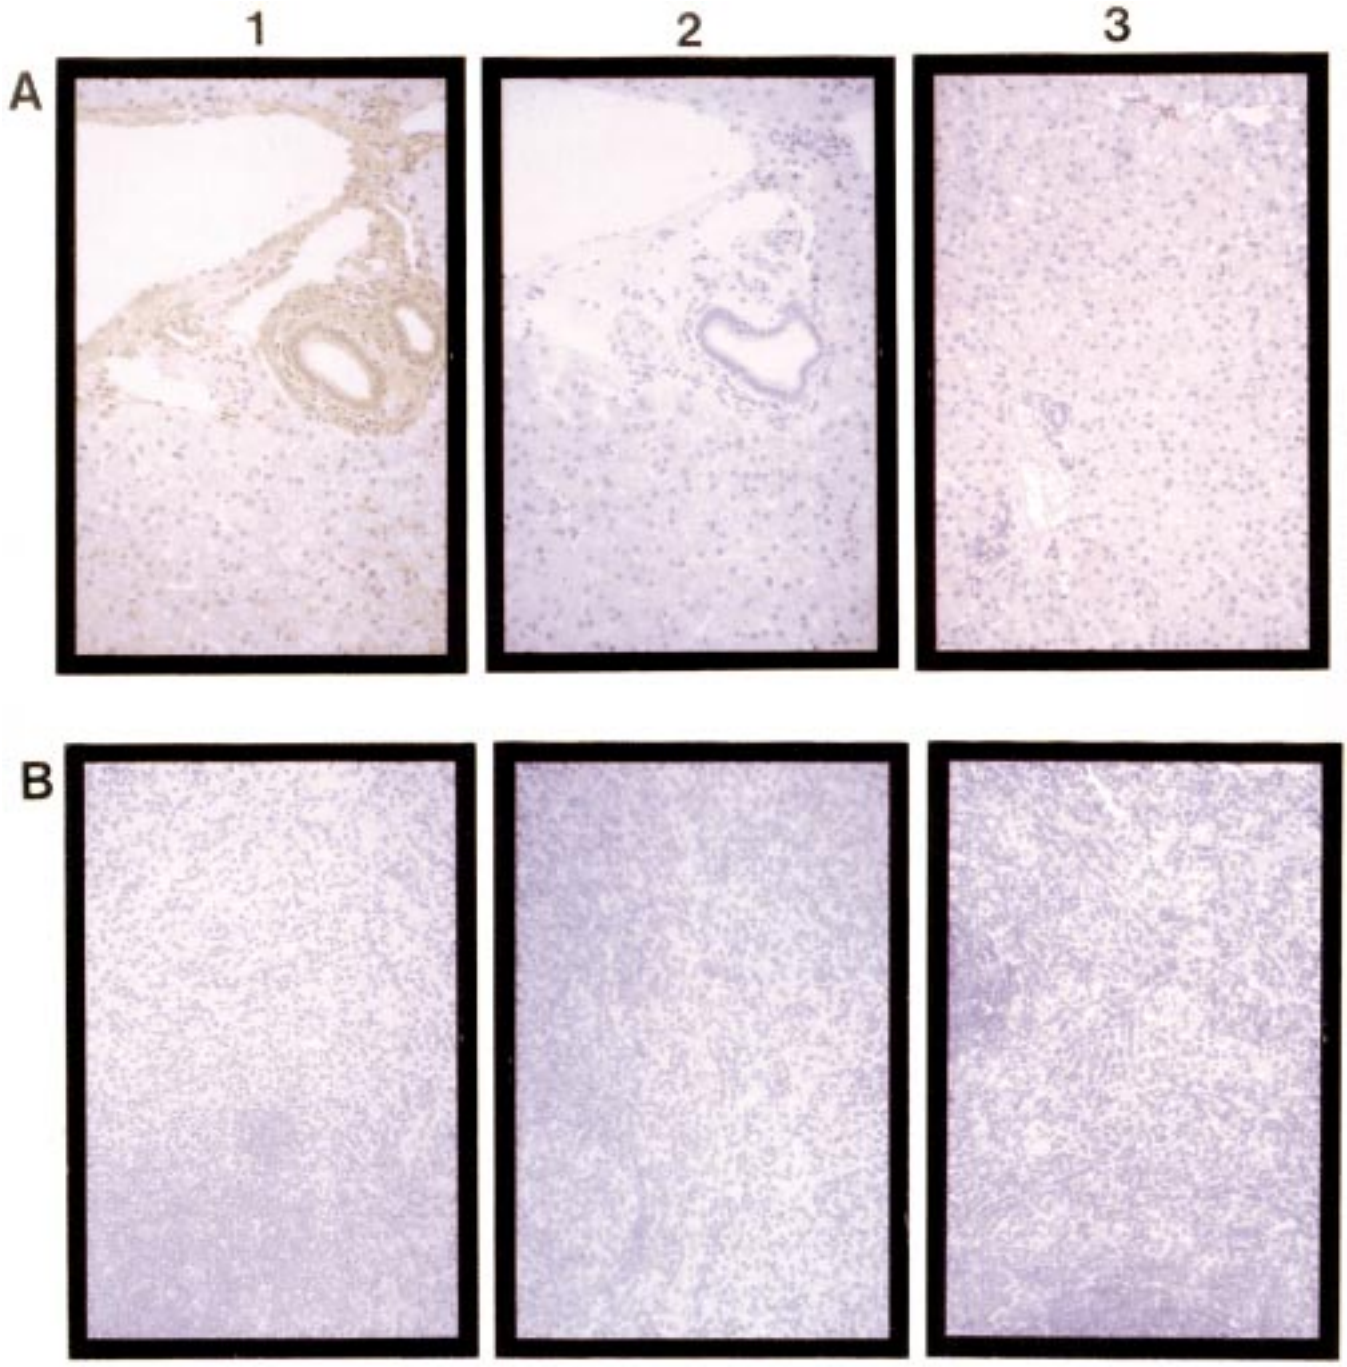

Figure 4—Light micrographs (enlarged 200X) of the (A) liver and (B) spleen. A1 and B1 are from baboons that received lepirudin. A2 and B2 are negative controls where no anti-hirudin antibody was used. A3 and B3 show the liver and spleen of the control baboon that did not receive lepirudin but was treated with anti-hirudin antibody.

The spleen did not stain for lepirudin (Figure 4, A1). On the other hand, staining of liver is ambiguous (Figure 4, B1). The cytoplasm of the hepatocytes did not stain strongly, but the cytoplasm of the endothelial cells of the hepatic artery and portal vein and that of the epithelial cells of the bile duct stained strongly.

Discussion

In a study of this nature, where the pharmacokinetics and mechanism of clearance of a compound labeled with a radioisotope is studied, it is vital that the labeled compound reacts in the same way as the native compound. There are several lines of evidence to show that the behavior of lepirudin, when labeled with ^{131}I, was not markedly affected by the labeling procedure. First, treatment with the labeled lepirudin lengthened the aPTT 3−4-fold (Table 1). In addition, when unlabeled and labeled hirudin, either alone or as a 50/50 mixture, were added to plasma in vitro, the lengthening in aPTT was equivalent. This result indicated that the labeled lepirudin was functional. Second, when the half-life was measured from the radioactive count rate in blood, it was 21 ± 6 min, which was not significantly different from that estimated for lepirudin (24 ± 9 min). These estimates were also not significantly different from that obtained in another study.[5] Third, after 90 min of treatment with labeled lepirudin, no accumulation of ^{131}I was imaged in the thyroid or spleen, both of which rapidly

remove free iodine in plasma.[13] It is therefore reasonable to conclude that labeling of lepirudin with ^{131}I did not adversely affect the function and plasma clearance of lepirudin and that the ^{131}I remained bound to the lepirudin. The results obtained with the labeled lepirudin can therefore be compared with those of lepirudin, and conclusions relating to the pharmacokinetics of lepirudin can be made from the results obtained with labeled lepirudin.

It is evident that lepirudin was mainly excreted by the kidneys (Figures 2A and B). Between 50 and 60% of the injected lepirudin was detected in the bladder 90 min after it was injected (Table 3), which agrees with results obtained in humans and rhesus monkeys.[6,14,15] Because the clearance of lepirudin approximates that of creatinine in humans, it was proposed that excretion be by glomerular filtration.[14,15] We used immunohistochemical techniques in an attempt to verify this proposal (Figure 3). The results were rather confusing and do not confirm glomerular filtration. Glomeruli in the renal cortex did not stain for lepirudin. Tissue surrounding the glomerulus and the blood vessel did stain. Even more surprising was the fact that the tubuli in the medulla, and especially the epithelial cells lining the tubules, stained intensely, which suggests tubular reabsorption and secretion. A well-planned study to investigate glomerular filtration and possible tubular reabsorption and secretion is called for. Such a study will provide definitive answers about the mechanisms by which the kidneys excrete lepirudin.

It is generally accepted that the fraction of lepirudin that is not excreted by the kidneys is distributed in the extravascular compartment.[14] The in vitro results in this study however showed that the liver plays a part in the catabolism of lepirudin and that lepirudin was excreted in the bile. Although we could not quantify appreciable quantities of [^{131}I]labeled lepirudin in the liver (Table 3), immunohistochemical studies showed that lepirudin was present in the hepatocytes and the tissues surrounding the blood vessels and bile ducts. The finding that lepirudin was present in the bile means that it has to be excreted into the digestive system. We explain the absence of lepirudin in the duodenal juices (Table 4) and the finding that lepirudin was not present in the feces of normal humans 24 h after it was administered[15] by digestion and absorption of lepirudin by the enzymes present in the duodenum. It is reasonable to assume that the 40% of administered lepirudin that was not excreted by the kidneys, could be excreted by the liver into the bile. However, a well-planned study is needed to quantify the contribution of the liver to the clearance of lepirudin from plasma. It is further evident that the spleen plays no part in the catabolism of lepirudin (Table 3, Figure 4).

The plasma elimination half-life of lepirudin was 18 ± 4 min when it was injected as a bolus. When the same quantity was infused over 30 min, the estimated half-life was not significantly different (23 ± 8 min). This result is similar to the estimated half-life that we determined in baboons where different dosages of lepirudin were infused over 30 min.[5] The half-lives estimated in the baboons are shorter than the 55−70 min measured in humans, rhesus monkeys, rats, rabbits, and dogs.[6,15−17] We have no easy explanation for this discrepancy.

The total clearance of lepirudin from plasma was ≈45 mL/min, whether the same amount was infused or given as a bolus. Similar results were obtained when clearance was calculated from the radioactive radioactive count rates (Table 2). This value is not very different from that determined in rhesus monkeys,[18] but differs greatly from the results reported for humans, rats, rabbits, and dogs.[6,15] Labeled lepirudin, infused over 30 min, was cleared by the kidneys at a significantly higher rate than that administered as a bolus (Table 2). However, when renal clearance was expressed as a percentage of plasma clearance, 62 ± 16% of infused lepirudin was cleared by the kidneys. The corresponding value for bolus administrated lepirudin, 55 ± 15%, was not significantly different ($p > 0.05$, Student's *t* test for paired data). Thus, although the rate of clearance was different, the relative contribution of the kidneys to plasma clearance was the same. It is important to note that in rhesus monkeys that received a bolus of lepirudin, renal clearance also contributed ≈50% to plasma clearance.[18] These results are similar to those obtained in this study. The method of administration of the labeled lepirudin did not affect the extravascular clearance (Table 2).

In summary, whether 0.3 mg/kg of labeled lepirudin was infused over 30 min or given as a bolus, it did not influence its plasma half-life and clearance. This result suggests that the study was performed with plasma concentrations below the maximum threshold levels of excretion of lepirudin by the kidneys. The mode of administration did not affect the clearance of lepirudin from plasma, nor that by the kidneys or the extravascular compartment. The kidneys were the main sites of excretion of lepirudin, where between 50 and 60% was excreted, probably by tubular secretion. It has been speculated that the remainder may be catabolized by the kidneys and that the methods used to determine lepirudin are unable to recognize the degradation products.[6,14,18,19] The quantification of the percentage labeled lepirudin found in the bladder argues against renal catabolisation. If the labeled lepirudin was catabolized, much more than 50 to 60% of administered labeled lepirudin would have been detected in the bladder at the end of the study. In addition, SDS-PAGE suggested excretion in an unchanged form. A surprising finding was that the bile contained appreciable amounts of lepirudin.

Abstract □ In recent studies we found that the topical effectiveness of acyclovir (ACV) formulations was a single-valued function of *C**—the target site free drug concentration. The topical efficacy was the same when the therapy was initiated 0, 1, or 2 days after intracutaneous herpes simplex virus type-1 (HSV-1) inoculation in hairless mice. The purpose of the present study was to examine the hypothesis that the topical effectiveness of cidofovir (HPMPC) would not be a single valued function of *C** and that it would be dependent upon when the therapy was initiated relative to the time of viral infection. Formulations of HPMPC and ACV in 95% DMSO as a vehicle were used. Hairless mice intracutaneously infected with HSV-1 were used, and 20 μL of the test formulation was topically applied twice a day. In protocol A, the treatment was continued until the fourth day after virus inoculation, whereas in protocol B the treatment was terminated on the day of virus inoculation. Treatment was initiated on various days ranging from day −6 to day 4, and the lesions were scored on day 5. Treatment of ACV according to protocol A proved efficacious whether started as early as 6 days before virus inoculation or later, whereas the efficacy of ACV was annihilated if applied following protocol B. For HPMPC, on the other hand, the in vivo efficacies were found to be strongly dependent on how early the therapy was initiated, and significant efficacy was observed even when the treatment was terminated on the day of virus inoculation. This difference was attributed to the virus-independent intracellular phosphorylation of HPMPC and slow clearance of its metabolites from the cell. It was also noted that, similar to ACV, for HPMPC the topical efficacy is likely to be a function of *C** for a fixed protocol. However, unlike for ACV, for HPMPC the efficacy was not a single-valued function of *C**.

Introduction

In a previous study,[1] we found that the topical effectiveness of acyclovir (ACV) formulations was essentially the same when the therapy was initiated 0, 1, or 2 days after intracutaneous herpes simplex virus type-1 (HSV-1) inoculation in hairless mice. Also, a good relationship was found between the free drug concentration at the skin target site (*C**) calculated from in vitro flux data and the in vivo antiviral efficacy for a variety of ACV formulations (i.e., topical efficacy was found to be a single-valued function of *C**).[2] We have hypothesized that this relatively straightforward behavior exhibited by ACV is the consequence of the relatively rapid local pharmacokinetics that ACV may exhibit at the cellular level. A long-term objective of this research has been to investigate the *C** concept using other anti-herpes model drugs that are similar to, as well as different from, ACV. A recent report assessed the relationship of *C** with the in vivo efficacy of (*E*)-5-(2-bromovinyl)-2-deoxyuridine (BVDU), an antiherpetic drug with a mechanism of action similar to that of ACV.[3] Cidofovir ((*S*)-1-(3-hydroxy-2-phosphonylmethoxypropyl)-cytosine or HPMPC) represents a new class of broad-spectrum antiviral agents that are active against a broad range of herpes viruses and exhibit rather slow cellular kinetics; particularly noteworthy is that the active metabolites are retained intracellularly for a very long time.[4] The purpose of the present study was to examine the hypothesis that because of the slow cellular pharmacokinetics, the topical effectiveness of HPMPC formulations would be strongly dependent upon when therapy is initiated relative to the time of virus infection and that, accordingly, the final outcome may not be a single-valued function of *C**.

Materials and Methods

Animals—Female hairless mice strain SKH/HR1 (Charles River, Bloomington, MA), 6−8 weeks old with average body weight of 22−27 g, were used throughout this study.

Virus—Samples from the same batch of herpes simplex virus type-1, strain E-377, with a final titer of 4×10^7 PFU/mL, were used for inoculation. They were stored at −70 °C in aliquots until used. The preparation and assay methods of the virus have been previously reported.[5]

Drug Formulations—HPMPC was generously provided by Gilead Sciences, Inc. (Foster City, CA). ACV was obtained from Thera Tech, Inc. (Salt Lake City, UT). DMSO was purchased from Baker Chemical Company (Phillipsburg, NJ). The formulations were made with 0.5 and 1% HPMPC and 0.1% ACV in 95% DMSO as a vehicle and 1% hydroxypropyl cellulose (Klucel, Hercules, Wilmington, DE) was added as a thickening agent.

In Vitro Flux Measurement and *C Predictions**—For the in vitro determination of HPMPC and ACV fluxes and *C** predictions, a combined in vivo−in vitro experimental procedure reported earlier[1,6] was adopted and performed in triplicate for each formulation. Briefly, a finite dose of 20 μL of the test formulation was applied over a rectangular skin area of 2 cm^2 on the animal

dressed in a Velcro jacket twice a day for 2 days. The in vivo pretreatment was followed by the in vitro flux experiment in which the pretreated skin was excised from the animal and mounted on a Franz diffusion cell. Flux measurements were carried out as reported earlier[1] after applying a 10 μL/cm^2 dose of the test formulation. ACV and HPMPC concentrations were analyzed using the previously reported reversed phase HPLC methods.[2,7]

The cumulative amount of the test drug transported into the receiver chamber was plotted as a function of time, and the instantaneous flux J was estimated from the slope of the line connecting the two consecutive points. The instantaneous C^* estimates were then calculated using the following equation.

$$C^* = J/P_D \quad (1)$$

where J is the skin flux and P_D is the in vivo dermis permeability coefficient of the drug. The details of the derivation of this equation have been reported in our previous study.[8] A P_D value of 1.4×10^{-3} cm/s was obtained for ACV. Since the molecular size of HPMPC is sufficiently close (for the present purpose) to that of ACV, it was deemed reasonable to use the in vivo P_D value of ACV for HPMPC as a good approximation.

In Vivo Antiviral Efficacy Studies—The in vivo antiviral efficacy was evaluated using a group of 8–10 hairless mice per experiment, and an average of two to six experiments were performed for each drug formulation. In each experiment a group of animals treated with a placebo formulation similar to the test formulation without the drug was always included as a negative control. For the purpose of these experiments, the animals were dressed in a Velcro jacket. The details of dressing the animals in the Velcro jacket and of virus inoculation have been described earlier.[2] Two general treatment protocols were followed. For both protocols, 20 μL of the test formulation was topically applied twice a day. In protocol A, the treatment was continued until the fourth day after virus inoculation, whereas in protocol B the treatment was terminated on the day of virus inoculation. The day of virus inoculation was always considered as day 0. Treatment was initiated on various days ranging from day −6 to day 4, as outlined in Table 1. The lesions were scored on day 5 as previously described,[9] and the antiviral efficacies were calculated using the following equations:[1]

$$\text{topical efficacy (\%)} = \frac{N_{St} + N_J + N_{NR}}{N_{Th} + N_{St} + N_J + N_{NR}} \times 100 \quad (2)$$

$$\text{systemic efficacy (\%)} = \frac{N_{NR}}{N_{Th} + N_{St} + N_J + N_{NR} + N_M} \times 100 \quad (3)$$

where N_{Th}, N_{St}, N_J, N_{NR}, and N_M are the number of animals corresponding to each of the five lesion categories and represent the cases where the lesion passes through (Th), stops (St) at the edge of, jumps (J) over, does not reach (NR), or misses (M) the treatment area, respectively.

During the treatment protocol coded −6A, the dosing was performed over 11 days, and hence the animal was dressed with the Velcro jacket for that period of time. This raised the question of the possible effect of stress (induced due to prolonged dressing in Velcro jackets) on the efficacy results. To assess this, an experiment was performed in which the animals were dressed in Velcro jackets on day −6 and the treatment with 0.5% HPMPC was initiated on day 1. The results of this experiment were compared with the results obtained with protocol coded 1A (where the dressing in the jacket and the treatment were both initiated on day 1). The results of these two experiments were comparable indicating that prolonged dressing in the Velcro jacket did not compromise the efficacy results (data not shown). The same conclusion was drawn from separate experiments with 0.1% ACV formulation.

Table 2—Mean C^* Estimates ($n = 3$) for 0.5% and 1% HPMPC and 0.1% ACV Formulations

formulation	C^* (μg/mL)	SD
0.5% HPMPC	1.2	0.14
1% HPMPC	2.13	0.38
0.1% ACV	0.12	0.02

Results

Table 2 shows the mean C^* estimates obtained from the combined in vivo–in vitro experiments for the three topical formulations. For HPMPC, an increase in the applied concentration resulted in an increase in the predicted C^* levels. The saturation solubility of HPMPC in DMSO was >10%, and hence an increase in the applied concentration resulted in essentially a proportional increase in the flux, which in turn resulted in proportionally higher C^* levels. These results are consistent with those previously observed with other anti-herpes agents such as ACV and BVDU.[2,3]

Figure 1 shows the results (mean ± SD) of our preliminary experiments with 1% HPMPC in 95% DMSO as vehicle. For this formulation, when the therapy was initiated 1 day after virus inoculation (and continued for 4 days, protocol 1A), around 45% topical efficacy and 0% systemic efficacy was observed. However, when the treatment was initiated sooner, high efficacies were obtained, rising to ~100% topical efficacy and ~45% systemic efficacy when the treatment was started 2 days before virus inoculation (and continued for 4 days after virus inoculation, protocol coded −2A).

To further extend these findings, we investigated the effect of starting the treatment even sooner (up to 6 days before virus inoculation). Also, a lower HPMPC level (of 0.5%) was employed to provide a greater dosage range, and therefore greater differentiation in the effects. Figure 2A presents the results of these experiments. As can be seen here, in general the earlier the treatment was initiated, the higher were the topical and systemic efficacies with both reaching a maximum of 100% with protocol coded −6A (treatment initiated 6 days prior to virus inoculation).

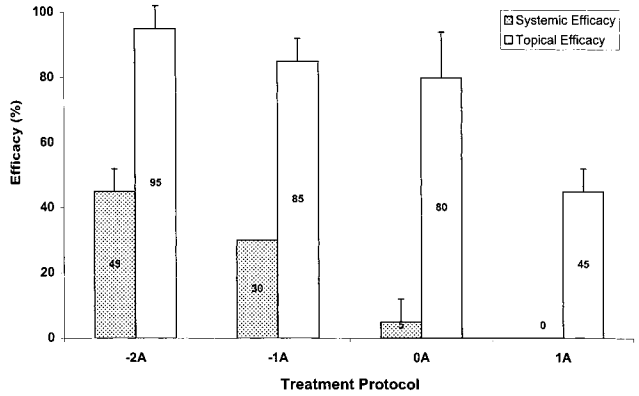

Figure 1—The topical and systemic efficacy of 1% HPMPC in 95% DMSO as a function of the treatment protocol ($n = 3$).

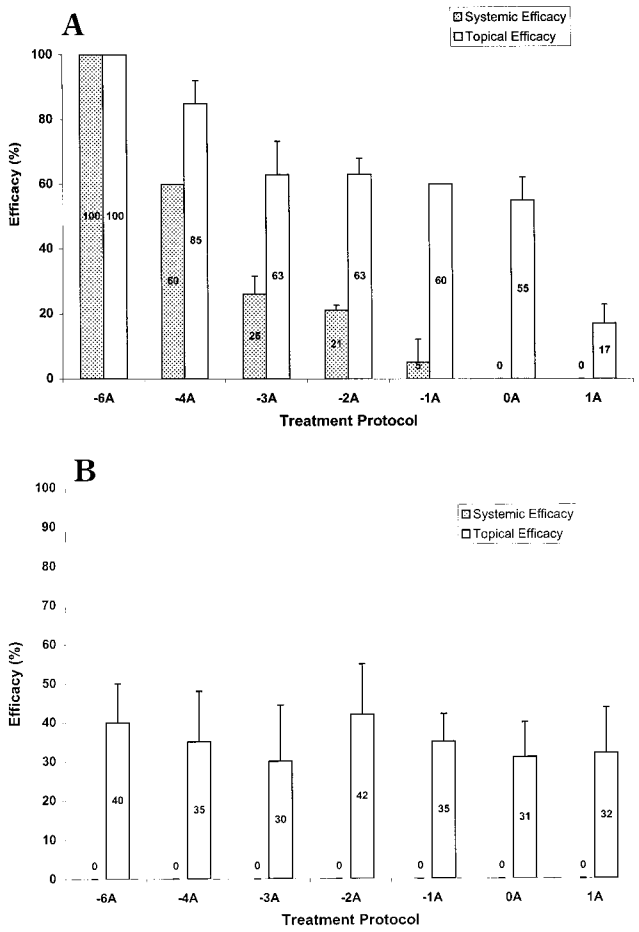

Figure 2—The topical and systemic efficacy of (A) 0.5% HPMPC and (B) 0.1% ACV in 95% DMSO as a function of the treatment protocol ($n = 3$–6).

A remarkable contrast is seen when the HPMPC results are compared to the ACV results. Figure 2B presents the results of similar experiments with 0.1% ACV. The figure clearly shows that treatment with ACV beginning as early as 6 days before virus inoculation (protocol coded −6A) had no effect on the outcomes when compared to the standard experiment of beginning the treatment 1 day after virus inoculation (protocol coded 1A). Clearly, the strong time dependency seen with HPMPC is absent with ACV.

In another series of experiments, the antiviral efficacies of 0.5% HPMPC and 0.1% ACV were tested as per protocol B (Figures 3A and 3B, respectively). In these experiments, the treatment was stopped on the day of virus inoculation. There was consequently no application of the drug formulation during the period of virus replication. Once again, there was a sharp difference in the outcomes with ACV and HPMPC. For ACV, terminating the treatment on the day of virus inoculation essentially rendered the treatment completely ineffective (Figure 3B), indicating that the application of ACV was required during the time of virus replication. However, for HPMPC, this was not the case. Topical efficacies ranging from 25 to 60% were found when the treatment was initiated 2−6 days prior to virus inoculation and stopped on the day of virus inoculation (Figure 3A). HPMPC applied prior to the infection acted prophylactically and continued to act against viral replication even though no HPMPC was applied during the time when the infection was progressing. The efficacy seen in this case seemed to be related to the duration of the exposure prior to the treatment, a longer duration of exposure with a given HPMPC formulation resulting in higher efficacy. For example, the topical efficacy obtained with 2 days (−2B) and 6 days (−6B) of exposure were 25 and 61%, respectively.

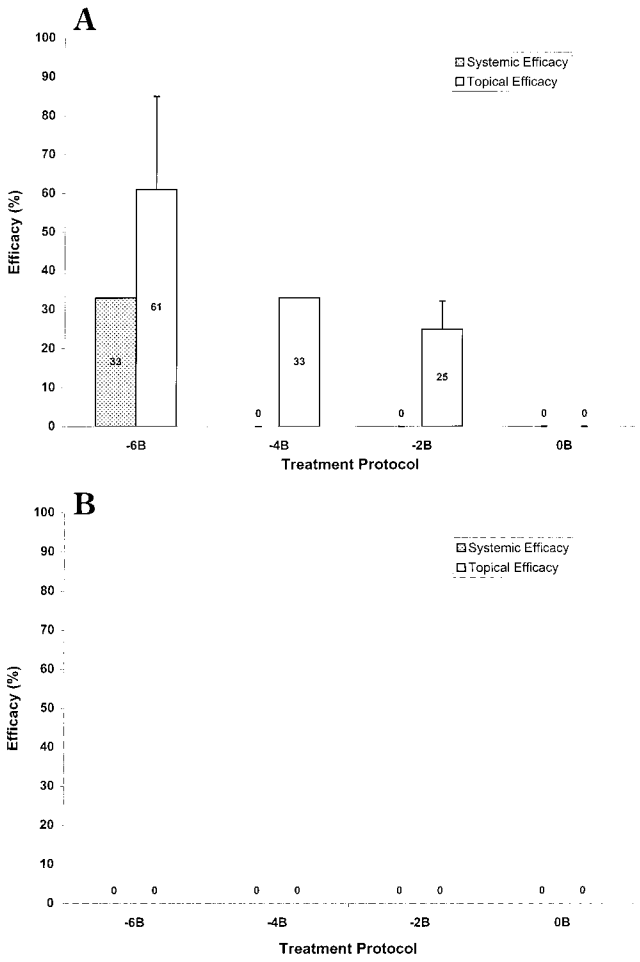

Figure 3—The topical and systemic efficacy of (A) 0.5% HPMPC and (B) 0.1% ACV in 95% DMSO as a function of the treatment protocol ($n = 2$).

Discussion

For ACV as the anti-herpes agent, starting treatment early did not alter its efficacy against cutaneous HSV-1 infections. These results extend the earlier work of Lee et al.,[1] who, employing controlled delivery transdermal systems, found that topical efficacy was independent of whether ACV treatment was started on day 0, 1, or 2 after

virus inoculation. The present data show that initiating treatment with ACV several days prior to virus inoculation essentially has the same effect as initiating treatment 1 day after virus inoculation. These results are consistent with our earlier findings[2] that topical efficacy of ACV formulations is a single valued function of *C** and can be explained by the relatively rapid pharmacokinetics of ACV at the cellular level.

Cell culture studies have shown that ACV is converted to its mono-, di-, and triphosphorylated forms (ACVp, ACVpp, and ACVppp, respectively) in cells infected with HSV-1.[10] The initial phosphorylation of ACV to ACVp is catalyzed by the HSV-1-induced thymidine kinase. Subsequent phosphorylation to ACVpp and ACVppp is carried out by cellular enzymes. In the uninfected cells, phosphorylation of ACV occurs to a very limited degree. The end product of phosphorylation, ACVppp, is a selective inhibitor of viral DNA polymerase and is the active metabolite responsible for efficacy.

The intracellular concentration of the active metabolite (species) can be regarded as a function of (a) *C** (extracellular drug concentration), (b) the rate of cellular uptake of the drug, (c) the rate of conversion of the drug to the active species, and (d) the rate of elimination of the active species. When the treatment with ACV is started prior to virus inoculation, step c is very slow. The uninfected cells lack the virally induced thymidine kinase which is responsible for conversion of ACV to ACVp (a required precursor for the active species). The rate of formation of ACVppp in the uninfected cells is approximately several orders of magnitude smaller than that in the infected cells.[11] On the other hand, step d, the rate of elimination of active species, is fairly rapid for ACV. In cell culture studies, the levels of ACVppp declined rapidly after the removal of the drug from the medium. The initial half-life of the triphosphate was 1.2 h in the absence of ACV in the medium with the levels reaching a plateau after 6 h.[11] The combined effect of the above would mean that the intracellular levels of the active species of ACV are negligible until the infection sets in. This can explain the results obtained with protocol B, where no protective effect was seen when ACV was applied as pretreatment only. With protocol A there was no additional effect afforded by ACV pretreatment. It should also be noted that in the infected cells, steps b−d are relatively rapid for ACV, and a steady state is reached quickly. Due to this rapid uptake and elimination, the intracellular level of the active ACV species and its efficacy seems to be a single-valued function of *C**, the extracellular drug concentration.

HPMPC is somewhat different from ACV in its mechanism of action. HPMPC is a nucleoside phosphonate (thus a nucleotide) analogue, in a way similar to ACVp. In cells, HPMPC is phosphorylated by host enzymes to its mono- and diphosphates (HPMPCp and HPMPCpp, respectively). HPMPCpp (similar to ACVppp) is a selective inhibitor of viral DNA polymerase and is the active species responsible for efficacy.[12] The HPMPCp−choline adduct is another intracellular moiety identified in cell culture studies. A significant difference from ACV is that the phosphorylation is carried out by the host cell enzymes and is therefore not dependent on virus infection. It has been shown that following treatment with a fixed extracellular HPMPC concentration, levels of HPMPCp, HPMPCpp, and HPMPCp−choline adduct in the cells infected with HSV-1 are the same as those in the uninfected cells.[12] This allows the opportunity for building up metabolites prior to virus infection and priming the cells to resist viral replication. It would also explain, at least in part, the results of Figure 3A where pretreatment with HPMPC acted prophylactically to resist a subsequent virus infection.

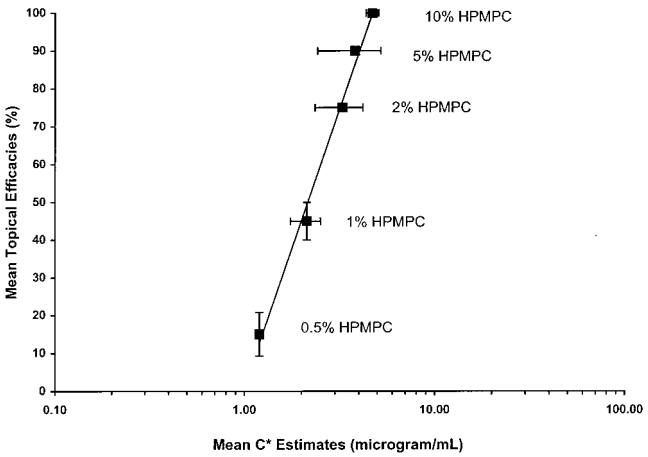

Figure 4—The topical efficacy of HPMPC as a function of *C**. The mean *C** estimates for different concentrations of HPMPC were obtained from combined in vivo–in vitro experiments ($n = 3$). The in vivo efficacies were obtained using protocol coded 1A ($n = 1$–6) (see text for details).

Another difference between ACV and HPMPC is their rate of cellular uptake and rate of conversion to the active metabolites. In cell culture studies (for ACV), the intracellular levels of ACVppp reach a maximum after 8 h of exposure of the cells to ACV.[11] For HPMPC, the intracellular levels of HPMPCpp continued to rise for 24 h after the cells were exposed to HPMPC.[13,14] More notable is the fact that the clearance of the metabolites of HPMPC from the cells is extremely slow. Various studies reported the intracellular half-life of HPMPCpp to be in the order of 17−24 h.[12−14] The long intracellular half-life of HPMPCpp after the extracellular drug is removed would be expected to lead to persistence of antiviral activity. The intracellular half-life of HPMPCp−choline adduct was reported to be >48 h. The long intracellular half-life of this adduct may produce an intracellular reservoir of drug from which the active metabolite is slowly released. This may contribute to the long duration of antiviral action of HPMPC. These facts further explain the protective effects seen with HPMPC pretreatment in Figure 3A. Also, because of the slow build-up of the metabolites and their slow elimination, it is expected that longer duration of exposure would result in higher levels of the active species and a correspondingly higher efficacy. This pattern is clearly seen in Figures 2A and 3A.

It must be noted that as for ACV, the intracellular concentration of active species of HPMPC, and in turn its in vivo efficacy, is also a function of its extracellular concentration or *C**. It was reported in cell culture studies that the HPMPCpp concentration inside the cell increased in response to increased extracellular HPMPC concentrations, and it was speculated that the antiviral efficacy should show dose responsiveness.[12] Results obtained for the treatment of HSV-1 infection with HPMPC in a murine model support this theory.[15] In a separate series of experiments we observed that for a fixed protocol coded 1A, increasing the dose of HPMPC from 0.5% to 10% resulted in an increase in the *C** values from 1.2 μg/mL to 4.7 μg/mL, which in turn resulted in an increase in topical efficacy from 17% to 100% (Figure 4). These results are very similar to those obtained with ACV.[2] However, for HPMPC, although efficacy is a function of *C**, it is not a single-valued function of *C**. Apart from *C**, the rate of its cellular uptake, rate of conversion to its active metabolites, and rate of elimination of active metabolites all have an effect on the efficacy. In conclusion, for ACV, because of the rela-

tively rapid pharmacokinetics, the intracellular level of the active metabolites as well as the in vivo efficacy may be time-independent and a single-valued function of the *C**. In contrast, for HPMPC, the in vivo efficacy is strongly time dependent and is not a single-valued function of *C** because of slow cellular kinetics of the drug and its active metabolites.

Accepted for publication February 16, 1999.

Abstract □ A spectrophotometric technique was used to determine the acidity constants of 4-dedimethylamino sancycline (Col-3), a new antitumor drug. The apparent pK_a values of Col-3 in 0.5% methanol aqueous media at approximately 25 °C with a constant ionic strength of 0.2 were calculated manually and graphically to be 5.64 ± 0.17 (pK_{a1}) and 8.35 ± 0.07 (pK_{a2}). In addtion, the computer program SQUAD was used to confirm Col-3 pK_a values. The pK_a values obtained by SQUAD were pK_{a1} 5.63 ± 0.14 and pK_{a2} 8.39 ± 0.04. These results are in agreement with the tetracycline-like structure of Col-3.

1. Introduction

4-Dedimethylamino sancycline (Col-3) is a new synthetic derivative obtained by chemical synthesis from sancycline methiodide. Col-3 exhibits in vitro and in vivo activity as an inhibitor of matrix metalloproteinases, tumor invasion, and metastasis of a variety of tumor types. Due to its oral biovailability, Col-3 has been formulated for oral administration by the National Cancer Institute (NCI).

Col-3 can be classified as the simplest tetracycline. Structurally, it differs from tetracycline by the absence of the 4-dimethylamino, 6-hydroxyl, and 6-methyl groups. The chemical structures of Col-3, sancycline, and tetracycline are presented in Figure 1.

Due to the absence of the 4-dimethylamino group, Col-3 cannot exist as a zwitterion and, therefore, differs from the tetracyclines in its acid−base properties. The main goal of this study is to determine the macroscopic acid dissociation constants of Col-3. Spectrophotometry was chosen for the determination of pK_a values of Col-3 because it is too insoluble ($S_w \approx 0.01$ mg/mL) for potentiometry, and also the ionized and neutral forms of this compound absorb differently in the UV/vis regions of the spectrum.

2. Materials and Methods

2.1. Materials—Col-3 was used as received from the National Cancer Institute (Bethesda, MD). Methanol was Burdick & Jackson (Muskegon, MI) HPLC grade. Phosphoric acid, monosodium phosphate, disodium phosphate, and sodium chloride were purchased from Sigma Chemical Co. (St. Louis, MO) and used without further purification.

2.2. Instrumentation—pH measurements were performed using a Corning pH meter (model no. 140) equipped with a combination glass electrode filled with potassium chloride gel. A Beckman DU-640 UV spectrophotometer was used for Spectral scan and fixed wavelength measurements.

Col-3	H	H	H

Figure 1—Chemical structure of Col-3, sancycline, and tetracycline.

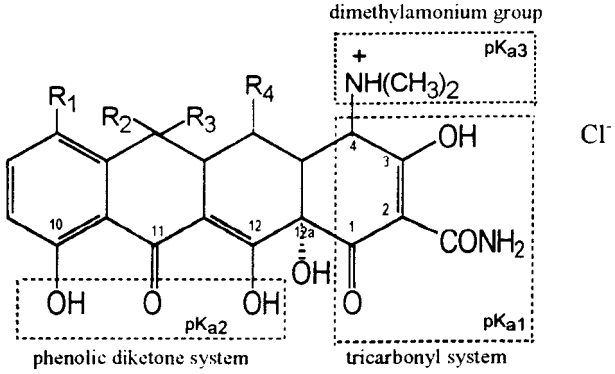

Figure 2—Structural groupings in the tetracyclines.

2.3. Methods—Aliquots of stock solution of Col-3 in methanol were added to buffers ranging from pH 2 to 11. All buffers were prepared with 0.05 M phosphate buffer and adjusted to an ionic strength of 0.2 with sodium chloride. Buffer solutions were spiked with 20 μL of the stock solution to produce 5.0 μg/mL (1.3×10^{-5} M) solutions with a final methanol concentration of 0.5%. The absorbance vs wavelength profiles of the resulting solutions were immediately obtained. All determinations were performed in duplicate at room temperature (approximately 25 °C).

3. Results and Discussion

It has been determined that the tetracycline antibiotics contain three ionizable groups[1−3] as shown in Figure 2. The first dissociation constant is due to the tricarbonyl system consisting of C1, C2, and C3 and their substitutes, the

second due to the phenolic diketone system consisting of C10, C11, C12 and their substitutes, and the third relates to the dimethylammonium functional group at C4.[2,3] The approximate pK_a values for each of these groups in some tetracycline derivatives are shown in Table 1.[1,3]

Col-3 has the first two of the acidic groupings of the tetracyclines. However, due to the absence of the dimethyammonium functional group at C4, Col-3 does not possess the third pK_a. The two pK_a values suggest that this drug can exist depending on the pH species as either the un-ionized, a monovalent anion, or a divalent anion. The UV/vis absorption spectra of Col-3 in aqueous solutions at various pH values are plotted in Figure 3.

As with most of the tetracyclines, an absorption band at about 260 nm is due to the β-tricarbonyl system, while a visible band at about 360 nm is produced by the phenolic diketone moiety.[4–7] Both anionic sites are stabilized by resonance, and they are separated from each other by carbon 12a. This sp^3 hybrid atom isolates the two light-absorbing regions and makes it possible to determine their pK_a values independently by spectrophotometry.

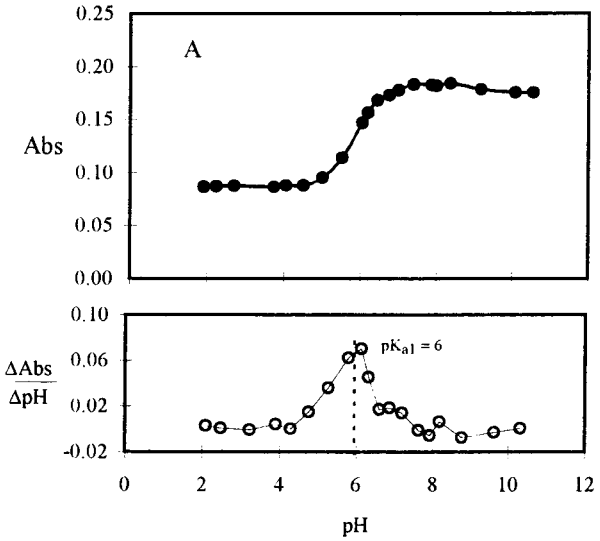

Figure 4—pH–absorbance profile of Col-3 at 286 nm (A) and the first derivative of absorbance respective to pH (B).

In this investigation, absorptions between 275 and 300 nm of the first band and between 370 and 390 nm of the second band were chosen as the analytical wavelengths for determining the first and the second pK_a values, respectively. These two wavelength intervals were chosen due to their maximum absorbance changes with pH.

The absorbance–pH curve of Col-3 at 286 nm is shown in Figure 4. The profile shows that the absorbance of the drug increases in the pH range of 4.0 to 7.0 and is constant below pH 4 and above pH 7.0. At this wavelength, the absorbance of the ionized species is higher than that of the un-ionized species, while the mono- and divalent species cannot be differentiated. The first pK_a of Col-3 was calculated at 275–300 nm using:

$$pK_a = pH + \log \frac{A_i - A}{A - A_u} \quad (1)$$

where A_i and A_u are the absorbance of the ionized and the un-ionized species, respectively. The results are shown in Table 2. The calculated pK_{a1} (5.64) is approximately equal to the pK_a determined using the derivative graph shown in Figure 4B.

Similarly, the second pK_a was calculated using the absorbance changes at 370–390 nm over the pH range of 7.39 to 8.37. At these wavelengths, the absorbance of divalent species is higher than that of the monovalent species, while the un-ionized and monovalent species cannot be differentiated. Thus, eq 1 can be used to calculate the second pK_a. The results are shown in Table 2. Both methods eq 1 and derivative graph were used to determine

the second pK_a as previously. The calculated value of 8.35 is again in good agreement with the value determined from the derivative graph.

From the results, the spectroscopically determined pK_a values of Col-3 are 5.64 (pK_{a1}) and 8.35 (pK_{a2}). Notice that its second pK_a value which corresponds to the loss of a proton from the phenolic diketone moiety is closed to those of the tetracyclines (∼7.8). However, the first pK_a value, which is due to the loss of a proton from the tricarbonyl methane system, is shown to be over two pH units higher than that those of the tetracyclines (∼3.3). This difference is due to the absence of the electron-withdrawing dimethylammonium group at the C-4. A similar increase of the pK_a value of this system due to the absence of the dimethylammonium group is found in desdedimethylaminotetracycline, which has a pK_a value of 5.94. In addition to the above methods, the computer program SQUAD (Stability QUotients from Absorbance Data) was used to confirm Col-3 pK_a values.[8] SQUAD calculates overall stability constant values such as pK_a values by means of a nonlinear least-squares approach. The data fed to SQUAD are absorption spectra, Col-3 total concentration, and a chemical model to describe the system (i.e., $H_2A \rightarrow HA^- + H^+ \rightarrow A^{2-} + 2H^+$). The p$K_a$ values obtained by SQUAD were pK_{a1} 5.63 ± 0.14 and pK_{a2} 8.39 ± 0.04. Note that the manually calculated (Table 2) and computer caluculated (SQUAD) pK_a values are in good agreement.

4. Conclusions

The macroscopic acid dissociation constants of Col-3 were determined by means of a spectrophotometric technique. The apparent pK_a values of Col-3 in 0.5% methanol aqueous media at approximately 25 °C with a constant ionic strength of 0.2 were calculated manually and graphically to be 5.64 ± 0.17 (pK_{a1}) and 8.35 ± 0.07 (pK_{a2}). The SQUAD calculated vales were pK_{a1} 5.63 ± 0.14 and pK_{a2} 8.39 ± 0.04. These results are in agreement with the tetracycline-like structure of Col-3.

Accepted for publication February 22, 1999.

Abstract □ A curve-fitting program based on the Finite Element Method, MULTI(FEM), was developed to model nonlinear local disposition of a drug in the liver under non-steady-state conditions. The program was written in FORTRAN on an IBM-compatible personal computer. The validity of MULTI(FEM) was confirmed by analyzing the outflow kinetics of oxacillin (a model drug) following a pulse input to isolated, perfused rat livers, according to both linear and nonlinear dispersion models. Four dose levels (300, 1000, 3000, and 5000 μg) of oxacillin were administered to observe the dose-dependency in the hepatic local disposition. First, the individual outflow time-profiles at the same dose were averaged, and the average time-profile was analyzed by MULTI(FEM) based on linear dispersion models to yield a single curve fit. The fitted parameters at each dose level were compared with parameters estimated using MULTI(FILT), a program based on fast inverse Laplace transform, to analyze linear pharmacokinetics. The estimated parameters by MULTI(FEM) were in good agreement with those by MULTI(FILT). The apparent elimination rate constant (k_e) decreased with an increase in dose, whereas other parameters showed no discernible dependency on an increase of dose. Second, the average outflow time-profiles at the four dose levels were simultaneously analyzed by MULTI(FEM) based on dispersion models featuring Michaelis–Menten elimination. The outflow time-profiles of oxacillin were well approximated by a two-compartment dispersion model with central Michaelis–Menten elimination. The maximum elimination rate constant (V_{max}) and the Michaelis constant (K_m) were estimated to be 1520 μg/mL/min and 41.3 μg/mL, respectively. Thus, the capability of MULTI(FEM) was demonstrated in evaluating capacity-limited local disposition in the liver.

Introduction

The liver is an essential organ for the metabolism and elimination of drugs. After oral administration, a drug absorbed into the portal system may be eliminated to a large extent during its first pass through the liver. Thus, the liver shields the body from the excess inflow of xenobiotics into the systemic circulation. However, hepatic clearance can exhibit capacity-limited kinetics. Therefore, when the portal drug concentration is extremely high and/or metabolic function is compromised by a hepatic malfunction or drug−drug interaction, a greater fraction of the absorbed dose escapes into the systemic circulation, bypassing first-pass hepatic elimination. Thus, the evaluation of capacity-limited (nonlinear) disposition in the liver is crucial for understanding the influence of dose and absorption kinetics on drugs which undergo significant first-pass metabolism.

In situ liver perfusion experiments following infusion or bolus injection have often been used to assess hepatic local disposition of drugs in vivo. The time-profile of drug outflow from the liver following a pulse input is more informative of intrahepatic disposition than data obtained at steady state. The well-stirred and parallel-tube models offer straightforward analysis of steady-state kinetic data from perfusion experiments.[1−6] In contrast, the dispersion model[5−11] and the distribution model[5,6,12−15] have been developed to explain the outflow time-profile following a pulse input. The dispersion model equations with flexible initial and boundary conditions can explain a variety of outflow drug kinetics at non-steady-state.[7,9] A local disposition model that features several linear dispersion processes has been proposed to analyze the distribution of a drug in the perfused rat hindlimb.[16] However, the dispersion model equations, which are second-order partial differential equations, are difficult to solve analytically. Linear mass-balance rate equations can readily be solved by the Laplace transform. MULTI(FILT)[9−11,18] is one well-recognized computer program for curve-fitting that is based on the transformed equations. However, no analysis program is available to quantitatively evaluate dose-dependent, non-steady-state, local disposition kinetics which are expressed by nonlinear partial differential equations.

Thus, the purpose of the present investigation is to develop a new curve-fitting program, MULTI(FEM), based on the Finite Element Method which has been used in structural[19,20] and hydrodynamic analyses.[21−23] MULTI(FEM) enables the use of local disposition models described by nonlinear partial differential equations with dispersion terms. To confirm the validity of MULTI(FEM), a rat liver perfusion experiment was performed at several dose levels of oxacillin to represent a typical local disposition system of a drug. First, linear dispersion models were adopted in the fitting of data at each dose level, and the estimated parameters were compared with those by MULTI(FILT). Second, outflow time-profiles at the different doses (300, 1000, 3000, and 5000 μg), which were confirmed to exhibit dose-dependent (nonlinear) kinetics, were simultaneously analyzed by MULTI(FEM) based on dispersion models with Michaelis−Menten elimination.[24]

Theory

Five dispersion models (two linear and three nonlinear) were considered. The linear dispersion models involve one-compartment model and two-compartment models with either central and peripheral elimination. However, it is known that the linear two-compartment models, unlike nonlinear models, are not kinetically distinct, because the parameters in the two-compartment model with central elimination are convertible (mapable) to those with peripheral elimination.[9] Thus, the only central elimination process is adopted in our analysis of the linear two-compartment dispersion model. In contrast, the nonlinear two-compartment model with central elimination is kineti-

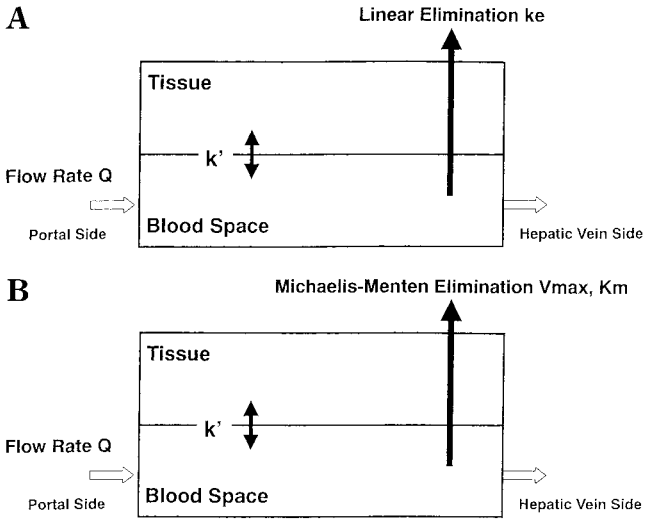

Figure 1—One-compartment dispersion model with linear elimination (A) and nonlinear elimination (B).

cally distinguishable from that with peripheral elimination. Therefore, the one-compartment model with Michaelis–Menten elimination and two-compartment models with central and peripheral Michaelis–Menten elimination were considered as the nonlinear dispersion models.

One-Compartment Dispersion Model—In the one-compartment dispersion model, complete mixing between perfusate and hepatic tissues is assumed as shown in Figure 1A. The equation of this model with linear elimination is described by

$$(1 + k')\frac{\partial C(t,v)}{\partial t} = D_c\frac{\partial^2 C(t,v)}{\partial v^2} - Q\frac{\partial C(t,v)}{\partial v} - k_e C(t,v) \quad (1)$$

where C(t,v) is the perfusate concentration in the liver, Q is the perfusate flow rate, k' is the partition ratio which is the measure of extent of drug partition into the hepatic tissue, D_c is the corrected dispersion coefficient, v is the volume axis, and k_e is the first-order elimination rate constant.

For a pulse input, eq 1 can be solved by Laplace transform under the initial and boundary conditions given by eq 2. The image equation is given by eq 3.[9]

$$C(0,v) = 0, \quad C(t,0) = \frac{M}{Q}\delta(t) \quad \text{and} \quad C(t,\infty) = 0 \quad (2)$$

$$\tilde{C}(s) = \frac{M}{Q}\exp\left[\left\{\frac{Q}{2D_c} - \sqrt{\left(\frac{Q}{2D_c}\right)^2 + \frac{k_e + (1 + k')s}{D_c}}\right\}V_B\right] \quad (3)$$

where V_B is the blood volume which was assumed to be 15.5% of liver weight.[25,26]

If the drug is eliminated according to Michaelis–Menten equation as shown in Figure 1B, the one-compartment dispersion model is described by

$$(1 + k')\frac{\partial C(t,v)}{\partial t} = Dc\frac{\partial^2 C(t,v)}{\partial v^2} - Q\frac{\partial C(t,v)}{\partial v} - \frac{V_{max}}{K_m + C(t,v)}C(t,v) \quad (4)$$

where V_{max} is the maximal elimination rate, and K_m is the Michaelis constant. It is noted here that V_{max} and K_m are the lumped parameters which reflect the transfer of a drug from the sinusoid to the tissue space, the uptake into hepatocytes by active transport, and the enzymatic activity in hepatocytes.

Two-Compartment Dispersion Model—A two-compartment dispersion model with linear elimination from central compartment, as shown in Figure 2A, is described by eq 5. The equilibrium distribution phase, which is kinetically included in the central compartment of the liver, was predicted in the previous paper using BOF-4272, a drug for treatment of hyperuricemia.[26]

$$\begin{cases} \dfrac{\partial C_1(t,v)}{\partial t} = Dc\dfrac{\partial^2 C_1(t,v)}{\partial v^2} - Q\dfrac{\partial C_1(t,v)}{\partial v} - \\ \qquad k_{12}C_1(t,v) + \epsilon k_{21}C_2(t,v) - keC_1(t,v) \\ \dfrac{\partial C_2(t,v)}{\partial t} = \dfrac{1}{\epsilon}k_{12}C_1(t,v) - k_{21}C_2(t,v) \end{cases} \quad (5)$$

where C_1(t,v) and C_2(t,v) are the concentrations in the central and peripheral compartments, respectively, k_{12} and k_{21} are the forward and backward transfer rate constants between central and peripheral compartments, ϵ is the volume ratio of peripheral compartment to central compartment, and k_e is the first-order elimination rate constant. Under the initial and boundary conditions given by eq 6 for a pulse input of drug, the image equation for the central compartment is described by eq 7.[9]

$$C_1(0,v) = 0, \quad C_2(0,v) = 0, \quad C_1(t,0) = \frac{M}{Q}\delta(t), \quad C_1(t,\infty) = 0 \quad \text{and} \quad C_2(t,0) = 0 \quad (6)$$

$$\tilde{C}(s) = \frac{M}{Q}\exp\left[\left\{\frac{Q}{2Dc} - \sqrt{\left(\frac{Q}{2Dc}\right)^2 + \frac{1}{Dc}\left(s + k_{12} + k_e - \frac{k_{12}k_{21}}{s + k_{21}}\right)}\right\}V_B\right] \quad (7)$$

where V_B is the volume of central compartment. It is noted that the volume ratio ϵ disappears in eq 7.

A two-compartment dispersion model with central Michaelis–Menten elimination (Figure 2B) is described by eq 8.

$$\begin{cases} \dfrac{\partial C_1(t,v)}{\partial t} = Dc\dfrac{\partial^2 C_1(t,v)}{\partial v^2} - Q\dfrac{\partial C_1(t,v)}{\partial v} - \\ \qquad k_{12}C_1(t,v) + \epsilon k_{21}C_2(t,v) - \dfrac{V_{max}}{K_m + C_1(t,v)}C_1(t,v) \\ \dfrac{\partial C_2(t,v)}{\partial t} = \dfrac{1}{\epsilon}k_{12}C_1(t,v) - k_{21}C_2(t,v) \end{cases} \quad (8)$$

A two-compartment dispersion model with peripheral Michaelis–Menten elimination (Figure 2C) is described by eq 9.

$$\begin{cases} \dfrac{\partial C_1(t,v)}{\partial t} = Dc\dfrac{\partial^2 C_1(t,v)}{\partial v^2} - Q\dfrac{\partial C_1(t,v)}{\partial v} - \\ \qquad k_{12}C_1(t,v) + \epsilon k_{21}C_2(t,v) \\ \dfrac{\partial C_2(t,v)}{\partial t} = \dfrac{1}{\epsilon}k_{12}C_1(t,v) - k_{21}C_2(t,v) - \\ \qquad \dfrac{V_{max}C(t,v)}{K_m + C_2(t,v)} \end{cases} \quad (9)$$

Although eqs 4, 8, and 9 are not solvable by Laplace transform, a numerical solution can be achieved with MULTI(FEM).

Danckwerts's condition[27] given by eq 10 is adopted as the boundary condition in MULTI(FEM), because it is easily programmed in MULTI(FEM).

$$Dc\left(\frac{\partial C(t,v)}{\delta v}\right)_{v=0} = QC(t,0) \quad \text{and} \quad Dc\left(\frac{\partial c(t,v)}{\partial v}\right)_{v=V_B} = 0 \tag{10}$$

Numerical Procedure

MULTI(FEM) written in Microsoft FORTRAN (ver. 3.2) was newly developed on a IBM-compatible personal computer (PentiumII, 266 MHz and 96 MB). Equations 3 and 7, which are given as Laplace-transformed equations, were numerically solved by fast inverse Laplace transform (FILT).[9−11] Equations 1 and 5, which are given as linear partial differential equations, were numerically solved by MULTI(FEM). The outflow time-profiles following the same dose of oxacillin (300, 1000, 3000, or 5000 μg) were averaged, and the average time-profile at each dose was fitted by MULTI(FILT) and MULTI(FEM) based on the linear dispersion model. Equations 4, 8, and 9, which are given as nonlinear partial differential equations, were fitted by MULTI(FEM) simultaneously to all four average time-profiles at the different doses.

Ten sets of outflow time courses at the four dose levels were generated by adding 10% random normal errors to theoretical curves calculated from parameter values estimated by MULTI(FEM). The generated time courses were fitted by MULTI(FEM), and the estimated parameters were compared with the original parameters to verify the stability of MULTI(FEM).

Materials and Methods

Chemicals—Oxacillin was purchased from Sigma Chemical Co. (St. Louis, MO). Sodium pentobarbital solution (NEMBUTAL forcanimal injection, Abbott Laboratories, Chicago, IL) was used to anesthetize the rats. All other reagents used for preparing the perfusate and HPLC mobile phase were of guaranteed reagents grade or HPLC grade.

Animals—Male Wistar rats weighing 200−240 g were purchased from Shimizu Experimental Materials Co. (Kyoto, Japan). All rats were maintained on standard rat chow, and water was allowed ad libitum before the experiments.

Single-Pass Perfusion Experiment Using Rat Liver—Isolated rat livers were prepared and perfused according to the Mortimore method[28] using Krebs-Ringer bicarbonate buffer (pH 7.4) containing 10 mM glucose and saturated with 95% O_2−5% CO_2. The bile duct was cannulated with a polyethylene tube (PE10). The perfusate was maintained at 37 °C and delivered by a roller pump (RP-NP2, Furue Science Co., Ltd., Tokyo, Japan) through a polyethylene cannula (1.67 mm o.d.) placed in the portal vein. The perfusate flow rate was 14.6−15.6 mL/min, and the recoveries of perfusate were greater than 99%. The bile flow rate was measured to monitor the viability of the liver. The liver perfusion data were rejected when the bile flow rate was less than 4 μL/min. At 20 min after the operation, a 250 μL volume of oxacillin in saline solution (1.2 mg/mL, $n = 3$; 4.0 mg/mL, $n = 3$; 12.0 mg/mL, $n = 2$; 20 mg/mL, $n = 3$) was injected into the liver using a six-way valve injector. The outflow sample was collected at intervals of 1 s. After the perfusate collection, the validity of the perfusion experiment was confirmed by uniform coloration and decoloration of the liver after injection of Evans Blue. The lag time was calculated from the total void volume (half volume of the injector tube plus full volume of the catheter) divided by the perfusate flow rate, and was subtracted from sampling times. The liver weights were 8.66−12.0 g.

Analytical Procedure—The perfusate sample (0.2 mL) was diluted up to 10-fold with blank perfusate, when oxacillin concentration was too high. Acetonitrile (0.3 mL) was added to the sample (0.2 mL) to precipitate proteins, and an aliquot of the supernatant (15 μL) obtained by centrifugation at 2000 rpm was injected into HPLC. An HPLC system (LC-10A series, Shimadzu Company, Kyoto, Japan) was equipped with the Chemcosorb 5-ODS−H reversed-phase column (5 μm, 150 × 4.6 mm i.d., Chemco Scientific Company, Ltd., Osaka, Japan). The HPLC conditions described by Yano et al.[9] were modified as follows. The mobile phase consisted of a 1:1 (v/v) mixture of 100 mM sodium acetate buffer (pH5.2)/methanol. Mobile phase flow rate, detection wavelength, and column temperature were 1.0 mL/min, 220 nm, and 40 °C, respectively. The peak area was recorded on Chromatopack C-R6A (Shimadzu Company). A linear calibration plot was made over the oxacillin concentration range of 1.0−300 μg/mL, according to the method of the variance-stabilizing transformation.[29] Accuracy and precision were within 10% at all concentrations.

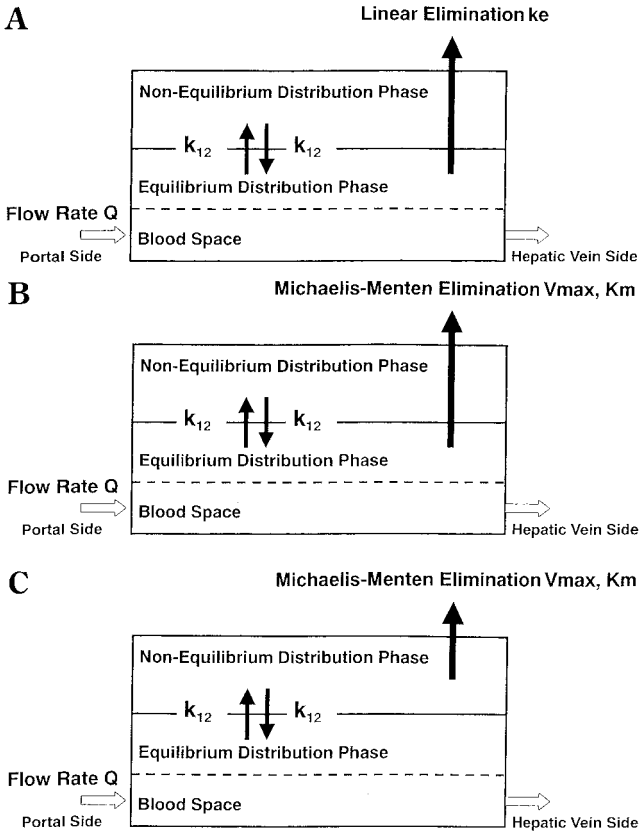

Figure 2—Two-compartment dispersion model with linear elimination (A), with central Michaelis–Menten elimination (B), and with peripheral Michaelis–Menten elimination (C).

Results and Discussion

Figure 3 presents the average outflow time-profiles and the predicted time courses by MULTI(FILT) and MULTI(FEM) based on a two-compartment dispersion model with linear elimination. Table 1 shows the parameter estimates. The curve fittings based on the one-compartment dispersion model gave much larger Akaike's Information Criterion (AIC)[30] values than those based on the two-compartment model and were deemed unacceptable. The predicted time courses by MULTI(FILT) and MULTI(FEM) agreed well with the experimental data points. The pharmacokinetic parameters by MULTI(FEM) coincided well with those by MULTI(FILT), which demonstrates the validity of MULTI(FEM). It is noted in Table 1 that k_e increases with a decrease in dose from 5000 to 300 μg, whereas other parameters show no systematic change with dose. Thus, this suggested that the average outflow time-profiles at the four dose levels would be better described by a dispersion model with capacity-limited elimination.

Figure 4 shows the outflow time profiles of oxacillin and the curves predicted by MULTI(FEM) fit to the two-

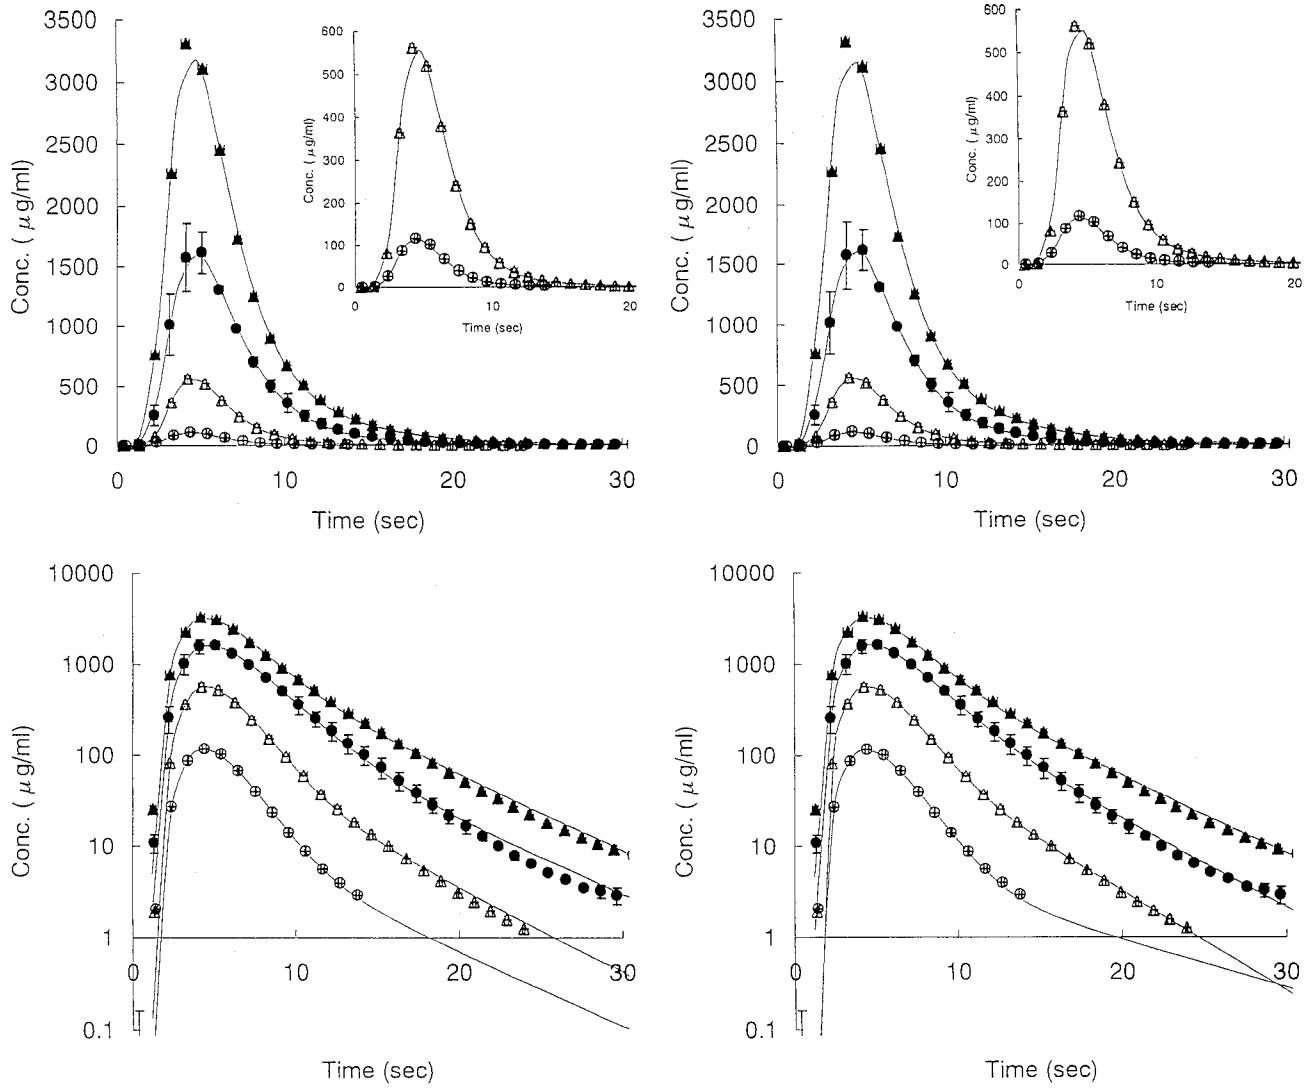

Figure 3—Outflow time-profiles averaged at 300 μg (○, $n = 3$), 1000 μg (△, $n = 3$), 3000 μg (●, $n = 2$) and 5000 μg (▲, $n = 3$) doses of oxacillin and theoretical curves predicted by MULTI(FILT) (left) and MULTI(FEM) (right). The time-profiles are given by means and standard deviations in two-compartment dispersion model with linear elimination. The bottom figures and the inserts at the top show the semilogarithmic and the expanded plots, respectively.

Table 1—Kinetics Parameters of Oxacillin Calculated Using MULTI(FILT) and MULTI(FEM) in Two-Compartment Dispersion Model with Linear Elimination

	dose (μg)			
	5000	3000	1000	300
	MULTI(FILT)			
D_c (mL^2/min)	1.93	2.37	1.63	1.71
V_B (ml)	1.46	1.63	1.49	1.51
k_{12} (min^{-1})	2.19	0.929	1.19	1.02
k_{21} (min^{-1})	13.4	11.7	13.8	11.7
k' (= k_{12}/k_{21})	0.163	0.0796	0.0856	0.0871
k_e (min^{-1})	1.01	2.52	4.14	8.80
	MULTI(FEM)			
D_c (mL^2/min)	2.10	2.40	1.68	1.95
V_B (mL)	1.45	1.58	1.47	1.53
k_{12} (min^{-1})	2.31	1.53	1.54	0.881
k_{21} (min^{-1})	13.9	15.2	16.4	7.44
k' (= k_{12}/k_{21})	0.167	0.101	0.0942	0.118
k_e (min^{-1})	1.05	2.58	4.24	8.65

compartment dispersion models with Michaelis–Menten elimination from the central compartment and from the peripheral compartment. The local disposition parameters estimated from curve-fittings are shown in Table 2. Because AIC assumed a smaller value for the central elimination model (AIC = 854) than for the peripheral elimination model (AIC = 996), the two-compartment dispersion model with central capacity-limited elimination was considered to better represent the outflow time-profiles of oxacillin. The maximum elimination rate constant (V_{max}) and the Michaelis constant (K_m) were estimated to be 1520 μg/mL/min and 41.3 μg/mL, respectively. Since the AIC based on the nonlinear one-compartment model was much larger than those based on two-compartment models, the results were not presented. To verify the stability of MULTI(FEM) fits, 10 sets of outflow time courses at four dose levels were generated by adding 10% random normal errors to theoretical curves calculated using mean parameter estimates from the earlier data fitting. The generated time courses were fitted by MULTI(FEM). The parameter values from the fit of noise-added data (D_c: 2.20 ± 0.18 mL^2/min, V_B: 1.50 ± 0.02 mL, k_{12}: 3.45 ± 0.21min^{-1}, k_{21}: 10.8 ± 0.49min^{-1}, k′: 0.319 ± 0.026, V_{max}: 1520 ± 120 μg/mL/min and K_m: 41.5 ± 6.8 μg/mL) were in good agreement with the original parameter estimates (D_c: 2.14 mL^2/min, V_B: 1.49 mL, k_{12}: 3.45 min^{-1}, k_{21}: 10.7 min^{-1}, k': 0.322, V_{max}: 1520 μg/mL/min and K_m: 41.3 μg/mL), respectively.

In conclusion, dose-dependency kinetics in local organ disposition kinetics at steady state[2,3] has been well-

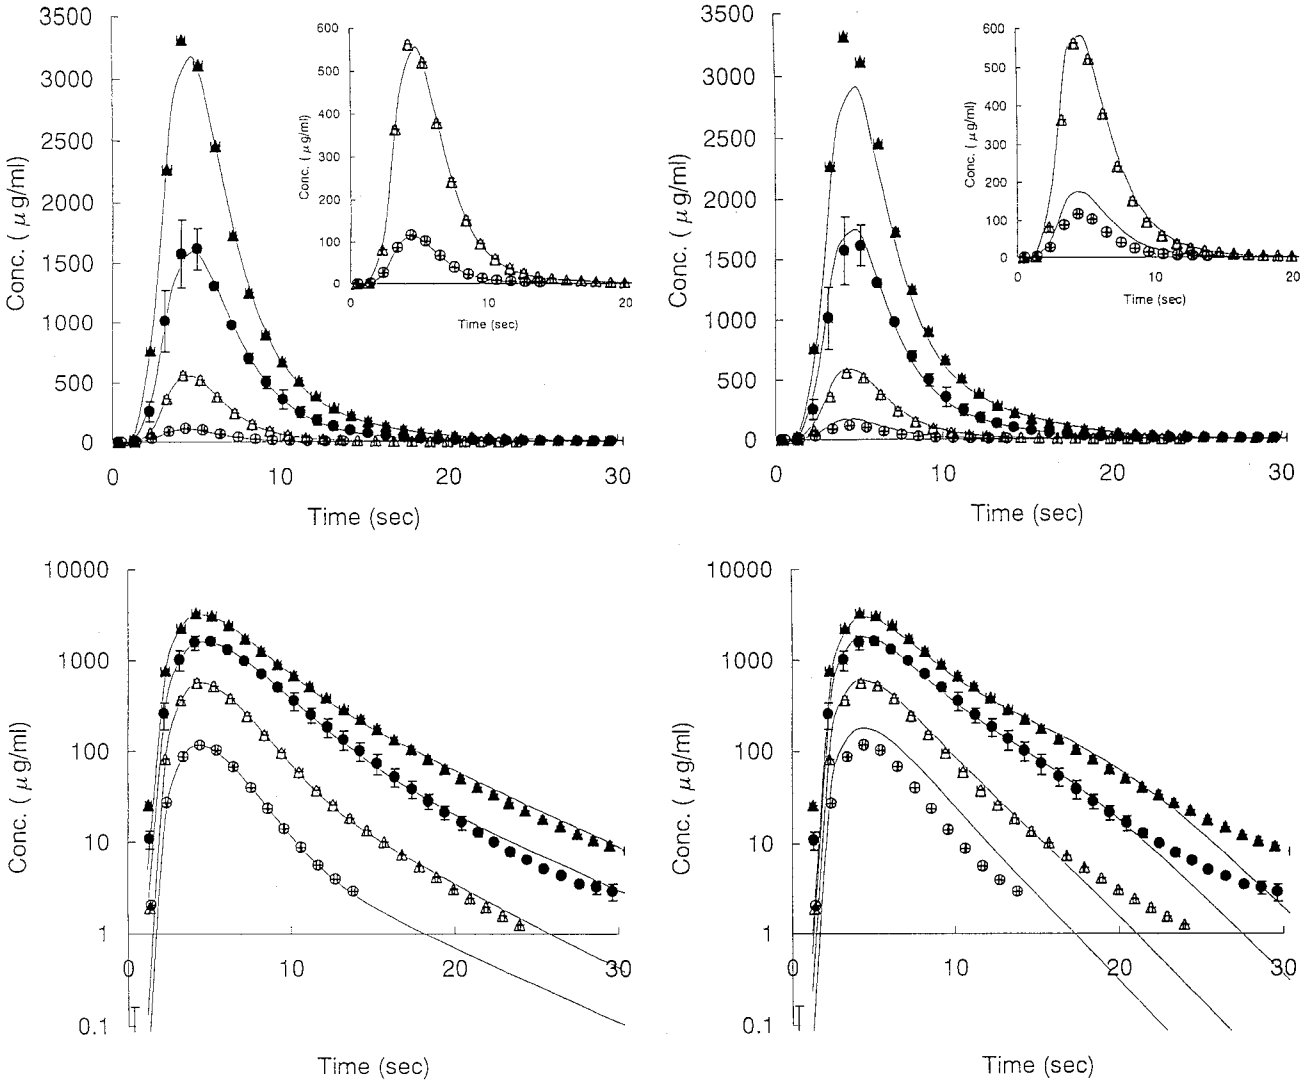

Figure 4—Outflow time-profiles of oxacillin (300 μg (○, $n = 3$), 1000 μg (○, $n = 3$), 3000 μg (●, $n = 2$), 5000 μg (▲, $n = 3$)) and theoretical curves predicted by MULTI(FEM) based on two-compartment dispersion models with Michaelis–Menten elimination from central compartment (left) and from peripheral compartment (right). The time-profiles are given by means and standard deviations. The bottom figures and the inserts at the top show the semilogarithmic and the expanded plots, respectively.

Table 2—Kinetics Parameters of Oxacillin Calculated Using MULTI(FEM) in Two-Compartment Dispersion Model with Central and Peripheral Michaelis–Menten Elimination

	central	peripheral
D_c (mL^2/min)	2.14	1.84
V_B (mL)	1.49	1.45
k_{12} (min^{-1})	3.45	4.93
k_{21} (min^{-1})	10.7	7.45
k' (= k_{12}/k_{21})	0.322	0.662
V_{max} (μg/mL/min)	1520	4250
K_m (μg/mL)	41.3	200
AIC	854	996

characterized, but investigations of the disposition under transient or non-steady-state conditions have been scarce. MULTI(FEM) enables the evaluation of dose-dependent drug clearance kinetics in the hepatic perfusion system following a pulse input, i.e., to allow detailed description of intrahepatic Michaelis−Menten disposition kinetics in the liver. The present analysis further showed that the central and peripheral elimination models can be distinguished based on perfusate outflow data under the nonlinear condition. With the availability of MULTI(FEM), the dispersion model may be applicable to analyzing the dose-dependency in other perfused organ experiments, such as those with intestine and kidney.

Accepted for publication February 12, 1999.

Abstract □ Four diastereomeric propranolol ester prodrugs (1*S*2*S*, 1*S*2*R*, 1*R*2*S*, 1*R*2*R*) were synthesized by treating pure *R*- and *S*-propranolol hydrochloride with pure enantiomers *R*- and *S*-phenylbutyryl chloride. A HPLC technique using α-1 acid glycoprotein (chiral AGP) column was developed to study the racemization of propranolol enantiomers during synthesis and hydrolysis studies. A reversed phase HPLC method was also developed to simultaneously analyze propranolol and the ester prodrug. Hydrolysis of these esters was studied in different rat tissue homogenates, i.e., liver, intestine, plasma, skin, brain, and pure plasma cholinesterases, i.e., butyryl cholinesterase (EC 3.1.1.8) and acetyl cholinesterase (EC 3.1.1.7). In vitro percutaneous permeation studies across full thickness shaved rat skin were performed using standard side-by-side diffusion cells at 37 °C. The disappearance of the diastereomeric ester prodrugs in rat tissue homogenates followed apparent first-order kinetics and was stereoselective. The ratio of brain to plasma hydrolytic rate constants are 27.8, 5.58, 6.07, and 2.97 for 1*S*2*S*, 1*R*2*R*, 1*R*2*S*, and 1*S*2*R* esters, respectively. Hydrolysis of all four diastereomeric ester prodrugs was faster by acetyl cholinesterase than butyryl cholinesterase and is stereoselective. The permeability coefficients [$K_p \times 10^3$ (cm h^{-1})] are 1.40 ± 0.30, 1.41 ± 0.27, 42.20 ± 1.24, 29.26 ± 3.41, 16.27 ± 3.12, 12.99 ± 2.84 for (*R*)-propranolol, (*S*)-propranolol, 1*S*2*S*, 1*R*2*S*, 1*S*2*R*, and 1*R*2*R* ester prodrugs, respectively. The results indicate that the 1*R*2*S* diastereomeric ester prodrug of propranolol shows greatest stability in liver and intestinal tissues while it exhibits fairly rapid conversion in plasma. The results also suggest the configuration on the second chiral carbon atom to be the determinant in the rate of hydrolysis of all the diastereomeric prodrugs in all biological media examined. The K_p of all four prodrugs markedly increased compared to that of the parent drug, with 1*S*2*S* showing a 30-fold increase in skin permeability, the highest among all four prodrugs.

Introduction

Propranolol (PL), an adrenergic β-blocker, is a widely accepted and clinically effective cardiovascular agent, indicated in the treatment of angina pectoris, hypertension, and cardiac arrhythmia. Very low and variable bioavailability of the drug follows oral administration, which may be attributed to extensive stereoselective hepatic first-pass metabolism.[1−4] Alternative noninvasive administration modes including rectal,[5] transdermal,[6] and nasal[7,8] routes have been explored to improve the systemic bioavailability of propranolol. These routes can allow the drug to reach the systemic circulation, bypassing the liver and escaping first-pass metabolism. Since one of the major metabolites is the *O*-glucuronide of PL,[9] O-acylation of PL may be a potentially useful way to reduce presystemic metabolism, as has already been demonstrated.[10,11]

The transdermal route of administration also allows systemic drug absorption bypassing hepatic first-pass effects, thus achieving higher bioavailability of the drug.[6,12] However, relative impermeability of lipoidal stratum corneum, the outermost keratinized layer of skin, offers considerable resistance to the permeation of PL through the skin. The prodrug approach represents an alternative and promising method of enhancing the skin permeability of drugs by increasing their lipophilicity. Permeability characteristics of individual enantiomers of chiral species in comparison to their racemates have been studied in some detail recently. Wearly et al.[13] reported that the maximum flux of a new antifungal compound from a saturated solution, through human cadaver skin, was 1 order of magnitude lower for the racemic compound than that of either of its enantiomers. Roy et al.[14] compared the permeability of pure enantiomers of keterolac acid, a potent analgesic, through human cadaver skin, and showed that there was no significant difference in the intrinsic permeability coefficients of the racemic compound and the enantiomers. Touitou et al.[15] proposed the Melting Temperature Membrane Transport concept, which showed the simple dependence of permeation flux ratio on the melting behavior of chiral compounds.

Propranolol has two optical isomers, dextro-PL ((*R*)-PL) and levo-PL ((*S*)-PL). The drug shows stereoselective activity, i.e., the S-isomer is 100 times more potent than the R-isomer as a β blocker.[16] A number of studies have demonstrated stereoselective disposition of the drug in various species including man[17] and dog.[18] In addition, Stoschitzky et al.,[19] reported that half the dose of optically pure (*S*)-propranolol generates an equally effective β-adrenergic receptor agonist activity relative to the racemic mixture and that (*R*)-PL inhibits thyroid hormone activity.

Esterases are ubiquitous in nature and have broad substrate specificity. Stereoselective hydrolysis of ester prodrugs including PL prodrugs is largely dependent on the type of species and the tissue of origin.[20−25] Variability in the esterase content may have a significant effect on the rate of regeneration, tissue uptake, and disposition of the prodrug. Thus, consideration of stereoselectivity during prodrug design is very important. The chirality of a compound is critical to receptor-binding interactions: therefore, differences in biological activity are common. Chirality can also effect the way in which molecules fit together in a crystal structure. Diastereomers may differ in crystal structure and may cause differences in melting point and thereby differences in solubilities.[13] Therefore, diastereomeric prodrugs having at least two chiral centers may

significantly alter the permeation of the enantiomeric parent drug.

This research article describes the influence of a chiral promoiety on the stereoselective hydrolysis and permeation of *R* and *S* propranolol prodrugs. Specifically the stereoselective hydrolysis and skin permeation of four diastereomeric PL ester prodrugs have been studied. 2-Phenylbutyryl chloride was chosen as a model chiral promoiety for the syntheses of four diastereomeric ester prodrugs of PL, as it offers both chirality and the aromatic group, which would aid in increasing the lipophilicity considerably.

Materials and Methods

Materials—The pure (*R*)- and (*S*)-propranolol hydrochloride, (*R*)- and (*S*)-2-phenylbutyric acids and pure esterases, acetyl cholinesterase (EC 3.1.1.7) and butyryl cholinesterases (EC 3.1.1.8), were obtained from Sigma Chemical Co. (St. Louis, MO). All other reagents were of analytical grade and used as received (Fisher Scientific).

Animals—Male Sprague Dawley rats (250−275 g) were obtained from Harlan Sprague Dawley, Indianapolis, IN. Animals were fasted overnight prior to conducting any experiment. Water was allowed ad libitum.

Synthesis of Acid Chloride—The acid chloride was synthesized by slightly modifying a previously published report.[26] Briefly, pure (*R*) or (*S*)-2-phenylbutyric acid (200 mg) was mixed with thionyl chloride (0.24 mL) (freshly redistilled) at 0 °C and then kept at 70 °C for 30 min. Dry benzene was added, and the mixture was evaporated to dryness. Another portion of dry benzene was then added, and the mixture was reevaporated to remove the last traces of thionyl chloride. The residue was dissolved in 2.4 mL of dry benzene and stored in the refrigerator in a glass-stoppered flask. The new acid chloride bands in the IR spectra appeared at about 1810 cm^{-1} with the concomitant disappearance of hydroxyl bands. The purity of the acid chloride was determined by TLC, HPLC, and ^1H NMR. No significant ($p > 0.05$) difference in the optical activity between the acid {$[\alpha]^{20}_D = -94/+93.8$ ($c = 0.9$, $C_6H_5CH_3$)} and acid chloride {$([\alpha]^{20}_D = -94.8/+94$ ($c = 0.9$, C_6H_5-CH_3)} was noticed for a particular enantiomer.

Synthesis of Propranolol Diastereomeric Ester Prodrugs—The synthetic method is a slight modification of the methods described previously.[27,28] Pure (*R*)- and (*S*)-propranolol HCl (100 mg, 0.34 mmol) was dissolved in chloroform and heated under reflux conditions for 5 h with pure (*S*)- or (*R*)-2-phenylbutyryl chloride (1.36 mmol). Excess acid chloride was removed under high vacuum, and the residue was repeatedly treated with toluene and evaporated to dryness to ensure removal of any remaining acid chloride. The diastereomeric esters were obtained as an oily residue. The ν_{max} at 1810 cm^{-1} in the IR spectrum due to acid chloride disappeared over 3 h and a strong ν_{max} at 1740 cm^{-1} due to O-acylation appeared. The structural identity and purity of the diastereomeric esters were confirmed by IR, ^1H NMR, mass spectrometry, TLC, and HPLC.

Solubility Determination—A normal equilibrium solubility determination was undertaken in 0.01 M acetate buffer (pH 4.0, 25 °C). To 1 mL of buffer, 2−3 mg of hydrochloride salts of ester prodrug or 300 mg of propranolol HCl was added. The samples were sonicated for 60 min at room temperature and subsequently shaken mechanically in a temperature-controlled water-bath at 25 °C for 16 h. The solution was then filtered through a 0.2 mm filter (Millipore) and, after dilution, the solubility of each diastereomer was determined by reversed phase HPLC. The solubility of each diastereomer was also determined in DMSO/acetate buffer mixture used in the skin permeation study according to the procedure outlined above.

Measurement of Partition Coefficient—Partition coefficients of propranolol and the prodrugs were determined in 1-octanol/pH 4.0 phosphate buffer ($\mu = 0.155$) since the prodrugs are most stable at pH 4.0. Aqueous buffer solution and 1-octanol were mutually presaturated at 25 °C before use. Propranolol or the prodrug concentration in pH 4.0 buffer was measured by a reversed phase HPLC method before and after shaking with equal volume of 1-octanol for 1 h. The partition coefficients were determined as the ratios between the concentrations measured in 1-octanol and pH 4.0 phosphate buffer.

Preparation of Liver and Intestinal Homogenates—Rats were sacrificed by decapitation and the upper two-thirds of the small intestine and liver were removed rapidly, washed with ice-cold 0.15 M KCl, blotted to dryness, and weighed. The intestine was cut into approximately 5 cm long sections, and the subsequent tissue manipulations were conducted at 4 °C. Fat and omentum from the small intestine were removed, and the lumen was washed with saline. The mucosal layer was collected by scraping with a glass slide. The mucosal cells and the liver were homogenized in five volumes of 1.15% KCl with a tissue homogenizer (Biospec) and then centrifuged at 10000*g* for 20 min at 4 °C. To adjust the protein content (2 mg/mL in liver sample and 1.5 mg/mL in intestine sample), the supernatant fraction was diluted with 1.15% KCl solution. Blood was collected in heparinized tubes, and plasma was separated by centrifugation (10000*g*) for 15 min at 4 °C. The protein content in the tissue homogenates was estimated by the method of Lowry et al.[29]

Preparation of Rat Brain Homogenate—Animals (male rats, Sprague−Dawley) were sacrificed by decapitation, and brains were removed and homogenized in ice-cold 1.15% KCl (w/v) solution [brain tissue/solution, 1:4] with a homogenizer (Tissue Tearor, Biospec). The homogenate was centrifuged at 9000*g* for 20 min. The supernatant fraction containing soluble and microsomal esterases was stored in aliquots at −80 °C until further use. Protein contents were determined by the method of Lowry et al. with bovine serum albumin as the standard.

Preparation of Skin Homogenate Fractions—All operations were carried out at 0−4 °C. After sacrificing the animal by decapitation, cutaneous strips were removed from the back and the abdomen. Fat and the surrounding muscular tissues as well as capillaries adhering to the dermis were removed. The skin was minced and mixed with 10 volumes of cold Tris-HCl buffer (pH 7.4) containing 0.15 M KCl and homogenized for 10 min. The whole homogenate was filtered with a funnel through buffer-soaked cotton and centrifuged at 10 000*g* for 20 min at 0−4 °C to remove mitochondria and nuclei. The postmitochondrial fraction was centrifuged at 100 000*g* for 1 h with a Beckman TL 100 ultracentrifuge, and the cytosolic supernatant was separated. The microsomes obtained from the pellet were resuspended in 5 mL of Tris buffer. Washed microsomes were isolated by recentrifugation at 100 000*g* for 1 h.

Hydrolysis Studies—*In Buffer*—Stock solution of diastereomeric ester prodrugs (0.05 M) was prepared in dimethyl sulfoxide. An aliquot (20 μL) was added to 10 mL of preincubated (37 °C) buffer solution (pH 7.4, $\mu = 0.155$) in a shaker water bath to initiate the hydrolysis reaction. At appropriate time intervals, samples (100 μL) were withdrawn and directly analyzed by HPLC.

In Plasma—Five microliters of stock solution of each diastereomeric prodrug was added to 2.5 mL of fresh plasma preincubated at 37 °C for 5 min to initiate the reaction. At appropriate time intervals 20 μL samples were withdrawn and immediately added to 100 μL of acetonitrile kept in an ice−water bath to precipitate the plasma proteins. The mixture was vortexed and centrifuged at 10 000*g* for 10 min at 4 °C. The supernatant was separated and stored at 4 °C until analysis by HPLC.

In Liver, Intestinal, and Brain Homogenates—Stock solutions of the liver, mucosal cells, and brain homogenate preparations were diluted to approximately 1 mg/mL protein content with ice-cold phosphate buffer (pH 7.4; $\mu = 0.155$). The rest of the procedure was similar to that described for hydrolysis in plasma.

In Skin Preparations—Protein concentrations of the cytosol and microsomal fractions were adjusted to 2 mg/mL with ice-cold pH 7.4 phosphate buffer ($\mu = 0.155$). The rest of the procedure was similar to that described for hydrolysis in plasma.

In Pure Esterase—Pure cholinesterases, i.e., buytyryl and acetyl, were diluted with phosphate buffer (100 mM, pH 7.4) to a suitable protein concentration (1 mg/mL) and were used to study the hydrolysis kinetics of diastereomeric propranolol esters. The rest of the procedure is similar to that described above.

Chromatography—A Beckman 100 A liquid chromatographic system equipped with a fluorescence spectrophotometer (Schoeffel FS 970) was used at excitation (λ_{ex}) and emission (λ_{em}) wavelengths of 290 and 340 nm, respectively. Propranolol and diastereomeric ester prodrug concentrations were determined with a C_{18} Novapak column (150 mm × 3.9 mm i.d., 5 mm, Waters). A chiral AGP column (100 mm × 4 mm, 5 mm, Alltech) was used to separate enantiomers of propranolol. The eluent systems were composed of acetonitrile: 2% v/v acetic acid (70:30), pH 4.0 adjusted with

ammonia (C_{18} column), and 20 mM ammonium acetate buffer (pH 4.1)/acetonitrile (98:2) (AGP column). A constant flow rate of 1.5 mL/min (C_{18} column), and 1.0 mL/min (AGP column) was maintained. The chromatographic separations were carried out at ambient temperature. Samples of 20 μL were injected onto the chromatograph. The retention times were 11.5, 13, 14.5, and 17 min for 1*S*2*R*, 1*S*2*S*, 1*R*2*R*, and 1*R*2*S*, respectively.

In Vitro Permeation Study—In vitro percutaneous permeation study was performed with a side-by-side diffusion cell apparatus. The rats were sacrificed by decapitation, and the hair of the abdominal region was removed immediately using an animal clipper (Oster A2) and a razor. A rectangular section of dorsal skin was excised from the animal with surgical scissors. Adhering fat and visceral debris were removed from the undersurface with tweezers. The excised skin was immediately mounted between the half-cells, with the dermis side in contact with the receptor fluid (0.01 M acetate buffer, pH 4). The area of skin available for diffusion was 0.636 cm^2. The prodrugs (7.5 mg) 1*S*2*S*, 1*S*2*R*, and 1*R*2*R* were solubilized in 7% v/v DMSO, and the volume was subsequently adjusted to 3 mL with 0.01 M pH 4 acetate buffer and added to the donor half-cell. The 1*R*2*S* prodrug (7.5 mg) was solubilized in 20% DMSO since this prodrug was the least soluble one. The saturation solubility of the prodrugs, determined in the buffer−DMSO system, was used for calculating the permeability. The solubility of the prodrugs in these systems ranged from 1 mM (1*R*2*S*) to 1.6 mM (1*S*2*S*). Enantiomer transport of propranolol hydrochloride from actate buffer (pH 4.0) was studied using 230 mM donor concentration. The half-cells were maintained at 37 °C connected to a circulating water bath (Isotemp, 1016P, Fischer Scientific). A 200 μL sample was withdrawn periodically for 24 h and replaced with equal volume of buffer. The fractions were stored at 4 °C until analyzed by HPLC for regenerated propranolol and the intact prodrugs. Cumulative amount of propranolol and the prodrugs transported (sum of intact prodrug and regenerated propranolol) was plotted against time, and the flux was obtained from the apparent steady-state linear portion of the graph.

The permeability coefficients of propranolol and its prodrugs were calculated[30] by

$$K_p = J_s/C_s$$

where K_p is the permeability coefficient, J_s is the steady-state flux, and C_s is the saturation solubility of the prodrugs in the buffer−DMSO system or PL in acetate buffer.

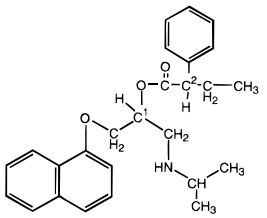
Statistical Analysis—Results of hydrolysis and permeation experiments were expressed as the mean ± SD. The student's *t* test was applied, where necessary, to evaluate significance of difference.

Results and Discussion

A major problem associated with the preparation of *O*-acetyl derivatives of propranolol and similar O,N-bifunctional compounds is the competing *N*-acetyl reactions. Indeed, the previously reported hemisuccinate derivative of propranolol has been shown to have the N- rather than the *O*-acetyl structure.[31] Irwin and Belaid[28] showed that O-acetylation is possible only by allowing the reaction of propranolol hydrochloride to take place with an appreciable, i.e., 4−5-fold, excess of the acid chloride without a catalyst. Under either synthetic or hydrolysis reaction conditions racemization at any one/two of the chiral centers of the prodrug can occur. It has been reported that, oxazepam undergoes racemization in aqueous medium.[32] The factors and the implications of racemization of enantiomers were discussed in detail elsewhere.[33] Such possible racemization was checked by reversed phase HPLC. Racemization of propranolol after prodrug hydrolysis is also possible, and this was also cross-checked under chiral column HPLC conditions. Interestingly, neither O to N transfer nor racemization were observed during synthesis or hydrolysis of the prodrugs.

Physicochemical Properties—Physicochemical parameters, such as aqueous solubility, have been shown to influence membrane flux, therapeutic activity, and pharmacokinetic profiles of medicinal agents. Therefore the physicochemical properties of propranolol and the prodrugs are important, especially in determining loading and release properties from a transdermal therapeutic device. The ester derivatives of propranolol used in this study undergo chemical hydrolysis, particularly under alkaline conditions as described later. Therefore the compounds are relatively unstable for normal equilibrium aqueous solubility determination around neutral pH range. To overcome this problem, the solubility of the prodrugs was determined at pH 4 (acetate buffer; $\mu = 0.155$) in which the prodrugs are found to be most stable. Analysis by HPLC showed insignificant degradation (<0.05%) of the esters during the solubility determination. The physicochemical properties such as solubility and partition coefficients (PC) of the four diastereomeric prodrugs are shown in Table 1. Diastereomers by definition exhibit different physicochemical properties. However, as shown in Table 1, only 1*R*2*S* showed significantly ($p < 0.05$) different aqueous solubility compared to the other diastereomers. The aqueous solubilities of the PL diastereomeric esters decreased and the partition coefficients increased compared to those of PL. Lipophilicity is very important for transdermal permeation because the stratum corneum, the major barrier to drug permeation, is lipid in nature and generally favors the permeation of lipophilic drugs. It has also been reported recently that an effective dermal prodrug should possess not only high lipophilicity but also adequate aqueous solubility.[34]

Table 1—Solubility and Partition Coefficients (PC) of Propranolol and Its Diastereomeric Ester Prodrugs



compound	solubility,[a] mg/mL	PC[b]
propranolol HCl	116.521[38]	2.50
1*S*2*S*	0.303 ± 0.031	11.85
1*R*2*R*	0.231 ± 0.005	17.90
1*S*2*R*	0.301 ± 0.021	11.00
1*R*2*S*	0.040 ± 0.006 *	20.70

[a] Determined in pH 4.0 acetate buffer at 25 °C. [b] Done in octanol–pH 4.0 phosphate buffer ($\mu = 0.155$) at 25 °C; *$p < 0.05$ compared to the other prodrugs.

Hydrolysis in Buffer and Tissue Preparations—Hydrolysis of all four diastereomeric prodrugs was investigated in aqueous solution at 37 °C over a wide pH range. At constant pH and temperature, the disappearance of the prodrugs displayed apparent first-order kinetics for several half-lives (data not shown). The prodrugs were completely hydrolyzed to propranolol in buffer (pH 1.2−8.0) although the propranolol prodrugs can undergo both hydrolysis and intramolecular aminolysis in alkaline solution.[35] The hydrolysis rate of prodrug increased with increasing pH. The shape of the pH−rate profile indicated proton- and hydroxyl-catalyzed degradation of the protonated prodrug together with a hydroxyl-catalyzed degradation of the unprotonated form. The V-shaped pH−rate profile (slope close to unity [0.78]) (Figure 1) indicated that water-catalyzed spontaneous degradation does not significantly contribute to the overall reaction. The maximum stability of the prodrugs was observed at around pH 4.0. No significant ($p > 0.05$) differences were observed among the hydrolytic rate constants of four diastereomeric PL ester

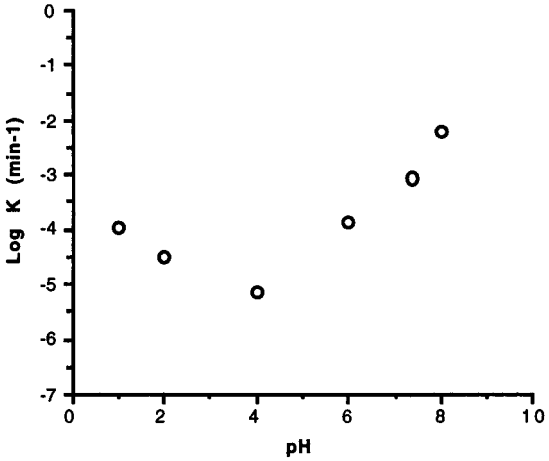


Figure 1—Typical pH–rate profile for the hydrolysis of diastereomeric ester prodrug (1*S*2*S*) in aqueous solution at 37 °C.

prodrugs in the phosphate buffer solution at a given pH, suggesting that H^+, OH^-, or spontaneous hydrolytic rate constants for an ester may not depend on the stereochemistry of the attached R group. The features of chemical kinetics are in agreement with those findings earlier reported for other propranolol esters.[20,35]

The first-order degradation of the diastereomeric ester prodrugs in plasma and liver homogenates is shown in Figure 2, and apparent first-order rate constants were determined from the slopes of the linear plots. Absence of any detectable peaks other than the propranolol and prodrug indicated the possibility of ester hydrolysis without rearrangement. Similar findings have been reported for other propranolol esters in rabbit serum.[36] The rate constants for the hydrolysis of four diastereomeric PL ester prodrugs with various tissue preparations are summarized in Table 2. Hydrolysis was accelerated by the addition of plasma or tissue homogenate, and stereoselectivity was observed. The order of hydrolytic rate constant of diastereomeric esters was found to be (1*S*2*S* < 1*R*2*S* < 1*R*2*R* < 1*S*2*R*) in plasma, and brain tissue homogenates. However, the order was changed in liver homogenates (1*R*2*S* < 1*S*2*S* < 1*S*2*R* < 1*R*2*R*) and intestinal homogenate (1*S*2*S* < 1*R*2*S* < 1*R*2*R* < 1*S*2*R*). The data clearly suggests that the configuration on the second chiral carbon atom (see prodrug structure in Table 1) to be the determinant in the rate of hydrolysis of all the diastereomeric prodrugs in all biological media examined (slowest 1X2S and fastest 1Y2R). The rate of hydrolysis of each diastereomer shows tissue dependency, with highest rate constants observed in intestinal homogenate and the lowest being in the plasma.

As judged from the rate constants shown in Table 2, the diastereomeric PL esters may be hydrolyzed mainly by esterases in the intestine and liver. These esterases consist of several isozymes, and esterase activity differs among various tissues. It was reported that oxazepam succinate was stereoselectively hydrolyzed and the selectivity differed between brain and liver.[37] This study clearly demonstrates that hydrolysis of diastereomeric PL prodrugs by plasma, liver, and intestine is stereoselective.

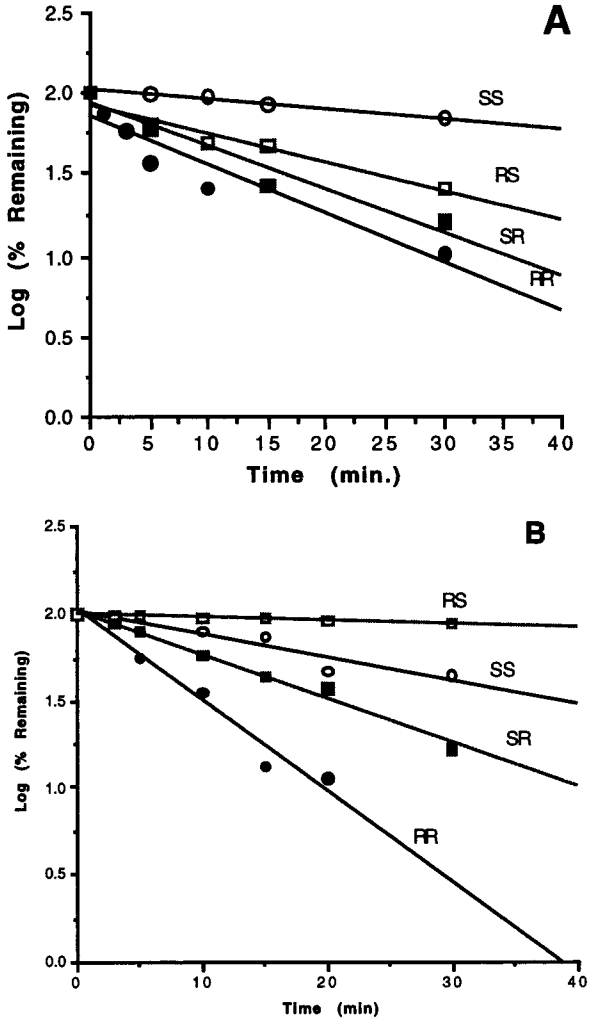

Figure 2—First-order plots for hydrolysis of diastereomeric propranolol ester prodrugs in plasma (A) and liver (B) homogenates.

In an attempt to characterize these differences, hydrolysis of these prodrugs was carried out with pure plasma esterases such as acetyl cholinesterase (EC 3.1.17) and butyryl cholinesterase (EC 3.1.1.8). The hydrolytic rate constants by these esterases were expressed in min^{-1} mg^{-1} and are tabulated in Table 2. It was found that the hydrolysis of all four diastereomeric ester prodrugs was faster by acetyl cholinesterase than by butyryl cholinesterase and was stereoselective.

The hydrolysis of these four diastereomeric ester prodrugs has also been studied in rat brain tissue homogenate, and results are shown in Table 2. Though there is no significant difference in the hydrolytic rate constants among the four diastereomeric ester prodrugs in the rat brain tissue homogenate, the plasma rate constants suggest significantly higher stability of the all diastereomers. In fact, when these rate constants were compared with those obtained in plasma, 1*S*2*S* prodrug was found to be 27 times

(*S*)-propranolol	–	95.61 ± 14.08	1.41 ± 0.27
1*S*2*S*	702 ± 48	29.63 ± 0.26	42.20 ± 1.24[b,c]
1*R*2*S*	450 ± 27	13.17 ± 0.16	29.26 ± 3.41[b,c]
1*S*2*R*	650 ± 39	10.58 ± 0.34	16.27 ± 3.12[b]
1*R*2*R*	628 ± 40	8.16 ± 1.24	12.99 ± 2.84[b]

[a] Each value is the mean ± SD ($n = 3$). [b] $p < 0.05$ compared to propranolol. [c] $p < 0.05$ compared to the other prodrugs. [d] Determined as described in Materials and Methods.

more stable in plasma (rate constant $0.189 \pm 0.03 \times 10^{-3}$ min^{-1} mg^{-1}), compared to the brain tissue (rate constant $5.259 \pm 0.99 \times 10^{-3}$ min^{-1} mg^{-1}), making it a likely prodrug candidate if brain targeting is needed for this drug.

Percutaneous Permeation—Topically applied drugs may be subject to considerable metabolic conversion. Simultaneous metabolism may affect the overall transport and disposition of the active species. It is possible to synthesize prodrugs, which permeate the skin more rapidly than the parent molecule, but are metabolized to the active form at the site of action. Simultaneous transport and metabolism after topical application of a drug is of interest to rationalize and develop a topical dosage form. Studies with propranolol have been conducted in the past using hairless mouse skin on the premise that there is no stereoselective penetration of propranolol.[38] In this study, shaved skin of male Sprague Dawley rats has been used. No stereoselective permeation of propranolol was observed. This is consistent with the findings of Heard et al., where no stereoselective permeation of propranolol through human skin was reported.[39]

All the diastereomeric ester prodrugs were hydrolyzed simultaneously during permeation and permeated as both intact prodrug and PL. To make the comparison simple only the total permeated amount (sum of intact prodrug and converted PL) of each diastereomeric prodrug was considered. The permeation parameters are shown in Table 3. The highest flux of the prodrugs was obtained with the 1*S*2*S* diastereomeric prodrug. The target rate of delivery (R_o) for propranolol and the prodrugs was calculated from reported values of the pharmacokinetic parameters for propranolol,[40] namely, clearance (Cl) and desired therapeutic steady-state concentration (C_{ss}) by:

$$R_o = C_{ss}\mathrm{Cl}$$

The clearance of (*S*)-propranolol is 16 mL min^{-1} kg^{-1}, and the required steady-state concentration for control of resistant ventricular arryhthmias is 1 μg mL^{-1}. Using these values, the target delivery rate for (*S*)-propranolol and its prodrugs is 0.672 mg h^{-1} and for (*R*)-propranolol and its prodrugs 67.2 mg h^{-1} for a 70 kg individual. This difference in delivery rate arises because the *S* isomer of propranolol is 100 times more potent than the *R* isomer. On the basis of this and the comparatively lower flux values obtained with the other prodrugs, the 1*S*2*S* prodrug is by far the best candidate for transdermal delivery. Taking into consideration the size of a patch for delivery, a patch size of 22.68 cm^2 is required for the 1*S*2*S* prodrug, and a size of 7.07 cm^2 is required for (*S*)-propranolol. Delivery of (*R*)-propranolol and its prodrugs is, however, problematic because of the relatively higher target for delivery and constraints in patch size.

From the in vitro diffusion studies, it appears that there is a 3- to 12-fold higher flux value associated with propranolol than with the prodrugs. However, it should be noted that the donor concentration of the 1*S*2*S* prodrug in the diffusion studies was approximately 1.6 mM and that of propranolol was 230 mM. The permeability coefficient (K_p) is independent of donor concentration and serves as an important parameter in comparing permeation potential. The K_p value was higher for all prodrugs compared to that of propranolol. From the flux and K_p values, it can be concluded that the 1*S*2*S* prodrug is promising in that it allows greater permeation with a lower concentration of the drug. This is preferable, since chances of skin irritation may be minimized.[38]

Hydrolysis of prodrugs in the cytosol and microsomal fraction of the skin were conducted to determine the location of the esterases. Stereoselective hydrolysis was observed in both fractions. The hydrolytic rate constants of the four diastereomeric ester PL prodrugs are summarized in Table 2. The prodrugs were hydrolyzed to a lesser extent in the cytosol as compared to microsomes. An interesting observation was that the prodrugs made with (*S*)-2-phenylbutyryl chloride were hydrolyzed to a lesser

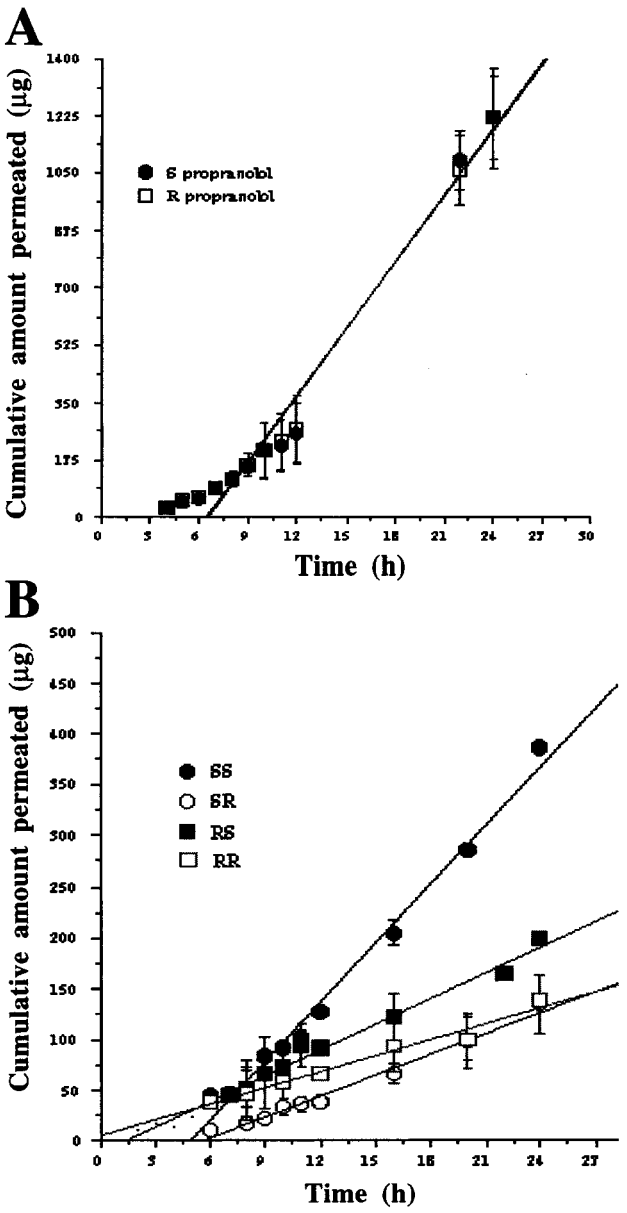

Figure 3—Penetration of propranolol enantiomers (A) and diastereomeric prodrugs (intact prodrug and transported propranolol) (B) across full thickness rat skin at 37 °C.

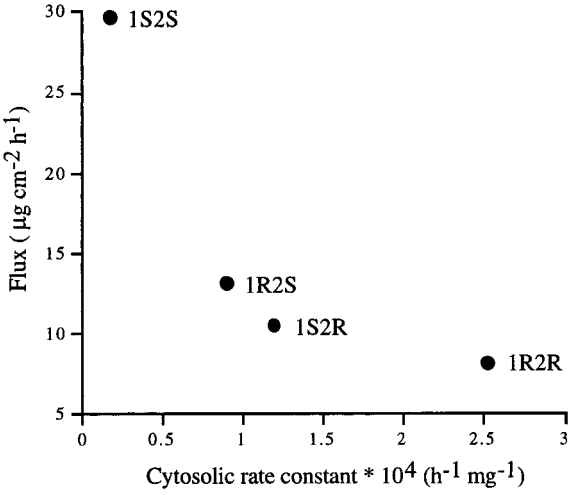

Figure 4—Plot showing inverse relationship between flux and skin cytosolic rate constants.

extent in the cytosol than those made with (*R*)-2-phenylbutyryl chloride. This assumes significance in light of the fact that the *S* isomer of propranolol is 100 times more potent than the *R* isomer. These prodrugs being more efficient at avoiding metabolism further help in improving the skin permeation of propranolol.

In Figure 3, the cumulative amount of propranolol and the diastereomeric ester prodrugs (sum of intact prodrug and regenerated propranolol) transported through the full thickness rat skin was plotted against time. It appears that all four drugs impart increase in lipophilicity as compared to parent PL as indicated by their PC data. The hydrolysis data in conjunction with the flux data clearly suggests that the prodrug, which has optimum stratum corneum partitioning and exhibits the most resistance to enzymatic hydrolysis, is able to cause the highest permeation. As shown (Figure 4), the transdermal fluxes may be inversely related to their skin cytosolic enzymatic rate constants. Therefore, a design of prodrugs should not only involve optimization of physicochemical parameters, i.e., lipophilicity and aqueous solubility, but must also include optimum evaluation of biochemical stability by membranes containing degradative enzymes.

Abstract ☐ A near-infrared (NIR) spectroscopic method based on the use of a fiber optical probe for the analysis of a commercially available pharmaceutical preparation is proposed. The analyte is identified by comparison with a second-derivative spectral library, using the correlation coefficient as the discriminating parameter. Once a sample has been positively identified, the active principle is quantified with partial least-squares (PLS) calibration. The proposed method was validated for use as a control method; to this end, the selectivity of the identification process, and the repeatability, intermediate precision, accuracy, linearity, and robustness of the active principle quantitation, were assessed.

Introduction

"Quality" is gaining crucial significance in many fields, where it is becoming a necessity rather than a secondary goal as in former times. Achieving and ensuring quality entails strict control of raw materials, production processes (via the analysis of intermediate products), and end-products. Controlling every single step and product involved in a manufacturing process entails performing a large number of analyses. Conventional analytical methodologies involve pretreating the sample, which accounts for most of the time expended in the analysis, produces most of the errors arising during the control process, and uses substantial amounts of reagents and solvents. This has promoted the development of expeditious, reliable alternative methodologies, enabling thorough control of a production process via the simultaneous determination of several parameters.

Near-infrared (NIR) spectroscopy is gaining wide acceptance in the pharmaceutical industry as both the expeditiousness with which information can be obtained and the fact that the NIR signal depends on the chemical composition and physical properties of the sample make this technique widely applicable.[1,2] The most important physical properties that affect the spectra of pharmaceutical samples are the particle size and granulation, bringing about modifications on the spectrum like shifts or drifts of the baseline.

One of its most appealing applications of NIR is the use of a fiber optical probe coupled to the spectrophotometer to make measurements with no sample preparation, thereby avoiding the need for reagents and solvents. Although the most common use of fiber optical probes in routine analyses is the identification of raw materials,[3] its potential for quantitative analyses has also been demonstrated.[4−6]

As regards qualitative applications, NIR spectroscopy has solved various problems such as preliminary investigations in the analysis of mixtures or discrimination among similar products;[7] more widespread, however, is the identification of pure chemicals by reference to an existing spectral library.[3,4,8] In this work, we used the correlation coefficient as the discriminating parameter to identify the spectrum for the unknown sample with one in the library.

As far as quantitative analysis is concerned, NIR spectroscopy allows the determination of active principles and/or excipients in various pharmaceutical preparations by use of different multivariate calibration techniques[9] (e.g. multiple linear regression, principal component regression) of which partial least-squares (PLS) regression, used in this work, is the most widely employed choice. In quantitative analysis the modification on the spectra due to the physical properties are minimized by applying spectral pretreatments (derivatives, SNV, MSC, etc.) and/or including variability in the calibration to model it; using these procedures it is expected that the physical characteristics of the sample do not affect on the prediction capability of the model.

One more advantage of the use of NIR is the possibility to identify and quantify a sample using the same experimental data. Mathematically both methods are independent; spectral pretreatment used in each method is optimized to get the best results. For the quantification method we optimized the spectral mode to get the best prediction capability, but for the identification procedure we used the second derivative because it is the usual method that the commercial softwares includes. After defining the spectral mode needed in each method (identification or quantitative) in routine analysis, the software automatically transforms the absorbance spectral data of the recorded spectrum to the proper spectral mode previously defined for each method.

Once a new analytical protocol has been developed, it must be validated if it is to be accepted for use in routine analyses; in this way, the method is guaranteed to perform in such a way as to provide quality results every time.

There are several reported guidelines for the practical validation of analytical methods.[10,11] Official ones such as those issued by the United States Pharmacopeia (USP),[12] the International Conference on Harmonization (ICH),[13] or the Food and Drug Administration (FDA)[14] provide a framework for the validation process. As a rule, methods for regulatory submission must include studies on specificity, linearity, accuracy, precision, range, quantitation limit, and robustness.

The ICH has lately made strong harmonization efforts aimed at validating methods for the control of formulations and substances. However, chemists continue to be faced with the problem that every existing regulation of this type is concerned with the validation of chromatographic methods. The lack of officially endorsed methodologies where sample treatment differs markedly from that of a chromatographic procedure makes validation a process for which no preset rules exist.

The objective of this work is the development and validation of a NIR quantitative method. To carry out this objective, two requirements are necessary. First, the validation regulation demands a guarantee of the sample identity before quantifying the sample. Second, once a method is established, conventional tests are adapted to the specific NIR needs in order to demonstrate their suitability.

Experimental Section

Samples—A pharmaceutical preparation (CBIC) commercially available in granular form contains ferrous lactate dihydrate (770 mg/g as anhydrous ferrous lactate) as active principle, and sodium croscarmellose (50 mg/g) and talc (20 mg/g) as excipients. Samples of the pure components and of the pharmaceutical preparation from different production batches were supplied by Laboratorios Menarini S.A.

Apparatus and Software—The spectra were recorded on a NIRSystems 5000 near-infrared spectrophotometer equipped with a reflectance detector and an AP6645 ANO3P fiber optical probe. The instrument was governed by the software package NSAS v. 3.30, from Perstorp Analytical, NIRSystems, which includes modules for acquisition and treatment of NIR spectra. It also includes IQ,[2] a program for developing the routine qualitative and quantitative analyses.

A Turbula Type T2C shaker mixer from WAB (Basel, Switzerland) was used to homogenize laboratory-made solid samples.

Calibration was performed by using the commercially available multivariate calibration software package Unscrambler v. 5.03, from Camo AS (Trondheim, Norway), which enables principal component analysis (PCA) and partial least-squares regression (PLS) and has additional capabilities for variable selection and outlier detection. The NIR spectra processed by this program were previously exported in JCAMP format from the spectrophotometer.

Sample Preparation—Two types of samples (laboratory and production) were used. Laboratory samples were prepared by weighing variable amounts of the active pure principle and adding different amounts of sodium croscarmellose and talc until the appropiate ferrous lactate concentration was obtained; the active principle content varied evenly over a concentration range about ±15% of the nominal value (viz. 650−850 mg/g). Each sample was shaken about 1 h and then a NIR spectrum was recorded; the shaking process was repeated again for 10 min and then a second NIR spectrum was recorded. When two consecutively recorded spectra were identical, the sample was considered homogeneous; otherwise, the shaking process was repeated.

The production samples were granulated samples obtained from different production batches, and their NIR spectra were recorded without any treatment.

Recording of NIR Spectra—The spectrum for each sample was recorded over the wavelength range 1100−2500 nm by inserting the fiber optical probe into the containers where the samples were received, so preparation of the sample for the analysis it was not necessary.

All samples were recorded in triplicate; after each single measurement the powder was stirred with the aid of a spatula to record different parts of the sample. The average of the three spectra for each sample was used for analysis.

Figure 1 shows the NIR spectrum for each individual component of the pharmaceutical preparation, together with that for a production sample.

Reference Method—The active principle in the pharmaceutical was determined by measuring the ferrous ion in ferrous lactate by redox titration[15] with Ce^{4+} ion. An amount of ca. 0.2 g of sample was supplied with 100 mL of 1:50 H_2SO_4:H_2O, 0.5 g of $NaHCO_3$, and 1−2 drops of ferroin (indicator) and titrated with a previously standardized 0.1 M Ce^{4+} solution.[16] The active principle content in each sample was obtained as the average of three determinations by the reference volumetric method.

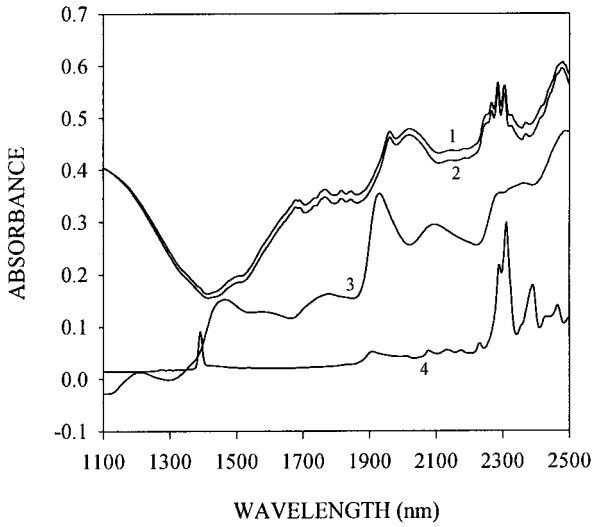

Figure 1—NIR spectra for a production sample and the pure components of the pharmaceutical. (1) Production sample. (2) Ferrous lactate dihydrate. (3) Sodium croscarmellose. (4) Talc.

The ferrous lactate content in the laboratory samples was calculated from weights of the pure components used to prepare them.

Data Processing—*Identification*—Samples were identified by comparison of their spectra with standard spectra in a reference library. To this end, a library containing spectra for the pharmaceutical preparation, the active principle, and the excipients was compiled; for each product, a set of sample spectra that met the specifications and represented all the variability in the manufacturing process were available. The library was constructed from second-derivative spectra in order to facilitate discrimination among different products and decrease spectral variability due to scattering.

Similarity between products was expressed through the correlation coefficient or match index, ρ_{jk}, given by

$$\rho_{jk} = \frac{\sum_{i=1}^{p}(x_{ij} - \bar{x}_j)(x_{ik} - \bar{x}_k)}{\sqrt{\sum_{i=1}^{p}(x_{ij} - \bar{x}_j)^2}\sqrt{\sum_{i=1}^{p}(x_{ik} - \bar{x}_k)^2}}$$

where the subscripts k and j denote the sample and product reference spectra, respectively, acquired at p wavelengths, x_{ik} and x_{ij} are measured values of the sample and the product reference at wavelength i, and $\bar{x}_j$ is the value of the average spectrum j over all p wavelengths.

The match index ranges between −1 and +1. A value of +1 indicates perfect similarity between the unknown product and a product in the library. However, random noise associated to measurements may preclude obtainment of this value, so an identification threshold must usually be established.

Quantitative Analysis—All models tested were based on the PLS algorithm[17] and constructed by cross-validation, using as many segments as samples in the calibration set. All were constructed for the spectral range 1100−2200 nm and thus avoided the upper zone of the spectrum and hence the high background noise associated with the use of a fiber optical probe. The number of significant PLS components was taken to be the minimum number for which the prediction error sum of squares (PRESS) was not significantly different from the lowest PRESS value.[18]

The quality of the results was assessed in terms of the relative standard error of prediction,[19]

$$\mathrm{RSEP}(\%) = \sqrt{\frac{\sum_{i=1}^{n}(C_{\mathrm{LAB}_i} - C_{\mathrm{NIR}_i})^2}{\sum_{i=1}^{n} C_{\mathrm{LAB}_i}^2}}$$

where C_{LAB_i} is the reference concentration and C_{NIR_i} the PLS calculated concentration.

Results and Discussion

The proposed analytical procedure uses a single spectral measurement for the simultaneous qualitative (identification) and quantitative analysis of a commercially available pharmaceutical preparation.

Unknown samples are identified by comparing their spectra with the average spectrum for each product in a library. If the sample is positively identified, then its active principle content is automatically quantified by reference to a previous PLS calibration.

After the proposed method was developed, it was validated for use as a routine control method.

Identification—A library consisting of 45 spectra for four different products, viz. the pharmaceutical preparation (five different CBIC production batches) and its three pure components (ferrous lactate dihydrate, sodium croscarmellose, and talc) was compiled. The spectra in the library were all recorded over the 1134−2200 nm range and converted into their second derivatives to lessen the effects of scattering. The library thus obtained exhibited no internal conflicts and correctly identified every spectrum used for self-validation.

All production samples studied (calibration and prediction sets) exhibited correlation coefficients between 0.95 and 1. An unknown sample was assumed to be positively identified if its correlation coefficient exceeded the established threshold (0.95). If any sample surpassed such a threshold for more than one product in the library, it was positively matched to that with the highest coefficient.

Quantitative Analysis—Available samples were split into a calibration set and a prediction set. The calibration set consisted of laboratory samples and samples from different batches of the pharmaceutical preparation (see Table 1). The laboratory samples used for calibration spanned the whole concentration range of interest in a uniform manner; these samples are powdered, and do not have the same physical properties that the real samples (granulation) have, so production samples were included in the calibration set in order to introduce the variability of the manufacturing process. Generally, a calibration set composed of only laboratory samples causes high prediction errors in production samples; in this case, using a calibration set composed of laboratory samples alone (12 samples) the prediction of production samples always gave underestimated results (except one) and a RSEP = 3.8%, an error that we considered too high.

To improve the prediction, we introduced production samples in the calibration set.[6,20] The Principal Component Analysis (PCA) was used to select the production samples to include to the calibration set. A PCA of second derivative spectra was calculated using the eight production samples available when the calibration was constructed; as can be seen from Figure 2, the samples selected were those exhibiting the greatest variability in a plot of the first component against the second, which, together, accounted for 89% of the variance. After this selection, the calibration set was composed of 17 samples, 12 of which were laboratory-made and 5 from production batches; the prediction set was composed of 19 samples, 9 laboratory-made samples, and 10 production batches.

Absorbance, first-derivative, and second-derivative PLS

models were tested. Table 2 shows the relative standard error of prediction (RSEP) for the different quantitative models studied. As can be seen, the best results were provided by derivative models, with no significant differences between first- and second-derivative ones. A quantitation model based on first-derivative spectra was chosen as optimal, as it was more simple; it used one fewer PLS component and gave slightly lower errors than the rest. As can be seen from the results (Table 1), this calibration model allows the accurate prediction of real-world samples with no adverse effect on the quantitation of laboratory samples.

The specification limit for acceptance of the active principle content in the pharmaceutical was ±5% of the nominal value, which is clearly larger than the prediction errors obtained with the optimum calibration procedure for the production samples; in fact, none of the samples assayed provided a relative error in excess of 1.5%. Therefore, the proposed calibration procedure is precise enough for use as a control methodology.

Validation of the Procedure—There is no universally accepted procedure for validating a quantitative method by NIR spectroscopy. In this work, we adapted the ICH general guidelines[13] to the purpose. The specific aspects of the NIR method that differ most markedly from the usual regulatory analysis are the use of a multivariate calibration method and the need for no sample pretreatment, i.e. sample spectra are directly recorded.

The factors considered in validating the proposed method included selectivity in the identification step, and repeatability, intermediate precision, accuracy, linearity, and robustness in the quantitation step. The concentration range spanned by the calibration is another parameter usually examined for validation; however, the use of PLS regression to determine the active principle entails the a priori selection of the concentration range of interest. During the validation process, solid evidence was obtained that the resulting quantitation errors were acceptable throughout the concentration range studied.

Identification—*Sensitivity*—The proposed method is able to positively identify the pharmaceutical and distinguish it from its pure components.

The identification selectivity of the proposed method was assessed by comparing the results of the NIR analysis of CBIC samples with those for the active principle and excipients in the pharmaceutical. Table 3 shows the correlations for a production sample and samples of the pure components with the different products included in the spectral library. As can be seen, the production sample was identified as CBIC (the material for which the highest correlation coefficient, in excess of 0.95, was obtained).

	operator 2	748	757	761	$CV_{global} = 0.7\%$
2	operator 1	754	751	758	
	operator 2	749	763	755	$CV_{global} = 0.7\%$

The closeness of the correlation coefficients between CBIC and ferrous lactate dihydrate reveals that the two products are very similar. To avoid conflicting identifications, Table 4 shows the correlation coefficients with CBIC and ferrous lactate dihydrate of the different production batches not used in compiling the library. No spurious identifications were made provided the established criterion was adhered to by virtue of the small spectral differences introduced by the presence of excipients in the pharmaceutical.

Quantitative Analysis—*Repeatability*—The repeatability of the proposed method was evaluated by performing 12 determinations of a production batch. Table 5 shows the results obtained from measurements made by the same operator on the same day. The active principle contents obtained in the 12 determinations exhibited a coefficient of variation CV = 0.3%, which is well below the usual accepted limits (<1%).

Intermediate Precision—The intermediate precision was assessed on two different production samples by evaluating two variable parameters in the routine control of the preparation, namely, day and operator. Table 6 shows the quantitative results obtained from measurements made by

K-24	771	759	1.5

two different analysts on three different days. As can be seen, the coefficient of variation for the two samples studied was slightly higher than that obtained in the repeatability study as a result of new sources of variation being introduced in the analyses; in any case, the CV values were within accepted limits for this type of test (<2%).

The variability between days and that between operators were evaluated jointly by two-way analysis of variance (ANOVA), which revealed that neither source produced any systematic errors.

Accuracy—Because the results could be affected by physical properties of the samples, the accuracy of the proposed procedure was only evaluated in production batches. For this purpose, the NIR results were compared with those provided by a well-characterized (reference) method.

A paired *t* test[21] was used to check whether the mean value and that held as true (viz. the average value provided by the volumetric method) were significantly different. From the results for 10 samples (Table 7), a t_{exp} value of 1.41 was obtained (the t_{tab} value for $P = 0.05$ and 9 degrees of freedom is 2.26). Because $t_{exp} < t_{tab}$, the results provided by NIR spectroscopy and the reference method are not significantly different.

Linearity—Linearity is usually estimated by evaluating the goodness of the variation of the analytical signal as a function of the analyte concentration.[10] With multivariate calibration (e.g. PLS regression), however, an alternative test suited to the methodology in question must be used. To determine the linearity of the proposed method, the NIR and reference results were compared via the following equation:

$$\text{NIR value} = a + b \times \text{reference value}$$

The samples used to check for linearity should span the whole concentration range studied, which is known to be the case with production samples only. To include samples of variable concentration with physical features as close as possible to those of the production samples, under- and overdosed samples were prepared in the laboratory. Such samples were obtained by adding variable amounts of the active principle or excipients, respectively, to samples from different production batches and homogenizing them in the shaker mixer before their NIR spectra were recorded. Their active principle contents were determined by using the reference procedure.

Table 8 shows the results for the 16 samples studied (5 of which were production samples and 11 samples used to assess linearity). As can be seen, the results provided by both techniques were quite consistent throughout the concentration range studied. A plot of NIR concentration against reference concentration was linear, with a slope of 1.03 ± 0.06, an intercept of -20 ± 51, and a correlation coefficient $r = 0.994$. The curve has an origin and a slope

16	837	841	0.4

[a] Production samples.

not significantly different from zero and one, respectivity, so the proposed method is subject to no systematic or matrix errors in relation to the reference method over the concentration range studied.[22]

Finally, a paired *t* test between the values provided by the two methods[21] was carried out in order to check whether the NIR method provided accurate results throughout the calibration range. The t_{exp} value thus obtained for the samples of Table 8 was 1.45 (t_{tab} for $P = 0.05$ and 15 degrees of freedom is 2.13); since $t_{exp} < t_{tab}$, the average results provided by the two methods are not significantly different.

Robustness—The proposed NIR method involves no sample pretreatment, so the only experimental variables potentially affecting the results are those inherent in the spectrophotometer, which are set before any spectra are recorded.

The proposed analytical method can be validated by comparing its results with those of a reference method over a period of time. The production samples analyzed in the accuracy study were manufactured over a 4-month period. Also, after the proposed method was accepted as a valid control method, an overall 10 production batches have been analyzed over a period of 8 months. The results exhibit more than acceptable accuracy (the average error relative to the theoretical value is 1.3%) and coefficients of variation (1.5%). The method is thus quite robust.

Conclusions

A near-infrared spectroscopic method for a commercially available pharmaceutical preparation that affords direct analyses of untreated samples in the solid phase was developed. The analytical process involves the identification of the unknown sample and the quantitation of the active principle in the pharmaceutical. Identification relies on the correlation coefficient; the method allows the positive identification of the pharmaceutical and discriminates it from its pure components, and also even from the active principle, which is the major component. After the sample is identified, PLS regression allows the quantitation of the active principle with a prediction error well below the accepted limit for the pharmaceutical.

The method was validated by determining its selectivity, precision, linearity, and robustness. The results demonstrate that the proposed NIR spectroscopic method for the identification and determination of ferrous lactate in the pharmaceutical preparation CBIC is a valid alternative to

existing methods for this purpose and that it allows the successful analytical control of its production process.

Accepted for publication January 19, 1999.

Abstract □ Phase plane plots are graphical expressions for differential equations ploting the state derivative d*c*/d*t* versus the state *c*. Using these plots, we developed a novel method for the estimation of the terminal slope from time–concentration data. The values of the derivatives used for the construction of the phase plane plots were calculated by two different methods of numerical differentiation. The first method (D1) is based on the classical calculation of slope of the line connecting two successive data points. The alternative method (D2) relies on an initial second-order polynomial interpolation utilizing three successive data points followed by the calculation of the derivative at each one of the concentration values. A forced-through-zero linear regression of the phase plane plot data is used to derive an estimate for the slope. For comparative purposes, the standard approach based on the semilogarithmic plot was also applied. For a hypothetical drug absorbed by first-order process into a one-compartment model, simulated time–concentration data disturbed by a Gaussian zero mean random error with various coefficients of variation were generated. Various sampling schedules, with two, three, four, or five data points, were utilized for the estimation of the terminal slope. Performances of the proposed methods on simulated data were expressed by means of root-mean-squared error, bias, and standard deviation. In all cases, D2 was superior to D1. The D2 method outperforms the standard method in that it furnishes estimates closer to the real values in all cases when two data points and in most cases when three data points were used. All methods behave similarly when four or five data points were used.

Introduction

The estimation of the terminal slope in time (*t*)–concentration (*c*) data can play an important role in pharmacokinetic, bioavailability, and bioequivalence studies. Routinely, this estimation is accomplished on the semilogarithmic plot of *c* vs *t*, where the slope is determined by the best line fitting the data. In some cases, two or three data points have been used to derive an estimate for the terminal slope.[1–6] Although the use of two data points to estimate terminal slope by log-linear regression is not statistically or theoretically justified, the method can be quite satisfactory when limited experimental error is encountered. However, a poor estimate may be obtained when the experimental error is high because measurements in the proximity of the least quantifiable concentration have been carried out and/or sampling has not been continued for a long enough time to ensure that absorption or disposition processes do not disturb the elimination process.

In the present study, a novel method is proposed for the estimation of the terminal slope. The method relies on the phase plane plot, which has been used for the analysis of various kinetic phenomena.[7–10] Moreover, phase plane plots of dye-dilution curves have been used to determine the cardiac output.[11] Also, this method was utilized recently for the discernment of absorption kinetics.[12]

Theoretical Section

In our previous study,[12] it was proven that for drugs obeying one-compartment model disposition and irrespective of the absorption kinetics, the slope of the terminal segment of the phase plane plot (d*c*/d*t* vs *c*) corresponds to the elimination rate constant. Similarly, when the computation was applied to a two-compartment model, this slope was equal to the smaller hybrid rate constant.[12] This observation applies to drugs following multiexponential disposition; for example

$$c(t) = \sum_{i=1}^{z} A_i e^{-\lambda_i t} \tag{1}$$

where A_i are fictitious constants in concentration units and λ_i ($i = 1, ..., z$) are hybrid rate constants ($\lambda_1 > \lambda_2 > ... > \lambda_z$). As time goes toward infinity, all but the terminal exponential term in eq 1 vanish and the latter is reduced to

$$c(t) = A_z e^{-\lambda_z t} \tag{2}$$

Taking the derivative of eq 2, we have

$$\frac{dc(t)}{dt} = -\lambda_z A_z e^{-\lambda_z t} = -\lambda_z c(t) \tag{3}$$

where λ_z is the terminal slope, which plays an important role in kinetic data analysis for determining the terminal half-life.

The last equation indicates that the negative slope of the last segment of the phase plane curve (d*c*/d*t* vs *c*) corresponds to the terminal slope. Obviously, the final state of the system ($t \rightarrow \infty$), when all the drug has been eliminated, corresponds to $c = 0$ and $dc/dt = 0$ [i.e., the last point of the phase plane is always the point (0,0)]. These observations encouraged us to examine the potential of estimating the terminal slope using the terminal limb of the phase plane curve and taking into consideration the last point (0,0), which is exact (Figure 1).

Methods

To illustrate feasibility of the proposed method and to evaluate its performances with respect to other computational approaches, a simulation study was undertaken. To this end, the one-

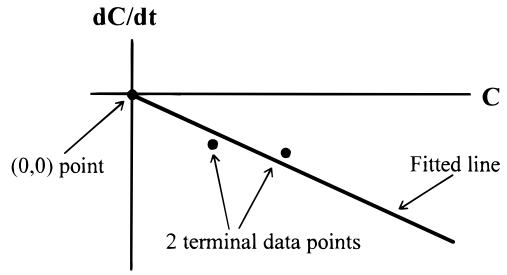

Figure 1—Schematic representation of the estimation of the terminal slope using the phase plane plot. In this example, two data points are used; the regression line is forced through (0,0), which is not an actual data point but a theoretical asymptotic limit for infinite time. The slope of the line is equal to $-k_e$.

compartment model was used associated with first-order absorption process. At time t, concentrations $c(t)$ are given by the following equation:

$$c(t) = \frac{fD}{V} \cdot \frac{k_a}{k_a - k_e} \cdot (e^{-k_e t} - e^{-k_a t}) \quad (4)$$

For normalization, the coefficient $[f \cdot D/V]$ is set to unity. The parameters k_a and k_e are absorption and elimination rate constants, respectively. Equation 4 was used to simulate concentrations in the following 5-factor controlled experimental protocol.

1. Model Parameters—One k_e value was set to reflect a 7 h half-life. Two k_a values set to reflect 1.7 and 4.6 h half-lives. Thus, the elimination rate constant was set to $k_e = 0.1\ h^{-1}$ while low and high $[k_a/k_e]$ ratios, equal to 1.5 and 4, respectively, were used.

2. Sampling Schedules—Short and long sampling schedules were examined [{6, 8, 12, 16, 20, 24} and {16, 20, 24, 28, 32, 36} h]; that is, the sampling lasts for 3.4 and 5.1 half-lives, respectively.

3. Measurement Error—Using eq 4, concentrations were computed at the sampling times and then they were corrupted by a Gaussian random zero mean measurement error. The error was variable with 5 levels of coefficient of variation (CV) at 10, 20, 30, 40, and 50%.

4. Computational Methods—The phase plane plots were constructed using two alternative methods of numerical differentiation. The first method (D1) is based on the classical calculation of slope of the line connecting two successive data points. This slope corresponds to the derivative for the mid-time point of the two data points considered. The alternative method (D2) is based initially on a second-order polynomial interpolation utilizing three successive data points. Further, the derivative is calculated at each one of the three time points considered. The method D2 as well as its application to the present study are described in the Appendix. Finally, a forced-through-zero linear regression analysis utilizing two, three, four, or five (dc/dt, c) data points is performed. In other words, a line of the form $y = ax$ is used for the fitting; the slope of this line provides an estimate for $-\lambda_z$ or for $-k_e$ for the model considered in this study. For comparative purposes, the data were also analyzed by the standard method (S) using linear regression on the semilogarithmic plot.

5. Data Analysis—Separate analyses were carried out utilizing either the last two, three, four, or five data points for both sampling schedules examined.

For each combination of the first two controlled factors (model parameters and sampling schedule) and at each one of the 5 levels of CV, 1000 measurements errors were randomly obtained and used to disturb the error-free simulated concentrations. Because of the high range of CV used, simulated data leading to positive slopes were excluded from the calculations for all methods studied. However, additional simulations were carried out to ensure a total of 1000 runs with negative slopes in all cases examined.

Simulations were done with Mathematica. The results of this simulation study were evaluated statistically. The root-mean-square error (RMSE), which provides the spread of the measures around the theoretical value ($0.1\ h^{-1}$) of the terminal slope, was calculated. Further, RMSE was split into its two components, namely, (i) the standard deviation (std), which evaluates the spread of the measures around their average value, and (ii) the bias, which provides the difference of the average of the measures from the theoretical value.

Results

For various combinations of the controlled factors utilizing either two or three data points (Figure 2) shows the results for RMSE, std, and bias. All results were derived only from data with negative slopes. The number of simulations leading to data with positive slopes increased as the level of the % CV increased for all combinations of the rest-controlled factors. Overall, the range of the percentages of data with positive slopes was 0−1.4, 0−15.2, 1−32.1, 5.6−42.8, and 18.5−57.0% for 10, 20, 30, 40, and 50% CV, respectively.

When two data points were utilized and irrespective of the CV levels, D2 yielded the lower RMSE and std values; in contrast, S yielded the higher RMSE and std values (Figure 2). In general, the higher the CV levels, the lower the performances of the methods in terms of RMSE and std. As far as the bias is concerned, D2 is the less dependent method on the CV levels.

When three data points were utilized, the performances of the methods were less dependent on the CV level (Figure 2). Moreover, in both sampling schedules, D2 method performs slightly better.

When four or five data points were utilized, the performances (not shown) of the methods were again less dependent on the CV level. All methods exhibit similar performance in terms of RMSE, std, and bias for all scenarios examined.

Discussion

The D1 and D2 methods based on the phase plane plot were developed for the estimation of the terminal slope. These methods were evaluated statistically and compared with the standard approach (S).

Two important arguments in support of the proposed D1 and D2 methods can be pointed out. First, the evaluation of the terminal slope in both methods relies on the slope of the "real terminal" segment of the phase plane curve irrespective of the sampling design applied. Second, the slope of this segment is drastically influenced by the theoretical (0,0) datum point; that is, the forced-through-zero linear regression (Figure 1).

When two data points were used, the proposed methods (D1 and especially D2) perform better than the S approach for all combinations of controlled factors examined. In particular, the D2 method had remarkably smaller RMSE, std, and bias than the D1 and S methods. The superiority of the D1 and D2 methods with respect to the S approach should be attributed to the considerable contribution of the exact datum point (0,0) in determining the slope of the regression line in the phase plane plot. In fact, the regression line (i) passes through this errorless datum point and (ii) satisfies the least squares condition for the other two (dc/dt, c) data points. These observations should be considered in conjunction with the low std and the negligible bias of the D2 method when applied to the long sampling interval conditions. Hence, the best performance of the D2 method is noted when two data points near the end of the sampling schedule are used. The poorer characteristics of the D1 method in comparison with the D2 method are most likely associated with the refined methodology used for the calculation of the derivatives in the D2 method. In addition, the D2 method utilizes the same number, whereas the D1 method utilizes one less of the data points (dc/dt, c) than the available (c, t) data points.

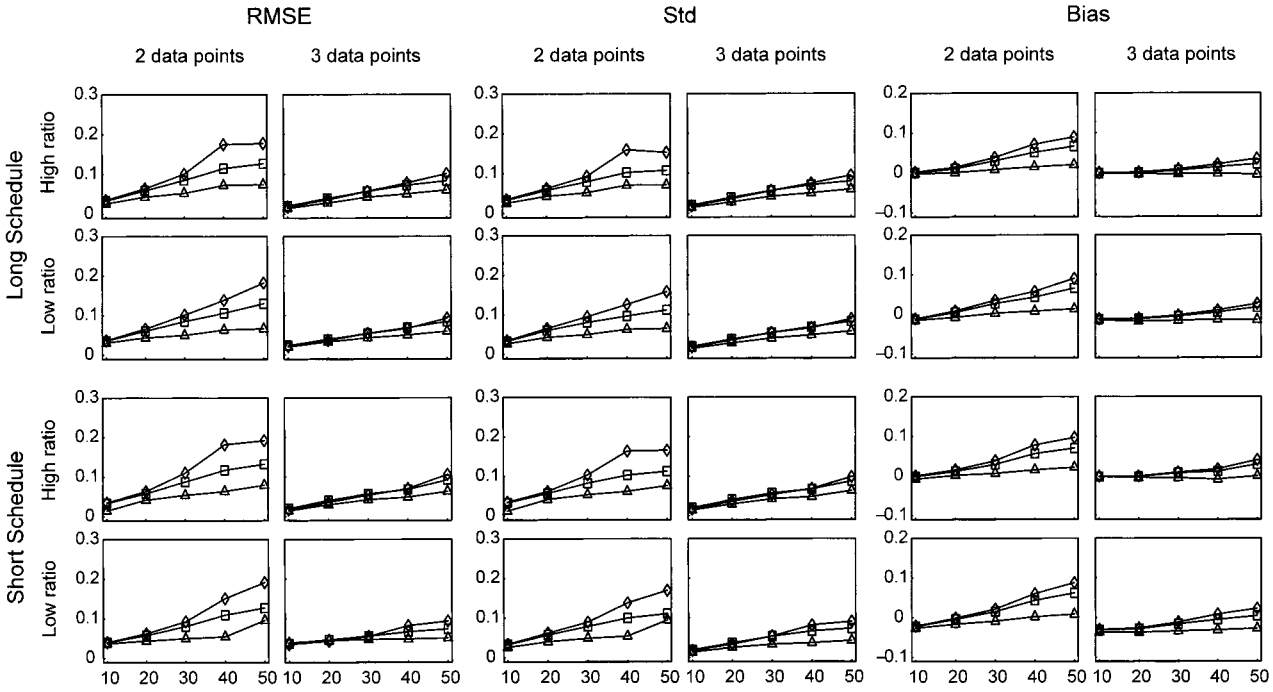

Figure 2—For all combinations of the controlled factors and for the three methods S, D1, and D2, utilizing either two or three data points, the RMSE, the std, and the bias are shown as a function of CV of measurement errors. Key: (◇) method S; (□) method D1; (△) method D2.

The D2 method draws power from the computational method that adds another data point at 0,0. Clearly, this power is more dramatic with few data points.

When three data points were used, the D2 method is marginally superior to the others for both sampling schedules. Methods D1 and S exhibit higher dependence on the CV levels for all parameters studied (Figure 2). This higher dependence is so despite the diminished contribution of the errorless datum point (0,0), which is now one out of four data points in determining the slope. However, for the worst scenario (short schedule-low ratio of rate constants), the D2 method underestimates the true value of k_e (Figure 2).

We recently used the phase plane approach jointly with the D1 method in investigating the absorption kinetics.[12] The results of the present study comparing the D1 and D2 methods in estimating the terminal slope allow someone to infer that the analytical power of the phase plane approach in investigating the absorption kinetics will be improved if the D2 method is used in place of the D1 method. Indeed, we carried out a number of simulations (results not shown), and the D2 method was superior.

For the sake of completion, one should add that the forced-through-zero classical linear regression analysis applied to the phase plane plot data does not take into account the error associated with the *x*-variable (*c* in abscissa). Special procedures are used in the literature in those situations where both variables are subject to error.[13,14] To this end, we applied the D2 method to our simulated data utilizing the geometric mean functional relationship (GMFR)[14] approach to linear regression for fitting. For the same sets of data, the GMFR approach did not provide better estimates for k_e when compared with the estimates derived from the classical linear regression. It seems likely that the error associated with the *y*-variable (d*c*/d*t* in ordinate) is considerably higher than the corresponding for *x*-variable (concentration *c*) and, therefore, the GMFR approach does not offer any advantage over the classical regression for the proper analysis of data.

Conclusions

The phase plane methods D1 and D2 perform better than the semilogarithmic approach for all scenarios examined when two or three data points are used for the estimation of the terminal slope. When four or five data points are available, all methods, D1, D2, and S, behave similarly.

The D2 method described here appears to be a robust approach to provide a reliable estimate for the terminal slope when two or three data points are available. Although essentially new, the D2 method can be handled computationally by simple calculations of the derivative at the various time points using interpolation techniques, such as spline functions, Lagrange polynomials, etc.[15] It should be emphasized that the technique of Lagrange polynomials used here provides a unique polynomial for a given (*c*,*t*) data set and, therefore, the method developed is not user dependent.

Appendix

The D2 method relies on the general problem of finding the Lagrange interpolating polynomial,[15] which is equal to the function describing the time course of drug in the body at a certain number of specified time points; that is, the experimental data points (c_j, t_j). We use three successive data points ($j = 1, 2, 3$) and derive the unique quadratic polynomial $c = pt^2 + qt + h$, which passes through these points.

The polynomial coefficients *p*, *q*, and *h* can be calculated by solving the following system:

$$\left.\begin{aligned} pt_1^2 + qt_1 + h &= c_1 \\ pt_2^2 + qt_2 + h &= c_2 \\ pt_3^2 + qt_3 + h &= c_3 \end{aligned}\right\} \qquad \text{(A1)}$$

Furthermore, the derivative dc_j/dt at any of these three points c_j is given by

$$\frac{dc_j}{dt} = 2pt_j + q \qquad j = 1, 2, 3 \tag{A2}$$

Solving the system A1 and replacing in A2 we obtain the following required derivatives:

$$\frac{dc_j}{dt} = c_1\left[\frac{2t_j - t_2 - t_3}{(t_1 - t_2)(t_1 - t_3)}\right] + c_2\left[\frac{2t_j - t_1 - t_3}{(t_2 - t_1)(t_2 - t_3)}\right] + c_3\left[\frac{2t_j - t_1 - t_2}{(t_3 - t_1)(t_3 - t_2)}\right] \tag{A3}$$

for every middle point of the data set $j = 2$. For the first and the last data points of the set that are not surrounded by other points, j is taken to be 1 and 3, respectively.

It is well-known that the derivative is more accurately calculated at the middle point.[15] In the present study, we took advantage of this fact and calculated all the derivatives of the data points used for the estimation of k_e by applying $j = 2$ in eq A3; for example, for the sampling schedule {6, 8, 12, 16, 20, 24} h, the derivatives at 8, 12, 16, and 20 h were calculated from the triplets (6, 8, 12), (8, 12, 16), (12, 16, 20), and (16, 20, 24) h, respectively. Unavoidably, the derivatives at the final points were calculated with eq A3 using $j = 3$ [e.g., for the sampling schedule just mentioned, the derivative at 24 h was calculated from the triplet (16, 20, 24) h].

Abstract □ Nipecotic acid (**1**), one of the most potent in vitro inhibitors of neuronal and glial γ-amino butyric acid (GABA) uptake, is inactive as an anticonvulsant when administered systemically. To obtain in vivo active prodrugs of (**1**), we synthesized four new nipecotic acid esters (**3**–**6**), which were obtained by chemical conjugation with glucose, galactose, and tyrosine. These compounds were assayed to evaluate their in vitro chemical and enzymatic hydrolysis. In addition, their anticonvulsant activity was evaluated in vivo in Diluted Brown Agouti (DBA)/2 mice, an excellent animal model for the study of new anticonvulsant drugs. Esters (**3**–**6**) appeared stable, at various temperatures, in a pH 7.4 buffered solution and showed susceptibility to undergoing in vitro enzymatic hydrolysis. Intraperitoneally injected nipecotic acid (**1**) and esters (**3**–**5**) did not protect mice against audiogenic seizures; conversely, nipecotic tyrosine ester (**6**) showed a significant dose-dependent anticonvulsant activity. The in vivo protective activity of the ester (**6**) and the inefficiency of nipecotic acid (**1**) in the same experimental conditions suggest that this ester prodrug could be actively transported intact across the blood–brain barrier, beyond which it could be hydrolyzed.

Introduction

Several potentially central nervous system (CNS)-active drugs have relatively unfavorable physicochemical characteristics that hinder their transport into the brain. In fact, the brain microvessel endothelium provides a barrier to the passive transport of hydrophilic drugs into the brain. Several strategies have been developed to overcome this problem.[1−3] The prodrug approach represents a very promising method to enhance drug delivery to the brain. In fact, prodrugs are normally inactive and must generate active drug at their target by enzymatically or chemically mediated cleavage of their promoiety. The development of CNS-active prodrugs has been generally aimed at obtaining an improvement in the lipophilic character of the drug by transiently masking ionized group(s) of the parent drug. However, the preferential delivery of drugs or their derivatives to brain may be improved by using endogenous facilitated transport systems present at the blood−brain interface. Thus, chemical conjugation of potentially CNS-active drugs with an amino acidic or glycoside moiety actively transported across the blood−brain barrier (BBB) represents a plausible means of improving their brain delivery by providing suitable substrates for active membrane transport. In particular, conjugation with tyrosine or glucose has recently been shown to be a successful means of selective drug delivery; for example, phosphonoformate-L-tyrosine conjugate is actively transported,[4] by means of active amino acid carriers, through monolayers of porcine brain microvessel endothelial cells, and a glycosyl phosphotriester prodrug of 3′-azido-3′-deoxythymidine (AZT) shows good delivery to the CNS.[5] Similarly, conjugating glucose or galactose to poorly absorbable drugs can improve their intestinal absorption by means of glucose transport carriers in the small intestine;[6−8] for example, tocopherol conjugation to a monocarboxylate or glycoside moiety has appeared to provide suitable substrates for active erythrocyte membrane transport.[9]

Nipecotic acid (**1**) is one of the most potent in vitro inhibitors of neuronal and glial γ-aminobutyric acid (GABA) uptake.[10] Disorders such as Parkinson's disease, Huntington's chorea, and epilepsy may result from abnormalities in the GABA system and, thus, enhancement of the activity of GABA may be a useful treatment for these disorders. Unfortunately, nipecotic acid is a highly polar compound that does not easily penetrate the BBB, and is therefore inactive as an anticonvulsant when administered systemically.[11,12]

Successful prodrugs of nipecotic acid should be readily transported into the CNS and hydrolyzed there to the parent drug. Several esters of nipecotic acid (e.g., alkyl-, substituted phenyl-, and triaryl-nipecotic esters) have been synthesized with the goal to increase drug lipophilicity and have been reported to have varying degrees of anticonvulsant activity and to inhibit in vitro GABA uptake after conversion to the parent drug.[13−15]

The purpose of our research was to synthesize new nipecotic acid esters (**3**−**6**) obtained by chemical conjugation with essential nutrients, such as glucose, galactose, or tyrosine, that are actively transported across the BBB. These compounds were assayed to evaluate their in vitro chemical stability and enzymatic hydrolysis. In addition, their anticonvulsant activity was evaluated in vivo in Diluted Brown Agouti (DBA)/2 mice, an excellent animal model for the study of certain kinds of epilepsy and for testing new anticonvulsant drugs.[16,17]

Methods and Materials

Materials—Nipecotic acid was obtained from Sigma Chemical Company, Boc-L-tyrosine was purchased from Fluka Chemical Company. All other reagent chemicals were from Aldrich Chemical Company.

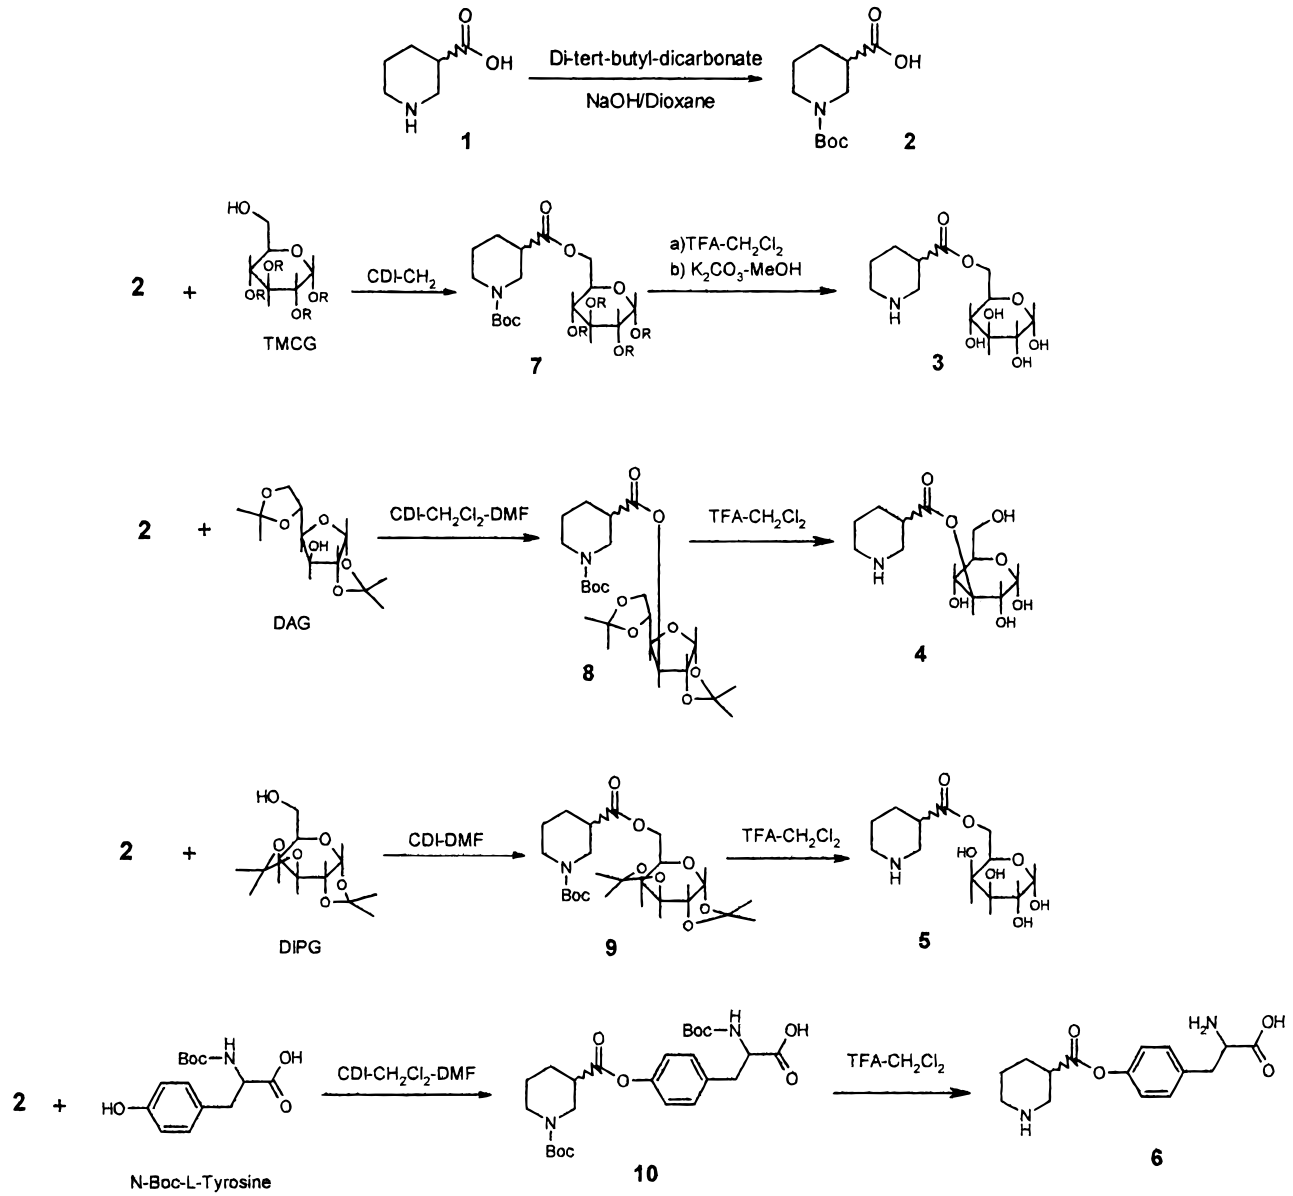

Scheme 1—Synthesis of nipecotic acid eters (**3**–**6**): synthetic routes and chemical structures of the obtained compounds (abbreviations: TMCG, 1,2,3,4-tetramethylcarbonate-D-glucose; DAG, diacetone-D-glucose; DIPG, 1,2,3,4-diisopropylidene-D-galactose).

Liquid Chromatographic (LC) grade acetonitrile and water, used in high-performance liquid chromatography (HPLC), were obtained from Merck and Carlo Erba, respectively.

Apparatus—Melting points were taken on Buchi 510 capillary melting point apparatus and are uncorrected.

The ^{1}H NMR and ^{13}C spectra were recorded on a Bruker WM 250 and on a Bruker AMX 500, respectively, using $CDCl_3$ as solvent. Chemical shifts are reported in ppm (δ) relative to tetramethylsilane as internal standard for ^{1}H NMR and in ppm relative to the solvent for ^{13}C NMR. Elemental analyses were performed on a Carlo Erba model 1108 elemental analyzer.

The flash chromatography was performed on Merck silica gel (0.040−0.063 mm) column. The HPLC apparatus consisted of a Varian 5000 system (Varian, Walnut Creek, CA) equipped with a 20-μL loop and an HP 1046A fluorescence detector (Hewlett-Packard, D-76337 Waldbrom, Germany). Integration of the chromatographic peaks was achieved with a 4290 integrator (Varian).

General Synthetic Method—All esters (**3**−**6**) were prepared as outlined in Scheme 1.

Initially we started from *N*-Boc nipecotic acid (**2**) obtained by treatment of (**1**) with di-*tert*-butyl-dicarbonate. Esterification of (**2**), in the presence of 1,1[1]-carbonyldiimidazole (CDI), with 1,2,3,4-*O*-tetramethyl carbonate-D-glucose (TMCG), diacetone-D-glucose (DAG), 1,2:3,4-di-*O*-isopropylidene-D-galactopyranose (DIPG), or *N*-Boc-L-tyrosine, afforded the corresponding esters (**7**−**10**). These esters, submitted to deprotection, allowed us to obtain compounds **3**−**6**.

N-Boc-Nipecotic Acid (2)—Nipecotic acid (**1**; 1 g, 7.75 mmol) was dissolved in dioxane (10.7 mL) and NaOH solution (1 N, 9.6 mL, 9.6 mmol). The resulting solution was stirred for 5 h, with the addition of the di-*tert*-butyl-dicarbonate (1.9 g, 10.0 mmol). The solvent was evaporated, and the resulting aqueous mixture was layered with ethyl acetate (EtOAc; 15 mL). Then, 1 N HCl solution was added with vigorous stirring until the pH of the aqueous phase was 2. The layers were separated, and the aqueous layer was extracted with EtOAc (3 × 10 mL). The EtOAc phases were combined, washed with brine (6 mL), dried over Na_2SO_4, filtered, and concentrated to give 1.42 g of (**2**) as a white solid (80% yield).

^{1}H NMR ($CDCl_3$): δ 4.1 + 3.85 (m, 2H, 2-H), 3.05 + 2.85 (m, 2H, 6-H), 2.50 (m, 1H, 3-H), 2.05 + 1.72 (m, 2H, 4-H), 1.70 + 1.46 (m, 2H, 5-H), 1.45 (m, 9H, -Boc).

N-Boc-Nipecotic Acid (1′,2′,3′,4′−O-Tetramethyl carbonate)-D-glucopyranos-6′-yl Ester (7)—To a stirred solution of *N*-Boc nipecotic acid (**2**; 1 g, 4.36 mmol) in CH_2Cl_2-dimethyl formamide (DMF) (9:1, 30 mL) was added CDI (706 mg, 4.36 mmol), and the mixture was stirred for 1 h at room temperature (RT). A solution of 1,2,3,4-tetramethyl carbonate-D-glucose (TMCG; 2.17 g, 5.26 mmol) in CH_2Cl_2/DMF (1:5, 30 mL) was added in a dropwise manner and

stirred for 24 h at RT. Most of the DMF was removed in vacuo, and the reaction mixture was taken up in EtOAc (30 mL), washed with water (20 mL) and brine (20 mL), and dried. Solvent was removed in vacuo and the crude was purified by flash chromatography eluting with hexane/EtOAc (6:4) to provide 1.90 g of (**7**) as a pale yellow oil (69.5% yield).

^{1}H NMR ($CDCl_3$): δ 6.00 (m, 1H, 1^1-H), 5.40 (m, 1H, 3^1-H), 4.92 (m, 1H, 2^1-H), 4.60 (m, 2H, 6^1-H), 4.15 (m, 2H, 4^1-H and 5^1-H), 4.05 + 3.85 (m, 2H, 2-H); 3.65 + 2.75 (m, 2H, 6-H), 3.55 (m, 12H, methyl carbonate groups), 2.55 (m, 1H, 3-H), 2.15 + 1.80 (m, 2H, 4-H), 1.45 + 1.35 (m, 2H, 5-H), 1.20(m, 9H, Boc).

Nipecotic Acid D*-glucos-6′-yl Ester* (**3**)—To a solution of **7** (1.90 g, 3.04 mmol) in CH_2Cl_2 (5 mL), 5 mL of trifluoroacetic acid (TFA) was added, and the mixture was stirred at RT for 2 h. Evaporation of the solvent gave a residue that was poured into a saturated solution of $NaHCO_3$ (20 mL) and extracted with $CHCl_3$ (3 × 15 mL). The organic layers were dried over Na_2SO_4 and concentrated in vacuo. This material (1.5 g) was taken directly into the next reaction without further purification. To a solution of crude (1.5 g) in MeOH (10 mL) was added K_2CO_3 (100 mg), and the mixture was stirred at RT for 12 h. Evaporation of the solvent gave a residue that was taken up in water and neutralized with 6 N aqueous HCl, diluted with more water, and washed with $CHCl_3$.The aqueous layers were concentrated in vacuo, and the residue was submitted to cation-exchange chromatography, eluting with 10% pyridine in water to give 610 mg of (**3**) (69% yield) as a pale yellow solid (mp 145−146 °C).

^{1}H NMR (D_2O): δ 4.65 (m, 1H, 1^1-H), 4.60 (m, 1H, 3^1-H), 3.70 (m, 1H, 2^1-H), 3.50 (m, 3H, 6^1-H and 5^1-C), 3.15 (m, 3H, 3^1-C and 2-H), 2.95 + 2.75 (m, 2H, 6H), 2.45 (m, 1H, 3-H), 1.90 + 1.65 (m, 2H, 4-H), + 1.55 (m, 2H, 5-H).

^{13}C NMR (D_2O + MeOD): δ 172 (−COOR), 96.84 (C-1^1), 76.86−76.66 (C-3^1), 75.71 (C-2^1), 75.31−75.08 (C-5^1), 70.56 (C-4^1), 63.57−63.33 (C-6^1), 48.78 (C-2), 45.02−44.91 (C-6), 39.57 (C-3), 26.63 (C-5), 21.98 (C-4).

*N-Boc Nipecotic Acid Diacetone-*α*-*D*-glucofuranos-3′-yl Ester* (***8***)—To a stirred solution of *N*-Boc-nipecotic acid (**2**; 1 g, 4.36 mmol) in CH_2Cl_2/DMF (9:1, 30 mL) was added CDI (706.97 mg, 4.36 mmol), and the mixture was stirred for 1 h at RT. A solution of DAG (1.36 g, 5.23 mmol) in CH_2Cl_2/DMF (9:1, 30 mL) was added in a dropwise manner and stirred for 24 h at RT. Most of the DMF was removed in vacuo, and the reaction mixture was taken up in EtOAc (30 mL), washed with water (20 mL) and brine (20 mL), and dried. Solvent was removed in vacuo, and the crude was purified by flash chromatography, eluting with hexane/Et_2O (8:2) to provide 1.34 g of **8** as a white oil (65% yield).

^{1}H NMR ($CDCl_3$): δ 5.85 (m, 1H, 1^1-H), 5.25 (m, 1H, 3^1-H), 4.41 (m, 1H, 2^1-H), 4.15 (m, 3H, 6^1-H and 5^1-H), 4.05 (m, 1H, 4^1-H), 3.95 (m, 2H, 2-H), 2.85 + 2.72 (m, 2H, 6-H), 2.48 (m, 1H, 3-H), 2.00 + 1.70 (m, 2H, 4-H), 1.70 + 1.55 (m, 2H, 5-H), 1.40 (m, 21H, -Boc and ketals).

Nipecotic Acid D*-Glucos-3′-yl Ester* (***4***)—To a solution of (**8**; 1.34 g, 2.84 mmol) in CH_2Cl_2 (5 mL) was added TFA (5 mL), and the mixture was stirred at RT for 12 h. Evaporation of the solvent gave a residue that was taken up in water (20 mL) and neutralized with 10% aqueous NH_4OH, diluted with more water, and washed with $CHCl_3$ (3 × 15 mL). The aqueous layers were concentrated in vacuo, and the residue was submitted to cation-exchange chromatography, eluting with 10% pyridine in water to give 690 mg of **4** (84% yield) as a pale yellow solid (mp 135−136 °C).

^{1}H NMR (D_2O): δ (m, 1H, 1^1-H), 4.41 (m, 1H, 3^1-H), 3.65 (m, 1H, 2^1-H), 3.50 (m, 2H, 6^1-H), 3.21 (m, 1H, 5^1-H), 3.15 (m, 2H, 4^1-H), 3.15 + 3.03 (m, 2H, 2-H), 2.90 + 2.81 (m, 2H, 6-H), 2.42 (m, 1H, 3-H); 1.81 + 1.67 (m, 2H, 4-H), 1.51 (m, 2H, 5-H).

^{13}C NMR (D_2O + MeOD): δ 180.03 (−COOR), 97.17−93.30 (C-1^1), 77.96 (C-3^1), 77.06 (C-2^1), 75.44 (C-5^1), 70.85 (C-4^1), 61.87 (C-6^1), 48.53 (C-2), 46.78 (C-6), 39.44 (C-3), 26.60 (C-5), 22.01 (C-4).

*N-Boc-Nipecotic Acid (1′,2′:3′,4′-diisopropylidene)-*α*-*D*-galactopyranos-6′-yl Ester* (***9***)—To a stirred solution of *N*-Boc-nipecotic acid (**2**; 1 g, 4.36 mmol) in CH_2Cl_2/DMF (9:1, 30 mL) was added CDI (706 mg, 4.36 mmol), and the mixture was stirred for 1 h at RT. A solution of DIPG (1.36 g, 5.23 mmol) in CH_2Cl_2/DMF (1:5, 30 mL) was added in a dropwise manner and stirred for 24 h at RT. Most of the DMF was removed in vacuo, and the reaction mixture was taken up in EtOAc (30 mL), washed with water (20 mL) and brine (20 mL), and dried. Solvent was removed in vacuo, and the crude was purified by flash chromatography eluting with hexane/Et_2O (8:2) to provide 1.75 g of **9** (85% yield) as a white oil.

^{1}H NMR ($CDCl_3$): δ 5.50 (m, 1H, 1^1-H), 4.60 (m, 1H, 3^1-H), 4.32 (m, 1H, 2^1-H), 4.20 (m, 3H, 6^1-H and 5^1-H), 4.00 (m, 1H, 4^1-H), 2.95 (m, 2H, 2-H), 2.75 (m, 1H, 3-H), 2.75 + 2.50 (m, 2H, 6-H), 2.05 + 1.70 (m, 2H, 4-H), 1.55 + 1.40 (m, 2H, 5-H), 1.40 (m, 21H, Boc and ketals).

Nipecotic Acid D*-Galactos-6′-yl Ester* (***5***)—To a solution of **9** (1.75 g, 3.71 mmol) in CH_2Cl_2 (5 mL), TFA (5 mL) was added, and the mixture was stirred at RT for 2 h. Evaporation of the solvent gave a residue that was taken up in water (20 mL), neutralized with 10% aqueous NH_4OH, diluted with more water, and washed with $CHCl_3$ (3 × 15 mL). The aqueous layers were concentrated in vacuo, and the crude was submitted to cation-exchange chromatography, eluting with 10% pyridine in water to give 915 mg of **5** (84% yield) as pale yellow solid (mp 138−139 °C).

^{1}H NMR (D_2O): δ 4.95 (m, 1H, 1^1-H), 4.28 (m, 1H, 3^1-H), 3.60 (m, 1H, 2^1-H), 3.42 (m, 2H, 6^1-H), 3.35 (m, 1H, 5^1-H), 3.25 (m, 1H, 4^1-H), 3.10 + 2.95 (m, 2H, 2-H), 2.80 (m, 2H, 6-H), 2.33 (m, 1H, 3-H), 1.75 + 1.65 (m, 2H, 4-H), 1.45 (m, 2H, 5-H).

^{13}C NMR (D_2O + MeOD): δ 179.41 (−COOR), 96.72 (C-1^1), 75.15 (C-3^1), 72.04 (C-2^1), 70.40 (C-5^1), 68.82 (C-4^1), 60.97 (C-6^1), 46.01 (C-2), 43.99 (C-6), 40.76 (C-3), 25.73 (C-4), 21.01 (C-5).

*N-Boc-Nipecotic Acid N-Boc-*L*-Tyrosyl Ester* (***10***)—CDI (0.71 g, 4.37 mmol) was added to a solution of **2** (1 g, 4.37 mmol) in CH_2Cl_2/DMF (3:1, 50 mL), and the resulting mixture was stirred at RT. After disappearance of the starting materials (determined by thin-layer chromatography), *N*-Boc-L-tyrosine (1.11 g, 4.15 mmol) in CH_2Cl_2/DMF (3:1, 150 mL) was added in a dropwise manner to the mixture over 120 min, and stirring was then continued for 12 h. After evaporation of the solvent, the residue was taken up in EtOAc (60 mL) and washed with water (2 × 30 mL). The organic layer was dried on Na_2SO_4 and evaporated to give a residue (3 g) that was submitted to flash chromatography, eluting with $CHCl_3$/MeOH/AcOH (95:4.5:0.5) to afford the title compound (**10**) as a pale yellow oil (1.5 g, 71%).

^{1}H NMR ($CDCl_3$): δ 6.85 (d, 2H J = 7 Hz, 2^1-H and 6^1-H), 6.64 (d, 2H J = 7 Hz, 3^1-H and 5^1-H), 4.91 (br, 1H, −NH−Boc), 4.45 (m, 1H, 8^1-H), 4.15 + 3.80 (m, 2H, 2-H), 2.85 (m, 2H, 7^1-H), 2.84 + 2.75 (m, 2H, 6-H), 2.40 (m, 1H, 3-H), 2.00 + 1.43 (m, 2H, 4-H), 1.40 (m, 20H, 5-H and -Boc).

Nipecotic Acid L*-Tyrosyl Ester* (***6***)—To a solution of **10** (1.75 g, 3.71 mmol) in CH_2Cl_2 (5 mL), TFA (5 mL) was added, and the mixture was stirred at RT for 2 h. Evaporation of the solvent gave a residue that was taken up in water (20 mL), neutralized with 10% aqueous NH_4OH, diluted with more water, and washed with $CHCl_3$ (3 × 15 mL). The aqueous layers were concentrated in vacuo, and the crude was submitted to cation-exchange chromatography, eluting with 10% pyridine in water to give 760 mg of **6** (73% yield) as a white solid (mp 134−135 °C).

^{1}H NMR (DMSO): δ 7.30 (d, 2H J = 7 Hz, 2^1-H and 6^1-H), 7.20 (d, 2H J = 7 Hz, 3^1-H and 5^1-H), 4.00 (m, 1H, 7^1-H), 3.50 + 3.30 (m, 2H, 2-H), 3.19 (m, 2H, 6^1-H), 3.05 (m, 2H, 6-H), 2.95 + 1.82 (m, 2H, 4-H), 1.82 + 1.70 (m, 2H, 5-H).

^{13}C (DMSO): δ 173.50 (−COOH); 172.84 (−COO−), 156.35 (C-4^1), 134.64 (C-1^1), 131.75−131.63 (C-2^1 and C-6^1), 116.79 (C-3^1 and C-5^1), 55.87 (C-7^1), 44.96 (C-2), 44.84 (C-6), 39.20 (C-3), 36.31−36.06 (C-6^1), 25.52 (C-5), 21.73 (C-4).

Chemical Stability—Nipecotic ester solutions were prepared by dissolving an aliquot of **3**−**6** in pH 7.4 phosphate buffer to give a final concentration of ≈10^{-5} M. The solution was maintained at 37 °C, and aliquots were withdrawn every 2 h for the initial 12 h of incubation and successively every 12 h for 7 days. The disappearance of the nipecotic esters was followed by HPLC analysis using the method reported later. Pseudo-first-order rate constants for chemical hydrolysis were determined from slopes of linear plots obtained by reporting the logarithm of residual nipecotic ester against time. All experiments were carried out in triplicate.

Enzymatic Stability—Enzymatic hydrolysis of nipecotic esters (**3**−**6**) was determined using the procedure described in the literature.[18] Porcine liver esterase (obtained from Sigma) was diluted 10 times with phosphate buffer and used to hydrolyze nipecotic esters. Nipecotic ester solutions were prepared by dissolving an aliquot of **3**−**6** in phosphate buffer to give a final concentration of ≈10^{-5} M. The solution was maintained at 37 °C, and 325 μL of porcine esterase were added to achieve a concentration of 1.3 U/mL. Aliquots of 300 μL were withdrawn every hour for 16 h and combined with 600 μL of 0.01 N HCl in methanol. After centrifugation at 5000 × *g* for 5 min, an aliquot of supernatant was derivatized by the method reported later and

then monitored by HPLC. Pseudo-first-order rate constants for enzymatic hydrolysis were determined from the slopes of linear plots obtained by reporting the logarithm of residual nipecotic ester against time. All experiments were carried out in triplicate.

Analytical Procedures—For dansyl derivatization of nipecotic acid (**1**) and of **3**−**5**, 100 μL of sample or of stock standard solutions (prepared in pH 7.4 phosphate buffer) were combined with 9 μL of dansyl chloride (1.5 mg/mL in acetonitrile) and 100 μL of 80 mM Li_2CO_3, pH 9.5. The mixture was kept at room temperature for 2 h in darkness. The reaction was stopped by adding 10 μL of 2% methylamine hydrochloride solution. For derivatization of nipecotic tyrosine ester (**6**), 125 μL of sample or of stock standard solutions (prepared in pH 7.4 phosphate buffer) were combined with 55 μL of fluorescamine (2 mg/mL in acetone) and 125 μL of 120 mM phosphate buffer, pH 8.0; then, the mixture was mixed by vortex for a few minutes. An aliquot of derivatized drug solutions (20 μL) was analyzed by the chromatographic method described next.

HPLC analysis was performed with an ODS Hypersil column (particle size, 5 μm; 125 × 4 mm i.d.; Hewlett-Packard, D-76337 Waldbrom, Germany). The mobile phase consisted of sodium acetate buffer (100 mM)/acetonitrile (75:25). The flow rate was set at 1.0 mL/min. Each sample was filtered prior to injection with a Millex HV13 filter (Waters-Millipore Corporation, Milford, MA), and an aliquot (20 μL) was injected into the HPLC apparatus. Dansyl derivatives of nipecotic acid (**1**) and **3**−**5** were monitored at 330 nm (excitation wavelength) and 510 nm (emission wavelength), and the fluorescamine derivative of the nipecotic tyrosine ester (**6**) was monitored at 260 nm (excitation wavelength) and 470 nm (emission wavelength). The retention times of dansyl derivatives of **1** and **3**−**5** were 6.29, 6.7, 6.9, and 7.37 min, respectively. The retention time of the fluorescamine derivative of ester **6** was 4.65 min. The limit of sensitivity was <2 μM for detection of dansyl derivatives of **1** and **3**−**5** and <3 μM for detection of the fluorescamine derivative of the ester **6**.

Anticonvulsivant Activity—DBA/2 mice, purchased from Charles River (Calco, Como, Italy), were used to evaluate the anticonvulsant activity of **1** and **3**−**6**. The DBA strain of the house mouse, *Mus musculus*, inbred since 1909, has been known since 1947 to be susceptible to sound-induced seizures. Nearly 100% of the males and females of the DBA/2 strain undergo an age-dependent, often fatal, sequence of convulsions (a wild running phase, followed by clonic convulsions and tonic extensions, ending in respiratory arrest or full recovery) when initially exposed to a loud mixed-frequency sound (12−16 kHz; 90−120 dB) such as a door bell. The age of maximum susceptibility of the DBA/2 strain to the sound-induced seizures has been reported as 20−39 days, 21−28 days, or 16−26 days. Other strains of audiogenic mice often require acoustic priming in the neonatal period to attain a similar degree of seizure susceptibility.[19]

In our study, male DBA/2 mice (10 for each experimental group), 21−28 days old, were exposed to auditory stimulation (109 dB for 60 s or until tonic extension occurred), 30 min following injection of the drugs tested **1** and **3**−**6** or of a same volume of their vehicle. Compounds **1** and **3**−**5** were dissolved in isotonic phosphate buffer, pH 7.4; **6** was dissolved in 20% EtOH/H_2O (v/v). The injection volume (both for drug solutions and the vehicle alone) was 0.1 mL/10 g body weight.

The intensity of seizure response (SR) was assessed on the following scale: 0 = no response, 1 = wild running, 2 = clonus, 3 = tonus, and 4 = respiratory arrest. The maximum response was recorded for each animal. Rectal temperature was recorded immediately prior to auditory testing using an Elektrolaboratoriet thermometer type T.E.3. Behavioral changes (spontaneous activity, explorative behavior, tremor, spontaneous convulsions) were observed during the period between drug administration and auditory testing.

Statistical comparisons between controls and drug-treated groups were carried out with Fisher's exact probability test (incidence of seizure phases) and the Mann−Whitney U test. The percentage of incidence of each seizure phase was calculated for the different doses of the drugs administered. Fifty percent efficient doses (ED_{50}s) with 95% confidence limits (95% CL) of the nipecotic tyrosine ester (**6**) were estimated, concerning tonus and clonus phases, by the method of Litchfield and Wilcoxon.

Table 1—Chemical and Enzymatic Stability of Esters 3–6

drug	$t_{1/2}$ (h)[a]	
	pH 7.4 buffer	esterase (1.3 U/mL)
3	150.00	8.30
4	169.42	10.70
5	197.48	14.0
6	27.37	2.5

[a] $t_{1/2}$ was calculated from the equation: $t_{1/2} = (\ln 0.5)/K^1$, where K^1 is the pseudo-first-order rate constant.

Results and Discussion

Data concerning chemical and enzymatic stability of ester prodrugs **3**−**6** are reported in Table 1. Figure 1 and Figure 2 show the times courses of disappearance of nipecotic esters (**3**−**6**) in pH 7.4 buffer solution and in the presence of porcine esterase. When we evaluated their chemical stability, the compounds appeared stable in a pH 7.4 buffered solution; however, prodrugs **3**−**5** disappeared more slowly than the ester **6**.

To confirm that the tested prodrugs can be enzymatically hydrolyzed, we evaluated their stability in the presence of porcine esterase. The findings indicate that each of the four esters **3**−**6** is capable of being cleaved in vitro by esterase.

Half-life times concerning enzymatic stability were notably lower than those obtained in buffer solution. Moreover, we found a good correlation between chemical and enzymatic decomposition rates of the prodrugs examined.

Table 2 shows the results obtained in in vivo experiments with a genetically seizure-prone strain (DBA/2) of mice. DBA/2 mice are a useful model to test compounds acting on the GABAergic system;[20] furthermore, this model avoids the problem of possible effects of tested substances on the absorption or metabolism of the convulsant compound that arises with drug-induced seizures.[21,22] According to data reported by other authors, we confirmed that nipecotic acid (**1**; 0.75 mmol/kg), given systemically 30 min before sound exposure, possesses no anticonvulsant effect.[11,12] Also, **3**−**5**, intraperitoneally injected in the same experimental schedule at dose levels up to 0.75 mmol/kg, did not protect mice against all phases of audiogenic seizures. Conversely, when the ester prodrug **6** was administered systemically, a significant dose-dependent anticonvulsant activity was observed. In fact, a marked reduction in the incidence of each phase (wild running, clonus, tonus, respiratory arrest) of audiogenic seizures was evident at the dose levels studied (0.125, 0.17, 0.21, 0.25, 0.5, and 0.75 mmol/kg). Furthermore, no behavior alteration or change in rectal temperature in comparison with control animals were recorded after administration of **3**−**6** (data not shown).

The in vivo protective activity of systemically administered nipecotic tyrosine ester **6** against audiogenic seizures and the inefficiency of nipecotic acid (**1**) under the same experimental conditions suggest that this ester prodrug is transported intact across the BBB, beyond which it could be hydrolyzed. Tyrosine enters the brain through the large neutral amino acid transporter system. This system, present in the brain microvessel endothelial cells, has been extensively characterized and is of particular interest in the transport of amino acid drugs into the brain.[23,24] Moreover, Walker and co-workers[4] have recently demonstrated that a phosphonoformate−L-tyrosine conjugate possesses a high affinity for large amino acid transporters in monolayers of porcine brain microvessel endothelial cells and so might be a substrate for facilitated transport at the BBB. As to our findings, one tempting hypothesis is that the tyrosine moiety acts as a vector, which should allow

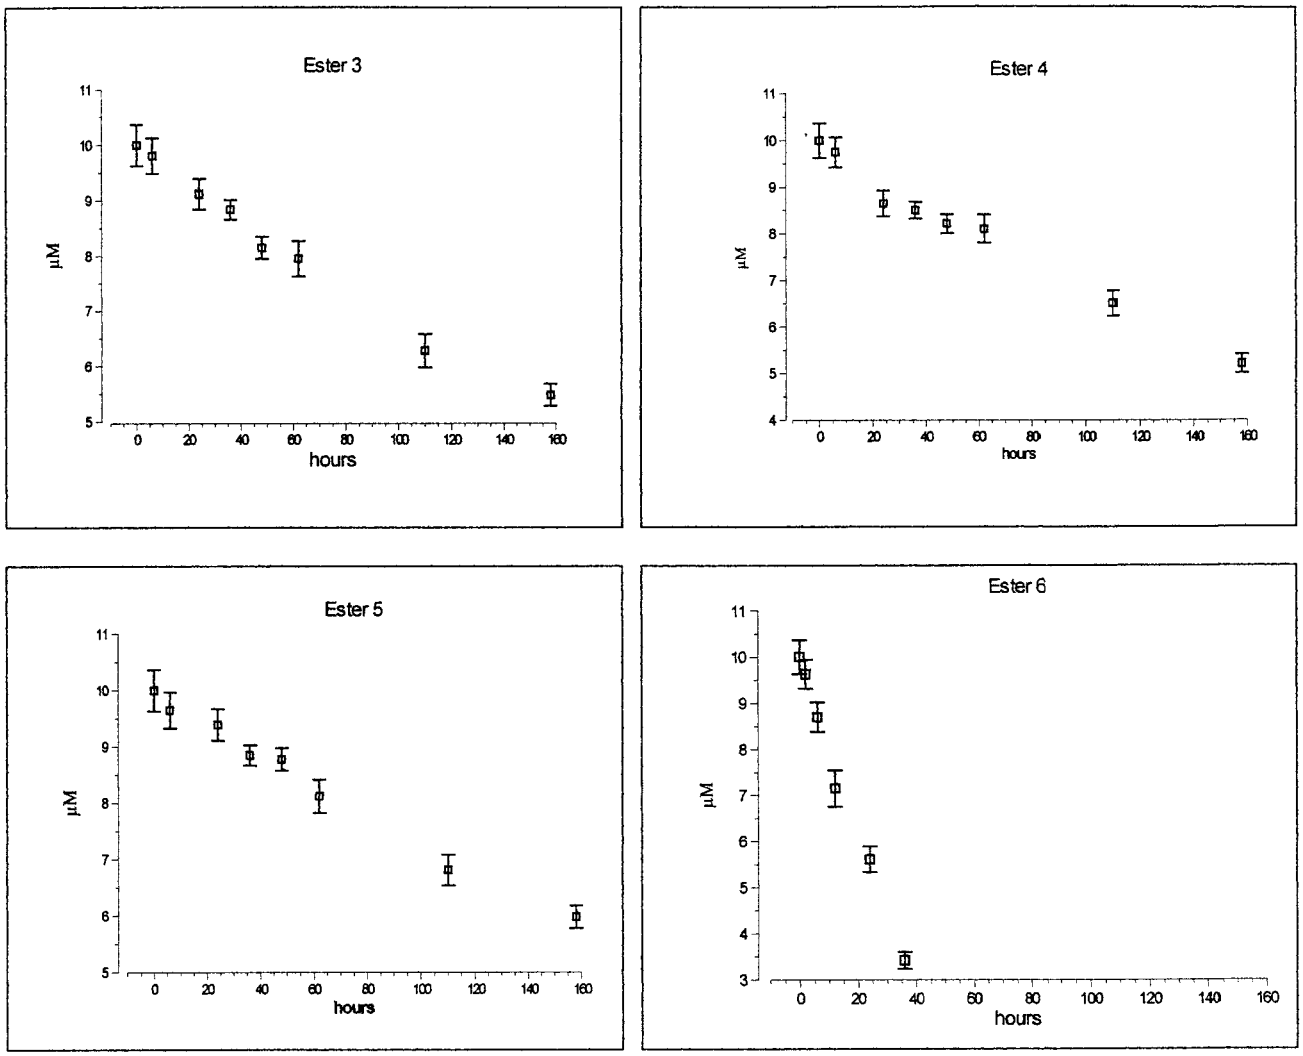

Figure 1—Time courses of disappearance of nipecotic esters (**3**–**6**) in pH 7.4 buffer solution obtained by plotting time (h) versus drug concentration (μM). Each point represents the mean ± SD of three experiments.

the transport of the nipecotic tyrosine ester (**6**) across the BBB; as the drug appears to achieve pharmacologically active concentrations in the brain, it could be supposed to be endowed with a high affinity for the amino acid carriers. Unfortunately, the almost absolute insolubility of nipecotic tyrosine ester (**6**) in water made it impossible to calculate its water/oil partition coefficient. Of course, further studies are needed to clarify if the ability of **6** to cross the BBB is dependent also on its lipophilicity. For example, Stark et al.[25] have demonstrated that des-tyrosine1-D-phenylalanine3-beta-casomorphin is able to cross the BBB by paracellular transport without using a carrier system. One could to point out that the nipecotic tyrosine ester (**6**) seems more potent than other lipophilic nipecotic acid esters, such as (+)ethyl nipecotate[12] or pivaloyloxymethyl ester;[11] however, its ED_{50}s calculated for tonus (ED_{50}, 0.130 mmol/kg; 95% CL, 0.115−0.146 mmol/kg) and clonus (ED_{50}, 0.173 mmol/kg, 95% CL, 0.162−0.186 mmol/kg) are very higher than those of tiagabine (a GABA uptake inhibitor, structurally related to nipecotic acid), as measured in the same experimental models[26] (tonus: ED_{50}, 1 μmol/kg; clonus: ED_{50}, 5 μmol/kg).

Furthermore, the present findings do not allow us to establish exactly whether the observed anticonvulsant activity of **6** could be due to nipecotic acid derived from its enzymatic hydrolysis or, partially at least, to the intact compound. However, several papers have provided information that the anticonvulsant effect and GABA uptake inhibition, induced by various esters of nipecotic acid, are mostly due to free nipecotic acid generated after hydrolysis in the brain.[27,28]

Similar results have also been reported for esters of isoguvacine, a GABA uptake inhibitor, structurally related to nipecotic acid.[29] Finally we can exclude that the observed anticonvulsant effect of **6** is due to the free promoiety (tyrosine) generated in the brain; in fact, tyrosine, systemically injected under the same experimental conditions at a dose level of 0.75 mmol/kg, elicited no protective effect against audiogenic seizures (data not shown).

Concerning prodrugs **3**−**5**, several possible explanations can be offered for their lack of anticonvulsant activity. First, β−D-glucose and galactose enter the brain through the transporter GLUT-1.[30] A high transporter affinity is required, so that a drug may be efficiently transported by the carrier across the BBB. Prodrugs **3**−**5** might have insufficient affinity for this carrier to achieve significant brain uptake and/or their transport through the BBB might be limited by competition with the endogenous substrate. In addition, the hydrophilic character of esters **3**−**5** would preclude their passive transport through the BBB.

Second, carbohydrate receptor-mediated targeting of drugs has been proposed as a potential method for site-specific delivery of drugs to cells possessing carbohydrate receptors on their surface. Several types of galactosylated drugs are reported to be interesting candidates for successful delivery to liver cells.[31] So, nipecotic derivatives

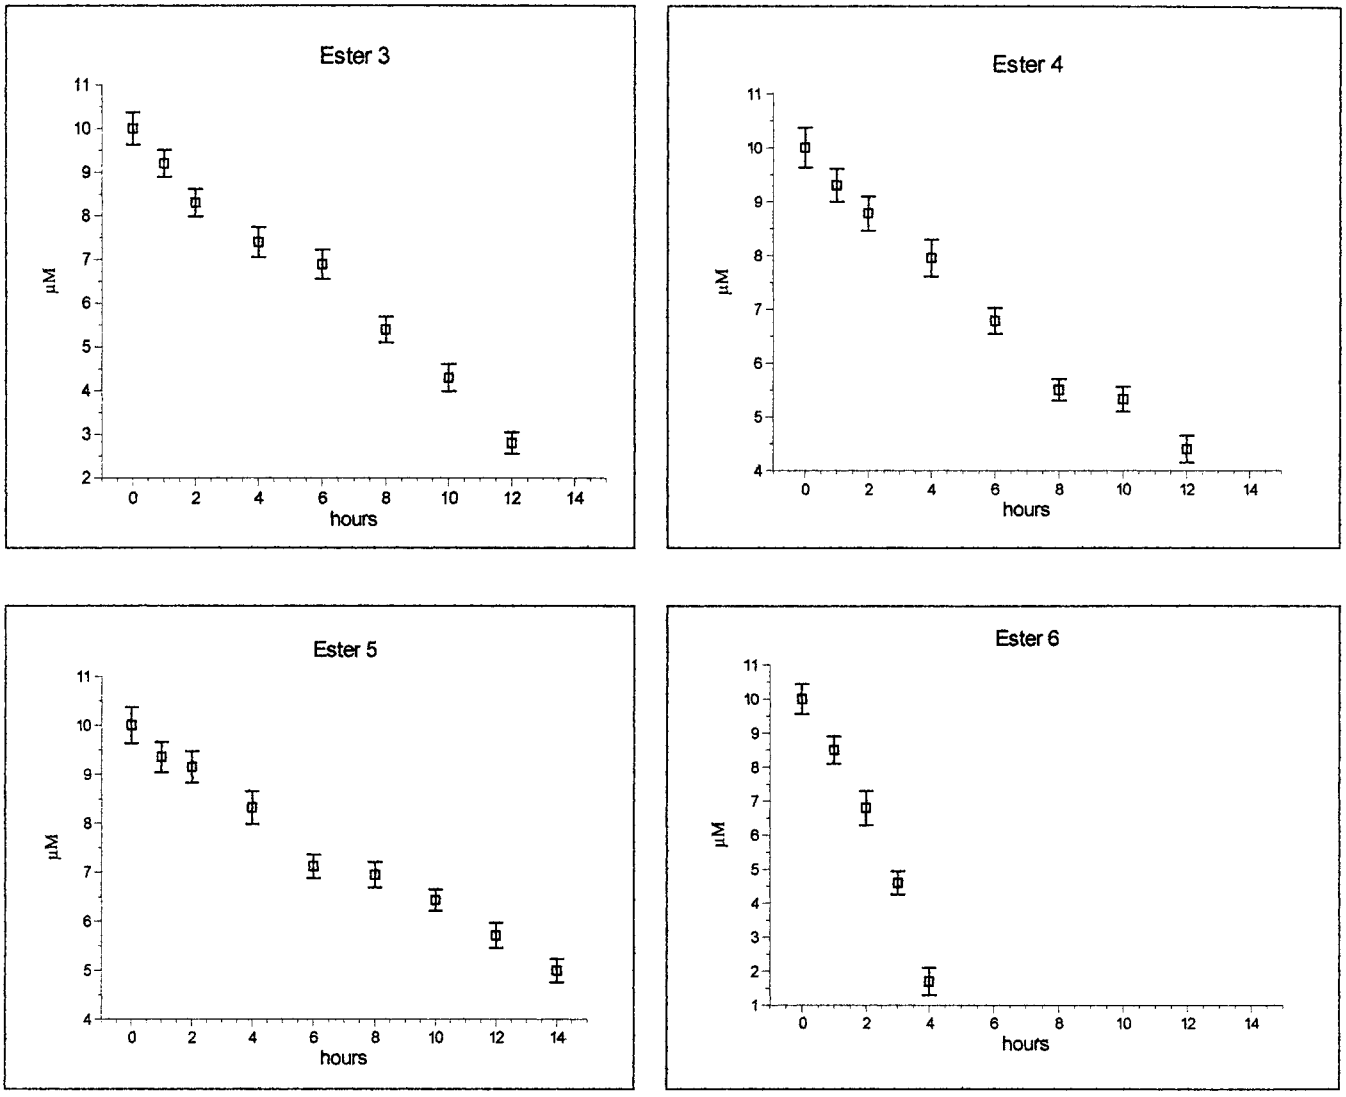

Figure 2—Time courses of disappearance of nipecotic esters (**3**–**6**) in the presence of porcine esterase obtained by plotting time (h) versus drug concentration (μM). Each point represents the mean ± SD of three experiments.

Table 2—Effects of Intraperitoneal Injection of 1, 3, 4, 5, and 6 on Audiogenic Seizures in DBA/2 Mice[a]

drug	dose, mmol/kg	% response					
		W.R.[b]	clonus	tonus	R.A.[b]	SR[b]	*n*[b]
controls A[c]	vehicle (0)	100	100	80	60	3.40	10

6	0.500	20[d]	10[d]	0[d]	0[d]	0.30[e]	10
6	0.750	20[d]	20[d]	0[d]	0[d]	0.40[e]	10

[a] The incidence of each seizure phase is expressed as the percentage of mice in each group displaying that phase. [b] W.R. = wild running; R.A. = respiratory arrest; SR = seizure response expressed as arithmetic mean of the maximum individual response in each group; *n* = number of mice. [c] Mice given buffer, pH 7.4, 10 mL/kg, ip. [d] Mice given 20% EtOH/H_2O solution, 10 mL/kg, ip. [e] $p < 0.05$ from controls B, as assessed by Fisher's exact probability test. [f] $p < 0.05$ from controls B, as assessed by Mann–Whitney U test.

3−**5**, obtained by the conjugation with glucose and galactose, could be rapidly taken up and degraded by the liver after systemic injection. Therefore, these derivatives are hindered in the achievement of pharmacologically active concentrations in the brain.

Finally, a correlation between in vitro rates of enzymatic hydrolysis and its pharmacologic activity is generally expected for CNS-active prodrugs.[29] In fact, the rate of hydrolysis in plasma would have to be sufficiently slow to allow the prodrug to gain access to the brain, but not so slow as to remain inactive within the brain. Compounds **3**−**5** appeared much more resistant to enzyme-catalyzed hydrolysis ($t_{1/2}$ = 8.30, 10.70, and 14.0 h, respectively, for **3**, **4**, and **5**) than the prodrug **6** ($t_{1/2}$ = 2.5 h), but unlike **6** do not give protection against audiogenic seizures 30 min after administration. Moreover, no anticonvulsant effect was observed when audiogenic seizures were induced 1, 2, or 3 h after injection of **3**−**5** (data not shown). Further investigations would clarify if a significant pharmacological effect may be detectable at longer times after administration of the very slowly hydrolyzed esters **3**−**5**.

In conclusion, the present findings indicate that nipecotic tyrosine ester **6** is an excellent prodrug for potential application in the treatment of epilepsy and of other disorders resulting from abnormalities in the GABA system. Further studies are in progress to investigate the bioavailability of this compound and to clarify its mechanism of action.

Abstract □ Indinavir follows nonlinear pharmacokinetics upon oral administration at clinical doses. A study employing the stable isotope administration technique in a three-treatment design was conducted to identify the source of the nonlinearity and to determine the dose-dependency of systemic bioavailability. In treatment A, 400 mg of unlabeled indinavir (D_0) was coadministered orally with 16 mg of a hexadeutero analogue of indinavir (D_6) intravenously. In treatment B, 800 mg of D_0 po was coadministered with 16 mg of D_6 intravenously. In treatment C, 16 mg of iv D_6 was infused concurrently with 16 mg iv of D_0. Plasma concentrations of D_0 and D_6 were determined by an LC/MS/MS assay method. Concentrations of indinavir in plasma increased greater than dose-proportionally over the 400- to 800-mg dose range. No meaningful kinetic isotope effects were found in treatment C. Plasma concentrations of D_6 were dependent on the coadministered D_0-indinavir dose and were lowest in treatment C, higher in treatment A, and highest in treatment B. The bioavailability of indinavir was high (60–65%) and comparable between the 400- and 800-mg doses. There was a significant contribution of nonlinear kinetics in the systemic circulation to the observed disproportional increase in plasma concentrations following oral dosing. The high bioavailability at clinically relevant doses suggests a high degree of saturation of first-pass metabolism. These results further demonstrate that the concomitant administration technique in combination with the LC/MS/MS method can provide a realistic and reliable means of elucidating important pharmacokinetic properties of drug candidates during product development.

Introduction

Characterization of biopharmaceutical and pharmacokinetic attributes of a drug candidate is an integral part of the drug product development. When properly studied and evaluated, such information provides the scientific basis for the optimal definition of dosage regimens. Among the many important properties are the pharmacokinetics of drug absorption and disposition and their dependence on dose or concentration. Procedures for bioavailability assessment differ, depending on whether linear kinetics prevail in the therapeutically relevant concentration range.

For a drug exhibiting linear pharmacokinetics, as demonstrated by proportional increases in plasma concentration with dose, plasma clearance can be assumed to be independent of the concentration. Clinical studies for determination of the systemic bioavailability are often conducted in a crossover fashion. The bioavailability of the oral treatment relative to the reference intravenous treatment is estimated by comparing the dose-normalized areas under the drug concentration curve (AUC). The crossover study design eliminates the intersubject variation and results in improved reliability of the estimates.

For a drug with nonlinear disposition kinetics, its clearance is concentration-dependent, and the above-cited crossover bioavailability study design may not be valid.[1−4] Under special circumstances, concomitant administration of the intravenous reference dose and the oral dose may provide a viable approach of obtaining reliable bioavailability estimates.[1−3,5] In this approach, the reference treatment is distinguished from the oral treatment by the use of a tracer dose of the isotopically labeled drug.[2,4,6] With recent advances in the LC/MS/MS assay detector technology,[7,8] simultaneous tracking and quantitation of both the unlabeled and labeled analytes can be reliably achieved.[9,10] Due to its potential of high specificity and sensitivity, the technique is most useful when the labeled dose, given intravenously, is small in mass relative to that of the unlabeled dose given orally. With the concurrent dosing study design, the intrasubject variation is eliminated. Further, stable isotope-labeled analogues may be repetitively administered in clinical studies. The concurrent dosing design may also provide a means of identifying the source(s) of pharmacokinetic nonlinearity.

Indinavir, a potent HIV protease inhibitor, exhibited greater than dose-proportional increases in plasma concentrations following oral administration in clinical studies.[11,12] Possible causes of the observed nonlinearity include the dose-dependent absorption or first-pass metabolism, nonlinear systemic disposition, or both. Based on the LC/MS/MS assay technology, a clinical study was conducted to examine the source(s) of the nonlinearity and to compensate for the observed nonlinearity and thereby enabling estimates of the systemic bioavailability in the therapeutic dose range. The purpose of this communication is to present the design and findings of the study.

Materials and Methods

Equation 1 forms the basis of computing the bioavailability (F) of a given dose (D) based on the observed drug concentration ($C(t)$):

$$F_{po} = \frac{F_{iv} D_{iv} \int_0^\infty CL_{po}(t) C_{po}(t) dt}{D_{po} \int_0^\infty CL_{iv}(t) C_{iv}(t) dt} \quad (1)$$

where CL(t) is the clearance at time t, and subscripts iv and po denote the mode of administration. In general, the time profile of CL(t) is concentration-dependent and is unknown in a system where the disposition kinetics are nonlinear. The integrated quantities in eq 1 represent the respective amount of the drug which has been eliminated from the systemic circulation following the administration of test and reference treatments. In the present case, F_{iv} is assumed to be unity.

Upon simultaneous administration of a tracer intravenous dose and an oral dose, the systemically available drug from both doses is subject to the same time-course of clearance, CL(t):

$$F_{po} = \frac{D_{iv}}{D_{po}} \frac{\int_0^\infty CL(t) C_{po}(t) dt}{\int_0^\infty CL(t) C_{iv}(t) dt} \quad (2)$$

Under the situation where $C_{iv}(t)$ is an exact multiple of $C_{po}(t)$ at all times, the ratio of the two would remain constant:

$$z = \frac{C_{iv}(t)}{C_{po}(t)} \quad (3)$$

Substituting eq 3 into eq 2:

$$F_{po} = \frac{D_{iv}}{D_{po}} \frac{\int_0^\infty CL(t) C_{iv}(t) dt}{z \int_0^\infty CL(t) C_{iv}(t) dt} = \frac{D_{iv}}{z D_{po}} \quad (4)$$

Expressions similar to eqs 2 and 3 in bioavailability assessment under concurrent administration conditions have been discussed and reported previously.[5] In actual practice, due to differences in the absorption rate and infusion rate, eq 3 is virtually impossible to achieve since the ratio of the two concentrations will invariably fluctuate with time. As an approximation, an apparent z_{app} is defined as follows:

$$z_{app} = \frac{\int_0^\infty C_{iv}(t) dt}{\int_0^\infty C_{po}(t) dt} = \frac{AUC_{iv}}{AUC_{po}} \quad (5)$$

By analogy to eq 4, the bioavailability is estimated by the following:

$$F_{po} \cong \frac{D_{iv}}{z_{app} D_{po}} \quad (6)$$

In a nonlinear disposition system, the bioavailability computed with eq 6 would not be exact but would be an approximation. The degree of the imperfection would depend on the degree to which the concentration ratios, shown in eq 3, fluctuated with time. The magnitude of fluctuations in such a system might be minimized, but not eliminated, with properly designed clinical studies. To reduce the errors, other study designs, such as delaying the iv bolus or varying the infusion period to various fractions of plasma peak time (T_{max}), have been discussed previously.[5]

With the present approach, the estimation of bioavailability is based on the comparison of dose-normalized AUCs, and specific assumptions regarding the underlying mechanism(s) of the nonlinearity are not required. This represents a model-independent approach, with its computational procedures being identical to that of the conventional AUC method. It is worth noting that in a linear pharmacokinetic system, the accuracy of bioavailability estimation is independent of the fluctuations shown in eq 3.

Study Subjects and Dosing Regimens—The study was conducted as an open-label, three-period, single-dose study with 12 healthy subjects (6 males and 6 females, age range: 21 to 31 years; mean age, 25.3 years; weight range: 53 to 92 kg; mean weight, 70.9 kg). The protocol was approved by the Medeval Independent Ethics Committee, and informed consent was obtained from all subjects. The study subjects received doses of the unlabeled indinavir (D_0) as well as indinavir which was labeled with six deuterium atoms on the pyridomethyl side chain (D_6). The three treatments were as follows:

Treatment A: 400 mg D_0 orally as one 400-mg dry-filled capsule (DFC) plus 16-mg D_6 dose intravenously as an infusion.

Treatment B: 800 mg D_0 orally as two 400-mg DFC's plus 16-mg D_6 dose intravenously as an infusion.

Treatment C: Simultaneous intravenous infusion of 16 mg D_0 and 16 mg D_6 over 30 min.

Subjects fasted from midnight before drug administration and remained fasted until 2 h after the dosing. In treatments A and B, each oral D_0-indinavir dose was administered at 0 h with 240 mL water, and each intravenous D_6 dose was administered as a 30-min infusion, starting at 15 min and ending at 45 min following the ingestion of the oral dose. The infusion regimen was designed to minimize the fluctuations in the ratio between the expected plasma concentrations of D_0 and D_6 over time. Previous clinical studies[11–13] indicated an average T_{max} of 0.8 h and often with a lag time <0.25 h in absorption following oral administration.

Treatment C was designed to examine (a) the disposition kinetics of indinavir at concentrations significantly lower than that generally achieved following oral dosing; and (b) the possible in vivo enzymatic isotope effect on the metabolism (and therefore the systemic disposition) of indinavir. Depyridomethylation is known to be one of the CYP3A-mediated oxidative biotransformations of indinavir in humans.[14,15]

Treatments A and B were administered according to a randomized two-period crossover design. Treatment C was administered in the third period. All iv solutions contained 0.05 mg/mL of D_6-indinavir. In treatment C, the iv solution also contained 0.05 mg/mL of D_0-indinavir. All indinavir doses were expressed as the milligram equivalent of anhydrous free base of unlabeled drug.

Plasma samples for assay of indinavir were obtained in treatments A and B at 0 (predosing), 20, 25, 35 and 45 min, and at 1, 1.5, 2, 4, 6, 8, 10, 12, 16, and 24 h following oral dosing; and in treatment C at 0, 5, 10, 20, 30, and 45 min, and at 1, 1.5, 2, 4, 6, 8, 10, 12, 16, and 24 h postdosing. All samples were stored at −20 °C until assayed.

Analytical Method—Concentrations of D_0-indinavir and D_6-indinavir in plasma were quantified by an LC/MS/MS method.[16] Briefly, the analytes and internal standard were isolated from plasma via liquid−liquid extraction with methyl *tert*-butyl ether. Multiple reaction monitoring of the parent → product ion combinations of m/z 614 → 465, 620 → 471, and 654 → 505 were used to quantify D_0-indinavir, D_6-indinavir, and internal standard, respectively, in the resulting extracts. The method was validated over the concentration range of 1 to 200 ng/mL for each analyte, using 1-mL aliquots of plasma. Precision of the assay, as measured by the coefficient of variation, ranged from 0.9 to 4.3% and 0.9 to 6.2% for D_0-indinavir and D_6-indinavir, respectively. Indinavir concentrations were converted to a molar basis using molecular weights of 613.81 for D_0-indinavir and 619.81 for D_6-indinavir. The limit of quantification was 1.63 and 1.61 nM for D_0 and D_6, respectively.

Pharmacokinetic Analysis—Peak plasma concentration (C_{max}) and the time to peak plasma concentration (T_{max}) following oral administration were obtained by inspection. All AUC values were computed up to the last sampling time point at 24 h without extrapolation, and were obtained by the modified trapezoidal method using stable piecewise cubic polynomials.[17] For the intravenously administered plasma concentration data, AUC values were obtained as the sum of AUC up to the end of infusion and the AUC after the end of infusion. Plasma concentrations below the limit of quantification were treated as zero in all calculations. Apparent plasma clearance was computed as the quotient of D_6-dose/D_6-AUC.

To further investigate the effect of the fluctuations in concentration ratio on the bioavailability estimates, a second analysis of the data with a modeling approach was taken. The model composed of three compartments with saturable elimination from the central compartment and saturable distribution in one of the peripheral compartments. Nonlinear regression analysis was employed to obtain the best-fit model parameters. The bioavailabilities of the oral doses were estimated using a mass balance approach. The computational procedures and the results based on this analysis have been reported.[18]

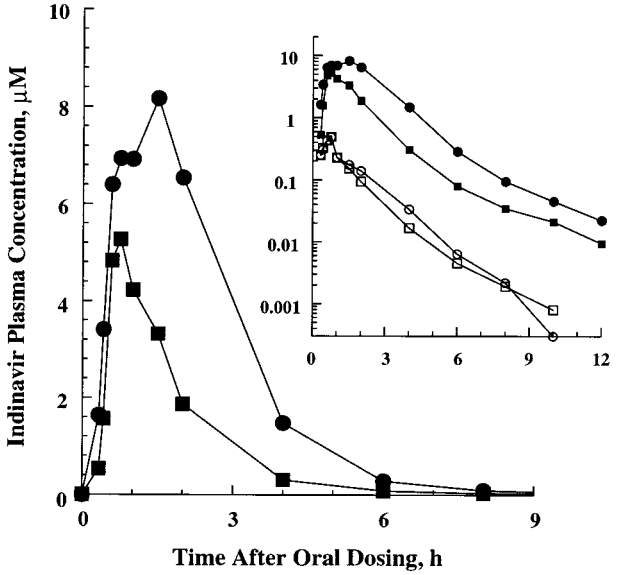

Figure 1—Mean plasma concentration profiles of D_0-indinavir following oral administration of D_0-indinavir in treatments A and B. Comparisons with the corresponding mean profiles of D_6-indinavir following intravenous administration of D_6-indinavir are shown in the inset. Key: ■ = 400 mg of D_0-indinavir po in treatment A; ● = 800 mg of D_0-indinavir po in treatment B; □ = 16 mg of D_6-indinavir iv in treatment A; ○ = 16 mg D_6-indinavir iv in treatment B.

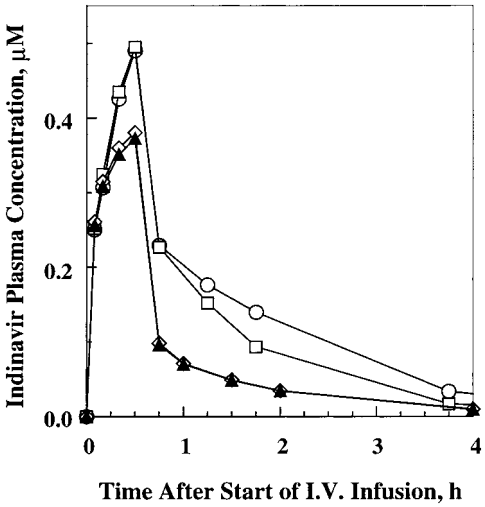

Figure 2—Comparisons of plasma concentration profiles of the intravenously administered indinavir from all three treatments. Key: □ = D_6 with 400 mg of oral indinavir in treatment A; ○ = D_6 with 800 mg of oral indinavir in treatment B; ◇ = D_6 in treatment C; ▲ = D_0 in treatment C.

Statistical Analysis—Statistical analysis was performed on the natural log-transformed individual bioavailability estimates based on dose-normalized D_6-AUC and D_0-AUC values. An ANOVA model for a two-period crossover design was used to test for the period effect. The systemic bioavailability for each treatment was estimated by the geometric mean (GM) ratio of the individual bioavailability estimates for that treatment. Ninety percent confidence intervals (CI) for the bioavailability estimates for each treatment were calculated on the log scale, and the limits were then exponentiated to yield the 90% CI for the GM ratio. To evaluate the kinetic isotope effect in treatment C, paired *t*-tests were performed to compare the AUC and the concentration at 30 min ($C_{30\ min}$) for D_0 and D_6. Dose-normalized geometric mean ratios and the corresponding 90% CI were similarly obtained.

Results

Concentration Profiles—Mean plasma concentration profiles of indinavir following the administration of oral and intravenous doses are shown in Figures 1 and 2. Summary values of the pharmacokinetic parameters are presented in Table 1.

The orally administered indinavir data in the present study were generally consistent with those observed previously following oral administration,[11,12] with the exception of a trend of a slightly prolonged T_{max} following the 800-mg dose in treatment B relative to that of the 400-mg dose in treatment A. As expected, there was a disproportionate increase in plasma concentrations; an increase of 2-fold in the dose from 400 to 800 mg resulted in a 2.67-fold increase in AUC. However, as a result of the delayed T_{max} following the 800-mg dose, C_{max} did not increase disproportionally as is generally seen over a wider dose range.[11] Plasma concentrations of D_0-indinavir and D_6-indinavir in treatment C were virtually superimposed. Differences between the D_6-AUC and D_0-AUC, although statistically significant, were small, suggesting the absence of meaningful kinetic isotope effect.

Plasma concentrations of the intravenously administered D_6-indinavir varied considerably with treatment and were dependent on the magnitude of the coadministered D_0-indinavir concentrations. The D_6-AUC values were highest when coadministered with the 800-mg oral dose in treatment B, lower with the 400-mg oral dose in treatment A, and lowest with the 16-mg D_0-indinavir iv dose in treatment C. Plasma concentrations at the end of the 30-min infusion also demonstrated a similar trend. Additionally, in the presence of coadministered D_0-indinavir in the two oral treatments, plasma concentrations of D_6-indinavir declined more slowly after the termination of infusion and near the plasma T_{max} for D_0-indinavir. Adjusted for the increase in D_6-AUC from treatment A to treatment B (ratio = 1.22), the net increase in D_0-AUC was reduced to 2.19-fold. These observations are consistent with nonlinearity in the systemic disposition kinetics contributing significantly to the disproportionate increase in D_0-indinavir concentrations over the 400- and 800-mg dose range.

Plasma Clearance—It was reported previously[11] that following oral administration, the indinavir terminal plasma concentration did not reach the log-linear phase until concentrations had declined to below ~0.1 to 0.5 μM. In the present study, the range of the total concentrations in treatment C (sum of D_0- and D_6-indinavir) did not completely fall within this range. However, concentrations generally did not exceed 0.8 μM and the computed apparent plasma clearance (1.29 L/min) was approaching the hepatic blood flow of 1.45 L/min. The decreased plasma clearances in treatments A and B reflected the increased D_6-AUC values in the presence of high concentrations of D_0-indinavir in these treatments and were consistent with the concentration-dependency of clearance in a nonlinear disposition system.

Bioavailability—The systemic bioavailability of indinavir appeared to be high, averaging 0.60 following the 400-mg dose, and 0.65 following the 800-mg dose. The corresponding values based on the modeling approach were 0.64 for both doses.[18] The dose-dependence of bioavailability values over this dose range was not statistically significant.

Discussion

This study was motivated by the desire to understand the underlying source(s) of the observed nonlinear pharmacokinetics in previous clinical studies and to examine the systemic bioavailability of indinavir. Recognizing the potential of bioavailability overestimation based on conventional crossover study design in a nonlinear system,[19] the concurrent administration technique was adapted for the present study. In addition, treatment C was incorpo-

rated to serve as a reference for identifying the source of nonlinearity.

While there are a number of factors that could result in the nonlinear disposition kinetics, plasma protein binding did not appear to be a contributing factor in the present case. Binding of indinavir to plasma protein is not extensive (39% unbound) and is not dependent on concentration up to 80 μM, which is significantly higher than the C_{max} of 10.6 μM achieved following the 800-mg dose. Other potential causes include saturable elimination and tissue binding. A more detailed study on the mechanism(s) of the systemic nonlinearity can be found elsewhere (Stone et al., unpublished results).

Increasing the mass as a result of isotope labeling generally increases the bond stability in the drug molecule.[20,21] In the present case, the deuterium isotope was chosen to be incorporated on the pyridomethyl moiety of the indinavir because of its relative ease of chemical syntheses. Since the bond cleavage leading to depyridomethylation is one of the metabolic pathways for indinavir,[15] the possibility that the metabolic rate and therefore the overall disposition kinetics of indinavir might be perturbed could not be ruled out. The most desirable deuterated analogue of indinavir would have contained the labeling placed at the metabolically stable site of the molecule. However, such an ideal analogue of indinavir was not available at the time of the study. Any significant difference in the disposition kinetics of indinavir between the two analogues of the drug would have made the D_6 a poor surrogate for D_0 in data analysis.

Prior to initiation of the present human study, the potential for the isotope effect was examined. In vitro studies with D_6 using rat liver and human microsome preparations indicated modest decreases (~23%) in the formation of the dealkylated product.[13] Intravenous administration of a 1:1 mixture containing the D_0 and D_6 in rats at a total dose of 10 mg/kg indicated no discernible difference in plasma concentration profiles.[13] In vitro metabolism studies indicated depyridomethylation was only one of the multiple CYP3A4-mediated pathways in the oxidative metabolism of indinavir in humans.[15] These experiments suggested that the potential kinetic isotope effects in human would be negligible, which was confirmed by the data from treatment C of the present study.

The mass of the intravenous D_6-indinavir dose administered in treatments A and B was considerably lower than that of the D_0 oral doses. The D_0-AUC data observed in the present study did not appear inconsistent with the historical data,[11] suggesting the D_6 dose did not have significant effect on the absorption or disposition processes of the D_0 oral doses.

The first-pass metabolism of indinavir has been characterized to be mediated by the CYP3A isoform of the cytochrome P450 enzyme system, primarily in the liver but also to some extent in the intestine.[22,23] This same isozyme is also known to be involved in the metabolism of other protease inhibitors ritonavir, saquinavir, and nelfinavir. It has been recently reported[24] that protease inhibitors as a class are also substrates for p-glycoprotein (Pgp) which functions as a transmembrane efflux pump.[25–27] Thus, in addition to the first-pass metabolism, the apical expression of Pgp in the epithelial cells of the GI tract and on the bile canalicular surface of hepatocytes would function as biological barriers and further limit the absorption for this class of drugs. The high bioavailability results of the present study would suggest a reduced impact of the Pgp-mediated transporter system at clinically relevant doses of indinavir.[28,29]

The use of a constant-rate infusion rather than a bolus intravenous administration in the study was designed to reduce the magnitude of fluctuations in the D_6/D_0 concentration ratios and to improve the reliability of bioavailability estimates.[5] Ideally, the infusion rates may be controlled to match closely the rate of drug delivery to the systemic circulation. In actual practice, the superposition can only be approximated since the drug input after an oral dose is not known a priori. Figure 3 shows the (D_6/D_0) plasma concentration ratios following the two oral treatments. These data indicated relatively constant ratios after about 1.5 h post oral dosing. However, substantial fluctuations were noted during the earlier time points. Prior to the start of the infusion at 15 min, D_0-concentrations were unmatched with ratios effectively zero for a brief period. The ratios then increased rapidly and reached the maximum within 5 min once the D_6 infusion was initiated. It should be noted that a perfect alignment of T_{max} with the end of infusion would only reduce, but not eliminate, the fluctuations, due to the differences in the input rate between the two administration modes. The magnitude of errors associated with such imperfection has been reviewed using model simulations.[5]

Cross comparisons of the bioavailability estimates based on the present method and those based on the modeling approach[18] are presented in Figure 4. Although the two computational procedures differed from each other, the results were numerically comparable, confirming the im-

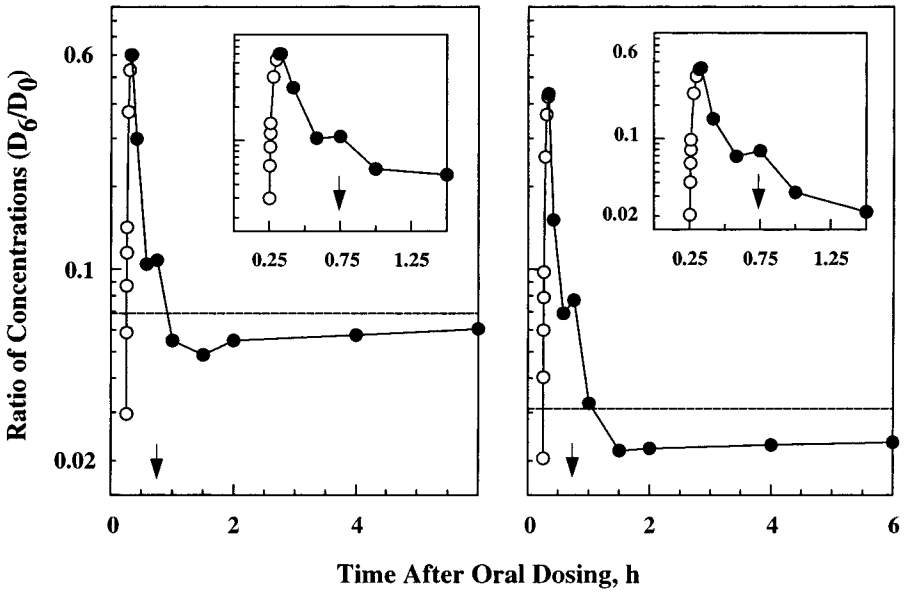

Figure 3—Ratios of plasma concentrations (D_6-indinavir/D_0-indinavir) following the administration of 16 mg of D_6-indinavir iv with 400 mg of D_0-indinavir po in treatment A (left panel) or with 800 mg of D_0-indinavir po in treatment B (right panel). Solid circles represent median ratios and open circles represent medians of simulated ratios during the first 5 min immediately after the initiation of the iv infusion. Simulated ratios were obtained using interpolated concentration values between 0 and 5 min for the po and iv curves, which were obtained by the piecewise cubic polynomial functions.[17] The arrows indicate the end of infusion at 0.75 h. The horizontal lines represent the apparent Z_{app} based on eq 5. The expanded initial ratios are shown in the insets.

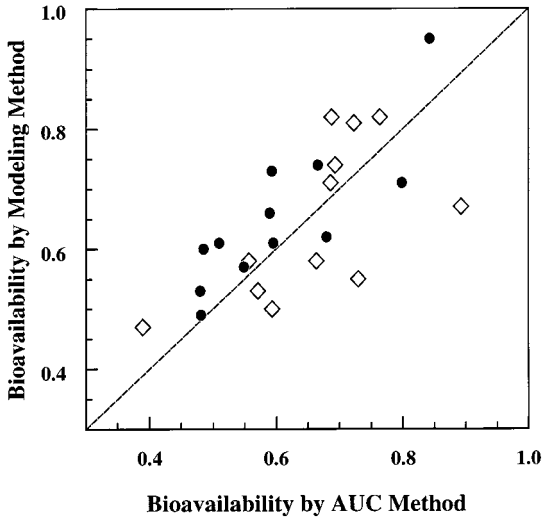

Figure 4—Comparison of the bioavailability estimates based on the present model-independent AUC method and that based on the kinetic modeling method.[18] The diagonal line represents the projected perfect agreement between the two estimation methods. Key: ● = 400-mg dose; ◇ = 800-mg dose.

portance of the delayed iv infusion regimen used in this study in reducing the imperfection of fluctuations in the (D_6/D_0) plasma concentration ratios. Lengthening the infusion period with a reduced input rate would likely have reduced the fluctuations at early time points (Figure 3) and improve the concordance between the two estimates for those data sets with greatly delayed T_{max}, although it also would have adversely affected the bioavailability estimates from the data sets with shorter T_{max}. On the other hand, errors in bioavailability estimates based on the modeling method would most likely arise from model miss-specification and thus would be model-dependent but would be less likely to be correlated with the D_0 T_{max}.

While the ratio of indinavir concentrations in blood to that in plasma was not available for humans, preclinical studies indicated the ratio to be approximately equal to unity for monkeys.[22] Thus, the plasma clearance and the blood clearance for indinavir could be assumed to be comparable for humans. It has been reported that the urinary excretion of intact indinavir constituted 5−12% of the dose over the 200−1000 mg dose range, indicating a significant contribution of hepatic metabolism to the overall elimination of the drug.[11,15] At low indinavir plasma concentrations, the extremely high clearance (1.29 L/min) relative to the hepatic blood flow of ∼1.45 L/min in man would suggest that at low doses, indinavir could be classified as a high hepatic extraction drug with low systemic bioavailability following oral administration,[30] and that dose-dependence of bioavailability would contribute significantly to the observed pharmacokinetic nonlinearity. In addition, the first-pass metabolism would gradually become more saturated with increasing doses, and as the doses approached the clinical range, the bioavailability would be high and would be only marginally dose-dependent.

In summary, the present study indicates that indinavir bioavailability was high (60−65%) and comparable over the 400−800 mg dose range and that there was a significant contribution of the nonlinearity in the systemic disposition to the observed nonlinear pharmacokinetics following oral administration. These results demonstrate that the concurrent administration approach can be used to identify the source(s) of pharmacokinetic nonlinearity and obtain bioavailability estimates in a nonlinear pharmacokinetic system. Characterizing important pharmacokinetic attributes of drug candidates during product development based on such an approach has become increasingly feasible as a result of recent advances in LC/MS/MS instrumentation.[31] The application of the model-independent method described in the present study requires that there is no kinetic isotope effect. The computed bioavailability is not exact and its reliability depends on the closeness of similarity between the plasma concentration profile following the test dose and that following the labeled tracer dose. However, the elaboration needed in the design and execution of such studies is compensated for by the simplicity in data analysis. With the conventional crossover study design, bioavailability in a nonlinear disposition system could only at best be estimated with a modeling

approach.[32] Additionally, due to the concentration-dependence in clearance, systemic bioavailability could be potentially overestimated unless the concentration ranges achieved in the intravenous treatment were sufficiently high and comparable to that achieved in the test treatment. For drugs with low aqueous solubility, it may not be feasible, if not impossible, to achieve the required plasma concentrations with clinically acceptable preparations.

Abstract □ Rhodium(II) carboxylates and their derivatives constitute a promising class of second-generation transition metal compounds with anticancer properties. While most transition metal anticancer compounds chelate DNA and cause extensive chromosomal damage, rhodium(II) carboxylates act on the enzyme DNA polymerase α and hence cause minimal chromosomal damage. Rhodium(II) citrate, a recent member of the rhodium(II) carboxylate family is highly promising as an antitumor agent. However, due to its high water solubility, a high systemic dose is necessary to achieve efficacy. In this paper, we have explored the complexation of rhodium(II) citrate with hydroxypropyl-β-cyclodextrin as a means to improve encapsulation and release kinetics from poly(*dl*-lactic-co-glycolic) acid (PLGA) and poly(anhydride) microspheres. We observed that complexation of rhodium(II) citrate with hydroxypropyl-β-cyclodextrin significantly increased both the encapsulation efficiency and duration of release in both polymer systems.

Introduction

A class of promising second-generation transition metal anti-cancer compounds are the rhodium(II) [Rh(II)] carboxylates.[1−4] Most anti-cancer drugs induce chromosomal damage in treated cells (e.g., cisplatin), resulting in the formation of chromosomal lesions.[5] In contrast, rhodium(II) butyrate only slightly increases the incidence of chromatid gaps and breaks.[3] It is believed that its mode of inhibition of DNA synthesis is via the inhibition of enzyme(s) essential for DNA synthesis, such as DNA polymerase α, rather than DNA chelation. In general, inhibition of DNA synthesis by R-substituted Rh(II) carboxylates derivatives in vitro increases with increasing side chain lipophilicity in the order: Rh(II) methoxyacetate < acetate < propionate < butyrate.[2,5] However, the simple extension of the carboxylate chain (R group) is not effective in increasing the therapeutic effects of the drug. Thus it appears that for Rh(II) compounds to be efficacious, they have to exhibit some degree of water solubility.[6] However, Rh(II) butyrate and analogues are very toxic; Rh(II) carboxylates irreversibly inhibit enzymes that possess sulfydryl groups.[4] Recently, a new class of Rh(II) carboxylates [i.e., Rh(II) citrates] have been synthesized and shown to be promising compounds for chemotherapy.[7−9] However, due to the high water solubility of Rh(II) citrate, high systemic doses of the drug would be required to achieve efficacious concentrations in tumor sites. Therefore, it is useful to develop controlled release systems wherein the Rh(II)-complex is shielded from the extracellular milieu to minimize local toxicity and prolong drug action.

To address this problem we have examined the host: guest complexation approach using cyclodextrins to alter solubility and improve the encapsulation and release from polymer microspheres.

Experimental Section

Materials—Rhodium(II) citrate was prepared as described elsewhere.[7] Hydroxypropyl-β-cyclodextrin (HPBCD) was generously donated by Cerestar Company to VPS and had a degree of substitution of hydroxypropyl groups between 5 and 7. Poly(vinyl alcohol) (PVA) was purchased form Aldrich (MW, 70 000; 90% hydrolyzed) and used as received. The poly((*dl*)lactic-*co*-glycolic)-acid (PLGA; RG503, MW, 30 000) was purchased from Boehringer Ingelheim (Indianpolis, IN) and poly(1,3-bis(*p*-carboxyphenoxy)-propane-*co*-sebacic acid) (CPP:SA, 20:80; (MW, 70 000) was prepared as described elsewhere.[10] All other chemical were purchased from Aldrich Chemical and used as received.

Methods—*Preparation of the Association Compound between Rhodium(II) Citrate and HPBCD*—The association compound was prepared by mixing 292 mg of HPBCD and 200 mg of Rh(II) citrate in 20 mL of distilled water and stirring overnight. The resulting solution was then frozen in liquid N_2 and lyophilized into a free flowing powder.

Characterization of Rh(II) Citrate−HPBCD Association Complex—the formation of the association complex of Rh(II) citrate with HPBCD was studied by infrared (IR) spectroscopy and thermogravimetric (TG) analyses. The IR spectra were obtained on a Nicolet Magna IR-550 FTIR equipped with a liquid nitrogen cooled helium−neon laser. All samples were pressed as KBr pellets. The TG and differential thermogravimetric (DTG) curves were obtained on 5−10 mg of sample under dynamic nitrogen atmosphere using a Perkin-Elmer Series 7 thermogravimetric analyzer interfaced to a PC. The curves were analyzed using Perkin-Elmer TGA software.

Preparation of the Microspheres—Polymer microspheres were prepared by a solvent evaporation technique.[11] In brief, 200 mg of the polymer (PLGA or CPP:SA) was dissolved in 1 mL of

methylene chloride. To this, 50 mg of the Rh(II) citrate or the association compound (corresponds to ≃20 mg of Rh(II) citrate) dissolved in 200 mL of water was added, and the solution was sonicated using a Vibra Cell ultrasonicator (Sonics and Materials, Danbury, CT, six pulses, 50% duty cycle, output 3) to prepare the first w/o microemulsion. The microemulsion was then dispersed in 100 mL of a 1% PVA solution with an homogenizer (Silverson L4R, Nottingham, England, 3/4 in. homogenization tip) at 5200 rpm for 1 min to stabilize the second emulsion (w/o/w). The PVA solution containing polymer microspheres was then stirred for 1.5 h to facilitate evaporation of methylene chloride (solvent) and induce hardening of the polymer microspheres. The microspheres were isolated by centrifugation at 1500 rpm for 5 min, subsequently washed three times with water to remove surface-adsorbed PVA, and finally resuspended in 2 mL of water and freeze-dried to a free powder. The size distribution of the microspheres was determined with a Coulter Counter multisizer.

Rhodium(II) Citrate Release Studies—the release studies were carried out on 10 mg of microspheres in 1.5 mL Eppendorf tubes containing 1 mL of phosphate buffer release medium (pH 7.4) at 37 °C. To ensure thorough mixing, the tubes were placed on a Labline orbital shaker. Sink conditions were maintained by periodically replacing the release medium with fresh release buffer throughout the duration of the study.

Quantification of Rhodium—The Rh(II) citrate released was quantified by visible spectroscopy (Beckman DU-6) and inductively coupled plasma mass spectrometry (ICP-MS). The visible absorbance was measured at 591 nm in 1X PBS using a quartz sample cell (1 cm path length). The calibration curve was established using known concentrations of Rh(II) citrate in 1X PBS. The loading in microspheres was determined by solvent extraction. In brief, 5.0 mg of microspheres (in triplicate) was first placed in 1 mL of methylene chloride to dissolve the polymer phase and then extracted with 1 mL of 1X PBS. The Rh(II) citrate, which was extracted in the aqueous phase, was quantified as described above.

Results and Discussion

Characterization of the Association Compound between the Rhodium (II) Citrate and HBCD—The formation of the association compound between Rh(II) citrate and HPBCD was verified by IR, TG, and DTG. The IR spectra of the association compound showed two important characteristics consistent with the formation of an associative complex between the Rh(II) citrate and HPBCD: (a) displacement of the IR band associated with the stretching the −OH bond to 3400 cm^{-1} in comparison with free HPBCD (3440 cm^{-1}) and (b) narrowing of this band due to the breakdown of hydrogen bonding in the CD cavity upon the release of the resident water molecules.[12,13]

The TG and DTG curves of Rh(II) citrate, HPBCD, and the association compound between Rh(II) citrate and HPBCD are shown in Figures 1a and 1b, respectively. The TG and DTG curves of Rh(II) citrate revealed an onset of mass loss beginning at 25 °C. However, significant changes in mass presumably due to the decomposition of the metal complex, occurred at 220 and 350 °C. In contrast, the TG and DTG curves of the Rh(II) citrate−HPBCD association compound showed only one thermal transition at higher temperature, around 310 °C, which was accompanied by an 80% mass loss. Thus, it appears that the thermal stability of Rh(II) citrate is improved significantly upon association with HPBCD. The increased thermal stability could have significant benefits when using high-temperature polymer processing techniques, such as compression or injection molding to manufacture polymer delivery devices.

Release of Rh(II) Citrate and its Association Complex with HPBCD from PLGA and CPP:SA Microspheres—The size distributions of PLGA and CPP:SA microspheres containing Rh(II) citrate and its association complex with HPBCD are shown in Table 1. An interesting observation was the significant enhancement of Rh(II) citrate encapsulation efficiency upon complexation with HPBCD. The encapsulation efficiency of the free Rh(II) citrate in PLGA microspheres was 30%, whereas that of the HPBCD complex system was 83%. Similarly, the encapsulation efficiencies of free Rh(II) citrate and Rh(II) citrate−HPBCD association complex in CPP:SA were 22 and 79%, respectively. This increase in loading efficiency upon complexation with HPBCD can be explained on the basis of the following observations.

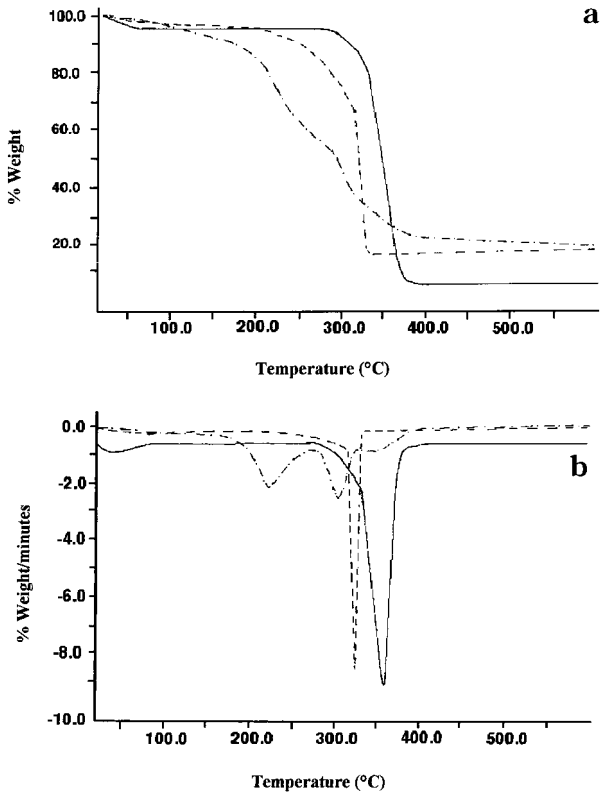

Figure 1—(a) TG curves of HPBCD (–), Rh(II) citrate (–•–•), and association complex between Rh(II) citrate and HPBCD (- - -). (b) DTG curves of HPBCD (–), Rh(II) citrate (–•–•), and association complex between Rh(II) citrate and HPBCD (- - -).

Table 1—Size Distribution and Percent Loading of PLGA and CPPSA Microspheres Containing Rh(II) Citrate and Rh(II) Citrate–HPBCD Association Complex

compound	polymer	size, μm	loading of Rh(II) citrate, %
Rh(II) citrate	PLGA	10.0	30.0
Rh(II) citrate	CPP:SA	20.5	22.4
Rh(II) citrate–HPBCD	PLGA	15.4	83.4
Rh(II) citrate-HPBCD	CPP:SA	25.0	79.2

The enhanced solubility of alkyl-substituted β-CD in comparison with the unsubstituted β-CD has been attributed to several factors, including breakdown of hydrogen bonding between CD molecules, changes in ring conformation, and lowering of the lattice free energy due to its enhanced interaction with surrounding water molecules.[14,15] However, the introduction of alkyl groups such as hydroxypropyl, can also increase the lipophilicity of substituted β-CDs in comparison with the unsubstituted β-CD. One possible mechanism could involve the delocalization of the hydrophobic core in the alkyl substituted β-CD toward the primary 6-CH_2OH hydroxy face.[16] Thus, it is plausible that the complexation of Rh(II) citrate with HPBCD can alter the partition coefficient of the Rh(II)

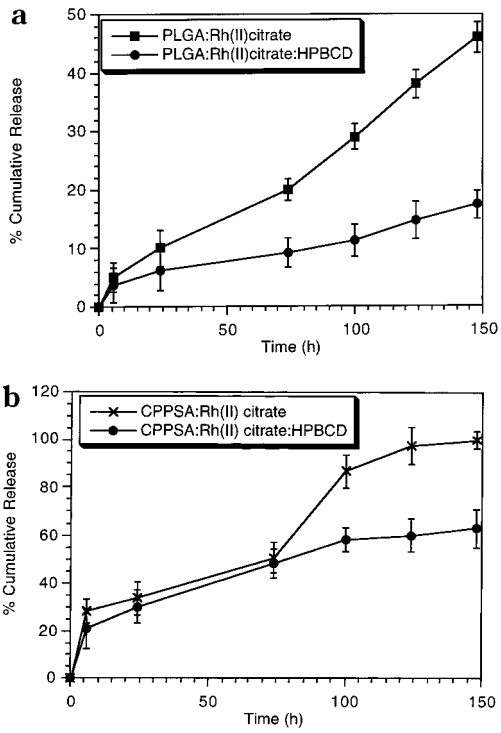

Figure 2—(a) Release of Rh(II) citrate and Rh(II) citrate–HPBCD from PLGA microspheres. (b) Release profiles of Rh(II) citrate and Rh(II) citrate–PBCD association complex from CPP:SA (20:80) microspheres. The error bars are represented as the standard deviation from the mean.

citrate molecule so as to bias its distribution in the hydrophobic polymer phase during microsphere preparation

The release profiles of Rh(II) citrate and its association complex with HPBCD from PLGA microspheres are shown in Figure 2a. The 'burst effect' (8 h) was almost identical in both the cases although the loading was nearly three times higher in the case of the Rh(II) citrate−HPBCD association complex. Beyond 24 h, near zero-order release kinetics was observed, with 45% of the encapsulated Rh-(II) citrate released at 148 h in comparison with 18% of the HPBCD complexed molecule. Thus, it appears that one can prolong the duration of release of small molecules from polymer microspheres by association with CDs.

Release profiles of Rh(II) citrate and Rh(II) citrate−HPBCD association complex from CPP:SA (20:80) microspheres are shown in Figure 2b. As in the PLGA system, the 'burst effect' was almost identical in both the cases, although the loading of the Rh(II) citrate−HPBCD association complex in the microspheres was nearly four times higher. As observed in the PLGA system, the association of Rh(II) citrate with HPBCD prolonged the duration of release from the CPP:SA microspheres as well. Whereas 100% of the encapsulated Rh(II) citrate was released at the end of 148 h, only 60% of HPBCD complexed molecule was released during the same period.

Finally, in this study we observed that although the size of the PLGA and CPP:SA microspheres containing Rh(II) citrate−HPBCD was larger (20.5 and 25.0 μm, respectively) when compared with microspheres containing uncomplexed Rh(II) citrate (10.0 and 15.4 μm, respectively), the cumulative release was lower in the former system. If one were to assume that the surface roughness of all the microspheres were similar, the lower cumulative release from the PLGA and CPP:SA microspheres containing the complexed Rh-(II) citrate is surprising, considering the fact that the surface area of these microspheres would be larger in comparison with the microspheres containing uncomplexed Rh(II) citrate. This result could be due to the decrease in the solubility of the Rh(II) citrate upon complexation with HPBCD, as discussed earlier.

Abstract □ The effect of radiolabeling liver-specific proteins on the in vivo disposition of radioactivity was investigated. The suitability of ^{111}In and ^{125}I as radiolabels for protein disposition studies in vivo was examined. Galactosylated and cationized bovine serum albumin were labeled with either ^{125}I by the chloramine-T method or ^{111}In, using 1-(4-isothiocyanatobenzyl)ethylenediaminetetraacetic acid (SCN-BZ-EDTA) or diethylenetriaminepentaacetic acid (DTPA) as bifunctional chelating agents (BCAs) and administered intravenously to rats. ^{125}I radioactivity disappeared rapidly from the liver with subsequent excretion in the urine and bile, mainly in the TCA soluble fraction. ^{111}In-associated radioactivity, on the other hand, remained in the hepatic tissue in considerably higher amounts during the experiment and was excreted in the bile and urine to a lower extent when compared with ^{125}I. When the effect of BCA on excretion of ^{111}In radioactivity was compared, no significant differences were observed in the urinary clearances. However, biliary excretion was significantly higher for ^{111}In-SCN-BZ-EDTA-bound radioactivity. In conclusion, when compared with ^{125}I, ^{111}In labeling seems to more accurately characterize the in vivo distribution of liver-targeted proteins after their iv administration in rats and allows a more accurate pharmacokinetic evaluation to be performed.

Introduction

Since biologically active proteins are receiving much attention as potential therapeutic agents, there has been a need to modify their structure in order to overcome difficulties associated with their clinical application. Consequently, it is necessary to quantitatively describe the disposition of these proteins in the body using pharmacokinetic evaluation. Labeling a protein in question with a radionuclide is the easiest way to trace it in the organism, and a variety of methods have been employed to label proteins with a radionuclide. Among these, radioiodine isotopes are the most widely used protein radiolabels for imaging studies.[1] Proteins may be easily labeled with radioisotopes of iodine by several methods; however, certain limitations to the use of radioiodine for imaging applications have become apparent, especially their poor target retention of radioactivity.[2,4]

Several alternative methods of radiolabeling proteins and peptides have been examined to overcome these difficulties and to increase and retain enough radioactivity at target sites for a sufficient period of time. After introduction of bifunctional chelating agents (BCAs), ^{111}In has become a convenient radiometal which has been used by many investigators.[4] This radionuclide is commonly attached to a protein via ethylenediaminetetraacetic acid (EDTA) or, alternatively, via diethylenetriaminepentaacetic acid (DTPA). In addition, several other modifications of these BCAs have been investigated to improve labeling efficiency and in vivo stability.[5−8]

When internalized by cells, these proteins undergo intracellular catabolism with subsequent formation of radiolabeled metabolites. In particular, after endocytotic internalization, the ligand is delivered to the endosome and then to the lysosome. In the lysosomal compartment, most

of the ligand is degraded by proteases and glycosidases.[9] Obviously, further disposition of radioactivity within the body will be determined by the nature of the radiolabeled degradation product(s) formed, mainly by their physicochemical characteristics such as lipophilicity and molecular weight and/or by their possible affinity for a carrier-mediated transport system. This problem becomes especially marked in cases where proteins are intended to be preferentially taken up by liver cells. In the case of radioiodine-labeled proteins, the final radioactive metabolite is mono- or diiodotyrosine[10] which seems to escape from the liver at a very fast rate with consequent interference with the pharmacokinetic analysis.

The aim of the present study was to investigate and quantitatively compare the difference between ^{125}I and ^{111}In radiolabeling of liver-specific proteins in terms of the whole body disposition of radioactivity. Galactosylated bovine serum albumin (Gal-BSA) and cationized BSA (Cat-BSA) were employed as carrier proteins for hepatic cells. Both have been reported to be taken up preferentially by hepatic parenchymal cells, although the mechanism and rate by which they enter cells differ. Hepatic uptake of Gal-BSA occurs via asialoglycoprotein receptors, whereas Cat-BSA enters hepatocytes by adsorptive endocytosis based on universal electrostatic interaction with the cell surface (for review see refs 11 and 12). In the present study, ^{111}In was attached to the proteins using 1-(4-isothiocyanatobenzyl) EDTA (SCN-BZ-EDTA) or DTPA as chelating agents as described by Meares et al.[13] and Hnatowich et al.,[14] respectively. Radioiodination of both proteins by ^{125}I was achieved by the chloramine-T method.[15] Radiolabeled compounds were administered to rats as a bolus intravenous injection. The radioactivity in the plasma, bile, urine, and several organs was measured, and its movement within the body was described using clearance concepts.

Materials and Methods

Chemicals—BSA (fraction V) was purchased from Sigma Chemicals (St Louis, MO). SCN-BZ-EDTA and DTPA anhydride were obtained from Dojindo Laboratory (Kumamoto, Japan). ^{111}Indium chloride ([^{111}In]$InCl_3$) was supplied from Nihon Medi-Physics Co. (Takarazuka, Japan). Chloramine T was supplied by Nacalai Tesque (Kyoto, Japan). Sodium (^{125}I) iodide ([^{125}I]NaI) was purchased from DuPont/NEN Co. (Boston, MA). All other chemicals were obtained commercially as reagent-grade products.

Synthesis of BSA Derivatives—The method of Lee et al.[16] was used to introduce galactose residues into BSA. Briefly, cyanomethyl 2,3,4,6-tetra-*O*-acetyl-1-thio-D-galactopyranoside was treated with 0.01 M sodium methoxide at room temperature for 24 h, and the syrup of 2-imino-2-methoxyethyl 1-thio-D-galactopyranoside was obtained after evaporation of the solvent. This resultant syrup was quantitatively added to BSA (100 mg) in 10 mL of 50 mM borate buffer (pH 9.0). After 24 h at room temperature, the reaction mixture was concentrated by ultrafiltration and applied to a Sephadex G-25 column equilibrated with 0.1 M acetate buffer (pH 6.0) to remove the unreacted compound. The number of sugars incorporated into the albumin was determined by the phenol/sulfuric acid method calibrated with galactose.[17]

Cat-BSA was synthesized by covalent coupling of hexamethylendiamine to BSA according to the method reported by Pardridge et al.[18] In brief, 5 mL of 10% BSA in distilled water was slowly added to 30 mL of 2 M hexamethylendiamine at pH 6.5. 1-ethyl-(3-dimethylaminopropyl)carboimide hydrochloride (0.5 g) was added to the solution after 30 and 60 min, and the solution was kept at a pH of 6.5 by addition of 1 M HCl. The solution was stirred overnight and then dialyzed thoroughly against distilled water. The protein was purified by chromatofocusing using Polybuffer exchanger 94 resin and Polybuffer 96 elution buffer (Pharmacia, Uppsala, Sweden). The major protein peak eluted in the void volume and was collected and concentrated by ultrafiltration. The cationic nature of Cat-BSA was confirmed by its absorption on a CM-Sephadex C-50 anion exchanger.

^{125}I Labeling—A modified chloramine-T method[15] was used to label both proteins with ^{125}I. Twenty μL 0.4 M phosphate buffer (pH 7.5) and 20 μL 10-fold diluted [^{125}I]NaI were added to 20 μL the sample solution (1 mg/mL) and vortexed. Two times 20 μL chloramine-T diluted in ice-cold distilled water (3.8 mM) was added and vortexed for 30 s. Finally, 50 μL of sodium metabisulfite solution (2.5 mM) was added and vortexed for 30 s. The solution was applied to a PD-10 column (Pharmacia, Uppsala, Sweden) and eluted with phosphate buffer (0.25 M, pH 7.5) containing 0.2% BSA. The eluent was collected into plastic tubes and the radioactivity counted using a survey meter. Appropriate fractions were taken and stored at −80 °C until use. The specific activity of the obtained sample was 74 MBq/mg protein.

^{111}In Labeling of BSA Derivatives—^{111}In labeling of BSA derivatives was performed using DTPA and SCN-BZ-EDTA as the

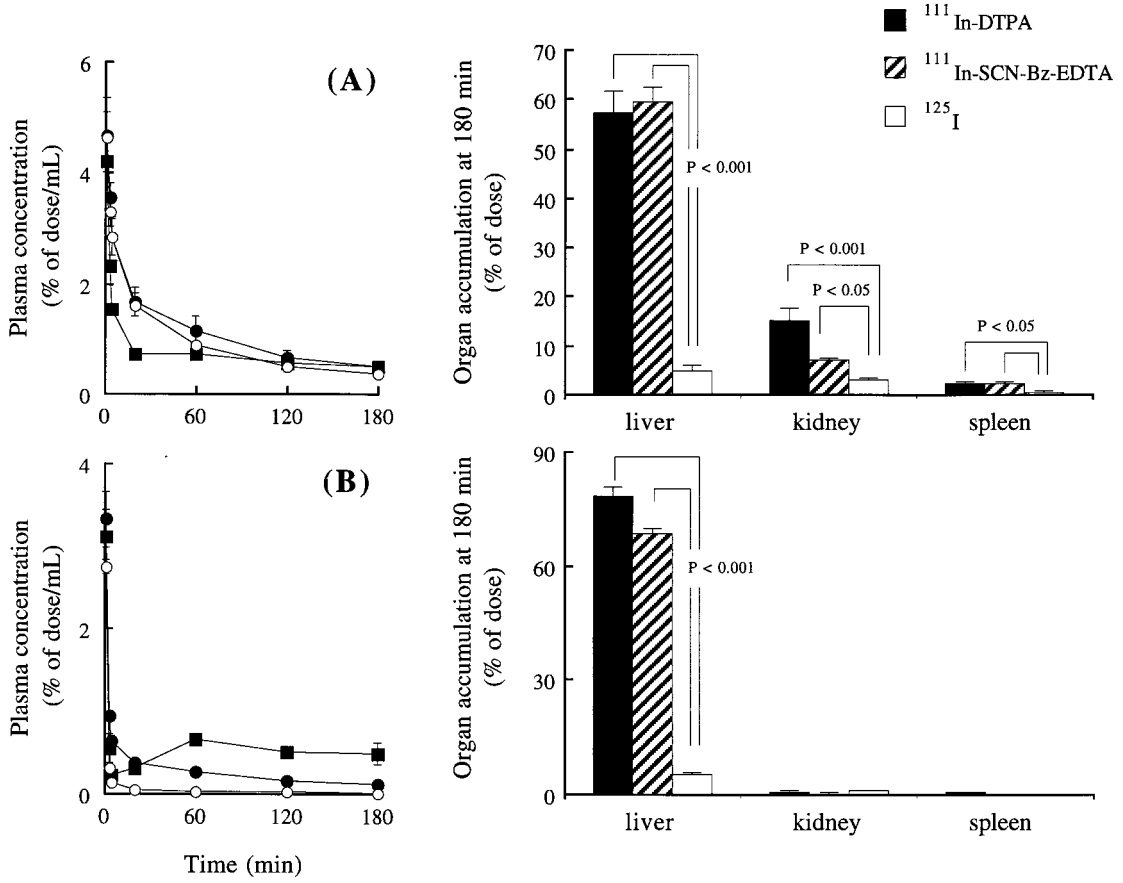

Figure 2—In vivo disposition of radioactivity after iv administration of Cat-BSA (A) and Gal-BSA (B) labeled with ^{111}In-DTPA (●), ^{111}In-SCN-BZ-EDTA (○), or ^{125}I (■). Data are expressed as mean ± SD of at least three experiments. Statistical significance was based on Student *t*-test.

bifunctional chelating agents by the method of Hnatowich et al.[14] and Meares et al.,[13] respectively.

Attachment of DTPA: Gal-BSA or Cat-BSA (2 mg) was dissolved in 1 mL of 4-(2-hydroxyethyl)-1-piperazineethane sulfonic acid buffer (0.1 M, pH 7.0), and a 2-fold molar excess of DTPA anhydride in 10 μL of dimethyl sulfoxide was added. After stirring 30 min at room temperature, the mixture was purified by gel-filtration chromatography using a Sephadex G-25 column (1 × 40 cm) and eluted with acetate buffer (0.1 M, pH 6.0) to separate the unreacted DTPA. Fractions containing DTPA−BSA were selected using spectrophotometry and concentrated by ultrafiltration.

Attachment of SCN-BZ-EDTA: Gal-BSA or Cat-BSA (5 mg) was dissolved in 1 mL of borate-buffered saline (50 mM, pH 8.5) and an equimolar amount of SCN-BZ-EDTA in 10 μL of dimethylformamide was added. After 24 h at 37 °C, the mixture was purified by gel-filtration chromatography using a Sephadex G-25 column (1 × 40 cm) and eluted with acetate buffer (0.1 M, pH 3.0) to separate the unreacted SCN-BZ-EDTA. The fractions containing SCN-BZ-EDTA-BSA were treated as described above.

Thirty microliters of $^{111}InCl_3$ solution was added to 30 μL of sodium acetate buffer (1 M, pH 6.0) and 60 μL of either the DTPA- (or SCN-BZ-EDTA)−BSA derivative was added to the mixture. After 30 min at room temperature (45 min at 37 °C, in the case of SCN-BZ-EDTA−BSA), the mixture was purified by gel filtration chromatography using a PD-10 column (Pharmacia, Uppsala, Sweden) and eluted with acetate buffer (0.1 M, pH 6.0). The appropriate fractions were selected based on their radioactivity and concentrated by ultrafiltration. The specific activity of the obtained samples was 37 MBq/mg protein.

In Vivo Animal Experiments—Prior to administration, trace amounts of radiolabeled proteins were diluted with saline, and the protein concentration was adjusted to 0.1 mg/mL by adding nonlabeled protein. Male Wistar rats (200 g) maintained on a standard rat food and water diet were anaesthetized by intraperitoneal administration of pentobarbital sodium at a dose of 50 mg/kg. Their urinary bladder and bile duct were cannulated using polyethylene and polyvinyl tubing to collect bile and urine samples, respectively. Then, 200 μL investigated protein was injected into the femoral vein at a dose of 0.1 mg/kg. Samples of blood, urine, and bile were collected throughout the 180 min of the experimental period. At the end of the experiment, each animal was killed by bleeding and the liver, kidney, and spleen were excised. Blood samples were centrifuged at 2000*g* for 2 min, and 100 μL of plasma was collected for analysis. The ^{111}In and ^{125}I radioactivity in the samples was measured in a well, NaI scintillation counter (ARC-500, Aloka, Tokyo, Japan).

Table 1—Physicochemical Properties of BSA and Its Derivatives Used in This Study

	molecular weight[a]	number of NH_2 groups[b]	number of galactose[c]	pI[d]
BSA	67000	60.0	–	4.2–4.8
Cat-BSA	70000	69.3	–	>9.0
Gal-BSA	69000	8.6	42	4.8–4.9

[a] Determined by size-exclusion chromatography (LC-6A, Shimadzu, Japan) using a Shim-pack Diol-300 column. [b] Determined by the TNBS method. [c] Determined by the phenol–sulfuric acid method. [d] Determined by chromatofocusing.

Organ Distribution of ^{125}I-Labeled BSA Derivatives—Male Wistar rats similar to these defined above were given 0.1 mg/kg ^{125}I-Cat-BSA or ^{125}I-Gal-BSA. Animals were sacrificed at 5, 20, or 60 min by bleeding, the liver, kidney, spleen, and thyroid were excised, and the radioactivity was measured as described above. Data from the interval of 180 min were adopted from the experiments described in the In Vivo Animal Experiments section.

Assessment of Degradation Products of ^{125}I-Labeled Proteins in Plasma, Bile, and Urine—To investigate the degradation products of ^{125}I-labeled proteins, the samples of plasma, bile, and urine were weighed, and an equivalent volume of 45% trichloracetic acid (TCA) was added. Samples were vortexed and centrifuged at 1500*g* for 10 min. Supernatant (100 μL) was separated into different tubes, and the radioactivity of the TCA-precipitable (protein) and TCA-soluble (degradation product) fractions was measured separately as described above.

Data Analysis—In this study, the radioactivity of particular samples and organs was employed to express the apparent organ uptake clearance of investigated proteins. The radioactivity of all samples and that of plasma was normalized to the % dose or % dose/mL, respectively. Plasma concentrations ($C_p(t)$) were analyzed by mono- or biexponential functions using the nonlinear least-squares program MULTI.[19] The one- or two-compartment model was chosen according to Akaike Information Criterion.

Total body clearance of radioactivity (CL_{total}) was calculated by:

$$CL_{total} = \frac{D}{AUC} \quad (1)$$

where D is the dose of radioactivity administered, and AUC is the area under the plasma concentration−time curve extrapolated to infinity.

Assuming zero or negligible leakage of radioactivity from organs, the apparent organ uptake clearance (CL_{organ}) may be expressed as:

$$CL_{organ} = \frac{X_{t_i}}{AUC_{t_0-t_i}} \quad (2)$$

where X_{t_i} is the amount of radioactivity in the organ of interest at the end of experiment and $AUC_{t_0-t_i}$ is the area under the curve over the time interval t_0 = administration of the compound and t_i = end of the experiment.[20] In studies with ^{125}I-labeled proteins, AUC of TCA-precipitable radioactivity was employed to estimate tissue uptake clearances.

Results

Characteristics of BSA Derivatives—Chemical structures of the radiolabeled proteins are depicted in Figure 1. Some physicochemical characteristics of BSA, Gal-BSA, and Cat-BSA are given in Table 1. The amount of galactose residues attached to BSA was estimated to be 42:1 (mol/mol). The BSA derivatives had nearly the same molecular weights as the original BSA as judged by gel-filtration chromatography. The isoelectric point of Cat-BSA indicated a highly positive charge caused by introduction of hexamethylenediamine into the BSA molecule.

Plasma Profile of ^{111}In and ^{125}I Radioactivity—The time-courses of the radioactivity in plasma and organ accumulation of radioactivity after injection of ^{111}In-DTPA, ^{111}In-SCN-BZ-EDTA, and ^{125}I-labeled compounds into rats are shown in Figure 2. Fast disappearance of radioactivity from the circulation was observed in all experiments and may be accounted for by the avid hepatic uptake of investigated proteins. In the case of Gal-BSA, the initial phase of plasma concentration did not seem to be influenced by the labeling method. However, in the later phase, ^{125}I radioactivity started to increase reaching a peak at 0.75% dose/mL at 60 min followed by a gradual decrease. In the case of Cat-BSA, on the other hand, the distribution patterns varied significantly depending on the labeling methods (see Table 2). Similarly, the latter phase of ^{125}I radioactivity in the plasma was influenced by the reappearance of a ^{125}I-metabolite in the circulation. This, however, did not result in the appearance of a peak. Kidney and spleen showed generally low radioactivity in the Cat-BSA studies and only negligible amounts were found in these organs in the Gal-BSA studies, 3 h after injection.

Biliary and Urinary Excretion of ^{111}In and ^{125}I Radioactivity—Statistically different features of urinary excretion of radioactivity were observed as far as the three methods of labeling are concerned (Figure 3). In the case of ^{111}In labeling, the total radioactivity excreted in the urine within the 180 min of the experimental period was less than 1% of the administered dose, regardless of the BCA used for labeling and regardless of the BSA derivative. On the other hand, the cumulative amount of ^{125}I radioactivity in the urine was 7.8% and 2.9% of the administered dose for Cat-BSA and Gal-BSA, respectively.

The biliary excretion of radioactivity after administration of radiolabeled Cat-BSA was highest for ^{125}I (2.2% of the administered dose) followed by ^{111}In-SCN-BZ-EDTA (1.1% of the dose) and ^{111}In-DTPA (0.3% of the dose). In the case of Gal-BSA, similarly, the radioactivity excretion of ^{111}In-DTPA-labeled compound was the lowest of all, representing 1.7% of the injected dose. There was no statistically significant difference in the biliary excretion of radioactivity of ^{111}In-SCN-BZ-EDTA and ^{125}I-labeled Gal-BSA (3.8% and 3.5% of the administered amount, respectively).

When the biliary excretion rate (BER) of radioactivity was investigated, differences in the rate of appearance of radioactivity in the bile were observed relating to the three methods of labeling (Figure 4). In particular, ^{125}I-bound radioactivity showed a rapid fall in BER after reaching a peak at 25 min. On the contrary, the rate of biliary excretion of ^{111}In-SCN-BZ-EDTA radioactivity, after reaching a maximum, was found to remain constant (Cat-BSA) or only fall gradually (Gal-BSA). The BER value of ^{111}In-DTPA radioactivity (BER_{DTPA}) during the last hour of the experimental period (calculated as the mean of the last three values) was significantly ($p < 0.001$) lower than that of ^{111}In-SCN-BZ-EDTA. The ratio BER_{DTPA}/BER_{EDTA} was 0.20 in the case of Cat-BSA and nearly identical for Gal-BSA (0.19).

Radioactivity Disposition of ^{125}I-Labeled BSA Derivatives and Their Metabolite(s)—The separation of TCA-precipitable ^{125}I radioactivity is shown in Figure 5. It can be seen that the increase in plasma radioactivity after injection of ^{125}I-Gal-BSA was exclusively caused by the appearance of a low molecular weight product in the circulation. Both the urinary and biliary excretion of ^{125}I radioactivity after the administration of ^{125}I-labeled Cat-BSA and Gal-BSA may also be accounted for by the excretion of a degradation product rather than the intact protein. In the urine, no TCA-precipitable radioactivity was detected.

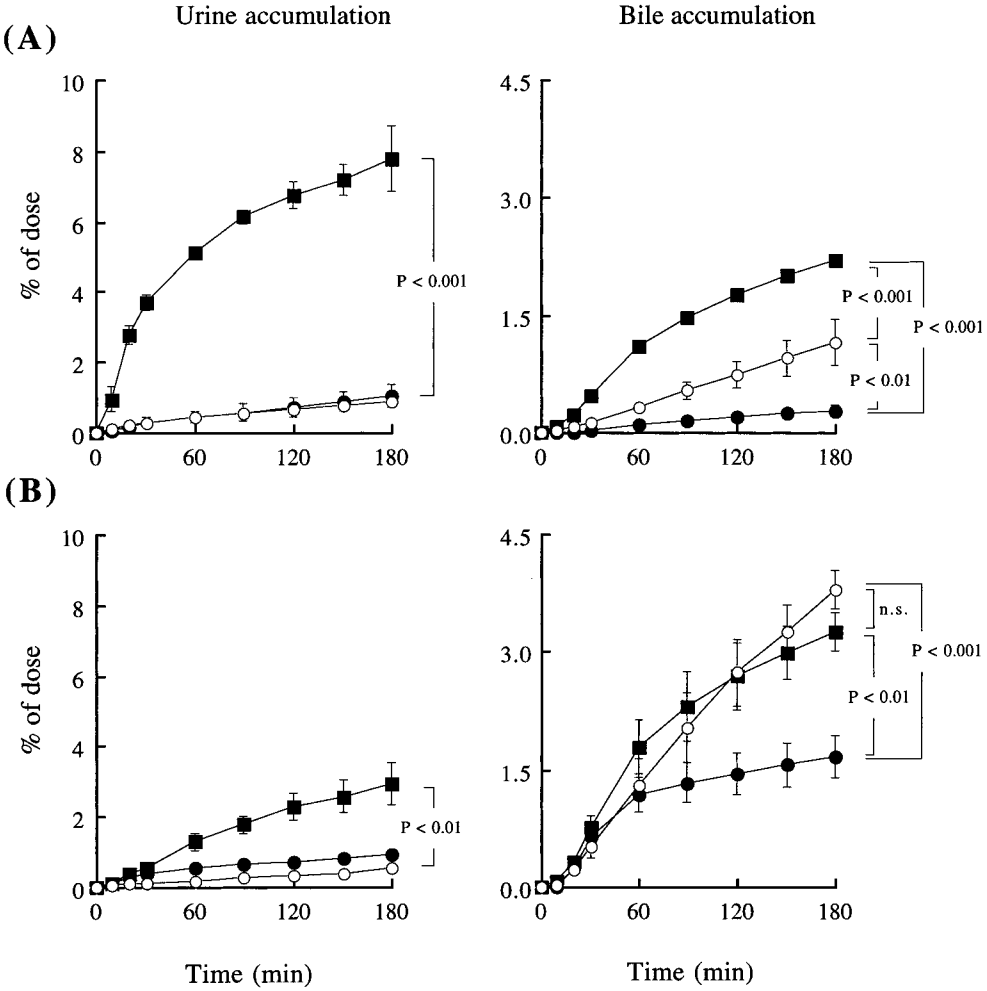

Figure 3—Time-courses of accumulation of radioactivity in the urine and bile after iv administration of Cat-BSA (A) and Gal-BSA (B) labeled with ^{111}In-DTPA (●), ^{111}In-SCN-BZ-EDTA (○), or ^{125}I (■). Data are expressed as mean ± SD of at least three experiments. Statistical significance was based on Student *t*-test; n.s. = statistically nonsignificant.

Apparent Organ Uptake Clearance after Intravenous Administration of BSA Derivatives Labeled with ^{111}In-DTPA, ^{111}In-SCN-BZ-EDTA, and ^{125}I—The apparent volumes of distribution, areas under the radioactivity concentration curve (AUC) and apparent organ uptake clearance of radiolabeled proteins after administration of the investigated compounds in rats are given in Table 2. The AUC of total radioactivity after administration of Cat-BSA was not significantly affected by the method of radiolabeling. However, in the case of Gal-BSA, a rapid release of ^{125}I-metabolite occurred (Figure 2), which resulted in significantly ($p < 0.001$) increased AUC of total radioactivity. When recalculated to infinity, the AUC of ^{125}I radioactivity was about 25 times larger than that of ^{111}In-labeled protein.

The apparent organ uptake clearance of ^{111}In-labeled compounds (regardless of the BCA employed) was consistent with the well-known mechanism of their hepatic uptake. Therefore, the CL_{liver} of ^{111}In-labeled Gal-BSA was very high, approaching the value of liver plasma flow (390 mL/h[21]) ^{111}In−Cat-BSA, on the other hand, was taken up by the liver at a significantly lower rate ($p < 0.001$), with CL_{liver} reaching only about 6% that of Gal-BSA. When ^{125}I was employed as a radiolabel, the apparent hepatic uptake clearance was statistically lower ($p < 0.001$) for both substances, representing approximately 35% of ^{111}In-labeled Cat-BSA. In the case of Gal-BSA, this difference was still more pronounced; the apparent hepatic uptake clearance of ^{125}I-labeled Gal-BSA was less than 10% that of ^{111}In-labeled Gal-BSA.

Statistically lower uptake and/or retention of ^{125}I radioactivity, when compared with ^{111}In, was also observed in the kidney. Uptake of radioactivity by the spleen was observed only for cationized proteins (2−3% of the administered dose), and only a negligible amount of radioactivity was detected in the spleen for the galactosylated proteins.

Time-Course of Organ Distribution of ^{125}I-Labeled BSA Derivatives—The time-courses of ^{125}I radioactivity distribution in the liver, kidney, spleen, and thyroid at 5, 20, 60, and 180 min after injection of ^{125}I−Cat-BSA and ^{125}I-Gal-BSA are shown in Figure 6. In both cases the radioactivity recovered in the liver, kidney, and spleen decreased with time. The most marked fall was seen in the liver during the first 60 min after injection. On the other hand, the thyroid showed an increasing tendency to accumulate ^{125}I radioactivity.

Schematic depiction of radioactivity disposition after administration of radiolabeled proteins in rats is shown in Figure 7.

Discussion

In the previous studies[6,22,23] it was pointed out that the radiolabeled metabolites of liver-specific proteins are the most important determinants of radioactivity elimination

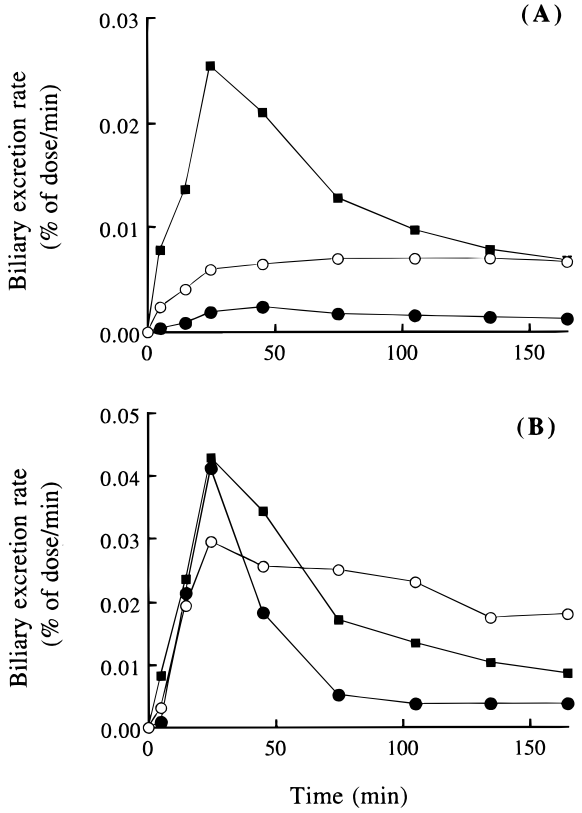

Figure 4—Biliary excretion rate of radioactivity after intravenous administration of radiolabeled Cat-BSA (A) and Gal-BSA (B) in rats. (●) ^{111}In-DTPA; (○) ^{111}In-SCN-BZ-EDTA; (■) ^{125}I. Data represent mean of three rats.

from the target site. Therefore, the choice of an appropriate radionuclide for protein labeling may be the critical step in studies where the body distribution of proteins is investigated and the interpretation of the obtained results is based on radioactivity measurements in various body compartments.

In the present study, we employed two radionuclides, ^{111}In and ^{125}I, to investigate the effect of the radioisotope on the whole body disposition of radioactivity. ^{125}I was attached to the tyrosine residues of proteins using the chloramine T method, and ^{111}In was incorporated into the protein using DTPA or SCN-BZ-EDTA as bifunctional chelating agents. Using these methods, two derivatives of BSA were radiolabeled, and the distribution and excretion of radioactivity was investigated. Gal-BSA and Cat-BSA were chosen as marker compounds because they are known to be taken up by the liver cells via receptor-mediated endocytosis and adsorptive endocytosis, respectively. Previously, we reported the different pharmacokinetics of liver uptake of these two derivatives in rat liver perfusion experiments.[24] Gal-BSA was found to enter the hepatocytes in a dose-dependent (nonlinear) manner with a very fast internalization rate. On the other hand, Cat-BSA was taken up by the liver cells more slowly (internalization constant was about 15% that of Gal-BSA) with a high capacity and was linear over a wide range of inflow concentrations.[24] Consistent results were also obtained in the present study. Both proteins were taken up by the liver in accordance with the type of chemical modification. The CL_{liver} of ^{111}In-labeled Gal-BSA was close to the hepatic plasma flow rate (390 mL/h[21]) and seemed to be limited by this value. On the other hand, the apparent CL_{liver} of ^{111}In-labeled Cat-BSA was significantly lower, representing about 5% that of Gal-BSA.

The fast disappearance of radioactivity from the plasma after intravenous administration of both compounds was caused preferentially by the hepatic uptake of the modified BSAs. In the case of Gal-BSA, there were no significant differences in the distribution phases among the labeling methods. Therefore, it seems plausible that the appearance of the protein in the liver was not influenced by the type of labeling. In the case of Cat-BSA, however, differences between ^{111}In and ^{125}I-labeled proteins were observed. In particular, the distribution half-lives of Cat-BSA labeled with ^{111}In were longer than that of ^{125}I−Cat-BSA (Table 2). We assume that this discrepancy was caused by the anionic character of the chelating agents introduced into the protein molecule. Consequently, the reduced positive charge of the complex resulted in a lower affinity of the protein for adsorptive endocytosis by hepatocytes. This assumption is further supported by the fact that when a 10-fold molar excess of SCN-BZ-EDTA was attached to Cat-BSA, the results obtained from in vivo experiments indicated markedly prolonged retention of radioactivity in the plasma ($t_{1/2\alpha}$ = 13.9 min) with a significantly reduced hepatic uptake clearance (CL_{liver} = 4.74 mL/h) (data not shown).

Significant differences were observed in the extent to which the radiolabel remained in the hepatic tissue. Three hours after drug administration, only a small portion of ^{125}I associated radioactivity was present in the liver (about 5% of the administered dose) when compared with ^{111}In (56−78% dose). Additional distribution experiments with iodine-labeled proteins have revealed a rapid disappearance of ^{125}I radioactivity from the liver within 1 h after drug administration (Figure 6). Then, when the apparent hepatic uptake clearances were calculated, iodinated proteins showed a CL_{liver} that represented only a small fraction of that of ^{111}In-labeled compounds. Therefore, it is evident that the hepatic uptake clearance of these two proteins cannot be simply estimated using ^{125}I radioactivity counts, ignoring the formation of radiolabeled metabolite(s) and radioactivity escaping from the liver. On the other hand, results obtained with ^{111}In-labeled proteins seem to adequately characterize the hepatic uptake of both Gal-BSA and Cat-BSA.

The reason iodine radioactivity escapes from the hepatic tissue much faster than indium radioactivity may be explained in terms of the metabolites that are produced within the hepatic cells. After internalization by the hepatocytes, the proteins are delivered to lysosomes where they undergo proteolytic cleavage and give raise to their metabolic products.[9] In the case of proteins labeled with iodine via tyrosine residues, the metabolites are likely to be mono- and/or diiodinated tyrosine.[10] Either the physicochemical properties or the possible affinity for a transporter system that may be present in the hepatocytes, as speculated by Gore et al.[25] and Duncan and Welch,[22] or a combination of both, enable these metabolites to leave the hepatocytes very easily. In addition, the metabolite may be converted to iodine by cytoplasmic deiodinase[26] and both radiolabeled monoiodtyrosine and iodine were found in blood in studies with ^{125}I-labeled asialofetuin.[27]

In the case of indium-labeled compounds with SCN-BZ-EDTA and DTPA as chelators, ^{111}In-SCN-BZ-EDTA-lysine and ^{111}In-DTPA-lysine were identified as the final metabolic products respectively.[28,23] Slow release of ^{111}In-DTPA-amino acid-associated radioactivity from the liver has previously been reported by Duncan and Welch[22] who pointed out that the compound, to leave the lysosomal compartment, had either to cross the lipid bilayer by simple diffusion or to use a transporter for amino acids. However, simple diffusion is greatly complicated by the ionic character of the chelate and the attached amino acid at intralysosomal pH (about 5.0); carrier-mediated amino acid transport is present for lysine, but the transfer is hindered

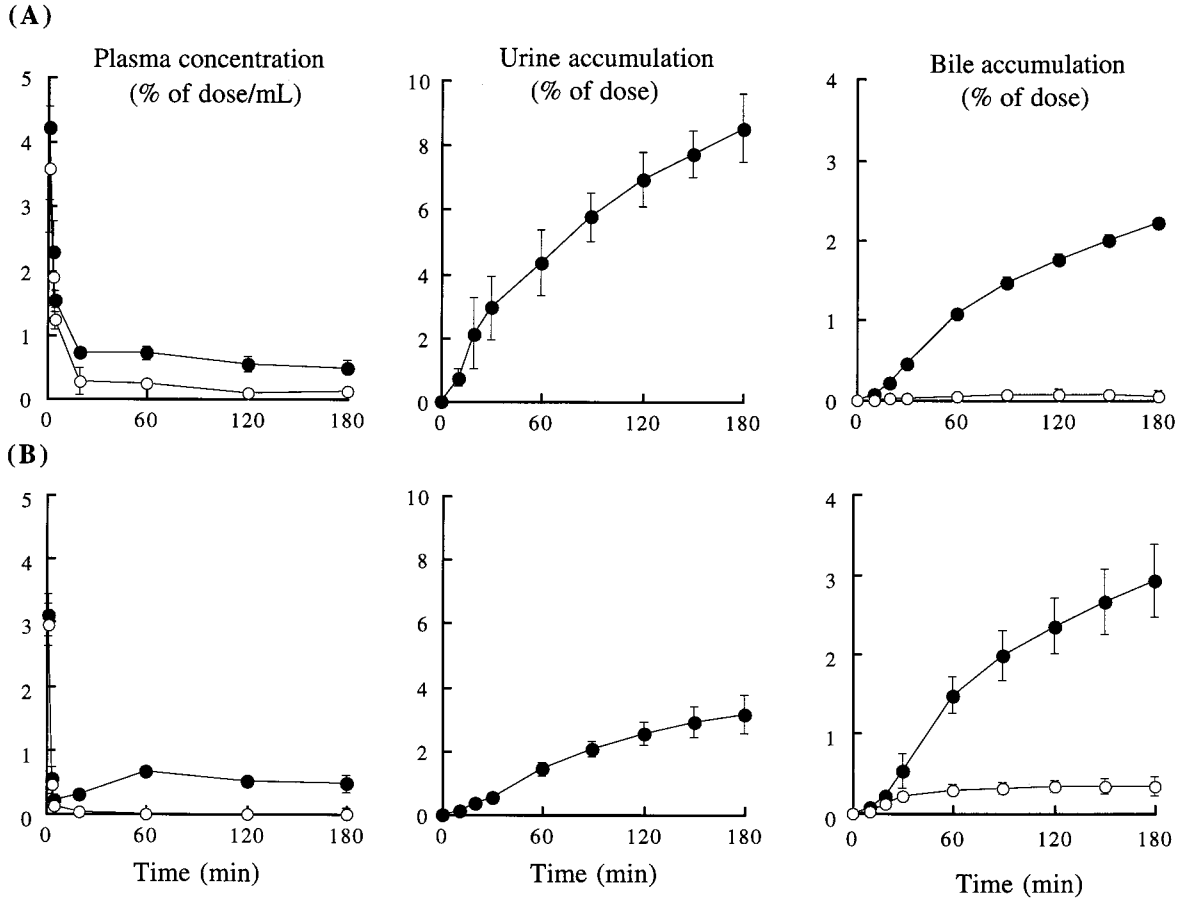

Figure 5—Body disposition of ^{125}I radioactivity; TCA-precipitable (○) and total radioactivity (●) of ^{125}I-labeled Cat-BSA (A) and ^{125}I-labeled Gal-BSA (B). In the urine, no TCA-precipitable radioactivity was detected. Data are expressed as mean ± SD of at least three experiments.

by derivatization of the ϵ-amine. Therefore, the possibility for ^{111}In-DTPA-amino acid to leave lysosomes/hepatocytes is rather limited.

In our study, the different mode and rate of hepatic uptake of both proteins resulted in a different disposition of ^{125}I-associated radioactivity. The internalization and degradation of Gal-BSA take place at a very fast rate. Consequent proteolytic degradation resulted in a rapid escape of radioactivity from the liver (Figure 6) and in the appearance of TCA-soluble ^{125}I radioactivity in the plasma and bile (Figure 5). As a result, the AUC of ^{125}I radioactivity in the plasma was 25 times larger than that of ^{111}In associated radioactivity. A similar course of iodine radioactivity has also been reported in rabbits after administration of ^{131}I-asialoorosomucoid.[29] However, the internalization of Cat-BSA and its delivery to the lysosomal compartment occur at a much slower rate when compared with Gal-BSA,[24] and the production of ^{125}I-metabolite(s) is supposed to be delayed. Therefore, it is unlikely that the fall in the liver radioactivity within 60 min of ^{125}I-Cat-BSA injection and the appearance of TCA-soluble radioactivity in the plasma and urine occurred only due to the formation of a metabolite in the lysosomes. We suppose that it might be caused by an enzymatic degradation (deiodination) of the protein in the plasma, or even when attached to the liver surface, with consequent glomerular filtration of ^{125}I or ^{125}I-radiolabeled metabolite. An attempt to distinguish between the ^{125}I radioactivity associated with protein and that of its degradation product has confirmed that the radioactivity in the urine was accounted for by a metabolite rather than an intact protein (Figure 5). However, the precise structure of the metabolite(s) has not been determined, and therefore we cannot speculate on the exact origin and pathways of the metabolite(s). Nevertheless, when compared with ^{111}In-labeled compounds, ^{125}I labeling resulted in a significantly higher accumulation of radioactivity in the urine in studies with both proteins. In addition, bifunctional chelating agents employed for attaching ^{111}In to protein molecules did not appear to affect the urinary excretion of ^{111}In radioactivity to a great extent.

When the biliary excretion rate was investigated (Figure 4), in the case of Gal-BSA, the curves of BER during the first 25 min followed nearly identical courses. As more than 90% of ^{125}I radioactivity in the bile was TCA-precipitable within 20 min of injection, we assume that during this period the protein avoided the lysosomal compartment and the radioactivity was excreted into the bile in protein-bound form, by means of transcytosis. In a different set of experiments, the gel separation of protein and metabolite-bound radioactivity in the bile in studies with ^{111}In-DTPA labeled Gal-BSA was performed. Similarly, it was found that 80−95% of radioactivity released into the bile was in protein-bound form within ca. 60 min after administration (unpublished results). After this interval, degradation of the protein in the lysosomal compartment occurred and the radiolabeled metabolites were leaving the hepatocytes at different rates in the following order: ^{125}I > ^{111}In-SCN-BZ-EDTA > ^{111}In-DTPA. This escape was in a good agreement with the theory of Duncan and Welch[22] described above. Similar patterns were also observed in the case of Cat-BSA. Interestingly, it was found that the ratio of BERs between ^{111}In-DTPA and ^{111}In-SCN-BZ-EDTA-associated radioactivity was nearly identical for both protein derivatives. Consequently, the cumulative amount of radioactivity in the bile during the 180 min experimental period has shown that, among the three methods of labeling

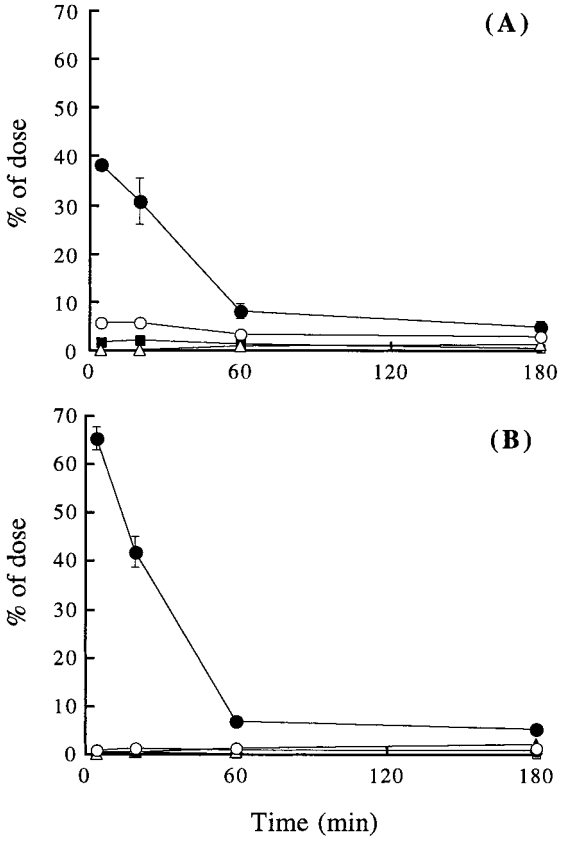

Figure 6—Time-courses of ^{125}I radioactivity distribution in rats after intravenous administration of ^{125}I-labeled Cat-BSA (A) and ^{125}I-labeled Gal-BSA (B). (●) liver, (○) kidney, (■) spleen, (△) thyroid. Data are expressed as mean ± SD of two experiments.

employed, ^{111}In-DTPA-associated radioactivity appeared in the bile in the lowest amount, regardless of the protein derivative. ^{111}In-SCN-BZ-EDTA radioactivity was excreted into the bile in a higher amount than that of ^{111}In-DTPA. This is consistent with the previous results of Arano et al.[30] who reported faster biliary elimination of ^{111}In-SCN-BZ-EDTA-lysine in comparison with ^{111}In-DTPA-lysine. Also, a similar set of experiments performed in mice revealed comparable behavior of these radiolabels. However, the difference between ^{111}In-DTPA and ^{111}In-SCN-BZ-EDTA radioactivity was much more pronounced.[31] The faster elimination of ^{111}In-SCN-BZ-EDTA-labeled metabolite might also be explained in terms of the physicochemical properties of the radiometabolites. However, the detailed mechanism of the disappearance of these compounds from the liver cells remains to be elucidated.

For a more accurate estimation of the CL_{liver} of ^{125}I-labeled proteins, the more sophisticated approach of a pharmacokinetic analysis has been adopted in our previous study in mice.[31] TCA-precipitable fraction was employed for data analysis and the time-courses of radioactivity in the plasma and liver were simultaneously fitted to exponential equations to calculate the CL_{liver}. However, even this approach, requiring much more experimental data, did not produce satisfactory results due to the pattern of liver accumulation.

In conclusion, this study has confirmed a significant influence of the radioisotope employed in the labeling of the liver-specific proteins on the fate of the radioactivity in the body. ^{125}I radioactivity rapidly escaped from the target tissue and was excreted into bile and urine, thus interfering with the pharmacokinetic analysis to a great extent. Therefore, ^{125}I labeling was found inappropriate for distribution studies of Gal-BSA and Cat-BSA in rats. On the other hand, the results obtained with ^{111}In were consistent with the well-known behavior of these proteins in the organism and allowed pharmacokinetic analysis to be performed without correction for radiolabeled metabolites. In particular, because of the restricted release of ^{111}In-DTPA-labeled metabolite from the liver, among the three methods of radiolabeling investigated, ^{111}In radiolabeling using DTPA as a bifunctional chelating agent was found to be the most suitable for in vivo disposition studies of liver-specific proteins.

Received December 28, 1998. Accepted for publication February 23, 1999.

Abstract □ Thermal analysis of propranolol/oleic acid mixtures prepared by solvent evaporation enabled construction of the binary system phase diagram. This allowed both physical and chemical interactions to be identified, including complex formation at the equimolar composition. An incongruent melting complex with a characteristic reaction point was identified in excess oleic acid compositions, a common property of fatty acid/fatty acid salt binary systems. The equimolar complex was confirmed to be propranolol oleate using infrared spectroscopy. Wide-angle X-ray powder diffractometry demonstrated that propranolol oleate possessed long-range positional order (~25 Å *d* spacing) accompanied by a degree of disorder over shorter *d* spacings. Such a pattern suggested mesophase formation, explaining the unctuous nature of propranolol oleate at room temperature. Accurate measurement of the long-range *d* spacing was achieved using small-angle X-ray scattering, permitting differentiation of the three different phases identified (phase I: 25.4 Å, phase II: 24.6 Å, phase III: 25.4–25.5 Å). The implications of drug fatty acid salt formation and also mesomorphism in pharmaceutical systems are discussed.

Introduction

The numerous gastrointestinal physiological effects of lipids can be utilized to manipulate drug oral bioavailability. Examples include extension of the gastrointestinal transit time, modified drug absorption, and stimulation of lymphatic drug transport.[1] Owing to the regional nature of these effects, drug and lipid must be released in a localized and controlled manner. During the initial development stages of such an oral drug delivery system, one must establish the physicochemical properties of drug, lipid, and the drug/lipid combination so that an appropriate system is chosen.

Oleic acid is a long chain fatty acid of considerable interest in oral drug delivery, as it has been shown to participate in all of the aforementioned physiological effects.[2−4] An example of oral bioavailability enhancement following coadministration of oleic acid has been reported for the β-adrenoceptor blocking drug, propranolol.[5] Administration of a propranolol/oleic acid binary mixture with a propranolol/oleic acid/polymer sustained release ternary mixture led to 3-fold bioavailability enhancement in humans. Propranolol human oral bioavailability is approximately 30% due to extensive first pass metabolism.[6] In light of this, the effect of oleic acid is particularly significant because a postabsorption event appeared to be responsible. Stimulation of propranolol lymphatic transport was considered but a cannulated lymphatic animal model failed to identify sufficient lymphatic drug transport that could impact on drug first pass metabolism.[7] We have undertaken a physicochemical investigation of the propranolol/oleic acid binary system to identify alternative mechanisms of improved bioavailability caused by oleic acid coadministration.

Little is known about the solid-state physical and chemical properties of drug/fatty acid binary systems. The linear structure and polar properties of lipid molecules predispose them to mesophase formation.[8] The term mesophase defines all levels of molecular order that are intermediate of the fully ordered crystalline state and the liquid or amorphous state. Subcategories are present within this broad definition, an example of which is provided by high purity oleic acid. At −6 °C the fully ordered crystalline phase (γ) converts to a conformationally disordered crystalline mesophase (α), followed by melting to a neat phase at 13 °C.[9] The α-phase of oleic acid contains long range positional order in three-dimensions, but orientational disorder of the fatty acid chains is present within the lattice. Structures with a lower degree of positional order, in only one or two-dimensions, are classed as liquid crystalline.[10]

The aim of this study was to investigate the phase behavior of the propranolol/oleic acid binary system using thermal analysis, infrared spectroscopy, and X-ray crystallography. Construction of the binary system phase diagram allowed physical and chemical interactions to be identified. The analytical and pharmaceutical implications of complex formation and mesomorphism in the propranolol/oleic acid system are discussed.

Materials and Methods

Materials—Propranolol base was prepared by addition of excess sodium hydroxide to an aqueous solution of propranolol HCl (Sigma, Poole, U.K.), followed by extraction into chloroform and solvent evaporation. Thermal analysis of six batches found the propranolol base extrapolated onset of melting temperature (91.6 ± 0.6 °C) and melting enthalpy (148.4 ± 1.8 J/g) to be in good agreement with literature values (92.9 °C, 146.4 J/g).[11] Thermogravimetric analysis demonstrated 0.6% w/w (± 0.1, n=3) weight loss during heating at 10 °C/min from 25 to 150 °C, and water content was found to be less than 0.1% w/w (n = 3) using Karl Fischer titration. Binary mixtures of propranolol base and high purity oleic acid (>99%, Sigma, Poole, U.K.) ranging from 5 to 95% P (% P: molar percentage of propranolol base) were prepared by evaporation from chloroform under 900 mbar vacuum at 25 °C for 24 h to yield approximately 1 g product. Drug and fatty acid chemical structures are shown in Figure 1.

Methods—*Thermal Analysis*—Differential scanning calorimetry (DSC) was carried out using the Perkin-Elmer DSC-7 (Beaconsfield, U.K.). Binary mixtures were accurately weighed in the range 5−7 mg into stainless steel pans, hermetically sealed, and then

stored at −17 to −15 °C for 18 h prior to analysis. Particle size control was not possible because many compositions were semisolid or liquid at room temperature. Cooled sample pans were rapidly transferred to the precooled DSC head and analyzed using varying heating rates from −30 to 110 °C. Temperature and enthalpy calibration was carried out using standard indium and zinc, with TAS-7 software for data analysis. All thermal event temperature values were the extrapolated onset temperature with the exception of the liquidus temperature calculation. This temperature represents the liquidus line of the phase diagram, the point above which a system is liquid. Peak melting temperature is therefore a more appropriate measure of the often broad liquidus endotherm and is used in this study.[12] DSC analyses were complemented with hot stage microscopy (HSM, Stanton Redcroft, London, U.K.) to confirm the nature of phase changes taking place.

Fourier Transform Infrared (FT-IR) Spectroscopy—FT-IR spectroscopy was carried out using a 6020 Galaxy spectrometer (Mattson, Newport Pagnell, U.K.) converting 250 scans over 4000 to 400 cm^{-1} at 4 cm^{-1} resolution to conventional frequency domain spectra. An attenuated total reflectance crystal (ATR crystal, Graseby-Specac, Orpington, U.K.) was used to allow analysis of solid, semisolid, and liquid samples. Samples were spread directly onto the crystal surface from chloroform solution and then analyzed at room temperature following solvent evaporation.

X-ray Crystallography—Wide-angle crystallographic data was obtained using a Siemens D5000 X-ray powder diffractometer (XRPD, Karlsruhe, Germany) with a Cu Kα radiation source at generator settings of 40 kV and 30 mA. XRPD diffractograms were obtained at 22 °C over 1−30° 2θ (2θ, the angle between incident and reflected X-rays) using a step size of 0.01° 2θ and a count time of 1 s. Small-angle X-ray scattering (SAXS) was also completed using the Kratky Compact Camera (M. Braun Graz Optical Systems, Graz, Austria). Samples approximately 1 mm thick were mounted in a transmission sample holder between mica windows and cooled below −15 °C for 18 h. The sample stage was cooled to 4 °C with an Anton Paar Peltier temperature control device before sample transfer to stage. The camera tube was evacuated to 0.1 mbar and data collected for 10 min, using Cu Kα radiation generated by the Philips 1830/40 generator at 40−45 kV and 35−40 mA. Measurements were made following 10 min isothermal holds to ensure sample temperature equilibration. Temperature control was accurate to ± 1 °C in the range 0 to 70 °C, with *d* spacings calibrated at 37 °C to 0.1 Å with tristearin.

Results

Thermal Analysis—Precooled propranolol/oleic acid binary mixtures prepared by solvent evaporation were analyzed using DSC. Representative DSC scans are shown in Figures 2a (excess propranolol) and Figure 3a (excess oleic acid). These data were used to construct the binary phase diagram, also presented in two parts (Figures 2b and 3b).

Binary mixtures containing excess propranolol were analyzed at 10 °C/min (Figure 2a). A new thermal event at 51 °C was present in all compositions increasing in

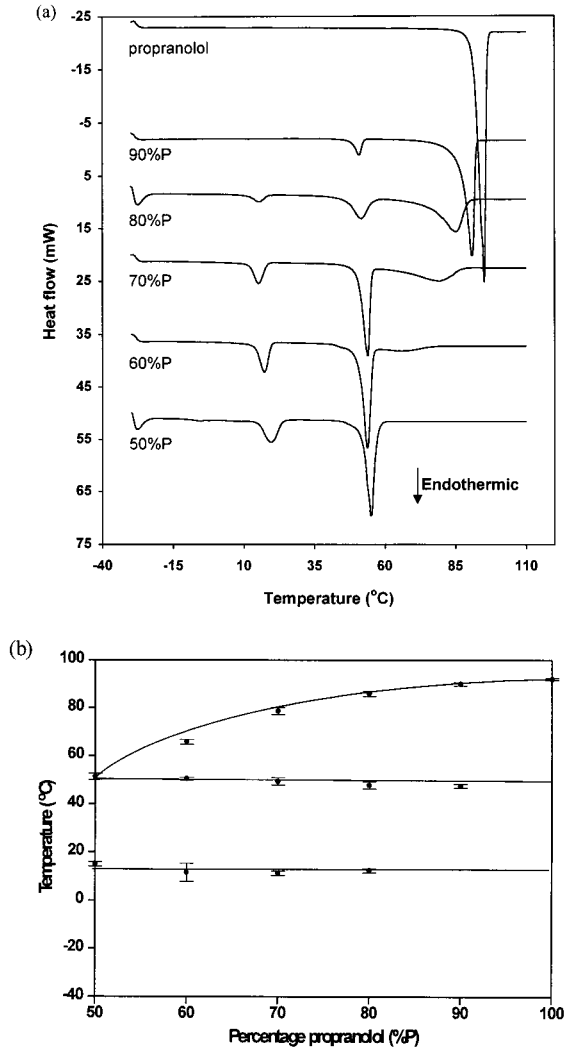

Figure 2—(a) DSC heating scans performed at 10 °C/min of propranolol/oleic acid binary mixtures containing excess propranolol (propranolol, 90% P, 80% P, 70% P, 60% P, 50% P). Compositions quoted as molar percentage % P. (b) Corresponding phase diagram. Three replicate DSC scans were used to obtain each phase transition temperature, the average of which is plotted with the standard deviation shown by an error bar.

magnitude as propranolol content decreased. The enthalpy of melting of excess propranolol decreased until absence at 50% P. The decreasing melting temperature of propranolol and also endotherm broadening suggested that solid propranolol was melting in a liquid phase. An initial melt at 51 °C followed by slow melting of excess propranolol was confirmed using HSM. Therefore, 51 °C corresponded to the solidus line of the phase diagram (the temperature below which the system was solid) and completion of excess propranolol melting represented the liquidus line. The 51 °C thermal event reached maximum enthalpy at 50% P, suggesting formation of an equimolar complex. The abbreviation POA is now used for this complex. The phase diagram indicated that propranolol had negligible solubility in molten POA immediately above the melting temperature of POA. Such a system is described as monotectic.[12] An endotherm at 13 °C also reached maximum enthalpy at POA, suggesting that POA underwent a phase change prior to melting at 51 °C. However, no macroscopic change could be observed when heating precooled POA using HSM.

Multiple thermal events in the second portion of the propranolol/oleic acid system were poorly resolved at 10 °C/min heating rate. Analysis at 2 °C/min provided improved thermal data presented in Figure 3a. The lower

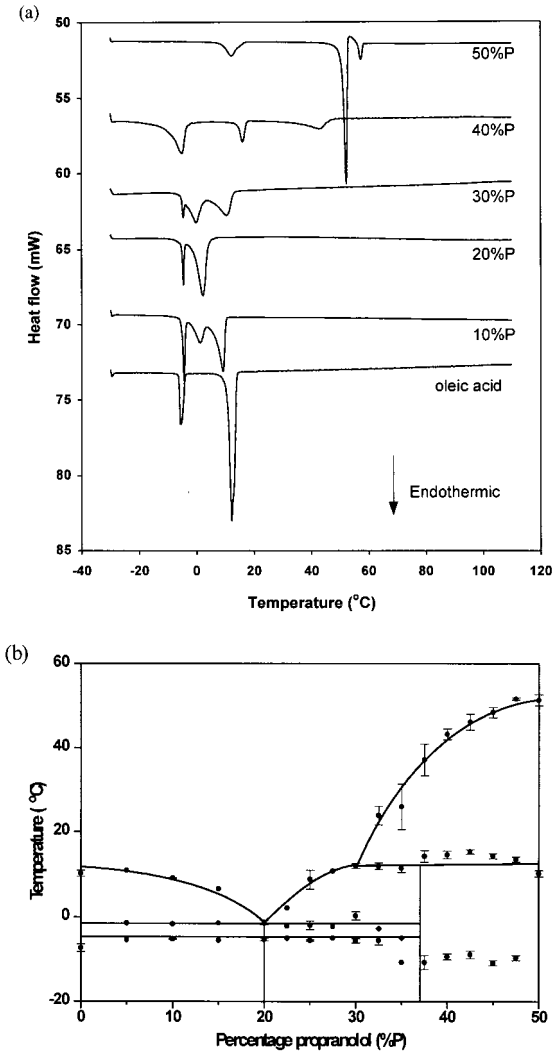

Figure 3—(a) DSC heating scans performed at 2 °C/min of propranolol/oleic acid binary mixtures containing excess oleic acid (50% P, 40% P, 30% P, 20% P, 10% P, oleic acid). Compositions quoted as molar percentage % P. (b) Corresponding phase diagram. For some compositions, three replicate DSC scans were used to obtain each phase transition temperature, the average of which is plotted with the standard deviation shown by an error bar.

heating rate produced a double endotherm at the POA melting event which is investigated in a following section. Eutectic system formation in excess oleic acid compositions was demonstrated by a depression in the liquidus line to a minimum of −1 °C, accompanied by eutectic melting at −1 °C in all 5−30% P compositions. The eutectic melt enthalpy was greatest at 20% P, the eutectic composition. The presence of the $\gamma-\alpha$ oleic acid phase transition at −6 °C in 5−30% P compositions confirmed eutectic system formation because an eutectic is a two-phase system in the solid state. This explains why the $\gamma-\alpha$ transition was present in compositions when the α-oleic acid melting endotherm was absent.

The absence of the eutectic melt in mixtures 35−47.5% P, plus the discontinuity in the liquidus arm of the phase diagram at approximately 30% P, indicated formation of a second complex. The complex did not undergo congruent melting (where both solid and liquid phase have the same chemical composition). When a complex is stable as a solid but is not stable as a liquid phase of the same composition, the process is described as an incongruent melt.[13] Such a melting process yields both a liquid and solid phase. This was apparent in the phase diagram (Figure 3b), and confirmation was obtained from the DSC curve for the

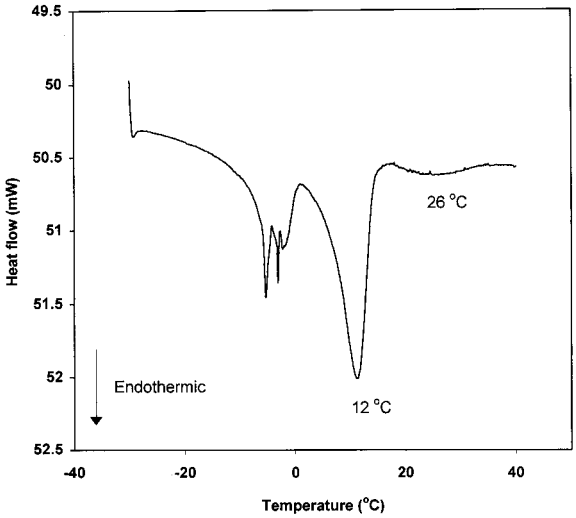

Figure 4—DSC heating scan performed at 2 °C/min of the 32.5% P binary mixture.

32.5% P composition shown in Figure 4. A complicated endothermic process between −6 and 0 °C indicated the presence of the eutectic melt and oleic acid polymorphism. According to the simple eutectic phase diagram,[12] an eutectic melt is followed by a single liquidus endotherm that represents the melt of the excess component. However, a second low enthalpy melting endotherm (peak temperature, 26 °C) could also be identified following the "liquidus" endotherm (peak temperature, 12 °C). The endotherm at 26 °C must be a product of the excess component melting event, confirming incongruent melting. The incongruent melting process of this complex, abbreviated as P/OA*, was as follows:

$$\text{P/OA* (s)} \rightarrow \text{POA (s)} + \text{oleic acid} \qquad (1)$$

The composition of the incongruent melting complex was approximately 35−37.5% P, as indicated on the phase diagram. The break in the liquidus curve at approximately 30% P, 12 °C, represented a reaction point and not the complex composition. Incongruent melting could not be identified using HSM because formation of a solid product during a melt cannot be distinguished from the final stages of a broad congruent melt. It was not possible to characterize the thermal event at approximately −10 °C due to inadequate low temperature equilibration. Incongruent melting processes are commonly identified in fatty acid/fatty acid salt systems, suggesting that the equimolar complex POA was propranolol oleate.[14]

Fourier Transform Infrared (FT-IR) Spectroscopy—The physical properties of propranolol/oleic acid binary mixtures varied widely with composition as indicated on the phase diagram, and so an ATR crystal was used for spectroscopic investigation at room temperature. Spectra obtained for propranolol, oleic acid, and POA are displayed in Figure 5. The high-intensity absorption band at 1710 cm^{-1} of oleic acid was due to asymmetric stretch of the C=O group present in the stabilized fatty acid dimer. O−H out of plane bending of the carboxyl dimer was also identified by an absorption peak at 910 cm^{-1}. Both peaks were absent in POA. The propranolol absorption band at 3270 cm^{-1} due to N−H stretch of the free base was also absent in POA. A new absorption band was present in POA at 1552 cm^{-1}. This suggested formation of a stabilized carboxylate anion (corresponding to asymmetric stretch of COO^-) as seen in propranolol laurate[15] and sodium oleate spectra.[16] FT-IR confirmed that the equimolar complex POA was propranolol oleate.

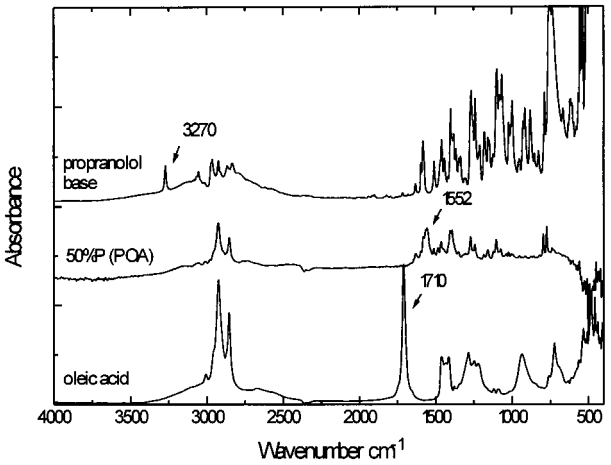

Figure 5—ATR FT-IR spectra of propranolol, 50% P (POA), and oleic acid at room temperature. The absence of secondary amine and carbonyl stretch bands at 3270 and 1710 cm^{-1}, respectively, and the presence of a new band at 1552 cm^{-1} (carboxylate anion) indicated salt formation.

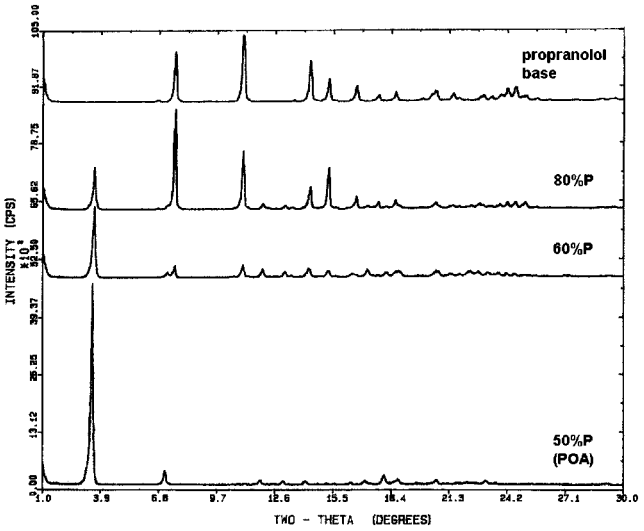

Figure 6—Wide-angle X-ray powder diffractometry (XRPD) patterns of propranolol, and binary mixtures 80% P, 60% P, and 50% P (POA) obtained over 1–30 °2θ at 22 °C.

Wide-Angle X-ray Powder Diffraction (XRPD)—POA existed as an unctuous waxlike solid at room temperature with pronounced birefringence when viewed under crossed polarized light, suggesting mesomorphism. Many phase changes in excess oleic acid compositions took place beneath 22 °C and could not be measured. XRPD diffractograms of 50, 60, 80% P and propranolol base were measured at 22 °C (Figure 6). As the quantity of excess propranolol decreased, the intensity of propranolol reflections reduced until absence at the equimolar composition. Increasing POA content was marked by a high-intensity reflection at 3.7° 2θ. The presence of both propranolol base and POA reflections at intermediate compositions indicated immiscibility of the two components in the solid state. This confirmed a two-phase monotectic system, as shown on the phase diagram (Figure 2b). The absence of high-intensity reflections in the 10−30° 2θ region of the POA spectrum indicated that this composition did not possess a rigid three-dimensional molecular lattice. Conversely, the absence of a broad "amorphous halo" in this region ruled out extensive molecular disorder. The high-intensity reflection at low angle demonstrated long-range positional order, approximate *d* spacing 24 Å. New reflections of much reduced intensity were present at 7.3 and 11.0° 2θ, corresponding to *d* spacings of 12.1 and 8.1 Å. These appeared to be higher order reflections originating from the ~24 Å repeat unit. The relationship between the primary reflection (~24 Å when $n = 1$) and higher order reflections (when $n = 2, 3, 4$, etc., from Bragg's Law $n\lambda = 2d \sin \theta$) can be used to identify mesophase structure. The ~24:12.1:8.1 Å ($1:^1/_2:^1/_3$) ratio of different order reflections for POA indicated a layered structure, such as lamellar or smectic.[17]

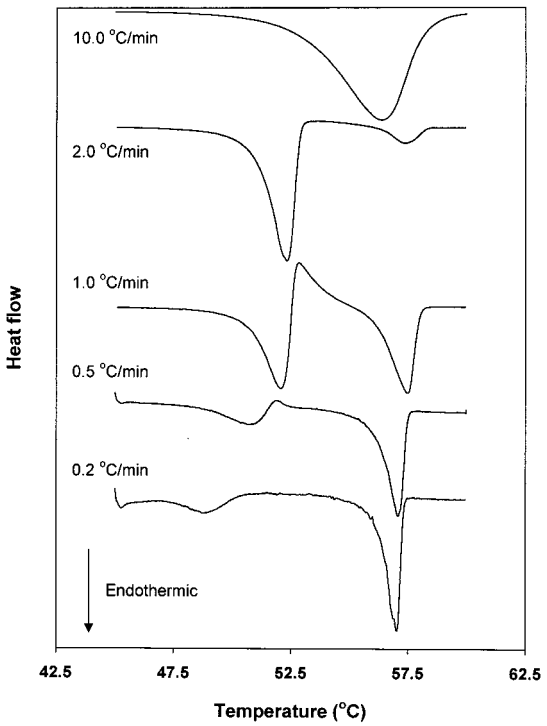

Figure 7—DSC heating scans of 50% P (POA) using variable heating rates (0.2, 0.5, 1.0, 2.0, and 10.0 °C/min). Reduced heating rate reduces the magnitude of thermal events so the heat flow scale is averaged to facilitate data interpretation.

Variable DSC Heating Rate Effect on POA Melting—Thermal analysis of precooled POA demonstrated an endothermic transition at 13 °C. The low-temperature POA solid phase was termed form I, and the phase present above 13 °C form II. A double endotherm at the POA form II melting temperature was observed when a DSC heating rate of 2 °C/min was used (Figure 3a). Further heating rate reduction led to identification of a third POA solid phase (III) that resolidified following form II melting (Figure 7). As heating rate was reduced, the magnitude of the higher temperature endotherm increased, because greater time was available for form III resolidification in a narrow temperature range. An isothermal period proceeding form II melting resulted in complete resolidification of form III. This permitted accurate measurement of melting temperature and enthalpy for this form in the absence of concurrent exothermic processes. At the lowest heating rate of 0.2 °C/min, the endothermic signal for form II melting was virtually absent due to simultaneous resolidification within the sample pan. HSM measurements were used to confirm simultaneous thermal events.

Small-Angle X-ray Scattering (SAXS)—In the absence of unique "fingerprint" XRPD patterns for POA forms I, II, and III, comprehensive thermal analysis provided the optimum tool for oleate salt mesophase characterization. Subtle changes in long-range positional order are commonplace during lipid phase changes (e.g., $\gamma-\alpha$ oleic acid phase transition).[18] SAXS analysis of POA I showed two signals corresponding to 25.4 and 12.7 Å (Figure 8a). The absence of high-intensity reflections at larger *d* spacings

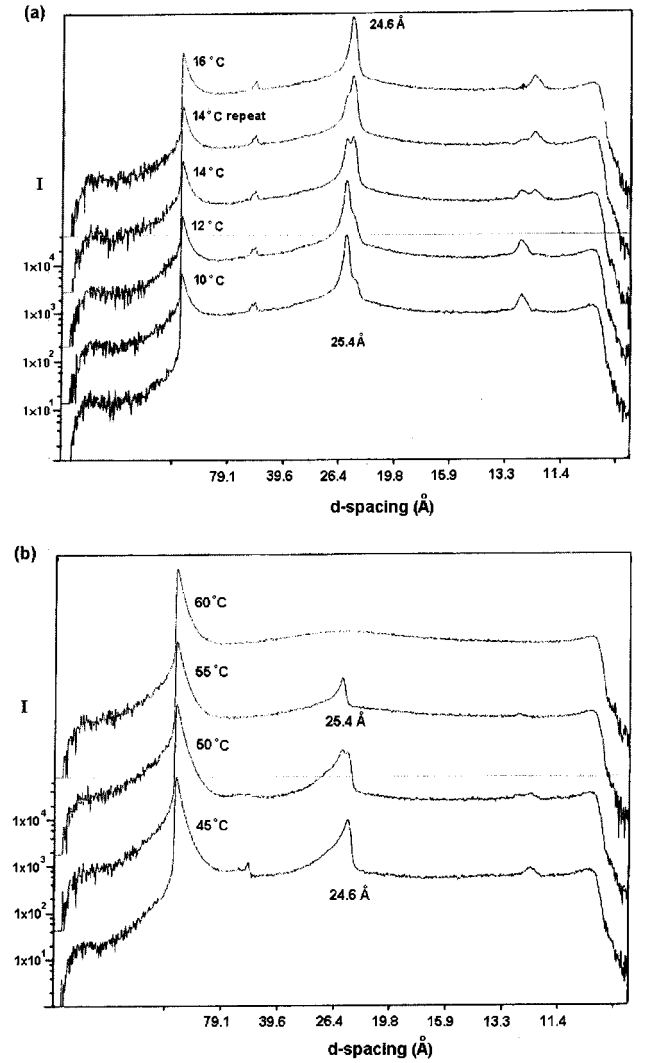

Figure 8—(a) Small-angle X-ray scattering (SAXS) patterns of precooled 50% P (POA) heated from 10 to 16 °C at 2 °C increments. (b) 50% P (POA) heated from 45 to 60 °C at 5 °C increments. For both plots, data collection time was 10 min with a 10 min interval between measurements to allow temperature equilibration.

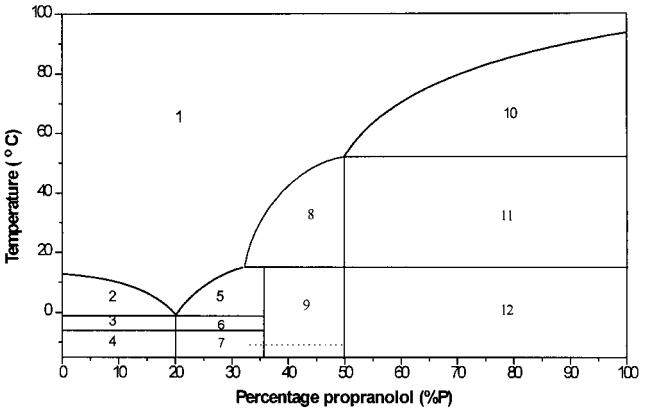

Figure 9—Propranolol/oleic acid binary system phase diagram. (**1**) miscible liquid phase, (**2**) α-oleic acid (s) and liquid, (**3**) α-oleic acid (s) and eutectic (s), (**4**) γ-oleic acid (s) and eutectic (s), (**5**) incongruent melting complex P/OA* (s) and liquid, (**6**) P/OA* (s) and eutectic containing α-oleic acid (s), (**7**) P/OA* (s) and eutectic containing γ-oleic acid (s), (**8**) equimolar complex POA II (s) and liquid, (**9**) P/OA* (s) and POA I (s), (**10**) propranolol (s) and liquid, (**11**) propranolol (s) and POA II (s), (**12**) propranolol (s) and POA I (s).

confirmed that the 25.4 and 12.7 Å signals represented the primary and secondary reflections. A decrease in the long-range repeating unit took place on I−II conversion, as indicated by a fall in reflections to 24.5 and 12.3 Å. A small but significant structural change was also identified following gradual heating through POA II melting point to enable form III resolidification (Figure 8b). The repeating unit in POA III was found to be 25.4/25.5 Å. Thermal and crystallographic properties of POA forms I, II, and III are summarized in Table 1.

Table 1—Summary of Propranolol Oleate Forms I, II, and III DSC (heating rate, 10 °C/min) and SAXS Data

form	temperature of melting/transition, °C (sd, $n = 6$))	enthalpy of transition, °C (sd, $n = 6$)	long-range *d* spacing, Å ($n = 3$)
I	13.1 (1.3)	23.9 (1.4)	25.4, 25.4, 25.4
II	51.4 (1.3)	77.3 (1.7)	24.6, 24.6, 24.6
III	55.7 (0.2)	58.7 (1.0)	25.5, 25.4, 25.5

Discussion

The propranolol/oleic acid binary phase diagram contained important information concerning physical interactions such as monotectic and eutectic systems and also chemical interactions (complex formation). The presence of an incongruent melting complex and reaction point is commonly reported in fatty acid/fatty acid salt binary mixtures.[14] In such systems "acid soap" complexes commonly form that undergo peritectic transformation at the reaction point. The peritectic transformation also marked by a reaction point, but the stable low-temperature solid phase is a solid solution.[19] The transformation temperature often corresponds to a thermotropic polymorphic change of the fatty acid salt, as was seen in the oleic acid/propranolol oleate (POA) portion of the phase diagram (Figure 3b). Solid solution formation was not identified in this system. However, the presence of multiple thermal events at many compositions obstructed accurate measurement of transition enthalpies which are required for such calculations, and so solid solution formation cannot be ruled out. The presence of incongruent melting in phase equilibria is significant because it leads to extremely slow equilibration on cooling. Such behavior is of great importance in the fields of ceramics and metallurgy, but is rarely reported in the pharmaceutical sciences with the following exceptions.[20−22] Incongruent melting complex formation in the propranolol/oleic acid system was thought to have contributed to the slow equilibration of binary mixtures in this region.

Incongruent melting can only be identified by interpretation of the phase diagram. DSC or HSM analysis of a single composition would consist of the incongruent melt followed by solid product melting, which would be interpreted as a two-phase solid sample undergoing separate melting processes. This melt is a single-step process, and so further decrease in heating rate will not alter the relative enthalpies of incongruent melt to solid product melt. However, the effect of heating rate was evident during DSC analysis of two simultaneous thermal events. A change in heating rate altered the relative magnitude of two simultaneous processes, causing marked changes in the DSC total heat flow signal (Figure 7). The latter example demonstrated the importance of complementing DSC data with HSM analysis under similar conditions.

It is emphasized that the phase diagram presented does not represent the equilibrium phase diagram for this system. In addition to the fact that phase behavior beneath −10 °C was not investigated, the impact of POA III formation was omitted. POA II was the most stable form

at room temperature, as shown by DSC analysis of 50−90% P compositions following 6 and 12 months. Therefore, the phase diagram presented was of practical relevance. XRPD indicated that POA II exhibited mesomorphic properties as seen by the presence of long range order accompanied by considerable molecular disorder over shorter distances. The fact that this phase underwent a high enthalpy melt, and that resolidification took place post-melting, strongly suggested that POA II was a conformationally disordered crystalline phase. Liquid crystalline transitions are generally of a lower enthalpy than the initial breakdown of three-dimensional order (crystalline phase) and do not revert to higher ordered structures on temperature increase.[10] XRPD data for POA III showed the absence of high intensity reflections at wide-angle, and so this phase was also classified as a conformationally disordered mesophase. XRPD data was not obtained for POA I so description of this phase is not possible. Nevertheless, SAXS enabled accurate measurement of the long-range repeating unit of all POA solid phases I, II, and III, for which small but significant differences were found.

Oral bioavailability improvement was reported following propranolol laurate administration,[23] and propranolol stearate modified drug entry into the systemic circulation following nasal administration.[24] Thus, the formation of propranolol oleate salt in the propranolol/oleic acid system is likely to have biopharmaceutical implications. In particular, oleate salt formation within the dosage form or in the gastrointestinal tract may have contributed to the increased bioavailability of a propranolol/oleic acid/polymer oral dosage form reported by Barnwell et al.[5] The encouraging effects of propranolol and fatty acid coadministration mean that such drug/lipid systems warrant further investigation, but their complicated phase behavior must be fully understood to enable optimal formulation.

Conclusion

The propranolol/oleic acid binary system phase diagram was constructed using thermal analysis, and equimolar complex and incongruent melting complex formation was demonstrated. The equimolar complex, POA, was identified as propranolol oleate using FT-IR. At room temperature, POA possessed substantial long range positional order accompanied by disorder over shorter *d* spacings as shown by XRPD. This phase (POA II) was classified as a conformationally disordered crystalline phase. SAXS allowed accurate measurement of the long-range repeating unit, leading to the identification of subtle structural changes following POA I, II, and III conversions. Formation of an oleate salt provides an interesting approach for oleic acid inclusion in solid oral dosage forms, but the propensity for complicated phase behavior must be considered. Characterization of the propranolol/oleic acid binary system has demonstrated that a thorough understanding of drug/lipid interactions is vital when formulating such materials.

Accepted for publication February 1, 1999.

Abstract □ In this study, the physicochemical properties and preliminary in vivo clinical performance of formulations containing hydroxyethylcellulose (HEC; 3, 5, 10% w/w), poly(vinylpyrrolidone) (PVP; 3, 5% w/w), polycarbophil (PC; 1, 3, 5% w/w), and flurbiprofen (5% w/w) were examined. Flurbiprofen release into PBS pH 7.4 was performed at 37 °C. The mechanical properties (hardness, compressibility, adhesiveness, initial stress) and syringeability of formulations were determined using a texture analyzer in texture profile analysis (TPA) and compression modes, respectively. In general, the time required for release of 10 and 30% of the original mass of flurbiprofen ($t_{10\%}$, $t_{30\%}$) increased as the concentration of each polymeric component increased. However, in the presence of either 5 or 10% HEC and 5% PC, increased PVP concentration decreased both $t_{10\%}$, $t_{30\%}$ due to excessive swelling (and disintegration) of these formulations. Increased concentrations of HEC, PVP, and PC significantly increased formulation hardness, compressibility, work of syringe expression, and initial stress due to the effects of these polymers on formulation viscoelasticity. Similarly, increased concentrations of PC (primarily), HEC, and PVP increased formulation adhesiveness due to the known bioadhesive properties of these polymers. Clinical efficacies of formulations containing 3% HEC, 3% PVP, 3% PC, and either 0% (control) or 5% (test) flurbiprofen, selected to offer optimal drug release and mechanical properties, were evaluated and clinically compared in an experimental gingivitis model. The test (flurbiprofen-containing) formulation significantly reduced gingival inflammation, as evaluated using the gingival index, and the gingival crevicular fluid volume, whereas, these clinical parameters were generally increased in volunteers who had received the control formulation. There were no observed differences in the plaque indices of the two subject groups, confirming that the observed differences in gingival inflammation could not be accredited to differences in plaque accummulation. This study has shown both the applicability of the in vitro methods used, particularly TPA, for the rational selection of formulations for clinical evaluation and, additionally, the clinical benefits of the topical application of a bioadhesive semisolid flurbiprofen-containing formulation for the treatment of experimental gingivitis.

Introduction

Periodontal diseases are a group of inflammatory conditions affecting the supportive structures of the teeth, the gingiva, periodontal ligament, and alveolar bone. Inflammation of the gingiva is referred to as gingivitis whereas extension of inflammation into deeper tissues is termed periodontitis.[1] The inflammation is in response to plaque bacteria residing on both the tooth surface and beneath the gingiva in periodontal pockets. Treatment of the disease, aimed at arresting the progression of the destructive process and preventing recurrence, is mainly through the mechanical cleaning of the tooth surface. However, as specific bacteria are thought to play a major role in the disease process, antimicrobial agents have also been used as adjuncts to treatment, particularly in early-onset and refractory cases.[2−4] The potential side-effects of administering systemic antibiotics, and the inability of antiseptic mouthwashes to penetrate the periodontal pocket, have fueled interest in the sustained delivery of such agents within the pocket. The attributes of, and indeed problems associated with, such drug delivery systems have been described by several authors.[5−7] One particular problem common to many drug delivery systems designed for use in the oral cavity is poor retention at the site of application.[1,8] This problem may be resolved by the incorporation of bioadhesive polymers, i.e., polymers that exhibit characteristic adhesive interactions with biological membranes, within the drug delivery system.[8,9] In so doing, several authors have reported improved retention and, hence, clinical performance of topical formulations designed for the oral cavity.[10,11]

New insights into the mechanisms underlying periodontal disease have placed greater emphasis on the role of the host response, rather than bacterial aetiology, as the primary determinant of disease progression. Inflammatory mediators, including the arachadonic acid derivative prostaglandin E_2 (PGE_2), have been associated with the condition. Levels of PGE_2 in the periodontal tissues, which are significantly increased at diseased sites, are reduced following successful treatment and may be used as predictors of further tissue destruction.[12,13] As a result of these findings, a number of studies have investigated the potential use of nonsteroidal antiinflammatory drugs (NSAIDs) as an adjunct to mechanical cleaning in the treatment of periodontal diseases. Results from both animal[14,15] and human[16−19] studies have shown the clinical benefit of flurbiprofen in the treatment of periodontal diseases. Given the potential problems associated with systemic NSAID usage, topical application of these agents may be of clinical value in the treatment of periodontal disease.

Therefore, this study describes the physicochemical properties, i.e., drug release and mechanical properties, of candidate flurbiprofen-containing, controlled-release bioadhesive semisolids, important determinants of clinical performance. In addition, a preliminary in vivo evaluation of a formulation exhibiting optimal physiochemical proper-

ties for the treatment of gingivitis, one of the periodontal diseases, is described.

Experimental Section

Materials—Flurbiprofen was a gift from Boots plc., Nottingham, England. Hydroxyethylcellulose (Natrosol HHX 250-Pharm), poly(vinylpyrrolidone) (Kollidon K90), and polycarbophil (Noveon AA-1) were donated by Aqualon LTD (Warrington, England), BASF (Ludwigshafen, Germany), and B. F. Goodrich Company, Cleveland, OH, respectively. All other chemicals were purchased from BDH Laboratory Supplies, Poole, England and were AnalaR, or equivalent, quality.

Methods—*Preparation of Flurbiprofen-Containing Formulations*—Initially, hydroxyethylcellulose (HEC; 3, 5, 10%w/w) was dissolved with stirring in the required amount of phosphate-buffered saline (PBS; pH 6.8, 0.03 M) using a mechanical stirrer. Poly(vinylpyrrolidone) (PVP; 3, 5% w/w), polycarbophil (1, 3, 5% w/w) and, finally, flurbiprofen (5.0% w/w, particle size <63 μm) were mixed thoroughly into this gel to form pharmaceutical semisolids. All formulations were stored in amber ointment jars at 4 °C until required.

In Vitro Release of Flurbiprofen—The release of flurbiprofen from the bioadhesive formulations into PBS (pH 7.2) at 37 °C was determined in triplicate using a Caleva 7ST dissolution apparatus with paddle stirrers (100 rev min^{-1}), as previously reported.[7,20] Formulations were retained within three-sided plastic molds and anchored to the bottom of the dissolution vessels, thus ensuring that drug release occurred principally from the top of the molds. Samples of the dissolution fluid were removed at predetermined intervals and their absorbances determined using ultraviolet spectroscopy at 290 nm. Flurbiprofen release was determined using a calibration curve, which was linear over the concentration range 1.0−100.0 μg mL^{-1} ($r > 0.99$, with zero intercept). The presence of formulation excipients was observed not to interfere with the analysis.

Drug release data generated from dissolution experiments were fitted to the general release equation (eq 1) using logarithmic transformations and least squares regression analysis, as previously described.[20−22]

$$\frac{M_t}{M_\infty} = kt^n \quad (1)$$

where M_t/M_∞ = the proportion of flurbiprofen released at time t, k = a constant incorporating structural and geometrical characteristics of the delivery system, and n = the release exponent, a measure of the primary mechanism of drug release.

Characterization of Bioadhesive, Flurbiprofen-Containing Semisolids Using Texture Profile Analysis—The method employed to characterize the mechanical properties of each formulation was texture profile analysis.[7,9,20] In brief, formulations were packed into identical 60 mL ointment jars to a fixed height, avoiding the introduction of air into the samples, and texture profile analysis performed using a Stable Micro Systems TA-XT2 texture analyzer (Haslemere, Surrey, UK). The analysis involved the double compression of the analytical probe (10 mm diameter) into each sample. The depth and rate of each compression were 15 mm and 2.0 mm s^{-1}, respectively, and a 15 s delay period between the end of the first and beginning of the second compression was allowed. All analyses were performed on four replicate samples. From the resultant force−time plot, several mechanical parameters may be determined, including[8] (1) product hardness (force required to attain a given deformation); (2) product adhesiveness (the work required to overcome the attractive forces between the surface of the sample and the surface of the probe with which the sample comes into contact) and compressibility (the force per unit time required to deform the product during the first compression of the probe); (3) product compressibility (the work required to deform the product during the first compression cycle of the probe); (4) initial stress (the resistance to probe compression over a defined time period, i.e., from 0.5 to 1.5 s of the initial compression.

Determination of the Work Required to Expel the Bioadhesive, Semisolid Formulations from a Syringe—The method employed to determine the work required to expel the formulations from a syringe (syringeability) has previously been reported by us.[7,20] Each formulation was packed into plastic syringes (of identical dimensions) to a preselected height (3 cm). The formulation was then expressed from the syringe using the Stable Micro Systems Texture Analyzer in compression mode and the work done determined by measuring the area under the resultant force−distance plot. Increased area under the force−distance plot is indicative of decreased ease of syringeability. All measurements were performed, at least, in quadruplicate.

Clinical Evaluation of Bioadhesive Semisolid Formulations in Experimental Gingivitis—The effects of two formulations containing 3% w/w HEC, 3% w/w PVP, 3% w/w PC and either 5% or 0% w/w (control) flurbiprofen on gingival inflammation were determined using an experimental gingivitis model, as described by Heasman et al.[17] Ethical approval for the study was obtained from the Faculty of Medicine Ethics Committee, The Queen's University of Belfast. Exclusion criteria for the study included use of, or allergy to, nonsteroidal, antiinflammatory drugs, recent antibiotic therapy, use of the contraceptive pill, pregnancy, gastric upset, smoking, inadequately attached gingiva, and crowding of the lower anterior teeth. Ten subjects were recruited, of whom nine successfully completed the study. Each subject was examined and, where required, dental prophylaxis was performed to ensure health of the gingival tissues. Each subject was provided with an individual bite guard designed to cover their lower six anterior teeth and associated attached gingiva. Subjects were instructed on normal toothbrushing techniques and asked to brush their teeth twice daily. Bite guards were worn during toothbrushing to allow plaque accumulation in the lower anterior region. During the third week of the study, subjects were given the test formulations and asked to apply 0.5 mL evenly over the attached gingiva around the lower six anterior teeth following toothbrushing at night for seven consecutive nights. Subjects continued to wear the bite guard during toothbrushing. Five subjects received the flurbiprofen-containing formulation, whereas the remainder received the control formulation, i.e., devoid of flurbiprofen. Both clinician and subject were unaware as to which formulation was administered. Clinical assessments were performed at weekly intervals over a three-week period. Plaque deposits were assessed at four surfaces (mesial, distal, labial, lingual) of each lower lateral incisor using the plaque index.[23] The level of inflammation in the gingival tissues was scored at the labial surfaces of the four lower incisor teeth using the gingival index (GI) on a ordinal scale of 0 to 3, as described by Loe and Silness.[24] The degree of inflammation was then recorded as the mean GI score for these four sites. Gingival crevicular fluid (GCF) was collected from the distal surfaces of the lower lateral incisors. Briefly, the area was isolated with cotton wool rolls and dried with a continuous air stream, and the GCF was collected onto a Periopaper strip inserted into the gingival sulcus for 30 s. The volume of GCF collected was determined using a Periotron 6000 (Louisville, KY).

Statistical Analysis of Results—The effects of HEC (3, 5, and 10% w/w), PVP (3 and 5% w/w), and PC (1 and 5% w/w) on the times required for the release of defined percentages (i.e., 10 and 30%) of the original mass of flurbiprofen from each formulation, formulation hardness, adhesiveness, compressibility, initial stress, and syringeability were evaluated statistically using a three-way Analysis of Variance (ANOVA, $p < 0.05$ denoting significance). In a subsequent analysis, the effects of increasing concentrations of PC from 1 to 3 to 5% w/w and HEC from 3 to 5 to 10% w/w on the release and mechanical properties of formulations containing 3% PVP were statistically evaluated using a two-way ANOVA.[8] Post-hoc statistical analyses of the means of individual groups were performed using Fischer's LSD test. In clinical studies, both the gingival indices, plaque indices, and gingival crevicular fluid of the two patient groups following the initial two-week study period, and the effects of flurbiprofen treatments and control treatments on gingival inflammation, gingival crevicular fluid volume, and plaque indices, were statistically compared and evaluated using a Mann−Whitney U-test. Finally, the differences in gingival inflammation, gingival crevicular fluid volume, and plaque indices of the patients over week two to three of the study period were statistically assessed using a Wilcoxon signed rank test. In all analyses, $p < 0.05$ denoted significance.

Results

Application of the generalized release equation to the flurbiprofen release data allowed calculation of the release

concn of PC (% w/w)	concn of PVP (% w/w)	concn of HEC (% w/w)	time (h) required for release of flurbiprofen (mean ± sd)	
			10%	30%
1	3	3	1.27 ± 0.05	3.19 ± 0.12
1	3	5	3.26 ± 0.11	13.51 ± 0.81
1	3	10	4.90 ± 0.21	24.57 ± 1.99
1	5	3	1.72 ± 0.09	4.73 ± 0.19
1	5	5	5.52 ± 0.25	17.10 ± 1.11
1	5	10	10.00 ± 0.56	32.33 ± 1.92
3	3	3	2.17 ± 0.17	8.73 ± 0.56
3	3	5	7.08 ± 0.61	21.21 ± 3.32
3	3	10	17.11 ± 0.99	40.96 ± 2.27
5	3	3	3.30 ± 0.22	10.99 ± 1.01
5	3	5	14.27 ± 0.91	40.45 ± 1.69
5	3	10	28.41 ± 3.01	101.11 ± 7.22
5	5	3	5.54 ± 0.21	16.52 ± 1.11
5	5	5	6.17 ± 0.51	20.17 ± 1.24
5	5	10	16.53 ± 1.34	40.51 ± 2.51

exponent (n) which, for the formulations under investigation, ranged from 0.6 to 1.0. Therefore, in light of the disparity of release rates exhibited by these formulations, statistical analyses were performed on the times required for the release of 10 and 30% ($t_{10\%}$, $t_{30\%}$, Table 1) of the original loading of flurbiprofen from each formulation, as previously reported by us.[20] A wide range of values of $t_{10\%}$ and $t_{30\%}$ were exhibited by the formulations under examination. Maximum $t_{10\%}$ and $t_{30\%}$ values were observed in the formulation containing 10% HEC, 3% PVP, and 5% PC and were 28.41 ± 3.01 and 101.11 ± 2.22 h, respectively. Conversely, minimum $t_{10\%}$ and $t_{30\%}$ values were 1.27 ± 0.05 and 3.19 ± 0.12 h, respectively, and were associated with semisolids containing 3% HEC, 3% PVP, and 1% PC. Increasing the concentration of either HEC (from 3 to 5 and from 5 to 10% w/w) or alternatively PC (from 1 to 3 and from 5 to 10% w/w) significantly increased both $t_{10\%}$ and $t_{30\%}$. Conversely, the effect of PVP on the release of flurbiprofen from the semisolid formulations under examination was dependent on the concentrations of both HEC and PC. Thus, in formulations containing either 3, 5, or 10% HEC and 1, 3, or 5% PC, increasing the concentration of PVP from 3 to 5% w/w significantly increased $t_{10\%}$, $t_{30\%}$. Conversely, increasing the concentration of PVP in the formulations containing 5 or 10% HEC and 5% PC significantly reduced $t_{10\%}$, $t_{30\%}$. These disparate effects accounted for the observed interactions in the statistical analysis of the effects of polymeric components on these release parameters.

The effects of HEC, PVP, and PC on the mechanical (textural) properties and syringeability of the formulations under examination are presented in Tables 2 and 3, respectively. Increasing concentrations of each polymeric component (HEC, PVP, and PC) significantly increased each parameter investigated. Hence, the minimum values of hardness, adhesiveness, compressibility, initial stress, and work of syringeability were exhibited by the formulation containing 3% HEC, 3% PVP, and 1% PC and were 0.52 ± 0.02 N, 2.24 ± 0.14 N mm, 2.36 ± 0.16 N mm, 0.50 ± 0.06 × 10^6 dynes cm^{-2}, and 19.58 ± 0.46 N mm, respectively. Conversely, maximum values of hardness, adhesiveness, compressibility, initial stress, and work of syringeability were 9.12 ± 0.20 N, 13.02 ± 0.48 N mm, 49.82 ± 1.12, 10.01 ± 0.61 dynes cm^{-2}, and 113.78 ± 2.82 N mm, respectively, observed in the formulation containing the highest concentration of each polymer investigated, namely 10% HEC, 5% PVP and PC 5%. Interestingly, statistical interactions were observed in the Analysis of Variance concerning the effects of these polymeric components on each mechanical parameter. In these, the effects of PVP and PC on the mechanical properties of semisolids containing 10% HEC were significantly (and disproportionately) greater than those containing either 3 or 5% HEC.

Following the initial two week period, the gingival indices of the two patient groups were 0.75 ± 0.44 and 0.81 ± 0.54. This difference in the two patient groups was insignificant. The comparative effects of seven daily (nightly) applications of two formulations, each containing 3% HEC, 3% PVP, 3% PC and either 0 or 5% flurbiprofen on the level of inflammation, as determined using the gingival index, are presented in Figure 1. As determined by the gingival index, the level of gingival inflammation increased in two of the four volunteers treated with the control formulation, but reduced in four out of five subjects treated with the test formulation containing flurbiprofen. Mean gingival crevicular fluid levels were also reduced in four out of five subjects treated with the flurbiprofen-containing formulation, but also in three out of four control subjects (Table 4). However, the mean gingival crevicular fluid volume of subjects treated with flurbiprofen-treated formulations was significantly lower when compared to that of subjects in the control group. Finally, the plaque indices did not significantly change between week two and three of the study period in either patient group (Table 4). No patients reported any side-effects following application of either formulation.

Discussion

The formulations examined in this study exhibited wide ranges of both drug release and mechanical properties that were dependent on the concentrations of each polymeric component present. In light of the relative structural complexity of these systems, it is appropriate to discuss the observed physicochemical properties in relation to the physical state of each polymeric component. In all formulations, HEC (3, 5, 10% w/w) was initially dissolved to form a primary gel into which PVP was added until the saturation solubility of this component in the primary gel was exceeded. Further additions of PVP resulted in the emergence of a two-phase semisolid system in which this polymer was present both in solution and as a suspended solid within the HEC gel. Hence, in gels containing 3% HEC, PVP (3 and 5%) was soluble, whereas in gels containing 5% and 10% HEC, PVP existed both in solution and suspension, the ratio of the mass of dissolved to suspended PVP decreasing as the concentration of HEC was increased. Following its addition, as a direct consequence of its cross-linked structure, PC did not dissolve in the formulation but exhibited swelling, the extent of which was dependent on the amount of available water present in the formulations. Thus, as the concentrations of HEC (primarily) and PVP increased, the degree of swelling of PC decreased. The range of physicochemical properties exhibited by the formulations under examination may be due to the states of PVP and PC within the primary HEC gel. Similarly, in a previous publication, the states of these polymeric components, namely dissolved/dispersed (in the cases of HEC and PVP) or swollen/unswollen (PC) were reported to directly influence the viscoelastic properties of related formulations containing chlorhexidine designed for the treatment of localized infection.[25] Thus, the effects of each polymeric component on both the release of flurbiprofen and the mechanical properties of each formulation will be considered in light of the state of each polymeric component in these formulations.

[a] Measured as the work required to express a defined amount of the formulation from a syringe of specified dimensions, as described in Materials and Methods.

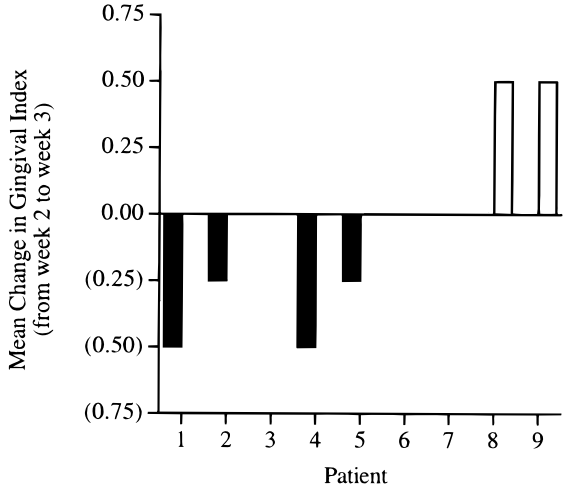

Figure 1—The effect of topical application of a test formulation (containing 5% w/w flurbiprofen, 3% w/w hydroxyethylcellulose, 3% w/w poly(vinylpyrrolidone), and 3% w/w polycarbophil) or a control formulation (containing 3% w/w hydroxyethylcellulose, 3% w/w poly(vinylpyrrolidone), and 3% w/w polycarbophil) for one week on the level of gingival inflammation (as evaluated using the gingival index) in clinical subjects. Subjects 1–5 received the test formulation whereas subjects 6–9 received the control formulation.

Increasing the concentration of HEC in aqueous gel systems has previously been reported to increase both gel elasticity (storage modulus) and, additionally, viscosity due to increased polymeric chain entanglement.[25,26] One consequence of these rheological alterations was observed in the effects of HEC on the release of flurbiprofen, in which the rate of drug diffusion through the polymer matrix and, hence, drug release was reduced. Similarly, in formulations containing 3% HEC (in which PVP was dissolved), increasing the concentration of PVP from 3 to 5% decreased flurbiprofen release due to the greater entanglement of dissolved polymeric chains. In general, the reduced release of flurbiprofen observed following increased formulation concentrations of PVP, in which this polymer was present in both the solid and solution phases in the primary HEC gel, may be due to the effects of both the increasing semisolid nature, and, hence, increased elasticity of these formulations.[25,26] A further retarding effect of PVP on drug release may be due to swelling following contact with dissolution fluid. These two mechanisms serve to enhance the elastic structure of the formulations, thereby decreasing the rate of drug diffusion through the semisolid matrix. Similarly, incorporation of PC into these formulations decreased flurbiprofen release, observations that may also be explained by the state of this polymer in each formulation. The extent of swelling of PC in the formulations under investigation was greatest in those formulations containing 3% HEC, 3% PVP, and 1% PC, as, first, the amount of free water, i.e., water not associated with the other polymeric components, was greatest in this system, and, second, the ratio of mass of free water to mass of PC was largest, thus allowing a greater percentage swelling of this polymer.

Table 4—The Effects of Application of Either a Control (devoid of flurbiprofen) or Test Formulation on the Gingival Crevicular Fluid Volume and Plaque Index of Subjects

		gingival crevicular fluid volume (periotron units)[c]		plaque index[c]

[a] Formulation contained 5% w/w flurbiprofen, 3% w/w hydroxyethylcellulose, 3% w/w poly(vinylpyrrolidone), and 3% w/w polycarbophil. [b] Formulation contained 3% w/w hydroxyethylcellulose, 3% w/w poly(vinylpyrrolidone), and 3% w/w polycarbophil. [c] All values are means. The coefficient of variation in all cases <6%. [d] Gingival crevicular fluid volume and plaque index at the end of the second week of the study. [e] Gingival crevicular fluid volume and plaque index at the end of the third week of the study.

In the swollen state, PC imparts both greater elasticity to the formulation, due to entanglement of the chains of poly(acrylic acid) with those of HEC and PVP, and also greater viscosity.[25] Thus, flurbiprofen release was further retarded. As the concentrations of HEC and PVP were increased in the formulations, the mass of free water available for swelling of PC decreased, and hence the percentage of unswollen PC particles increased. In this scenario, the greatest mass of unswollen particles of PC occurred in formulations containing 10% HEC, 5% PVP, and 5% PC. Following immersion in dissolution fluid, the unswollen particles of PC imbibed fluid and commenced swelling, the extent of which was dependent on the initial percentage of unswollen PC. This swelling process established the presence of a swelling front that opposed further ingress of dissolution fluid and hence retarded drug dissolution and diffusion. The presence of PC as dispersed, unswollen particles had a significantly greater retarding effect on drug release than when primarily present as swollen or partly swollen particles due to the influence of this extensive swelling front. In certain formulations, namely those in which the mass of unneutralized PC was greatest (i.e., HEC 5 or 10%, PVP 5%, PC 5%), the extent of swelling resulted in extension of the formulation beyond the retaining molds, leading to disintegration of the formulation. In this fashion, the surface area for drug dissolution and diffusion was significantly increased, and, as a result, the release of flurbiprofen from these formulations was greater than their counterparts containing 3% PVP. The role of formulation swelling on flurbiprofen release accounted for the statistical interactions between HEC and PC and between PVP and PC, as the concentration of HEC (primarily) and PVP directly influenced the state of PC in, and hence swelling of, the formulations. Therefore, as the mass of suspended solids within the formulations increased, there was a significant (and statistically unpredicted) effect on the release of flurbiprofen.

It is accepted that the mechanical properties of topical formulations will directly influence their clinical performance. Therefore, in the design of such systems, it is important to fully characterize these properties. Recently, we have successfully reported the use of texture profile analysis (TPA) for the mechanical characterization of a range of topical formulations, e.g., semisolids,[7,8] gels,[26] and creams,[27] and, consequently, this technique was employed for the characterization of the formulations examined in this study. In particular, TPA provides information for several relevant rheological parameters, including formulation hardness and compressibility, properties that may be related to both mouth feel and ease of removal of the formulation from the container and also ease of application of the formulation onto the proposed substrate,[8,26] initial stress, a measure of the stress required to initiate flow, and adhesiveness, a property that is related to bioadhesion.[8] Thus, both the versatility of sample consistencies that may be analyzed by TPA and the type of information provided by this technique have established its use in the development of topical formulations. In this current study, TPA has been successfully employed to characterize the range of flurbiprofen-containing formulations. Furthermore, the syringeabilities of formulations have been measured using a Texture Analyzer, as, in many cases, it is appropriate to apply formulations to remote supragingival sites/periodontal pockets using syringe systems. Once more, the wide ranges of hardness, compressibility, adhesiveness, initial stress, and work of syringeability exhibited by these formulations may be attributed to the state of the polymeric components.

Formulation hardness, compressibility, initial stress, and work of syringing are parameters that measure the resistance of the product to probe compression, and, indeed, their relationships with product viscosity have been reported previously.[8,29,30] Hence, the effects of HEC, PVP, and PC on these parameters may be directly related to their effects on product viscosity and, indeed, elasticity. Consequently, increasing the amount of dissolved HEC and PVP increased these mechanical properties due to increased elasticity and viscosity of the formulations,[25,26] resulting from the increasing entanglement of the polymeric chains. Increasing the mass of solid particles in the formulation, however, offers greater semisolid properties to the formulations and, hence, greater resistance to probe compression. Interestingly, statistical interactions were observed between HEC and PVP and between HEC and PC with respect to hardness, compressibility and work of syringeability that may again be explained by the state of each polymeric component in the formulations. In these interactions, the effects of PC and PVP on these parameters were significantly (and unexpectedly) greater in the presence of 10% HEC than either 3 and indeed 5% HEC. Thus, as the concentration of HEC increases, the mass of suspended PVP and unswollen PC increase, and thus the formulations adopted greater semisolid nature due to the increasing content of suspended solids. At lower concentrations of HEC, the effects of PVP and PC on formulation hardness, compressibility, and work to syringe may be attributed, in part, to the entanglement of the dissolved chains of HEC with PVP and also the swollen chains of PC. As the mass of solid particles increases, the relative contribution of chain entanglement to these mechanical properties decreases due to the overwhelming effects of the increasing mass of dispersed polymeric solid materials. The observed imbalance of the contribution of polymeric chain entanglement and suspended solid particles accounted for the statistical interactions.

In textural analysis, adhesiveness refers to the work required to overcome the attractive bonds between the sample and probe and is determined from the area under the force−distance curve in the tension section of the plot. However, at this point it is useful to record that the removal of the probe from the sample may involve the destruction of cohesive bonds within the sample in addition to the cleavage of bonds between the sample and probe. Interestingly, a correlation has been reported between the mucoadhesive properties of formulations and their adhesiveness,[8,26] and, consequently, quantification of adhesiveness provides a useful, rapid method by which the mucoadhesive properties of related formulations may be reliably ranked. In this current study, increasing concentrations of HEC, PVP, and PC significantly increased formulation adhesiveness. As these polymers have been described as bioadhesive,[9] these observations may be due to both their ability to form adhesive bonds (in a concentration-dependent fashion) with the probe in TPA, and to increase viscosity (tack) of the formulations, a property that has been reported to influence the adhesiveness of certain formulations.[8]

It is important to consider specifically the role of PC in the adhesiveness of the formulations under examination. PC possesses the ability to strongly interact with biological substrates, the degree of interaction being dependent on the number of unneutralized carboxylic acid groups on the poly(acrylic acid) chains.[8,9] In this study, and indeed in related earlier publications,[8,31] the contribution of unneutralized carboxylic acid groups to adhesiveness in TPA was confirmed. Hence, in formulations containing 3% HEC, 3% PVP, and 1% PC, the extent of neutralization, and hence swelling of PC, was greatest, and this formulation exhibited lowest adhesiveness. Conversely, in formulations where the amount of water available to neutralize PC is lowest, i.e.,

10% HEC, 5% PVP, and 5% PC, the mass of unneutralized (and hence unswollen) particles of PC was greatest, and hence adhesiveness is maximal. Given the correlation with mucoadhesion, this formulation would be expected to possess the greatest mucoadhesive properties of all formulations studied.[26] The statistical interactions observed between HEC and PC, PVP and HEC, and PVP and PC reflect once more the effects of the state of each polymeric component on formulation adhesiveness. Thus, the presence of solid polymeric particles may be associated with dramatic increases in adhesiveness due both to the effects on formulation viscosity (and hence tack) and additionally to the effects on the mass of free water present and, hence, the mass of unneutralized carboxylic acid groups in PC.

The ideal formulation for clinical examination for the treatment of periodontal diseases should possess a number of desirable attributes, including adequate prolonged and controlled release of therapeutic agent, ease of removal from the container, and ease of application to, and good retention at, the desired site. In addition, it should be comfortable to the patient during the residence period of the formulation. The various in vitro methods employed in this study have allowed quantification of all of these attributes. Hence, in vitro release methods defined the nature of the release of flurbiprofen from all formulations. The TPA parameters of hardness/compressibility and adhesiveness described the ease of removal from the container/ease of application to the desired site and product retention, respectively. Finally, acceptability of the product by the patient during the period of residence in the oral cavity may be conveniently described by hardness measurements in TPA, as previously reported,[28,31] whereas the syringeability of the formulations to, e.g., subgingival or remote supragingival regions, was conveniently described using a modified compression test.

Ideally, candidate formulations for clinical examination should exhibit low hardness, initial stress, compressibility, work of syringeability, yet high adhesiveness. However, as may be observed in Tables 2 and 3, increased formulation adhesiveness (and hence increased retention at the site of application) may be achieved by increasing the concentration of PC (primarily), HEC, and PVP. However, such increases also resulted in increased formulation hardness, compressibility, and work of syringing, undesirable formulation attributes. Therefore, in terms of mechanical properties, a compromise must be attained between formulation adhesiveness and formulation hardness, compressibility, and syringeability. Examples of formulations that exhibited acceptable mechanical properties included HEC 3%/PVP 3 or 5%/PC 1, 3 or 5% and HEC 5%/PVP 3%, PC 1 or 3%. Furthermore, in light of the proposed daily (nightly) administration of the formulation and based on information from related clinical studies,[14,17] the formulations containing 3% HEC, 3% PVP, and either 3 or 5% PC exhibited the required release properties, namely $t_{30\%}$ values of 8.73 $\pm$ 0.56 and 10.99 $\pm$ 1.01 h, respectively. Therefore, following consideration of both the mechanical and release properties, the formulation selected for clinical examination contained 3% HEC, 3% PVP, 3% PC, and 5% flurbiprofen. Initial clinical assessment of this formulation, using an experimental gingivitis model, indicated significantly beneficial effects in the treatment of gingivitis, as denoted by the improvement in the gingival index and the gingival crevicular fluid volume. Of further interest were the insiginificant differences in the plaque indices of the two patient groups during weeks 2 to 3 of this study period. Therefore, changes in gingival crevicular fluid volume could not be explained by differences in plaque accumulation. It is known that levels of the cyclooxygenase metabolites of arachadonic acid, PGE_2 and TxB_2, both of which are potent vasodilators, are elevated during the onset of gingival inflammation.[17] The clinical effects of flurbiprofen, an inhibitor of the cyclooxygenase pathway, observed in this study may thus be attributed to prolonged reduced levels of both mediators in the gingival tissue. Quantification of these levels is the subject of current clinical investigations.

In conclusion, a series of formulations containing HEC, PVP, PC, and flurbiprofen has been designed and characterized in vitro in terms of both flurbiprofen release and mechanical properties. The use of texture profile analysis to characterize the mechanical properties has been shown to be particularly useful as the mechanical parameters defined by this technique (e.g., hardness, compressibility, syringeability, adhesiveness) have direct relevance to both the potential clinical and sensory performance of these formulations.[8] A candidate formulation was chosen for clinical evaluation containing 3% HEC, 3% PVP, 3% PC, and 5% flurbiprofen that offered optimal flurbiprofen release over the proposed daily application of the product and, additionally, offered a compromise between formulation adhesiveness (and hence persistence at the site of application) and hardness (comfort during the period of application), and compressibility/syringeability (ease of removal from the container and ease of spreading/application to the inflamed site).

The comparative clinical efficacies of this chosen flurbiprofen-containing formulation and an otherwise identical placebo formulation (devoid of flurbiprofen) were evaluated in an experimental gingivitis model in nine volunteers, in which gingival inflammation was measured using the gingival index. Following seven nightly applications, volunteers who had received the flurbiprofen-containing formulation exhibited decreased gingival inflammation and gingival crevicular fluid volume, whereas those who had received the control formulation displayed increased gingival inflammation and gingival crevicular fluid volume. This preliminary clinical study has therefore shown the clinical improvements associated with the use of topical bioadhesive, flurbiprofen-containing semisolid formulations. The clinical efficacy of this formulation, including quantification of the concentrations of inflammatory mediators, is currently ongoing in multicentered clinical evaluations.

Abstract □ ^{1}H NMR spectroscopy was used for determining the optical purity of *cis*-ketoconazole enantiomers obtained by fractional crystallization. The chiral analysis was carried out using β-cyclodextrin in the presence of (+)-L-tartaric acid. The mechanism of the chiral discrimination process, the stability of the complexes formed, and their structure in aqueous solution were also investigated by ^{1}H and ^{13}C chemical shift analysis, two-dimensional NOE experiments, relaxation time measurements, and mass spectrometry experiments. Theoretical models of the three-component interaction were built up on the basis of the available NMR data, by performing a conformational analysis on the relevant fragments on ketoconazole and docking studies on the components of the complex. The model derived from a folded conformation of ketoconazole turned out to be fully consistent with the molecular assembly found in aqueous solution, as inferred from NOE experiments. An explanation of the different association constants for the complexes of the two enantiomers is also provided on the basis of the interaction energies.

Introduction

Ketoconazole, 1-acetyl-4-[4-[[2-(2,4−dichlorophenyl)-2-(1*H*-imidazol-1-yl-methyl)-1,3-dioxolan-4-yl]methoxy]phenyl]piperazine, is a potent, orally active broad-spectrum antifungal agent[1,2] which is marketed as a racemic mixture of the *cis*-(2*S*,4*R*) and -(2*R*,4*S*) enantiomers.

The (−)-stereoisomer is (2*S*,4*R*).[3] Both the enantiomers of ketoconazole (KC) were stereoselectively prepared,[3,4] as it has been claimed that the optically pure compounds are more effective than the racemic one for treating local and systemic fungal infections in humans.[5] One of the current active research areas in host−guest or supramolecular chemistry is chiral recognition by cyclodextrins (CDs). Both naturally occurring (α, β, and γ) and derivatized CDs are indeed extensively used in chromatography (bonded to the stationary phase or in the eluate) for the separation of enantiomers[6] and as chiral shift reagents for NMR determination of enantiomeric composition.[7,8] In this paper we report a ^{1}H NMR method for determining the optical purity of the ketoconazole enantiomers obtained by fractional crystallization. Chiral analysis was carried out using β-cyclodextrin (βCD) in the presence of (+)-L-tartaric acid (hereafter TA), as it has been found that simultaneous inclusion and salt formation yield complexes freely soluble in water. For instance, KC solubility is enhanced by several orders of magnitude, while that of βCD increases by more than 10 times.[9−13] The stability of the complexes formed and their structure in aqueous solution were investigated by NMR spectroscopy and ionspray tandem mass spectrometry.[14] In addition, a model of the KC:TA:βCD complex was built up by computational techniques, on the basis of the available NMR data, with the aim of elucidating the chiral discrimination process. Among the different conformations of KC, only those in accordance with intramolecular NOE cross-peaks were selected and submitted to docking studies. The intermolecular distances were measured and related to the intensities of NOE cross-peaks, allowing the selection of a unique interaction pattern. The energies of interaction between the components were calculated for the proposed complexes of both the enantiomers of KC.

Materials and Methods

(±)-*cis*-Ketoconazole was a kind gift from RGR Co. (Milan, Italy).

Samples of (+)-(2*R*,4*S*) (ee ≈ 98%) and (−)-(2*S*,4*R*)-ketoconazole ee ≈ 98%) were obtained from the racemate by fractional crystallization of the diastereomeric salts with (−)- and (+)-10-camphorsulfonic acid, respectively. The corresponding equimolar tartrate salts were prepared by freeze-drying their aqueous solutions. β-cyclodextrin (water content ≈ 10%) and D_2O (99.8%) were purchased from Roquette Co. (Lestrem, France) and from Merck Co. (Milan, Italy), respectively. All other reagents were of analytical grade. Solutions of 10 mM drug concentration and guest-to-host ratio at 1:1.5 were used unless otherwise specified.

NMR spectra were acquired on ACF 200 and ARX 400 spectrometers (Bruker, Karlsruhe, Germany). Chemical shifts were referred to external TSP (sodium, 3-(trimethylsilyl)propionate) at 0 ppm (accurate to ± 0.001 ppm). The phase-sensitive ROESY (Rotating-frame Overhauser Effect SpectroscopY) experiments were performed using a 3.5 kHz spin-lock field and a mixing time of 350 ms. T_1 relaxation time measurements were made using the inversion recovery method. Fifteen different τ delays varying from 0.05 to 10 s between 180° and 90° pulses were used. A regression procedure was used to fit the relaxation data to the exponential equation $M = \mathrm{Mo}(1 - 2e^{-\tau/t})$.

For the determination of the association constants k of the two enantiomers, the concentration of *rac*-ketoconazole tartrate was kept at 1 mM while that of βCD varied between 5 and 20 mM. The change in the chemical shift of the H20 proton, which splits upon βCD addition, was monitored during the titration. The data were evaluated according to the Foster−Fyfe[15] modification of the Benesi−Hildebrand equation:[16]

$$\Delta\delta_{obs}([B]_t)^{-1} = k(\Delta\delta_c - \Delta\delta_{obs})$$

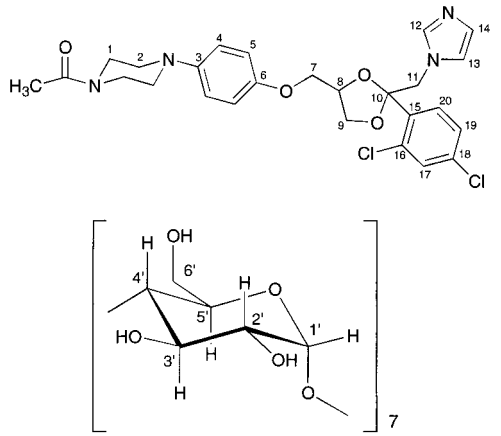

Figure 1—Hydrogen-labeling scheme for KC and βCD.

where $[B]_t$ is the total concentration of host, $\Delta\delta_{obs}$ is the difference between the chemical shift observed and the chemical shift of the free guest for a given proton, and $\Delta\delta c$ is the chemical shift difference (for a given proton) between the free guest and the pure complex.

The statistical analysis was performed by using SAS program version 3.1 (SAS Institute Inc., Cary, NC).

The mass spectra were acquired on a benchtop API 300 triple quadrupole mass spectrometer (Perkin-Elmer, Norwalk, CT), equipped with a standard API−Ionspray ionization source. Tandem MS experiments were carried out operating with a collision energy (E_{lab}) of 30 eV, using nitrogen as collision gas at a pressure of 8 mTorr. The 1:1:1 (+)-KC:TA:βCD and (−)-KC:TA:βCD samples were dissolved in 50/50 (v/v) water/acetonitrile and diluted to a concentration of 1000 ppm. The tandem MS analysis was repeated six times for each sample.

Molecular modeling studies were performed with the Sybyl 6.3 Software (Tripos Inc., 1699 South Hanley Rd., St. Louis, MO, 63144), running on a Silicon Graphics R4400 (200 MHz 64 Mb RAM) Indigo2 workstation. Three-dimensional models of (+)-TA and *cis*-KC were built and energy-minimized using the standard Tripos force field, with the Powell minimization method[17] and a convergence gradient of 0.05 kcal/mol·Å. The minimum-energy geometry of *cis*-(2*R*,4*S*)-KC was in good agreement with the crystal structure reported in Cambridge Structural Database (CSD) (ref code: KCONAZ),[18] with the exception of the torsion angle between the benzene and the piperazine rings; in fact, they lie on the same plane in the crystal structure and are perpendicular in the minimum-energy conformation obtained with Tripos force field. βCD structure was taken from CSD (ref code: BCDEXD10),[19] deleting the cocrystallized water molecules, and its geometry was kept fixed. Charges were calculated using the Gasteiger−Hückel method, giving an initial formal charge of +1 to the N^3 atom of the imidazole ring of KC and of −0.5 to the two O atoms of one of the carboxylic groups of TA, to simulate the same conditions of ionization as supplied in NMR studies (pH = 3.5); the dielectric function was dependent on 1/*r*.

A systematic conformational analysis on KC, with rotation of bonds C10−C11, C8−C7, C7−O with steps of 120°, and of O−C6 (Figure 1) with two steps of 90° (that is, with C7−O coplanar and perpendicular to the phenoxy ring), was performed in order to generate the possible KC conformations and was followed by energy minimization (with electrostatic term ignored). The orientations of the imidazole and the dichlorophenyl rings were not changed, nor were all possible conformations of the dioxolane and acetylpiperazine rings created (see Results and Discussion for a comment). Only those conformations having H−H distances lower than 3.5 Å for couples of protons giving high-intensity NOE cross-peaks were selected for subsequent docking studies.

Docking was performed with the DOCK routine of Sybyl, in a region of space including the three components of the complex, with a 0.5 Å grid resolution. Docking between KC (considered as the ligand in the docking routine) and βCD (considered as the site) was based on steric interaction energy only; the electrostatic contribution was considered for the subsequent docking of TA (ligand) onto the KC:βCD complex (site); during the docking procedure, the geometry of the site was kept fixed. Inter- and intramolecular distances were measured after energy minimization of the whole complex, with fixed geometry of the βCD ring (considered as an aggregate in Sybyl); for equivalent hydrogens, the minimum distance was chosen. βCD was eventually rotated around the axis connecting C15 and C18 of KC with steps of 30°, and the 12 resulting models were energy-minimized as reported.

MOLCAD[20] was used for the representation of the lipophilicity potential at the solvent accessible surface of KC and βCD.

Results and Discussion

NMR Studies—The formula of ketoconazole in Figure 1 shows the numbering system employed, which is different from the IUPAC notation. The spectral features of its tartrate salt in the absence and in the presence of βCD in 1.5 molar ratio are given in Table 1 and Table 2. An excess of the host was used in order to improve the separation between the pair of signals of the two enantiomers of the drug.

The difference between the enantiomers in the bound state and the free state ($\Delta\delta$) and the difference between the two bound states ($|\Delta\Delta\delta|$) are given in frequency units (Hz) rather than ppm, as, in this way, small changes can be better appreciated. In the ^{1}H NMR spectrum of (±)-*cis*-ketoconazole tartrate, on addition of βCD, two sets of resonances are observed for most of the protons or groups of equivalent protons, indicating that inclusion complex formation with βCD induces nonequivalence in the proton nuclei of the two enantiomers of the drug. As far as βCD is concerned, the ^{1}H resonances of the inner protons H3′ and H5′ show the diagnostic upfield shift due to the inclusion of the aromatic ring of the guest in the cavity.[21] Among the aromatic resonances, the largest shifts in δ were observed for the protons belonging to the imidazolium moiety, which also show splitting upon inclusion. The protons belonging to the dichlorophenyl moiety, which is the part of the molecule involved in the inclusion complex formation (vide ultra), experience smaller downfield shifts[22] and only the proton H20 shows splitting of the signal as well ($|\Delta\Delta\delta| = 8.8$ Hz). The upfield shift of the alkyl- and H4 aromatic protons may be due to conformational changes produced by the inclusion. Similar changes in the ^{13}C NMR spectra were also observed. Doubling of some of the aromatic resonances was observed, while only the C9 and C7 aliphatic carbons split. Analysis of the complexation-induced ^{13}C chemical shift changes allows some preliminary considerations on the geometry. According to Inoue,[23] the inclusion of the guest molecule into the CD cavity causes upfield shifts of the signals of the included carbons and downfield displacements of the signals of the carbons externally close to the rims of the truncated cone of CD. The changes observed for the carbons of the dichlorophenyl moiety may suggest that the insertion occurs from the wider rim of the cavity in such a way as to leave the carbons C15 and C18 exposed to the aqueous medium. The downfield shift of the carbon C16 is probably a consequence of the steric interaction[24] between the chlorine atom and the closely spaced hydrogens.

The coupling constants of the single enantiomers of KC were measured to check whether conformational changes were induced upon complexation. Since all values show no difference (Table 1) between the enantiomers, it seems to be the different orientation inside the cavity and/or outer-sphere interaction (intermolecular hydrogen bonds), rather than a different conformation of the enantiomers upon inclusion, that makes chiral discrimination possible. The more evident changes in differential chemical shifts for the signals of the imidazolium moiety in comparison to the signals of the dichlorophenyl moiety directly involved in the inclusion complex formation may indicate that the

strength of the "outer-sphere" interactions between the nitrogen atoms and the secondary hydroxyl groups probably plays the main role in the chiral discrimination process. For most of the signals, both the shielding and deshielding are more pronounced for the (–)-KC:TA:βCD complex than for the (+)-KC:TA:βCD complex, suggesting a stronger intermolecular interaction for the former enantiomer.

The H14 signal has the greatest potential for optical purity determination. It occurs as a pair of well-resolved narrow triplets (J = 1.6 Hz) of 12 Hz separation at 400 MHz, allowing the most accurate integration of each signal. Larger splitting in substrate resonance can be observed (e.g., H8 gives rise to a pair of well-resolved multiplet – $|\Delta\Delta\delta|$ = 27 Hz), but no attempts were made to determine the optical purity from these changes. By monitoring the H14 signal at 400 MHz, the resolved (–)-enantiomer turned out to contain about 2% of isomeric impurity (see Figure 2). The results we obtained would suggest that 1% optical purity measurements could be attainable by this method.

To further explore differences in these weakly bound diastereomeric complexes, T_1 measurements were made on free (±)-*cis*-ketoconazole tartrate and its βCD complex. The results are presented in Table 3. Only the protons for which it was possible to determine the T_1 values with sufficient accuracy (no overlapping with other signals) are reported. In general, the T_1 values for KC protons reduce in the presence of βCD in accordance with the fact that the correlation time of the guest increases upon complex formation. In particular, a dramatic reduction was observed for proton H17, which relaxes very slowly as it lacks nearby protons. Among the resonances which split, T_1 reduces more for protons H14 and H13 of the (–)-enantiomer; this difference in reduction may once again be attributed to a tighter binding of this enantiomer.

In the case of proton H20, both (–)- and (+)-form display equal reduction in T_1, confirming that the orientation of the dichlorophenyl ring inside the cavity is probably very similar for the two enantiomers. T_1 of the tartrate protons also reduces dramatically, suggesting that the counterion is strictly involved in the molecular assembly. Since complexes stability is important in determining chiral discrimination, a correlation was sought with the findings reported above, i.e., larger differences in shift and in T_1 reduction for the (–)-enantiomer. The two enantiomers of (±)-ketoconazole form 1:1 inclusion complexes as they possess only one binding site, i.e., the dichlorophenyl ring. The consistency of the stoichiometric model with the solubility diagram has also been reported in the litera-

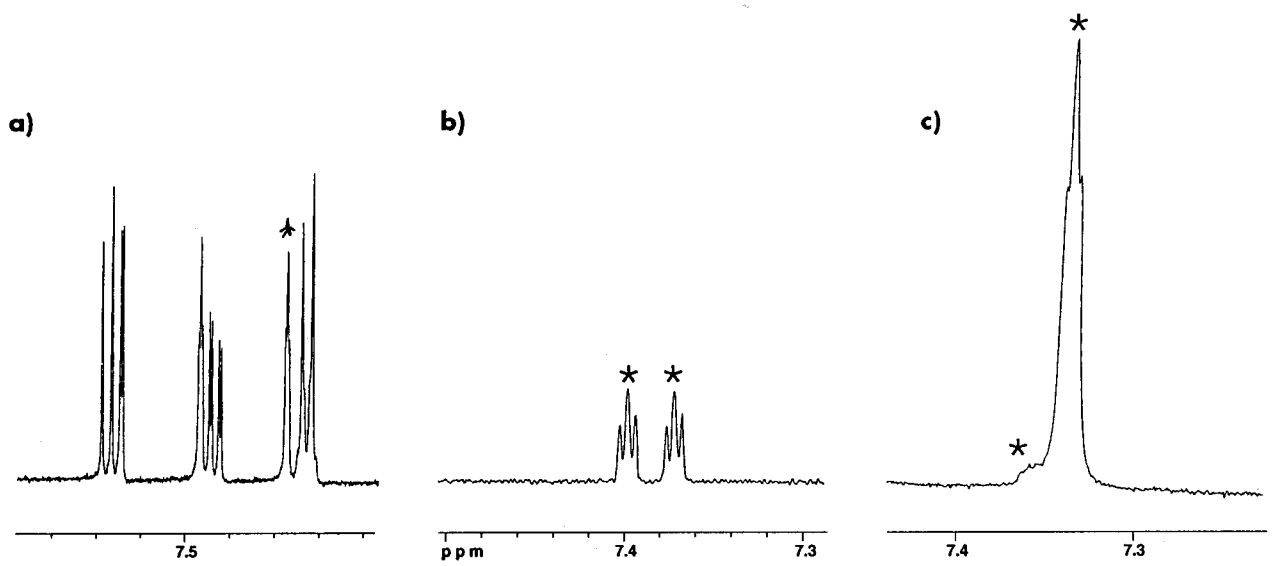

Figure 2—400 MHz H14 signal (*) of (a) (±)-KC:TA 1:1; (b) (±)-KC:TA:βCD 1:1:1.5; (c) (–)-KC:TA:βCD (ee = 98%).

ture.[12] Therefore, the association constants for the two complexes were evaluated by using the Foster–Fyfe equation (see Materials and Methods). The k at 25 °C, obtained from the slope of the straight lines, resulted as being 750 ± 100 M^{-1} for the (+)-enantiomer and 1146 ± 419 M^{-1} for the (–)-enantiomer (Figure 3). The test for heterogeneity of the slopes was positive, indicating that the difference in the complexes stability is statistically significant.

Finally, the stereochemistry of the two complexes was investigated by means of two-dimensional rotating frame NOE (ROESY) spectroscopy. An expansion of the spectrum of the complex of the (–)-enantiomer is reported in Figure 4. Both the enantiomers gave the same NOE pattern. A set of cross-peaks is observed between the inner protons H3′ and H5′ of βCD and the protons H17, H19, and H20, indicating that the inclusion occurs by accommodation of the dichlorophenyl ring. In addition, significant dipolar contacts are observed between H12, H13 (imidazolium), H4, and H5 (phenolic ring) with the H3′ proton of βCD, suggesting that the inclusion must occur from the wider-diameter side of the truncated cone of βCD. The H4 and H5 protons probably interact with H2′ of βCD as well, reflecting the major mobility of the phenolic ring around the "mouth" of the host. Anyway, an unambiguous interpretation is not possible as the signals H2′ and H5′ of βCD and H9 of KC are overlapped (vide ultra).

Mass Studies—Since some authors have recently drawn attention to the use of mass spectrometry for studying chiral selectivity in the inclusion complex formation,[25,26] the relative strength of the interaction binding of the two enantiomers was investigated by ionspray tandem mass spectrometry (ISMS/MS) experiments.[27] The positive ISMS spectra of the samples (Figure 5) exhibit the protonated 1:1:1 KC:TA:βCD (m/z 1815.5), which, upon collision, dissociate, yielding protonated KC:βCD complex (m/z 1665.6) and protonated KC (m/z 531.2). The ratio between the ion current of the two product ions is significantly higher for the (–)-enantiomer, suggesting that it forms a more stable inclusion complex than the other one in the gaseous phase. These findings are in agreement with the data obtained in aqueous solution (vide supra).

Molecular Modeling Calculations—Molecular modeling proved to be an excellent tool for the study of drug–cyclodextrin interaction.[28] The three components of the title complex, namely βCD, KC, and TA, can assume, in aqueous solution, a number of interconverting conformations and can perform different mutual interactions. For βCD alone, for example, the round-shaped conformation is not a minimum energy one, but can be regarded as the result of a time average in the ns-scale.[29] Given the high number of possible βCD conformations and the absence of a correction for the anomeric effect[29] in the Tripos force field here employed, the internal energy for the βCD molecule was not minimized, and its geometry was kept fixed in one of the crystal conformations reported in CSD.[19]

Although KC is a rather flexible compound, the complexation with βCD should select some of the allowed conformations which, in turn, could be identified by the analysis of the intramolecular NOEs (see Figure 4). Pos-

sible conformations were thus chosen on the basis of the cross-peaks between the signals H20−H8, H20−H7, and H5−H9′ (the NMR signal marked as H9′ was assigned to the proton trans to H8). An intramolecular cross-peak between H9 (the dioxolane hydrogen opposite to the side chain) and H5 is also recognizable although it is partly overlapped with the intermolecular cross-peak between H5 and H2′ and/or H5′ of βCD; therefore, the relevant averaged distance was included in the conformation selection criteria. The minimum-energy conformations of KC were generated by rotation of the bonds, causing a variation in the mutual disposition of the fragments showing NOE interactions with βCD, i.e., the dichlorophenyl, the imidazole, and the side-chain phenyl rings. Some preliminary considerations allowed a reduction in the number of conformations to be generated. The dichlorophenyl ring has two possible orientations, with the plane of the ring perpendicular to the C10−C11 bond; the presence of a cross-peak between H20−H8 and H20−H7, but not between H20−H9′, prompted us to consider only the rotamers having H20 pointing toward H8. The imidazole ring is quite free to rotate around C11−N; we kept it in one of the possible orientations because its rotation caused slight variations

in the spatial arrangement of the complex, compared to the uncertainty of the model. This means that each generated rotamer is representative of a family of conformations attainable from imidazole rotation. The same applies to the acetylpiperazine moiety, which gave no recognizable NOE interaction with βCD, and whose conformations were not explored. Rotation of the other four single bonds (see Materials and Methods) gave a set of 54 conformations, which were energy-minimized before the calculation of H5−H9 and H5−H9′ distances. Only six conformers, described in Table 4, had these two distances lower than 3.5 Å, and were submitted to docking studies.

While the intramolecular distances between hydrogen atoms of the isolated KC molecule are the same for the corresponding conformers of the two enantiomers (with

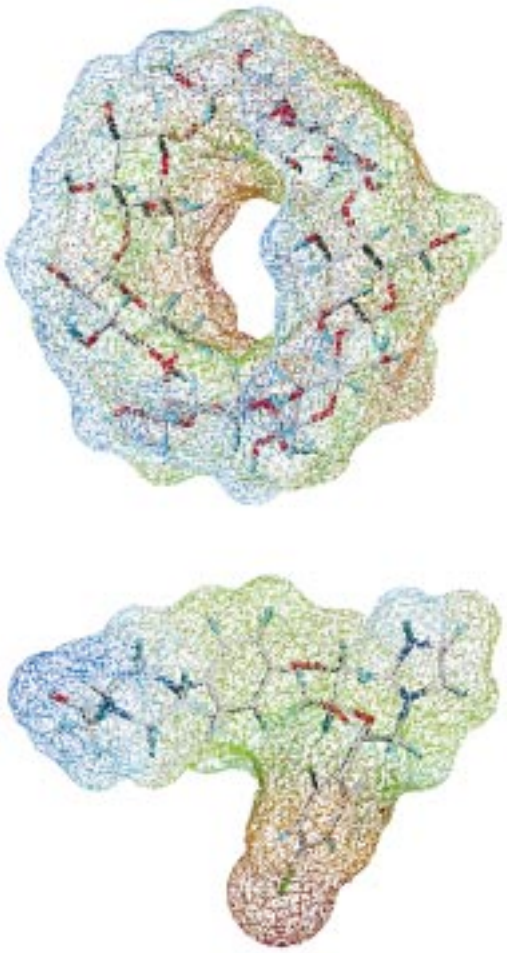

Figure 6—Lipophilicity potential contour maps of βCD, in the crystal structure conformation, and KC in conformation **3** (Table 4), colored according to a lipophilicity scale, ranging from blue (hydrophilic) to brown (lipophilic). opposite torsional angles), the complexation with the chiral βCD molecule leads to different interactions for the (+)- and (−)-KC. The docking procedure described as follows was therefore performed on both the KC enantiomers. The analysis of NMR data, in particular NOEs, gives evidence that complexation occurs by involving the dichlorophenyl ring, which is inserted in the βCD cavity from the wider rim (vide supra). This is also supported by the lipophilicity potential of the host and guest molecules at their solvent accessible surface, which is maximum in correspondence to the dichlorophenyl ring and βCD cavity (Figure 6).

Only three (**1**, **2**, and **3**) of the six selected conformations of KC could be docked into the βCD, as the spatial disposition of the side chain, having the phenoxy ring stacked beneath the dichlorophenyl one, prevented the arrangement of βCD around the dichlorophenyl moiety for the other three conformations. The chosen conformations differed from each other only by the imidazolylmethyl group orientation around C10−C11 (Table 4). As a first step, KC was docked into the βCD cavity on the basis of the van der Waals contribution of intermolecular interactions; monoanionic tartrate was then docked onto the KC:βCD complex with the charged carboxylate group involved in a saline bond with the protonated imidazolium ring, and with the uncharged carboxylic group, in gauche conformation, pointing toward the βCD secondary hydroxyl groups, as suggested by the dramatic relaxation time variation of tartrate C−H signal. The multicomponent complexes thus obtained were energy minimized, always keeping the geometry of βCD fixed as it was in the crystal structure.

Table 5—Intra- and Intermolecular Distances (Å) for the Proposed Complexes of the Two Enantiomers of *cis*-KC with βCD and TA, Represented in Figure 7, and Mean Values for the 12 Models Obtained after Rotation of the βCD around the Dichlorophenyl Ring, with Steps of 30°

[a] The lower distance between H12–H3βCD and H13–H3βCD is reported, since the imidazole ring was not rotated (see Results and Discussion). [b] The H2′βCD and H5′βCD ^{1}H NMR signals were overlapped, and a unique assignment of NOE cross-peaks was impossible; the lower distances are reported. [c] With H2′βCD. [d] With H5′βCD.

Intermolecular distances were calculated in order to select those complexes which were consistent with the NOE cross-peaks observed. The cross-peaks were thus grouped on the basis of their intensity, each group corresponding to a different distance range: H17−H3′βCD and H17−H5′βCD were considered strong (protons closer than 2.5 Å) intensity peaks; H20−H3′βCD, H20−H5′βCD, H19−H5′βCD were considered medium (closer than 3.5 Å) intensity peaks; H19−H3′βCD, H4−H3′βCD, H4−H2′/H5′βCD, H5−H3′βCD, H12−H3′βCD, H13−H3′βCD were considered weak (closer than 5 Å) intensity peaks.[30] The intensity of H5−H2′/H5′βCD cross-peak cannot be assigned unambiguously, being overlapped with the H5−H9 intramolecular peak; therefore, distances lower than 5 Å were considered acceptable (vide supra).

Analysis of the intermolecular distances gave similar results for the two KC enantiomers, allowing the selection of a multicomponent complex, corresponding to KC conformer **3** in Table 4, which was in full agreement with NOE data; the intra- and intermolecular distances of the best multicomponent complex are reported in Table 5. The most significant difference between this complex and the other two, built up from conformer **1** and **2** of KC, concerns H20−H5′βCD distance: for the (−)-enantiomer this was 3.1 Å in the complex of conformer **3**, and 4.4 and 4.6 Å in the other two, while for the (+)-enantiomer it was 3.0, 4.4, and 5.7 Å respectively. These differences reflect the lower degree of inclusion of the dichlorophenyl ring into the βCD cavity in the two discarded models; in fact, the inclusion is partially forbidden by the position of the imidazole ring which "bumps" against the rim of βCD.

The βCD structure used for the docking studies is not symmetrical; to better explore the possible mutual orientations of the components of the complex, βCD was rotated, with 12 steps of 30° around the dichlorophenyl ring, keeping the ketoconazole tartrate fixed. Analysis of the intermolecular distances, after energy minimization, showed

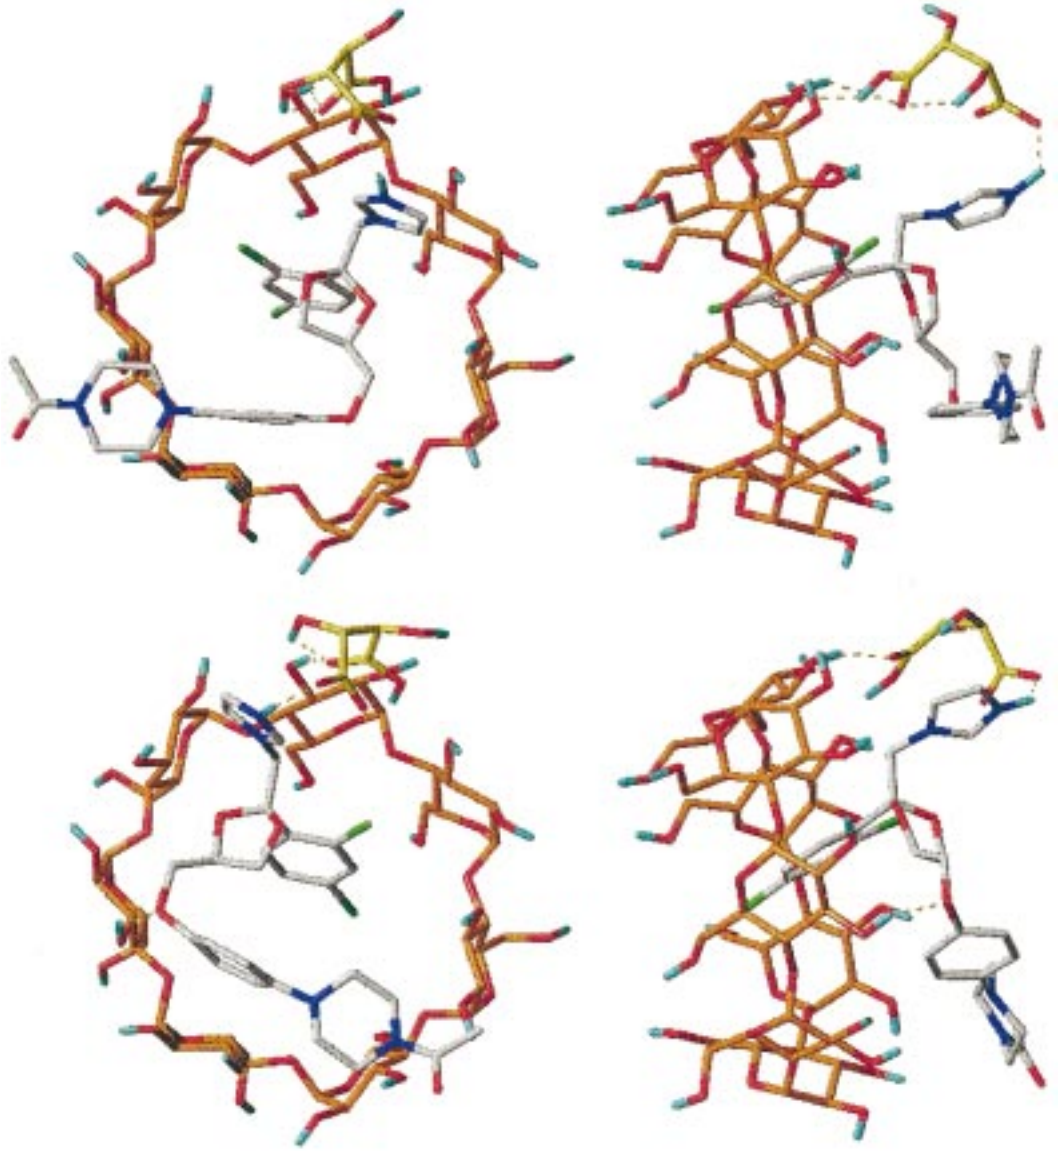

Figure 7—Representation of the multicomponent complex models for (+)- and (–)-KC (top and bottom, respectively) from the wider rim of βCD (left) and rotated by 90° on the *Y* axis (right); only polar hydrogens are displayed. Hydrogen bonds are indicated by dashed lines. Atom color codes – white: KC carbon; orange: βCD carbon; yellow: TA carbon; red: oxygen; blue: nitrogen; cyan: hydrogen; green: chlorine.

minor differences in some interatomic distances, compared to the starting geometry, but the mean values were still in agreement with the NOE cross-peak intensities, as reported in Table 5.

It has been stated that one of the major driving forces of drug−βCD complexation is a hydrophobic interaction between the guest molecule and the internal cavity of βCD.[31] Furthermore, the net entropy contribution was negligible in some cases,[28] but this fact could be attributed to the sum of entropy-favorable hydrophobic interaction and entropy loss due to conformational restriction. Under the hypothesis of similar entropy contribution for the two KC enantiomers, the interaction energy between the components, which is a rough estimate of the enthalpy contribution, can be regarded as an indication of different expected association constants. The interaction energy was therefore calculated for the multicomponent complexes of both the enantiomers of the selected KC conformation, to assess whether the higher association constant of the (−)-(2*S*,4*R*)-KC could be explained on the basis of tighter interactions. The energy values for the starting geometry of each complex, and the mean values calculated from the 12 models obtained after βCD rotation, are reported in

[a] El. = electrostatic energy; St. = steric energy.

Table 6. Comparison between the two enantiomers in terms of interaction energies can only be considered on a qualitative basis, being related only to the complementarity of the van der Waals surfaces (steric) and to the attractive and repulsive interactions between the assigned partial charges

(electrostatic). While significant differences in the interaction energies were observed for the starting geometry of the two complexes, they were much less pronounced, considering the mean values calculated for the 12 rotated models. However, the complex of the (−)-enantiomer was still characterized by a higher mean total interaction energy, although the small difference was comparable to the SEM of the data. This difference of about 1 kcal/mol, consistent with the small difference of association constant, was mainly due to the steric interaction between βCD and KC, but also to the electrostatic interaction of βCD with KC and TA, while the total (steric and electrostatic) interaction energy between KC and TA was approximately constant.

The starting geometry of the complexes formed by the two KC enantiomers are represented in Figure 7. As can be observed, besides the insertion of the dichlorophenyl ring into the internal βCD cavity, two additional interaction points are represented by the tartrate, bridging KC and βCD, and by the phenoxy fragment, located near the wider rim of βCD. Therefore, enantioselectivity results from the inclusion of an aromatic ring into the βCD cavity, the strong electrostatic interaction between the imidazolium tartrate moiety and βCD hydroxyl groups, and the accessory interaction of the phenoxy fragment with the wider rim of βCD, in agreement with the rule suggested by Armstrong.[31]

The real situation should be represented by an ensemble of different interconverting relative dispositions of the components of the complex; however, the reported model can be considered highly representative, as βCD seems to select some of the possible conformations of KC, as indicated by the H5−H9 and H5−H9′ intramolecular NOE cross-peaks. The different states of the complex include (i) the unexplored conformations of KC; in particular, those resulting from the rotation of the imidazole ring around C11−N bond could be related to enantioselectivity, as suggested by the different relaxation time variations of the imidazole protons for the two KC enantiomers; (ii) different orientations of the tartrate molecule with similar energy content, corresponding to each imidazole rotation; this multiplicity makes the arrangement of the imidazolium tartrate bridging region less defined, and, as a consequence, we considered H12 and H13 as equivalent in the calculation of the intermolecular distances; (iii) different possible relative orientations of KC and βCD, which we partially explored by rotation of the βCD; inclusion of other fragments into the βCD cavity could also occur at high CD concentrations, but the calculated lipophilicity profiles and the NMR data indicate that complex formation preferably occurs by inclusion of the dichlorophenyl moiety.

The Tripos force field put the piperazine ring of KC perpendicular to the benzene ring, while in the crystal structure they lie roughly on the same plane. Moreover, 24 different compounds containing a piperazinylphenyl substructure reported in CSD have the two rings almost in the same plane. The coplanar disposition of the two rings in our multicomponent complex could also be suggested by the presence of the very intensive H4−H2 NOE cross-peak; in fact, the distance between the two hydrogens is significantly lower in the coplanar disposition than in the perpendicular one. While our studies were conducted with the geometry resulting from energy minimization by the force field, repeated runs performed imposing the crystal geometry to the non-H atoms of the piperazinylphenyl fragment gave similar results in terms of intermolecular distances and chiral recognition.

Conclusions

An interaction model for both enantiomers of *cis*-KC with βCD in the presence of (+)-L-tartaric acid was built on the basis of preliminary ^{1}H NMR and ^{13}C NMR data. The measured intra- and intermolecular distances are in qualitative agreement with 2D NOE cross-peak intensities. This model, which probably represents the predominant solution structure, indicates that the inclusion of the dichlorophenyl moiety into the βCD cavity occurs from its wider-diameter side. Tartaric acid is strictly involved in the recognition process by establishing electrostatic interaction with the imidazolium ring and hydrogen bonds with 2- and/or 3-hydroxyl groups of βCD. A third interaction site is represented by the phenoxy fragment, involved in van der Waals and electrostatic interaction with the wider rim of βCD, with the possibility of hydrogen bond formation. These sites allow the definition of a chiral interaction; in fact, the association constants for the two KC enantiomers are slightly different, the (−)-one giving rise to the stronger interaction, in agreement with the calculated interaction energies for our models. The results are also consistent with patterns of chiral interactions proposed in the literature,[31,32] where the interactions with the 2- and 3- hydroxyl groups at the wider rim of CD appear to be the key element for the chiral recognition process.

Abstract □ Sorbitan monostearate, a hydrophobic nonionic surfactant, gels a number of organic solvents such as hexadecane, isopropyl myristate, and a range of vegetable oils. Gelation is achieved by dissolving/dispersing the organogelator in hot solvent to produce an organic solution/dispersion, which, on cooling sets to the gel state. Cooling the solution/dispersion causes a decrease in the solvent–gelator affinities, such that at the gelation temperature, the surfactant molecules self-assemble into toroidal inverse vesicles. Further cooling results in the conversion of the toroids into rod-shaped tubules. Once formed, the tubules associate with others, and a three-dimensional network is formed which immobilizes the solvent. An organogel is thus formed. Sorbitan monostearate gels are opaque, thermoreversible semisolids, and they are stable at room temperature for weeks. The gels are affected by the presence of additives such as the hydrophilic surfactant, polysorbate 20, which improves gel stability and alters the gel microstructure from a network of individual tubules to star-shaped "clusters" of tubules in the liquid continuous phase. Another solid monoester in the sorbitan ester family, sorbitan monopalmitate, also gels organic solvents to give opaque, thermoreversible semisolids. Like sorbitan monostearate gels, the microstructure of the palmitate gels comprise an interconnected network of rodlike tubules. Unlike the stearate gels, however, the addition of small amounts of a polysorbate monoester causes a large increase in tubular length instead of the "clustering effect" seen in stearate gels. The sorbitan stearate and palmitate organogels may have potential applications as delivery vehicles for drugs and antigens.

Introduction

Gels are an intermediate state of matter, containing both solid and liquid components. The solid component comprises a three-dimensional network of interconnected molecules or aggregates which immobilizes the liquid continuous phase. Hydrogels have an aqueous continuous phase, and organogels have an organic solvent as the liquid continuous medium. Gels may also be classified based on the nature of the bonds involved in the three-dimensional solid network—chemical gels arise when strong covalent bonds hold the network together, and physical gels when hydrogen bonds and electrostatic and van der Waals interactions maintain the gel network.[1]

Interest in the physical organogel field has increased, with the discovery and synthesis of a number of substances able to gel organic solvents. Examples of such organogelators) include 12-*d*-hydroxyoctadecanoic acid (12-HOA),[2] D-homosteroidal nitroxide (SNO),[3] calixarenes,[4] 1,3:2,4-di-*O*-benzylidene-D-sorbitol (D-DBS),[5] ALS compounds (an Aromatic moiety attached by a Linker segment to a Steroidal group),[6] lecithin,[7] bis(2-ethylhexyl) sodium sulfosuccinate (AOT),[8] gelatin,[9] 2,3-bis-*n*-decyloxyanthracene (DDOA),[10] and some azobenzene cholesterol derivatives.[11] These organogels exhibit interesting properties such as acute temperature/moisture sensitivities,[12,8] the ability to solubilize guest molecules[12] and to act as templates[13] and nonaqueous media for synthesis,[14–19] uses for purification and separation purposes,[20] as transdermal delivery vehicles,[21] and as carriers for liquid crystals.[22] Some of these potential applications are discussed in a review by Hinze et al.[12]

We have previously reported the gelation of certain organic solvents, e.g. *n*-alkanes, cyclohexane, vegetable oils, isopropyl myristate by the nonionic surfactant, sorbitan monostearate (Span 60).[23–25] Gelation is achieved by dissolving/dispersing the gelator in the solvent at 60 °C and then cooling the resulting solution/suspension, which conseqently gels as thermoreversible organic systems that are opaque and semisolid with a smooth, silky "feel". Microscopical examination reveals a network of tubular aggregates in the liquid disperse phase. Since these aggregates were large enough to be visualized by a light microscope, we followed their formation and the establishment of a gel network as a hot suspension was cooled to the gel state, using hot-stage light microscopy. X-ray diffraction measurements have provided further information on the microstructure of the gels, and we report here the possible arrangement of the gelator molecules in the gel network. Other members of the sorbitan ester family were also studied as were the effects of additives with the aim of finding the structural features responsible for gelation.

Materials and Methods

Sorbitan monostearate was purchased from Sigma (UK) and used as received. Like most sorbitan esters, sorbitan monostearate is a mixture of sorbitan esters, with the stearate and palmitate esters predominating. Other sorbitan esters (sorbitan monolaurate, sorbitan monopalmitate, sorbitan monooleate, and sorbitan tristearate) were also purchased from Sigma (UK). Like sorbitan monostearate, these sorbitan esters are mixtures, their fatty acid compositions being as follows: sorbitan monolaurate, lauric acid ~50%, and the balance primarily myristic, palmitic, and linolenic acids; sorbitan monopalmitate, palmitic acid ~90%, and the balance primarily stearic acid; sorbitan monooleate, oleic acid ~75%, and the balance primarily linoleic, linolenic, and palmitic acids; sorbitan tristearate, stearic acid ~50%, and the balance palmitic acid. The polysorbates (polysorbates 20, 40, 60, 65, 80, and 85) were purchased from Fluka (UK). The organic solvents were all of analytical grade. Hexadecane, *cis*-decalin, *trans*-decalin, isopropyl myristate, ethyl oleate, ethyl formate, squalene, and the vegetable oils (cottonseed oil, soybean oil, sesame oil, corn oil, and olive oil) were bought from Fluka (UK); hexane and cyclohexane were purchased from Rathburn (UK); octane, isooctane, decane, dodecane, tetradecane, and octadecane were obtained from Sigma (UK); benzene and toluene were from BDH (UK). All the reagents were used as received, except for hexadecane, isopropyl myristate, and the vegetable oils, which were dried in a vacuum oven

(Gallenkamp, UK) at room-temperature overnight to ensure the absence of any moisture which might affect gelation.

Gel Preparation—Sorbitan monostearate (10% w/v) was dispersed/dissolved in the organic solvent at 60 °C. The resulting dispersion/solution was then allowed to cool by standing at room temperature. An opaque, semisolid gel was obtained. To obtain gels containing polysorbate additives, sorbitan monostearate (10% w/v) and the polysorbate (2% w/v) were weighed into a vial, and the organic solvent was added. The mixture was heated in a water-bath at 60 °C and then allowed to cool and set to a gel at room temperature.

Light Microscopy—A light microscope (Nikon Microphot-FXA, Japan) was used, with attached camera (Nikon FX-35DX, Japan) or a high-speed camera (Microscope Service & Sales, UK) and a hot-stage (Linkam TC93, UK). A video recorder was also used to record the events in selected experiments.

Differential Scanning Calorimetry (DSC)—A Perkin-Elmer DSC7 (UK) differential scanning calorimeter was used to determine gelation temperatures. Samples were weighed into aluminum pans using a Perkin-Elmer AD-4 autobalance and the pans then sealed nonhermetically. The samples were heated at a rate of 10 °C/min from 20 °C to 70 °C. The melting point was taken as the temperature corresponding to the melting endotherm. The equipment was calibrated using indium, and low temperatures were maintained using liquid nitrogen.

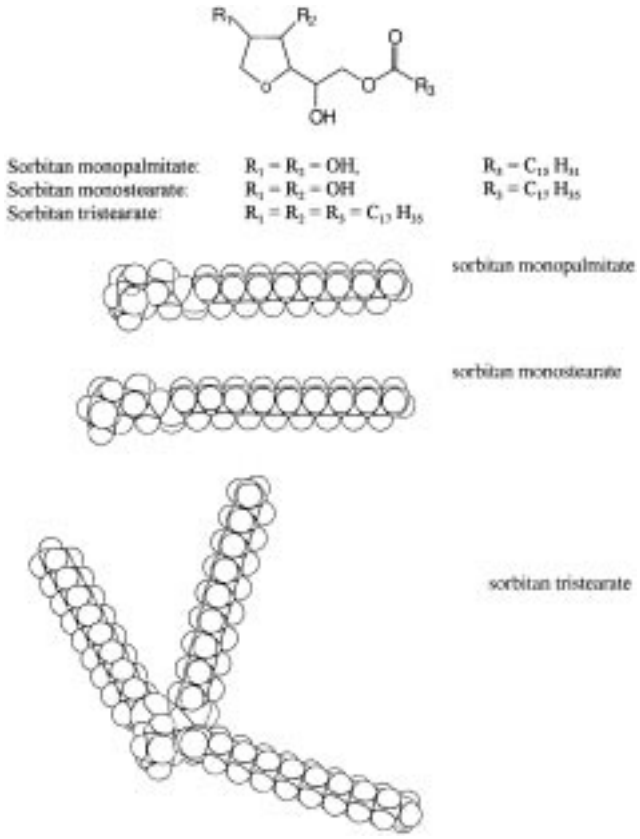
X-ray Diffraction Studies—X-ray data on the gel sample was collected on a Siemens D500 diffractometer (in the Department of Crystallography, Birkbeck College) equipped with a copper tube and a quartz primary-beam monochromator giving a wavelength (λ) = 1.54056 Å. The X-ray tube was run at 45 kV and 30 mA. The sample was mounted in a flat-plate specimen holder and flattened with a glass microscope slide. The sample was spun about an axis normal to its flat-plate surface. Diffraction patterns were measured using a scintillation detector. The data were obtained for the 2θ range 1−35° in steps of 0.05° at 10 s per point.

Results and Discussion

Sorbitan Monostearate Gels—Sorbitan monostearate is a small (MW = 431), monoalkyl, lipophilic (HLB 4.7), nonionic surfactant (Scheme 1). A waxy solid with a grainy texture, it disperses in hexadecane (at 10% w/v) on heating at 60 °C to give a slightly turbid suspension. On cooling, the latter suspension sets to an opaque, white, semisolid gel with a smooth texture. Cooling the suspension results in reduced affinities between the solvent and the surfactant, and this appears to cause surfactant self-assembly into aggregates. The aggregates join with one another to form a three-dimensional network which captures the solvent. The latter is thus immobilized and a gel is formed, as the bulk viscosity is increased by the network.

Solvents Gelled by Sorbitan Monostearate—The solvent has a prime role in gel formation. It must provide the correct solubility/insolubility balance toward the gelator so that the latter is dissolved or dispersed at high temperatures and is sufficiently insoluble when the organic solution/suspension is cooled such that the gelator molecules self-assemble into aggregates or otherwise associate. We tested a number of solvents by incubating the gelator (10% w/v) in the solvent at 60 °C for 0.5 h and then cooling by standing at room temperature. Sorbitan monostearate gels alkanes (C > 5), e.g., hexane, cyclohexane, octane, decane, *cis*- and *trans*-decalins, dodecane, tetradecane, hexadecane, octadecane, the alkene squalene, vegetable oils, e.g., corn oil, sesame seed oil, olive oil, cottonseed oil, and the long-chain synthetic esters, isopropyl myristate, ethyl oleate, and ethyl myristate.

The ungellable solvents include the more polar alkanols, ethanol, 2-propanol, and butanol, and chloroform and dichloromethane, which dissolve sorbitan monostearate (10% w/v) on heating, but which allow the sorbitan ester to precipitate on cooling. Benzene and toluene proved to be too good solvents in which the surfactants do not gel.



Scheme 1—Structures and Space-Filling Models of Some Sorbitan Ester Surfactants

Gelation Temperature—The gelation temperature of a hexadecane gel containing 10% w/v sorbitan monostearate was found to be 41−44 °C by differential scanning calorimetry. This relatively broad gelation temperature range is typical of physical organogels, involving the rupture of the junctions between aggregates and dissolution of the surfactant aggregates as the temperature rises, causing a corresponding increase in the surfactant solubility in the solvent. The melting point of the solid sorbitan monostearate is 51 °C. A melting point of the neat gelator higher than that of the gel seems to be a universal property of organogels. The organogel is thermoreversible, i.e., it melts on heating to the sol phase which can once again be gelled upon cooling. Heating and cooling cycles can be repeated a number of times without any appreciable change in gel properties.

Gelling Concentration—Sorbitan monostearate gels hexadecane at concentrations as low as 1% w/v (0.02 M). At this concentration, 170 solvent molecules are immobilized by each surfactant molecule. At lower concentrations, e.g., 0.2% w/v, a white fibrous gel mass is formed within the hexadecane solvent. The fibrous mass within the solvent becomes denser with increasing surfactant concentration until all the hexadecane is gelled. An increase in surfactant concentration was expected to cause a gradual increase in the viscosity of the bulk sample due to an isotropic dispersion of the increasing number of aggregates in the solvent until gelation occurred at the critical gelling concentration. It seems however, that aggregate−aggregate interactions are stronger than solvent−aggregate affinities, resulting in a preferential ordered flocculation of aggregates to form a three-dimensional network within the solvent. The surfactant network, anisotropically dispersed in the solvent, is then able to gel only that part of the solvent, and a fibrous gel mesh is observed within the

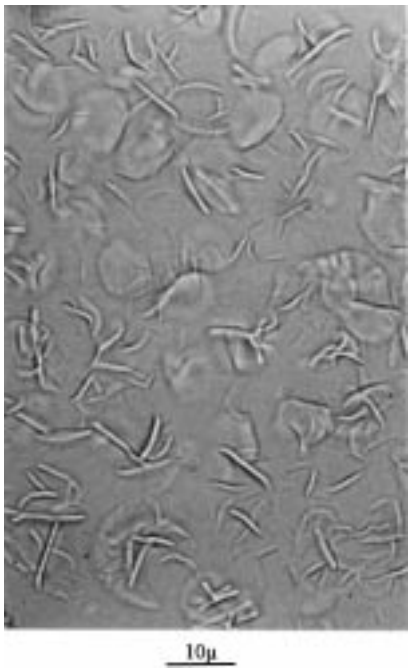


Figure 1—Organogel microstructure: tubular aggregates formed by the self-assembly of sorbitan monostearate molecules in hexadecane solvent.

excess solvent. The excess solvent is defined here as the fluid not gelled by the surfactant network.

This partial gelation within the excess solvent was most strikingly apparent in hexadecane. Other solvents such as isopropyl myristate, decane, corn oil, and squalene showed the anticipated isotropic dispersion of surfactant aggregates and a gradual increase in viscosity with increasing surfactant concentration until all the solvent was gelled. This difference in the gelation phenomenon with insufficient amounts of gelator, reflects the importance of the solvent, which influences the attractive forces between the gelator aggregate structures. In hexadecane, aggregate–aggregate interactions are maximized so that the aggregates join to form a meshwork which immobilizes part of the solvent. In other solvents, e.g., isopropyl myristate, the aggregate–aggregate interactions required for entanglement and formation of a three-dimensional network seem to be less favored, probably because of stronger solvent–aggregate attractions. The latter promote an isotropic dispersion of gelator aggregates in the solvent and consequently a progressive increase in the sample viscosity is observed upon increasing the sorbitan monostearate concentration until the critical gelling concentration is reached.

Gel Microstructure—Light microscopy of the organogels has revealed the surfactant aggregates to be rodlike tubules (Figure 1). The aggregates associate with others through contact points and a three-dimensional network is established which immobilizes the solvent. Figure 2 shows examples of gel networks in different solvents. The three-dimensional network acts as the gel skeleton. The importance of the contact points between tubules is seen when small amounts of ethanol are added to a gel sample. The contact points are disrupted with a consequent loss of the gel state even though tubules are still present.

Events Occurring at Gelation—In an attempt to understand the formation of tubular aggregates, the gelation process was followed microscopically as a hot suspension of sorbitan monostearate in isopropyl myristate was slowly cooled using a hot-stage. As the suspension cools and the solvent–surfactant affinities decrease, doughnut shaped, membrane-bound, inverse toroidal vesicular structures are seen to form as the sorbitan monostearate surfactant

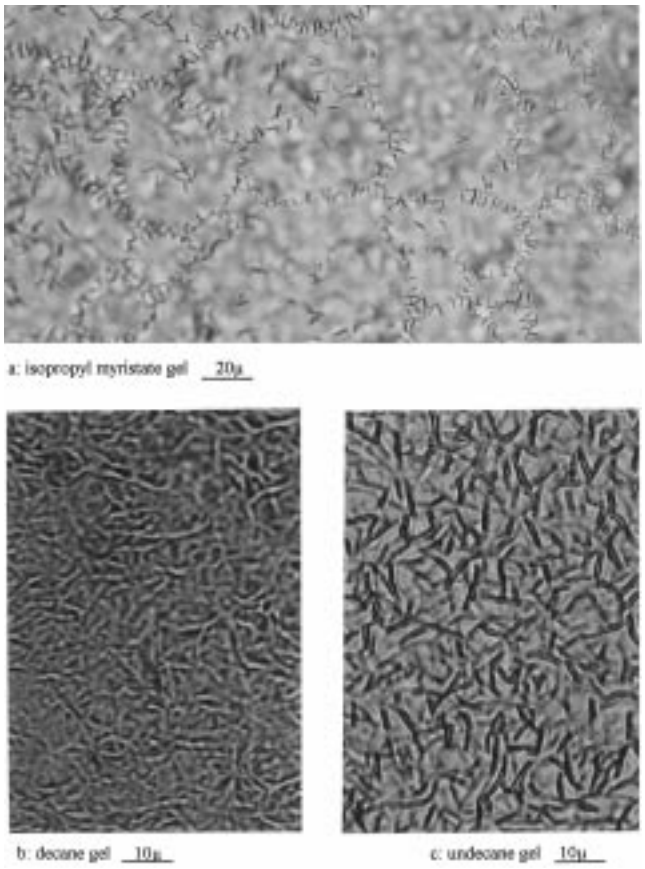

Figure 2—Examples of gel networks in different solvents.

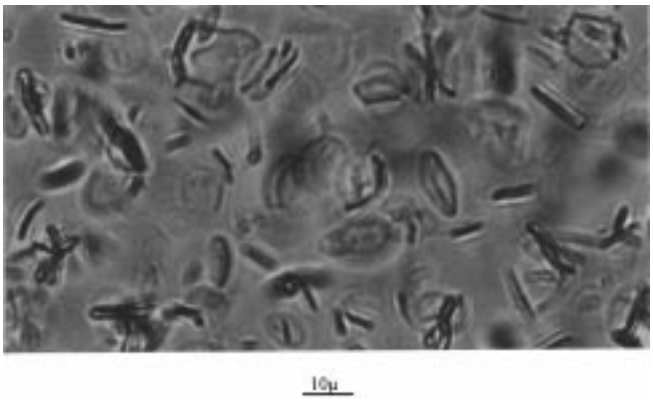

Figure 3—A photomicrograph of an isopropyl myristate formulation at the transition temperature between sol and gel phases. A number of toroidal vesicular structures can be seen.

molecules self-assemble. These toroidal vesicles (Figure 3) are in constant motion about their axis. Using a high-speed camera, one of the toroidal vesicles was photographed in quick succession as it rotated about its axis (Figure 4), and the toroidal rather than spherical shape of the vesicle was confirmed.

The toroids are short-lived structures, existing only at the gelation temperature (44–41 °C). Further cooling results in their conversion into tubules. The mechanism of such a change is not understood at present. The toroid might contract into a more tubular shape or it might split into one or more cylindrical segments, giving rise to the tubules seen in Figure 1. The latter structures are believed to be tubular and not toroidal vesicles lying perpendicular to the plane of the micrograph as the probability that all the toroidal vesicles would lie at such an angle is rather small.

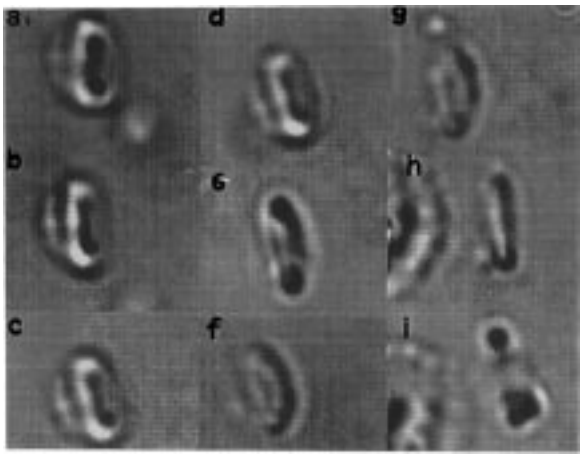

Figure 4—One of the inverse toroidal vesicular structures seen in Figure 3 was photographed in rapid succession as it rotated about its axis.

Formation of the surfactant aggregates is followed by random association between the aggregates and the establishment of junction points. The sequential pictures in Figure 5 obtained from a video recording of gelation demonstrates the migration of one aggregate to join another. From the sequential stills, the aggregate–aggregate interaction seems to be an active process, probably due to relatively strong forces of attraction between the surfactant assemblies and an overall negative energy change. Extensive joining of individual tubules finally creates a three-dimensional network which acts as the skeleton, "holds" the solvent, and forms the gel. Such flocculation of the surfactant aggregates and the obvious attractive forces among them (most clearly seen in Figures 2a and 5) suggest the existence of long-range forces of attraction in the system and provides another example of how large structures "seem to recognize each other's presence at rather great distances" as suggested by Adamson.[26] Further work is required to be done to more fully understand the energetics of gel formation.

Ultrastructure of Tubules and the Possible Molecular Organization of Surfactant Molecules—The toroids most probably consist of bilayers of surfactant molecules, in a fashion similar to other well-known vesicles—liposomes and niosomes. The difference lies in their toroidal shape and the inverted nature of the bilayers. Preferential self-assembly of surfactant molecules into toroidal vesicles may be due to the reduced membrane curvature required in toroids. Figure 6 shows a diagrammatic representation of such a toroidal vesicle consisting of surfactant bilayers. Assuming this surfactant organization is retained upon gelation, the tubules present in the gel would also consist of concentric sheets of bilayers (Figure 6). A bilayer organization of surfactant molecules in the tubules is suggested by X-ray diffraction measurements on a sorbitan monostearate/hexadecane gel, which show peaks corresponding to distances 5.9 and 0.4 nm. These distances relate to the bilayer thickness and the distance between two adjacent surfactant tails, respectively, as shown in Figure 6. These values agree with the corresponding to theoretical calculated distances (using Quanta and CHARMm software), which are 5.91 and 0.46 nm, respectively, assuming close packing of the surfactant molecules in the bilayers. Such an arrangement of the amphiphiles ensures the solvophobic headgroups are shielded from the organic solvent.

Gel Stability—The two markers of gel stability normally used are gelation temperature and gel lifetime. Gelation temperature usually increases with gelator concentration and is dependent on the solvent. The gel lifetime is the

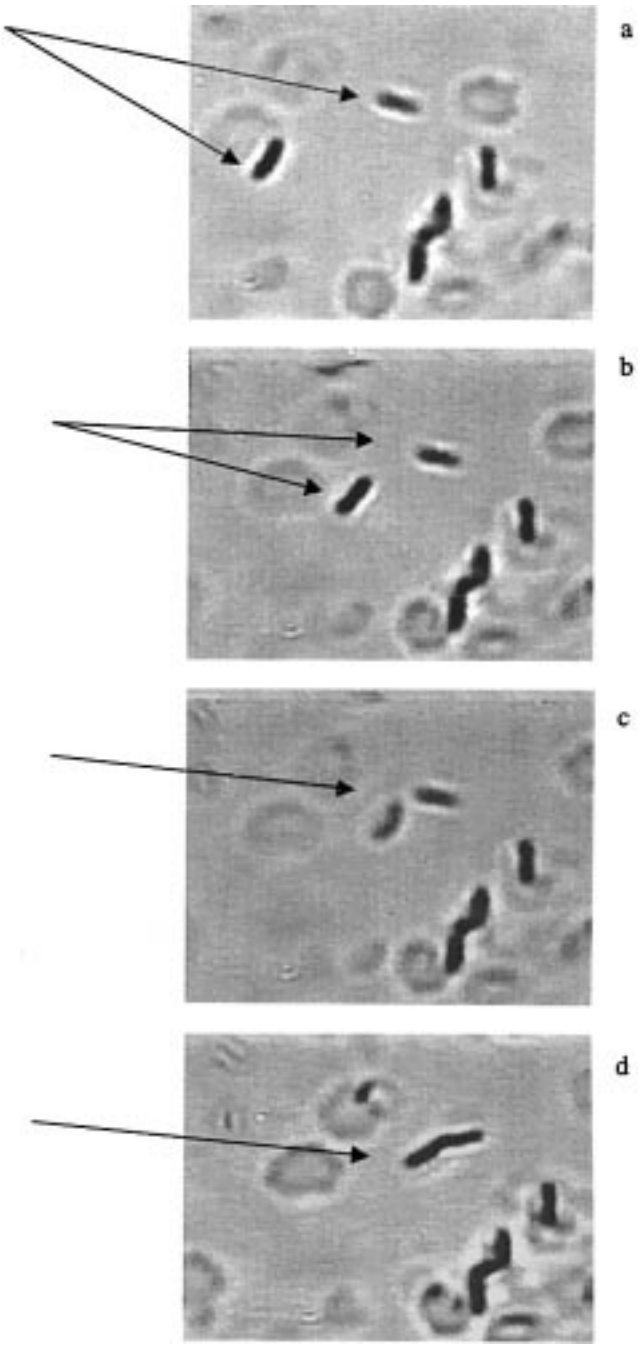

Figure 5—Sequential micrographs (a–d) show the migration of one surfactant aggregate to join another in the formation of the three-dimensional network.

length of time a gel remains intact when stored in sealed vessels at room temperature, without syneresis (the separation of the solid and liquid components). Like gelation temperature, the gel lifetime depends on gelator concentration and the solvent. A hexadecane gel containing 10% w/v sorbitan monostearate remains intact for a few weeks before syneresis occurs. Hexadecane gels also have a longer lifetime compared to isopropyl myristate and vegetable oil gels.

Gel stability was found to be drastically altered when small amounts of a second nonionic surfactant, polysorbate 20, was included in the formulation.

The Influence of Polysorbate Additives on Sorbitan Monostearate Gels—Small amounts of polysorbate 20 (Tween 20), a hydrophilic nonionic surfactant (HLB 16.7), was included in a sorbitan monostearate/hexadecane organogel when the latter was used as the continuous

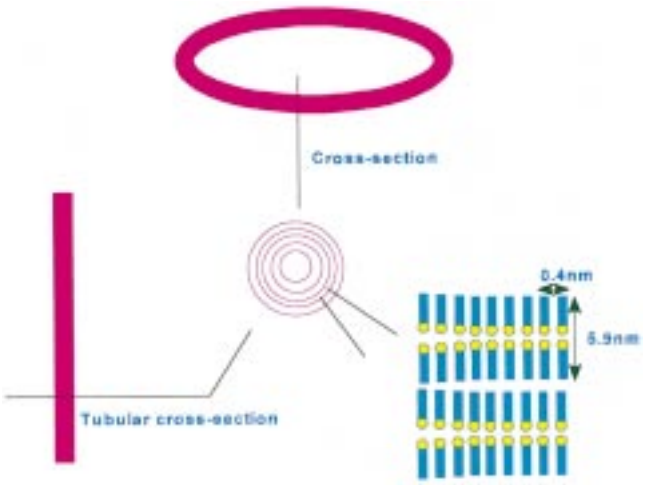

Figure 6—Diagrammatic representations of a surfactant tubule, its precursor, an inverse toroidal vesicle and the aggregates' cross-section. A segment of the cross-section has been magnified to show the suggested surfactant organization, i.e., inverse bilayers.

external oil phase in the formation of multiple emulsions.[24] It was anticipated that the addition of the hydrophilic polysorbate 20 would stabilize the emulsion due to the formation of mixed surfactant films at the w/o interface. This was indeed realized. Addition of polysorbate 20 also had interesting effects on the gel lifetime and stability.

Polysorbate 20 seems to enhance the solubility of sorbitan monostearate in hexadecane, such that a sorbitan monostearate/polysorbate 20/hexadecane system is a clear, transparent solution at 60 °C (compared to a slightly turbid suspension in the absence of polysorbate 20). The enhanced solubility is probably mediated via the formation of mixed inverse micelles of the two surfactants in the hexadecane solvent at high temperatures.

The transparent mixed surfactant solution cools to a semisolid, opaque gel which is similar in appearance to the gel without polysorbate 20. The gel lifetime and stability is, however, drastically improved. Hexadecane gels spiked with polysorbate 20 were found to be stable for months (compared to weeks in the absence of polysorbate 20) at room temperature without syneresis. Penetrometer studies also showed a slight increase in gel consistency upon the addition of polysorbate 20 (unpublished results). Such an enhanced gel stability seems to be a direct result of the enhanced solubility in the system described above. Inclusion of polysorbate 20 in hexadecane gel moves the solubility toward the optimum level required for stable gel formation.

This solubility-enhancing effect of polysorbate 20, is, however, not universal: solubility was enhanced in some solvents, but it was reduced in others. An enhanced solubility is always followed by improvement in gel lifetime and stability. Polysorbate 20 reduces the solubility of sorbitan monostearate in the shorter chain alkanes (C < 14) with consequent deterioration of the gels, as evidenced by syneresis. Polysorbate 20 has no effect in tetradecane. The solubility of sorbitan monostearate is increased in longer chain hydrocarbons, e.g., hexadecane, octadecane, and squalene, with a consequent enhancement of the gel formed. The long chain esters, ethyl oleate, isopropyl myristate, and ethyl myristate, and the vegetable oils also show an enhancement of the gel upon the addition of polysorbate 20. Table 1 recapitulates these findings. The key feature seems to be the size of the solvent molecule: a relatively large size or a long hydrocarbon chain seems to be required for polysorbate 20 to exert a beneficial effect on solubility and gelation. It is unclear at present why this should be so.

Table 1—The Effects of Polysorbate 20 on the Solubility of Sorbitan Monostearate in Hot Solvents (60 °C) and on the Resulting Gels

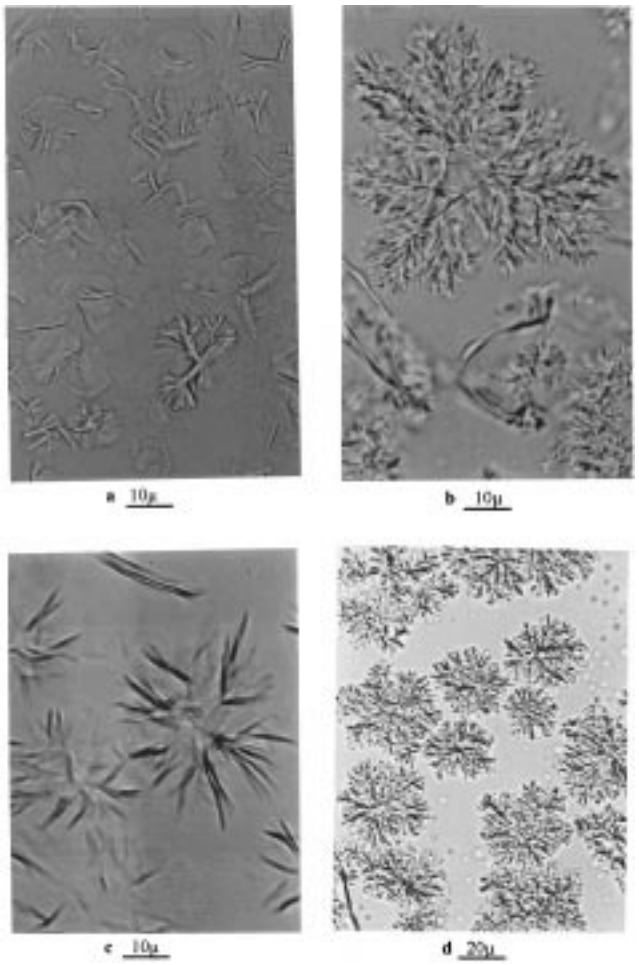

Figure 7—Microstructures of sorbitan monostearate gels: (a) absence of polysorbate surfactant, (b) + polysorbate 20, (c) + polysorbate 60, and (d) + polysorbate 80.

Gel microstructure is affected by the inclusion of polysorbate 20. Gels spiked with the hydrophilic surfactant comprise star-shaped "clusters" of surfactant tubules in the

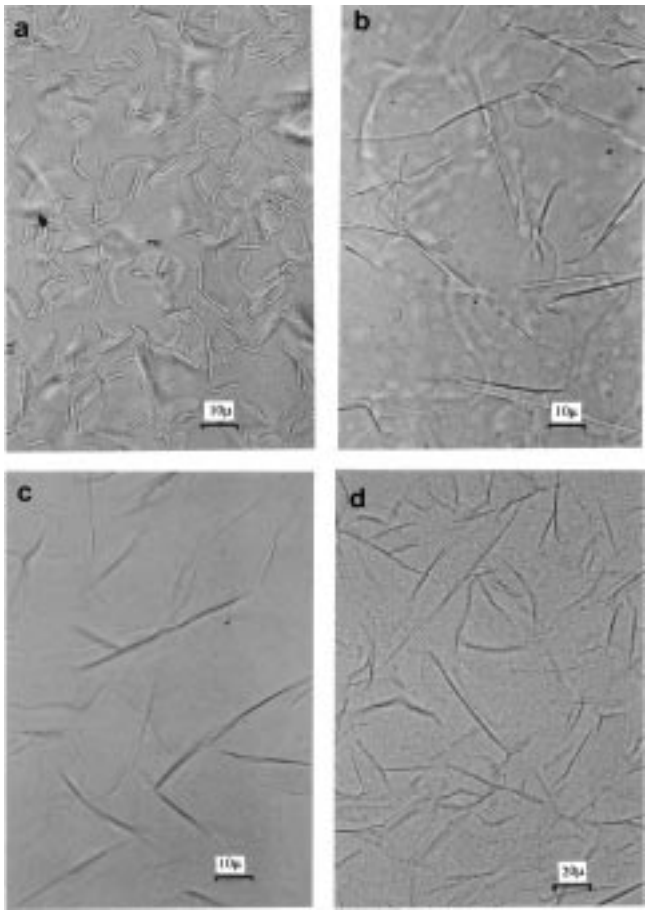

Figure 8—Microstructures of sorbitan monopalmitate gels: (a) absence of polysorbate surfactant, (b) + polysorbate 20, (c) + polysorbate 60, and (d) + polysorbate 80.

organic medium (Figure 7). On cooling a hot solution, these "clusters" were found to grow as an entity, rather like the opening of a clenched fist. The polysorbate 20 molecules are thought to become incorporated into the inverted surfactant bilayers and thus into the tubular aggregates.

The other polysorbates tested, polysorbate 40, 60, and 80 showed similar effects to polysorbate 20 in hexadecane gels. The solubility of sorbitan monostearate in hexadecane was enhanced, presumably due to the formation of mixed inverse micelles and the resulting more stable gels resulted from star-shaped clusters of surfactant tubules (Figure 7). The triesters, polysorbates 65 and 85, do not affect the solubility of sorbitan monostearate in hexadecane. It is possible that their large size and shape do not allow mixed micelle formation, and thus the solubility of the gelator is not enhanced.

The Gelling Abilities of Other Sorbitan Esters—To determine the key properties of sorbitan monostearate as an organogelator, other members of the sorbitan ester family which are in the solid state at room temperature, namely, sorbitan monopalmitate (Span 40) and sorbitan tristearate (Span 65), were investigated for any gelling ability. Sorbitan monopalmitate was found to gel hexadecane. The thermoreversible gel obtained is similar in appearance to sorbitan monostearate gel described, i.e., it is opaque, semisolid, with a smooth silky "feel" and the microstructure comprises rodlike tubular aggregates (Figure 8a). When gelation was followed using hot-stage microscopy, the surfactant tubules were found to be formed from toroidal vesicular precursors as described above for sorbitan monostearate.

Sorbitan tristearate does not gel hexadecane, but crystallizes out on cooling the hexadecane. The conical shape of the triester (Scheme 1) is not conducive to the formation of bilayers and thus tubule formation. Reports on vesicle formation by sorbitan tristearate in aqueous media could not be found in the literature. On the other hand, the cylindrical shape (Scheme 1) of the sorbitan monoesters (monostearate and monopalmitate) seems to allow molecular packing in bilayers such that the surfactant molecules can assemble into tubular aggregates responsible for gelation.

Sorbitan monopalmitate gels are less stable than the stearate gels at 10% w/v gelator concentration. Gelation temperature is lower, and syneresis occurs at a faster rate. As in the case of monostearate gels, the addition of polysorbate monoesters (polysorbates 20, 40, 60, and 80) increases the solubility of sorbitan monopalmitate in hexadecane, presumably via the formation of mixed inverse micelles, with consequent enhanced gel stability. The effects on the microstructures of the palmitate gels were, however, very different: the tubular length was drastically increased when the gels were spiked with polysorbates (Figure 8). These long tubules were formed from large toroidal vesicular precursors generated at the gelation temperature. Why the polysorbates have such widely different effects on the two sorbitan esters which only differ in their hydrocarbon chains by a C_2H_4 group remains to be solved.

Abstract □ Novel multicomponent organogels containing an aqueous phase are described, and some properties which influence their potential as delivery devices for hydrophilic drugs and vaccines are discussed. The gel is produced by preparing a hot water-in-oil (w/o) emulsion using sorbitan monostearate, a nonionic surfactant which is also the organogelator, as the principal emulsifying agent. On cooling at room temperature, the w/o emulsion sets to an opaque, semisolid, thermoreversible organic gel. Cooling the emulsion results in a reduced solubility of the sorbitan monostearate in the oil, with a corresponding decrease in solvent–surfactant affinities, causing surfactant self-assembly into aggregates. The microstructure of the w/o gel is seen by light microscopy to consist of a network of tubules and fibrils (containing the aqueous phase) dispersed in the organic medium. X-ray diffraction and freeze-fracture studies suggest that the tubular aggregates in the w/o gel are made up of surfactant molecules arranged in inverted bilayers and that the aqueous phase is accommodated within these inverted bilayers, bound by the polar headgroups of the surfactant molecules. The presence of water in the tubular skeleton of the organic gels results in the establishment of percolating electroconductive aqueous channels in the organogel. Increasing the water content of a w/o gel causes the surfactant tubules to swell with a corresponding increase in conductivity until the tubules are saturated. Further increase in the water content results in the excess water accumulating in droplets within the organic medium and a decrease in conductivity as the gel integrity is compromised. The w/o gels (containing a model antigen, radiolabeled bovine serum albumin, in the aqueous phase) have demonstrated depot properties after intramuscular administration to mice, entrapped antigen being released over a period of days.

Introduction

Interest in organic gels has increased, and a number of applications of these nonaqueous systems are being investigated.[1] Examples include transdermal drug delivery devices,[2] biosynthetic media,[3−8] moisture sensors,[9,10] synthetic templates,[11] purification and separation media,[12] and carriers for liquid crystals.[13] We previously reported the gelation of organic solvents by the nonionic surfactant, sorbitan monostearate.[14] These are opaque, thermoreversible semisolids whose microstructures consist of interconnected tubular aggregates, which, as suggested by freeze-fracture and X-ray diffraction measurements, are assemblies of the gelator molecules arranged in bilayers.[15]

The nonionic surfactant-based organogels, comprising pharmaceutically acceptable excipients (sorbitan monostearate, polysorbate 20, and a biodegradable oil, e.g., isopropyl myristate) may have potential as delivery devices for hydrophobic and hydrophilic drugs and vaccines. The hydrophobic active entity can be dissolved or dispersed in the sol phase at high temperatures before gel formation on cooling. This ensures a homogeneous distribution of the active ingredient in the organogel. A hydrophilic substance (dissolved in an aqueous medium) may also be incorporated in the organogel, by adding the aqueous phase to the organic solution at high temperatures (60 °C). A water-in-oil (w/o) emulsion is thus produced, where discrete aqueous droplets, bounded by surfactant films, are dispersed in the continuous external oil phase. On cooling, the w/o emulsion is converted to the gel state i.e., a w/o organogel is produced. We have previously reported the preparation of organogels where the aqueous phase was a niosome suspension, such that a vesicle-in-water-in-oil (v/w/o) gel is produced.[14,16] An active agent such as dissolved or suspended drug or antigen can thus be delivered in vivo within a nonaqueous medium. The latter may present a barrier to the diffusion of the active after in vivo administration, and it was speculated that a w/o gel may act as an intramuscular/subcutaneous depot for hydrophilic drugs and vaccines. In turn, the addition of the aqueous phase alters the organic gel. In this paper we report on the effects of the addition of an aqueous phase on sorbitan monostearate organogels. The gelation mechanism, the location of the aqueous phase in the w/o gel, and the maximum amount of aqueous phase which can be incorporated in the gel are explored. The in vivo release rate of a model hydrophilic antigen from a w/o gel was investigated, and an aqueous solution and a w/o emulsion (liquid state) were used as controls.

Materials and Methods

Sorbitan monostearate, 5,6-dicarboxyfluorescein, and bovine serum albumin (BSA) were purchased from Sigma (UK) while polysorbate 20, hexadecane (analytical grade), and isopropyl myristate (analytical grade) were from Fluka (UK). ^{125}I used to radiolabel BSA was from Amersham Pharmacia Biotech (UK). All were used as received, except for hexadecane and isopropyl myristate which were dried at room temperature overnight in a vacuum oven (Gallenkemp, UK) to ensure the absence of moisture which might affect gelation. Ultrahigh quality (double distilled) water was used throughout. In-bred male Balb/c mice (weighing approximately 20 g) were from Bantin & Kingman, Hull, UK.

Organogel Preparation—Sorbitan monostearate (10% w/v) and polysorbate 20 (2% w/v) were weighed into a vial, and the organic solvent (hexadecane or isopropyl myristate) was added. The mixture was heated to 60 °C in a water-bath and a transparent organic solution was produced. After the latter sol was cooled at room temperature, an opaque, thermoreversible semisolid gel was obtained.

Preparation of w/o Gel—The aqueous phase (water/5,6-dicarboxyfluorescein solution/radiolabeled bovine serum albumin solution) was added dropwise to the oil phase (the gel prepared

10.1021/js980343j CCC: $18.00 Published on Web 04/21/1999

above) while vortexing, both phases being at 60 °C. A w/o emulsion was obtained. On cooling at room temperature, the w/o emulsion gelled to an opaque, thermoreversible semisolid.

Preparation of w/o Emulsion—The aqueous phase (radiolabeled bovine serum albumin solution) was added dropwise to the oil phase (10% w/v sorbitan monooleate + 2% w/v polysorbate 20 in isopropyl myristate) while vortexing, both phases being at 60 °C. A water-in-oil (w/o) emulsion was obtained.

Light Microscopy—A light microscope (Nikon Microphot-FXA, Japan) with an attached camera (Nikon, FX-35DX, Japan) and a hot-stage (Linkam TC 93, UK) was used to analyze the gel microstructures.

X-ray Diffraction Studies—X-ray data on hexadecane organogels were collected on a Siemens D500 diffractometer (in the Department of Crystallography, Birkbeck College) equipped with a copper tube and a quartz primary-beam monochromator giving a wavelength $\lambda = 1.54056$ Å. The X-ray tube was run at 45 kV and 30 mA. Samples were mounted in a flat-plate specimen holder and flattened with a glass microscope slide. The sample was spun about an axis normal to its flat-plate surface, and diffraction patterns were measured using a scintillation detector. The data were obtained for the 2θ range 1−35° in steps of 0.05° at 10 s per point. A w/o gel containing 48 μL water per milliliter of gel was studied to investigate the effect of the added water on the surfactant organization in the tubular aggregates, and an anhydrous gel was used as control.

Freeze Fracture Investigations—The gel (containing 167 mL water/mL of hexadecane organogel) was sandwiched between copper plates and then quickly frozen using liquid propane (−180 °C). The frozen samples were loaded in a holder under liquid nitrogen, transferred to a Balzers BAF 400, and fractured at −150 °C. The frozen planes were replicated with platinum (2 nm) at an angle of 45° and with carbon (20 nm) from an angle of 90°. The replicas were then cleaned with distilled water, mounted on copper grids, dried, and examined using a transmission electron microscope.

Conductivity Measurements—A Wayne−Kerr conductivity bridge was used to measure the conductance of hexadecane gel samples containing increasing amounts of water. Two carbon electrodes (diameter 5 mm, 5 cm apart) were used while a constant voltage from a DC source was applied. Five conductance readings were taken for each gel sample, and the mean was calculated.

Intramuscular Administration—The presence of a depot property was investigated by measuring the amount of a model radiolabeled antigen, bovine serum albumin (BSA), which remains at the site after intramuscular injection. A biodegradable oil (isopropyl myristate) was used as the organic solvent in the w/o gel. An aqueous radiolabeled BSA solution and a w/o emulsion were used as controls. At time $t = 0$, each group of mice (15 mice/group) was injected intramuscularly with 50 μL of a formulation (each mouse received the same amount of radiolabeled BSA, around 108 Bq). Three mice from each group were killed at different times, t, postinjection, the injected leg was amputated, and the radioactivity in the leg was measured using a mini-γ counter. The count obtained was expressed as a percentage of the initial total radioactivity at time $t = 0$.

The injection technique was very important to ensure reproducibility, especially for the w/o gel; the latter was taken up into a glass syringe when hot and thus in the liquid state. The sol phase was then allowed to cool and set to the gel state (observed visually) before intramuscular administration. Both w/o gel and w/o emulsions were administered using glass syringes; plastic syringes were avoided as their rubber plunger tips absorb the oily vehicle and swell such that the force needed to expel and thus administer syringe contents would be dramatically increased, and the formulation would be altered through loss of oil.

Results and Discussion

Water-in-Oil Gel Formation—A w/o gel is prepared by first forming the w/o emulsion (the sol phase) at high temperatures: the aqueous phase at 60 °C is added dropwise to the oil phase (oil solution of the nonionic surfactants, sorbitan monostearate, and polysorbate 20), while vortexing. A w/o emulsion is produced, where the aqueous droplets, bound by surfactant interfacial films, are dispersed in the continuous external oil phase (Figure 1a). The hydrophilic nonionic surfactant, polysorbate 20, was included in the organosol prior to emulsion preparation, as it increases the gel lifetime[15] and enhances emulsion stability by forming mixed surfactant films with the sorbitan monostearate molecules at the w/o interface. On cooling, the w/o emulsion gels to an opaque, thermoreversible semisolid. Cooling results in a decrease in the solubility of the sorbitan monostearate gelator in the oil and consequently lowered solvent−gelator affinities. As a result, the surfactant molecules self-assemble into tubular aggregates (Figure 1b) which join and interact with one another. Junction points are established (Figure 1b), and a three-dimensional network is formed which immobilizes the oil phase. The fluorescent aggregates in Figure 1b indicate that the aqueous phase (in this case, fluorescent, 5,6-dicarboxyfluorescein solution), previously bound by the surfactant interfacial layer at 60 °C, is incorporated into the surfactant tubules upon gel formation. The w/o gel is physically stable for months at room temperature.

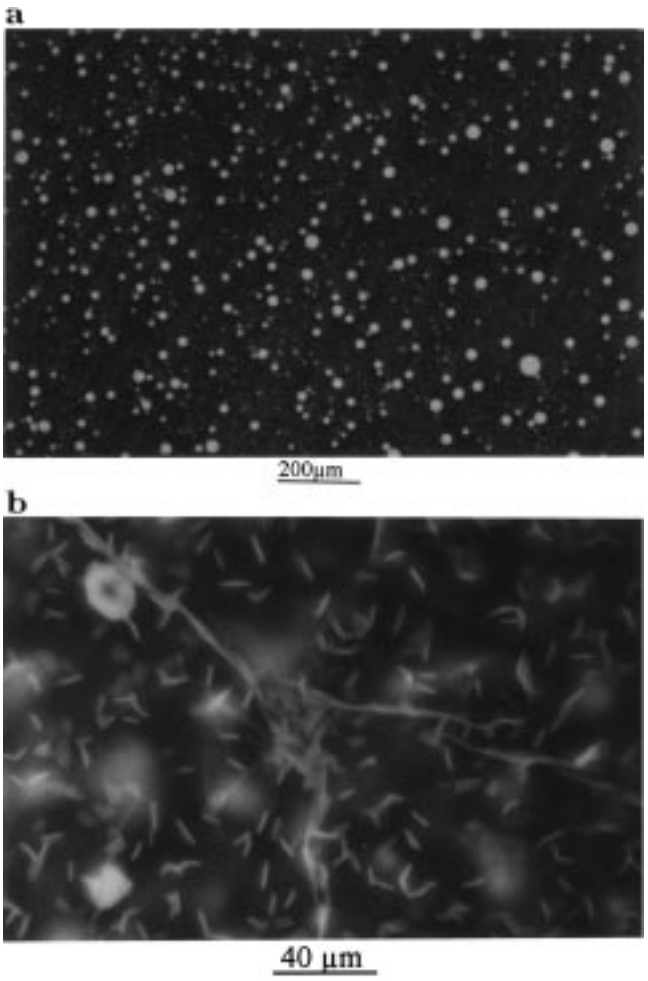

Figure 1—(a) The microstructure of a w/o emulsion at 60 °C: aqueous droplets (fluorescent CF solution) dispersed in the continuous oil phase. (b) The microstructure of a w/o gel at 25 °C: tubules and fibrils incorporating the aqueous fluorescent CF solution in the organic medium. Junction nodes are responsible for the integrity of the gel skeleton.

The w/o gel is thermoreversible: on heating it melts to a liquid w/o emulsion, as an increase in temperature causes a corresponding increase in the gelator solubility in the oil phase and the tubular aggregates disassemble. The w/o emulsion can, in turn, be cooled to the gel state. The gelation temperature (T_g) at which the w/o gel melted to the emulsion was found to be 41−44 °C by hot-stage microscopy.

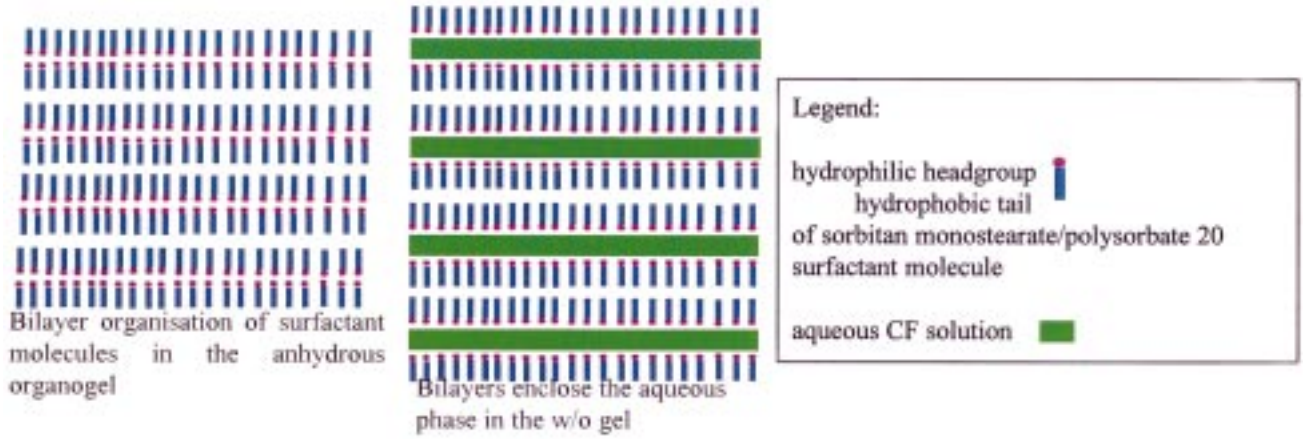

Figure 2—Schematic diagram shows the suggested location of aqueous phase within bilayers, bound by surfactant headgroups. The structures here are highly idealized.

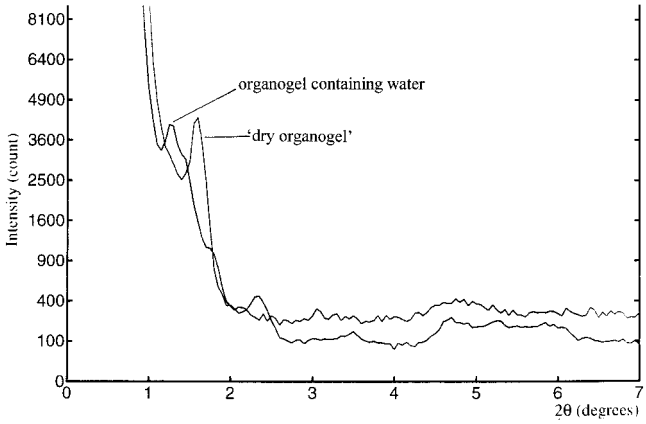

Figure 3—X-ray diffraction measurements show an increase in bilayer width upon the incorporation of an aqueous phase in the organic gel ($\downarrow \theta \equiv \uparrow$ distance).

Location of the Aqueous Phase within Surfactant Tubules—The tubular aggregates in sorbitan monostearate organogels are thought to be composed of surfactant molecules arranged in multiple inverted-bilayers (Figure 2). Such an arrangement was suggested by freeze-fracture investigations which revealed the presence of bilayers, and X-ray diffraction measurements which showed peaks at 5.9 and 0.4 nm. These values (relating to the bilayer width and the distance between two adjacent surfactant molecules, respectively) were found to correlate with the theoretical calculated values, 5.91 and 0.46 nm, obtained using the software QUANTA & CHARm (unpublished results).

Figure 1b shows the aqueous phase to be located within the tubular surfactant aggregates in the w/o organogel. The aqueous phase is most likely accommodated within the surfactant bilayers as schematically shown in Figure 2. The water molecules will also hydrogen bond with the surfactant headgroups, which may further stabilize the w/o gel. The water-in-bilayer hypothesis is supported by X-ray diffraction measurements which show an increased bilayer width, from 5.9 to 6.9 nm when water is incorporated in the gel (Figure 3). Freeze fracture microscopy also shows that the bilayered nature of the organogel is retained in the w/o gel (Figure 4).

Water in Tubules: Effect on Gel Microstructure and Electrical Conductivity—Water-in-oil gels containing increasing amounts of aqueous phase were prepared and examined using light microscopy to determine first the effect on gel microstructure and second, the maximum

Figure 4—Freeze-fracture micrograph shows a bilayered arrangement in a w/o gel sample.

amount of aqueous phase that can be incorporated in sorbitan monostearate/hexadecane organogels. Upon the addition of increasing amounts of water, the star-shaped clusters of surfactant tubules (Figure 5a) break up gradually, initially coexisting with individual tubules until all the clusters break and individual tubules and fibrils are seen in the medium. Further addition of water results in swollen tubules as their bilayers enclose increasing volumes of water (Figure 5b). Swelling of tubules is, however, a limited process as the bilayers can only enclose a certain amount of water while retaining their integrity. Excess water added after the saturation point has been reached, accumulates in droplets, bound by surfactant films (Figure 5, parts c and d). Addition of excessive amounts of water finally results in gel breakdown as aggregate integrity is lost, the surfactant molecules being in interfacial films

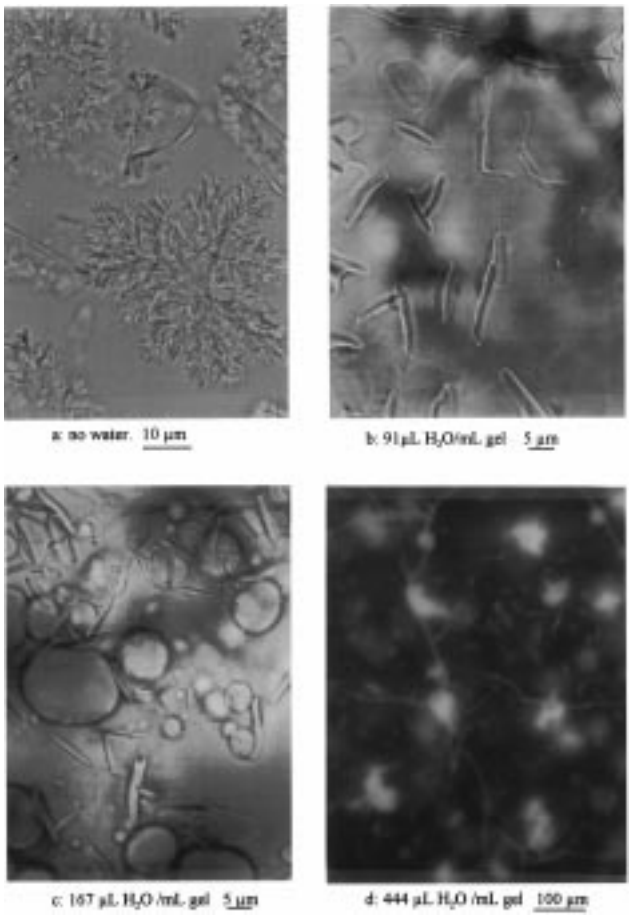

Figure 5—The changing microstructure of the w/o gel containing increasing amounts of water.

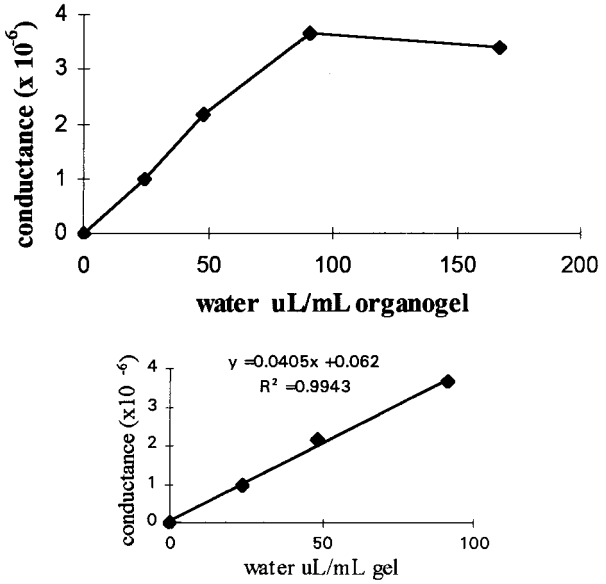

Figure 6—The electrical conductivity (1/Ω) of w/o gels containing increasing amounts of water (μL/mL organogel).

around the water droplets and in monomeric or spherical micellar form in the bulk oil.

The changing microstructures of the w/o gels is reflected in the electrical conductivity changes (Figure 6). The presence of water in the interconnected surfactant tubules results in the establishment of electroconductive aqueous channels in the organic gel. Electrical conductivity increases linearly with increasing amounts of water until a

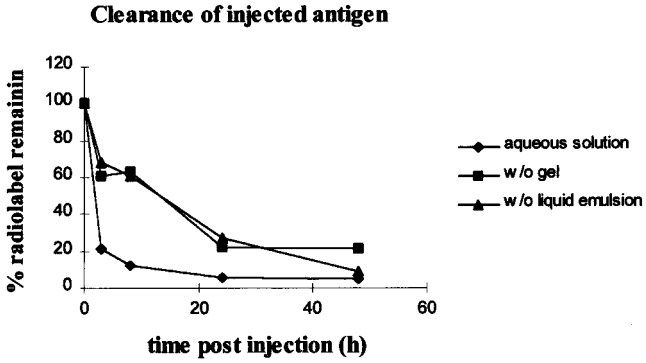

Figure 7—The clearance rates of radiolabeled model antigen after intramuscular administration in a w/o gel and controls, a w/o emulsion, and an aqueous solution.

peak is reached after which the conductivity decreases. The peak lies between 91 and 167 μL of water/mL of organogel and corresponds to the saturation level of water in surfactant bilayers in the tubules. This tallies with the light micrographs in Figure 5 which also indicate a saturation point between 91 and 167 μL water/mL of organogel. After the saturation point is reached, the distorted water droplets containing the excess aqueous phase cause a deterioration of the gel structure and integrity. This interferes with the electrical conductivity of the gel and the latter decreases, as part of the surfactant molecules are involved in interfacial films around the water droplets and fewer surfactant tubules providing aqueous channels are available for electrical conduction.

The Water-in-Oil Gel: A Delivery System for Drugs and Vaccines? The water-in-oil gel is a formulation in which hydrophilic drugs and vaccines may be administered in vivo, in an organic vehicle. Such incorporation may confer certain advantages to the active entity, e.g., the organic gel may present barriers to diffusion, such that after administration, the active entity, incorporated within the surfactant bilayers in the organogel is slowly released from the w/o gel, and a depot effect may be achieved.

To determine any depot effect after intramuscular injection, we measured the clearance rate of a model antigen (bovine serum albumin) administered in a w/o gel to mice. Figure 7 shows the clearance rates (defined as the rate at which injected antigen disappears from the site of injection) of BSA from a w/o gel and from the controls, aqueous solution, and w/o emulsion. After injection of the aqueous BSA solution, almost all the BSA is cleared within 8 h. On the other hand, the w/o emulsion and the w/o gel release the antigen slowly over a period of days. The clearance rate of antigen from the w/o emulsion is similar to that from the w/o gel except at 48 h postinjection, where the w/o gel is superior as a depot. After 48 h, 20% of the injected antigen is still present at the injection site. Gelling of the oil phase, though apparently not important in the initial stages of antigen clearance, seems to confer some advantage in increasing the duration of the antigen at the injection site.

After injection, the organic gel probably remains at the site of injection and assumes, like oils, a pea-shaped depot,[17] unlike aqueous formulations which spread along the muscle fibers. The local interstitial fluid then penetrates into the gel mass via the interconnected tubular network. This invasion of the interstitial fluid into the gel mass slowly breaks down the gel into smaller fragments. At the same time, emulsification occurs at the gel surface between the oil and the interstitial fluid and oil droplets bud off from the gel. The model hydrophilic solute is thus released as the gel slowly breaks into smaller fragments and erodes. This suggested release mechanism is based on

in vitro investigations where an aqueous solution was made to contact with a gel mass. This gel disintegration after administration explains why the depot effect achieved by the organogel is more transient than anticipated. A short depot effect may, however, be sufficient for certain applications, e.g., as immunoadjuvants, where a short depot action is thought to be effective in enhancing the immune response to antigens.[18]

Conclusions

We have reported the gelation of water-in-oil emulsions when a gelator, sorbitan monostearate, is used as the emulsifying agent. The w/o gels are thermoreversible semisolids whose microstructure consists of interconnected tubular aggregates within which the aqueous phase is trapped. The latter aqueous phase is believed to be entrapped within the inverted surfactant bilayers, bound by polar headgroups in the tubules. The presence of water in the surfactant tubules allows electrical conduction through the gel, conductivity being proportional to the aqueous content in the gel. The w/o gels enable the delivery of hydrophilic active entities within an organic medium, and we have demonstrated an in vivo depot over several days, but their longevity is compromised by the access of water to the system by percolation.

In Vitro Models of the Blood–Brain Barrier to Polar Permeants: Comparison of Transmonolayer Flux Measurements and Cell Uptake Kinetics Using Cultured Cerebral Capillary Endothelial Cells

MARK D. JOHNSON AND BRADLEY D. ANDERSON*

Contribution from *Department of Pharmaceutics and Pharmaceutical Chemistry, University of Utah, Salt Lake City, Utah 84112.*

Received July 31, 1998. Final revised manuscript received December 31, 1998.
Accepted for publication March 25, 1999.

Abstract □ Given that the cerebral microvasculature within the brain constitutes the rate-limiting barrier to drug entry, primary cultures of cerebral capillary endothelial cells would appear to offer a potentially useful model system for predicting drug delivery to the central nervous system. In the present study, the predictive capabilities of two potential models of the in vivo blood–brain barrier (BBB) to the passive diffusion of polar permeants were assessed. A comparison of the logarithms of the in vitro transmonolayer permeability coefficients ($P_{monolayer}$) for several polar permeants varying in lipophilicity (from this study and literature data) with the well-established relationship between the logarithms of the in vivo BBB permeability coefficients (log P_{BBB}) and permeant lipophilicity as measured by the logarithm of the octanol/water partition coefficient (log $PC_{octanol/water}$) demonstrated that in vitro permeation across these monolayers is largely insensitive to polar permeant lipophilicity as a result of the predominance of the paracellular component in the transmonolayer flux. Conversely, kinetic studies of uptake of the same compounds into monolayers yielded transfer rate constants (k_p) reflecting membrane permeability coefficients ranging over several orders of magnitude, similar to the variation in permeant lipophilicity. Furthermore, a linear relationship could be demonstrated between the logarithms of k_p and in vivo BBB log P (slope $= 1.42 \pm 0.35$; $r = 0.92$). In conclusion, this preliminary investigation suggests that monitoring the kinetics of cell uptake into cerebral capillary endothelial cell monolayers may be superior to transmonolayer flux measurements for predicting the passive diffusion of polar permeants across the BBB in vivo.

Introduction

An in vitro model of the blood−brain barrier (BBB) that could mimic its in vivo barrier properties and thus allow one to predict the outcome of in vivo experiments would be extremely useful. Assuming the rate-limiting barrier to drug uptake to be the cerebral microvasculature, primary cultures of cerebral capillary endothelial cells offer a potentially useful model system for predicting drug delivery to the CNS.[1,2] Indeed, recent studies have led several investigators to conclude that primary cultures of cerebrovascular endothelial cells exhibit a barrier function that correlates with BBB function in vivo.[3−5] In vivo, the BBB permeability depends on permeant lipophilicity in a manner consistent with predominantly transcellular diffusion even for permeants as polar as sucrose, which has a log octanol/water partition coefficient (log $PC_{octanol/water}$) of approximately −4.[6] The present study confirms, however, that transmonolayer permeabilities across primary cultures of BBB endothelial cells, a popular in vitro model of the BBB, fail to display the expected dependence on permeant lipophilicity for polar permeants having log $PC_{octanol/water} \leq 0$. This paper therefore explores the utility of monolayer uptake kinetics as an alternative to transmonolayer flux measurements in an attempt to identify a more reliable model of the BBB for predicting permeability coefficients of polar permeants.

Materials and Methods

Reagents—[1-^{3}H]Sucrose (20 Ci/mmol) was obtained from NEN Research Products, DuPont, Wilmington, DE. [^{14}C(U)]Sucrose (600 mCi/mmol) and [^{14}C]urea (59 mCi/mmol) were obtained from Moravek Biochemicals, Brea, CA. [1-^{3}H]Mannitol (15 Ci/mmol), [2-^{3}H]glycerol (30 Ci/mmol), and [1-^{14}C]acetamide (55 mCi/mmol) were obtained from American Radiolabeled Chemicals Inc., St. Louis, MO. All radiolabeled compounds were purchased >98% pure and were used without further purification. 3′-Azido-3′-deoxythymidine (zidovudine, 98% purity) was obtained from Aldrich Chemical Co., Milwaukee, WI. All other reagents were of analytical grade. Culture media consisted of minimum essential media (MEM)/F-12 Ham's nutrient mixture 1:1 (HyClone Laboratories, Logan, Utah) supplemented with 10 mM HEPES/13 mM sodium bicarbonate (pH 7.4), 100 μg/mL penicillin G (Sigma Chemical Co., St. Louis, MO), 100 μg/mL streptomycin (Sigma), 100 μg/mL heparin (170 units/mg), and 10% plasma-derived horse serum (HyClone Laboratories).

Isolation and Culture of Cerebrovascular Endothelial Cells—Capillary segments were isolated from bovine cerebral gray matter (Dale T. Smith & Sons Meat Packing Company, Draper, UT) by a two-step enzymatic dispersion treatment followed by centrifugation over preestablished 50% Percoll density gradients as described previously.[1] Sequential filtering of the preparation through 500 μm and 95 μm nylon mesh filters yielded a relatively purified and homogeneous capillary suspension containing 5−20 individual endothelial cells per cluster. The isolated microvessels were cultured immediately or stored at −70 °C in culture medium to which had been added DMSO (10% v/v). Microvessels were seeded onto various surfaces at approximately 50 000 cells/cm^2 and cultured at 37 °C under 95% humidity and 5% CO_2/95% air. Culture media were changed every other day.

Transmonolayer Flux Measurements—Microvessels were seeded onto fibronectin-coated Biocoat (Becton Dickinson) cell culture inserts (fibrillar collagen matrix, 10.5 mm diameter, $A =$ 0.9 cm^2, 1.0 μm pore size, 1.6×10^6 pores/cm^2) and cultured as described above. Confluent monolayers were obtained within 9−10 days as determined visually via an inverted microscope. To provide clearance for a magnetic stir bar between the bottom of the plate well (six-well companion plate) and the microporous membrane of the insert, a 2 mm thick shim (60.0 mm diameter) was placed around the top of the well. Culture media (9.6 mL) was placed in the plate well (receiver chamber), and 0.9 mL was added to the insert (donor chamber) to maintain hydrodynamic stability. The system was allowed to equilibrate for 15 min at 37 °C in an air incubator with continuous magnetic stirring. To initiate an experiment, the media in the insert was replaced with an equivalent volume of media containing [^{3}H]- or [^{14}C]-labeled and/or nonra-

diolabeled solute(s). At selected time points, samples (100 μL) were removed from the receiver chamber and immediately replaced with an equal volume of media. After the experiment, the donor concentration was analyzed to verify its constancy (i.e., >97% of initial concentration) throughout the experiment.

In some cases, transmonolayer flux measurements were also conducted using a vertical diffusion chamber system (Corning Costar Corp., Cambridge, MA) and Snapwell inserts (Corning Costar Corp.). Brain microvessels were seeded onto the cell culture inserts, which were thinly coated with rat tail collagen (type I) cross-linked with ammonia fumes[2] and cultured as described above. The two-piece cell culture devices consisted of 12 mm diameter, 0.4 μm polycarbonate (10^8 pores/cm^2) or polyester (10^6 pores/cm^2) microporous membranes assembled in detachable rings. Confluent monolayers were typically obtained in 12−14 days, at which point the Snapwell insert ring was removed from the upper assembly and placed between the two halves of the diffusion chamber, thus minimizing cell monolayer disruption. Equal volumes (5 mL) of transendothelial assay buffer (122 mM NaCl, 25 mM $NaHCO_3$, 10 mM D-glucose, 3 mM KCl, 1.2 mM $MgSO_4$, 0.4 mM $NaHPO_4$, 1.4 mM $CaCl_2$, and 10 mM HEPES adjusted to pH 7.4 with NaOH)[1] were placed in both the donor (side facing the monolayer) and receiver sides. The chamber temperatures were maintained at 37 °C with a water-heated metal block. Both chambers were mixed using a 5% CO_2/95% O_2 airlift. After 15 min of equilibration, the donor chamber was spiked with 0.5 mL buffer containing [^{3}H]- or [^{14}C]-labeled and/or nonradiolabeled solute(s). An equal volume of assay buffer was simultaneously added to the receiver chamber. Aliquots (100 μL) of the receiver solution were removed at various times along with equal volumes from the donor solution to maintain constant hydrostatic pressure.

Apparent permeability−area products ($P_{app}A$) were obtained from the slopes of linear plots of permeant flux into the receiver compartment versus time, $\Delta M_R/\Delta t$, where ΔM_R ($= \Delta C_R V_R$) is the change in permeant mass over a given time interval,Δt, using the following relation:

$$P_{app}A = (\Delta M_R/\Delta t)/(C_D - C_R) \cong (\Delta C_R V_R/\Delta t)/C_D \qquad (1)$$

where C_R was the concentration in the receiver and C_D was the donor concentration. Constant donor concentrations and sink conditions, respectively, were maintained (i.e., $C_D - C_R \approx C_D$) by ensuring that less than 10% mass transfer occurred over the time of the assay and by using large buffer volumes (V_R) in the receiver chamber.

Monolayer permeability−area products, $P_{monolayer}A$, were determined from the following relationship:

$$1/P_{app}A = 1/P_{monolayer}A + 1/P_{insert}A \qquad (2)$$

where permeability−area values for the collagen-coated insert ($P_{insert}A$) were measured independently. Monolayer permeability coefficients, $P_{monolayer}$, were then obtained by dividing $P_{monolayer}A$ by the surface area of the insert (i.e., $A = 0.9$ cm^2, Biocoat system; $A = 1.13$ cm^2, Snapwell system). $P_{monolayer}$ includes contributions from both paracellular and transcellular flux of solute across the cell monolayer (i.e., $P_{monolayer} = P_{paracellular} + P_{transcellular}$).

Monolayer Uptake Experiments—Rat tail collagen (type I) was attached to tissue culture dishes (35 × 10 mm^2) with a cross-linking reagent, 1-cyclohexyl-3-(2-morpholinoethyl)carbodiimide-metho-*p*-toluenesulfonate (Aldrich) to provide a uniform and durable surface for cell attachment and growth that would withstand multiple media changes and the wash procedure.[7] Brain microvessels were seeded onto the treated dishes, and confluent monolayers were obtained 8−10 days after initial plating. Uptake was initiated by the addition of fresh culture media containing [^{3}H]- and/or [^{14}C]-labeled or nonradiolabeled compounds (sucrose, mannitol, urea, and zidovudine at donor concentrations of 1×10^{-6}, 2.1×10^{-7}, 5.1×10^{-5}, and 5.4×10^{-3} M, respectively). At selected times, uptake was terminated by the rapid (~1 s) removal of uptake solution using a pipettor followed by a series of washes (50 mL per wash) with ice-cold Dulbecco's phosphate-buffered saline solution (pH 7.4). Dishes were immersed repeatedly (4 times) in wash solution and gently agitated (5 s per wash). (Validation experiments using urea and zidovudine detected no change in cellular content after the first wash.) Cells were solubilized with 1 N NaOH (15 min at room temperature) and neutralized with an equivalent volume of 1 N HCl, and aliquots were analyzed for both permeant and protein content.

The mmoles solute per mg protein ($M(t)$) in each monolayer versus time (one monolayer per time point) were recorded. $M(t)$ includes potential contributions from both intracellular ($M_{monolayer}(t)$) and any residual extracellular or surface bound permeant (M_i) remaining after the washing procedure. Assuming that intracellular uptake is due to simple passive diffusion, the mass of permeant in the monolayer can be described by the following equation:

$$M(t) = M_{monolayer}(t) + M_i = C_D V_{monolayer}(1 - e^{-k_p t}) + M_i \qquad (3)$$

where the monolayer volume per mg protein is $V_{monolayer}$, k_p is the apparent first-order rate constant governing cell uptake ($k_p = P_{membrane}A_{monolayer}/V_{monolayer}$), and C_D is the donor concentration of permeant. Experimental uptake versus time profiles were fit by nonlinear least-squares regression analysis to obtain estimates of $V_{monolayer}$, k_p, and M_i.

Values of k_p for metabolizable compounds (i.e., glycerol and acetamide) were obtained from initial rates of cell uptake at glycerol donor concentrations of 2.9×10^{-7} and 1.0×10^{-3} M and acetamide donor concentrations of 0.9×10^{-6} to 1.6×10^{-5} M. Intracellular concentrations of permeant ($C_{monolayer}(t)$) were calculated by dividing the intracellular mass (mmole/mg protein) by $V_{monolayer}$ (7.2 μL/mg protein, determined above from the nonmetabolized permeants). Plots of concentration vs time for these permeants were fit to eq 4 by linear least-squares regression

$$C_{monolayer}(t) = k_p C_D t + C_i \qquad (4)$$

analysis to obtain the first-order rate constants for simple passive diffusion, k_p. Values of k_p for urea were also determined by this method over a concentration range of nearly 4 orders of magnitude (2×10^{-5} to 0.1 M) to compare the two kinetic methods and to examine the concentration dependence of the cellular uptake of urea.

Analytical Methods—Samples containing [^{3}H]- and/or [^{14}C]-radionuclides were diluted with liquid scintillation cocktail (Opti-Fluor) and analyzed with a Beckman LS 1801 scintillation counter. Samples containing zidovudine were quantified with a modular reversed-phase HPLC system (Supelcosil LC-18-S analytical column) with UV detection at 254 nm. The mobile phase consisted of 15% acetonitrile in phosphate buffer (pH = 7.4, $I = 0.02$). Protein content for each monolayer was determined by the Lowry method.[8]

Statistical and Regression Analyses—Statistical significance was determined using either a one-tailed or two-tailed Student's *t* test for unpaired data. Values were determined to be significantly different when $P \leq 0.05$. Nonlinear least-squares regression analysis was performed using a computer and commercially available software (SCIENTIST, MicroMath, Salt Lake City, UT).

Results And Discussion

Isolation and Culture of Cerebrovascular Endothelial Cells—The isolation and culture of cerebral microvascular endothelial cells have led to the development of in vitro models designed to rapidly and conveniently examine various aspects of BBB function.[2,9−11] Primary cultures of these cells retain many characteristics of their cerebral counterparts, including specific BBB and endothelial "markers", the absence of fenestrae, few micropinocytotic vesicles, an abundance of mitochondria, and well-developed junctional complexes.[1,2,12−14]

Bovine cerebral microvessels were isolated and characterized as described previously.[15] When seeded onto collagen-coated microporous surfaces, these cells showed excellent attachment and growth, with confluent monolayers forming within 8−10 days. Monolayers completely covered the insert, including along the edges, when examined microscopically and exhibited the characteristic spindle-shaped morphology described in the literature.[1,13] Furthermore, the permeability coefficients of polar permeants

frequently used as paracellular markers (e.g., sucrose and mannitol) were comparable to those reported in the literature.[1,16,17]

To establish that the in vitro culture system is a useful model system for predicting in vivo BBB permeability coefficients for passively diffusing polar permeants, it is essential that the in vitro model exhibit comparable barrier properties and similar selectivity to permeant structure (e.g., lipophilicity) as that observed in vivo. As demonstrated below, monolayers of cultured endothelial cells are too leaky and therefore provide neither the barrier properties nor the selectivity to polar permeant structure found in vivo.

Transmonolayer Flux Measurements—To evaluate the reliability of transmonolayer flux measurements for predicting in vivo brain uptake rates of passively diffusing polar permeants, several model permeants, listed in Table 1, were selected for transmonolayer experiments. The compounds chosen had molecular weights <400 daltons and varied in lipophilicity as measured by $PC_{octanol/water}$ by nearly 4 orders-of-magnitude. With the exception of zidovudine, the permeants employed, namely, sucrose, mannitol, glycerol, urea, and acetamide, have been used in numerous cerebrovascular permeability studies in vivo or in situ in which their transfer across the BBB was shown to occur via simple passive diffusion.[18,19] Zidovudine has also been shown to cross monolayers of bovine capillary endothelial cells primarily via passive diffusion,[20] although there is substantial evidence that its in vivo brain efflux is at least partially carrier-mediated.[20–23] Zidovudine's stability in endothelial cell homogenate made it a useful model permeant for this study, and its inclusion extended the range of lipophilicity explored, as measured by $PC_{octanol/water}$, to 4 orders-of-magnitude (~10^{-4} to 1).

Plots of % of permeant in the receiver compartment ($100 \cdot C_R/C_D$) versus time for two representative permeants, mannitol and acetamide, in control (collagen-coated insert only) and transmonolayer flux experiments are shown in Figure 1. In all experiments, sink conditions were maintained, and consequently, linear profiles were observed, as demonstrated in Figure 1. As shown in Figure 1, fluxes across inserts containing monolayers were significantly ($P \leq 0.05$) smaller than those across inserts without monolayers, indicating the presence of additional barrier function due to the monolayers. Least-squares regression analyses of the permeability data were performed to obtain permeability coefficients for the inserts (P_{insert}) and for the monolayer/insert combinations (P_{app}), as displayed in Table 1. Transmonolayer permeability coefficients ($P_{monolayer}$), also shown in Table 1, were then obtained using eq 2 and the surface area of the insert.

log $P_{monolayer}$ values generated in Table 1 are plotted in Figure 2 versus log $PC_{octanol/water}$ for each of the six permeants. The dashed line in Figure 2 represents the in vivo relationship between the logarithm of the BBB permeability coefficient and log $PC_{octanol/water}$ according to eq 5,

$$\log P_{BBB} = -2.14 + \log PC_{octanol/water} \qquad (5)$$

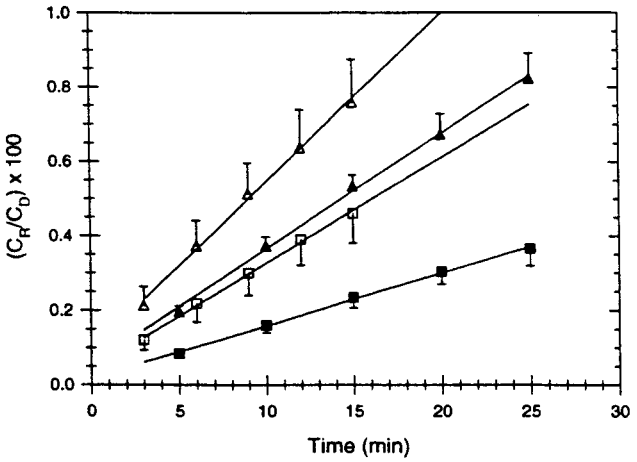

Figure 1—Representative transmonolayer flux ($100 \cdot C_R/C_D$) profiles of mannitol (squares) and acetamide (triangles) across cell culture inserts with (filled symbols) and without (open symbols) confluent monolayers attached. Each time point represents the mean ± SD of 2 or 3 individual experiments. The two solutes were present as a mixture. Donor concentrations of mannitol and acetamide were 8.9×10^{-8} and 3.1×10^{-5} M, respectively.

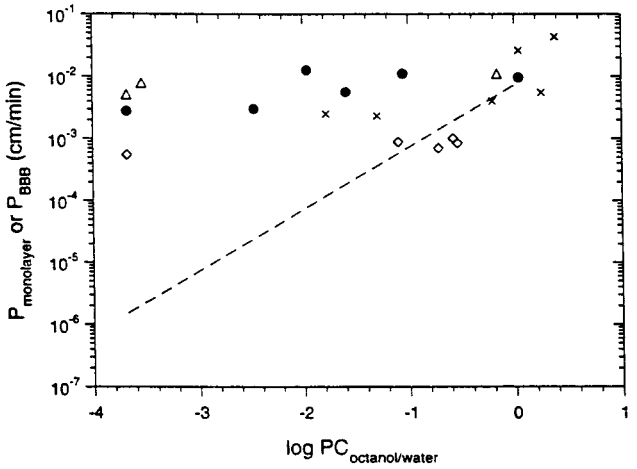

Figure 2—Semilogarithmic plots of $P_{monolayer}$ versus log $PC_{octanol/water}$ for polar permeants having log PC values less than one. Results are from several laboratories, including this one (●); van Bree et al. (x);[3] Pardridge et al. (△);[4] and Glynn and Yazdanian (◇).[24] The dashed line is adapted from the literature regression line for BBB permeability–area product in vivo from Fenstermacher.[6]

which was adapted from the regression line for the logarithm of BBB permeability−area product versus log $PC_{octanol/water}D_m$ published by Fenstermacher[6] by assuming a BBB surface area of 240 cm^2/g of brain tissue and a permeant diffusion coefficient (D_m) of 1×10^{-5} cm^2/s. The literature regression line was based on in vivo BBB permeability data for a variety of permeants, including some from this study. It applies to approximately the same lipophilicity range as that covered in Table 1. As is evident in eq 5 and from the dashed line in Figure 2, the passive permeability of similarly sized polar permeants across the BBB in vivo appears to depend approximately linearly on $PC_{octanol/water}$ (i.e., the slope of log P_{BBB} versus log $PC_{octanol/water}$ is ~1). This is the primary evidence for the conclusion by Fenstermacher[6] that passage across the BBB is transcellular, even for solutes as polar as sucrose. In stark contrast, the log $P_{monolayer}$ values exhibit virtually no dependence on log $PC_{octanol/water}$ within the range of lipophilicities explored, suggesting that the transmonolayer transfer of these solutes is mainly via a paracellular route (i.e., through leaks in the monolayer).

Because the extent of tight junction formation may vary with isolation technique, culturing conditions, etc., the results from several studies of the transmonolayer passage of low molecular weight permeants (log $PC_{octanol/water} < 1$) are also displayed in Figure 2, including data published by van Bree et al.,[3] Glynn and Yazdanian,[24] and Pardridge et al.[4] These data similarly show virtually no dependence of transmonolayer permeability on permeant lipophilicity for compounds having a log $PC_{octanol/water} < 1$. Again, paracellular diffusion appears to predominate in these experiments.

Several investigators have observed that the barrier properties of endothelial cell monolayer cultures can be better maintained by coculturing with astrocytes[25−27] or with a combination of astrocyte-conditioned media and treatment with agents that elevate cyclic AMP.[28] Raub, for example, was able to demonstrate that noncontact coculture of postconfluent bovine brain cerebral capillary endothelial cell monolayers with rat C_6 glioma cells reduced $P_{monolayer}$ for sucrose from 1.47×10^{-3} cm/min in primary cultures to 7.7×10^{-4} cm/min. An additional decrease to 1.5×10^{-4} cm/min was acheived with adenylate cyclase activators.[27] Dehouck et al. reported a sucrose permeability coefficient of 6.3×10^{-4} cm/min for monolayers in coculture.[25,29] These investigations indicate that some progress is evident in terms of improving barrier integrity by coculturing, but a comparison of these sucrose values with those shown in Figure 2 indicates that they are still orders-of-magnitude above the in vivo regression line.

Monolayer Uptake Experiments—Rate constants for permeant uptake into capillary endothelial cell monolayers (k_p), which reflect the product of the membrane permeability coefficient, P_m, and monolayer surface-area-to-volume ratio (i.e., $k_p = P_m A_{monolayer}/V_{monolayer}$), were determined by measuring the accumulation of permeant in confluent monolayers after normalizing for the protein content in each monolayer.

Displayed in Figure 3 are plots of % uptake ($100 \cdot M(t)/M_{monolayer}(\infty)$) versus time for the nonmetabolizable permeants sucrose, mannitol, urea, and zidovudine, along with the fitted curves obtained using eq 3. Independent estimates of monolayer volume, normalized to protein content, were obtained from each permeant as listed in Table 2. These estimates were not significantly different from each other as judged by their 95% confidence intervals and were therefore combined to give an average value of 7.2 ± 1.1 (SEM) μL/mg protein, which, given an average protein content of 0.17 ± 0.01 (SEM) mg protein per monolayer corresponds to an intracellular volume in the monolayer of ~1.2 μL.

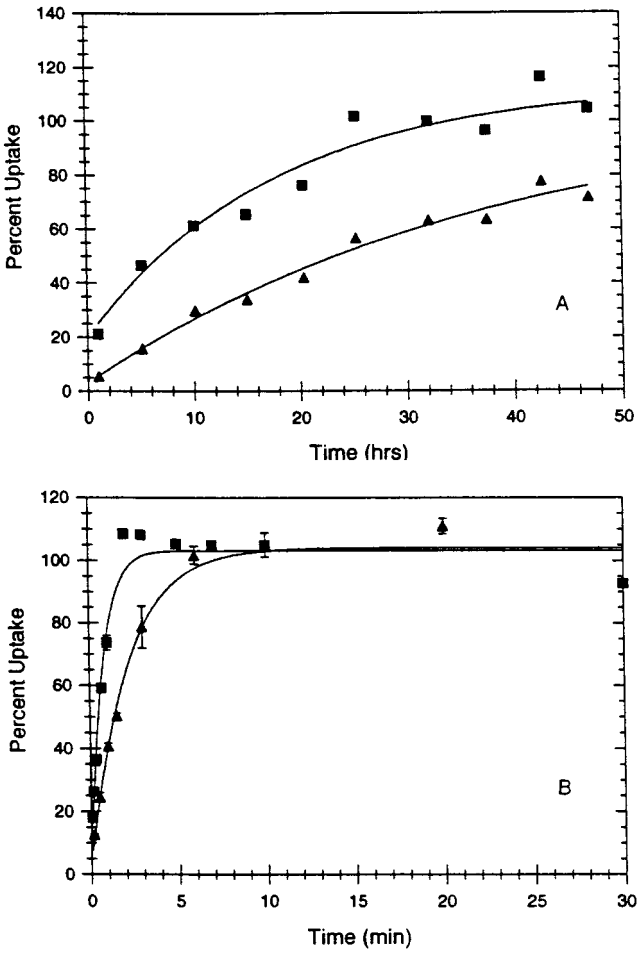

Figure 3—Percent uptake versus time profiles for (a) sucrose (▲) and mannitol (■) and (b) zidovudine (■) and urea (▲) into brain capillary endothelial cell monolayers. Each point represents an individual monolayer incubated at 37 °C for a given period of time in the presence of 1 mL of culture media containing 1.0×10^{-6} M sucrose, 2.1×10^{-7} M mannitol, 5.4×10^{-3} M zidovudine or 5.0×10^{-5} M urea, washed, and lysed for analysis. Values for urea (mean ± SD) represent duplicate measurements at each time point.

Table 2—Parameters Obtained from Monolayer Uptake Experiments for Various Polar Permeants

permeant	$V_{monolayer}$[a] (μL/mg protein ± SD)	k_p ($min^{-1} \times 10^3$ ± SD)	$t_{1/2}$ (min)
sucrose	7.2 ± 1.1	0.45 ± 0.05[a]	1540
mannitol	7.9 ± 0.8	0.85 ± 0.27[a]	815
urea	5.6 ± 0.3	453 ± 55[a] 373 ± 13[b] ($n = 6$)	1.6
glycerol	N/D	155 ± 7[b] ($n = 2$)	4.5
acetamide	N/D	645 ± 347[b] ($n = 3$)	1.1
zidovudine	7.9 ± 0.7	1175 ± 268[a]	0.59

[a] Parameters determined from computer fits of the uptake versus time profiles to eq 3. [b] Parameters determined from computer fits of initial uptake rates to eq 4.

Intercepts in these plots reflect the residual percentage of permeant in cells at zero time due to extracellular or cell-surface-bound permeant remaining after the wash procedure. This residual percentage was <5% in all cases except for mannitol, where it was 18.5%. However, in every case, including that of mannitol, the residual percentage was not significantly different from zero as judged by the 95% confidence range.

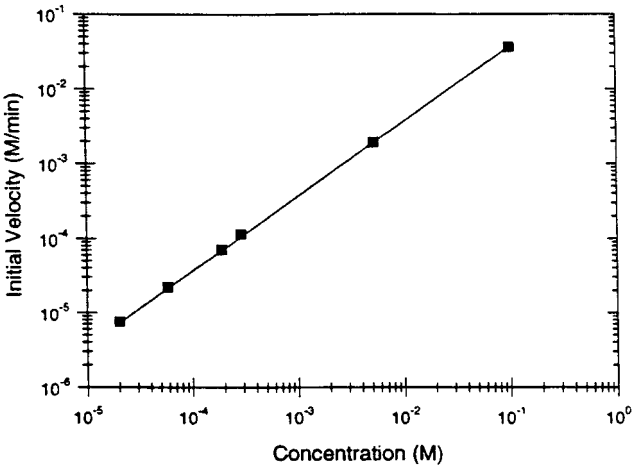

Figure 4—Dependence of initial rate of urea uptake into brain capillary endothelial cell monolayers on urea concentration. The solid line represents the fit using eq 4.

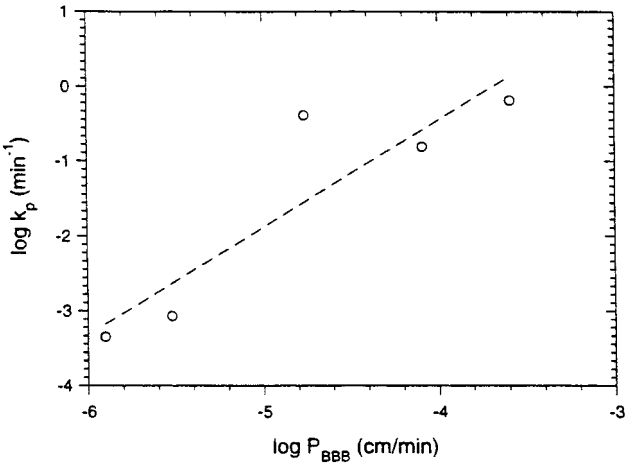

Figure 5—Relationship between log k_p for uptake into brain capillary endothelial cell monolayers to log P_{BBB} from published in vivo data.

As evident in Figure 3a,b, concentrations of permeant in the monolayer appeared to reach equilibrium at distinctly different times. Zidovudine and urea attained apparent equilibrium within approximately 4 and 10 min, respectively, whereas the more hydrophilic molecules mannitol and sucrose took >24 h to approach a constant intracellular concentration. Indeed, the monolayer accumulation of sucrose had not yet achieved a steady-state concentration after 48 h when the study was terminated. In contrast to the similar $P_{monolayer}$ values obtained in transmonolayer experiments, calculated values of k_p for each permeant obtained from these plots (Table 2) vary by >3 orders-of-magnitude from the slowest (sucrose) to the most rapidly permeating compound (zidovudine).

In addition to the % uptake versus time profiles in Figure 3a,b, initial rates of uptake were determined for urea over a concentration range of 2×10^{-5} to 0.1 M. Initial velocities were obtained from the slopes of plots of urea concentration in monolayers versus time as described by eq 4. These velocities, plotted versus urea concentration in Figure 4, demonstrate a linear relationship between rate of uptake and urea concentration consistent with uptake via passive (nonsaturable) diffusion. The first-order rate constant for urea uptake obtained from these data (Table 2) compared favorably with that obtained from the % uptake versus time profile in Figure 3b, thus validating the initial rate method for obtaining k_p values.

The initial rate method was employed to obtain k_p values for glycerol and acetamide after preliminary experiments suggested intracellular metabolism was occurring. Linear uptake kinetics were observed in the initial rate region for both permeants, consistent with eq 4, allowing the k_p values listed in Table 2 to be determined from linear least-squares regression analysis. The mean value for glycerol reflects initial rate studies conducted at concentrations of 2.9×10^{-7} and 1.0×10^{-3} M, which yielded k_p values of 0.16 and 0.15 min^{-1}, indicating that uptake of glycerol was concentration-independent over this range.

All of the above results are consistent with a passive diffusion uptake mechanism. The adherence of the uptake curves in Figure 3a,b to a passive uptake model, the absence of concentration dependence in the initial rates of uptake of glycerol and urea, and the dramatic differences in k_p values, which qualitatively appear to be sensitive to permeant size and lipophilicity, support a passive diffusion mechanism. Estimates of monolayer volume were independent of the permeant employed to obtain the estimate for nonmetabolizable compounds, again consistent with passive diffusion.

The k_p values for monolayer uptake are related to the membrane permeability coefficient of each permeant ($k_p = P_m A_{monolayer}/V_{monolayer}$). Therefore, these values would be expected to correlate with in vivo BBB permeability coefficients, provided that brain uptake in vivo is also passive for these permeants. Figure 5 displays the log k_p values from this study plotted versus the average log P_{BBB} values determined in vivo. The in vivo results for sucrose, mannitol, and urea were obtained from a compilation by Fenstermacher;[6] the glycerol value was the average of data from publications by Fenstermacher and Rapoport[18] and Takasato et al.;[30] and the acetamide literature value was from Rapoport et al.[19] Zidovudine was not included in this comparison because carrier-mediated processes have been implicated in its in vivo brain uptake/efflux.[20,21,31] The dashed line in Figure 5 represents the least-squares fit to the data, which yielded a slope not significantly different from one and an excellent correlation (slope = 1.4 ± 0.4; r = 0.90). There appears to be some size-dependent permeability behavior manifested more strongly in monolayer uptake than in vivo, as evident in the deviation of the k_p for urea, the smallest permeant examined, from the regression line. Why a larger size dependence would exist in the endothelial cell monolayers than in the cerebrovascular system in vivo is not known, if indeed it is the size of urea that accounts for the difference.

In conclusion, transmonolayer flux measurements appear to be poor predictors of blood−brain barrier passage in vivo for polar, small molecule permeants (log $PC_{octanol/water}$ < 0), as transmonolayer permeability coefficients lack the sensitivity to permeant lipophilicity that is observed in vivo. This reflects the predominantly paracellular passage of polar permeants across brain endothelial cell monolayers. However, monolayer uptake kinetics of several polar permeants were found to be highly dependent on permeant lipophilicity and well correlated with in vivo BBB permeability coefficients, with a slope in the plot of log k_p versus log P_{BBB} near one. This preliminary investigation suggests that uptake studies into cerebral capillary endothelial cell monolayers may be superior to transmonolayer flux measurements for probing the role of simple passive diffusion in the passage of polar permeants across the blood−brain barrier. Additional studies are underway to assess the utility of the monolayer uptake method for predicting the in vivo BBB permeability of dideoxynucleoside anti-HIV agents which may also undergo intracellular metabolism during their passage across the BBB.[15]

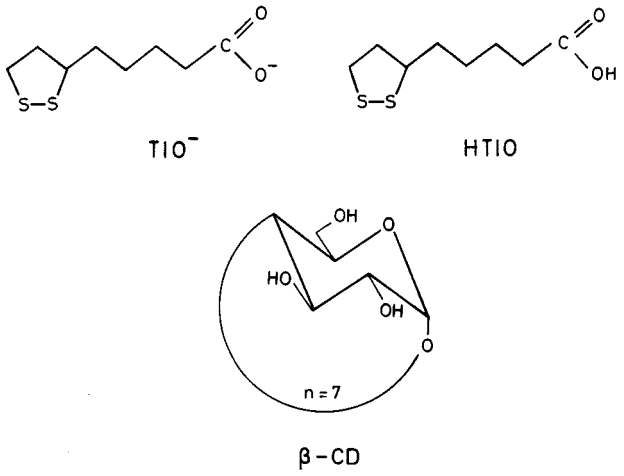
Abstract □ Spectroscopic and thermodynamic studies of the binding of a hepatoprotectant drug, thioctic acid, by β-cyclodextrin (β-CD) have been carried out using UV–vis and pH potentiometric measurements. The UV–vis spectra and the pH of the aqueous solutions of the drug were measured (i) as a function of total drug concentration in the absence of cyclodextrin, and (ii) as a function of cyclodextrin concentration at constant drug concentration. The spectroscopic study was done at pH = 7 and 25 °C, while the potentiometric study was performed at several temperatures ranging from 15 to 40 °C. From the spectroscopic data, the molar absorption coefficient, ϵ, for the pure drug in aqueous media and the stoichiometry of the inclusion complex with β-CD were determined. The dissociation constant, K_a, of the pure drug (which is a weak acid), and the association constants of the complexes formed by β-cyclodextrin and both the nonionized (HTIO) and ionized (TIO^-) forms of the drug, have been simultaneously determined at several temperatures from the pH data, without the necessity of working with buffered solutions. The nonionic forms are complexed by the β-CD with higher affinity than their ionic counterparts. From the dependency of the association constants on temperature (van't Hoff analysis), the inclusion complexes formed by HTIO or TIO^- and the β-CD were found to be enthalpy driven, with a favorable enthalpic term dominant over an unfavorable entropic term. Both contributions were found to show a possible dependence with temperature ($\Delta C_p^0 \neq 0$). This pattern may reveal the contribution of van der Waals interactions, hydrophobic effect, and solvent reorganization as the main driving forces promoting the complexation.

Introduction

The use of cyclodextrins as a new family of pharmaceutical excipients and drug carriers[1−6] has become an increasingly successful method to improve the general bioavailability of drugs. Particularly, it is known[7−10] that CD formulations of some drugs show a better tolerance since they cause fewer adverse side effects, this effect being more acute as the duration of the treatment increases. The parent cyclodextrins (CD's) are well-known nontoxic macrocyclic sugars, with doughnut-shaped structure, consisting of α(1→4) joined glucopyranose units. As a result of their hydrophobic inner surface, CD's are the most important simple organic compounds, capable of forming noncovalently bonded inclusion complexes with a variety of drug molecules in aqueous solution.

Thioctic acid, the oxidized form of α-lipoic acid (see Scheme 1), is hepatoprotectant drug used in the treatment of liver disease and as an antidote to poisonous mushrooms. It is expected that the formulation of this drug as a CD:



Scheme 1

Drug inclusion complex may help to avoid the undesirable side effects which the administration of the drug alone may provoke, thus improving its therapeutic usefulness. Structural information, such as the stoichiometry and geometry of the complex, and thermodynamic information, such as the association constant ($K_{CD:DRUG}$) and the change on the enthalpy ($\Delta H°$), entropy ($\Delta S°$), and heat capacity ($\Delta C_p°$) of binding, are necessary to draw a complete picture of the driving forces governing the CD−drug interaction. It is generally accepted[11−15] that a balance between van der Waals contacts and hydrophobic and solvent effects is mainly responsible for the overall stability of the complex.

Our group has examined the encapsulation of antiinflammatory and analgesic agents[14−18] by a series of β-cyclodextrins. These drug molecules and thioctic acid have a common characteristic: the presence of an acidic functional group. Thus, in aqueous solution both the ionized and the nonionized forms of the drug can be encapsulated by the cyclodextrin. There are two possible methods for studying the associations of these species with the CD: (i) follow the change in a physicochemical property (i.e., solubility, absorbance, fluorescence intensity, etc.) as a function of cyclodextrin concentration, but fixing the pH of the aqueous drug solution under conditions where only one of the two species is present; or (ii) directly monitor the pH of the aqueous unbuffered solution of the drug as the CD is added. In this work, we study the encapsulation of thioctic acid by β-cyclodextrin[19] in aqueous media by both methods: examination of the buffered drug solution (pH = 7) by UV−vis spectroscopy, and determination of pH of the unbuffered drug solutions in the absence and in the presence of β-CD by potentiometry. The spectroscopic study was performed at 25 °C, while the potentiometric experiments were carried out at temperatures from 15 °C to well above the temperature of human body (40 °C). We expect that the results of this work will show the strength of the potentiometric

method for characterizing the inclusion complexes formed by CD and the nonionized and ionized forms of an acid/base pair.

Experimental Section

Materials—DL-1,2-Dithiolane-3-pentanoic acid, named as DL-6,8-thioctic acid, and β-cyclodextrin, with purities higher than 99%, were purchased from Sigma and used without further purification. β-Cyclodextrin has been found through a thermogravimetric analysis to consist of 11% of mass water content, which was considered in the calculations of solute concentrations. All the solutions were prepared with distilled and deionized water (taken from a Millipore Super-Q System, with a conductivity lower than 18 $\mu\Omega^{-1}$ cm^{-1}). The initial solutions were brought to homogeneity by sonicating them for 3 h in an ultrasonic bath. The buffer at pH = 7, used in the UV−vis experiment, was a standard Metrohm NaH_2PO_4/Na_2HPO_4 buffer solution.

UV−vis Measurements—The UV−vis spectra of aqueous buffered solutions (pH = 7) of thioctic acid, in the absence and in the presence of β-CD, were recorded at 25 °C with a Varian Cary 5G double beam UV−vis−NIR spectrophotometer from 260 to 500 nm with 1 nm intervals. The equipment was connected to a PC Pentium via a IEEE-Bus interface. Data acquisition and analysis of UV−vis spectra were performed with the software supported by the manufacturer. Two 10 mm, stoppered, rectangular silica UV cells (sample and reference cells) were placed in a stirred cuvette holder, whose temperature was kept constant at 25.00 ± 0.05 °C with a recirculating water bath. The scan rate was selected in all the cases as 300 nm/min. On the experiments with the drug−water binary systems, the thioctic acid concentration was varied from 0.0 to 5.8 mM, while for the CD−drug−water ternary systems, the thioctic acid concentration was kept constant at 4 mM, and β-CD concentration was varied from 0.0 to 4.5 mM, both in the sample and in the reference cells.

pH Potentiometric Measurements—Potentiometric data were collected with a Metrohm 713 Ion Meter (sensitivity of ± 0.001 units), using a combined glass electrode containing 3 M KCl as reference electrolyte solution. The adjustment of both the asymmetry potential and the Nernst slope of the combined glass electrode was made by daily calibration of the electrode with three Metrohm buffer solutions of pH = 1, 4, and 7, at each working temperature. The equipment and the fully computerized experimental procedure used on the pH determination were described previously.[14] The accuracy on the molarity of the solutions is better than 0.1%, and the temperature is held constant within ±0.001 K. The statistical average of 250 pH measurements for each concentration allow us to improve the reproducibility of the pH data by up to 60%, with respect to that reported by the manufacturer. In these experimental conditions, the pH measurements were made (i) as a function of thioctic acid concentration, in the absence of β-CD; and (ii) as a function of cyclodextrin concentration, keeping the drug concentration at 1 mM. The cyclodextrin concentration ranges were chosen to cover at least 80% of the saturation curve in order to guarantee a proper binding constant determination.[20]

Results and Discussion

An aqueous solution of thioctic acid in the presence of cyclodextrin may include the equilibria shown in Scheme 2, where K_a is the dissociation constant of HTIO, and $K_{CD:HTIO}$, $K_{CD_2:HTIO}$, $K_{CD:TIO^-}$ and $K_{CD_2:TIO^-}$ are the association constants of the 1:1 and 2:1 inclusion complexes formed by the β-CD and the acid and base forms of thioctic acid, respectively. From geometrical considerations and also from previous studies[2−5] of similar systems, 1:2, 2:2, and/or even CD:drug complexes with higher stoichiometries are not expected.

The equilibrium constants can be expressed as a function of the activities of the species, as follows:

$$K_a = (a_{H^+}a_{TIO^-})/(a_{HTIO}) \quad (1)$$

$$K_{CD:HTIO} = (a_{CD:HTIO})/(a_{CD}a_{HTIO}) \quad (2)$$

$$K_{CD:TIO^-} = (a_{CD:TIO^-})/(a_{CD}a_{TIO^-}) \quad (3)$$

$$K_{CD_2:HTIO} = (a_{CD_2:HTIO})/(a_{CD:HTIO}\, a_{CD}) \quad (4)$$

$$K_{CD_2:TIO^-} = (a_{CD_2:TIO^-})/(a_{CD:TIO^-}\, a_{CD}) \quad (5)$$

The constants K_a' and K_a'' are related to the others through simple expressions. The study reported in this work focuses on the determination of these equilibrium constants.

Thioctic Acid−Water System—It is of crucial importance, when studying the association of an acid/base pair with CD's, to measure the pK_a of the acid in order to know at which pH the presence of one of the two possible species in solution is negligible. For that purpose, the pH of the aqueous solutions of thioctic acid was measured as a function of drug concentration at 25 °C (Figure 1). From a nonlinear regression analysis (NLR)[14] of these pH data, which works with eq 1, the value of K_a for thioctic acid is 1.51×10^{-5} at 25 °C (pK_a = 4.82). Thus, in agreement with

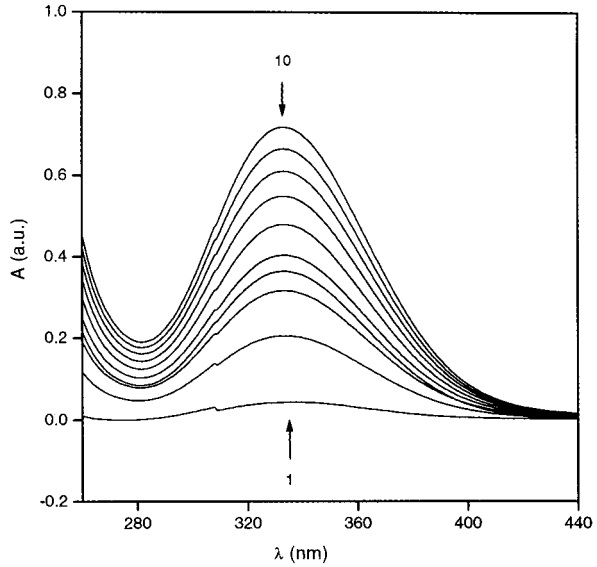

Figure 2—UV–vis spectra of aqueous solutions of thioctic acid at different concentrations, in the absence of cyclodextrin, at 25 °C and pH = 7: **1**, 0.39 mM; **2**, 1.23 mM; **3**, 2.23 mM; **4**, 2.90 mM; **5**, 3.03 mM; **6**, 3.70 mM; **7**, 4.30 mM; **8**, 4.84 mM; **9**, 5.32 mM; **10**, 5.76 mM.

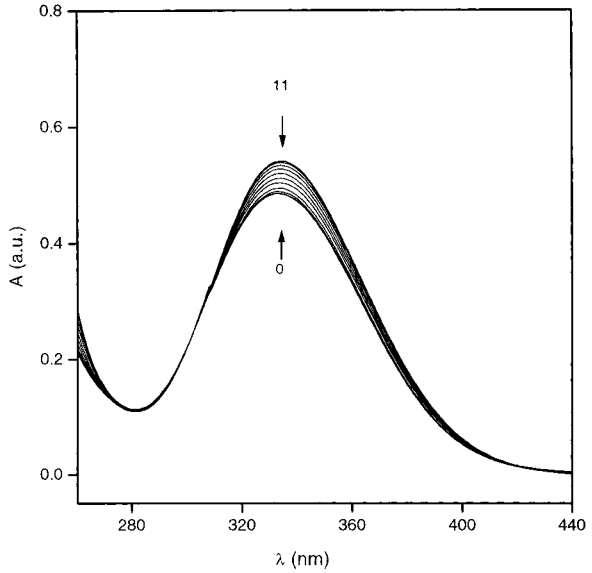

Figure 3—UV–vis spectra of an aqueous solution of thioctic acid at constant concentration (4 mM), 25 °C and pH = 7, in the absence and presence of different concentrations of β-CD: **0**, 0.00 mM; **1**, 0.12 mM; **2**, 0.35 mM; **3**, 0.77 mM; **4**, 1.34 mM; **5**, 1.94 mM; **6**, 2.52 mM; **7**, 3.10 mM; **8**, 3.62 mM; **9**, 4.10 mM; **10**, 4.53 mM.

what we have previously demonstrated,[17] the contribution of the nonprotonated (TIO^-) and protonated (HTIO) species of thioctic acid is negligible at only at pH $\leq$ 2.8 and pH $\geq$ 6.8, respectively. With this conclusion in mind, the UV–vis spectra of aqueous solutions of thioctic acid, buffered at pH = 7, were recorded at 25 °C for different drug concentrations, ranging from 0.0 to 5.8 mM (Figure 2). It can be observed that the spectra show a peak centered at λ_{max} = 333 nm, with absorbance values increasing with drug concentration, following a typical Lambert–Beer behavior. From the linear regression of the A vs [drug] values, the molar absorption coefficient, ϵ, was determined at different wavelengths. At λ_{max} = 333 nm, ϵ = 125 M^{-1} cm^{-1} (fit correlation = 0.99997), in concordance with literature values.[21,22] The experiment at pH = 1, where the nonionized form of the drug (HTIO) is the unique species in solution, was not performed since the absorbance values recorded at λ_{max} were extremely low (A < 0.1 within the whole concentration range).

Thioctic Acid-β-CD-Water System—*UV–vis Results*—Figure 3 shows the UV–vis spectra of a buffered solution of thioctic acid (pH = 7) at a constant concentration of 4.0 mM and 25 °C, at various β-CD concentrations ranging from 0.0 to 4.5 mM. As can be seen in the figure, the spectra show a peak centered at λ_{max} = 333 nm, with two isosbestic points at 300 and 420 nm, which indicate a 1:1 stoichiometry of the β-CD:TIO^- inclusion complex.[23] Although the spectroscopic characteristics of a system are known to be affected by the pH of the media, the geometry of the complex is not expected to change. Thus, once the 1:1 stoichiometry was found at pH = 7, it was assumed at pH = 1 as well. The addition of β-CD results in an increase in the absorbance intensity of the peak at 333 nm, but does not cause a shift in λ_{max}. However, the maximum change in A (ΔA_{max} = 0.06) was so small that the association constant $K_{CD:TIO^-}$ could not be determined accurately by fitting the experimental data to the well-known UV binding isotherm.[23] This feature, often found for other CD:substrate systems,[24,25] reveals that UV spectroscopy is not sensitive enough to study the β-CD–thioctic system, or any other system where the presence of cyclodextrin does not result in a clear change in the spectroscopic properties of the drug.

pH Results—Since H^+ is one of the species involved in the equilibria shown in Scheme 2, variation of pH of an aqueous drug solution, at constant concentration, as a function of β-CD concentration can be used as an indication of the shift in the equilibria, depending on the magnitude of the association constants of eqs 1–5. Figure 4 shows the plot of the ΔpH (= pH–pH_0) values, taken as the difference between the pH of the CD–drug–water system and that of the initial drug–water system (pH_0), as a function of β-CD concentration at different temperatures ranging from 15 to 40 °C. Equations 1–5, together with the following charge and mass balances for the CD and the drug:

$$[H^+] = [TIO^-] + [CD{:}TIO^-] + [CD_2{:}TIO^-] + [OH^-] \quad (6)$$

$$[drug]_{total} = [HTIO] + [TIO^-] + [CD{:}HTIO] + [CD{:}TIO^-] + [CD_2{:}HTIO] + [CD_2{:}TIO^-] \quad (7)$$

$$[CD]_{total} = [CD] + [CD{:}HTIO] + [CD{:}TIO^-] + 2\,[CD_2{:}HTIO] + 2\,[CD_2{:}TIO^-] \quad (8)$$

permit us to obtain the equilibrium constants from the pH (= $-\log a_{H^+}$) experimental data. The fitting procedure is a NLR (nonlinear regression) method based on a Newton–Raphson and a Marquardt algorithm, widely explained elsewhere.[14] The activities in eqs 1–5 are related to the concentrations shown in eqs 6–8 through the activity coefficients, determined with the extended Debye–Hückel theory. The coefficients of the fit are the equilibrium constants we are interested in, whose values for thioctic acid are reported in Table 1 at various temperatures. The data in Table 1 lead us to some general conclusions: (i) The dissociation constant, K_a, of thioctic acid is (1.5 ± 0.1) × 10^{-5}, in excellent agreement with the value obtained from the experiment done with the thioctic–water binary system, thus confirming the appropriateness of the model. It can be observed as well that K_a does not depend on the temperature within the range of temperatures studied herein. (ii) None of the equilibrium constants of Scheme 2 are fixed to zero during the fitting procedure. The inclusion complexes formed by β-CD and HTIO or TIO^- show 1:1 stoichiometries, in agreement with UV–vis results, since $K_{CD_2:HTIO}$ and $K_{CD_2:TIO^-}$ have been found to be negligible and

always below the uncertainty of the fits. This 1:1 stoichiometry is usually found for a wide variety of drug molecules upon binding β-CD or β-CD derivatives.[2–8] (iii) The affinity of β-CD by the protonated form ($K_{CD:HTIO}$) of the drug is around 1.4 times higher at all temperatures than that of the nonprotonated form ($K_{CD:TIO^-}$). This behavior, previously reported[14–17,26–29] for other carboxylic derivatives, has been attributed to either the random character of the inclusion,[27] or the repulsive interaction between the negative charge on the ionic species and the negatively charged end of the CD dipole,[29] or the differences in the entropic balance upon binding related to the structure-breaking character of the carboxylate anions.[14] However, it is worth noting that the ratio $K_{CD:HTIO}/K_{CD:TIO^-}$ found for this system is lower than that obtained for other CD:drug systems previously studied by us,[14–17] thus justifying the lower ΔpH observed for the system reported here in, compared with that observed for the other systems. This ratio implies that the therapeutic effects of β-CD as an excipient for thioctic acid are not much affected by the pH of the medium, the % of free drug being similar either in an acid medium, for example in the stomach, or in other biological media, with higher pH. Anyway, the values of $K_{CD:HTIO}$ and $K_{CD:TIO^-}$ at body temperature fall in the range of 1700−1000 M^{-1}, which can be considered optimum values regarding the use of CD's as effective drug carriers. The confirmation of all these estimations in vivo, although out of the scope of this work, would be welcomed.

It can be observed as well in Table 1 that as the temperature increases, the affinity of the cyclodextrin for

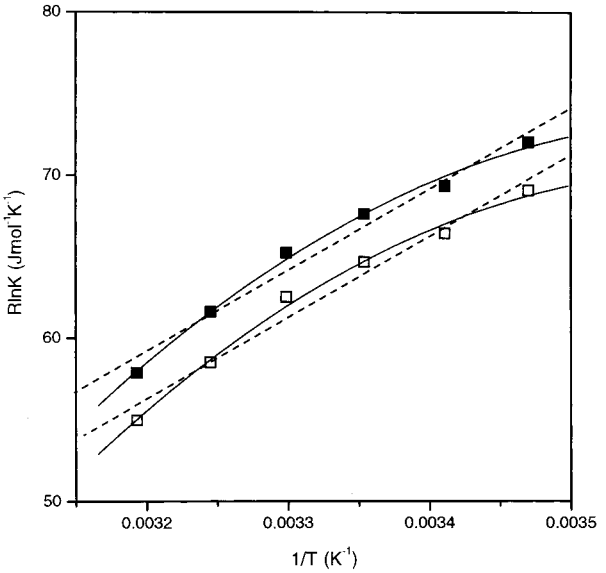

Figure 5—van't Hoff plots for the associations of β-CD with HTIO and TIO^-. Dash lines for linear fits and solid lines for nonlinear fits of eq 11.

both ionized and nonionized forms of the drug decreases. Figure 5 shows the van't Hoff plots of both association processes. A linear relationship of the R ln K vs $1/T$ data indicates the independence of $\Delta H°$ and $\Delta S°$ on T ($\Delta C_p^o \sim 0$), while the absence of such linear behavior reveals that $\Delta H°$ and $\Delta S°$ are temperature dependent, pointing to an association process with $\Delta C_p^o \neq 0$. If we assume that ΔC_p^o is temperature independent and that the dependence on temperature for ΔH and ΔS can be expressed by,

$$\Delta H = \Delta H° + \Delta C_p^o\,(T - 298.15) \quad (9)$$

$$\Delta S = \Delta S° + \Delta C_p^o \ln(T/298.15) \quad (10)$$

where 298.15 K has been taken as the reference temperature, and the thermodynamic quantities $\Delta H°$, $\Delta S°$, and ΔC_p^o at 25 °C are related to R ln K through the van't Hoff equation:

$$R \ln K = -[\Delta H° + (T - 298.15)\Delta C_p^o]/T + \Delta C_p^o \ln(T/298.15) + \Delta S^o \quad (11)$$

Equation 11 explains either the linearity or the curvature of the plots in Figure 5. When $\Delta C_p^o = 0$, eq 11 is simplified to the well-known linear relation (R ln $K = -\Delta H°/T + \Delta S°$), where $\Delta H°$ and $\Delta S°$ can be estimated from the slope and intercept of the fit, respectively. On the contrary, when $\Delta C_p^o \neq 0$, $\Delta H°$, $\Delta S°$, and ΔC_p^o can be determined by using a nonlinear regression of the experimental K values at various temperatures. We have performed both the linear and the nonlinear van't Hoff analysis of the experimental data, and both are drawn on the van't Hoff plots of Figure 5. Table 2 reports the results obtained for $\Delta H°$ and $\Delta S°$ in both cases, and for ΔC_p^o in the case of the nonlinear fit. Although the uncertainty in these results is high (up to 30%) in both the linear and the nonlinear fits, as usual for van't Hoff analysis, it can be observed in the table that both HTIO and TIO^- species bind to β-CD with a favorable enthalpic term ($\Delta H° < 0$) and an unfavorable entropic term ($\Delta S° < 0$). Both processes are exothermic and enthalpy driven ($|\Delta H°| > T\,|\Delta S°|$), as usually found[11–15,31–33] for associations between small guest molecules and an apolar cavity in water. A combination of hydrophobic effect ($\Delta H° \sim 0$; $\Delta S° > 0$), van der Waals forces

($\Delta H° < 0$; $\Delta S° < 0$), and solvent reorganization could account for such a thermodynamic pattern. It appears that the contribution of van der Waals interactions and hydrophobic effect could be similar in both inclusion processes, while the contribution of solvent reorganization could be the factor which makes the binding of β-CD and HTIO energetically more favorable than that of β-CD and TIO^-. Furthermore, although the use of the nonlinear form of the van't Hoff equation may be risky, given the uncertainty on K values, it is clear that the van't Hoff plots of Figure 5 are not straight lines, as indicated by the standard deviations of the fits. Thus, we would conclude that, within the uncertainty of the fits, a dependence of $\Delta H°$ and $\Delta S°$ on T, i.e., $\Delta C_p° \neq 0$, is an appropriate conclusion. From our data, we may say that $\Delta C_p°$ is negative, as usually found for the inclusion of apolar solutes by cyclodextrins[12,15,31] and cyclophanes,[11] and for carbohydrate association with lectins[33] in aqueous solution. Particularly, $\Delta C_p°$ values of around -2000 J mol^{-1} K^{-1} are typical of biological associations and recognition processes where hydrogen bonds and/or polar groups are present.[31−33] Assigning a value to $\Delta C_p°$, however, given the high error associated with this magnitude, would be just a speculation. Direct calorimetric results would be necessary to confirm these conclusions.

It has been demonstrated that the pH potentiometric technique, together with the model previously reported by us to determine association constants,[14] show clear advantages over the UV−vis technique for the examination of CD's complexing with ionizable guests. The advantages of this method include the following: (i) one pH−potentiometric experiment at each temperature, without buffering the solution, gives a complete thermodynamic description of the system, i.e., dissociation constant of the drug, association constants of both ionic and nonionic species of the drug with the CD, and the stoichiometry of the complex; (ii) the characterization of the CD:HTIO and CD:TIO^- complexes, not available through UV−vis measurements, may be studied from the pH−potentiometric experiments; (iii) the potentiometric technique accurately allows for the study of CD−drug systems for which the experimental properties of the drug in aqueous solution (such as the absorbance or the pH) are not very much affected by the presence or the absence of the CD. The only requirement of this method is that the association constants of the complexes formed by the CD and the nonionized and ionized forms of the guest must be neither very similar, nor very different. In the first case, the experimental ΔpH would be quite small, while in the second case the uncertainty in the highest binding constant would mask the value of the lowest binding constant.

Accepted for publication March 24, 1999.

Abstract □ *Taraxacum mongolicum* (TM), also known as dandelion, is a herb widely used in the East for its antibacterial activity. The high mineral content of TM presents a potential problem for the absorption of quinolone antibiotics. This study was undertaken to discern the significance of a drug–drug interaction between TM and ciprofloxacin. Two groups of Sprague Dawley rats (220–250 g) were employed; one received a single oral dose of ciprofloxacin (20 mg/kg) with concomitant oral administration of an aqueous TM extract (2 g crude drug/kg) while the control group received oral ciprofloxacin (20 mg/kg) only. Ciprofloxacin in plasma and urine, collected over 6 and 24 h, respectively, was determined by HPLC. Noncompartment analysis was employed for pharmacokinetic parameter estimation. Results indicated that, as compared to control, maximum plasma concentration (C_{max}) of ciprofloxacin was significantly lowered by 73% in rats receiving concurrent TM dosing. Oral TM also caused a 3-fold increase in both apparent drug distribution volume ($V_{d,\lambda z}/F$: 92.0 vs 30.8 L/kg) and terminal elimination half-life ($t_{1/2,\lambda z}$; 5.71 vs 1.96 h). Partly due to the changes in drug distribution and elimination, relative bioavailability of ciprofloxacin, as assessed by $AUC_{0\rightarrow\infty}$, remained similar for both dosing groups. These findings suggest the possibility of a multifactorial drug–drug interaction between TM and ciprofloxacin. Thus, the implications of concomitant dosing of the two agents should not be overlooked.

Introduction

Ciprofloxacin is a fluoroquinolone-type antibiotic with excellent activity against Gram positive and negative bacteria as well as Mycobacteria. Its oral absorption, however, has been shown to be drastically impaired by concomitant administration of agents containing metal cations.[1,2] This phenomenon has been extensively studied for antacids, mineral supplements, and milk products.[3] Information on such an interaction is currently unavailable for herbal medicines and health foods.

The possibility of a drug−drug interaction between ciprofloxacin and a mineral rich antiinflammatory/antibacterial herbal medicine, *Taraxacum mongolicum* Hand-Mazz. (Compositae), was investigated in this study. Traditionally, the dried whole plant of *T. mongolicum* (TM) is used for the treatment of boils, sores, mastitis, lymphadenitis, inflammation of the eye, sore throat, lung and breast abscess, acute appendictis, jaundice, and urinary tract infections.[4,5] In addition, this herb has been shown to exert a bactericidal effect on numerous pathogens showing ranges of MIC from 1:10 to 1:640 with its aqueous extract.[4] In addition, in vitro antifungal, antileptospiral, and antiviral effects of the herb have also been documented.[4] Chemical investigation of TM indicates the presence of triterpenoids (e.g., taraxasterol, taraxacin, taraxarol), inulin, pectin, asparagin, and phenolic compounds.[4,6] To collect more definitive information, the content of metal cations in dried TM was independently measured. A full pharmacokinetic evaluation was conducted in the rat to elucidate the potential of a drug−drug interaction, if any, between TM and ciprofloxacin.

Experimental Section

Plant Materials—The whole dried plant of *T. mongolicum* (TM) was purchased from a local herbal shop and was authenticated by macroscopic examination and microscopic identification in the Pharmacognosy Laboratory, Department of Pharmacy, The Chinese University of Hong Kong, where the voucher specimen (TM01) was deposited. For the preparation of the aqueous TM extract used in animal studies, the powdered crude plant material (5 g) was treated with boiling deionized and distilled water (50 mL) for 1 h, and the extract was evaporated to a concentration equivalent to 0.5 g crude drug/mL.

Chemical Reagents and Apparatus—Ciprofloxacin hydrochloride was kindly provided as a gift by Bayer AG (Leverkusen, Germany). The internal standard, enoxacin, was purchased from Sigma Chemical Co. (St. Louis, MO). Acetonitrile (HPLC grade, Mallinckrodt-Baker, Inc., Phillipsburg, NJ), triethylamine (Riedel-de Haen AG, Germany), and other chemical reagents were acquired commercially.

An HPLC system (Hewelett Packard series 1050) consisting of an UV-detector, an autosampler, a reversed-phase ODS column (4.6 mm i.d. × 250 mm; particle size: 5 μm, Phenomenex), and a guard column (Novapak C_{18}, Waters) was employed for the quantitation of ciprofloxacin in plasma and urine smaples. For the assessment of the content of various cations in the TM extract, an inductive plasma emission spectrometer (Shimadzu ICPQ-1012) was used.

Assessment of Cation Content in *T. mongolicum* Extract—The TM extract was digested with an acid mixture consisting of HNO_3:$HClO_4$ (9:1). A plant-free acid control was also prepared for comparison. The content of Zn, Fe, Cu, Ca, Mn, Mg, Sr, Cr, Pb, and Ni was determined by plasma emission spectrometry.

Pharmacokinetic Studies—Male Sprague−Dawley rats (220−240 g) were housed under a controlled condition (23−25 °C, 55% relative humidity and 12 h light/dark light cycle) and were allowed free access to food and water before experiments. Under anesthetization with an ip injection of 80 mg/kg of ketamine and 10 mg/kg of xylazine, a cannula was surgically inserted into the right jugular of each animal. All study rats were fasted overnight prior to the scheduled blood sampling postdosing on the next day. In the test group, rats (n = 5) were dosed orally with the aqueous TM extract (2 g crude drug/kg) immediately followed by a single oral dose of ciprofloxacin (20 mg/kg). Rats (n = 5) that received a single oral dose of ciprofloxacin (20 mg/kg) alone were used as controls. Blood (0.6 mL) was withdrawn via the cannular just prior to ciprofloxacin dosing (t = 0) and at 5, 30, 60, 90, 120, 150, 180, 240, 300, and 360 min postdosing. Plasma was immediately separated by centrifugation at 10000g for 5 min. Urine samples were collected over 0−2, 2−4, 4−6, and 6−24 h intervals, and the total volume within each interval was recorded. Both plasma and urine samples were stored at −80 °C until assayed.

HPLC Assay for Ciprofloxacin—The HPLC assay developed by Nix et al.[7] was utilized in the present study with minor modifications. For the quantitation of ciprofloxacin in plasma, acetonitrile (200 μL) was added to the plasma sample (0.3 mL) for protein precipitation and was followed by the addition of enoxacin (internal standard, final concentration: 1.0 ng/μL). The mixture was centrifuged at 10000*g* for 5 min, and 200 μL of the supernatant was tried using a Concentrivap Concentrator (Labconco, Kansas City, MO) at 35 °C. The residue was reconstituted in 70 μL of mobile phase, and a 50 μL aliquot of which was injected onto the HPLC. As for the urine assay, the sample was first diluted with deionized–distilled water containing 10 ng/mL internal standard. The dilution factor was 1:50 for samples collected over the 0–2, 2–4, 4–6 h intervals and 1:10 for the sample collected over the 6–24 h interval. The diluted samples were then centrifuged at 10000*g* for 5 min, and the supernatant (50 μL) was submitted to the HPLC assay.

The HPLC mobile phase consisted of 16% acetonitrile, 1% methanol, and 83% aqueous buffer (pH 3.0) which was comprised of sodium dihydrogen phosphate monohydrate (0.1 M), glacial acetic acid (1% v/v), and triethylamine (0.5% v/v). The flow rate was set at 1.1 mL/min, and detection was preformed at 278 nm. Complete separation of ciprofloxacin and enoxacin (internal standard) was achieved with retention times at 9.0 and 7.0 min, respectively. The calibration curves were linear over the range from 0 to 3 μg/mL and from 1.0 to 10 μg/mL for the respective plasma and urine assays with correlation coefficients >0.999 for both biomatrixes. The lower limit of quantitation of ciprofloxacin was 25 ng/mL for both assays. Adequacy of this analytical methodology was supported by the <9.3% coefficient of variations for the interday assay variability obtained from quality control samples.

Analysis of Pharmacokinetic Parameters of Ciprofloxacin—The plasma concentration–time data of ciprofloxacin were assessed by noncompartmental analysis. The maximum plasma concentration (C_{max}) and the time achieving C_{max} (T_{max}) were directly observed from the individual concentration vs time profiles. Least-squares regression analysis was employed on the terminal elimination phase for estimation of elimination rate constant (λ_z). Elimination half-life ($t_{1/2,\lambda z}$) was computed as 0.693/λ_z, and the area under curve from time zero to infinity ($AUC_{0\to\infty}$) was estimated by trapezoidal integration as:

$$AUC_{0\to\infty} = AUC_{0\to t} + C_t/\lambda_z$$

where $AUC_{0\to t}$ is the AUC from time zero to time t and C_t is the plasma ciprofloxacin concentration at time t. Other parameter estimates including oral clearance (CL/F), renal clearance (CL_r), and apparent volume of distribution ($V_{d,\lambda z}/F$) were estimated by standard procedures.[8] The relative bioavailability (F') of ciprofloxacin was estimated as the ratio of the mean $AUC_{0\to\infty}$ values for the animals receiving both ciprofloxacin and TM to that of ciprofloxacin alone. Statistical significant differences in the derived pharmacokinetic parameter estimates between the groups were assessed by Student-t-test with the level of statistical significance (α) set at 0.05.

Results

Assessment of Cation Content in *T. mongolicum*—Concentrations of the 10 metal cations contained in the aqueous TM extract were determined to be 5760, 4941, 2311, 111.3, 62.4, 31.4, 16.1, 15.3, 6.0, and 1.5 μg/g for Mg, Ca, Fe, Mn, Zn, Sr, Cr, Cu, Ni, and Pb, respectively.

Pharmacokinetics of Ciprofloxacin in Rats—Data obtained from the control group revealed that ciprofloxacin, administered as a single oral dose (20 mg/kg), was rapidly absorbed with C_{max} (1.31 ± 0.49 μg/mL) achieved at 0.42 ± 0.17 h. Distribution of the drug was extensive with $V_{d,\lambda z}/F$ estimated to be 30.8 ± 11.1 L/kg and is approximately 50-fold of total body water. Though affected by F, this large distribution volume suggests a significant degree of tissue penetration and uptake. Oral clearance (CL/F) of the antibiotic was estimated to be 10.8 ± 2.7 L/h/kg and a mean ± SD $t_{1/2,\lambda z}$ of 1.96 ± 0.43 h was observed. Urinary recovery (X_u) of the antibiotic represented approximately 20% of the oral dose administered. All pertinent paramacokinetic parameter estimates are listed in Table 1.

Table 1—Mean (±SD) Pharmacokinetic Parameter Estimates[a] (n = 5) of Ciprofloxacin after a Single Oral Dosing (20 mg/kg) with or without Aqueous Preparation of *T. Mongolicum* (TM, 2 g crude drug/kg) Coadministration

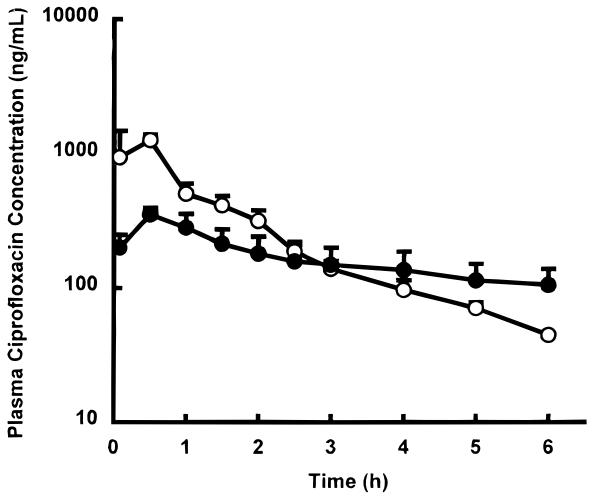

Figure 1—The plasma versus concentration time profiles of ciprofloaxcin. concentration (mean ± SD) measured for oral ciprofloxacin only (20 mg/kg) and oral ciprofloxacin (20 mg/kg) plus TM (2 g crude drug/kg) are depicted by ○ and ●, respectively.

Pharmacokinetics of Ciprofloxacin: Impact of *T. mongolicum* Coadministration—The mean plasma concentration–time profiles of ciprofloxacin for the control group and that with concomitant oral administration of TM are shown in Figure 1. The derived pharmacokinetic estimates for this study group are also available in Table 1. In comparison to the control group, significant alterations in certain pharmacokinetic estimates of ciprofloxacin were observed with concurrent TM administration. In particular, C_{max} of ciprofloxacin was lowered by 73% ($p < 0.005$) with T_{max} slightly prolonged by 16% ($p > 0.05$) (Table 1). Despite the reduction in C_{max}, the $AUC_{0\to\infty}$ estimate for ciprofloxacin remained similar (Figure 1). Although not statistically significant ($p = 0.2$), mean urinary ciprofloaxcin recovery in the TM group showed a 20% decrease. The mean $V_{d,\lambda z}/F$ estimate significantly increased (3-fold) with TM dosing (92.0 vs 30.8 L/kg, $p < 0.01$). In line with this, the average $t_{1/2,\lambda z}$ value was 3 times longer than that observed in the control group (5.71 vs 1.96 h, $p < 0.005$). However, the CL/F estimates were not significantly different between the two groups (Table 1). As a result, the relative bioavailability (F') of ciprofloxacin in the TM group as compared to control was estimated to be 0.96.

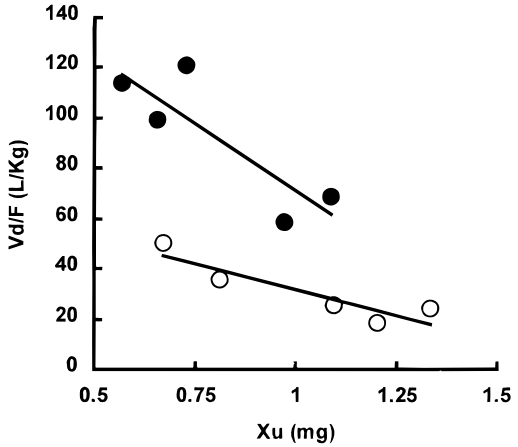

Figure 2—The relationship between apparent tissue distribution ($V_{d,\lambda z}/F$) and urinary drug recovery; equations describing the regression are $y = -40.9x + 72.6$, $p < 0.05$ for oral ciprofloxacin only (20 mg/kg) (○), and $y = -106.7x + 177.7$, $0.05 < p < 0.1$ for oral ciprofloxacin (20 mg/kg) plus TM (2 g crude drug/kg) (●).

Discussion

Ciprofloxacin is one of the newer fluoroquinolones that shows good oral absorption; however, the presence of cation-containing agents can impair oral absorption of this antibiotic.[1,9] In this study, coadministration of TM significantly decreased the C_{max} of ciprofloxacin by 73% with T_{max} essentially unaltered (Table 1). These observations suggest a reduction in oral ciprofloxacin absorption when TM was given concurrently. Independently, the TM extract was shown to contain a large amount of magnesium (5.8 mg/g,) calcium (4.9 mg/g), iron (2.3 mg/g), manganese (0.1 mg/g), zinc (0.06 mg/g), and copper (0.02 mg/g). Since the cation content of the TM extract, i.e., 5−6 mg of total cations received by the study rats, was high relative to the 4−5 mg of oral ciprofloaxcin, the lower ciprofloxacin absorption observed is not unexpected. It has been shown that chelation of quinolones generally requires ligands possessing positive charges and suitable molecular sizes.[1] Therefore, triterpenoids and inulin, the major components of TM reported,[4] should induce a minimal effect on the absorption of this antibiotic because they do not meet the structural requirements for chelation.

A 3-fold increase in the mean $V_{d,\lambda z}/F$ estimate for ciprofloxacin was observed in the rats concomitantly dosed with TM. Such alteration can be a result of an increase in tissue distribution ($V_{d,\lambda z}$) and/or a reduction in F. To further delineate the contribution of these two factors, plots of $V_{d,\lambda z}/F$ vs urinary recovery were constructed with individual data collected for the two animal groups (Figure 2). As anticipated for the control animals, $V_{d,\lambda z}/F$ decreased as the amount of ciprofloxacin excreted into the urine was larger. Interestingly, the regression line derived from the data of the TM group shifted higher and leftward with a steeper slope indicating that, in addition to the decrease in F, an increase in $V_{d,\lambda z}$ is also evident.

The magnitude of the change observed for $V_{d,\lambda z}$ appears to correspond to that of drug elimination (Table 1). The exact reason of this association is unclear but it may be a result of chelate formation in the systemic circulation when both ciprofloxacin and cations existed simultaneously following their independent absorption. Although not statistically significant ($p > 0.05$), the presence of TM caused a lowering of CL_r (Table 1). Interestingly, the pharmacokinetic perturbations observed for ciprofloaxcin in this study were also evident in a number of recent studies with another herb, *Sanquisorba officinalis*,[10] and also with ferrous sulfate when the antibiotic was given intravenously.[11] Although the data were not as vigorously scrutinized, prolongation of elimination half-life for a number of oral quinolones was also noticed in a human study as a result of iron supplementation.[2] All the pharmacokinetic perturbations observed for ciprofloxacin, i.e., lower C_{max}, wider tissue distribution, and slower elimination induced by TM, might be a direct result of an increase in molecular size and thus lipophilicity of metal-ciprofloxacin chelates. Therefore, the factor affecting drug absorption, in this case, may also play a role in the changes observed for drug distribution and elimination.

The relative bioavailability of ciprofloxacin, assessed using $AUC_{0\to\infty}$ estimates obtained for the concomitant TM dosing group relative to control, was 0.96. The similar $AUC_{0\to\infty}$ estimate observed in the TM group is a mixed result of lower drug absorption, wider distribution, and slower elimination. From a pharmacokinetic prospective, comparison of relative bioavailability of a drug under different testing conditions is based on the assumption of a stationary pharmacokinetic system. The secondary effects on drug distribution and elimination induced by TM may have complicated the use of $AUC_{0\to\infty}$ as an estimator for bioavailability. Because CL/F was derived from $AUC_{0\to\infty}$, this estimate should also be interpreted with caution.

The *Taraxacum* species, commonly known as dandelion, can be found in most parts of the globe. In addition to its claimed therapeutic activities, dandelion is also consumed as food and even as beverages in the form of a coffee substitute.[6] Regardless of its intended use, the high mineral content of this herb greatly increases the chance of drug−drug interactions with the conventional medicines that are sensitive to cations. Findings in the present study suggest that coadministration of TM may have clinical implications on the dosing of ciprofloxacin or other quinolone antibiotics.

Abstract □ The influence of propantheline bromide incorporation on the phase structure of glyceryl monoolein/water systems has been investigated using low-frequency dielectric spectroscopy over a frequency range of 10^{-2} to 10^{6} Hz at 20 °C. The responses of glyceryl monoolein systems composed of 10% and 30% w/w were measured and the spectra modeled using an equivalent circuit based on the Maxwell–Wagner theory.[1,2] Marked changes in the dielectric responses of the systems were noted on addition of the propantheline bromide at concentrations up to 10% w/w. For the lamellar (10% w/w water) glyceryl monoolein systems, an increase in the imaginary permittivity was seen, corresponding to an increase in conductivity due to the presence of additional ionic species within the system. Evidence was also obtained for the incorporation of the drug directly into the lipid bilayers, particularly at higher concentrations (10% drug) at which dielectric behavior corresponding to bilayer disruption was seen. Incorporation of 3% and 5% w/w drug into the cubic phase systems (30% w/w water) resulted in a change to the lamellar phase. However, circuit modeling indicated that the system formed structures which showed features of both the lamellar and cubic phases at 3% w/w drug loadings. The study has therefore demonstrated that dielectric analysis may provide a novel means of studying the effects of drug incorporation on the phase behavior of complex gel systems.

Introduction

Glyceryl monoolein has attracted interest as a pharmaceutical excipient, particularly for controlled drug delivery and bioadhesive systems.[3−7] This material is known to form four mesophases depending on the water content and temperature, namely the reverse micellar (L_2), lamellar (L_α), cubic (C), and reverse hexagonal (H_{II}) phases. Among these, the lamellar and cubic systems have received particular attention within the drug delivery field. The lamellar phase is a semifluid liquid crystalline system consisting of lipid bilayers alternating with water layers, while the cubic system is a highly viscous, ordered, bicontinuous structure with curved lipid bilayers extending in three dimensions separated by water channels.

The multilayer structure and/or high viscosity of the liquid crystalline phases results in the generation of diffusional barriers; hence, there has been interest in studying drug incorporation and release from these systems. The amphiphilic nature of the lipid allows incorporation of a range of drugs of varying lipophilicity; indeed, it has been suggested that hydrophobic drugs may be trapped within the lipophilic bilayers, and hydrophilic drugs are located in the aqueous channels, while amphiphilic drugs may partition into the lipid bilayer−water interface.[8] One would therefore expect the release pattern to depend on the microstructure and physicochemical properties of the liquid crystalline phases. To date, the majority of work in the field has focused on the examination of drug diffusion and release from the liquid crystalline systems. However, it is also necessary to consider the effects of drug addition on the formation and structure of the various phases. Previous studies using polarized light microscopy have reported induced phase changes at high levels of incorporated drugs.[4−6] The study of the effects of drug incorporation has arguably been limited by the difficulties associated with effectively characterizing the physical structure of these complex systems; hence, while drug-induced phase changes are a recognized phenomena, comparatively little is known regarding the mechanisms involved.

The work presented here describes an investigation into the influence of propantheline bromide loading on the phase structure of monoolein/water systems using low-frequency dielectric spectroscopy, with a view to developing the technique as a potential means of characterizing complex pharmaceutical materials. Propantheline bromide is an antimuscarinic agent which has been previously investigated as a means of treating urinary incontinence via vaginal delivery in a monoolein/water gel system.[5] This drug is itself surface active[9] and undergoes self-association in aqueous solution via an open aggregation process, whereby no discontinuity is seen in light-scattering intensity with concentration.[10] Geraghty et al.[5] reported that monoolein/water systems with a water content of less than 15% w/w retained their lamellar structure when an increasing quantity of propantheline bromide was added. However, systems that formed a cubic phase gel in the absence of drug could only maintain their structure up to propantheline bromide loadings of less than 5% w/w. At or above this drug loading, the gels were formed in the lamellar phase. Our previous work on glyceryl monoolein/water systems[1,2] showed that low-frequency dielectric spectroscopy may be used to identify and characterize the liquid crystalline phases. Furthermore, by modeling the dielectric data in terms of an equivalent circuit, it is possible to interpret the response in terms of specific structural features of the samples. The objectives of this study are therefore to develop the use of the dielectric approach by examining a system for which the basic behavior is already known and second to gain more specific information on the effects of propantheline bromide incorporation on the phase structure of glyceryl monoolein.

Materials and Methods

A single batch of Myverol 18-99 (Eastman Chemical Co.), a distilled monoglyceride with 60.9% glyceryl monoolein content, was

used throughout the study. Propantheline bromide (Sigma Co.) was used as supplied. All mixes were prepared using water with a resistivity greater than 18 MΩ/cm, obtained from an ultrahigh quality water purification system (Elga Co.). Two sets of gel samples containing 10% and 30% w/w water and 1%, 3%, 5%, and 10% propantheline bromide were prepared. The drug was added to Myverol 18-99 at 60 °C and mixed for 2 min, followed by the addition of water at the same temperature to produce the desired (% w/w) gel composition. The mix was stirred at 2000 rpm using a Heidolph RXR50 mixer. The resulting samples were centrifuged at a speed of 3000 rpm for 20 min and then stored in sealed containers at room temperature for 7 days before use to allow equilibration of the samples, following the recommendation of Geraghty et al.[5]

The dielectric measurements were carried out using a BDC-N broad band dielectric converter (Novocontrol GmbH) and a frequency response analyzer (SI 1255, Solatron-Schlumberger) linked to a Quatro temperature control system (Novocontrol GmbH). The technique involves the application of an oscillating electrical field to a sample and the subsequent measurement of the real and imaginary components of the response over a range of frequencies (ω). This response may be expressed in terms of the complex permittivity $\epsilon^*(\omega)$, where

$$\epsilon^*(\omega) = \epsilon'(\omega) - i\,\epsilon''(\omega) \quad (1)$$

with $\epsilon'(\omega)$ and $\epsilon''(\omega)$ being the real and imaginary components at frequency ω and i being the square root of -1. These components may be measured in terms of the extrinsic parameters $C(\omega)$ and $G(\omega)/\omega$, where $C(\omega)$ is the capacitance and $G(\omega)/\omega$ is the dielectric loss, $G(\omega)$ being the conductance (representing the sum of the a.c. and d.c. contributions). The relationship between the real permittivity and the capacitance is given by

$$\epsilon'(\omega) = \frac{C(\omega)\,d}{\epsilon_0 A} \quad (2)$$

where ϵ_0 is the permittivity of free space, and d and A are the interelectrode distance and electrode area, respectively. Similarly, the imaginary permittivity is related to the dielectric loss via

$$\epsilon''(\omega) = \frac{G(\omega)\,d}{\omega\epsilon_0 A} \quad (3)$$

During a measurement, the sample was placed in a circular dielectric cell designed for liquid and semisolid samples with diameter of 20 mm and an interelectrode distance of 0.5 mm. The dielectric responses were obtained at 20 °C over a frequency range of 10^{-2} to 10^{6} Hz. At least four samples for each concentration were examined, with at least two repeat measurements being made for each sample; excellent reproducibility was found between spectra. The fitting of the data was carried out by employing a modified generalized Maxwell–Wagner equivalent circuit with dispersive RC elements, and using Winfit 2.0 program supplied by Novocontrol GmbH. The main feature of Winfit 2.0 is nonlinear curve fitting of the measured data in the frequency domain, with both real and imaginary components being fitted simultaneously. In general impedance mode, the software supports up to four single fit terms which may hold several combinations of resistance, inductance, and capacitance elements and will also incorporate power law functions for these circuit features. Microscopic observations were obtained under polarized light using an Olympus differential interference contrast (DIC) microscope at room temperature.

Results and Discussion

Two sets of Myverol 18-99/water systems with waters content of 10% w/w and 30% w/w and propantheline bromide concentration of 1% w/w, 3% w/w, 5% w/w, and 10% w/w were investigated. According to the phase diagram determined by Geraghty et al.,[5] the 10% w/w water system is expected to be lamellar phase, while the 30% w/w water system is predicted to be cubic phase at 20 °C in the absence of drug.

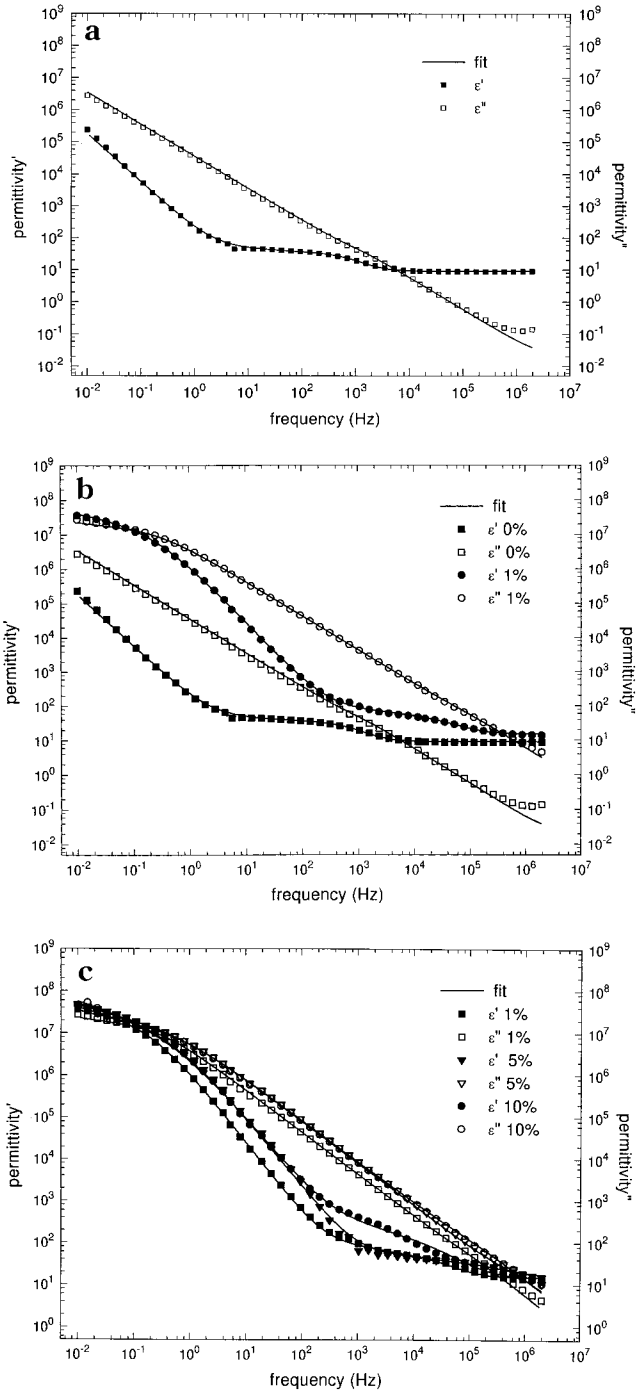

Figure 1—Low-frequency dielectric spectra of Myverol 18-99/water/propantheline bromide systems containing 10% w/w water with propantheline bromide concentration of (a) 0%, (b) comparison of 0% and 1%, and (c) comparison of 1%, 5%, and 10%. Solid lines indicate curve-fitted data.

Influence of Drug Loading on Lamellar Phase System—Both microscopy observations and dielectric spectroscopy measurements confirmed that the monoolein/water system containing 10% w/w water without addition of propantheline bromide was lamellar phase at 20 °C. The dielectric response, as shown in Figure 1a, exhibited the expected lamellar phase spectrum[1] with three principle dielectric processes: a high frequency process, corresponding to the bulk response, which is seen as a frequency independent real permittivity value of approximately 8, together with an inverse frequency dependent imaginary component, $\epsilon'' \propto (\omega)^{-1}$, reflecting a frequency independent value of $G(\omega)$ (see eq 3). A relaxation process in the Hz

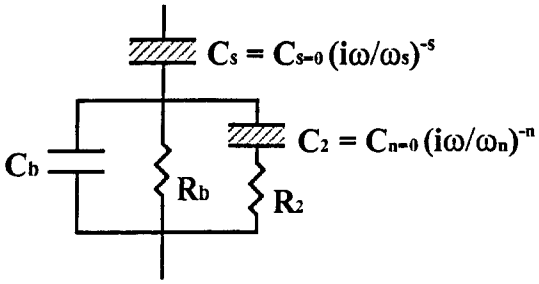

Figure 2—Modified generalized Maxwell–Wagner equivalent circuit employed to model the dielectric responses.

range was indicated by a discontinuity in the real component between frequencies of 5 Hz and 5 kHz which is thought to be caused by the relaxation of weakly bound dipoles and charge transport processes which are partially impeded by the lamellar network.[1,2] In the sub-Hz frequency range, the values of both the real and imaginary components increased, indicating the presence of a low-frequency dispersion caused by adsorbed barrier layers on the electrodes. Such layers have been described in a number of previous studies (e.g.,[11,12,13]) and are discussed in more detail in the context of these systems in a previous publication.[1]

On adding 1%, 5%, and 10% propantheline bromide to the 10% water sample, the systems remained in the lamellar phase, as indicated by the low viscosity and "oil streak" seen using microscopy.[5] The polarized light microscopy studies were unable to unequivocally distinguish between the various drug-containing systems, although the viscosity of the 10% w/w drug systems was visibly lower. However, the dielectric spectra for these systems exhibited marked differences in terms of both shape and magnitude. In comparison to the dielectric response for the 10% w/w gel system alone, the inclusion of 1% w/w drug resulted in a marked increase in imaginary permittivity of approximately 2 orders of magnitude over the frequency range of 10^{-1} to 10^{6} Hz, while the crossover frequency shifted from approximately 5 kHz to 400 kHz (Figure 1b). This crossover frequency (ω_τ) represents the inverse bulk relaxation time ($1/\tau$) of the system at $\epsilon' = \epsilon''$, given by

$$\omega_\tau = G(\omega)/C(\omega) = 1/\tau \qquad (4)$$

Therefore, the bulk relaxation time of the 1% sample decreased by approximately 2 orders of magnitude. The second relaxation process seen in the real component which is characteristic of the lamellar phase was, however, retained and shifted from a frequency of approximately 400 Hz to 400 kHz.

The responses of the 5% and 10% w/w drug systems are shown in Figure 1c in comparison to the 1% response. The spectrum of 5% drug sample showed a further slight increase in overall magnitude, but the change in spectral shape was less marked, indicating the system remained as a lamellar structure with only a slight increase of conductance. The response of the 10% drug sample had similar values of real and imaginary permittivity as the 5% material over the majority of the spectrum, although a marked increase in the magnitude of the real permittivity for the second relaxation process was seen in over a frequency range of 200 Hz to 50 kHz.

The above spectra were modeled in terms of a modified generalized Maxwell−Wagner equivalent circuit which was developed for these systems in a previous study[1] based on work by Hill and Pickup[14] (Figure 2). The circuit consists of a fractional power law dispersive capacitor, C_s, representing a layer formed at the electrode surface, in series with a parallel RC circuit (C_b and R_b), corresponding to the principal bulk processes; these are long range phenomena which are dispersed spatially in a uniform manner throughout the system. A series connection (C_2 and R_2) was employed to model the additional bulk polarization behavior, which represents the effect of the substructure within the sample. Previous studies[1,2] have related this circuit feature to the structure of the lamellar network within the system. The C_2 element is a dispersive capacitor showing power law behavior described by

$$C_2 = C_{n=0}(i\omega/\omega_n)^{-n} = C_{n=0}(\omega/\omega_n)^{-n}[\cos(n\pi/2) - i\sin(n\pi/2)] \qquad (5)$$

where $C_{n=0}$ is the capacitance when $n = 0$ and ω_n is a characteristic frequency. The exponent n is related to the extent of cooperativity between the relaxing dipoles and the immediate environment and is therefore a reflection of the degree of ordering of the system. When $n = 0$, C_2 is frequency independent and the dipoles may be considered to be totally coupled to their surroundings, while when $0 < n < 1$, the dipoles are uncoupled and the value of $C_2(\omega)$ is complex. More details of the physical significance of the exponent n may be found in a number of texts (e.g.,[14,15]).

The fitted parameters for the 10% water content samples with 0, 1%, 5%, and 10% propantheline bromide are given in Table 1. Without drug incorporation, the monoolein/water gel exhibited relatively high resistance values for both R_b and R_2, low values for the bulk capacitance C_b and the frequency dependent C_2, and a value for the exponent n of approximately 0.1. By adding 1% propantheline bromide, the resistance R_b and R_2 decreased by approximately 2 orders of magnitude which may be at least partially interpreted in terms of the increase in drug and counterion concentration. However, in addition to this effect a 10-fold increase in the $C_{n=0}$ value and a 2-fold increase in the value of n were observed, both indicating that the presence of the drug is causing disruption of the lamellar bilayer. Consequently, in addition to charge addition effects the observed decrease in bulk resistance may be a function of changes to the structure of the lipid lamellae. As the drug concentration increased to 5%, the R_b and R_2 values further decreased, while at the highest drug concentration of 10% the resistances R_b and R_2 showed only small decreases compared to the 5% value. However, at this drug concentration marked changes in $C_{n=0}$ and n were seen, indicating that the drug may be causing further alterations to the substructure of the system.

Overall, therefore, the incorporation of the drug appears to maintain the system within the lamellar phase but increases the conductance of the gel, probably due to a combination of ion addition effects and lamellar disruption. However, the increase of the conductance with increase of drug loading was nonlinear, with considerably less marked changes seen for the 5% and 10% drug systems. This could be a consequence of the surface active properties of the drug, with a decreased change in conductance seen due to the formation of assemblies which make a relatively small contribution to the charge-carrying properties of the system as a whole. In addition to this effect, however, the drug also appears to alter the substructure of the gel in a concentration dependent manner. At 1% and 5% levels, the changes in $C_{n=0}$ and n provide evidence for the presence of the drug within the lamellar bilayers themselves, while at 10% w/w the drug appears to cause substantial changes to the bilayers, with the marked increase in the exponent n reflecting disruption of the uniformity of the charge transport path. Taken together with the observation that the 10% drug systems were visibly less viscous than the

lower concentration drug samples, the data indicate that the drug is incorporated into the bilayer, causing disruption which in turn alters the viscous properties of the gels.

Influence of Drug Loading on Cubic Phase System—The monoolein/water system containing 30% water formed an optically isotropic cubic phase. The dielectric response of this phase, as shown in Figure 3a, consisted of a high-frequency bulk process with greater magnitudes for the imaginary component (i.e. a higher conductance) than for the lamellar phase, and a sub-Hz barrier process caused by an adsorbed layer at electrode. The high conductivity and lack of substructure relaxation processes reflect the homogeneity and bicontinuous structure of the system.[1]

On incorporating 1% drug into the system, the gel still had the appearance of the cubic phase (both visually and using microscopy), while the low frequency dielectric response still showed the same basic shape as the system with no added drug. An increase in imaginary permittivity of approximately 2 orders of magnitude was seen, which again may be attributed to the ionization of the propantheline bromide within the aqueous phase. However, the addition of further propantheline bromide was shown to promote the formation of the lamellar phase. The samples containing 3% and 5% drug concentrations were clearly of lower viscosity, and, under polarized light microscopy, exhibited similar "oily streak" textures. Examination of the dielectric responses (Figures 3b and 3c) revealed marked differences between the two higher concentration systems. The spectrum for the 3% gel showed a second relaxation process which was seen in the real component of the permittivity over a frequency range of 10^5 to 10^6 Hz, while the imaginary component of permittivity maintained similar values to that of the 1% drug sample. Consequently, the system showed features characteristic of the lamellar phase but did not exhibit the decrease in imaginary permittivity associated with the change from the cubic to lamellar phases. The dielectric spectrum of the 5% drug sample, however, showed typical lamellar behavior with the three dielectric processes outlined earlier. In addition, the values of the imaginary permittivity were 1−2 orders of magnitude lower than for the 1% and 3% drug systems over the majority of the response.

The values of the parameters obtained from fitting to the circuit model shown in Figure 2 for the 30% water samples with 0, 1%, 3%, and 5% propantheline bromide are given in Table 2. The cubic structure of the pure monoolein/water system was characterized by a low bulk resistance R_b (2 orders of magnitude lower than the bulk resistance of pure lamellar gel). The R_2 value was also low, while C_2 was frequency independent ($n = 0$) and showed similar values to that of the bulk capacitance, C_b. These features reflect the homogeneous structure of the cubic phase and are in good agreement with findings from the earlier studies.[1,2]

For the sample containing 1% drug, the bulk resistance R_b decreased approximately 30-fold, almost certainly as a result of ionization of the drug, while C_b and R_2 showed little change, implying that the system was still in the cubic phase. However, the 10-fold increase in $C_{n=0}$ and a change of the value of the exponent *n* from 0 to 0.14 reflect the effect of incorporation of drug molecules on interfaces leading to local inhomogeneity. For the 3% drug sample,

the values of the substructure elements R_2 and $C_{n=0}$ showed marked increases while the bulk resistance R_b and capacitance C_b remained largely unchanged compared to the 1% systems. As the drug concentration increased up to 5%, all bulk and substructure elements R_b, C_b, R_2, and $C_{n=0}$ exhibited similar values for lamellar systems shown in Table 1.

These data indicate that the incorporation of propantheline bromide causes the system to change from the cubic to the lamellar phase at 20 °C, as reported by Geraghty et al.[5] However, the dielectric study has allowed further information to be obtained regarding the transformation. In particular, while the systems containing 0 and 5% drug show spectra typical of the cubic and lamellar phases, respectively, the gels containing 1% and 3% drug show features of both systems which indicate that these systems have structures which appear to be intermediate between the two phases.

Conclusions

The objectives of this study were to explore the use of dielectric analysis as a means of characterizing glyceryl monoolein gel systems containing a model drug and to gain further information on the effects of that drug on the phase behavior of the gel systems. The technique has been shown to be capable of detecting the phase behavior of the gels by matching the spectra of drug-containing systems to those of the cubic and lamellar phases, yielding trends which are in good agreement with those previously reported.[5] However, in addition to gross identification of the phases present the technique also appears to allow a more sophisticated analysis of the effects of incorporated drug than has been previously possible. In particular, the circuit modeling has yielded information on the location of the drug within the gel as well as identifying structures which are intermediate between the lamellar and cubic phases. Such findings may have important implications for understanding not only the drug release properties of these gels but also their mechanical and bioadhesive behavior.

Abstract □ Lysozyme was encapsulated in biodegradable polymer microspheres which were precipitated from an organic solution by spraying the solution into carbon dioxide. The polymer, either poly(*l*-lactide) (*l*-PLA) or poly(DL-lactide-*co*-glycolide) (PGLA), in dichloromethane solution with suspended lysozyme was sprayed into a CO_2 vapor phase through a capillary nozzle to form droplets which solidified after falling into a CO_2 liquid phase. By delaying precipitation in the vapor phase, the primary particles became sufficiently large, from 5 to 70 μm, such that they could encapsulate the lysozyme. At an optimal temperature of −20 °C, the polymer solution mixed rapidly with CO_2, and the precipitated primary particles were sufficiently hard such that agglomeration was markedly reduced compared with higher temperatures. More uniform particles were formed by flowing CO_2 at high velocity in a coaxial nozzle to mix the droplets at the CO_2 vapor–liquid interface. This process offers a means to produce encapsulated proteins in poly(DL-lactide-*co*-glycolide) microspheres without earlier limitations of massive polymer agglomeration and limited protein solubility in organic solvents.

Introduction

Microencapsulation of pharmaceutical compounds in biodegradable polymer particles is of great interest for controlled-release in oral, inhalation, or injection methods of delivery. Typical methods of microencapsulation include emulsion−solvent-extraction, spray-drying, and phase-separation techniques.[1−7] Potential drawbacks associated with these techniques include the use of toxic organic solvents for solubility, residual solvent in the microspheres, low encapsulation efficiencies due to partitioning of the pharmaceutical compound between two immiscible phases, and denaturation. The biodegradable homopolymers poly(*l*-lactic acid), poly(DL-lactic acid), poly(glycolic acid), and copolymers of these have been of particular interest as carrier substances.[8−13]

Several supercritical fluid processes have been utilized to form microparticles of polymers and pharmaceutical compounds. To manipulate particle morphology, the solvent power of compressed CO_2 can be changed by adjusting the temperature and pressure.[14,15] The critical conditions of CO_2 are easily attainable, i.e., T_c = 31 °C and P_c = 73.8 bar. This environmentally benign solvent is essentially nontoxic, nonflammable, and inexpensive. Phase separation techniques based upon supercritical fluids include rapid expansion from supercritical solution (RESS),[13,16−27] gas antisolvent recrystallization (GAS),[27−30] and precipitation with a compressed fluid antisolvent (PCA),[31−43] also known as aerosol solvent extraction system (ASES)[44−47] or supercritical antisolvent technique (SAS).[44] RESS is useful for materials which are soluble in CO_2. Unfortunately, CO_2, with no dipole moment and a very low polarizability, is a very weak solvent and dissolves very few polymers.[48,49] RESS of a highly soluble polymer, poly(1,1,2,2-tetrahydroperfluorodecyl acrylate),[24] from CO_2 produced submicron particles and fibers.

Recently, microparticles have been formed by precipitation with compressed CO_2 in the liquid and supercritical fluid states.[31−47] The PCA process consists of atomizing a solution into compressed liquid or supercritical fluid CO_2. The atomization process may be accomplished by spraying at high velocities through a small nozzle (typically 100 μm) or by sonication[43] through a larger nozzle. The organic solvent diffuses rapidly into the bulk CO_2 phase, while CO_2 diffuses into the droplets, thereby precipitating the polymer. The rate of diffusion in both directions and thus the degree of supersaturation are higher than in the case of conventional liquid antisolvents, often resulting in submicron to micron-sized particles. More viscous polymer solutions at higher polymer concentrations lead to fibers with micron-sized features.[33,37] Several studies have shown very low concentrations of residual solvent in the product materials, especially after a CO_2 extraction step upon completion of the spray.[29,50−52]

Microspheres may be formed for semicrystalline polymers such as poly(*l*-lactic acid) (*l*-PLA) without flocculation and agglomeration at 40 °C.[29,30,38,41,43,45,46] Amorphous polymers, on the other hand, such as polystyrene (PS),[32,39,41] poly(methyl methacrylate) (PMMA),[39] and poly(DL-lactide-*co*-glycolide) (PGLA)[38] often flocculate and agglomerate. The loss of individual particles is a result of plasticization of the polymer by CO_2, which can be further influenced by residual solvent in CO_2. CO_2 can depress the T_g of PMMA by 100 °C below the normal value of 105 °C.[39,53] Upon exposure of PS to CO_2, the temperature at which stationary particles agglomerate corresponds closely with the depressed T_g.[34] For PGLA, agglomeration was present from 0 to 23 °C.[38] Severe agglomeration can occur when poly(d,l-lactide) microspheres precipitate from toluene solution by addition of 2-propanol as the phase-separating agent.[54] However, at temperatures between −40 °C and −100 °C the microspheres become sufficiently firm to avoid agglomeration.

A novel variation of the PCA process was used to form hollow spheres (microballoons) of polystyrene from polystyrene in toluene solutions with concentrations above 6 wt %.[38] In this case the cell was filled only partially with liquid CO_2, with its equilibrium vapor phase above it. The solution was atomized in the vapor phase, and the droplets subsequently fell into the liquid phase where they solidified. By delaying precipitation in the vapor phase, hollow microspheres were formed. The microballoons were slightly larger than the diameter of the nozzle, and it is conceivable that they could be used to encapsulate a pharmaceutical compound.

A key challenge in the PCA process is to maintain the biological activity of proteins, peptides, and enzymes.[35] The dissolution of insulin, lysozyme, and trypsin into a typical solvent for PCA, like DMSO, denatures these proteins, probably due to a change in conformation.[55] Each of these materials remained denatured after processing via PCA. The bioactivity of certain proteins such as insulin and lysozyme recover upon redissolution into an aqueous

10.1021/js980237h CCC: $18.00
Published on Web 04/24/1999

environment, suggesting the interactions causing denaturation can be partially reversible.[44,56] A recent study also suggests that long-term storage of proteins which have been denatured by supercritical fluid processing, such as lysozyme, does not severely alter the stability and ability to recover bioactivity.[57]

The objective of this study was to encapsulate chicken egg-white lysozyme into uniform 50−100 μm poly(DL-lactide-*co*-glycolide) (PGLA) spheres. Smaller particles would be too small to encapsulate a significant number of 5−10 μm protein particles for controlled-release purposes. Larger particles would be undesirable for certain administration methods; for example, parenteral administration requires particles <100 μm in diameter.[58] The first part of this study examines the particle morphology for PGLA particles formed by PCA without any protein present. To produce larger primary particles than the 1−5 μm particles typically produced by PCA in liquid or supercritical CO_2,[31,32,35,36,38−42,44,45,59] we chose to delay precipitation by spraying into a CO_2 vapor phase above a CO_2 liquid phase. Another goal was to achieve high enough local concentrations of polymer in the droplets striking the CO_2 liquid phase to allow significant particle growth, while avoiding agglomeration. To attempt to minimize agglomeration caused by plasticization of the polymer by CO_2, the temperature was varied from 23 to −40 °C. The effects of nozzle diameter, solution flowrate, CO_2 flowrate, and solution concentration were also evaluated. In the second part, we address microencapsulation of chicken egg-white lysozyme into the polymer particles. Lysozyme was suspended in dichloromethane, in contrast with earlier studies where a protein was dissolved in an organic solvent.[27,30,38,43,46] Suspensions may be formed for a broad range of peptides and proteins, many of which are insoluble in organic solvents. Suspension of a protein in an organic solvent typically produces less denaturation than dissolution. The knowledge gained from the study of PGLA particle formation in the first part was utilized to encapsulate lysozyme in nonagglomerated particles with diameters in the 50−100 μm range as desired. In both parts of this study, separate sections are presented to delineate between experiments in static (nonflowing) and flowing CO_2.

Experimental Section

Materials—Semicrystalline poly(*l*-lactic acid) (*l*-PLA) (MEDISORBTM 100L, Stolle-Dupont Co. Cincinnati, OH) had a M_w of 94100 and a M_w/M_n of 1.85. Poly(DL-lactide-*co*-glycolide) (PGLA) was purchased from Birmingham Polymers, Inc. (Birmingham, AL) and had a M_w of 30000. Chicken egg-white lysozyme (Sigma, St. Louis, MO) was spray-dried from aqueous solution to form 1−10 μm particles. Ruthenium tetroxide (Electron Microscopy Sciences, Fort Washington, PA), reagent grade dichloromethane, and bone dry grade CO_2 were used as received.

Apparatus—The apparatus for precipitation with compressed CO_2, shown in Figure 1, is based upon earlier designs.[35,40] The solutions were sprayed into a 1.27 cm. i.d. sapphire tube with a volume of 13 mL. This tube allowed visual observation of skin formation in falling droplets, jet dynamics, and polymer precipitation. Visual observations proved invaluable in optimizing the PCA process. A thermostated water bath was utilized for experiments performed above 0 °C, while a dry ice−ethanol bath was used for subzero temperatures. For all experiments, the CO_2 level inside the cell was maintained 1 cm below the tip of the spray nozzle. The CO_2 inlet line (30 feet long, 0.030 in. i.d. by 1/16 in. o.d.) was immersed in the bath to equilibrate the CO_2 temperature prior to introduction into the cell.

A cylindrical tube (1 in. o.d. by 11/16 in. i.d. by 8 in. long, Autoclave Engineers, model CNLX 1608−316) rated up to 689 bar equipped with a piston was used to pressurize the polymer solution. This tube was pressurized with dichloromethane by using a computer-controlled syringe pump (ISCO, model 260D). The

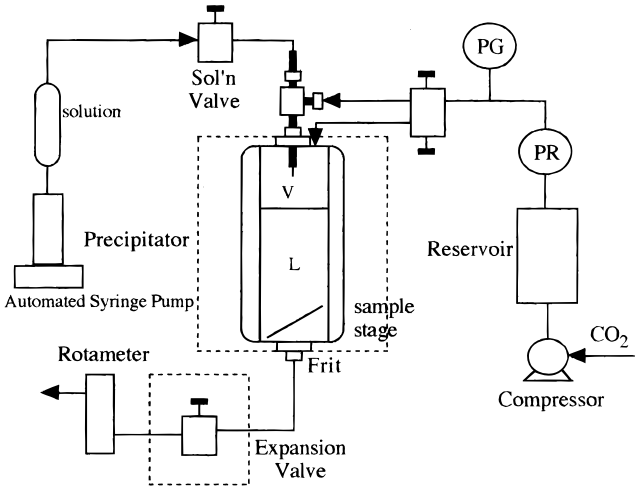

Figure 1—Schematic of the apparatus for precipitation with a vapor-over-liquid compressed fluid antisolvent.

polymer solution was sprayed into the cell via a 100 μm i.d. fused silica capillary tube or a 0.030 in. i.d. stainless steel tube. In all cases, the nozzle length was 6.5 in. Nozzles smaller than 100 μm could not be used because they were plugged by the suspended lysozyme particles. To ensure smoothness, the capillary tips were inspected with a microscope. The lysozyme was suspended in the polymer solution by using an ultrasonic bath.

To collect particles, two small rectangular glass plates (1 in. by 1/4 in.), slanted at an angle of 60°, were stacked in the bottom of the cell with approximately 5 mm between them. These glass plates were partially covered with double-sided carbon conductive tape. Also, a 1/4 in. diameter 0.5 μm filter was placed in the CO_2 effluent line at the base of the precipitation cell.

The solution flow rate was controlled with the automated syringe pump, and in most cases the solution was dripped into the cell at 0.1−1.0 mL/min. The solution was injected into a vapor CO_2 phase residing above a liquid CO_2 phase. In some cases, the solution flowrate was increased to ~1.8 mL/min where the solution no longer dripped, but instead streamed into the cell. This stream subsequently broke up into smaller droplets upon contacting the CO_2 liquid surface. For most cases, the CO_2 was not flowing. In experiments with flowing CO_2, the CO_2 entered the cell either through a port in the top of the cell or through an annular region in a coaxial nozzle, described in detail elsewhere.[41] The CO_2 flow rate was controlled by a needle valve (Whitey, SS-21RS4) in the effluent line and measured by a rotameter (Omega, model FLT-40ST). To prevent freezing due to CO_2 expansion, the valve was heated in a water bath to greater than 50 °C. Upon completion of solution injection, the cell was filled with liquid CO_2 to a pressure of 103 bar. Liquid CO_2 was swept through the cell for 10 min to remove the dichloromethane and further dry the particles. After drying, the cell depressurized over a 15 min span.

Characterization—Scanning electron microscopy (SEM) (JEOL JSM-35C) was used to analyze the morphology of the polymer particles. The glass slides were mounted on a SEM stage and coated to an approximate thickness of 200 Å (Pelco Model 3 Sputter Coater).

To detect lysozyme within the particles, two techniques were used. In the first method, the lysozyme was stained by ruthenium tetroxide prior to suspension in the polymer solution, and the product was observed with an optical microscope (Olympus VANOX-T or Olympus C-35AD-2)) and compared with SEM images of the same particles. Energy dispersive spectroscopy (EDS) was used as the second method (Kevex Analyst 8000 Microanalyzer). Two of the amino acids present in lysozyme, cysteine and methionine, contain sulfur, which is not present in the polymer, and can be detected by this technique.

Results and Discussion

Effect of CO_2−Dichloromethane Mixtures on Morphology of Polymers—For the CO_2 antisolvent process to be successful, the polymer must be highly insoluble in

the CO_2–organic solvent mixture, and this mixture must not cause too much agglomeration of the polymer. Previously, it was shown that lower molecular weight *l*-PLA is only slightly soluble in CO_2–cosolvent mixtures.[18] CO_2 does not cause *l*-PLA particles to agglomerate, since they are semicrystalline.[38] *l*-PLA has a melting temperature (T_m) of 173–178 °C and a glass transition temperature (T_g) of 60–65 °C (manufacturer's data). The amorphous biodegradable polymer poly(DL-lactide-*co*-glycolide) (PGLA), however, is highly plasticized by CO_2. PGLA has a T_g of 45–50 °C.

Experiments were performed to determine if CO_2 causes PGLA particles to agglomerate. PGLA, as a powder, and in some cases dichloromethane, as a liquid, were fed into a high-pressure cell equipped with a sapphire window which has been described previously.[60] The cell was sealed, and then liquid CO_2 was injected slowly into the cell. From ambient temperature down to 0 °C, PGLA powder quickly gels into a viscous mass when in the presence of liquid CO_2 for concentrations from 0.01 to 1.0 wt %. At these concentrations, very little polymer dissolved, even with up to 5 wt % CH_2Cl_2 as a potential cosolvent. The cosolvent concentrations were chosen to mimic conditions used in the PCA process. Upon depressurization, the polymer foamed. At −20 °C, the polymer powder occasionally stuck to the wall of the cell, but was also partially suspended throughout the cell. At temperatures below −40 °C the polymer remained as a free-flowing, nonsticky powder. Since CO_2 acts as a plasticizer, it can lower the T_g of the polymer. The T_g of PGLA containing dissolved CO_2 could easily be as low as −40 °C, or even lower, based upon other systems mentioned previously.[34,39,53,54]

Organic Solvent–CO_2 Miscibility and Mixing—Dichloromethane is highly miscible with CO_2 at ambient temperature and pressures above 61 bar. In our investigations, concentrations as high as 73 wt % CH_2Cl_2 were miscible with liquid CO_2 at temperatures from 23 °C down to −46 °C. The mixing behavior of CH_2Cl_2 and CO_2 was observed inside the sapphire cell. The cell was filled partially with liquid CO_2 and equilibrated at the desired temperature and pressure. Pure dichloromethane was then injected into the cell through the 100 μm i.d. capillary nozzle. For conditions where the cell was only partially filled with liquid CO_2, i.e., vapor and liquid CO_2 phases were both present, the solvent was injected at flow rates of 0.5 mL/min or slower. This flow rate range prevented the solvent stream from atomizing and allowed the solvent to drip into the liquid phase. At temperatures ranging from ambient to −20 °C, the drops quickly dispersed into the liquid CO_2 phase upon contact. At colder temperatures (−30 °C and below) however, the drops were seen to fall about 1 cm through the liquid CO_2 phase before breaking up. Operating at temperatures at or below −30 °C therefore may be expected to delay precipitation of the polymer and/or lead to agglomeration due to insufficient mixing between the drop and liquid phases. While the solvent is still miscible with CO_2 at low temperatures, the rate of mixing decreases significantly.

Polymer Particles Formed in Static Vapor-over-Liquid CO_2—As shown in Table 1, the concentration of the polymer solution, temperature, solution flow rate, and CO_2 flow rate were manipulated to observe the effect on particle formation. In this section, the CO_2 was static (nonflowing). Since both a vapor and a liquid phase are present in each experiment, the initial pressure was simply the vapor pressure of CO_2 at a given temperature. At 0 °C the pressure was 35 bar, and at −20 °C it was 20 bar. As the solution was injected, the pressure decreased slightly, corresponding to the pressure of the CO_2/CH_2Cl_2 mixture. The liquid CO_2 level was maintained at 1 cm below the tip of the nozzle to allow droplet formation and release from the tip before contact with the liquid phase. With the low flow rate and low shear through the vapor phase, ~200 μm drops were formed at a frequency of approximately one per second.

l-PLA is a semicrystalline polymer which has been used many times in PCA to form microparticles without agglomeration.[13,29,38,41,43,45,46] Therefore, we first present results for *l*-PLA to serve as a basis for understanding the more challenging experiments with amorphous PGLA. When a 1.0% solution of *l*-PLA in dichloromethane was dripped into vapor-over-liquid CO_2 at 0.5 mL/min and 20 °C, the result was microspheres 1–4 μm in diameter, as shown in Figure 2 (top) and Table 2. On the basis of visual observation, it appeared that little precipitation occurred before each droplet contacted the liquid phase. After the droplet fell into the liquid CO_2 phase, rapid mass transfer led to intense nucleation resulting in the small microspheres. This result indicates atomization does not play as important a role in achieving small particles as suggested previously.[41] The particles formed a free-flowing powder and could be sprayed for several minutes with no agglomeration even as solvent accumulated inside the cell.

Figure 3 is a schematic of a ternary phase diagram consisting of a polymer, organic solvent, and compressed CO_2.[32] The mass transfer pathways are shown only for the lower liquid CO_2 phase. Two of the binary systems are completely miscible at most conditions in this study, but the polymer–CO_2 binary system is only slightly miscible. The binodal (coexistence) curve separates the one-phase and two-phase regions in the ternary system. Between the binodal and spinodal curves is the metastable region. The system is stable to small concentration fluctuations in this region, and phase separation will be by nucleation and growth. Upon crossing the binodal curve for dilute polymer

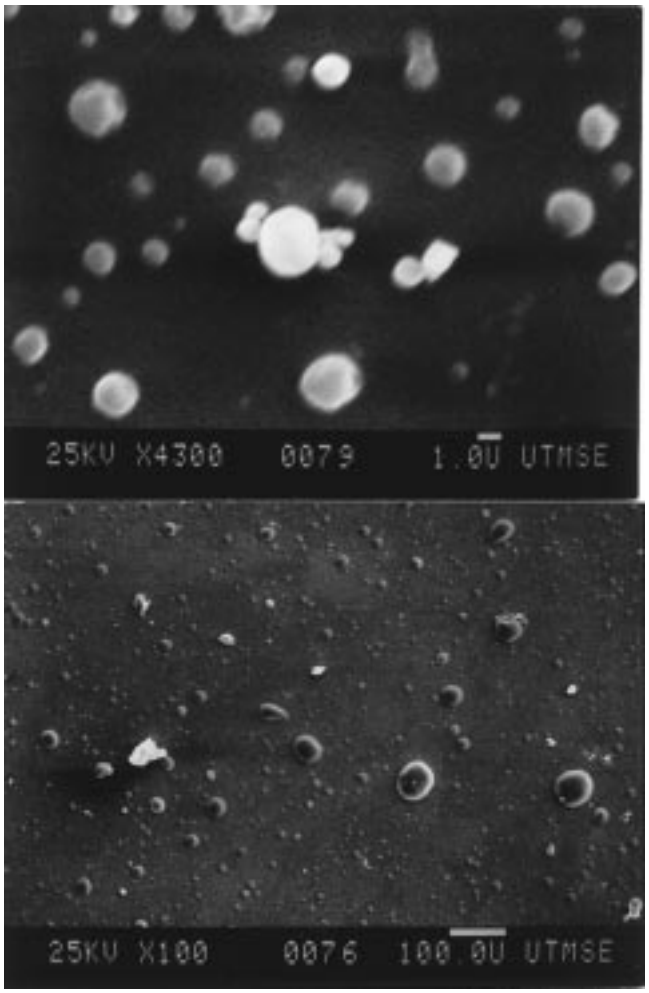

Figure 2—SEM micrographs of *l*-PLA microspheres (top) formed by spraying a 1.0 wt % *l*-PLA in dichloromethane (CH_2Cl_2) solution at 0.5 mL/min at 20 °C and PGLA microspheres (bottom) formed by spraying a 5.0 wt % PGLA in CH_2Cl_2 solution at 0.22 mL/min (T= –20 °C), both through a 100 μm capillary nozzle into static CO_2.

solutions, a polymer-rich phase will nucleate and grow within a solvent-rich continuous phase.

For a 5.0% solution of *l*-PLA sprayed at similar conditions, we observed skin formation on the backlit droplet while it was in the vapor-phase, and the resulting particles were 250−500 μm in diameter. It was easy to observe that the liquid droplet became opaque as it fell through the CO_2 vapor. A viscous skin appeared to form on the surface of the drop, and the drop did not break up upon contact with the liquid CO_2. This observation of skin formation is entirely consistent with SEM micrographs, which indicated that the particles were the same size as the droplets. In other experiments, at lower concentrations, where a skin did not form, a clear transparent droplet fell through the vapor. With the higher polymer concentration, the dissolution of CO_2 into the droplet forms a skin on the droplet while it is still in the vapor phase. At this concentration for *l*-PLA, the mass transfer pathway on the phase diagram in Figure 3 passes above the critical point on the binodal curve (curve B), thus a solvent-rich phase nucleates and grows within a polymer-rich phase causing skin formation. The polymer entanglement and viscosity in the skin are sufficient to maintain the integrity of the droplet as it solidifies in the liquid CO_2, as was observed in a similar system, as shown in Figures 4−10 of ref 34.[34] Here, the final particle size produced in each droplet is larger than the nozzle diameter, 100 μm, which was also the case for PS in toluene solutions sprayed into vapor-over-liquid CO_2.[34]

In vapor-over-liquid PCA when drops fall through vapor and atomization is not present, mass transfer is still fast enough in dilute solutions and is fast enough to produce 1−4 μm *l*-PLA particles, apparently following mass transfer pathway A in Figure 3. However, in a previous study with intense atomization into liquid CO_2 at a high density of 0.96 g/mL, the primary particle sizes were even smaller, from 0.1 to 1 μm.[41] Not only was atomization more intense producing smaller droplets, but the phase boundary was reached more quickly from the faster mass transfer. In addition, the polymer solidified more rapidly leading to smaller particles. Dilute solutions were not studied in the past for V/L CO_2, as, for example, the concentration was 6 wt % or higher for PS solutions and particles were larger than 100 μm.[34]

For PGLA, the solution concentration was varied from 1.0 to 10.0 wt %. To prevent agglomeration, most experiments were performed at −20 °C to raise the polymer solution viscosity sufficiently, while maintaining high enough rates of CO_2−organic solvent mixing (on the basis of the above visual observations of mixing). Also, spray times were generally kept short, <30 s, to avoid accumulating large concentrations of dichloromethane in the static CO_2, which causes agglomeration. As the polymer concentration and thus the solution viscosity increased, it became necessary to raise the solution flow rate to maintain a constant droplet size. The size was chosen to be slightly larger than the nozzle's inner diameter. At 1.0 wt % and −20 °C, small 0.5−5 μm particles were formed by dripping the solution at a flow rate of 0.22 mL/min into CO_2. These nonagglomerated particles were similar to the *l*-PLA microspheres shown in Figure 2 (top). The same experiment conducted at 0 °C and above produced some small (0.5−5 μm) primary particles but mostly large (>500 μm) solid agglomerates. Therefore, the polymer particles are significantly more viscous and less susceptible to agglomeration at −20 °C.

As shown in Figure 2 (bottom), a 5.0 wt % solution resulted in 5−70 μm microspheres. At this higher concentration, larger particles may be expected because of the higher solution viscosity. When the large droplet strikes the liquid surface, the more viscous solution mixes more slowly with the surrounding liquid CO_2 and mass transfer rates are slower. With slower mixing and mass transfer, the degree of supersaturation is lower than with less viscous solutions (lower concentrations), resulting in fewer nuclei per weight of polymer. Because most of the nuclei tend to be formed in a small volume where the droplet falls, coalescence of primary particles is more prevalent than for the experiments with lower polymer concentrations, where faster mixing occurs. With the reduction in nucleation rate and higher polymer concentrations (which produces faster agglomeration), especially in a local volume where the drop falls, larger particles are formed.

Unlike previous studies for polystyrene with the same vapor-over-liquid technique, these particles are much smaller than the initial droplet size, which was ~200 μm. For 6 wt % polystyrene (200000 MW) in toluene solutions, 300 μm diameter microballoons are formed with a 151 μm nozzle.[34] A skin, about 20 μm thick, forms on the droplet while still in the vapor phase which then hardens upon contact with the liquid phase. The polymer entanglement and viscosity in the skin are sufficient to maintain the integrity of the droplet as it solidifies in the liquid CO_2. The PGLA in this study has a much lower molecular weight (~30000), and the solutions are much less viscous. Also, the miscible region in the phase diagram in Figure 3 is

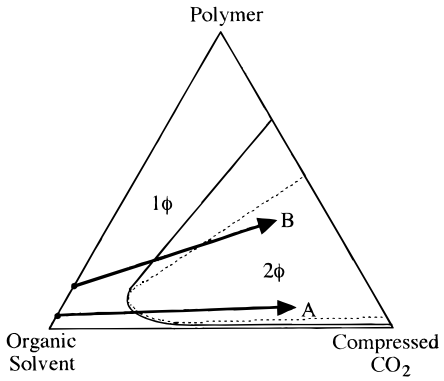

Figure 3—Schematic ternary phase diagram comparing mass transfer pathways for precipitation with a compressed fluid antisolvent: (—) binodal curve, (---) spinodal curve.

larger for PGLA−dichloromethane−CO_2 than for PS−toluene−CO_2 because of the lower molecular weight for PGLA versus PS and the lower solubility parameter of dichloromethane versus toluene. Consequently, it will take longer for PGLA to precipitate on the mass transfer pathway on the phase diagram (Figure 3), delaying skin formation.[34] Without any visual indication of skin formation in the vapor phase, smaller particles are produced, as the droplet breaks up on contact with the liquid phase.

At dilute concentrations, PGLA does not appear to form a skin when contacting CO_2 vapor, and the particles do not form until the large droplet has begun to disperse in the liquid CO_2 phase. When the solution concentration is increased to 10 wt %, the solution becomes extremely viscous and individual particles are not formed, only large agglomerates, >1000 μm. Here, a thin skin is visible on the droplets while they are being formed in the vapor phase, although the microscopic structure of the skin could not observed with the naked eye. The formation of a skin was confirmed by examination of the samples with SEM (not shown). Skin formation is favored by the higher solution viscosity and high concentration, which may shift the mass transfer pathway above the critical point (see Figure 3). This shift would cause solvent-rich domains to nucleate and grow within a polymer-rich domain.[34,37] The thin skin is weak, since it contains a high concentration of dissolved CO_2, and it was easy to observe visually that the skin immediately ruptures upon hitting the CO_2 liquid surface. The ruptured skin appeared as large agglomerates or films when examined by SEM (not shown). The mixing and diffusion of solvent away from the droplet are very slow due to the high polymer concentration and viscosity, resulting in severe agglomeration.

When a polymer solution is sprayed at 1.0 mL/min into flowing liquid CO_2 (without a CO_2 vapor phase), we found that fibers are produced for PGLA concentrations above 1.0 wt %. Fibers are formed from the jet due to the rapid nucleation, high solution concentration, high solution viscosity (to prevent atomization) and skin formation.[33] In experiments with vapor-over-liquid CO_2, the large droplets are formed instead of a jet (at the same flow rate) due to much higher interfacial tension because of the low CO_2 density. The precipitation in the droplets is slower than in the case of a jet due to the larger dimensions of the solution phase and lower miscibility between the phases for CO_2 vapor compared with CO_2 liquid. As a result, fibers are not formed.

The opposing effects of temperature on particle growth, coalescence, and mixing between the phases must be properly balanced to produce large nonagglomerated particles. As temperature is decreased the polymer solution becomes more viscous, which will cause coalescence to be less prevalent. Some coalescence, however, will aid the formation of the desired 50−100 μm particles rather than the typical 1−5 μm particles. As mentioned earlier, decreasing the temperature below −20 °C slows the mixing between the solvent and CO_2 phases. When a 1.0% solution of PGLA in dichloromethane was dripped into liquid CO_2 at −30 °C, no distinct particles were formed, only large agglomerates, due to the slow mixing. When the solution droplets fell, they initially formed a pool at the liquid surface and then penetrated the surface. The polymer began to precipitate at the interface, forming a film, and occasionally droplets fell through the film and agglomerated. Previously, we showed that PGLA particles exposed to CO_2 do not tend to agglomerate at −40 °C, indicating hard particles or even a glassy state. Unfortunately, the rate of mixing between the organic solvent and the liquid CO_2 is too slow at −30 °C and −40 °C to disperse the polymer.

At temperatures higher than 0 °C, agglomeration also occurred readily. As seen in Figure 4 (top), a 5.0 wt % solution dripped into liquid CO_2 at 1 °C yielded some distinct particles in the 10−50 μm range, but the polymer was partially agglomerated. This occurred for every experiment at 0 °C or above since the polymer is excessively swollen by CO_2 and the viscosity is too low at these temperatures.

A 0.030 in. i.d. (~750 μm) stainless steel nozzle was used to form larger initial droplets in order to attempt to produce the desired particle size. For PGLA concentrations of 1.0 and 5.0 wt %, and temperatures from −20 °C to 4 °C, the particles were always severely agglomerated with few, if any, distinct particles. The large drops formed more slowly, providing more time for precipitation to occur which allowed a thin skin to form on the large droplets while in the vapor phase. On the basis of visual observation, this skin was weak and ruptured upon impact with the liquid

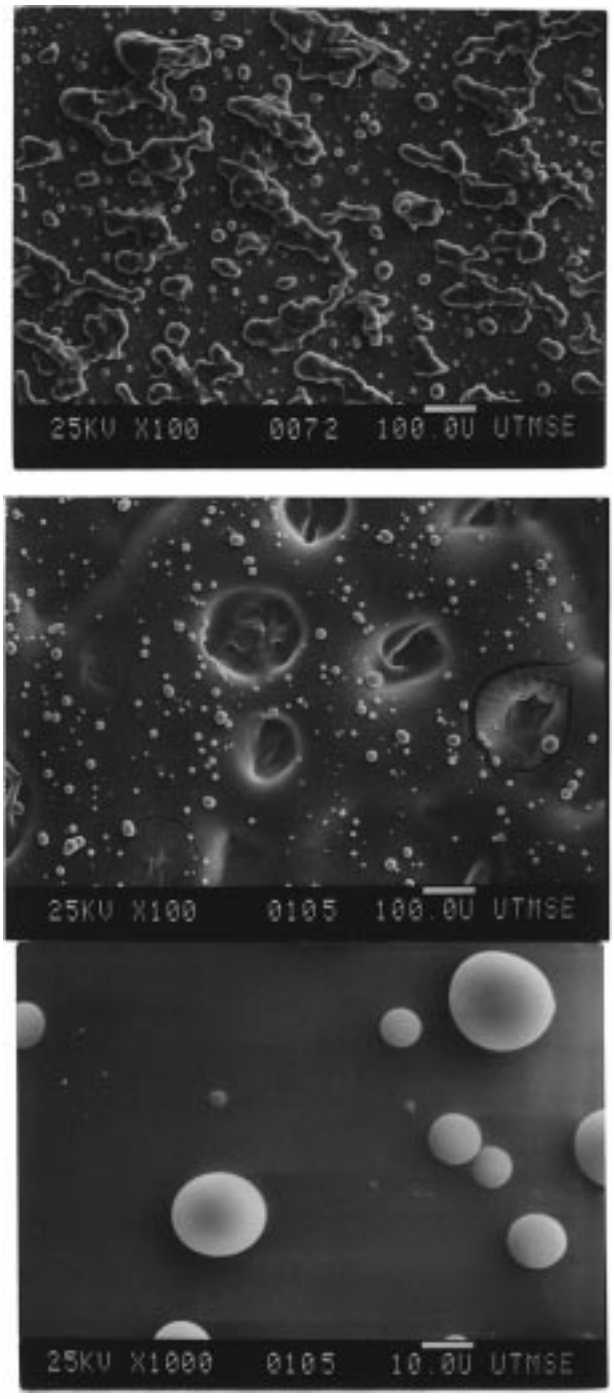

Figure 4—SEM micrographs of PGLA microspheres formed by spraying a 5.0 wt % PGLA in CH_2Cl_2 solution at 0.1 mL/min ($T = 1$ °C) into static CO_2 (top) and at 0.5 mL/min into CO_2 flowing at 17.5 mL/min at –20 °C (middle and bottom) through a 100 μm capillary.

CO_2 surface. The larger droplet size produced a larger local concentration of polymer and solvent which caused severe agglomeration of the polymer.

Polymer Particles Formed in Flowing Vapor-over-Liquid CO_2—Experiments were performed with flowing CO_2 to minimize CH_2Cl_2 accumulation. CO_2 was passed through the annular region of a coaxial nozzle, described previously,[41] at high velocity (69−138 cm/s) to agitate the surface of the liquid phase to enhance mixing. Figure 4 (middle and bottom) shows PGLA particles formed by spraying a 5.0 wt % solution at 0.5 mL/min into the cell through a 100 μm capillary nozzle with CO_2 flowing at 17.5 mL/min and at −20 °C. Vigorous mixing was observed at

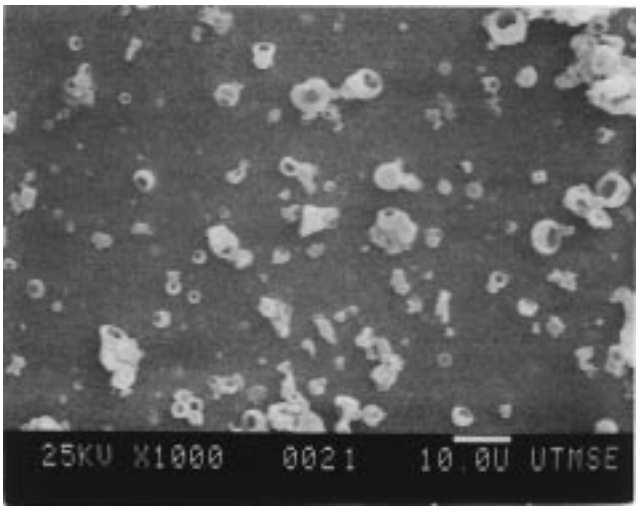

Figure 5—SEM micrograph of spray-dried lysozyme particles.

the interface, such that particles nucleated and grew throughout the liquid-phase rather than in a local region where the droplets fell. The resulting spherical particles ranged in size from 3 to 25 μm in diameter with no agglomeration even after almost 2 min of spraying. The difference in results was dramatic compared to the case for static CO_2. The particles were suspended throughout the cell, but plugging of the frit in the effluent line at the bottom of the cell limited spray times. This problem could be reduced in the future with a larger filter. The increased mixing causes a higher degree of supersaturation, more nucleation, faster solvent removal and quenching, and less time for growth. The result was far less coalescence and agglomeration when compared to the case with static CO_2. Experiments were also run at higher temperatures to determine if the increased mixing was enough to prevent agglomeration. For all cases where the temperature was 0 °C or higher, some 10−50 μm particles were formed, but mostly large (>500 μm) agglomerates were formed. The particles were not sufficiently hard at the higher temperatures to prevent coalescence.

Encapsulation of Lysozyme into PGLA with Static CO_2—In control experiments, lysozyme suspensions in CH_2Cl_2 were sprayed into CO_2 through a 100 μm capillary nozzle at temperatures from 23 to 0 °C. The lysozyme suspensions were formed with an ultrasonic bath and were stable for hours. The suspension flowed smoothly through the capillary, and the particle size (1−10 μm) and morphology of the product were identical to those of the original lysozyme, which is shown in Figure 5. The original spray-dried lysozyme particles and those removed after spraying into CO_2 were "bowl-shaped" when examined by SEM. Since the polymer particles discussed previously were spheres, it is easy to distinguish between polymer and protein particles.

Table 2 summarizes results of encapsulating lysozyme into PGLA. Again, the temperature was chosen as −20 °C to strike a balance between mixing favored at high temperatures and formation of hard, nonsticky particles in CO_2 which is favored at low temperatures. An initial loading of 10:1 by weight of polymer to protein was maintained in each case. Figure 6 (top) shows the result of spraying a 1.0 wt % solution of PGLA with lysozyme into static CO_2. The primary particle size was 0.5−5 μm in diameter with very little encapsulation of the similarly sized protein particles. The solution was too dilute for polymer particles to encapsulate a significant fraction of the protein particles. This result was anticipated, since it was shown above that small 0.5−5 μm PGLA particles are formed by precipitation

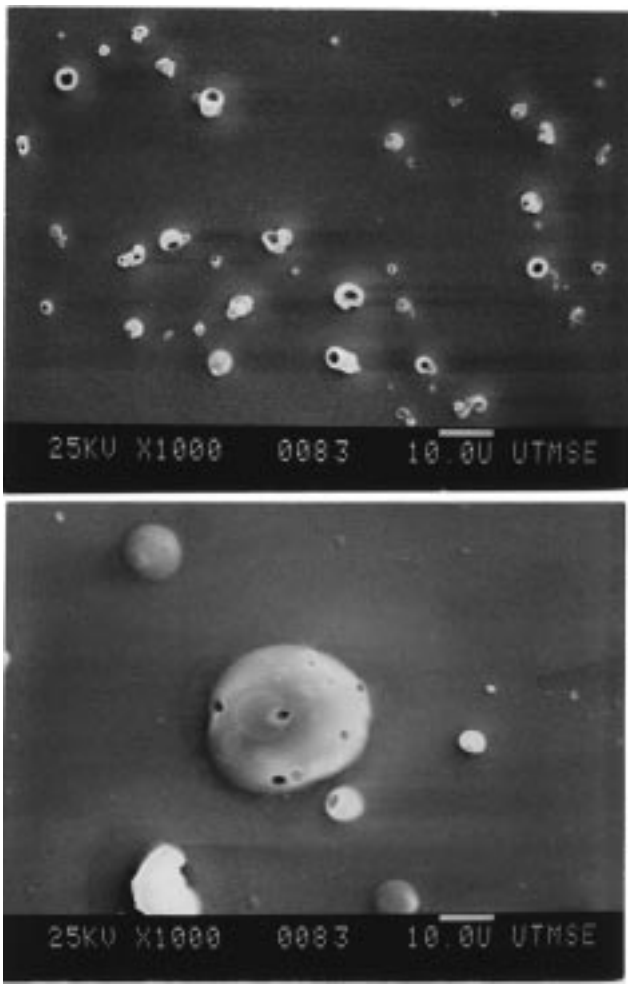

Figure 6—SEM micrographs of PGLA microspheres formed by spraying a 1.0/0.1 wt % (top) and a 5.0/0.5 wt % (bottom) PGLA/lysozyme suspension at 0.1 mL/min in CH_2Cl_2 through a 100 μm capillary nozzle into static CO_2 at –20 °C.

from a 1.0 wt % solution, which are too small to coat the lysozyme particles.

For a PGLA concentration of 5.0 wt %, the particles are in the 5−60 μm diameter range, and the encapsulation efficiency is substantial, as demonstrated in Figure 6 (bottom). Here, the magnification is high enough to examine a single particle. The craters or holes in the polymer particle represent protein particles for the following reasons. In identical experiments without protein, the craters were never present. Also, the size of the craters match those of the pure protein particles. Further evidence that the craters represent protein particles is given below in the subsection on experiments with flowing CO_2.

At lower magnifications, the particles looked similar to those shown in Figure 2 (bottom). Apparently, the presence of the small encapsulated protein particles does not have a significant influence on the polymer particle size. The polymer particles are much larger than in the case of a 1.0 wt % solution and are large enough to encapsulate multiple protein particles. Also, since the solution is more concentrated, the probability of a polymer particle nucleating and growing next to a lysozyme particle is enhanced. Also, the protein has the potential to act as a nucleating agent for the polymer. The large droplets formed in the CO_2 vapor phase lead to relatively slow mixing when the droplets strike the liquid CO_2 phase. The high local concentrations of the sticky CO_2-swollen polymer and protein lead to a large amount of growth.

A desirable feature of this spray geometry is that a polymer-rich phase nucleates in the presence of the protein in the confined space of the droplets, which occupy a small volume fraction compared to the total volume. Such nucleation may be expected to produce higher encapsulation efficiencies than if the polymer nucleated throughout the total cell volume. This advantage of compartmentalization of polymer and protein is not present in the GAS process cited above where CO_2 is added to a liquid solution. A disadvantage of the V/L PCA process is that the primary mass transfer takes place at the vapor−liquid surface rather than throughout the entire volume, which can lower the production rate.

Varying the size of the droplets leaving the nozzle could potentially lead to a change in size of the polymer particles. As the flow rate of the polymer solution increased, it was observed that the droplet size decreased. However, no significant change in particle morphology occurred when the solution flow rate was increased from 0.1 to 1.5 mL/min for a 5.0 wt % solution at −20 °C. In each case, the particles appeared as those shown in Figure 6 (bottom). A complication of extremely slow flow rates is plugging of the nozzle, which occurred very often at 0.1 mL/min, but infrequently at 0.5 mL/min or higher. This plugging is likely a result of precipitation inside the nozzle, caused by CO_2 diffusing upward into the nozzle and/or entrapment of the solid protein particles.

The degree of agglomeration of the polymer product is dependent upon the solution flow rate and spray time. When conducting the spray, at a certain time large particles could easily be seen with the naked eye. When analyzed by SEM, these large particles were agglomerates and not simply large flocculates of small primary particles. At a solution flow rate of only 0.1 mL/min, the experiment could be run for 1 min before agglomeration began to occur. For higher flow rates, the observed time where large particles appeared decreased accordingly to 40 and 20 s at flow rates of 0.5 and 1.5 mL/min, respectively. This agglomeration could potentially be avoided by either flowing CO_2 continuously through the cell as described in the next section or by spraying into a larger volume cell. At 1.8 mL/min, streaming of the solution begins to occur rather than dripping. Here, the range of particle sizes did not change, but there was a higher percentage of large particles compared to the previous cases at lower flow rates. Due to the large amount of solution flowing into the cell, agglomeration began to occur after only 10 s.

Encapsulation of Lysozyme into PGLA with Flowing CO_2—Figure 7 compares an optical micrograph and a SEM micrograph of polymer particles with protein particles visible on the surface. These particles were formed by spraying a 5.0 wt % PGLA solution with suspended lysozyme at 0.5 mL/min along with CO_2 flowing in the annulus at a velocity of 138 cm/s. The SEM image (top) shows particles with craters or holes in their surfaces, which may be identified as the "bowl"-shaped spray-dried lysozyme particles. The micrograph taken with the optical microscope (bottom) shows the same polymer particle with encapsulated stained protein particles. The stained protein directly corresponds to the craters observed in the SEM micrograph. This correspondence between optical and SEM photomicrographs was always observed where we compared images of particles formed by the vapor/liquid PCA process. Figure 8 (top) shows 40−70 μm particles with encapsulated lysozyme formed at the same conditions as Figure 7, except at a higher CO_2 flow rate. By varying the focal plane throughout the depth of the particle (not shown), we observed in the optical microscope that the protein particles were encapsulated throughout the PGLA particles and were not just on the surface. While there did

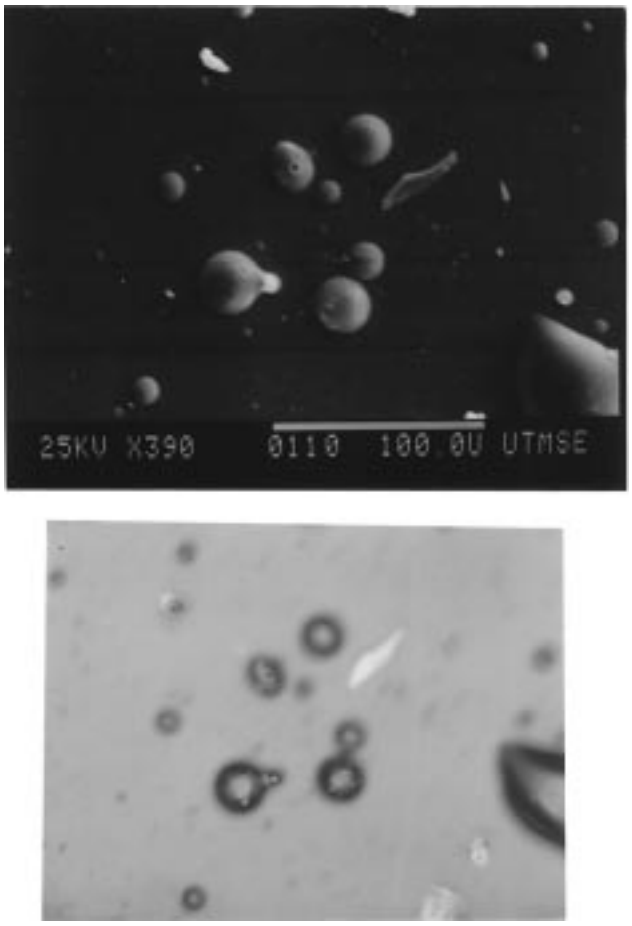

Figure 7—SEM micrograph (top) and optical micrograph (bottom) of PGLA microspheres formed by spraying a 5.0/0.5 wt % suspension of PGLA/lysozyme in CH_2Cl_2 at 0.5 mL/min through a 100 μm capillary nozzle into CO_2 flowing at 15 mL/min at –20 °C.

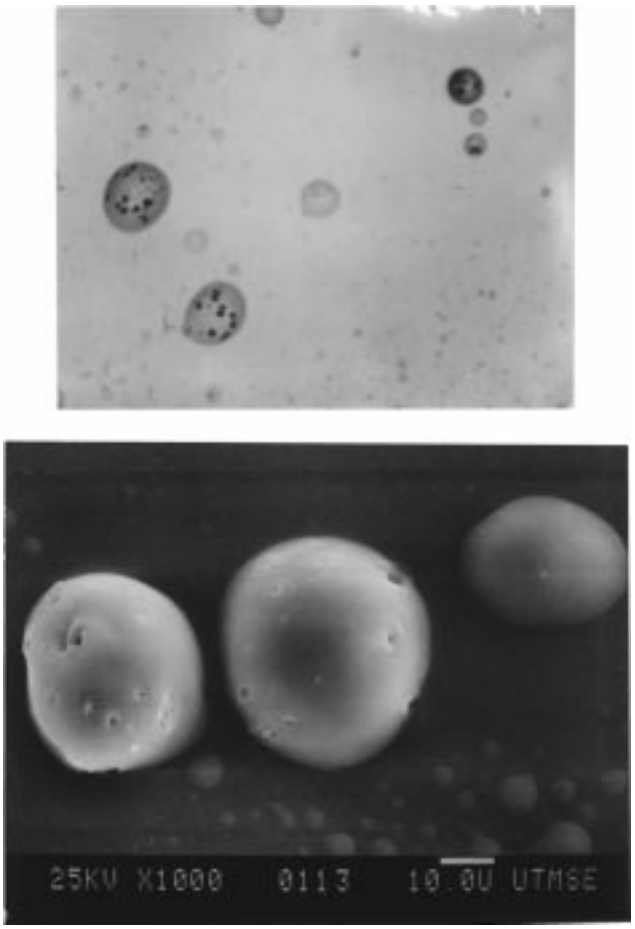

Figure 8—SEM micrograph (bottom) and optical micrograph (top) of PGLA microspheres formed by spraying at 0.5 mL/min a 5.0/0.5 wt %PGLA/lysozyme suspension in CH_2Cl_2 through a 100 μm capillary nozzle into CO_2 flowing at 25 mL/min at –20 °C.

not appear to be any protein particles which were not encapsulated, polymer particles without encapsulated protein were present.

Flowing CO_2 at high velocity during the spray delayed the time at which large particles were observed visually in the tube. This time corresponded to the time where agglomeration was observed in the SEM micrographs. Flowing CO_2 through the annular region surrounding the nozzle at high velocity caused a large amount of mixing at the vapor/liquid interface and suspended the precipitated particles throughout the cell, yielding spherical, nonagglomerated particles. Spraying a 5.0%/0.5% PGLA/lysozyme solution at 0.5 mL/min into the cell at −20 °C with CO_2 flowing at 25 mL/min yielded spherical particles 5−30 μm in diameter, with encapsulation of the protein as seen in Figure 8 (bottom). These particles are more uniform in size and shape than those formed in static CO_2 and appear like those in Figure 4 (middle). The particle sizes are more uniform in this case due to better mixing at the vapor−liquid interface.

In another type of experiment, CO_2 was introduced into the cell through a large opening located in the top of the cell 1 cm above the tip of the nozzle. Here, the CO_2 velocity was relatively low and turbulence from the CO_2 did not have much effect on the solution stream nor on the CO_2 vapor/liquid interface. The purpose of flowing CO_2 was to reduce the accumulation of solvent in the cell. Spraying a 5.0%/0.5% PGLA/lysozyme solution at 0.5 mL/min into CO_2 flowing at 35 mL/min at −21 °C yielded little change in particles size and failed to delay the onset of agglomeration, compared to the case with static CO_2. The same was true for higher CO_2 flow rates up to 52 mL/min. With this cell configuration, the CO_2 stream does not cause significant turbulence or mixing inside the cell. Since agglomeration occurred at the same time as in static CO_2 experiments, most of the agglomeration occurs immediately after precipitation and not after solvent buildup in the cell. In this case the particles were concentrated at the liquid−vapor interface and were not suspended throughout the liquid phase.

Elemental analysis via energy dispersive spectroscopy (EDS) was also used to confirm the presence of lysozyme in the polymer particles. Lysozyme has 2 amino acid constituents containing sulfur, cysteine, and methionine, which can be detected via EDS. Chicken egg white lysozyme is reported to contain eight cysteine molecules and two methionine molecules per protein chain.[61,62] Both of these amino acids have one sulfur atom per molecule, resulting in 10 per lysozyme molecule. EDS scans of the pure protein (top) and particles with encapsulated protein (bottom) are shown in Figure 9. The analysis of the pure lysozyme shows peaks corresponding to the presence of phosphorus, chlorine, and potassium impurities as well as the sulfur. Analysis of the peaks is only qualitative, unfortunately, due to multiple scattering of the X-rays. Particles formed by spraying a 5.0% PGLA solution with suspended lysozyme were analyzed as shown in Figure 9 (bottom). The lower curve represents a polymer particle with no protein present, while the upper curve corresponds to a single polymer particle with entrapped lysozyme. The particles were collected on a section of a glass slide, thus explaining the presence of the silicon impurity peak. The presence of the

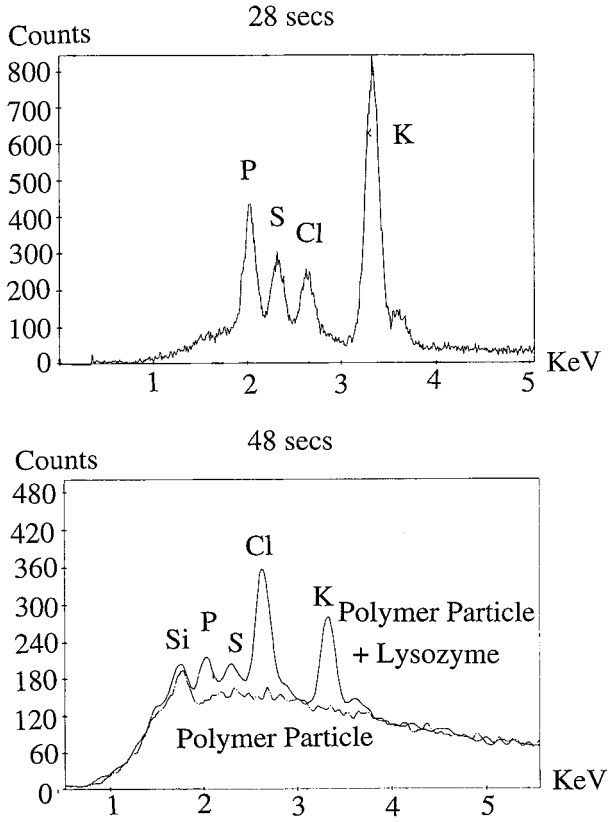

Figure 9—EDS scans of spray-dried lysozyme (top) and PGLA microspheres (bottom) formed by spraying a 5.0/0.5 wt % suspension of PGLA/lysozyme at 0.5 mL/min in CH_2Cl_2 through a 100 μm capillary nozzle into CO_2 flowing at 15 mL/min at –20 °C.

other peaks, excluding silicon, indicates that lysozyme was encapsulated within the polymer particle examined.

Encapsulation of Lysozyme into *l*-PLA—When polymer particles are similar in size to the protein particles, little or no encapsulation is expected to occur. Figure 10 (top) shows particles formed by spraying a 1.0% *l*-PLA solution with suspended lysozyme at 0.1 mL/min and 20 °C. As shown, the 1−4 μm polymer particles do not tend to encapsulate the lysozyme particles. Therefore, the polymer precipitation occurs without requiring the protein as a nucleation site. Solutions with higher polymer concentrations will tend to form larger particles as evidenced earlier for PGLA. Spraying a 5.0% *l*-PLA solution at 0.5 mL/min and 24 °C resulted in particles 250−500 μm in diameter, Figure 10 (bottom). This polymer precipitates very rapidly, and a polymer skin quickly forms on the droplet while still in the CO_2 vapor phase. The high solution viscosity caused the drop size to be larger than the nozzle inner diameter, and the resultant particle diameter was the same as the initial drop size. In this case the large polymer particles appeared to encapsulate all of the protein particles, as no individual protein particles were found on the sample slides.

Conclusions

Several major challenges for the PCA process were overcome in order to encapsulate a protein into PGLA. The PGLA particles were large enough to encapsulate the protein and did not agglomerate. In contrast, the primary particles (0.5 to 5 μm) were too small for encapsulation when the solution was sprayed into liquid or supercritical CO_2; furthermore, the particles were highly agglomerated. By delaying precipitation in a vapor CO_2 phase over a

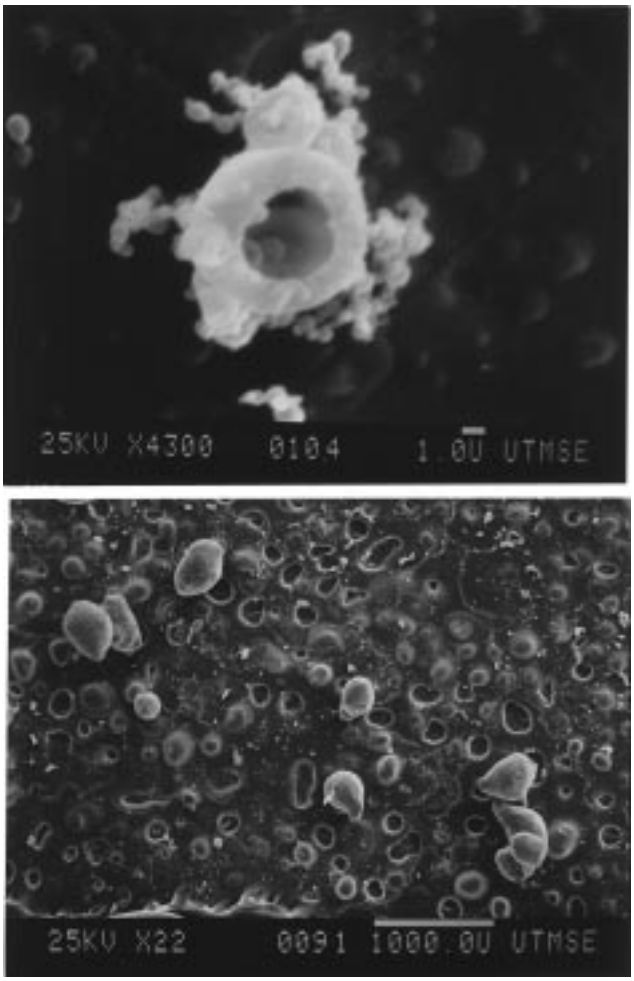

Figure 10—SEM micrographs of *l*-PLA microspheres formed by spraying a 1.0/0.1 wt % *l*-PLA/lysozyme suspension at 0.1 mL/min at 20 °C (top) and a 5.0/0.5 wt % *l*-PLA/lysozyme suspension at 0.5 mL/min at 24 °C (bottom) through a 100 μm capillary nozzle into static CO_2.

liquid CO_2 phase, much larger primary particles were formed, from 5 to 70 μm. At an optimal temperature of −20 °C, the polymer solution mixed rapidly with CO_2, and agglomeration of primary particles was minimal due to harder particles than at higher temperatures.

The amorphous polymer PGLA is highly plasticized by CO_2. Dissolution of CO_2 into PGLA depresses the T_g from the normal value of 45 °C to approximately −40 °C at 276 bar, based upon observation of particle agglomeration. Below −40 °C, the polymer remains as a nonsticky, free-flowing powder in the presence of CO_2 at 276 bar. Below −30 °C, the rate of mixing between CH_2Cl_2 and liquid CO_2 decreases appreciably. At an optimal temperature of −20 °C, the highly viscous PGLA microspheres do not agglomerate, yet the temperature is high enough to achieve adequate mixing between liquid CO_2 and the organic solution. An additional benefit of operating at colder temperatures is the relatively low pressure. At −20 °C, the saturation pressure of CO_2 is 19.7 bar, compared to 61.4 bar at 23 °C.

The vapor-over-liquid PCA process forms microspheres in the 5−70 μm range when a 5.0% solution of PGLA in dichloromethane is sprayed at 0.22 mL/min through a 100 μm diameter nozzle into static CO_2 at −20 °C. Experimental temperatures of 0 °C or above or below −30 °C yielded only large (>1000 μm) agglomerates. At high temperatures the particles are too sticky due to dissolved CO_2, and at low temperatures, the organic solution and CO_2 mix too slowly. Lower concentrations yielded smaller primary

particles whereas highly viscous concentrated solutions above 10.0 wt % led to skin formation in the vapor phase and subsequent agglomeration in the liquid CO_2 phase. The thin skin is weak due to low molecular weight and dissolved CO_2, and hence rupturing occurs upon impact at the liquid interface leading to agglomeration. Particle sizes did not change appreciably with solution flow rate in the "dripping" regime. At the onset of streaming flow, there was a higher percentage of large particles, while the particle size range remained the same. The most spherical and uniform particles ranging in size from 3 to 25 μm in diameter were produced by flowing CO_2 at high velocity through an annular region in a coaxial nozzle to provide mixing at the interface.

Encapsulation of 1−10 μm lysozyme particles proved successful for the 5−70 μm PGLA microspheres for a 1:10 ratio by weight of protein to polymer and a 5 wt % polymer solution. The presence of lysozyme in the particles was demonstrated by SEM analysis, optical microscopy, and EDS. A high encapsulation efficiency for this process is favored by the fact that the protein and polymer precipitate together in small droplets. The use of protein suspensions extends the applicability of the PCA process substantially, since many proteins are insoluble in organic solvents and are less likely to be denatured when suspended.

Introduction

Metastable thermodynamic states are frequently encountered in pharmaceutical systems, in the intentional or unintentional creation of supersaturation, in the crystallization of desired solid-state modifications, and in the control of solid-phase conversions during isolation, manufacturing, storage, and dissolution.[1−4] Some examples in which metastable states are encountered include solid solutions, freeze-concentrated solutions, solutions of weak acids or bases exposed to a pH change, solutions prepared by dissolving a solid-state modification with a higher solubility (higher free energy), and residual solutions during filtration, granulation, and drying. Because crystallization provides a way of reducing the free energy of metastable thermodynamic states, the extent to which metastable states can be maintained is determined by the crystallization mechanisms and kinetics.[5−16] What is surprising, however, is that despite the important role that crystallization has in process control and in determining solid-phase outcomes, crystallization phenomena are often neglected in the pharmaceutical industry until a problem is encountered.

While emphasis is often given to the knowledge of equilibrium phase diagrams with the purpose of identifying the concentration and temperature regions of thermodynamic stability of solid phases, information on crystallization processes can only be obtained by combining studies of thermodynamic properties with kinetic measurements. Cases of unwanted or previously unknown nucleation events abound. Dunitz and Bernstein[17] documented cases of "disappearing or elusive polymorphs" that provide evidence for the consequences of poor process control in crystallization of polymorphic systems. The recent shortage in the supply of capsules of the HIV protease inhibitor Norvir (indinavir), due to the sudden formation of a crystalline structure different from the one harvested for months,[18] illustrates the decisive role that nucleation mechanisms and kinetics have on crystallization. Nichols and Frampton[19] have reported considerable efforts that failed to crystallize the metastable polymorph of paracetamol as described in the initial publication of the crystal structure.[20] The critical role of crystallization kinetics in determining the appearance of crystalline modifications is also recognized by the FDA and described in the guidelines for the manufacture of drug substances:[21] "Appropriate manufacturing and control procedures (including in-process testing when needed) should be established for the production of the desired solid-state form(s). It should be emphasized that the manufacturing process (or storage condition) is responsible for producing particular polymorphs or solvates; the control methods merely determine the outcome."

Even when the parameters that regulate crystallization phenomena are neglected, the illusion of process control is motivated by a crystallization process that yields the desired product—solid phase modification, shape, or size distribution—and by the robust analytical methods used for solid state characterization. This situation is greatly complicated by the recent emphasis on an exclusively

structural approach due to the availability of commercial software for the prediction of crystal structure from molecular structure (ab initio predictions) while kinetic processes are scarcely investigated. Desiraju[22–24] and Gavezzotti[25–29] have discussed the various methods for crystal structure and polymorphism prediction and the capabilities and shortcomings of the various computer simulation techniques. The main challenge lies in determining the relationships between the molecular aggregation pathways that cause some nuclei to grow and the structure and thermodynamics of the crystalline solids. Recent work from various groups[14,30–40] highlight the importance of combining computer simulations with experimental methods to investigate the molecular events that lead to crystallization.

The purpose of this review is to describe ways in which crystal structure, morphology, and crystallization kinetics can be utilized to reproducibly maintain metastable states and control solid-state outcomes. Experimental methods that can be employed to investigate the factors that regulate crystallization from solution will be presented.

Crystallization

A crystalline phase is created as a consequence of molecular aggregation processes in solution that lead to the formation of nuclei (with a configuration compatible with the crystal structure), which achieve a certain size for a sufficient time to enable growth into macroscopic crystals. The rate and mechanisms by which crystals are formed in liquid solutions is determined by the solubility, supersaturation, rate at which supersaturation is created, diffusivity, temperature, and the reactivity of surfaces toward nucleation.[41–45]

Transferability of crystallization microtechniques to larger scale processes that are reproducible requires identification of crystallization mechanisms and kinetics. While operationally useful variables that describe crystallization methods are often related to crystallization outcomes, this approach lacks meaningful information for developing a process that yields reliable outcomes, since the factors that determine the crystallization kinetics and outcomes are not explicitly considered. For instance, compare the following two approaches to describe the processes for the selective crystallization of polymorphs: (1) form I obtained by cooling, form II obtained by evaporation, and (2) form I obtained at a supersaturation x, temperature y, and time z at which crystals were harvested after crystallization onset; form II obtained at supersaturation x', etc. While the former approach is at best anecdotal, the latter employs the causative factors and leads to relationships between the crystallization kinetic parameters and the outcomes.

Control of the processes of nucleation and crystal growth is possible as long as the required information is available. Dunitz and Bernstein[17] have explained the mystery of disappearing polymorphs by considering various examples and the relevant questions that were left unanswered. They state that "once a particular polymorph has been obtained, it is always possible to obtain it again; it is only a matter of finding the right experimental conditions."

Supersaturation

Knowledge of the driving force for crystallization is essential, not only to characterize the kinetics, but also to relate the crystallization outcomes to the parameters that regulate crystallization. The number of molecules necessary to achieve an effective nucleating cluster is inversely proportional to the supersaturation. Therefore, as the supersaturation is increased the probability of nucleation increases. However, nucleation is energetically more demanding than crystal growth, and there are supersaturation regions in which crystal growth proceeds while nucleation is suppressed.[41,42,44]

The driving force for nucleation and growth is the difference in chemical potential of the solute in a supersaturated solution, μ_1, and in a saturated solution, μ_{eq}:

$$\Delta\mu = (\mu_1 - \mu_{eq}) \tag{1}$$

Since $\mu = \mu^\circ + RT \ln a$, then

$$\Delta\mu = \mathrm{RT} \ln (\mathrm{a}_1/\mathrm{a}_{eq}) = \mathrm{RT} \ln (\gamma_1 \mathrm{c}_1/\gamma_{eq}\mathrm{c}_{eq}) \tag{2}$$

and the supersaturation is

$$\sigma = \Delta\mu/\mathrm{RT} = \ln (\mathrm{a}_1/\mathrm{a}_{eq}) = \ln (\gamma_1 \mathrm{c}_1/\gamma_{eq}\mathrm{c}_{eq}) \tag{3}$$

If the activity coefficient, γ, is independent of concentration, in the given concentration regime, then $\gamma_1 = \gamma_{eq}$ and the supersaturation becomes

$$\sigma = \ln (c_1/c_{eq}) = \ln (c/s) \tag{4}$$

where c is the concentration of the crystallizing substance in the supersaturated solution and s is the solubility. (This notation is adopted to avoid the use of subscripts.) A frequently used definition for the supersaturation is

$$\sigma \equiv (c - s)/s \tag{5}$$

For c/s values smaller than 1.15,

$$\sigma = \ln (c/s) \approx (c - s)/s \tag{6}$$

Supersaturation may be created by various methods that regulate the solute activity (concentration) or activity product. These include (a) solvent removal (evaporation or freezing), (b) addition of indifferent salts with ions that participate in precipitation, and (c) dissolution of metastable solid phases. Supersaturation can also be created by methods that regulate the solute solubility, such as temperature change, pH change, and addition of a solvent that lowers the solubility of the solute.

Nucleation

Nucleation is often the decisive step in the crystallization process and is of practical importance in pharmaceutical systems. For instance, questions regarding the concentration threshold above which crystallization is observed at times shorter than the desired product shelf life, or dilution rates and concentrations above which precipitation occurs upon injection, are related to the kinetic stability of supersaturated solutions and are regulated by the nucleation mechanisms and kinetics. Nucleation phenomena are equally important in the control of micromeritic properties and in the selective crystallization of a particular polymorph.

In general, nucleation mechanisms can be divided into two main categories: homogeneous and surface or interface catalyzed.[42–44,46] Homogeneous nucleation rarely occurs in large volumes (greater than 100 μl) since solutions contain random impurities which may induce nucleation.[47,48] This type of nucleation is referred to as heterogeneous. A surface or an interface of different composition than the crystallizing solute may serve as a nucleation substrate, by decreasing the energy barrier for the formation of nuclei that can grow into mature crystals. Nucleation that is promoted by crystals of the crystallizing solute is known

as secondary nucleation. These mechanisms are thoroughly discussed by Mullin,[42] Myerson,[44] and Zettlemoyer.[46]

Homogeneous Nucleation—Thermodynamic considerations for nucleation are based on the work of Gibbs,[49] Volmer [50] and others, where the free energy change for an aggregate undergoing a phase transition ΔG is given by

$$\Delta G = \Delta G_v + \Delta G_s \tag{7}$$

where ΔG_s is the surface free energy change associated with the formation of the aggregate (a positive quantity), and ΔG_v is the volume free energy change associated with the phase transition (a negative quantity). For homogeneous or heterogeneous nucleation

$$\Delta G_v = -\alpha l^3 v k_B T \ln\left(\frac{c}{s}\right) \tag{8}$$

where α is the volume-shape factor, l is the characteristic length, v is the molecular volume of the crystallizing solute, k_B is Boltzmann's constant, and T is temperature. For homogeneous nucleation

$$\Delta G_s = \beta l^2 \gamma_{12} \tag{9}$$

where β is the area shape factor and γ is the interfacial energy per unit area between the crystallization medium, 1, and the nucleating cluster, 2. Consequently, the overall free energy change for nucleation is decreased by a large supersaturation ratio (c/s) and by a low interfacial energy.

The factors that regulate nucleation are best appreciated by considering the equation for the rate of homogeneous nucleation from solutions:

$$J = N_o \nu \exp\left(\frac{-\Delta G^*}{k_B T}\right) = N_o \nu \exp\left(\frac{-4\beta^3 v^2 \gamma_{12}^3}{27\alpha^2 (k_B T)^3 \left(\ln\left(\frac{c}{s}\right)\right)^2}\right) \tag{10}$$

J is the number of nuclei formed per unit time per unit volume, N_o is the number of molecules of the crystallizing phase in a unit volume, ν is the frequency of atomic or molecular transport at the nucleus–liquid interface, and ΔG^* is the maximum in the Gibbs free energy change for the formation of clusters, at a certain critical size, l^*. The nucleation rate was initially derived for condensation in vapors by Becker and Döring,[51] where the preexponential factor is related to the gas kinetic collision frequency. In the case of nucleation from condensed phases, the frequency factor is related to the diffusion process.[52] The value of l^* can be obtained by minimizing the free energy function with respect to the characteristic length

$$l^* = \frac{2\beta v \gamma_{12}}{3\alpha k_B T \ln\left(\frac{c}{s}\right)} \tag{11}$$

For spherical clusters, $\alpha = 4\pi/3$ and $\beta = 4\pi$ based on the cluster radius. Therefore,

$$r^* = \frac{2v\gamma_{12}}{k_B T \ln\left(\frac{c}{s}\right)} \tag{12}$$

Considering these geometric factors, the rate for homogeneous nucleation of spherical clusters is

$$J = N_o \nu \exp\left(\frac{-16\pi v^2 \gamma_{12}^3}{3(k_B T)^3 \left(\ln\left(\frac{c}{s}\right)\right)^2}\right) \tag{13}$$

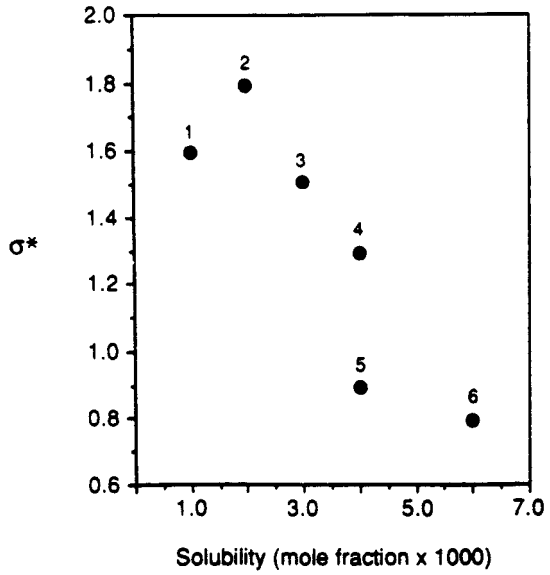

Figure 1—Dependence of the critical supersaturation for nucleation on solubility of nitrofurantoin in (1) formic acid, (2) formic acid:water (4:1), (3) formic acid:ethanol (2:1), (4) formic acid:dioxane (2:1), (5) formic acid:methanol (2:1), (6) formic acid:water (2:1). Data from ref 55.

While the classical theory of nucleation is limited by the implicit assumptions in its derivation (described in detail in ref 41) it successfully predicts the nucleation behavior of a system.[42–44,46,53] Inspection of the equation above clearly suggests that the nucleation rate can be experimentally controlled by the following parameters: molecular or ionic transport, viscosity, supersaturation, solubility, solid–liquid interfacial tension, and temperature.

Nucleation kinetics are experimentally determined from measurements of nucleation rates, induction times and metastability zone widths (the supersaturation or undercooling necessary for spontaneous nucleation) as a function of initial supersaturation.[41–43,54] The nucleation rate will increase by increasing the supersaturation while all other variables are constant. However, at constant supersaturation the nucleation rate will increase with increasing solubility. Solubility affects the pre-exponential factor and the probability of intermolecular collisions. Furthermore, when changes in solvent or solution composition lead to increases in solubility, the interfacial energy decreases since the affinity between crystallizing medium and crystal increases.[41] Consequently, the supersaturation required for spontaneous nucleation decreases with increasing solubility,[55] as shown in Figure 1.

The dependence of nucleation rate on solubility is also consistent with Ostwald's law of stages[56] regarding the preferential formation of a metastable solid phase, that states the following: "when leaving an unstable state, a system does not seek out the most stable state, rather the nearest metastable state which can be reached with loss of free energy". This indicates that if the unstable solid-state modification (the system with highest solubility) precipitates before more thermodinamically stable solid phases, it must have higher nucleation and growth rates than solid states of lower solubility. However, Ostwald's law of stages is not universally valid because the appearance and evolution of solid phases are determined by the kinetics of nucleation and growth under the specific experimental conditions.[5,6,13]

Accounts of nucleation inhibition in the pharmaceutical literature are sometimes confusing because the dependence of the nucleation event (nucleation rate, metastability zone width, or induction time) on supersaturation is not considered. In search for additives that inhibit nucleation,

Table 1—Comparison of Crystallization Behavior of Disodium Phosphate during Far-from-Equilibrium Freezing of Buffer Solutions

crystallization behavior of $Na_2HPO_4 \cdot 12H_2O$		$C_{Na_2HPO_4}$[a] (mM)
reference	observation	
Murase and Franks[63,64]	crystallization begins to decrease	≤200
	does not crystallize	≤10
Cavatur and Suryanarayanan[65]	readily crystallizes	190
	crystallization is inhibited by $C_{NaH_2PO_4}$[b] ≥ 730 mM	190
Gómez[66]	crystallization begins to decrease	≤15
	crystallization readily occurs	≥0.3
	crystallization is not inhibited at $C_{NaH_2PO_4}$ ≤ 94 mM	6

[a] $C_{Na_2HPO_4}$ = initial disodium phosphate concentration in solution at 25 °C. [b] $C_{NaH_2PO_4}$ = initial monosodium phosphate concentration in solution at 25 °C.

induction times are often measured as a function of additive concentration while the dependence of the nucleation event on supersaturation is neglected. Results from such studies possibly lead to the erroneous conclusion that the additive inhibited nucleation[57,58] when indeed the additive decreased the supersaturation, and frequently led to an undersaturated state. Hence, the system is under *thermodynamic* control instead of *kinetic* control.

An important factor contributing to the nucleation mechanism and kinetics is the volume of solution in which nucleation occurs. The dispersal of a bulk liquid into a collection of small droplets has been shown to be an effective way of achieving large supersaturations or undercoolings.[47,48] Precipitation and solidification in small volumes (droplets) involving emulsions have been used to study homogeneous nucleation processes,[59] and to control purity, particle size, and morphology.[60,61] Dispersing a solution into small volumes isolates heterogeneous nucleants within a fraction of the drops and makes nucleation more difficult. Consequently, larger supersaturations need to be reached for nucleation to occur. The boundaries of possible outcomes are represented by the following scenarios: (1) crystals of very small size (even in the nanometer range) are formed as a result of the high nucleation rates,[60,61] or (2) a glass or amorphous solid is formed due to the low diffusion rates of molecules that inhibit the evolution of clusters to crystals within the time scale of the experiment.[62]

Nucleation outcomes from solutions with initially the *same composition* may vary as a consequence of impurities, rates at which supersaturation was created, thermal histories, experimental techniques employed to detect precipitation, and solution volumes in which nucleation occurred. An important factor contributing to the changes in pH during freezing of buffer solutions is the selective crystallization of buffer components.[63–66] The salt and buffer concentrations for precipitation of disodium phosphate during freezing of sodium phosphate buffer solutions among various laboratories are shown in Table 1. Murase et al.[63,64] report higher initial buffer and disodium phosphate concentrations for the precipitation of disodium phosphate, compared to results from our laboratory.[66] The fraction of disodium phosphate precipitated was observed to decrease with decreasing the initial buffer concentration below 500 mM, at 200 mM disodium phosphate concentration, versus an initial buffer concentration below 8 mM, at 0.3 mM disodium phosphate concentration in our studies;[66] furthermore, disodium phosphate did not precipitate at initial disodium salt concentrations below 10 mM[63,64]

Table 2—Experimental Conditions and Methods of Measuring Progress of Sodium Phosphate Crystallization during Freezing

reference	vol of solution (μL)	cooling rate (°C/min)	temp (°C)	method
Murase and Franks[63,64]	2–5	0.62	–52	DSC, SEM
Cavatur and Suryanarayanan[65]	300[a]	15	–40	XRPD
Gómez[66]	25×10^3	0.3–0.5	–10	pH

[a] Personal communication.

while our studies show that precipitation occurs at salt concentrations as low as 0.3 mM.[66] Inspection of the experimental conditions under which these studies were done (Table 2) shows a trend toward slower salt precipitation rates with decreasing volume of solutions from 25 mL to 3 μl and increasing rates of cooling to lower temperatures.

Neglecting the factors that regulate nucleation leads to misleading generalizations when developing guidelines to control precipitation by the addition of noncrystallizing additives. Consider, for example, the conflicting interpretation of additive effects on nucleation when these are expressed in terms of concentration ratios (additive to crystallizing solute) while ignoring other parameters. Data in Table 1 indicates that disodium phosphate precipitation is inhibited at ($H_2PO_4^-/HPO_4^{2-}$) = 4 (0.73 M/0.19 M)[65] while it is not inhibited at ($H_2PO_4^-/HPO_4^{2-}$) = 16 (0.094 M/0.006 M).[66] Compared to the systems we studied,[66] the buffers studied by Cavatur and Suryanarayana[65] have much higher concentrations of monosodium phosphate (which increase the viscosity of solutions), smaller solution volumes, and faster rates of cooling to lower temperatures. All these factors contribute to delaying salt precipitation.

The effect of the viscosity of the crystallization medium on the nucleation rate has been described by Turnbull and Fisher.[52] The frequency of atomic or molecular transport at the nucleus–liquid interface can be related to the bulk viscosity, η, with the Stokes–Einstein relation:

$$\nu \approx \frac{kT}{3\pi a_o^3 \eta(T)} \tag{14}$$

where a_o is the mean effective diameter of the diffusing species. If the viscosity dependence on temperature is described by Arrhenius behavior, then

$$J = \frac{K}{\eta_o} \exp\left(\frac{-\Delta G^* - \Delta G_a}{k_B T}\right) \tag{15}$$

where ΔG_a is the activation energy for transport across the nucleus–liquid interface. Thus, the nucleation rate may go through a maximum when an increase in undercooling or supersaturation is accompanied by an increase in viscosity. This behavior has been observed in the nucleation of citric acid in aqueous solutions,[67] and the crystallization of ice.[68]

Heterogeneous Nucleation—Heterogeneous nucleation processes are of fundamental and practical importance in pharmaceutical systems since unintentionally or intentionally added surfaces or interfaces may promote nucleation. The reactivity of crystals surfaces as heterogeneous nucleants has significant consequences in the isolation of the desired solid-state modification and in the control of conversions between these modifications, since the free energy required for the formation of two-dimensional nuclei is lowered by the presence of an appropriate substrate. Quantitatively this is described by the following equation:[69,70]

$$\Delta G_s = \gamma_{12}A_{12} + (\gamma_{23} - \gamma_{13})A_{23} \quad (16)$$

where γ is the interaction energy per area, A is the surface area of the interfaces, and the subscript 3 represents the substrate. The total change in surface free energy will be lowered by favorable surface interactions between the aggregate and the substrate and unfavorable interactions between the crystallization medium and the substrate, due to the negative value of the second term in eq 16. Consequently, nucleation will be enhanced by increasing the surface area of the substrate.

The effectiveness of crystal seeding in controlling crystallization outcomes relies on the potential of crystal surfaces to promote heterogeneous or secondary nucleation,[42,43] while avoiding heterogeneous nucleation mediated by unknown contaminants. A review by Ward[71] on the structure, properties, and reactivity of organic crystal surfaces is recommended to develop strategies for the choice of surfaces that promote nucleation. Various studies[8,72−75] have demonstrated the influence of substrate topography, lattice parameters, crystallographic symmetry and intermolecular interactions on surface-directed nucleation.

Heterogeneous nucleation mechanisms can significantly affect dissolution of metastable solid phases, because this form of nucleation can occur at low driving forces. While the choice of a metastable solid phase with a solubility higher than other crystalline modifications is motivated by the expectation of faster dissolution rates, achievement of faster dissolution rates and higher concentrations in solutions is jeopardized by surface-mediated nucleation events. We have reported[8] that the surface of the metastable phase of theophylline promoted the nucleation of the stable monohydrate crystals. The observed oriented growth of monohydrate crystals on the anhydrous surface is consistent with a close lattice match between the *b* and *c* crystallographic axes.[8] Other studies on the dissolution of metastable solids such as anhydrous theophylline[76] and anhydrous carbamazepine[77−79] have shown that crystallization of the stable phase occurs during dissolution, Figure 2. It is unfortunate that in view of the important influence that nucleation mechanisms have on dissolution of metastable solid phases, very seldom are studies carried out to identify the potential of substrate-mediated nucleation by the metastable modification. The information gained from this type of study can be used in the design of methods to regulate crystallization during dissolution as well as during isolation of the desired solid form.

Carter and Ward[70] have identified a surface-mediated nucleation mechanism that involves a geometric shape match between planes of a ledge site on the substrate and planes of prenucleation aggregates. They have applied these concepts to the directed nucleation of polymorphs.[72,74] This work provides us with the attractive possibility that "a library of organic seeds can be used to control polymorphism, or to search for unknown polymorphs".[71] Molecular interpretations based on this approach are experimentally more accessible than those based on solvent-selective polymorph crystallization.

Experimental and Computational Strategies—While nucleation phenomena have their origin at the molecular level, they are often described in terms of macroscopic properties due to the scarcity of experimental techniques that allow for monitoring events at the molecular level. Nevertheless, information about molecular association processes in supersaturated systems obtained by laser Raman spectroscopy and laser light scattering has been used to identify prenucleation clusters and growth units under well-defined experimental conditions. Methods that measure cluster size distributions are more appropriate for studying crystallization of macromolecules[80−84] due to the large sizes of prenucleation clusters, while Raman and fluorescence spectroscopic techniques are capable of providing information about the solution structure or the species present in solution.[85−88] The implications for crystallization pathways are examined by comparing the solution and crystal structures at a molecular level, and by combining information obtained from macroscopic analysis with results from molecular simulations.[14,31−40]

Figure 2—Nucleation and growth of dihydrate carbamazepine on crystal faces of anhydrous monoclinic carbamazepine in aqueous solutions of sodium lauryl sulfate (17.3 mM, 0.5%), supersaturation ratio of 1.15 at 25 °C. From ref 79.

Desiraju[22−24] and Gavezzotti[26−29] have described crystal engineering strategies to understand the molecular aggregation processes involved in crystallization and to elucidate the supramolecular motifs in organic crystals. In this context, crystals are viewed as solid-state supermolecules assembled by intermolecular interactions, with the basic approach of establishing a relation between molecular interactions and supramolecular structure. Recent studies by Gavezzotti[29] show how molecular dynamics calculations allow for simulation of solvent and kinetic effects on molecular aggregation.

The supramolecular assembly process can be controlled so that the precursor nuclei in solution adopt a structure that resembles the structure of the desired crystalline modification.[29,89,90] This concept has been used in the design of nucleation inhibitors to prevent growth of the stable polymorph and enhance the growth of the metastable polymorph.[13,15,16] Davey et al.[14] have explained the solvent-dependent polymorph appearance of sulfathiazole by analyzing the intermolecular interactions in the various polymorphic structures and comparing them with the supramolecular assemblies that could exist in the different solvents. In this case, however, the solvent-dependent selective crystallization of a polymorph was not correlated with solubility.[14,91]

Strategies used for the rational choice of additives to selectively inhibit nucleation or growth of the thermody-

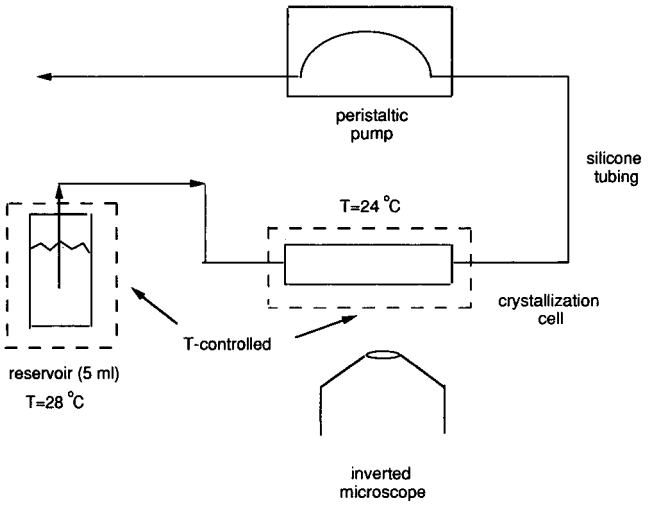

Figure 3—Schematic diagram of a flow system used to measure growth rates of crystal faces. The volume of the crystallization cell is 300 to 500 μL.

namically stable modification are based on the work of Davey,[12–14,92] Leiserowitz,[15,16] and others.[40,93,94] The main features of these strategies are as follows:

(1) identification of the fastest growing faces of the stable crystalline modification,
(2) characterization of intermolecular interactions along the crystallographic direction with fastest growth,
(3) selection of additives that can be incorporated in the crystalline structure along this direction, and
(4) development of experimental methods to investigate the effectiveness of the additive to kinetically stabilize the metastable modification.

The selection of additives can be guided by molecular visualizations of the crystal structure based on geometric fits[13,95] or binding energy calculations.[36,96]

Growth Mechanisms and Kinetics

Once the nucleation step has been overcome, nuclei grow into macroscopic crystals. This stage of the crystallization process is known as crystal growth. The nucleation and growth processes compete for solute in terms of their respective dependence on supersaturation, and their relative rates will determine the crystal size distribution.

Crystal growth is governed by both internal and external factors. Internal factors such as the three-dimensional crystal structure and crystal defects will determine the nature and strength of the intermolecular interactions between the crystal surface and the solution, whereas external factors such as temperature, supersaturation, solvent, and the presence of impurities will affect the type of interactions at the solid–liquid interface.

Depending on the objectives and applications of growth rate measurements, the growth rate may be expressed as (1) overall linear growth rate which is the rate of change of the volume equivalent diameter with time, (2) linear growth rate of a face which is the rate of displacement of a crystal face in a direction perpendicular to the face, and (3) velocity, height, and spacing of growth steps spreading across a crystal surface. The linear growth rate of a face can be expressed in terms of the step velocity, the step height, and the step spacing. Techniques used for in-situ measurement of crystal growth rates as a function of supersaturation include (1) monitoring the crystal population by methods that measure particle size and number,[97,98] (2) monitoring the growth rates of individual crystal faces by optical microscopy with the use of a flow cell system shown in Figure 3,[39,95,99–101] and (3) monitoring the development of surface morphology at the molecular level by atomic force microscopy (AFM)[101–105] and interferometric microscopy.[37,38]

The external shape or morphology of a crystal is a consequence of the relative growth rates of the faces and reveals the molecular events occurring at the crystal face–liquid interfaces during growth. Even when morphology does not play a significant role in quality control, studying it is essential to understand the kinetics of crystallization.[106] The morphological importance of a face (surface area) is inversely related to its growth rate. Based on these concepts, one of the standard methods used for identifying solvents or dissolved additives that influence nucleation and growth is to investigate the relation between crystal morphology and growth conditions.[13,95,107] A common approach is to compare the experimentally observed morphology with the theoretical morphology and to interpret differences on the basis of experimental growth parameters and assumptions of molecular modeling techniques.[37–39]

Batch-to-batch differences in crystal morphology may result from small but significant changes in growth conditions during the crystallization process. For instance, the presence of a small amount of impurity can have a significant effect on the crystal habit. The most potent inhibitors of growth are impurities which are structurally similar to the host molecule (i.e., tailor-made additives and synthetic impurities). For example, the growth of L-alanine in the presence of hydrophobic L-amino acids at concentrations as low as 0.02 m (0.3 g additive/100 g solvent or 0.18 g additive/100 g L-alanine) results in a change in crystal morphology from prismatic to needle-shaped.[95,101] The supersaturation at which crystal growth occurs can also significantly affect growth rates along different crystallographic axes and crystal habit. Growth of phenytoin crystals along the *a* crystallographic axis has a stronger dependence on supersaturation than growth along the *c* axis.[39]

The process of crystal growth consists of several stages through which growth units pass. These include (a) transport from the bulk solution to a site at the crystal surface, (b) adsorption of the growth unit onto the impingement site, or (c) diffusion from the impingement site to a growth site, and (d) incorporation into the crystal lattice. Desolvation can take place in steps b–d; however, the solvent has the possibility of being adsorbed.

Any one of the above steps may be rate-limiting depending on the growth conditions, such as the supersaturation, temperature, additives or solvent, and hydrodynamics of the system. Consequently, crystal growth mechanisms fall into two main categories:[41–44] volume diffusion control and surface integration control, and the goals of crystal growth theories are to determine the source of steps and the rate-controlling step for crystal growth.

As a crystal grows from a supersaturated solution, the solute concentration is depleted in the region of the crystal–solution interface. If diffusion of solute from the bulk solution to the crystal surface is rate limiting, growth is *volume-diffusion controlled*. A diffusion-controlled process is not applicable if there is no dependence of growth rate on hydrodynamic conditions such as flow rate or stirring rate. In practice it is difficult to completely eliminate volume diffusion resistance, and experimental growth kinetics can be misinterpreted as being purely surface-integration controlled when in fact diffusive resistance is still present. Garside has defined an effectiveness factor that is a measure of the relative importance of diffusion and surface integration as the rate-controlling factors for crystal growth.[108]

If incorporation into a crystal lattice is the slowest process, growth is *surface-integration controlled*. Many

crystallization studies involving proteins, small organic electrolytes, and nonelectrolytes have reported growth controlled by surface integration.[37−39,95,99−105] Depending on the roughness of the crystal surface, layer growth or continuous growth may result. If the crystal−solution interface at the molecular level is rough, there are many potential kink (growth) sites. In this case, *continuous or normal growth* models apply. Growth proceeds isotropically resulting in nonfaceted crystals and responds to very small gradients in the growth driving chemical potential (temperature, concentration, etc.). If the interface is smooth, growth proceeds through a *layer growth* model. Kink sites are only found on the edges of two-dimensional nuclei or steps; hence, surface diffusion and surface topography become more important.

Layer growth models describe the formation of steps by two mechanisms: screw dislocation and two-dimensional nucleation. Details of the derivation of these models can be found in the literature.[42,44,109−111]

The spiral growth mechanism or screw dislocation model was first described by Burton, Cabrera, and Frank (BCF).[112] Bennema[111,113,114] modified this theory for crystals growing from aqueous solution. Flat crystal surfaces have a high energy barrier for nucleation at low supersaturations, and the presence of screw dislocations provides a source of steps for the addition of growth units in an infinite sequence of equidistant and parallel steps. In the simplest case, these steps will develop as a spiral which rotates about its axis during growth.

Two-dimensional nucleation requires the formation of clusters above a critical size for growth of layers. The same concepts discussed in the nucleation section apply to the nucleation of a two-dimensional cluster above a critical size. This model accounts for crystal growth at high supersaturations. These models were developed by Volmer[115] and Stranski.[116] Variations in the mode that nuclei spread after being formed lead to the various two-dimensional nucleation models: mononuclear, polynuclear, and birth and spread.

Each crystal growth model describes the growth rate dependence on supersaturation, temperature, and face area. Although the various models can be used to identify the growth mechanism by fitting the various equations to the experimentally measured face-growth rate dependence on supersaturation, it may be difficult to discriminate between models.[39,101,117] This approach is often combined with observations of surface topography to confirm the growth mechanism.

Surface microtopographic observations can reveal growth mechanisms of crystal faces under different growth conditions, as shown for human insulin crystals in Figure 4. Monitoring the development of surface topography and transport processes during crystal growth will reveal events that are not evident from morphology studies. Interactions of growth units and additives with different crystal planes exposed on a surface may be deduced from the shape of two-dimensional nuclei, and the kinetic anisotropy of the growth steps along crystallographic directions. These techniques have been successfully applied for identifying the crystal growth mechanisms and kinetics of small molecules[37,38,101] and proteins.[102−105,118]

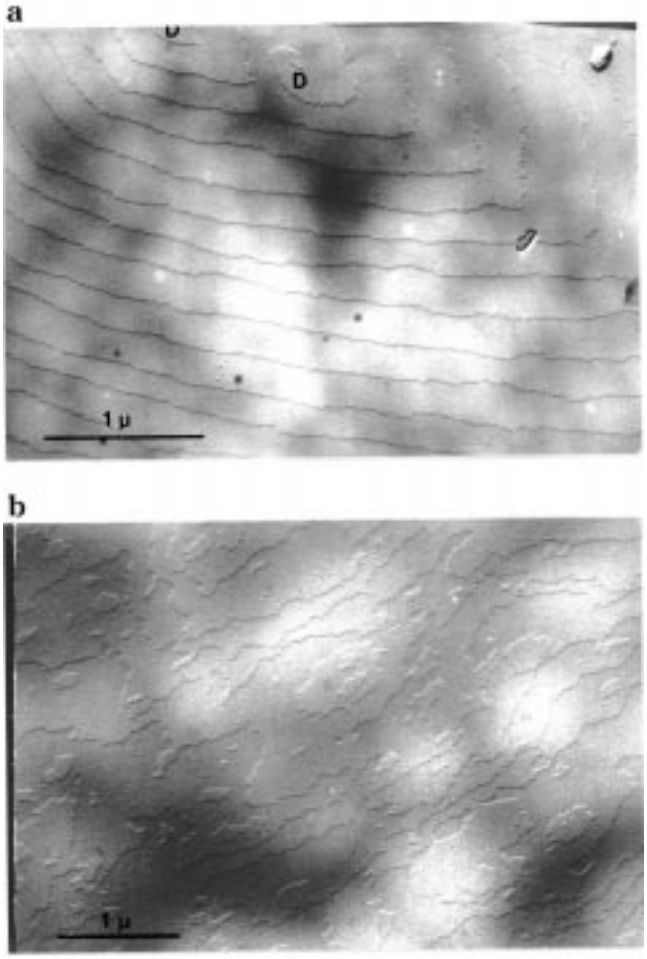

Figure 4—Micrographs of human insulin crystals showing that steps arise by different mechanisms depending on supersaturation. (a) At low supersaturation, steps are created by screw dislocations, D. (b) At high supersaturation, c/s >10, steps occur at the edges of islands as a consequence of two-dimensional nucleation.

Solution-Mediated Transformations

Knowledge of the propensity of a metastable solid phase to dissolve in a liquid phase from which a stable solid phase nucleates and grows is crucial in many stages of pharmaceutical development, because pharmaceutical solids are designed to be dissolved and to come in contact with solvents since the early stages of development (isolated by crystallization from solution) and during processing (wet granulation, spray-drying, freeze-drying, etc.). Given that the sudden disappearance or appearance of a crystalline modification can threaten process development, characterization of the kinetics and mechanisms of solvent-mediated transformations is of practical importance. It will provide answers to questions such as the following: What is the relation between processing conditions and the solid-state modification manufactured? Is there a correlation between dissolution conditions, solid phase(s) dissolving, and concentration of drug dissolved?

The importance of phase transition kinetics, molecular interpretations, and process implications are emphasized by several investigators.[5−9,12−14,119] Cardew and Davey[5] developed a theoretical framework to investigate solvent-mediated transformations in terms of dissolution kinetics of one phase and growth of a second phase. The model represents the time development of the supersaturation with respect to the stable phase, or solute concentration in solution, and solid phase composition during the transformation. The experimental approach involves saturating the solution with respect to the metastable phase under consideration and to monitor both solution concentration and solid phase composition in the presence of the metastable phase, under constant external conditions. More useful information is obtained from the concentration or supersaturation profiles than from the solid phase composition profiles with time. Since the former is related to the

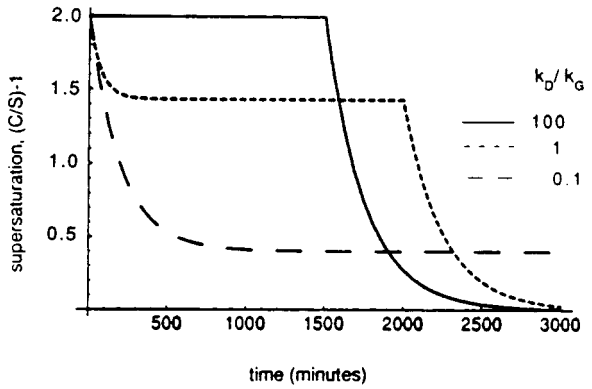

Figure 5—Numerical simulation of the supersaturation–time profiles, as a function of the relative rates of dissolution and crystallization during a solution-mediated transformation. Generated from a kinetic model developed by Cardew and Davey,[5] assuming that both dissolution and growth rates are linearly dependent on their respective driving forces.

Table 3—Information on Crystallization Kinetics and Mechanisms Provided by Various Experimental Techniques

techniques	information
optical microscopy (inverted microscope)	- study crystallization processes *in situ* - monitor transformations in suspensions - determine transformation times - screen and characterize additive/solvent interactions with specific crystal faces - identify nucleation mechanisms - measure crystal growth rates
electron microscopy	- characterize additive/solvent interactions with specific crystal faces - identify nucleation and growth mechanisms - measure crystal growth rates
atomic force microscopy	- study crystallization processes *in situ*
interferometric microscopy	- examine surface topography - identify nucleation and growth mechanisms - measure crystal growth rates
Raman spectroscopy	- monitor molecular association processes that direct nucleation and crystal growth
spectrophotometry chromatography	- monitor concentration of solute in solution and supersaturation
diffraction calorimetry spectroscopy	- monitor solid phase composition

driving forces that regulate the transformation rate and can be used to identify the rate-controlling process: dissolution or growth. A calculated supersaturation profile with growth-limited and dissolution-limited regimes is shown in Figure 5, for the case in which dissolution and growth are linearly dependent on supersaturation.[5,6] Experimental studies of the phase transitions of organic crystals have shown this model to be applicable to explain the solution-mediated transformation kinetics of polymorphs[5,6,119] and solvates,[8] and to be applicable to process development.[119] Some useful experimental techniques for studying small and large scale crystallization and solution-mediated transformations are summarized in Table 3.

Summary

In this review we have presented the significance of crystallization mechanisms and kinetics in directing crystallization pathways. Given the recent advances in computational and analytical techniques that provide access to the molecular events that direct nucleation and crystal growth, there is no reason for the development of ill-defined crystallization processes even when the desired product is obtained. Understanding the thermodynamic and kinetic behavior of the system is vital for the design of reliable processes; thus, at least a holistic approach that identifies the relevant experimental parameters is required. While the objectives of formulation or process development may not explicitly include interpretations at the molecular level, the information concealed in the interfaces present during the process, the structure of the solution, and the solids harvested (crystal structure, morphology, particle size and number) can be significant in the identification of nucleation and growth mechanisms, and will reveal molecular events associated with crystallization. Although the significance of crystallization mechanisms and kinetics has been underestimated in the pharmaceutical industry, we hope that the recent developments in crystallization engineering and techniques will inspire interest in the application of this field to pharmaceutical systems.

Abstract □ A series of ternary gel systems based on cetostearyl alcohol (CSA) and cetomacrogol 1000 or sodium lauryl sulfate have been studied using oscillatory rheology, differential interference contrast (DIC) microscopy, cryoscanning electron microscopy (cryo-SEM), and low-frequency dielectric analysis in order to elucidate the nature of the lamellar structures formed in relation to composition. The effects of altering the concentration of CSA (0.25% to 8% w/w) for 1% and 2% w/v cetomacrogol 1000 and 0.5% and 1% w/v sodium lauryl sulfate systems have been investigated, with marked increases in the storage and loss moduli seen on increasing the concentration of CSA for both surfactants. DIC microscopy indicated that at low CSA concentrations, needlelike structures were seen which, on increasing the concentration, were observed to congregate into nuclei. At concentrations of 4% CSA and above, neospherical structures were also observed. Cryo-SEM revealed that the needlelike objects were sheet structures ascribed to lamellar gel phases, while the nuclei were folded "rosettes" formed by those sheets, with the spherical structures being ascribed to cetostearyl alcohol. It was also noted that the lamellae were more tightly folded at 8% w/w CSA, which may be associated with the higher rheological moduli for these systems. Low-frequency dielectric analysis was performed over a frequency range of 10^4 Hz to 10^{-2} Hz. A decrease in both the dielectric loss and capacitance was observed as the concentration of cetostearyl alcohol was increased. The dielectric data were described in terms of an equivalent circuit model based on a modified Maxwell–Wagner response. A good correlation was found between the fitted and experimental data and the effect of altering the gel composition on specific features of the equivalent circuit are discussed.

Introduction

Despite the widespread use of semisolid emulsions for topical application, the physical characterization of these systems remains a persistent difficulty. This problem may be ascribed to the physical complexity of creams as the emulsifying agents, which are present in excess of the quantities required to form interfacial monolayers between the oil and aqueous phases, form a range of structures within the continuous phase, resulting in the system exhibiting viscoelastic behavior. Several authors (e.g., refs 1−6) have emphasized the importance of interdroplet liquid gel network formation in determining the rheological properties and physical stability of creams. For example, Barry and Saunders[7] have demonstrated that the influence of alkyltrimethylammonium bromide chain length on the rheological properties of liquid paraffin creams may be attributed to differences in smectic structure formation with cetostearyl alcohol, while Eccleston[8] has correlated changes in the rheological properties of cetrimide creams to alterations in the physical structure of the continuous phase formed via the interaction of cetrimide and fatty alcohols in water.

A number of techniques have been used for the evaluation of creams, including rheology (e.g., refs 1−3), microscopy,[9,10] and thermal analysis.[5,11,12] In addition, a limited number of studies using low-frequency dielectric spectroscopy have also been described.[13−16] This method involves the application of an oscillating electric field to a sample and the measurement of the response in terms of the real and imaginary components of the complex capacitance C^* at frequency ω, with

$$C^*(\omega) = C'(\omega) - iC''(\omega) = \frac{A\epsilon_0}{d}[\epsilon'(\omega) - i\epsilon''(\omega)] \quad (1)$$

where C' and C'' are the real and imaginary capacitances, i is the square root of -1, A is the electrode area, d is the sample thickness, ϵ_0 is the permittivity of free space and ϵ' and ϵ'' are the real and imaginary permittivities. The term C' is synonymous with the measured (real) capacitance while C'' is also referred to as the dielectric loss G/ω where G is the conductance. The dielectric loss incorporates both a.c. and d.c. conductance processes. More details of the approach are available from a number of texts.[17−19] A facet of the approach is to develop a circuit model which gives an equivalent response to that of the sample, thereby facilitating assignment of circuit elements to specific structures within the system. This approach has been adopted in a recent study[16] in which the response of Aqueous Cream BP was successfully modeled in terms of a modified Maxwell−Wagner response, thereby presenting the possibility of relating specific features of the cream to components of the circuit. With further development, this approach has clear potential as a means of characterizing complex semisolid materials.

It is now well established that the interaction between the surfactant and long chain alcohol (and the chemical

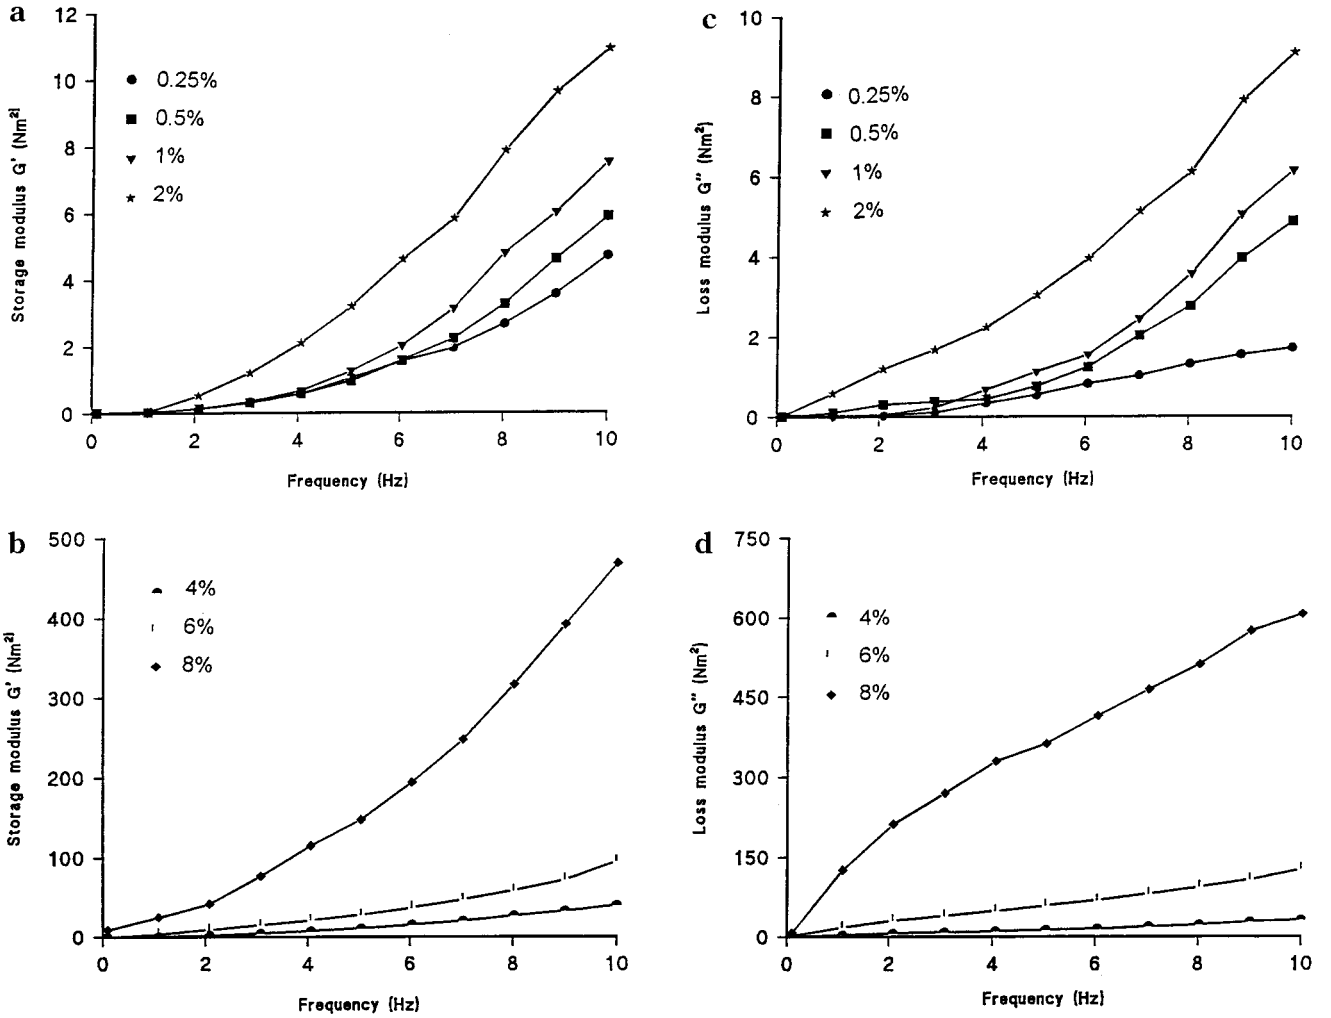

Figure 1—Rheological storage moduli (a, b) and loss moduli (c, d) for ternary systems containing 1% cetomacrogol 1000, water, and cetostearyl alcohol (concentrations as indicated) at 298 K.

compositions of both components) is a key factor in determining the rheological properties of the cream. In addition, it is also accepted that the basic structure of o/w creams consists of hydrated lamellae composed of the alcohol and surfactant, bulk aqueous and oil phases, and, depending on composition, precipitated hydrates of the long chain alcohol. However, considerably less is known regarding the distribution of components on a supramolecular level and how this distribution may be related to product performance. In this investigation, a series of ternary gels (systems containing surfactant, alcohol and water) have been prepared using a range of compositions in order to systematically study the development of structure within the gels. Such systems have been previously used as model creams (e.g., refs 20–22), as these gels may contain all the components of the cream except for the oil phase, thereby simplifying analysis and aiding understanding of the nature of the lamellar phases formed. The rheological behavior of each system has been characterized using oscillatory rheometry and the appearance of the gels noted using differential interference contrast (DIC) microscopy, an optical technique which allows high contrast imaging of unstained samples, and cryo-SEM. In addition, the use of low-frequency dielectric spectroscopy as a means of cream characterization has been further developed via examination of these relatively simple controlled systems. Particular emphasis has been placed on monitoring the cetostearyl alcohol concentration dependence on structure formation in relation to viscoelastic properties. The influence of this ratio on the rheological behavior has not been extensively studied; hence, there is a clear relevance of such knowledge to cream formulation. In addition, the study of systems containing varying ratios facilitates examination of the formation of macroscopic structures, thereby aiding understanding cream structure.

Materials and Methods

Materials—Cetostearyl alcohol was supplied by Unilever Research, Port Sunlight, Wirral; commercial grades of this material contain 50–70% stearyl alcohol and 20–35% cetyl alcohol, with smaller quantities of other alcohols such as myristyl alcohol present. Cetomacrogol 1000 was also supplied by Unilever Research, Port Sunlight, Wirral and is based on the formula $CH_3(CH_2)_m(OCH_2CH_2)_nOH$, where m is 15–17 and n is 20–24. Sodium lauryl sulfate was obtained from BDH. Deionized water was used throughout the study.

Composition and Manufacture of Ternary Systems—Systems were prepared containing 1% w/v and 2% w/v cetomacrogol 1000 and 0.5% and 1% w/v sodium lauryl sulfate with up to 8% cetostearyl alcohol. The water phase was heated in a jacketed and baffled mixing vessel to 70 °C, after which the surfactant was dissolved and the cetostearyl alcohol added and allowed to liquefy. The mixture was then mixed at 10000 rpm using a Heidolph Diax 600 homogenizer disperser mixer for 15 min. The heater was then turned off, and the system was mixed to ambient temperature at 500 rpm. All systems were stored for 14 days prior to testing in order to allow time for the microstructure to develop.

Rheological and Microscopic Measurements—Oscillatory rheological determinations were carried out using a Carrimed CSL

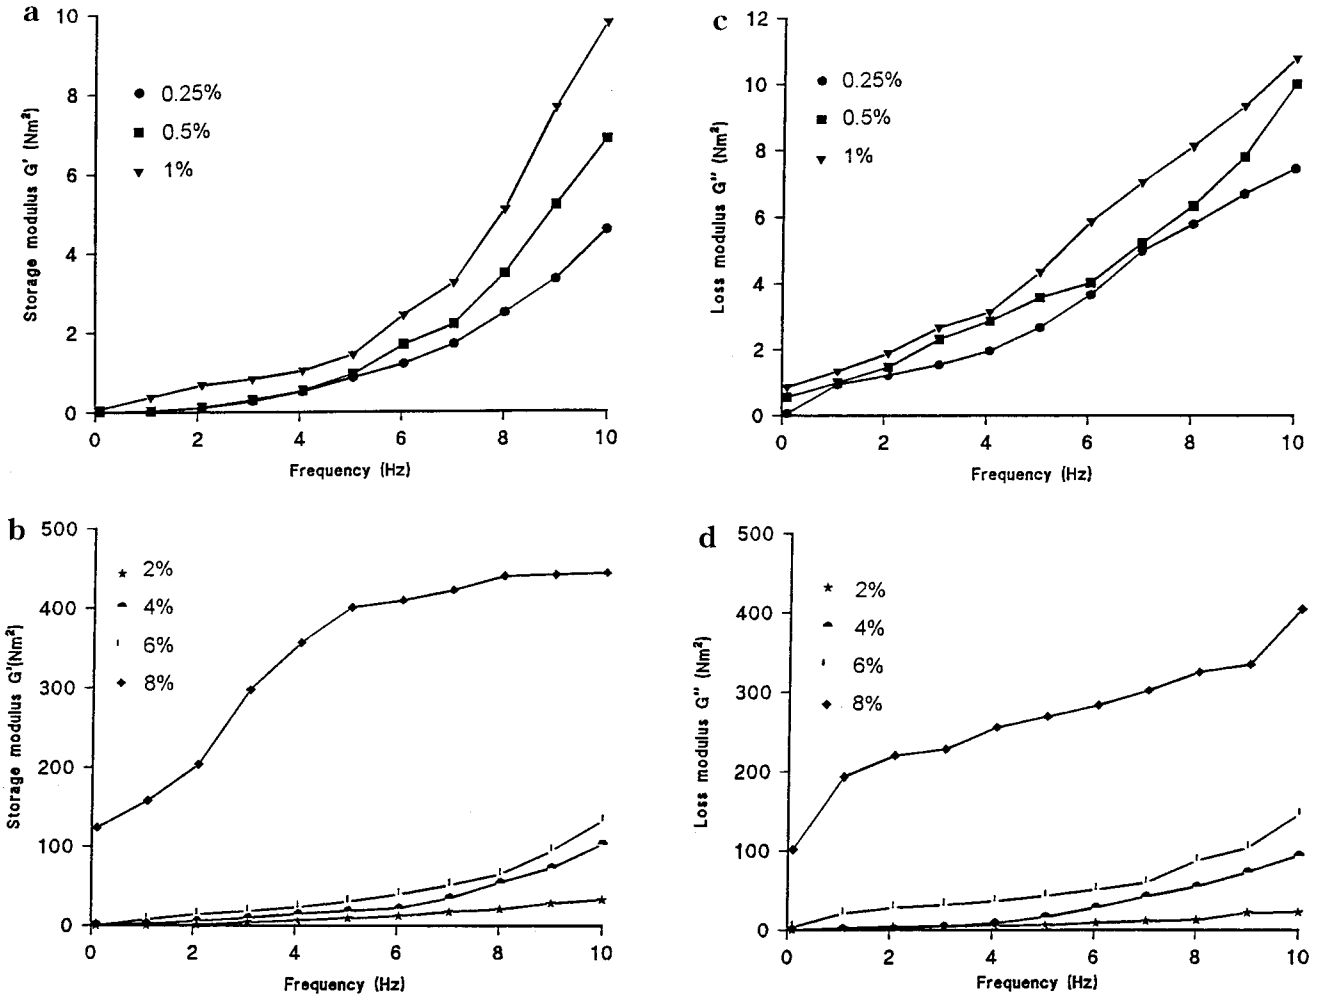

Figure 2—Rheological storage moduli (a, b) and loss moduli (c, d) for ternary systems containing 0.5% sodium lauryl sulfate, water, and cetostearyl alcohol (concentrations as indicated) at 298 K.

500 controlled stress rheometer (TA Instruments Ltd., Surrey, UK), used in cone and plate mode. An oscillating stress of 0.1−10 Hz was applied to each sample at 298 K. The torque used was 200 μN which was established by torque sweep to be within the linear viscoelastic range. Samples were run at least three times to ensure reproducibility, with the values having a coefficient of variation within 5%. The plate and cone were cleaned thoroughly between runs.

Differential interference contrast microscopy was carried out using an Olympus BX50 microscope. A Nikon fully automatic single lens reflex camera was employed for the photographic work. The scanning electron microscopy studies were carried out using a Cambridge Scientific S360 instrument fitted with an Oxford Instruments cold stage. Undiluted samples were placed on the sample holder which was immersed in liquid nitrogen (−196 °C). The material was then loaded into the microscope fracture chamber, also at −196 °C, and fractured. The sample was subsequently transferred to the vacuum chamber (−196 °C), the vacuum applied, and the surface water sublimed. After removal from the vacuum chamber, the sample was electroplated with gold under an argon atmosphere.

Dielectric Analysis—Dielectric studies were conducted using a low-frequency dielectric spectrometer (Dielectric Instrumentation Ltd., Worcs.) which measures between the limits of 10^6 to 10^{-4} Hz. Measurements were conducted in a stainless steel cell comprising two circular parallel plates (area 12.6 cm^2, electrode separation distance 1 mm), as described in a previous study.[16] Three measurements are taken at each frequency, with averaged results being within a coefficient of variation of 2%. Samples were measured over a frequency range of 10^5−10^{-2} Hz at 25 °C using a field of 0.1 V rms. Empty cell runs were performed between runs to ensure cell cleanliness; repeat runs of each sample showed the spectra to be superimposable. Equivalent circuit analysis was performed based on the model proposed by Hill and Pickup[23] using the Winfit 2.0 computer program supplied by Novocontrol GmbH, as described in previous studies.[16,24]

Results

Rheological Studies—The frequency-dependent rheological responses of the nonionic systems containing 1% cetomacrogol 1000 are shown in Figures 1a−d in terms of the storage and loss moduli. A marked increase in both storage and loss were noted on increasing the concentration of cetostearyl alcohol, with a similar trend being noted for the 2% w/v cetomacrogol 1000 systems. Likewise, Figure 2a−d shows the responses of the ionic systems containing 0.5% sodium lauryl sulfate, with an increase in storage and loss again being noted as the concentration of CSA increases. However, it was noted that in this case a more marked increase in both components was seen between 6% and 8% w/v CSA. A similar trend was seen for the 1% w/v SLS systems, although the increase in moduli at higher CSA concentrations was considerably more marked. The relationship between the loss modulus at 10 Hz and cetostearyl alcohol composition is summarized in Figure 3 for the four surfactant systems. The same general trend of a nonlinear increase in loss moduli was observed in all cases, although clearly the 1% ionic gels gave the highest responses, particularly at higher CSA contents.

Microscopy Studies—Representative DIC photomicrographs for the 1% cetomacrogol 1000 systems are shown

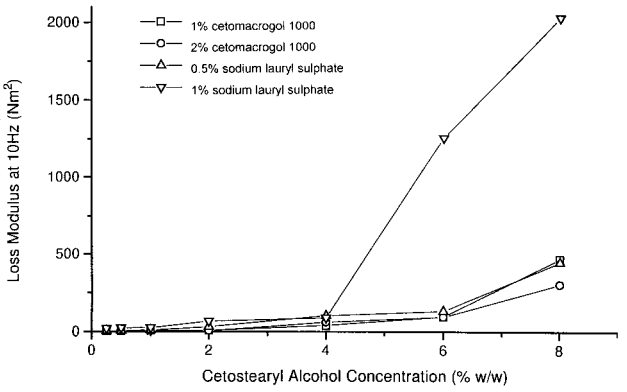

Figure 3—The effect of cetostearyl alcohol concentration on the rheological loss moduli (10 Hz) of ternary systems containing cetomacrogol 1000 or sodium lauryl sulfate.

in Figure 4a–d. At low concentrations of CSA (0.25% w/w, Figure 4a), needlelike structures are seen, while as the concentration increases to 1% (Figure 4b), nuclei are seen in the center of clusters of the needle structures. This effect is further enhanced at 4% w/w CSA (Figure 4c), with a number of small (<5 μm) spherical structures seen. At 8% w/w CSA, a preponderance of these spherical structures is seen (Figure 4d). Similar trends were seen for the 2% cetomacrogol systems, with a representative photomicrograph being shown in Figure 4e. The appearance of the ionic creams was similar, with a representative photomicrograph being given in Figure 4f. However, it is interesting to note that for equivalent CSA concentrations (8% w/w), the ionic creams showed a lower density of the spherical structures than was seen for the cetomacrogol 1000 systems; the significance of this will be discussed in a subsequent section.

Figure 5a,b shows representative cryo-SEM images of the 2% w/w and 8% w/w CSA for the 2% cetomacrogol 1000 systems. Figure 5a shows rosette-type structures which correspond in size and appearance to the nuclei seen in Figure 4b; the SEM images indicate that these nuclei are in fact concentric layers rather than continuous structures. The highest concentration CSA systems (Figure 5b) showed a highly folded structure in which neospherulitic objects were distributed. The size range of these spheres (approximately 5–10 μm) corresponds reasonably well to that the spherical objects seen at the equivalent concentration using DIC microscopy (Figure 4).

Dielectric Analysis—The dielectric responses of the ternary systems containing 1% and 2% cetomacrogol 1000 and a concentration range of 0.25 to 8% cetostearyl alcohol are shown in Figure 6a,b. The real and imaginary relative permittivities are expressed in terms of the capacitance $C(\omega)$ and dielectric loss $G(\omega)/\omega$, where $G(\omega)$ is the conductance, which are related to the former parameters via

$$\epsilon'(\omega) = \frac{C(\omega)d}{A\epsilon_o} \tag{2}$$

and

$$\epsilon''(\omega) = \frac{G(\omega)}{\omega}\frac{d}{A\epsilon_o} \tag{3}$$

where d and A are the interelectrode distance and electrode area, respectively. An increase in the cetostearyl alcohol concentration led to a fall in both the capacitance and loss components of the sample over the majority of the frequency range under study, with a marked decrease seen between 0.5% and 2%. Similar trends were seen for systems containing 2% cetomacrogol 1000. Furthermore, the responses of systems comprising 0.5% and 1% sodium lauryl sulfate and varying quantities of cetostearyl alcohol showed similar concentration dependence, as shown in Figure 7a,b. The capacitance of some of these systems became noisy at frequencies between 10^3 and 10^4 Hz due to the instrument approaching the limits of measuring capability; hence, these data have not been included. Clearly, however, the real and imaginary permittivities show a general trend of a decrease with CSA concentration. Such observations are of interest but somewhat limited in applicability in the absence of more sophisticated structural analysis; hence, the responses have been studied in terms of an equivalent circuit model.

Circuit Analysis of the Response—The circuit model which was developed for this study is based on earlier studies on related systems[16–18] and our own studies on complex semisolid systems.[19,24,25] The diagram which was found to yield the optimum fit is shown in Figure 8. The circuit corresponds to a modified Maxwell–Wagner response,[23] comprising a dispersive (frequency dependent) capacitor C_s in series with a parallel RC circuit, these two main features corresponding to a barrier (electrode surface) and a bulk response, respectively. The barrier response corresponds to a thin layer adsorbed onto the electrode surfaces and may be described by

$$C_s = C_{s=0}\,(i\omega/\omega_s)^{-s} \tag{4}$$

where s is the power law index which indicates the frequency dependence of C_s and $C_{s=0}$ is the capacitance when $s = 0$ and ω_s is a characteristic frequency. It is essential to incorporate the response of such electrode barrier layers when modeling dielectric data of liquid and semisolid systems, particularly in the low-frequency region, as such features may result in high real and imaginary C values in the sub-Hz range. The nondispersive parallel RC circuit R_1C_1 represents the bulk resistance (inverse conductivity) and capacitance of the sample, while the series element R_2C_2 comprises a nondispersive resistance in series with a dispersive capacitor given by

$$C_2 = C_{n=0}(i\omega/\omega_n)^{-n} \tag{5}$$

which is identical in form to eq 4, the index n indicating the power law behavior of the capacitance element. The fitted data are shown as continuous lines in Figures 6 and 7 and the circuit element values for the various systems given in Table 1. While minor changes in capacitance and resistance values may not be regarded as significant due to the inevitable approximations involved in the modeling, changes of 1 order of magnitude or more represent differences which are greater than those expected from the errors arising from the modeling process. The values of C_1 did not show a marked sensitivity to changes in formulation; this value can be considered to be equivalent to the dielectric constant of the sample which, given the high content of water in all the creams, may not be expected to vary greatly with comparatively small changes in the concentration of the minor components. It was noted, however, that the 2% cetomacrogol systems appeared to have higher C_1 values, the reasons for this being unclear at present. The values of R_1 increased on raising the CSA composition, reflecting the greater tortuosity of charge movement through these systems. It is also noted that the R_1 values for the ionic creams were lower than the nonionic by approximately 1 order of magnitude. The values of R_2 and $C_{n=0}$ have been associated with the behavior of thin layers within samples,[19,24] as indicated by the high values of capacitance compared to C_1. Indeed it has been argued

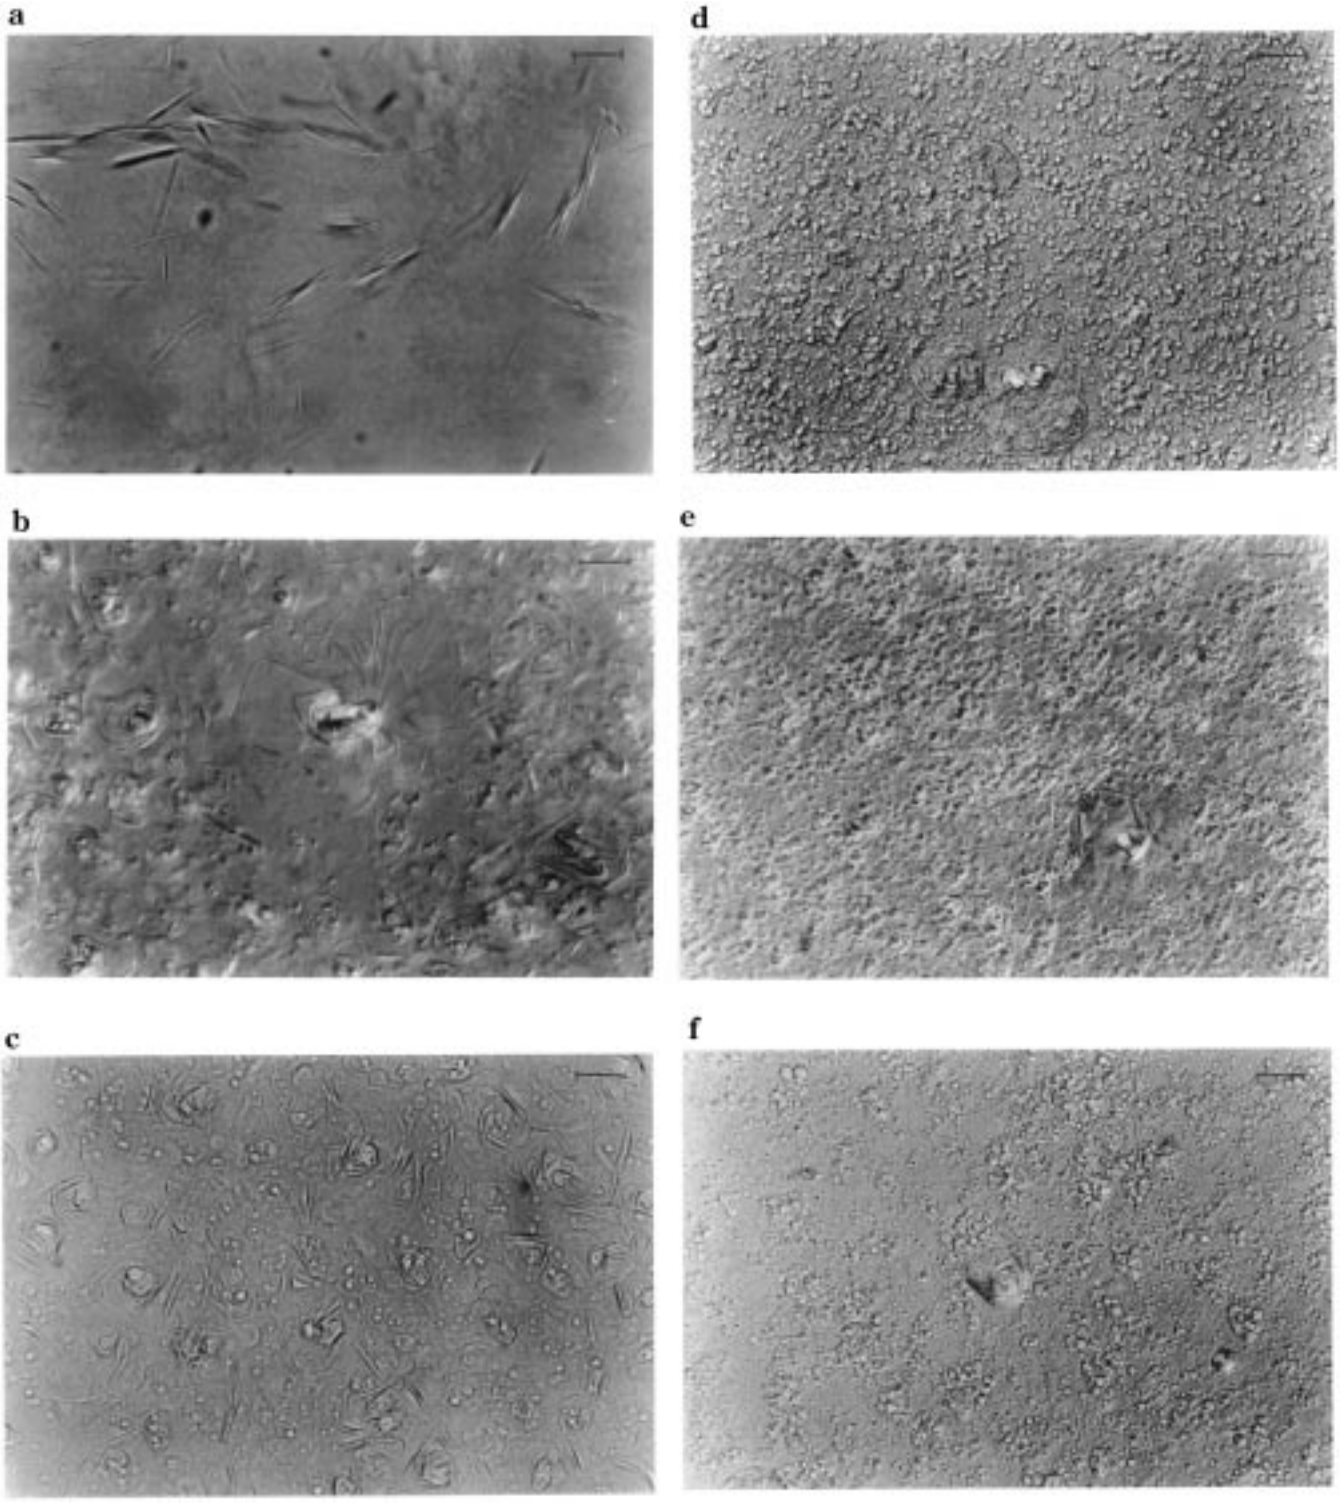

Figure 4—DIC images of ternary systems containing water and (a) 1% cetomacrogol 1000, 0.25% w/w CSA; (b) 1% cetomacrogol 1000, 1% CSA; (c) 1% cetomacrogol 1000, 4% CSA; (d) 1% cetomacrogol 1000, 8% CSA; (e) 2% cetomacrogol 1000, 8% CSA; (f) 0.5% sodium lauryl sulfate, 8% CSA. Bar = 25 μm.

that examination of these values may yield insights into the lamellar structure of creams.[19]

Discussion

The study has demonstrated clear compositional dependence of the supramolecular structure and behavior of ternary gel systems. Such changes must be considered in the context of the existing knowledge base associated with cream formation and structure. During the preparation of creams (or ternary systems), heat is applied which results in the melting of the fatty alcohol which, on dispersion, interacts with the aqueous surfactant to form smectic liquid crystals.[26] Barry and Shotton[27] have suggested that these liquid crystalline phases are elongated into lamellar ("threadlike") structures via turbulence effects. These lamellae form hydrated networks on cooling to the gel phase, this network being largely responsible for the viscoelastic properties of the cream. Interestingly, on the

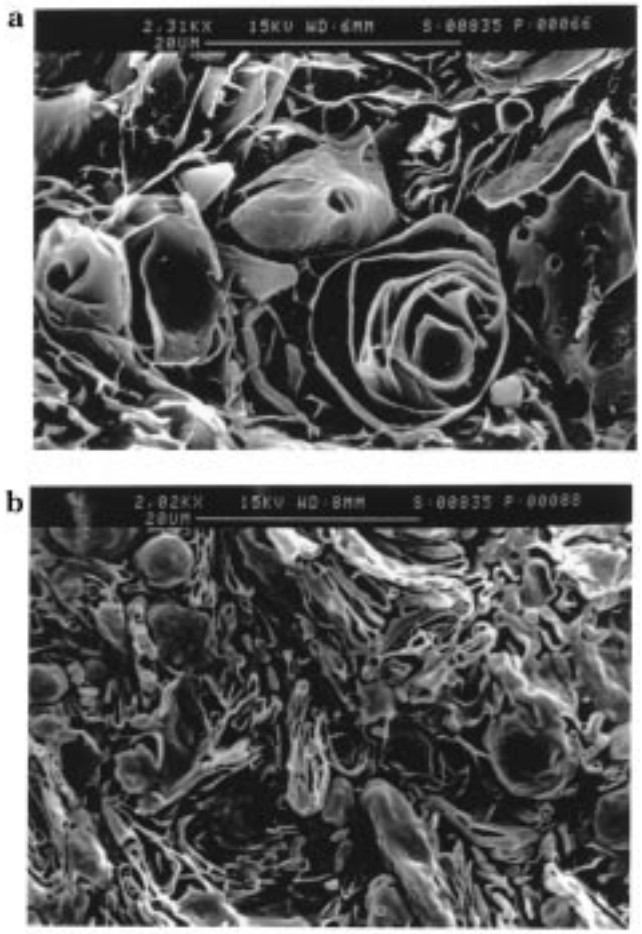

Figure 5—Cryo-SEM images of ternary systems containing 2% cetomacrogol 1000, water and (a) 2% w/w CSA (b) 8% CSA.

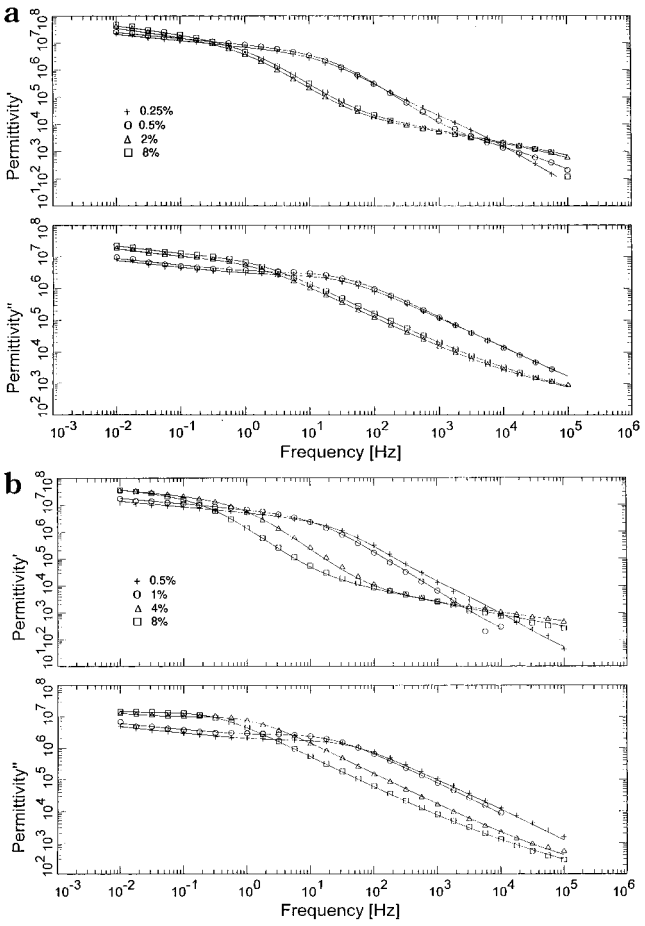

Figure 6—Real and imaginary permittivies of ternary systems containing (a) 1% cetomacrogol 1000 and (b) 2% cetomacrogol 1000, water and cetostearyl alcohol (concentration as indicated) at 298K. Solid lines indicate fitting according to circuit diagram shown in Figure 9.

basis of optical microscopic observations, these authors also suggested the formation of spherulites composed of the liquid crystal/gel phases. The remaining cetostearyl alcohol solidifies either as one of a number of polymorphs or as a hydrate due to the ability of this material to undergo limited swelling in water.

The majority of studies which have examined the rheological properties of creams and ternary systems have used the standard ratios of 9:1 (ionic) and 4:1 (nonionic) alcohol to surfactant; hence, the influence of the ratio used has not been extensively studied. Indeed, Barry and Saunders[28] have reported that the ratio may not be a critical factor in determining the rheological properties of creams. The data presented here do not directly contradict this statement in that the earlier study used a fixed concentration of emulsifier, while the present investigation involved increasing absolute concentrations. Nevertheless, the clear observed dependence of the storage and loss moduli on composition is of interest in terms of controlling the rheological properties of creams and complements earlier studies which have examined the effects of varying the total emulsifier concentration.[26]

The comparison between ternary systems containing nonionic and ionic surfactants is of interest in that the behavior of the two sets of systems is comparable at low CSA contents. However, at 1% SLS a marked increase in storage and loss moduli is observed at high CSA contents. Earlier studies have suggested that the rate of interaction between ionic surfactants and CSA is far greater than for nonionics, leading to formation of a kinetically stable system over a shorter time period when using the former.[26,28] As the samples under examination here were tested at comparable time periods after manufacture, one would expect higher moduli for the ionic systems. In fact, such effects were only observed for the higher CSA content systems, implying that the nature of the surfactant only becomes critical when the structure formed between 4% and 6% CSA is present.

The rheological studies allow characterization of the macroscopic behavior of the sample but in themselves yield little information on the specific structural origin of the observed effects. In this respect the microscopic studies (both using optical and electron beam techniques) are of considerable use. DIC microscopy is particularly well suited to the study of such systems as it allows high contrast images to be obtained in complex samples containing materials of similar refractive index. At low CSA concentrations, the DIC microscopy indicated threadlike structures which almost certainly correspond to those described by Barry and Shotton.[27] On raising the concentration of CSA, spherical structures are observed which may again correspond to the observations of Barry and Shotton.[27] However, the cryo-SEM studies indicated that these "nuclei" are in fact folded lamellae rather than continuous structures; hence, their formation may be related to the quantity and degree of curvature of the lamellae. Similarly, as the CSA content was raised to 4%, further spherical structures were seen which, again in the light of cryo-SEM studies, appears to correspond to solid-phase CSA; similar observations using cryo-SEM with regard to the presence of excess CSA have been reported by Rowe and Bray.[10] It is also interesting to note the considerably more extensive

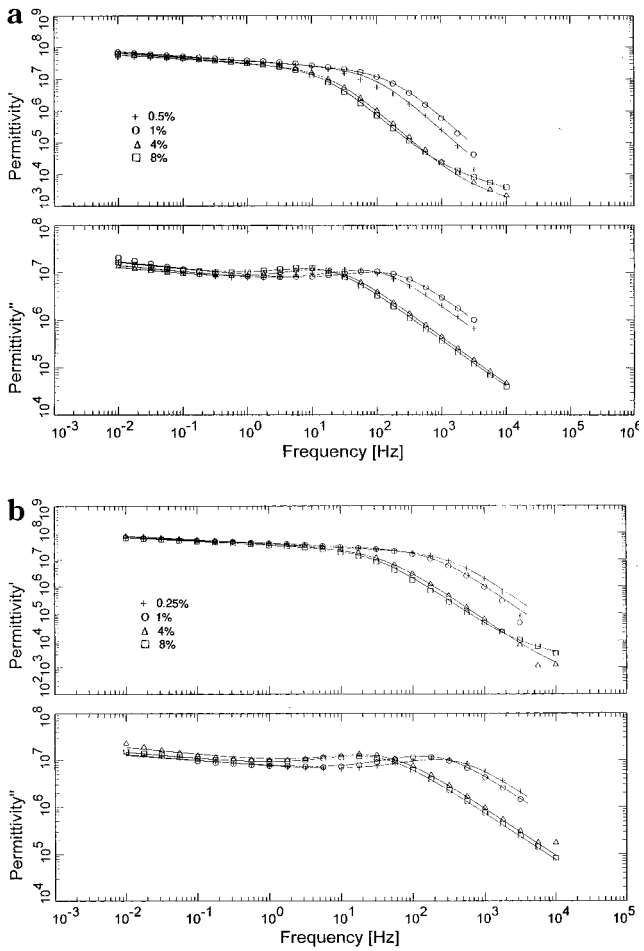

Figure 7—Real and imaginary permittivies of ternary systems containing (a) 0.5% sodium lauryl sulfate and (b) 1% sodium lauryl sulfate, water and cetostearyl alcohol (concentration as indicated) at 298K. Solid lines indicate fitting according to circuit diagram shown in Figure 8.

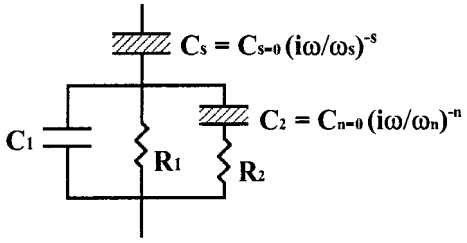

Figure 8—Equivalent circuit diagram for the dielectric responses shown in Figures 6 and 7. For explanation of notation see text.

folded lamellar network observed for the 8% systems shown in Figure 5b. Overall, the data presented here indicate that the observed rheological effects may be due to a combination of factors, including the nature of the lamellar material in terms of bilayer composition and water entrapment, the quantity of such material, and the supramolecular organization of the lamellae (e.g., presence as nuclei as opposed to folded lamellae, nature of the folding). The study suggests that this supramolecular structure may be an important consideration in terms of the understanding of the rheology of creams and ternary systems which has yet to be fully explored.

It is noteworthy that the DIC photomicrographs of the ionic ternary systems indicated a smaller quantity of solid-phase CSA compared to the equivalent nonionic systems, suggesting greater integration of the CSA into the lamellar phase (similar observations in a different context have been made by Eccleston[2]). This may in turn result in more extensive structuring and hence higher viscoelastic moduli. The microscopic observations also serve to explain the concentration dependence of the difference between ionic and nonionic systems, as at low CSA concentrations the quantity of both ionic and nonionic surfactant may be sufficient to allow efficient incorporation of the CSA into the bilayers. As the concentration of CSA is raised, however, the differing penetration properties of the two surfactants becomes a critical factor in determining lamellar formation.

The dielectric data indicated that the bulk resistances of the gels increase with increasing CSA concentration, which may be attributed to more extensive lamellar structuring, as discussed previously.[16] Given the now reasonably well-established link between the bulk resistance and lamellar formation,[16,24,25] it is of interest to compare the dielectric and rheological data, as while the overall trends between the two are comparable, there are also a number of differences. For example, there is no marked change in resistance for 1% SLS systems at high concentrations of CSA, as there was in the rheological responses. The resistance will be a function of the nature of the charge carriers present and the tortuosity of the conduction path within the system. Increasing the content of insoluble CSA is unlikely to result in significant increases in the number and nature of charge carriers present (further evidenced by the increase in resistance with added CSA); hence, the observed effects are almost certainly due to changes in tortuosity of the system. If, however, no parallel trends with the rheology of systems with high CSA content are seen for the ionic systems, then the logical conclusion to be drawn is that the tortuosity (i.e., quantity and folding of the lamellae) is not the determining factor. Instead, the rigidity of the lamellae may be greater for the ionic systems at high CSA contents. As previously stated, the relative importance of the lamellar nature, quantity, and folding in determining the rheological moduli have not yet been fully deconvoluted; hence, it is not yet possible to ascertain these roles with certainty. The data presented here, however, suggest that dielectric analysis may have a role to play in making such determinations. In addition, the circuit model used in the present study appears to allow an excellent fit to a wide range of experimental data. The use of the technique to quantify the bulk resistance has been clearly demonstrated. However, values such as $C_{n=0}$, which have been previously associated with lamellar structure,[19] and which here show a decrease with increasing CSA content, may also provide useful information with regard to the structure of these systems. On a crude level, one can, with reference to eq 1, suggest that the observed decrease may be due to greater thickness of the lamellae, although clearly further studies are required before such direct correlations can be made. Nevertheless, the development of this modeling approach will depend first on being able to provide satisfactory fits with a range of experimental data and second with the fitting parameters to be at least intuitively compatible with the observed behavior of the system. In both these respects, the study described here has proved satisfactory.

Conclusions

The study has provided insights into both the supramolecular structures formed in ternary systems and the use of low-frequency dielectric analysis as an analytical tool, with particular emphasis on circuit modeling. With respect to the former, increasing the CSA content leads to an increase in rheological moduli which may be associated with the formation of a range of supramolecular structures, including previously unreported folded "rosette" systems,

although the relative roles of the nature, quantity, and arrangement of the lamellae in determining the rheological properties is still not fully understood. The dielectric data showed a clear decrease in imaginary permittivity with CSA content which, via circuit modeling, could be related to an increase in bulk resistance which was associated with the tortuosity of charge movement through the system. Further dielectric parameters were derived which, with further development and correlation using supportive technique, may yield further insights into the structure of these complex systems. Despite the considerable number of cream and gel products on the market, there are still numerous difficulties associated with these systems, including the predictability of viscoelastic properties, issues associated with physical stability, and a poor understanding of the effects of added drugs on both consistency and release. It is hoped that by understanding the macro- and microscopic structure in greater detail using techniques such as those described here these problems may be overcome on a rational basis.

Received January 11, 1999. Accepted for publication April 7, 1999.

Abstract □ A linear free energy relationship, LFER, has been used to correlate 150 values of gas–chloroform partition coefficients, as log L^{chl} with a standard deviation, sd, of 0.23 log units, a correlation coefficient r^2 of 0.985, and an *F*-statistic of 1919. The equation reveals that bulk chloroform is dipolar/polarizable, of little hydrogen-bond basicity, but as strong a hydrogen-bond acid as bulk methanol or bulk ethanol. However, the main influence on gaseous solubility in chloroform is due to solute–solvent London dispersion interactions. A slightly modified LFER has been used to correlate 302 values of water–chloroform partition coefficients, as log P_{chl}. The correlation equation predicts log P_{chl} for a further 34 compounds not used in the equation with sd = 0.17 log units. When the LFER is applied to all 335 log P_{chl} values, the resulting equation has sd = 0.25, $r^2 = 0.971$, and F = 2218.

Introduction

The partition coefficient of a solute, as log *P*, has widespread applications in such diverse areas as environmental chemistry, biochemistry, pharmaceutical chemistry, toxicology, and chemical engineering.[1] Following the work of Hansch and Leo,[2] the water−octanol partition coefficient, as log P_{oct}, has become a standard parameter in quantitative structure−activity relationships (QSARs), and in the definition of solute lipophilicity.[3] However, other water−solvent systems have been used, especially as models for biochemical proceses;[3,4] indeed the first such system used in this way was water−olive oil.[4]

The water−chloroform system has been used to estimate solute lipophilicity, as log P_{chl},[5] and both the water−cyclohexane and water−chloroform systems have been used to examine the hydrophobicities of nucleic acid bases.[6] The later system has been put forward as one of a "critical quartet" of water−solvent systems that encapsulates most of the information contained in water−solvent systems, in general.[7] Comparisons of water−solvent log *P* values, including log P_{chl}, have been made,[8] but only recently have attempts been made to compute log P_{chl} values. Some of these computations refer to relative partition coefficients,[9,10] but others to absolute values;[11−14] we comment only on these latter calculations.

All the reported computations of log P_{chl} involve the separate calculation of gas−water partition coefficients, L^w, and gas-chloroform partition coefficients, L^{chl}. Various standard states can be used to define *L*, or the related Gibbs free energy change, $\Delta G° = -RT \ln L$. We prefer to work with equilibrium constants[15] and define *L* as a dimensionless quantity via eq 1.

$$L = \text{concn (M) solute in solvent/concn (M) solute in gas phase} \quad (1)$$

Then log P_{chl} is given by eq 2. As we shall see, eq 2 is valuable, not only in the calculation of log P_{chl}, but also as one method of experimental determination of log P_{chl}.

$$\log P_{chl} = \log L^{chl} - \log L^w \quad (2)$$

A GB/SA continuum model together with the OPLS all atom force field was used by Reynolds[11] to compute log L^w, log L^{chl}, and hence log P_{chl} for 30 diverse, but monofunctional, compounds. The standard deviation, sd, between the 30 calculated and observed log P_{chl} values was 0.87 log units with sd defined as $[(Y_{calcd} - Y_{obsd})^2/(n-V-1)]^{1/2}$; n is the number of data points and V the number of variables (zero in the present case). The average deviation, $(Y_{calcd} - Y_{obsd})/n$ was only 0.01 log units, but it was suggested that systematic deviations at low log P_{chl} and high log P_{chl} values occurred. A plot of observed vs calculated log P_{chl} values indeed yielded a smaller standard deviation; see eq 3. In eq 3 and elsewhere *r* is the correlation coefficient and *F* is the Fischer *F*-statistic.

$$\log P_{chl}(obsd) = 0.055 + 0.732 \log P_{chl}(calcd) \quad (3)$$

$$n = 30,\ sd = 0.51,\ r^2 = 0.919,\ F = 318$$

Various other computations of log L^{chl} have been made[12−14] on data sets that vary from only 16 compounds to 88 compounds; see Table 1. In general, the computations summarized in Table 1 lead to log L^{chl} values with an sd of 0.3 to 0.7 log units and to log P_{chl} values with a much larger sd of 0.5−1.0 log units, even when trained on experimental values. The larger error in log P_{chl} is expected, because this will include errors in both log L^{chl} and in log L^w. Additionally, any experimental errors in log P_{chl} will also contribute to the overall sd value, and it is not easy to assess this contribution, especially for small data sets. In general, the more compounds in a data set, the larger will be the sd value, because of the more varied and more complicated structures in the data set.

The method of multiple linear regression analysis (MLRA) has been applied to the correlation of log P_{chl} values, using various physicochemical parameters as descriptors.[1,6,18−20] A summary of results is in Table 1. Only one, preliminary MLRA of log L^{chl} has been reported,[19] as shown in Table 1 also. The disadvantage of the MLRA method, as compared

with computational methods, is that it requires experimental values to use as a training set. However, the untrained computations reported in Table 1 lead to very considerable errors, and if computations have to be trained on experimental data in order to reduce errors to reasonable values, much of the computational advantage disappears. In the event, the trained MLRA method seems capable of leading to rather smaller sd values than do the trained computational methods reported to date. Hence the aim of this work is to determine further log P_{chl} values in order to extend the experimental database and then to apply MLRA methods to a very much enlarged database. Not only will this provide very general correlations, but it will overcome difficulties inherent in the use of small data sets.

There are several problems with the use of small data sets. First, the data set might not be representative. Indeed, a very small data set cannot be representative, in that it will not contain examples of many types of compound that could be included in a full data set. For example, neither the 30 compound data set[11] nor the 16 compound data set[14] contain any compound with a sulfur or with an iodine atom. Second, it is very difficult to assess the effect of possible experimental error when using a small data set. It was suggested that large values of (calculated − observed) log P_{chl} for trimethylamine (1.68) and dimethylamine (1.29) in the 16 compound data set and for diethylamine (1.24) in the 30 compound set were possibly due to experimental errors arising from protonation of the amine in the aqueous layer, but the large differences could also be due to a systematic computational error for aliphatic amines. Third, we know from our own experience in the measurement of log P_{chl} values, that experimental errors, especially with large values of log P_{chl}, can be much greater than expected from measurement of log P_{oct}, for example. A very erroneous experimental value in a small training set might bias a correlation so that the error becomes undetected (and the correlation becomes incorrect), whereas this is much less likely to occur with a large training set.

Methodology

A number of sources of data were used to compile the log P_{chl} and log L^{chl} values. Most of the log P_{chl} values were taken from the MedChem database,[21] and others were measured by the usual shake-flask method. For compounds that are gaseous at room temperature, log P_{chl} could often be obtained from experimental values of log L^{chl} and log L^{w} through eq 2. Directly determined log L^{chl} values were available[22] for the rare gases, hydrogen, oxygen, nitrogen, nitrous oxide, carbon monoxide, and a few organic solutes. Other log L^{chl} values could be obtained from known infinite dilution activity coefficients of solutes in chloroform together with known vapor pressures,[23] through $K^{H} = \gamma^{\infty} p^{o}$ where K^{H} is Henry's constant; L is the inverse of K^{H} with due regard to units. A large number of log L^{chl} values were deduced from log P_{chl} and known[24,25] values of log L^{w} through eq 2. We finally assembled 335 values of log P_{chl} and 150 values of log L^{chl} to use in our correlative equations, as set out in Table 2.

The MLR equation we use to correlate log L^{chl} is the linear free energy relationship (LFER)[26] shown as eq 4.

$$\log SP = c + rR_2 + s\pi_2^{H} + a\Sigma\alpha_2^{H} + b\Sigma\beta_2^{H} + l \log L^{16} \quad (4)$$

Here, SP is a set of solute properties in a given system, for example L^{chl} values, and the independent variables are solute descriptors as follows.[26] R_2 is an excess molar refraction, π_2^{H} is the dipolarity/polarizability, $\Sigma\alpha_2^{H}$ is the overall hydrogen-bond acidity, $\Sigma\beta_2^{H}$ is the overall hydrogen-bond basicity, and L^{16} is the gas−liquid partition coefficient on hexadecane at 298 K.[28]

The coefficients in eq 4 are found by MLRA. They are not just fitting constants, but contain information on the properties of the system under investigation; in particular they refer to chemical properties of the solvent phase. The *r*-coefficient reflects the interaction of the phase with solute π- and σ-lone pairs, the *s*-coefficient is a measure of the phase dipolarity/polarizability, the *a*-coefficient is a measure of the phase hydrogen-bond basicity, the *b*-coefficient is a measure of the phase hydrogen-bond acidity, and the *l*-coefficient is a measure of the phase hydrophobicity. Equation 4 has been applied to numerous sets of gas−liquid chromatographic data,[26,27] to gas−solid adsorption,[28] to the solubility of gases and vapors in water,[24] organic solvents,[20] biological systems,[29] polymers,[30] and petroleum oils,[31] to the characterization of phases for chemical sensors,[32] to the characterization of fullerene,[33] and in the analysis of the effect of gases and vapors in nasal pungency[34] and eye irritation.[35]

A very similar equation to eq 4 is used[26] to correlate processes within condensed phase; it differs only in that the final descriptor is the McGowan[36] characteristic volume, V_X, in (mL mol^{-1})/100. The interpretation of eq 5 follows closely that of eq 4, but now the coefficients refer to the difference of properties of the (two) condensed phases. Equation 5 is also a well-tested equation and has been applied to the solubility of gases and vapors in water,[24] to numerous water−solvent partition systems,[19] to HPLC systems,[37] to thin-layer chromatography,[38] to microemulsion electrokinetic chromatography,[39] to water−micelle partitions,[40] to micellar electrokinetic chromatography,[41] to aqueous anesthesia,[42] to blood−brain distribution,[43] to brain perfusion,[44] and to skin permeation.[45]

$$\log SP = c + rR_2 + s\pi_2^{H} + a\Sigma\alpha_2^{H} + b\Sigma\beta_2^{H} + vV_X \quad (5)$$

Results

The values of log L^{chl} and log P_{chl} that were used in the regression equations are in Table 2. There are far fewer

Table 2—Values of log L^{chl} and log P_{chl} Used in the Regressions

digitoxin	4.50	5.60	1.47	4.52	5.6938

log L^{chl} values, because the values of log L^{w} required in order to obtain log L^{chl} from log P_{chl} via eq 2 were unavailable. Descriptors for most of the compounds have been published before,[19,20,24,26–45] but some new values are in Table 3.

Analysis of log L^{chl}—The 150 values of log L^{chl} in Table 2 cover quite a good range of compound type, from inorganic gases such as hydrogen to organic molecules such as triethyl phosphate and benzamide, with a total range of 9.4 log units in log L^{chl}. When regressed according to eq 4, the 150 log L^{chl} values yielded the statistically very good eq 6, considering that the experimental uncertainty in log L^{chl} must be not less than 0.1 log units. The calculated log L^{chl} values from eq 6 are given in Table 2.

$$\log L^{chl} = \underset{3.19}{0.168} - \underset{-6.46}{0.595} R_2 + \underset{14.13}{1.256}\pi_2^{H} + \underset{3.45}{0.280}\Sigma\alpha_2^{H} + \underset{14.39}{1.370}\Sigma\beta_2^{H} + \underset{41.82}{0.981}\log L^{16} \quad (6)$$

$$n = 150,\ \mathrm{sd} = 0.23,\ r^2 = 0.985,\ r^2_{cv} = 0.984,\ F = 1919$$

In eq 6, r^2_{cv} is the cross-validated squared correlation coefficient; the *t*-ratio for each coefficient is given below the coefficient. The correlation matrix in r^2 is given below,

	R_2	π_2^{H}	$\Sigma\alpha_2^{H}$	$\Sigma\beta_2^{H}$
π_2^{H}	0.591			
$\Sigma\alpha_2^{H}$	0.051	0.108		
$\Sigma\beta_2^{H}$	0.005	0.042	0.006	
log L^{16}	0.677	0.599	0.077	0.019

There are three pairs of coefficients that have rather high cross-correlations, but it must be stressed that we have not designed the data set; we have had to use the available data. The sd value of only 0.23 log units suggests that eq 6 could be useful for the estimation of further values of log L^{chl}. However, the importance of eq 6 lies also in the information that can be extracted from the coefficients in the equation. As outlined above, these coefficients are related to definite chemical properties of the condensed solvent phase. To put these coefficients in context, especially the *b*-coefficient, we summarize in Table 4 the corresponding coefficients for some other solvent phases.[24,43–45] The *r*-coefficient in eq 6 is not exceptional and seems to be related, at least in part, to lone pair–lone pair repulsion. The *s*-coefficient is a measure of the solvent dipolarity/polarizability; the rather large coefficient for chloroform is clearly due to polarizability effects, just as for 1,2-dichloroethane. The *a*-coefficient, a measure of solvent hydrogen-bond basicity, is very low, as expected, but the *b*-coefficient indicates that bulk chloroform can act as a hydrogen-bond acid. However, the magnitude of the *b*-coefficient (1.37) is of the same order as that for methanol (1.43)[46] and ethanol (1.31)[47] solvents, so that to external solutes chloroform is as strong a hydrogen-bond acid as are the alcohols. We give in Table 5 some previous measures of the hydrogen-bond acidity of bulk chloroform; the acceptor number (AN),[49] the solvatochromic α-value,[50,51] and the enthalpic $\Delta_{acid}H$ scale.[51] None of these scales ranks

Table 6—Factors That Influence the Solubility of Gases and Vapors in Chloroform and in Water at 298 K

solute	rR_2	$s\pi_2^H$	$a\Sigma\alpha_2^H$	$b\Sigma\beta_2^H$	l log L^{16} cav	disp	total[a]
			Solvent Chloroform				
methane	0.00	0.00	0.00	0.00	–2.38	2.06	–0.15
ethanol	–0.15	0.53	0.10	0.66	–3.31	4.77	2.77
butanone	–0.10	0.88	0.00	0.70	–4.19	6.43	3.89
hexane	0.00	0.00	0.00	0.00	–4.85	7.47	2.79
			Solvent Water				
methane	0.00	0.00	0.00	0.00	–4.04	4.11	–1.34
ethanol	0.20	1.15	1.44	2.31	–5.81	5.49	3.51
butanone	0.14	1.92	0.00	2.46	–7.50	7.01	2.76
hexane	0.00	0.00	0.00	0.00	–8.78	8.21	–1.84

[a] This includes the constant 0.168 in eq 6 and –1.271 in eq 7. Observed values are in chloroform 2.80 (ethanol), 3.87 (butanone) and 2.87 (hexane) and in water –1.46 (methane), 3.67 (ethanol), 2.72 (butanone), and –1.82 (hexane).

chloroform as acidic as alcohols, although it must be noted that only the $\Delta_{acid}H$ scale is based on a thermodynamic property, the enthalpy, in contrast to the *b*-coefficient that is related to Gibbs energy. The *l*-coefficient in eq 4 can be regarded as a measure of the solvent hydrophobicity; chloroform is not exceptional, with an *l*-coefficient close to those for benzene or hexadecane.

From the coefficients of eq 6 and solute descriptors, it is possible to dissect the observed log L^{chl} value for any given solute into contributions from the various terms in eq 6. However, the l log L^{16} term includes two opposing effects: (i) an endoergic cavity term that arises through disruption of solvent−solvent interactions, and which will make a negative contribution to l log L,[16] and (ii) an exoergic term due to London dispersion solute−solvent interactions, and which will make a positive contribution to l log L.[16] Indeed, as we have pointed out,[24,32,52] the London interaction term is nearly always larger than any specific solute−solvent interaction involving nonionic solutes.

We can make some headway by calculating the cavity term using scaled particle theory (SPT),[53] and then obtaining the London dispersion term by difference. Even an approximate estimation will suffice to show general trends, and as noted before,[13] there may be a number of possible divisions of experimental log L values into various contributions. To apply SPT we need to know the solvent hard-sphere diameter, σ_1, and Lennard−Jones potential, ϵ_1/k. We calculated these from log L^{chl} for nonpolar solutes, as indicated before,[54] and obtained values of 4.80 Å and 320 K, respectively. Then taking σ_2 as 3.82 (methane), 6.03 (hexane), 4.75 (ethanol), and 5.51 (butanone) for representative solutes, we can calculate the cavity term (Cav) and deduce the dispersion term (Disp) as [Disp = l log L^{16} − Cav]. For comparison, we have done the same for solvent water using eq 7,[24] with σ_1 taken as 2.77 Å.[53] Results are in Table 6. Note that our calculation refers to the separation of cavity and dispersion effects in the l log L^{16} term only. The constant term, which is appreciably more negative for solvent water than for any nonaqueous solvent, may also contain some cavity/dispersion contribution.

$$\log L^{w} = -1.271 + 0.822R_2 + 2.743\pi_2^H + 3.904\Sigma\alpha_2^H + 4.814\Sigma\beta_2^H - 0.213 \log L^{16} \quad (7)$$

In chloroform, the solute−solvent dispersion term, that increases with increase in solute size, outweighs the various specific interaction terms. This is not unique to chloroform solvent, but is the case for all the nonaqueous solvents we have investigated. The specific interaction terms merely discriminate between solutes of about the same size and hence of about the same cavity/dispersion effect. Thus butanone is more soluble than hexane, even though it is somewhat smaller. In any homologous series, with a constant functionality, log L^{chl} increases with carbon number because the positive dispersion effect increases faster than the negative cavity effect. However log L^{w} decreases along any homologous series because the positive dispersion effect now increases slower than the cavity effect.

In summary, application of the MLR eq 4 to the 150 log L^{chl} values yields eq 6 that can be used for the prediction of further values and can be used to quantify the various solute and solvent factors that influence the magnitude of log L^{chl}.

Analysis of log P_{chl}—Table 2 contains 335 values of log P_{chl}, enough to divide into a training set and a test set for the purpose of assessing the predictive capability of any MLR equation. We arbitrarily removed 10% of all the log P_{chl} values to leave 302 as a training set. Application of eq 5 to this set yielded eq 8, where again the *t*-scores are given below the coefficients.

$$\log P_{chl} = \underset{5.87}{0.321} + \underset{2.59}{0.168}R_2 - \underset{-5.94}{0.379}\pi_2^H - \underset{-52.04}{3.170}\Sigma\alpha_2^H - \underset{-52.00}{3.409}\Sigma\beta_2^H + \underset{59.10}{4.149}V_X \quad (8)$$

$$n = 301,\ \text{sd} = 0.28,\ r^2 = 0.965,\ r^2_{cv} = 0.963,\ F = 1635$$

The correlation matrix for eq 8 is,

	R_2	π_2^H	$\Sigma\alpha_2^H$	$\Sigma\beta_2^H$
π_2^H	0.539			
$\Sigma\alpha_2^H$	0.077	0.067		
$\Sigma\beta_2^H$	0.075	0.234	0.004	
V_X	0.312	0.278	0.010	0.251

The statistics of eq 8 are not as good as those for many other water−solvent partitions,[19] but we have already referred to the difficulty of the experimental measurement of log P_{chl} values. The predictive capability of eq 8 can be assessed by the calculation of log P_{chl} for the 34 compounds left out as a test set. These are in Table 7 together with the predicted and observed values of log P_{chl}. Over a range of 6 log units in log P_{chl} the sd between predicted and observed values is only 0.17 log unit; the average unsigned error is 0.13 log unit, and the average signed error is −0.03 log unit. As shown in Figure 1, there are no systematic deviations. None of the other computational or calculational methods summarized in Table 1 employed a test set of compounds to estimate predictive power, so that comparisons are not possible.

Once the predictive power of eq 8 is established, we can use all the available data to construct eq 9. The differences between eq 8 and eq 9 are marginal, but the latter equation is preferred since it covers more compounds, with log P_{chl} covering a range of over nine log units, from −3.25 (guanine) to 6.01 (octane). The calculated values of log P_{chl} on eq 9 are given in Table 2.

$$\log P_{chl} = \underset{8.57}{0.327} + \underset{2.86}{0.157}R_2 - \underset{-7.17}{0.391}\pi_2^H - \underset{-61.93}{3.191}\Sigma\alpha_2^H - \underset{-61.23}{3.437}\Sigma\beta_2^H + \underset{72.40}{4.191}V_X \quad (9)$$

$$n = 335,\ \text{sd} = 0.25,\ r^2 = 0.971,\ r^2_{cv} = 0.970,\ F = 2223$$

The correlation matrix of eq 9 is very similar to that of eq 8. The interpretation of eq 9 follows closely that of eq 6,

Table 7—Predicted Values from Eq 8 and Observed Values of log P_{chl} for the 33 Compound Test Set

compound	predicted	observed
cyclohexane	3.87	4.16
bromoethane	2.18	2.24
propyl acetate	2.28	2.56
ethyl trifluoroacetate	1.94	2.00

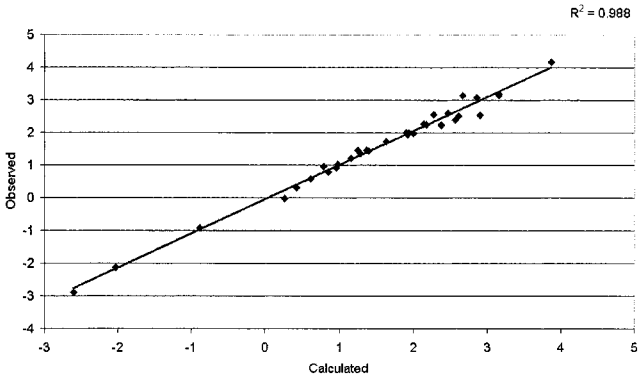

Figure 1—A plot of observed log P_{chl} vs predicted log P_{chl} values on eq 8.

except that now the coefficients refer to differences in properties of chloroform and water. A comparison with coefficients for other water–solvent partitions[19,20] is in Table 8. The *c*- and *r*-coefficients are not exceptional. The *s*-coefficient refers to the difference in dipolarity/polarizability of chloroform and water; a value of −0.39 places chloroform between CCl_4 (−1.15) and 1,2-dichloroethane (0.00) or dichloromethane (0.02). The hydrogen-bond basicity of bulk chloroform, as indicated by eq 6, is very small; hence, the *a*-coefficient in eq 9 is very negative (−3.19) and approaches that for the systems with nonbasic solvents such as hexadecane, cyclohexane, and CCl_4. In view of our discussion, above, on the hydrogen-bond acidity of chloroform, the *b*-coefficient in eq 9 is of some interest. A value of −3.43 places chloroform as acidic as wet octanol (−3.46), exactly in line with the *b*-coefficients in Table 4, and much more acidic than dichloromethane ($b = -4.14$) or 1,2-dichloroethane ($b = -4.29$). The *v*-coefficient in eq 5, just as the *l*-coefficient in eq 4, can be regarded as a measure of the solvent hydrophobicity. Chloroform is no different to most non-hydroxylic solvents which have *v*-coefficients between 4.2 and 4.6 units.

Table 8—Coefficients in Eq 5 for Water–Solvent Partitions

solvent	*c*	*r*	*s*	*a*	*b*	*v*

cocaine	4.26	6.67	1.21
hydrocortisone	2.21	3.67	0.81

[a] This work. [b] As in ref 13 (see text).

It is possible to analyze eq 9 term-by-term in order to quantify the particular interactions leading to log P_{chl} values for a given solute, just as we have done for log L^{chl} in Table 6, but the arithmetic is trivial. We conclude by examining a number of solutes for which log P_{chl} has not been well calculated by previous methods or by eq 9. The experimental values of log P_{chl} for aliphatic amines have been questioned[11,14] on the grounds that protonation in the aqueous phase could lead to erroneously low values. In Table 9 we collect observed and calculated log P_{chl} values for the aliphatic amines noted before. Values calculated through eq 9 are in good agreement with the observed values, and in our view the experimental log P_{chl} values must be substantially correct. Other workers[13] also calculate values reasonably close to those observed. Values of log P_{chl} for benzene[11] and methyl acetate[14] are also poorly computed, Table 9, but again our procedure suggests that the observed values are correct. We did find that there were three log P_{chl} values that were considerable outliers to eq 9, and which we omitted in the regression analysis; these outliers are shown in Table 10.

We can check our descriptors for hydroquinone, because values of log *P* are available[21] for many water–solvent partition systems for which we have[19] the coefficients in

[a] With original descriptors: $R_2 = 1.063$, $V_x = 0.8338$, $\pi_2^H = 1.00$, $\Sigma\alpha_2^H = 1.16$, and $\Sigma\beta_2^H = 0.60$. [b] With "best value" descriptors: $R_2 = 1.063$, $V_x = 0.8338$, $\pi_2^H = 1.25$, $\Sigma\alpha_2^H = 1.05$, and $\Sigma\beta_2^H = 0.58$. [c] Average of –3.89 and –4.04. [d] Average of –4.24 and –4.28; another value is 0.05. [e] Average of 0.36, 0.37, 0.38, and 0.46. [f] Average of –0.13, 0.01, 0.01, and 0.20. [h] Another value is 0.32. [i] Another value is 0.04.

eq 5 (log SP = log *P*). In addition, values of the HPLC capacity factor, *k′*, are known for hydroquinone in systems for which we have again the coefficients in eq 5 (logSP = log *k′*), see Table 11.[37a,57–59] Our original descriptors for hydroquinone reproduce the log *P* and log *k′* values for 33 systems with an sd of 0.20 units. We can calculate the set of descriptors that best reproduces the 33 log *P* and log *k′* values, with an sd value of only 0.15 units, but there is not much difference between the two sets of descriptors, Table 11. In either case, the calculated log P_{chl} value (−2.18 and −1.84) is over two log units smaller than the observed value (0.23). We have to conclude that the experimental value is in error. Such discrepancies are not uncommon, thus log *P* for hydroquinone in water−benzene is given[21] as −2.16, −1.85, and 0.15, and log *P* in water−heptane is given as −4.28, −4.24, and 0.05!

In the case of cocaine, only six log *P* values are available[21] as a check. Our present descriptors reproduce these with an sd value of 0.45 units, and the best fit we can obtain still results in an sd value of 0.38 units, see Table 12. However, either set of descriptors leads to a calculated log

Table 12—Water–Solvent Partitions for Cocaine

[b] With "best value" descriptors: $R_2 = 2.03$, $V_x = 2.7976$, $\pi_2^H = 2.77$, $\Sigma\alpha_2^H = 0.85$, and $\Sigma\beta_2^H = 2.13$. [c] Average of 1.53 and 1.81. [d] Average of 0.11, 0.15, 0.18, and 0.21.

P_{chl} value over 3 log units greater than that recorded.[21] We have no explanation other than that the experimental value is in error. It is worth noting that lipophilic strong bases are very difficult to study by the "shake-flask" method.

The number of water−solvent log *P* values for hydrocortisone is surprisingly small, but a few log *k′* values are available in calibrated HPLC systems,[57,60] see Table 13. Our usual descriptors lead to an sd value of 0.49 units, rather large but not unreasonable, and to a discrepancy of 1.4 log units in log P_{chl}. We can define a set of descriptors that leads to an sd value of 0.22 for the same eight systems and to a smaller discrepancy of only 0.45 log units in log P_{chl}. It is thus possible that in the case of hydrocortisone there is some error in the experimental log P_{chl} value combined with errors in our assigned descriptors.

In an attempt to resolve these problems, Dr. Cramer kindly calculated log P_{chl} for the three outliers using his computational method.[13] Results are in Table 10. They seem to confirm our suggestion that the three experimental values are in error.

Finally, we can find no evidence for the suggestion[14] that water-saturated chloroform may behave differently to dry chloroform as a partitioning medium. Other workers[13] also regard water-saturated and dry chloroform to be essentially the same as solvating media.

Care must be taken over experimental values, however. A case in point is 4-hexylpyridine with a calculated value of log P_{chl} as 3.99 with a trained computation,[11] as compared to an observed value of 5.00 log units. This latter value does not refer to water−chloroform partition, but to partition between 1 M sodium chloride and chloroform. Correction for the salting-out effect would lower the value

by 0.15 to 0.55, leading to an "experimental" value of 4.85 to 4.45, more in line with the computational value of 3.99,[11] and in good agreement with another computational value[13] of 4.7 and our calculated value of 4.47 through eq 9.

Our data set of 335 compounds therefore leads to a MLR eq 9 that from a training set of 301 compounds seems capable of predicting further log P_{chl} values with sd = 0.17. Equation 9 can also be used to analyze the solute and solvent interactions that affect log P_{chl}, with results almost identical to those obtained by an analysis of log L^{chl} through eq 6. The importance of these results lies in the recent use of the water−chloroform system as a measure of solute lipophilicity,[5,6,11,12] and of recent calculations of the transfer of nucleic acids from water to chloroform.[9,61] The nucleic acid transfers have been analyzed in terms of functional group contributions,[61] but a breakdown into contributions due to dipolarity/polarizability, hydrogen-bond acidity, etc., through eq 9, leads to more information as to the exact solute influences on the water−chloroform partitions.

Furthermore, if the water−chloroform system is to be generally used as a measure of solute lipophilicity in drug design, it will be of very considerable help to have a predictive procedure available. We have shown, see Table 1, that the MLRA method is capable of correlating log P_{chl} values rather better than computational methods, although the present MLRA method suffers from the possible lack of availability of the required descriptors. Recently, we have remedied this deficiency through a simple method (ABSOLVE) for the calculation of descriptors from structure.[62] Together with eq 6 and eq 9 the ABSOLVE method will enable log L_{chl} and log P^{chl} to be predicted from structure.

Accepted for publication April 16, 1999.

Abstract □ The purpose of this study was to investigate the mechanism by which the H_2-antagonists ranitidine and famotidine interacted with the paracellular space during their transport across Caco-2 cell monolayers. Transport experiments with ranitidine and famotidine across Caco-2 cell monolayers were performed to determine the apical-to-basolateral flux at various concentrations. Kinetic analysis of the transport data showed that ranitidine and famotidine were transported by both saturable and nonsaturable processes. Na^+,K^+-ATPase inhibitor ouabain and metabolic inhibitors sodium azide + 2-deoxy-D-glucose did not affect ranitidine transport, suggesting that the active transport was not involved. Famotidine and some other guanidine-containing compounds, e.g., guanethidine, Arg-Gly, L-arginine methyl ester, and L-argininamide, inhibited the transport of ranitidine, whereas other guanidine-containing compounds with an additional negative charge, e.g., L-arginine, did not. 2,4,6-Triaminopyrimidine (TAP), an inhibitor of paracelluar cationic conductance, also inhibited the transport of both ranitidine and famotidine. On the basis of these results, it is proposed that the saturable transport of ranitidine and famotidine across Caco-2 cell monolayers appears to be via a facilitated diffusion process mediated by the paracellular anionic sites. This mechanism is consistent with the observation that ranitidine and famotidine caused a concentration-dependent increase in transepithelial electrical resistance (TEER) across Caco-2 cell monolayers, presumably by blocking the paracellular anionic sites and thus inhibiting the flux of cations (e.g., Na^+).

Introduction

Intestinal epithelium presents a major barrier to orally administered drugs.[1,2] The drug molecules have to traverse this barrier by entering the epithelial cells from the apical (or luminal) side and exiting from the basolateral (or serosal) side (i.e., the transcellular transport), or by passing through the intercellular space (i.e., the paracellular transport). The transcellular transport occurs either via a passive diffusion process or via a carrier-mediated process, involving one of many carrier proteins (i.e., carrier for amino acids, di/tri peptides, glucose, bile acids, etc.).[3] The paracellular transport, involving passive diffusion of compounds in aqueous solution, is less efficient than the transcellular process because of the much lower surface area available to the compounds entering the intercellular space. In addition, presence of the highly specialized structure in the intercellular space restricts the free passage of compounds traversing the intestinal epithelium via the paracellular process.[4−7] Hence, only hydrophilic compounds of low molecular weight (e.g., mannitol) cross the intestinal epithelium predominantly via the paracellular route.

The H_2-antagonist ranitidine appears to be absorbed predominantly via the paracellular pathway based on the studies with Caco-2 cell monolayers as in vitro model of intestinal mucosa.[8] This conclusion was based on the observation that the permeability coefficient (P_{app}) of ranitidine across Caco-2 cell monolayers increased by 15−20-fold when Ca^{2+} was removed from the transport medium, thereby compromising the integrity of the tight junctions.[8] This was further confirmed by the observation that the uptake of ranitidine into Caco-2 cells was minimal.[8] The paracellular transport of ranitidine is consistent with the report that absorption of ranitidine in humans after oral administration is incomplete and that its bioavailability is ∼50% despite little or no first pass metabolism.[9] During the investigation of the mechanism of transport of ranitidine it was uncovered that H_2-antagonists—ranitidine, famotidine, cimetidine, and nizatidine—appeared to affect the tight junctions in Caco-2 cell monolayers as evidenced by a concentration-dependent increase in the transepithelial electrical resistance (TEER) across Caco-2 cell monolayers,[10] which is an indicator of paracellular ionic permeability.[11−13] The increase in TEER was accompanied by a decrease in their own permeability across Caco-2 cell monolayers.[10] These results suggest that H_2-antagonists may affect their own absorption by a mechanism that is related to the mechanism by which they cause an increase in TEER. An inverse relationship between the ability of the four H_2-antagonists to cause an increase in TEER across Caco-2 cell monolayers and their human bioavailability[9,10,14] provides support to this hypothesis.

In light of these observations, we have investigated the mechanism by which the H_2-antagonists cause an increase in TEER and affect their own transport across Caco-2 cell monolayers. Our results suggest that H_2-antagonists cause an increase in TEER by binding to the anionic centers in the paracellular space and thereby decreasing the cationic conductance across the cell monolayers. During our investigation, we have found that ranitidine and famotidine traverse the Caco-2 cell monolayers by a combination of saturable and nonsaturable mechanisms. In this report we have characterized the saturable transport of ranitidine and famotidine and proposed a mechanism of transport for these compounds that is consistent with the saturable transport kinetics as well as their ability to cause an increase in TEER across Caco-2 cell monolayers.

Materials and Methods

Materials—Eagle's minimum essential medium (with Earle's salts and L-glutamate), fetal bovine serum (FBS), nonessential amino acids (NEAA, ×100), and 0.05% trypsin-EDTA solution were obtained from Gibco Laboratories, Grand Island, NY. Hank's balanced salt solution (HBSS, ×1), ranitidine hydrochloride,

famotidine, 2,4,6-triaminopyrimidine (TAP), guanethidine monosulfate, Arg-Gly hydrochloride, Gly-Gly, L-arginine hydrochloride, L-argininamide dihydrochloride, L-arginine methyl ester dihydrochloride, glycylsarcosine (Gly-Sar), mannitol, ouabain, sodium azide, 2-deoxy-D-glucose, 2,4-dinitrophenol, antibiotic antimycotic solution (×100), 2-(*N*-morpholino)ethanesulfonic acid (MES), and D-(+)-glucose were purchased from Sigma Chemical Co., St. Louis, MO. *N*-Hydroxyethylpiperazine-*N*′-2-ethanesulfonate (HEPES, 1 M) was purchased from Lineberger Comprehensive Cancer Center, the University of North Carolina, Chapel Hill, NC. Lucifer yellow CH was purchased from Molecular Probes, Eugene, OR. [^{14}C]-Mannitol (51.5 mCi/mmol) and [^{14}C]PEG-4000 (11.0 mCi/g) were obtained from NEN Research Products, Boston, MA. [^{3}H]Gly-Sar (30 Ci/mmol) was purchased from American Radiolabeled Chemicals Inc., St. Louis, MO.

Cell Culture—The Caco-2 cell line was obtained from Glaxo-Wellcome, Inc., Research Triangle Park, NC, and cultured as described previously.[10] Briefly, Caco-2 cells were cultured at 37 °C in minimum essential medium, supplemented with 10% FBS, 1% NEAA, 100 U/mL penicillin, 100 μg/mL streptomycin, and 0.25 μg/mL amphotericin B in an atmosphere of 5% CO_2 and 90% relative humidity. The cells were passaged every 4−6 days at a split ratio of 1:20 at about 90% confluency, using trypsin−EDTA. Caco-2 cells (passage 50∼55) were seeded at a density of 60 000 cells/cm^2 on polycarbonate membranes of Transwells (12 mm i.d., 3.0 μm pore size, Costar, Cambridge, MA). Medium was changed the day after seeding and every other day thereafter (apical volume 0.5 mL, basolateral volume 1.5 mL). The cell monolayers were used 20−25 days postseeding. TEER was measured as described later. TEER and apical-to-basolateral flux for [^{14}C]mannitol, a paracellular transport marker, were used to ensure cell monolayer integrity. Monolayers having TEER values above 300 Ω·cm^2 and the mannitol flux < 0.5%/h were used in the studies.

Measurement of TEER—EVOM Epithelial Tissue Voltohmmeter (World Precision Instruments, Sarasota, FL) and Endohm-12 electrode (World Precision Instruments, Sarasota, FL) were used to measure TEER across the Caco-2 cell monolayers.[10] The cell monolayers were preincubated for 1 h at 37 °C with transport buffer (HBSS supplemented with 25 mM D-glucose and 10 mM HEPES, pH 7.2), and TEER was measured. The experiments were initiated by replacing the apical buffer with the compound of interest dissolved in an appropriate transport buffer (HBSS supplemented with 25 mM D-glucose and 10 mM HEPES, pH 7.2 or HBSS supplemented with 25 mM D-glucose and 10 mM MES, pH 6.0). The cell monolayers were incubated at 37 °C, and TEER was measured at selected times. All the experiments were performed in triplicate.

Transport Studies—Transport experiments were performed as described previously.[10] Briefly, cell monolayers were incubated for 1 h at 37 °C with the transport buffer (pH 7.2), and TEER was measured. Transport experiments were initiated by replacing the apical buffer with 0.4 mL of the transport buffer (pH 7.2 or 6.0) containing the compound being investigated. The inserts were transferred at selected times to a 12-well cell culture cluster (Costar, Cambridge, MA) containing fresh transport buffer (pH 7.2). The temperature was maintained at 37 °C during the transport experiments. TEER was measured after the experiments. No treatment caused a significant decrease in TEER compared to the control monolayers. The amount of drugs in the receiver side was determined as a function of time (see Figure 3A) to calculate the flux (J) across the cell monolayers. All transport experiments were carried out under sink conditions as the concentrations of drugs in the basolateral side remained at least 100-fold lower than those in the apical side. The amount of radiolabeled compounds was measured by using liquid scintillation counter (Tri-Carb 4000, Packard, Downers Grove, IL). The amount of ranitidine or famotidine was quantified by HPLC (1100 series, Hewlett-Packard, Waldbronn, Germany) using an ODS-AQ C18 column (250 × 4.6 (i.d.) mm, YMC Inc., Wilmington, NC) of 5 μm packing and 120 Å pore size and an isocratic mobile phase (65% 50 mM phosphate buffer, pH 6.0 and 35% methanol for ranitidine, and 80% 50 mM phosphate buffer, pH 6.0 and 20% methanol for famotidine).[8,10] The flow rate was 1.0 mL/min. Ranitidine and famotidine were detected by UV at 320 and 280 nm, respectively. Under these conditions, the retention times for ranitidine and famotidine were 5.6 and 9.6 min, respectively, and no other peaks were detected after the transport experiments.

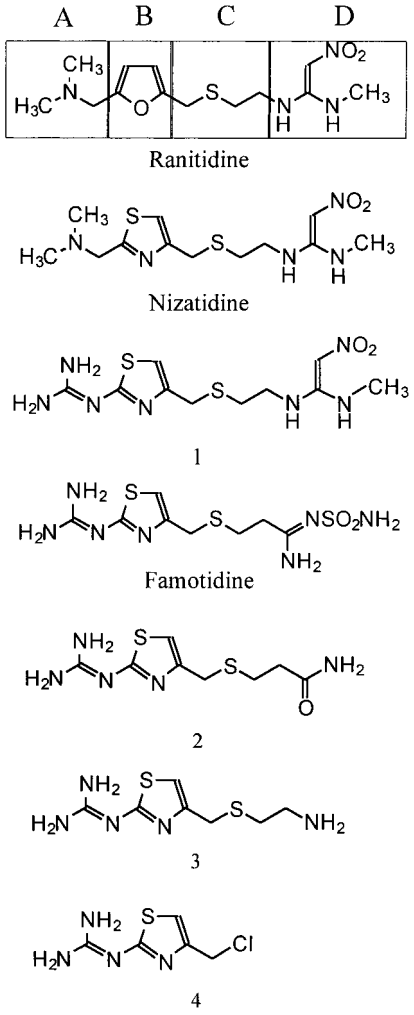

Figure 1—Structures of H_2-antagonists and their derivatives.

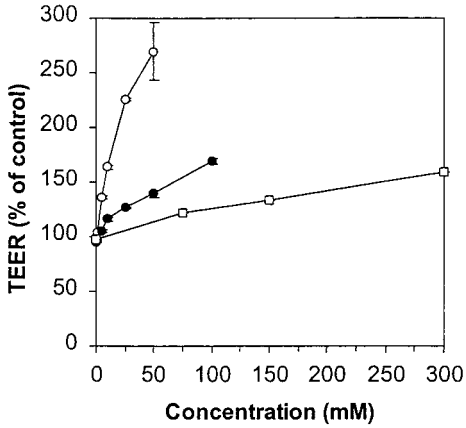

Figure 2—Effect of ranitidine and famotidine on TEER across Caco-2 cell monolayers. Effect of mannitol on TEER was evaluated to demonstrate that the effect of ranitidine and famotidine was selective and not just due to the change in osmolality. TEER was measured 15 min after incubating the cell monolayers with various concentrations of drugs on the apical side (pH 7.2). Percent change of the TEER values was calculated relative to the value at time zero (303 ∼ 419 Ω·cm^2). ○, Famotidine; ●, ranitidine; □, mannitol. Values are the mean of three measurements ± sd. The pH of the famotidine solutions above 10 mM was 6.5 (instead of 7.2); however, the change in pH alone did not contribute to the increase in TEER.

Inhibition of Active Transport—For all the studies described in this section, cell monolayers were preincubated for 30 min at 37 °C with the transport buffer (pH 7.2) and TEER was measured. For the inhibition of Na^+,K^+-ATPase,[15] cell monolayers were

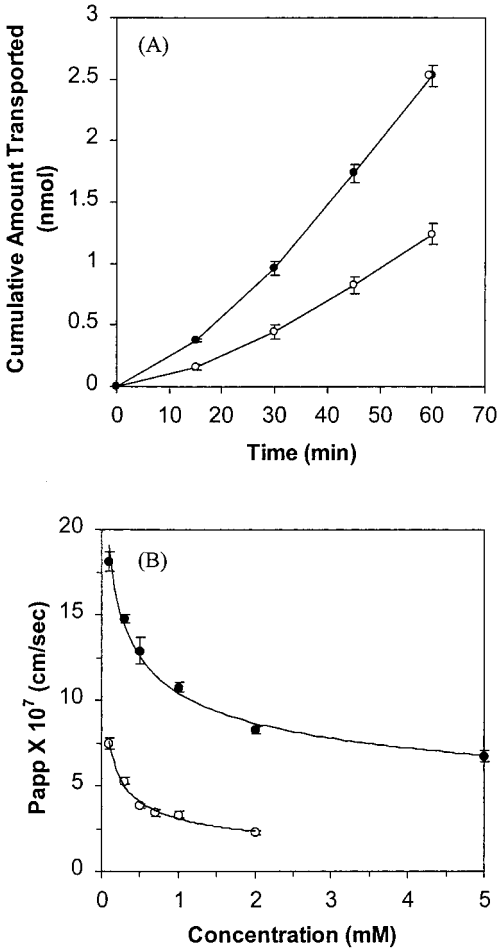

Figure 3—(A) Time course of apical-to-basolateral transport of ranitidine (0.5 mM) and famotidine (0.5 mM) across Caco-2 cell monolayers; (B) permeability of ranitidine and famotidine across Caco-2 cell monolayers as a function of concentration. P_{app} values were calculated from the apical-to-basolateral flux (J) determined in a linear transport region (30–60 min) at various concentrations. The pH of both apical and basolateral sides was 7.2. ●, Ranitidine; ○, Famotidine. Values are the mean of three measurements ± sd.

further incubated for 30 min at 37 °C with ouabain (5 mM) dissolved in the transport buffer (pH 7.2) on both apical and basolateral sides. Ranitidine (0.1 mM) in the transport buffer (pH 7.2) containing ouabain (5 mM) was then added to the apical side. For metabolic inhibition,[15] cell monolayers were incubated for 30 min at 37 °C with sodium azide (1 mM) and 2-deoxy-D-glucose (50 mM), or 2,4-dinitrophenol (1 mM), dissolved in the transport buffer (pH 7.2) on both apical and basolateral sides. Ranitidine (0.1 mM) in the transport buffer (pH 7.2) containing metabolic inhibitors was then added to the apical side. The transport experiments were conducted for 1 h. For control studies, a mixture of [^{3}H]Gly-Sar (0.1 mM, 0.5 μCi/ml) and [^{14}C]mannitol (0.1 mM, 1.0 μCi/ml) in the transport buffer (pH 6.0) was applied to the apical side after incubating the cell monolayers with active transport inhibitors.[16] The pH of the apical solution was adjusted to 6.0 for the control experiments since Gly-Sar (positive control) is a substrate of H^+-coupled dipeptide transporter.[16]

Data Analysis—Apparent permeability coefficients (P_{app}, cm/s) were calculated using eq 1.[10]

$$P_{app} = \frac{1}{AC_o}\frac{dQ}{dt} \quad (1)$$
