where dQ/dt is the flux (J) across the monolayer (nmol/s) determined experimentally by measuring the amount of the compounds transported as a function of time (e.g., see Figure 3A for measurement of ranitidine and famotidine flux), A is the surface area of the porous membrane (cm^2), and C_o is the initial concentration (nmol/mL) in the donor side. Kinetic parameters for the transport

Table 1—Effect of Famotidine Derivatives on TEER across Caco-2 Cell Monolayers

compound[a]	TEER[b] (% of control)
1	217 ± 7
2	201 ± 1
3	158 ± 17
4	235 ± 11
ranitidine	127 ± 0.3
nizatidine	117 ± 3[c]
famotidine	193 ± 22

[a] The concentration of nizatidine was 50 mM while others were 25 mM. [b] Measured 15 min after incubating the cell monolayers with a compound in the apical side. Percent change of the TEER values was calculated relative to the value at time zero (366–442 Ω·cm^2). Values are the mean of three measurements ± sd. [c] Taken from ref 10.

of ranitidine and famotidine were calculated by fitting the data to eq 2 using nonlinear regression analysis (WINNONLIN 1.1, Scientific Consulting Inc., Apex, NC):[17,18]

$$J' = \frac{J'_{max}S}{K_m(app) + S} + K_dS \quad (2)$$

where J' (pmol·min^{-1}·cm^{-2}) is the flux (J) normalized to unit surface area, K_m(app) (mM) is a constant equivalent to a Michaelis–Menten constant, J'_{max} is the maximal flux for the saturable term (pmol·min^{-1}·cm^{-2}), K_d is the constant for the nonsaturable term (nL·min^{-1}·cm^{-2}), and S is the concentration in the donor side (mM). The statistical significance of differences between treatments was evaluated using Student's t tests, with a significance level of $p < 0.05$.

Synthesis of Famotidine Derivatives—Famotidine derivatives used in this study (cf. Figure 1) were prepared as described in the literature.[19,20]

Results

Effect of H_2-Antagonists on TEER—Ranitidine and famotidine caused a concentration-dependent but saturable increase in TEER when applied to the apical side of Caco-2 monolayers (Figure 2), as reported previously.[10] A much smaller increase was observed when the monolayers were treated with mannitol solutions of similar osmolality (Figure 2). These results indicated that the increase in TEER caused by ranitidine and famotidine did not simply result from the hyperosmolality of the drug solutions. The specificity of this effect was further evidenced by the fact that famotidine was much more potent than ranitidine in causing the TEER increase across Caco-2 cell monolayers (Figure 2).

Structural Requirements for the Effect of H_2-antagonists on TEER—A systematic study was undertaken to define the structural requirements for the effect of H_2-antagonists and related compounds on TEER. The role of the four key moieties in the H_2-antagonists (Figure 1) in causing an increase in TEER was investigated by comparison of the potencies of appropriate pairs of compounds (Table 1). The heteroaromatic ring (part B) does not seem to play a significant role, as indicated by the marginal difference in the potency between ranitidine and nizatidine (see Figure 1 and Table 1 for all comparisons). The thioether linker (part C) is not a primary determinant of the effect since the potency varies dramatically among compounds which share this moiety. Substitution of the *N*-sulfamoylamidine moiety of famotidine by 1-nitro-2-(methylamino)-2-aminoethylene group (compound **1**) caused no significant change in the potency, indicating that part D is also not a primary determinant of the activity. This was confirmed by the observation that the potency was maintained when part D was replaced with various func-

Table 2—Effect of Famotidine on the Transport of Paracellular Markers

Paracellular Markers	net charge	mol wt	% of control[a]
[^{14}C]mannitol (100 μM, 20 μCi/μmol)	0	182	114 ± 9
[^{14}C]PEG-4000 (100 μM, 5 μCi/μmol)	0	4000	97 ± 2
lucifer yellow CH (250 μM)	–2	457	79 ± 13
ranitidine (100 μM)	+1	314	22 ± 0.2[b]

[a] Determined by measuring the apical-to-basolateral transport of compounds for 1 h across Caco-2 cell monolayers in the absence (control) or presence of famotidine (5 mM) on the apical side (pH 7.2). Values are the mean of three measurements ± sd. [b] $p < 0.05$ compared to control.

tional groups such as amide (compound **2**), amine (compound **3**). Similarly, potency was maintained when part (C + D) was replaced with a chloromethyl group (compound **4**). The basic side chain represented in part A appears to be the essential moiety for the effect since a dramatic increase in the potency was observed when the dimethylaminomethyl group of nizatidine was substituted with guanidine group (compound **1**). This observation also indicates that the potent effect of famotidine may be due to the presence of the guanidine group.

Effect of Famotidine on the Transport of Paracellular Markers—The effect of famotidine on paracellular permeability was examined by measuring the permeability (P_{app}) of various paracellular markers across Caco-2 cell monolayers in the presence of famotidine (Table 2). This was done to determine if the increase in TEER by H_2-antagonists was caused by tightening of the paracellular space. Famotidine did not cause a significant decrease in the permeability of neutral ([^{14}C]mannitol, and [^{14}C]PEG-4000) or anionic (Lucifer Yellow) paracellular markers. In contrast, famotidine inhibited the transport of ranitidine, a cationic compound that is transported via the paracellular route.[8] These results suggest that the increase in TEER caused by famotidine (and other H_2-antagonists) is not due to tightening of the tight junctions in the paracellular space; rather, famotidine appears to inhibit the transport of only positively charged entities through the paracellular space. Thus, the increase in TEER caused by famotidine (and other H_2-antagonists) is likely to be due to inhibition of the cation-selective ionic conductance, i.e., Na^+ transport, mediated by the anionic centers in the paracellular space.[21–23] This mechanism is consistent with our earlier finding that guanidine group, which is positively charged at neutral pH, is essential for causing an increase in TEER across Caco-2 cells by famotidine and its derivatives (Table 1).

Transport of Ranitidine and Famotidine—Consistent with above observations, the apical-to-basolateral permeability of both ranitidine and famotidine through Caco-2 cell monolayers was found to be dependent on concentration (Figure 3B). The P_{app} values decreased exponentially with concentration, but appeared to reach plateau above 2 mM for ranitidine and 0.7 mM for famotidine (Figure 3B). The decrease in P_{app} as a function of concentration suggests that both ranitidine and famotidine inhibit their own transport (Figure 3B). These results also indicate that ranitidine and famotidine are transported by a process other than simple passive diffusion, because the P_{app} values should remain constant over the entire concentration range (under sink condition) if passive diffusion is the major transport mechanism. We have previously reported a concentration-dependent decrease in P_{app} values for ranitidine and famotidine;[10] however, those studies were conducted at concentrations ≥ 5 mM. At these high

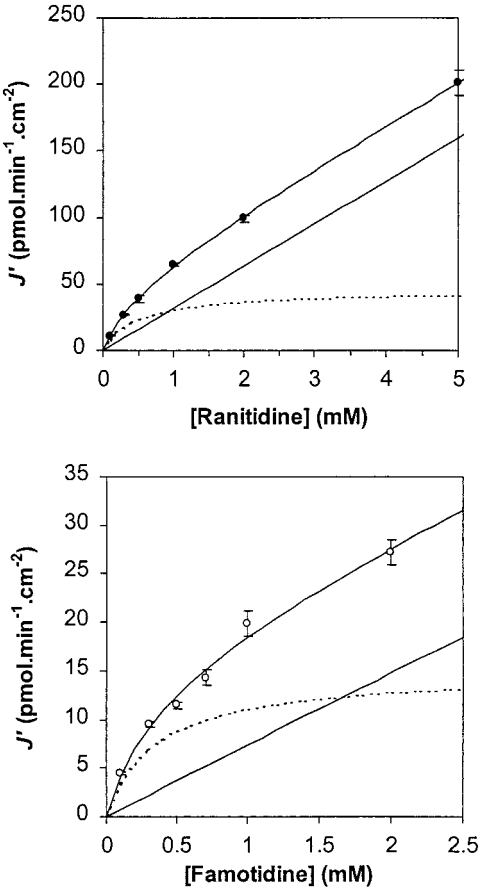

Figure 4—Transport of ranitidine and famotidine across Caco-2 cell monolayers as a function of concentration. Apical-to-basolateral flux (J') (same data used in Figure 3) was plotted as a function of concentration. The straight lines represent the calculated nonsaturable transport and the dotted curves represent the calculated saturable transport (see eq 2). ●, Ranitidine; ○, Famotidine. Values are the mean of three measurements ± sd.

concentrations, the decrease in P_{app} could be due to multiple effects, i.e., saturation of the anionic sites, osmotic effects, and a decrease in pH (famotidine only) necessary to keep the drug in solution. To obtain a better insight into the transport process for these compounds, their flux (J') was plotted as a function of concentration on the donor side (Figure 4). Under sink conditions (as is the case here, see Materials and Methods and Figure 3A), the flux (J') should increase linearly as a function of concentration in the donor side if the compounds are transported by the passive diffusion process. The flux (J') of ranitidine and famotidine increased nonlinearly with concentration (hyperbolic relationship) at relatively low concentrations (<1 mM) and then increased linearly at higher concentration. These results suggested that the apical-to-basolateral transport of ranitidine and famotidine was mediated by both saturable and nonsaturable processes.[17,18] This was also indicated by an excellent fit of the data to the curves obtained from nonlinear regression analysis with an equation consisting of both saturable and nonsaturable terms (Figure 4 and eq 2).[17,18] The calculated equivalent to Michaelis–Menten constant (K_m(app)) and the maximal flux for the saturable process (J'_{max}) for ranitidine were 0.48 mM and 45.6 pmol·min^{-1}·cm^{-2}. The corresponding values for famotidine were 0.36 mM and 15.0 pmol·min^{-1}·cm^{-2}, respectively.

Effect of Inhibitors of Active Transport on the Transport of Ranitidine—Gan et al.[8] have shown that ranitidine is transported predominantly via the paracellular pathway across Caco-2 cell monolayers. This was

Table 3—Effect of Active Transport Inhibitors on the Transport of Ranitidine

inhibitor (mM)	amount transported (%)[a]		
	ranitidine	[^{3}H]Gly-Sar	[^{14}C]mannitol
control	2.60 ± 0.08	4.52 ± 0.25	0.23 ± 0.01
ouabain (5)	2.68 ± 0.05	2.55 ± 0.11[b]	0.28 ± 0.07
sodium azide (1) + 2-deoxy-D-glucose (50)	2.49 ± 0.21	2.91 ± 0.11[b]	0.25 ± 0.002
2,4-dinitrophenol (1)	1.40 ± 0.06[b]	0.76 ± 0.16[b]	0.32 ± 0.10

[a] Determined by measuring the apical-to-basolateral transport across Caco-2 cell monolayers for 1 h in the absence (control) or presence of active transport inhibitors. The monolayers were first incubated with an inhibitor for 30 min, and ranitidine (0.1 mM) or control compound (0.1 mM) was added to the apical side to initiate the experiment (see Materials and Methods for details). [b] $p < 0.05$ compared to control. Values are the mean of three measurements ± sd.

evidenced by a dramatic increase in ranitidine transport by Ca^{2+} depletion, and by relatively low cellular uptake of ranitidine compared to that of lipophilic compounds such as testosterone and ondansetron.[8] Therefore, it is unlikely that transcellular saturable mechanisms are significantly involved in the transport of ranitidine.

It is difficult to conceive an active transport process to explain the saturable transport of ranitidine and famotidine in the absence of a significant transcellular component associated with the transport of these compounds across Caco-2 cell monolayers. However, the transport of ranitidine across Caco-2 cell monolayers was examined in the presence of Na^+,K^+-ATPase inhibitor ouabain, or metabolic inhibitors such as sodium azide + 2-deoxy-D-glucose, and 2,4-dinitrophenol, to determine if the saturable component of the transport is an active transport process.[3,15,17] In our control experiments, the active transport inhibitors significantly inhibited the apical-to-basolateral transport of [^{3}H]Gly-Sar (positive control)[16] without affecting that of [^{14}C]mannitol (negative control) at concentrations that were reported to be inhibitory to active transport processes (Table 3).[3,15,17] Ouabain and sodium azide (+ 2-deoxy-D-glucose), however, did not affect the apical-to-basolateral transport of ranitidine across Caco-2 cell monolayers (Table 3), suggesting that ranitidine is not a substrate for active transport systems (e.g. amino acids, di/tri peptides, glucose, bile acids, etc.) in Caco-2 cells. Interestingly, 2,4-dinitrophenol significantly decreased the transport of ranitidine (Table 3). The inhibitory effect of 2,4-dinitrophenol on the transport of ranitidine may argue for an active transport mechanism; however, there is no precedent for an active transport process that is inhibited by 2,4-dinitrophenol, but is insensitive to sodium azide or ouabain.

Inhibition of Ranitidine Transport by Guanidine Derivatives—To determine if the saturable transport of ranitidine and famotidine occurred via a common mechanism, the permeability (P_{app}) of ranitidine was measured in the presence of famotidine. Indeed the apical-to-basolateral transport of ranitidine (0.5 mM) was significantly inhibited by famotidine (10 mM) (Figure 5). Interestingly, other guanidine-containing compounds such as guanethidine, L-arginine methyl ester, and L-argininamide also significantly inhibited the transport of ranitidine (Figure 5). Arg-Gly, a guanidine-containing dipeptide, significantly inhibited ranitidine transport whereas Gly-Gly, a non-guanidine-containing dipeptide had little effect (Figure 5). The common structural feature shared by all these compounds that inhibited the transport of ranitidine across Caco-2 cell monolayers is the presence of a cationic center. It has been shown that the cell surface, including that making up the paracellular space, has net negative charge.[5–7] These results suggest that the saturable transport of ranitidine and famotidine may involve binding to the anionic cellular components via their basic side chains (dimethylamino group or guanidine group). Taking the predominantly paracellular transport of ranitidine[8] into consideration, it seems likely that the saturable transport of ranitidine and famotidine is mediated by the anionic sites in the paracellular space. This mechanism is consistent with our proposed mechanism for the TEER increase by ranitidine and famotidine. Interestingly, L-arginine did not cause a significant effect on the transport of ranitidine (Figure 5). However, L-arginine methyl ester and L-argininamide (in which the carboxylate group is blocked) effectively inhibited ranitidine transport, suggesting that the negative charge of the carboxylate group in L-arginine interferes with its ability to bind to the anionic sites in the paracellular space. The fact that structural components other than the cationic groups are involved in the interactions of these compounds with the anionic sites is also evident from the observation that tetramethylammonium ion does not inhibit the transport of ranitidine across Caco-2 cells (data not shown).

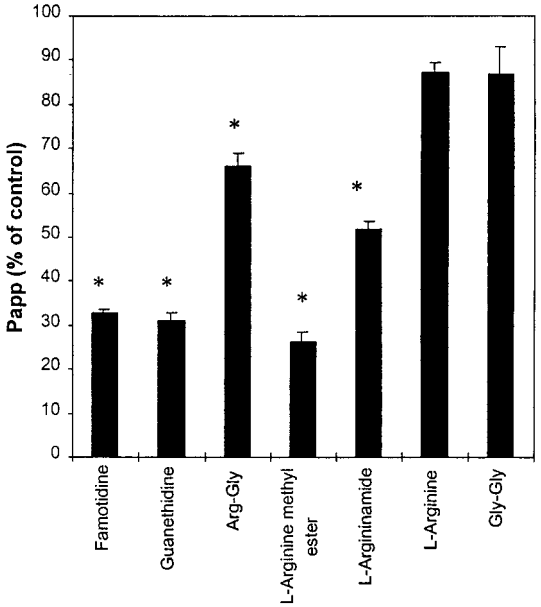

Figure 5—Effect of famotidine and other guanidine-containing compounds on the transport of ranitidine across Caco-2 cell monolayers. P_{app} values were calculated from the apical-to-basolateral flux (J) of ranitidine (0.5 mM) determined in the linear transport region (30–60 min) in the presence or absence of a guanidine-containing compound (10 mM) on the apical side (pH 7.2). The control P_{app} value was $(1.1 \pm 0.04) \times 10^{-6}$ cm/s. Values are the mean of three measurements ± sd. *, $p < 0.05$ compared to control.

Discussion

We have recently reported that ranitidine and other H_2-antagonists cause an increase in TEER across Caco-2 cell monolayers.[10] In the present study we have further characterized this effect and showed that the increase in TEER does not cause any decrease in the permeability of paracellularly transported compounds that are either neutral of anionic in nature. In contrast, paracellular transport of cationic compounds (including their own transport) is inhibited by ranitidine and famotidine. Thus, the effect of ranitidine and famotidine on TEER is clearly not due to tightening of the tight junctions as is the case for protamine.[24] We propose that H_2-antagonists cause an increase in TEER by binding to the anionic sites such as carboxylate and phosphate groups[5–7] on the cell surface in the paracellular space and inhibiting cation-selective ionic conduc-

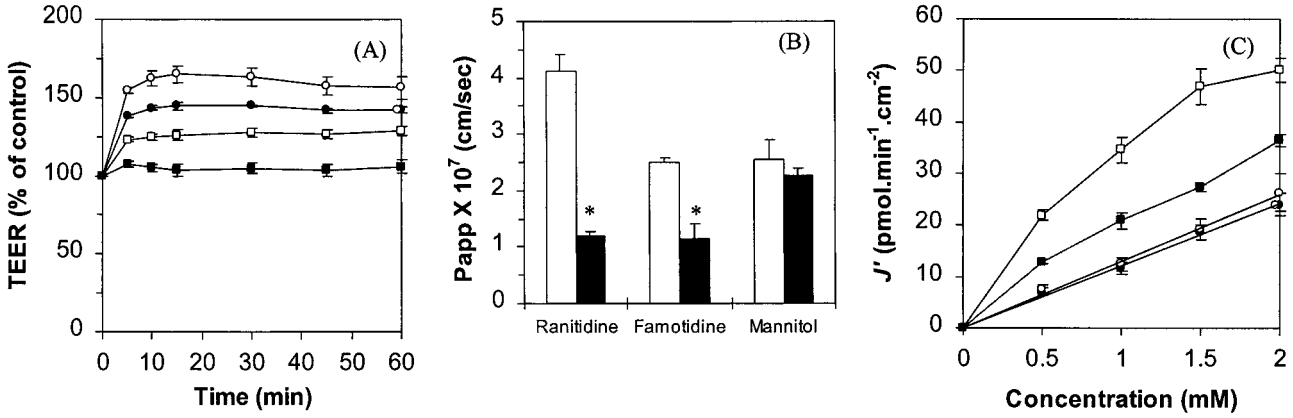

Figure 6—Effect of TAP on TEER and the transport of ranitidine and famotidine across Caco-2 cell monolayers. (A) TEER was measured at selected times after initiating the incubation of the cell monolayers with various concentrations of TAP on the apical side. Percent change of the TEER values was calculated relative to the value at time zero (370–417 $\Omega \cdot cm^2$). ■, Control; □, 5 mM; ●,10 mM; ○, 20 mM TAP. (B) P_{app} values for ranitidine, famotidine (both 1 mM) and [^{14}C]mannitol (1 mM; 2.0 μCi/ml) were calculated from the apical-to-basolateral flux (J) determined in a linear transport region (30–60 min) in the absence or presence of TAP (10 mM) on the apical side; open bars, control (– TAP); solid bars, + TAP (10 mM). (C) ●, Ranitidine and ○, famotidine flux determined in the presence of 10 mM TAP; □, ranitidine and ■, famotidine flux determined in the absence of TAP. All experiments were done at apical pH 6.0/basolaterlal pH 7.2 because TAP (pK_a = 6.72) caused an increase in TEER only in the protonated form.[21] Values are the mean of three measurements ± sd. *, $p < 0.05$ compared to control.

tance,[21–23] and not by tightening of the tight junctions as was previously suspected.[10] Such interactions between cationic compounds and paracellular anionic functionality are not without precedent. 2,4,6-Triaminopyrimidine (TAP) has been shown to inhibit paracellular cation permeation across frog gall bladder and several other epithelia with concomitant increase in TEER.[21–23] In our study, TAP caused a concentration-dependent increase in TEER across Caco-2 cell monolayers (Figure 6A). TAP also caused a significant decrease in the permeability of both ranitidine and famotidine across Caco-2 monolayers without affecting that of [^{14}C]mannitol (Figure 6B). Partial inhibition of the transport of ranitidine (1 mM) and famotidine (1 mM) by TAP is consistent with the fact that at these concentrations both the compounds traverse the cell monolayers via a combination of saturable and nonsaturable mechanisms.

The investigation of the effect of H_2-antagonists on TEER has led to the hypothesis that these compounds not only interact with anionic sites on the cell surface in the paracellular space, but that this interaction may contribute to a saturable transport mechanism. This saturable mechanism is characterized by the hyperbolic relationship between flux and the concentration in the donor side. As expected, certain cationic compounds (e.g., TAP) inhibit the transport of ranitidine and famotidine (cf., Figure 6B). In fact, in the presence of TAP the saturable component of the paracellular transport of ranitidine and famotidine is completely inhibited, such that the flux is linear with concentrations (Figure 6C).

Because TAP can also block Na^+ channels,[25] it can be argued that the increase in TEER caused by TAP as well as by ranitidine and famotidine is due to their effect on these Na^+ channels on the apical surface of Caco-2 cells. However, inhibition of ranitidine and famotidine transport, coupled with virtual elimination of the saturable component of their transport by TAP cannot be explained by its effect on the Na^+ channels because these compounds are not likely to be transported across the cell membrane through these channels.

The saturable transport of ranitidine and famotidine does not appear to be an active transport process as it is unaffected by known active transport inhibitors, i.e., Na^+,K^+-ATPase inhibitor ouabain and metabolic inhibitor sodium azide (+ 2-deoxy-D-glucose). However, the active transport cannot be completely ruled out as a possible mechanism for the saturable transport of ranitidine and famotidine, since ranitidine transport was significantly inhibited by a different metabolic inhibitor 2,4-dinitrophenol. The reason for this is unknown at this stage.

It is clear that some of the well-accepted approaches to evaluate the involvement of an active transport process (e.g., metabolic inhibition) cannot provide clearly interpretable results regarding the involvement of an active transport process for the transport of ranitidine and famotidine. However, if we take into consideration (i) the evidence for predominantly paracellular transport of ranitidine,[8] and (ii) the lack of any effect of some inhibitors of active transport (Table 3), then it is reasonable to conclude that an active transport is not likely to be involved in the translocation of ranitidine or famotidine across Caco-2 cell monolayers.

We propose a mechanism for the transport of H_2-antagonists, ranitidine and famotidine, across Caco-2 cell monolayers to explain the increase in TEER[10] caused by these compounds as well as their saturable (plus nonsaturable) transport kinetics (Figure 7). As depicted in Figure 7, ranitidine and famotidine can interact with anionic sites present on the cell surface in the paracellular space,[5–7] and thus compete with Na^+ ions (and other cations) for these binding sites resulting in decreased ionic transport and increased TEER across the cell monolayers. A similar mechanism has been proposed to explain an increase in TEER caused by the cationic hydrophilic compound TAP across frog gall bladder and several other epithelia.[21,22] The fact that ranitidine affects TEER only when it is applied from the apical side[10] of the Caco-2 cell monolayers suggests that the anionic sites are asymmetrically disposed in the paracellular space, either in the junctional complexes or to the apical side of the junctional complexes. It is conceivable that the effect of ranitidine and famotidine on TEER is due to a mechanism unrelated to their proposed binding to the paracellular anionic sites, i.e., via blocking of the Na^+ channels on the apical surface of the cells. Extensive electrophysiological studies will be necessary to determine the relative contribution of the two mechanisms in causing an increase in TEER.

As shown in Figure 7, these interactions of ranitidine (and famotidine) with anionic sites can also explain how the translocation of these compounds through the paracellular space can occur by a combination of saturable and nonsaturable processes. Their interaction with the anionic sites can assist in their translocation across the cell

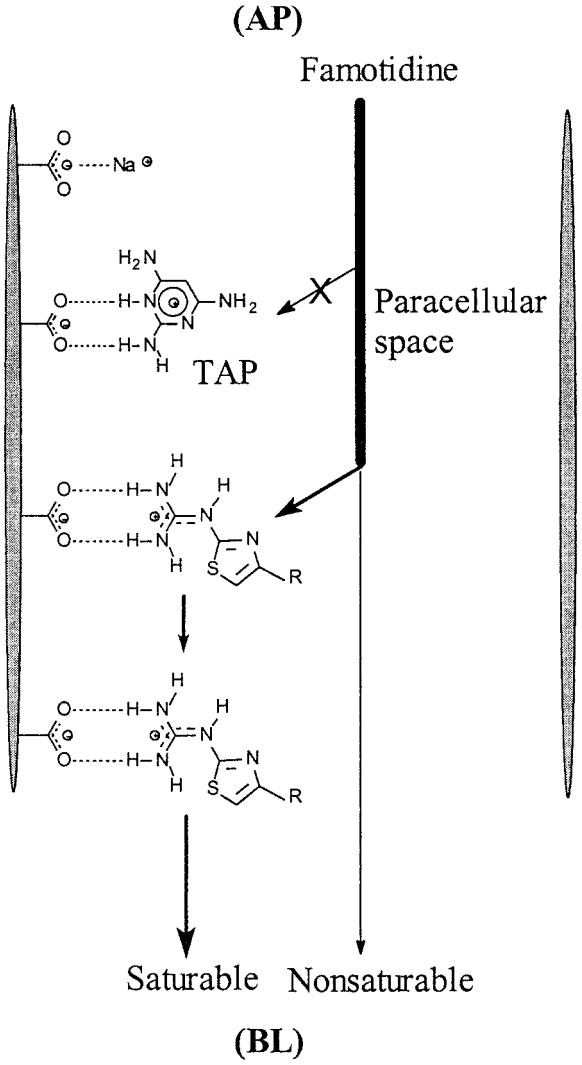

Figure 7—Model for the proposed transport mechanism of H_2-antagonists as exemplified by that for the transport of famotidine. Ionic interaction between Na^+ ions δ and the negatively charged group (as exemplified by carboxylate group here) in the paracellular space mediates cation-selective ion transport.[21] Likewise, the positively charged species of famotidine is transported by facilitated diffusion through interaction with the negatively charged group in the paracellular space (saturable transport). Famotidine can also traverse the paracellular space by simple diffusion (nonsaturable transport). This figure also shows how a cationic compound such as 2,4,6-triaminopyrimidine (TAP) can compete for the anionic site and inhibit the transport of famotidine (or ranitidine).

monolayers in the same way the transport of Na^+ ions is assisted by interactions with the anionic sites. Our results show that this process is not likely to be an active transport process; rather it can be characterized as facilitated diffusion. A population of ranitidine (and famotidine) molecules that do not interact with the anionic sites would traverse the paracellular space by a passive diffusion process (Figure 7). The overall transport of these compounds is thus a sum of the saturable facilitated diffusion process and nonsaturable passive diffusion process. The proposed mechanism is consistent with the observed transport kinetics for ranitidine and famotidine, inhibition of their own transport at high concentration, and inhibition of their transport by cationic compounds such as TAP. The possible involvement of the paracellular anionic sites in the drug transport has been also suggested in some recent reports[26–28] based on the higher paracellular permeability of cationic compounds compared to that of anionic compounds. However, this is the first report in which saturable transport of cationic hydrophilic compounds across epithelial cells has been described that can be explained by a (proposed) molecular mechanism involving their interactions with the anionic sites in the paracellular space. We want to emphasize that other mechanisms can be proposed to explain the observed saturable kinetics for the transport of ranitidine and famotidine across Caco-2 cell monoalyers; however, the mechanism proposed here serves as a good working model to help design further studies[29] that can provide greater insights into the mechanism of intestinal transport for hydrophilic cationic compounds such as ranitidine and famotidine.

The results presented here and the proposed mechanism for transport of ranitidine and famotidine raise an interesting possibility of potential drug interactions and food effects, because the oral absorption of cationic hydrophilic compounds is likely to be affected by coadministered drugs with similar structural characteristics and by hydrophilic cationic peptides generated from hydrolytic digestion of proteins in the diet.[30]

Abstract □ During the lyophilization process, formulations containing protein, bulking agent, or lyoprotectant form a dry product layer that can affect the transport of sublimed water vapor. We carried out an investigation of the primary drying segment of lyophilization to evaluate the relationship between the resistance to water vapor flow through the dried layer and the microstructure of the dried cake. Recombinant humanized antibody HER2 (rhuMAb HER2) formulated in trehalose was studied, as were protein-free formulations containing trehalose and sucrose. Sublimation rate and product temperature data were used to compute the resistance to mass transfer. Dried cake structure was examined by scanning electron microscopy and a novel fluorescence microscopy method. Collapse temperatures were determined by freeze-drying microscopy. Mass transfer resistance was found to decrease with increases in temperature for each material. Resistance also depended on composition, decreasing in the formulation series, rhuMAb HER2, trehalose, sucrose. The lyophilized material consisted of porous cakes, with a distinct denser region at the top. Formulation and temperature affected the microstructure of the dried cakes. The formulated trehalose and sucrose were seen, by both microscopy techniques, to possess small (2–20 μm) holes in their platelike structures after lyophilization. The quantity of holes was higher for material dried at higher temperature. The collapse temperature (T_c) of a material appeared to play a role in the process, as lower T_c was correlated with lower resistance and a greater extent of holes. Our results are consistent with the theory that lower resistance to water vapor flow in the primary drying stage of lyophilization may be due to small-scale product collapse.

Introduction

Lyophilization is commonly used to prepare protein pharmaceuticals in dry form to extend shelf life. Operating cycles may be several days in length and typically involve three process segments: freezing, primary drying, and secondary drying. Freezing transforms the protein−excipient solution in a vial into two or more phases, usually crystalline ice and an amorphous freeze-concentrate containing the protein, lyoprotectant, and water. Additional phases may also form if the excipient precipitates or crystallizes out during freezing. Primary drying is the sublimation of ice from the frozen vial content under vacuum. Secondary drying, also under vacuum, involves the removal of water from the freeze-concentrate, reducing the residual moisture content to a level (e.g. ≤ 3 wt %/wt) suitable for long-term storage.[1]

In the lyophilization of protein pharmaceuticals, the longest process segment is usually the sublimation of ice from frozen vials. The rate of ice removal is a function of the lyophilizer shelf temperature and chamber pressure.[2−6] The product temperature, which is also dependent on the shelf temperature and the pressure, is often 20−30 °C below that of the shelf as a result of the energy consumed by the transformation of ice to water vapor. The product temperature during primary drying is critical, because too high a temperature can result in product meltback or collapse[7] (potentially degradative events), whereas too low a temperature will result in lengthy lyophilization cycles. The product temperature accompanying a given temperature−pressure combination may vary between formulations.

A key parameter governing the relationship between the independent variables (the lyophilizer's shelf temperature and chamber pressure) and the dependent variables (ice sublimation rate and product temperature) is the resistance to water vapor flow exhibited by the growing dry layer. This layer is composed of the freeze-concentrated protein/excipient solid solution and the voids left after the ice crystals have sublimed. Pikal et al. determined the resistance to vapor flow for potassium chloride, povidone, mannitol, and dobutamine hydrochloride−mannitol solutions using a microbalance with capillary tubes and a method involving pressure measurement inside the vial to characterize vial freeze-drying.[7,8] They demonstrated that the resistance increases with increasing thickness of the dried layer, in a nonlinear fashion. They also reported that the resistance decreases with increasing temperature, a phenomenon ascribed to "hydrodynamic surface flow" of the sublimed water through the pores.

Milton et al. later proposed a different mechanism for the observed temperature dependence of resistance to mass transfer, involving product collapse on a microscopic scale.[9] In that study, the investigators determined the resistance to water vapor flow based on the time-dependent chamber pressure increase during brief interruptions of the flow from the chamber to condenser (by closing a valve between the two). For mannitol, lactose, and potassium chloride solutions, they reported that under some conditions, the resistance to vapor flow increased with thickness of the dried layer, as described above. However, at product temperature values near a material's collapse temperature, the resistance was not affected by increases in thickness. This constant-resistance phenomenon was hypothesized to be due to "microcollapse," the development of additional pathways for vapor flow in the form of holes in the dried material, a proposition supported by SEM photomicrographs of freeze-dried lactose.

Further research on the relationship between temperature, pressure, and sublimation rate was described by Chang and Fischer in their study of lyophilization cycle

10.1021/js980445+ CCC: $18.00
Published on Web 06/09/1999

development for rhIL-1ra formulated at 100 mg/mL.[6] In that study, the authors gave a comprehensive description of product temperatures and sublimation rates resulting from 35 different combinations of shelf temperature and chamber pressure. Unlike the reports described above, they observed the resistance to vapor flow to be independent of product temperature, over a wide range of temperatures (−32 to −14 °C).

This report describes our investigation of primary drying in lyophilization of recombinant humanized antibody HER2 (rhuMAb HER2) formulated in a trehalose−histidine−polysorbate system. This lyophilized product has recently received regulatory approval for breast cancer therapy (based on its capacity to inhibit growth of human breast carcinoma cells[10]). rhuMAb HER2 is formulated at high concentration (relative to other Genentech products), and we believe that the results of our investigation will be useful to others in the field. In this study, we measured sublimation rates and product temperatures for formulated rhuMAb HER2, for a range of lyophilization conditions, and determined mass transfer resistances. In addition, protein-free formulations containing either trehalose or sucrose were studied. Sucrose and trehalose have been shown to stabilize proteins in the dried state,[11−14] i.e., function as "lyoprotectants." The structure of materials after drying was examined by scanning electron microscopy and a newly developed fluorescence microscopy method. This study provided a better understanding of the relationship between resistance to vapor flow and small-scale product collapse in protein lyophilization.

Experimental Section

Materials—rhuMAb HER2, molecular mass approximately 160 kD, was produced at Genentech, Inc. by Chinese hamster ovary cells. It is a glycoprotein of 1328 amino acid residues. The bulk was formulated to contain 25 mg/mL rhuMAb HER2, 20 mg/mL trehalose, 0.1 mg/mL polysorbate 20, and 5 mM histidine, pH 6.0. Two excipient formulations also were tested: 45 mg/mL trehalose, 0.1 mg/mL polysorbate 20, and 5 mM histidine, pH 6.0; and 45 mg/mL sucrose, 0.1 mg/mL polysorbate 20, and 5 mM histidine, pH 6.0. Solutions were prepared in distilled water and 0.2-μm filtered. All components used were reagent grade or better.

Sublimation Rate and Product Temperature Measurement in Vial Freeze-Drying—The sublimation of ice in the formulations of interest was evaluated by carrying out primary drying in Leybold−Heraeus GT20 lyophilizers at constant shelf temperature and chamber pressure. Formulations were filled at 5.0 mL in 10-mL Wheaton tubing glass vials (inner diameter 2.37 cm) with 20-mm neck finish. Vials were stoppered for lyophilization using West gray butyl rubber stoppers. Vials were cooled to −50 °C at 20 °C/h and held for 5 h before proceeding with drying. After the chamber was evacuated to the pressure set point, the lyophilizer shelf was warmed to the temperature set point over a 2-h period. Ice sublimation was allowed to proceed, with constant temperature and pressure set points. Such primary drying tests were conducted at various conditions with the shelf temperatures in the range −20 to +25 °C and the chamber pressure at 100 mTorr (regulated with nitrogen gas). Tests also were carried out at −30 and −35 °C under 50 to 75 mTorr and 25 °C under 200 and 300 mTorr.

The temperature of the vial contents was measured by a 30-gauge Type T thermocouple sensor placed vertically through the vial opening, the tip positioned 1−4 mm above the vial base. For each formulation lyophilized in a run, the product temperature stated is the mean of two to four sensors.

At selected time points throughout primary drying, three preweighed vials of each formulation were stoppered in the chamber using a thief arm installed in the dryer. After lyophilization, the stoppered vials were reweighed to determine the water loss. The sublimation rate was determined from the mean water loss determined at four to six timepoints. It has been reported that a vial adjacent to an empty vial or the edge of the shelf shows a sublimation rate increase of 5% or 20%, respectively, relative to a vial in the middle of an array of subliming vials, presumably due to radiation from the shelf and chamber wall.[3] Thus, in this study only those vials adjacent to equivalent filled vials were sampled for temperature or rate determination.

Determination of Mass Transfer Resistance—The resistance to vapor flow through the dried layer in the vial was determined using a method adapted from the work of Pikal et al.[3,8] In our method, the sublimation rate (essentially time-invariant) and the time-dependent product temperature data were used in order to estimate the product temperature (and the corresponding ice vapor pressure) at the ice sublimation front and the overall mass transfer resistance exhibited by the dried product layer. A brief summary of the pertinent equations is given below.

The overall dried product resistance, $\hat{R}_p$, describes the proportionality between the specific sublimation rate, $\dot{m}/A_p$, and the pressure driving force, $P_o - P_v$:

$$\frac{\dot{m}}{A_p} = \frac{1}{\hat{R}_p} \times (P_o - P_v) \tag{1}$$

where $\dot{m}$ is sublimation rate (g/h), A_p is cross-sectional area of product in the vial (cm^2), $\hat{R}_p$ is normalized dried product resistance (cm^2 mTorr h g^{-1}), P_o is equilibrium vapor pressure of ice at the temperature of the subliming ice (mTorr), and P_v is pressure in the vial (assumed equal to chamber pressure P_c) (mTorr).

In our analysis, we assume that the cross-sectional area of product in the vial, A_p, is equal to the internal area of the vial. Recent work suggests that in certain lyophilization cases this may not be true.[15] The investigators provided some evidence that the sublimation front may be nonplanar (concave down) due to faster drying along the vial wall, following cake shrinkage; for further consideration see the Results and Discussion.

In our application of eq 1, we estimate the pressure in the vial to be approximately equal to the chamber pressure. The substitution of P_c for P_v means that the resistance quantity we determine is the sum, $\hat{R}_p + \hat{R}_s$ (where $\hat{R}_s$ is the resistance to vapor flow exhibited by the stopper). Previous investigators, using modified vials for direct measurement of P_v, reported that the contribution of $\hat{R}_s$ (20-mm stoppers) to the sum ($\hat{R}_p + \hat{R}_s$) was less than 4%[3], supporting our approximation.

The temperature dependence of the ice vapor pressure P_o (mTorr) is given by:[16]

$$P_o = 2.7 \times 10^{13} \times \exp[-6145/(T_i + 273.15)] \tag{2}$$

where T_i is the temperature (°C) of the subliming ice interface.

Inserting the vapor pressure expression (eq 2) in the mass transfer equation (eq 1) and substituting P_c for P_v, we obtain:

$$\frac{\dot{m}}{A_p} = \frac{1}{\hat{R}_p} \times (2.7 \times 10^{13} \times \exp[-6145/(T_i + 273.15)] - P_c) \tag{3}$$

During ice sublimation, heat is supplied by the shelf to the bottom of the vial and is consumed at the sublimation front. The temperature gradient in the ice/solute matrix can be estimated by the Fourier heat conduction model and shown to have the axial length dependence described in eq 4:

$$\frac{dT}{dx} = -\frac{\Delta H_s \times \dot{m}}{A_v \times K_I} \tag{4}$$

where x is the axial position relative to bottom of vial (cm), ΔH_s is the heat of sublimation (cal/g), A_v is the cross-sectional area of vial base (cm^2), and K_I is the thermal conductivity of the product (estimated as the area-weighted sum of thermal conductivities of glass (Wheaton) and ice,[17] as described previously[3]).

By integration of eq 4, we obtain an estimation of the temperature at the subliming ice interface in terms of the measured product temperature (eq 5). The interface can be seen to have the lowest temperature in the vial.

$$T_i = T_p - \frac{\Delta H_s \times \dot{m}}{A_v \times K_I} \times (L - l) \tag{5}$$

where T_p is the product temperature (°C) at the temperature sensor, L is the thickness of product, from temperature sensor to initial fill height (cm), and l is the thickness of dried layer (cm), determined from the interpolated weight loss data, with the assumption that the sublimation front is planar, by the formula $l = (\dot{m} \times t + m_0)/(\rho \times A_v)$, where t is the elapsed time, measured from the time at which the shelf temperature reaches the set point, m_0 is the weight loss at $t = 0$, and ρ is the frozen matrix density.

Uncertainty in the sublimation front temperature, as estimated by eq 5, could result from several sources, including the thermal conductivity of the frozen product in the vial, the relative quantities of radial and axial heat flow, the measured product temperature, the vial geometry, and the shape of the subliming interface. In our experiments, the effect of uncertainty in the thermal conductivity of the frozen product in the vial may be low, due to the use of solutions of constant solute concentration (4.6% w/v) for all tests. The effect of radial heat flow was minimized by surrounding all thermocouple and sublimation rate vials with filled, subliming vials.

The act of measuring product temperature may influence the sublimation process: thermocouple vials may nucleate before "normal" vials, resulting in a different microstructure and, possibly, faster sublimation.[18] In our experiments, the potential effect of thermocouples on microstructure would be constant, independent of drying temperature or formulation composition. Uncertainty in the measured product temperature and in the vial geometry were reduced by using replicate measurements (2−4) for each condition.

We obtain our final equation by substituting eq 5 for the interface temperature term in eq 3 and rearranging:

$$\hat{R}_p = \frac{A_p}{\dot{m}} \times \left(2.7 \times 10^{13} \times \exp\left[\frac{-6145}{T_p - \frac{\Delta H_s \times \dot{m}}{A_v \times K_I} \times (L - l) + 273.15} \right] - P_c \right) \quad (6)$$

Equation 6 allows us to estimate the resistance to mass transfer as a function of the dried layer thickness using the measurable quantities sublimation rate, product temperature, and vial dimensions.

Examination of Dried Cake Structure—The microscopic structure of lyophilized material was evaluated by two methods, scanning electron microscopy (SEM) and a novel fluorescence microscopy technique. Samples to be analyzed were prepared by lyophilization using one of two primary drying conditions, 10 °C, 100 mTorr for 30 h or −30 °C, 70 mTorr for 90 h. Following an increase (at 5 °C/h) in the shelf temperature, secondary drying was conducted at 20 °C, with the pressure unchanged, for 8 h. Vials were stoppered under 720 Torr ± 40 Torr nitrogen and then transferred to a desiccator for further drying. Desiccation over phosphorus pentoxide was initiated at <25 Torr pressure and carried out at 20−25 °C for 7−14 d. Samples for SEM were prepared in a nitrogen-purged glovebox under low (<10%) relative humidity by removing the dried cakes from the vials, sectioning vertically by hand using a single-edge razor blade, mounting to a sample stub, and coating under vacuum with a 10 nm gold−palladium layer. Images were obtained by SEM (Philips model 525M; acceleration 5 kV).

Dried cake structure was also evaluated using a second technique, the fluorescence microscopy of rhodamine-containing "cakes" embedded in wax. To selected vials, rhodamine B aqueous solution (20 μL at 0.5 mg/mL) was added before lyophilization. Solutions were lyophilized and desiccated as described in the previous paragraph. These cakes were then placed under vacuum and heated to 60 °C in the presence of low melting paraffin (The Hygenic Corp., Akron, OH) in which Sudan Black B was dissolved. The melted paraffin was allowed to fill the vial until the entire cake was covered by several millimeters. The vacuum was released, and the vials were cooled to room temperature. The vials were broken carefully and the intact paraffin plugs removed. The paraffin plugs containing the lyophilized cakes were sliced vertically as described above. Images of sections were acquired with a Nikon Optiphot-2 microscope using the filter cube for rhodamine (excitation 510−560 nm, emission > 610 nm). Thermal analysis of the dried material was carried out by differential scanning calorimetry (DSC; Seiko model 120 with model SSC/5200H data station). Samples of approximately 12−20 mg were sealed in Al containers, equilibrated to room temperature, and warmed at 5 °C min^{-1} to 200 °C.

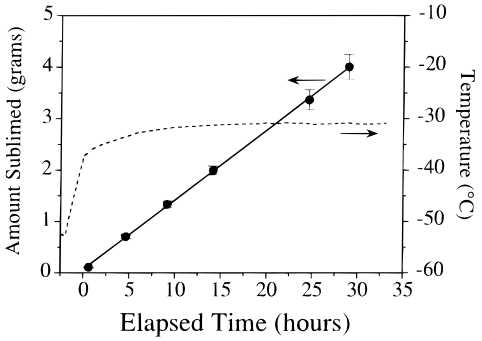

Figure 1—Weight loss (●) and product temperature (- - -) measurements during primary drying of rhuMAb HER2 formulation at –20 °C shelf temperature; 100 mTorr chamber pressure. Note the linearity of the weight loss data.

Collapse Temperature Assessment Using Freeze-Drying Microscope—The presence or absence of collapse during freeze-drying of the rhuMAb HER2, trehalose, and sucrose formulations at various temperatures was investigated using a freeze-drying microscope. This technique was reported by MacKenzie to be useful in identifying structural changes occurring during ice sublimation.[19] In the present study we used a microscope system that includes a compact freeze-drying chamber and a thermoelectric heat pump for cooling. Details of the system were reported previously.[20] The sample to be investigated is held between two glass cover slips on the cooling stage, cooled to approximately −45 °C, and lyophilized as desired.

In our tests, sample freezing was executed in a manner described below to form larger ice crystals for ease of viewing and for faster ice sublimation. A sample aliquot, approximately 4 μL, was cooled to −1.5 °C and held for 1 min to allow for temperature equilibration. The chamber cover was briefly removed, and a dry ice pellet was held against the top glass cover slip for about 5 s to nucleate ice crystals in the sample (at a location away from the microscope viewing area). The sample was held at −1.5 °C for about 2 min and then at −3.5 °C before cooling at 10 °C/min to −45 °C. After a 15-min hold, the chamber was evacuated to approximately 100 mTorr and the stage temperature was increased at 5 °C/min and held at the temperature of interest. It has been shown that the stage temperature and sample temperature are equivalent in this system.[20] The temperature was increased stepwise from −40 °C to −15 °C, in 2−5 °C steps, for each formulation. At the location of the sublimation front, the degree to which the structure of the glassy matrix was retained was evaluated visually. Collapse temperature of the frozen sample was identified as the stage temperature at which the structure was observed to distort or flow. The identification of a collapse temperature is an estimate, since collapse (unlike melting) does not occur at a sharply defined temperature.

Thermal analysis of the frozen aqueous material was carried out using the DSC described above, fitted with a cooling head (mod. CA-5) for controlled cooling by liquid nitrogen. Samples of approximately 15 mg were sealed in Al containers, equilibrated to 5 °C, and cooled at 5 °C min^{-1} to −90 °C. Following equilibration, the sample was warmed at 5 °C min^{-1} to 20 °C.

Results and Discussion

Sublimation Rate and Product Temperature in Vial Freeze-Drying—At a given lyophilizer shelf temperature and pressure, the amount of ice sublimed from vials was approximately linear with respect to time; see Figure 1, depicting rhuMAb HER2 subliming on a −20 °C shelf. Table 1 shows that the sublimation rate was found to increase with higher temperature and pressure set points, as expected. This trend is similar to that reported by

Table 1—Sublimation Rate and Product Temperature for rhuMAb HER2, Trehalose, and Sucrose Formulations (see text) as Functions of Lyophilizer Shelf Temperature and Chamber Pressure

shelf temp (°C)	pressure (mTorr)	specific sublimation rate(g h^{-1} cm^{-2})			product temperature (°C)		
		rhuMAb HER2	trehalose	sucrose	rhuMAb HER2	trehalose	sucrose
25	300	0.19			–20		
25	200	0.16	0.15		–21	–28	
25	100	0.11	0.13		–26	–30	
10	100	0.084	0.083	0.098	–26	–30	–34
–20	100	0.031	0.031	0.035	–31	–36	–37
–30	70			0.019			–37
–30	50	0.014	0.015		–37	–37	
–35	75		0.011	0.012		–37	–37

others.[2–6] The data also indicate that under the same shelf temperature and chamber pressure conditions, sublimation rates for all formulations were approximately equal, except for two conditions at which sucrose rates were slightly higher. The rates reported in Table 1 have coefficients of variation (defined as the standard error divided by the mean) of 1.2 to 3.4%.

During each run, the product temperature was observed to increase as the shelf temperature was ramped from −50 °C to the primary drying shelf temperature set point, then level off (Figure 1). The product temperature was sensitive to shelf temperature, chamber pressure, and formulation (Table 1; data correspond to the middle portion of the sublimation process, at which time the product temperature was approximately constant). The product temperatures during primary drying followed the formulation series, rhuMAb HER2 > trehalose > sucrose, at most process conditions. It might be expected that product temperature and sublimation rate are connected, yet under some process conditions we observed differences in product temperatures between formulations, even though the sublimation rates were approximately equivalent. This situation may be due to differences between formulations in resistance to vapor flow, as is discussed below.

Determination of Mass Transfer Resistance—The measured resistance to mass transfer was seen to increase with increased dry layer thickness (Figure 2; rhuMAb HER2, −20 °C temperature), as expected. The thickness dependence gave a good fit to the nonlinear model proposed by Pikal et al.[8] and shown in eq 7:

$$\hat{R}_p = \frac{A_0 + A_1 l}{1 + A_2 l} \qquad (7)$$

where A_0, A_1, A_2 are constants determined from fitting of data. Figure 2 also illustrates the increase in resistance to vapor flow per unit thickness ($d\hat{R}_p/dl$). As reported previously,[8] the derivative function was high at low values of dried layer thickness and low at higher thicknesses, suggesting that a denser layer was present at the top of the vial.

Figure 3 shows the resistance to mass transfer determined for ice sublimation in the rhuMAb HER2 formulation at several temperature and pressure set points. The mass transfer resistance was sensitive to the shelf temperature, with higher resistance values shown by material processed at lower temperatures. This functionality was reported previously,[8,9] as described above.

Mass transfer resistance was also determined for formulated trehalose (Figure 4) and sucrose (Figure 5). These materials showed similar effects of thickness and shelf temperature on resistance as those seen with rhuMAb HER2. However, the resistance to mass transfer was lower, under most conditions, for trehalose than for rhuMAb HER2, and the resistance for the sucrose-containing material was lower still. Only at lower shelf temperatures (−30 and −35 °C) did the three materials appear equivalent.

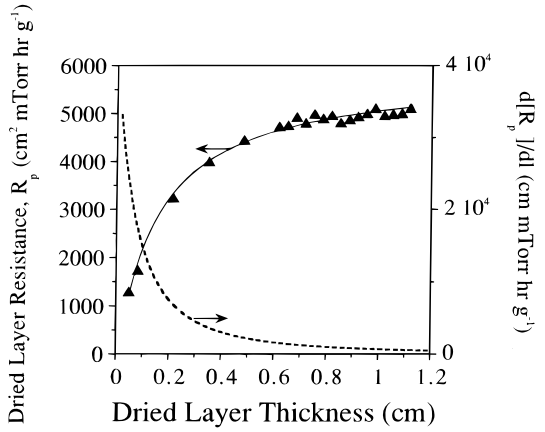

Figure 2—Resistance to mass transfer, $\hat{R}_p$, as a function of dried layer thickness for rhuMAb HER2 at –20 °C, 100 mTorr (▲). The equation for the $\hat{R}_p$ curve fit (solid line) is described in the text (eq 7). Also shown is the derivative (dotted line) of the curve fit, representing the increase in resistance as a function of the increase in dried layer thickness. The derivative curve shows that the upper layer of the dried cake contributes more to the resistance than does the lower portion, suggesting a nonuniformity in the dried layer with respect to vertical position.

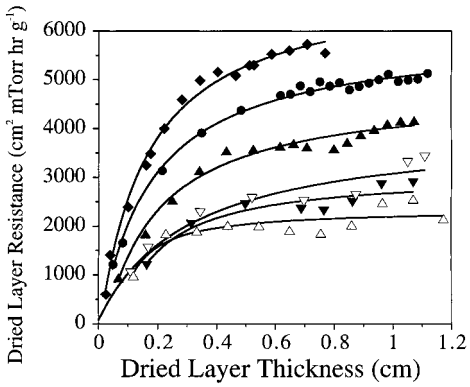

Figure 3—Resistance to mass transfer as a function of dried layer thickness for rhuMAb HER2 at a variety of processing conditions (pressure = 100 mTorr unless noted): –30 °C/50 mTorr (◆), –20 °C (●), 10 °C (▲), 25 °C (▼), 25 °C/200 mTorr (▽), 25 °C/300 mTorr (△). Higher temperature and pressure were observed to result in lower resistance.

The relationships between vapor transfer resistance and temperature at the ice−dry layer interface, determined at the dry layer thickness $l = 0.8$ cm, are summarized for the three formulations in Figure 6. These measurements yield "snapshots" of the ice sublimation processes at points at which approximately 70% of the material had sublimed, enabling the examination of mass transfer resistance as functions of formulation and temperature. The resistance followed the series rhuMAb HER2 > trehalose > sucrose,

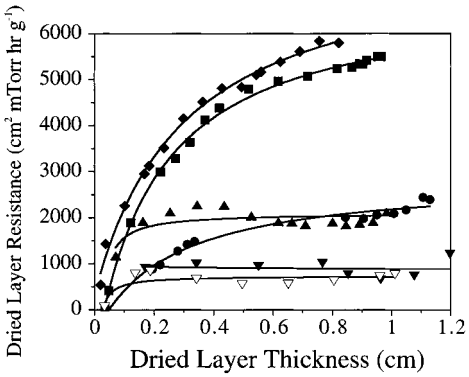

Figure 4—Resistance to mass transfer as a function of dried layer thickness for formulated trehalose at a variety of processing conditions (pressure = 100 mTorr unless noted): –35 °C/75 mTorr (■), –30 °C/50 mTorr (◆), –20 °C (●), 10 °C (▲), 25 °C (▼), 25 °C/200 mTorr (▽). Resistance generally decreased with increased temperature and pressure and was lower at most conditions than that observed for formulated rhuMAb HER2 (Figure 3).

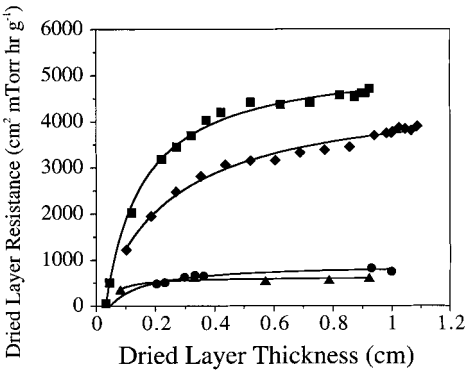

Figure 5—Resistance to mass transfer as a function of dried layer thickness for formulated sucrose at a variety of processing conditions (pressure = 100 mTorr unless noted): –35 °C, 75 mTorr (■), –30 °C, 70 mTorr (◆), –20 °C (●), 10 °C (▲). Resistance decreased with increased temperature and pressure and was lower than that observed for the rhuMAb HER2 (Figure 3) and trehalose (Figure 4) formulations.

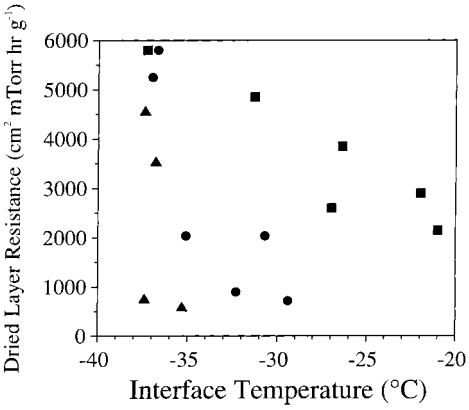

Figure 6—Mass transfer resistance for formulated rhuMAb HER2 (■), trehalose (●), and sucrose (▲) vs interface temperature. Data shown represent values at a dried layer thickness of 0.8 cm. Resistance followed the series rhuMAb HER2 > trehalose > sucrose and decreased with increased interface temperature.

except at interface temperatures below −36 °C, for which the resistances were approximately equal. Figure 6 also illustrates the decrease in resistance with increased temperature. The temperature sensitivity of resistance was highest for sucrose and lowest for rhuMAb HER2.

It is interesting to note that, even under operation conditions which showed large differences between formulations in mass transfer resistance (e.g., 45−80%), the differences in sublimation rate were moderate (8−17%). Limitations in the transfer of heat from the lyophilizer shelf to the vial may be responsible for this phenomenon, although its study was beyond the scope of this work.

As described above, some investigators have hypothesized that when cake shrinkage occurs in lyophilization, the sublimation front may be nonplanar (the magnitude of deviation from a planar sublimation front is not described).[15] In our study, slight shrinkage was observed, so the mass transfer resistance values we determined may be affected by the hypothesized nonplanar nature of the subliming interface. One might expect that the impact of a nonplanar interface would be minimized by the study of relatively thin, flat sections of material. In our study, we monitored the sublimation of 0.8 to 1.0 cm material (average thickness) in vials of diameter 2.4 cm. The effect of nonplanarity, therefore, may have been small. The formulations evaluated in this study exhibited similar cake shrinkage during lyophilization, so the shape of the subliming interface (if not planar) may have been independent of the formulation and drying conditions which we compared.

Overall, uncertainty in the mass transfer resistance results from variability in the measured parameters. In our study, the highest observed uncertainty in sublimation rate (C.V.) was 3.4%; the variation between replicate product temperature values (standard deviation) was 0.1 to 0.8 °C. Analysis of eq 6 shows that "worst-case" errors in rate and temperature have the following effects: An error of ±10% in the sublimation rate gives rise to a variation in mass transfer resistance of ±10%; uncertainty in product temperature of 1 °C induces a variation in resistance of ±20%. These errors in the calculated resistance, while not insignificant, are less than the magnitude of differences between temperatures and formulations shown.

Examination of Dried Cake Structure—The dried material produced by the two lyophilization cycles tested formed white, porous cakes showing slight shrinkage; no large-scale collapse was observed. The morphology of lyophilized material was observed using two techniques, fluorescence microscopy of wax embedded cakes and SEM. The fluorescence images revealed the dried material to have a microporous structure, with a distinct denser layer at the top of the cake (Figure 7A; rhuMAb HER2 dried with a 10 °C primary drying shelf temperature). Examination of this layer at higher magnification (not shown) revealed the layer to have fewer, smaller channels relative to the rest of the dried cake. The layer may contribute to the high $d\hat{R}_p/dl$ corresponding to low dry layer thicknesses, as described above.

At a smaller scale, SEM showed that lyophilization of formulated rhuMAb HER2 using a 10 °C primary drying shelf temperature produced a smooth, platelike structure built around the pores left by the sublimed ice (Figure 7B). The fluorescence microscopy method also illustrated a structure composed of smooth plates and channels (Figure 7C). Formulated rhuMAb HER2 prepared by a −30 °C primary drying shelf temperature was seen, by both methods, to have a similar appearance (not shown).

Lyophilization of formulated trehalose gave a structure which, like rhuMAb HER2, was composed of plates but also contained holes approximately 2−8 μm in diameter. These holes are illustrated by SEM for the 10 °C (Figure 8A) and −30 °C (Figure 8B) primary drying conditions, with lower temperature giving smaller and fewer holes. Holes were also detected by the fluorescence microscopy technique (Figure 8C; 10 °C). As with SEM, fluorescence microscopy detected fewer holes for the −30 °C process (not shown) than for the 10 °C version. Holes of this size range were also reported by others in the lyophilization of lactose.[9]

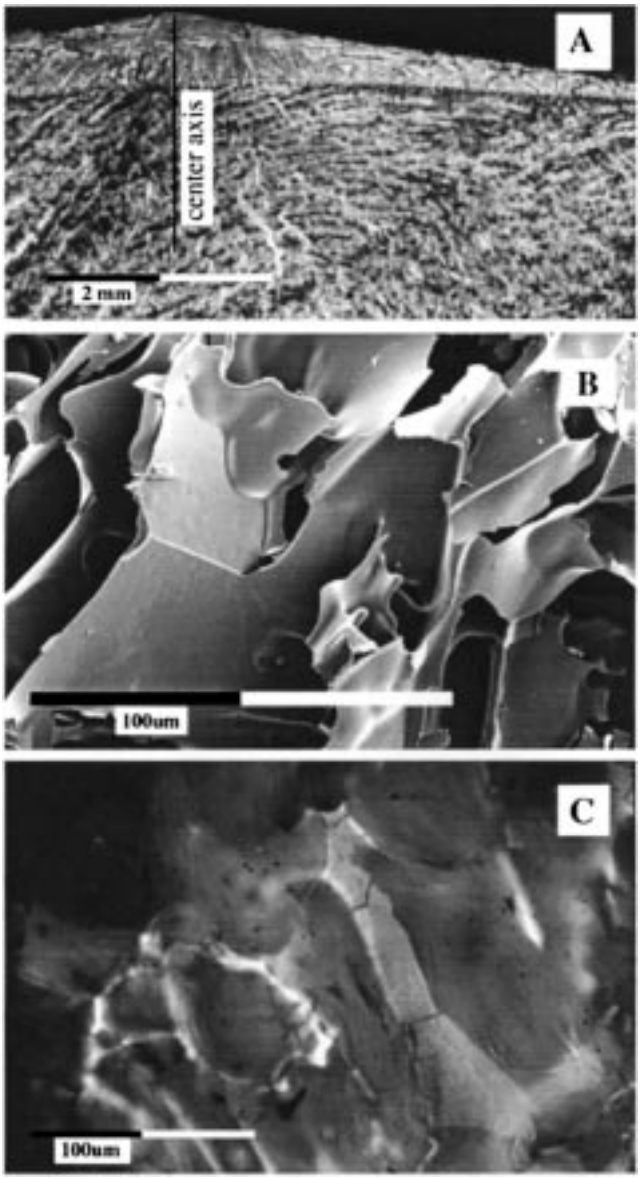

Figure 7—Structure of lyophilized rhuMAb HER2 formulation (10 °C primary drying shelf temperature). (A) Note the denser layer present at the top. The denser layer may be responsible for the higher resistance per unit thickness corresponding to low dried layer thicknesses (Figures 2–5). Fluorescence microscopy, 8X magnification. (B) Note the smooth, plate-like features, separated by open pores. SEM, 270X magnification. (C) Note the smooth structure. Fluorescence microscopy, 150X magnification.

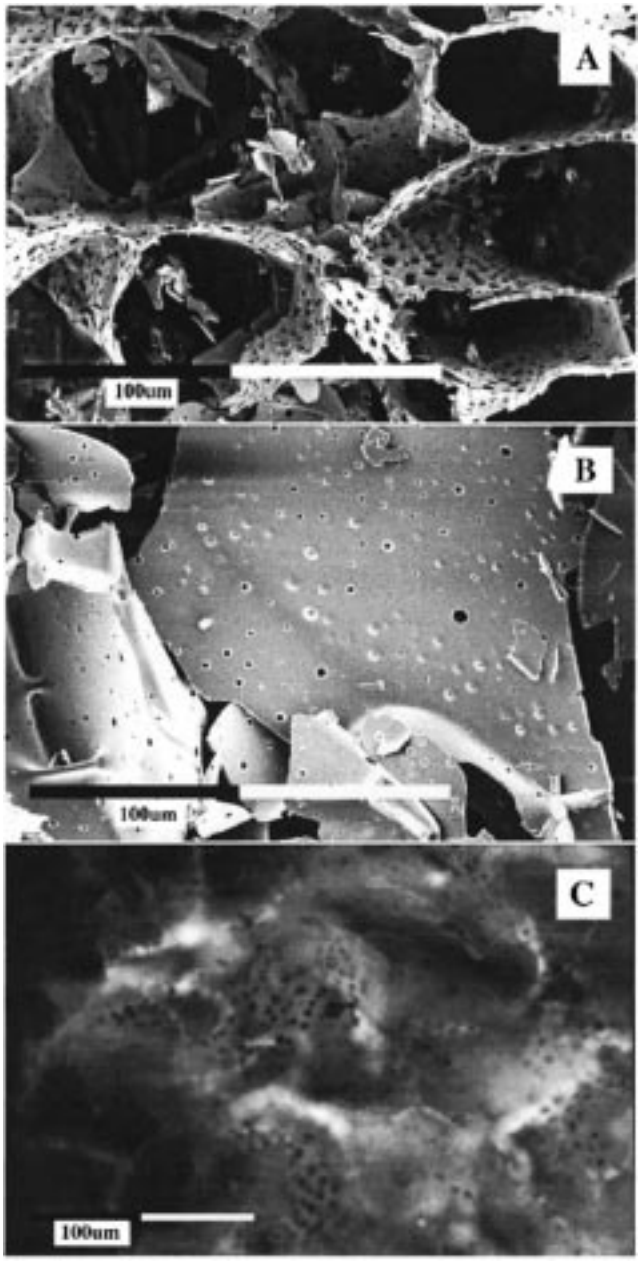

Figure 8—Structure of lyophilized trehalose formulation. Note the appearance of small holes (diameter ~2–8 μm) in the "plates." (A) 10 °C shelf: The large pores (diameter ~100 μm) are thought to be established when the ice crystals grew into the freeze-concentrate. SEM, 270X magnification. (B) –30 °C shelf: The holes are smaller and fewer than those observed in formulated trehalose prepared at the 10 °C shelf temperature. SEM, 270X magnification. (C) 10 °C shelf: Fluorescence microscopy, 150X magnification.

Interestingly, Figure 8A illustrates the pores, approximately 100 μm in diameter, formed by the ice crystals and providing the main avenue for vapor flow through the dried product layer.

The sucrose formulation was seen by SEM to possess holes in the dried structure, both for the 10 °C (Figure 9) and −30 °C process conditions. In addition, the sucrose structures were more "rounded" than the other formulations, with an appearance (Figure 9) suggesting viscous flow of the freeze-concentrate. As with the trehalose formulation, the lower temperature process gave fewer, smaller holes (not shown). Fluorescence microscopy also detected holes in the lyophilized sucrose from both the 10 °C and −30 °C processes (not shown).

The images acquired using the two microscopy techniques indicate that the structure of dried material is sensitive to composition and to the drying process used. Microscopy indicates that the formulated rhuMAb HER2 dries into intact plates, whereas the trehalose and sucrose formulations develop holes in the structure. These holes are more prevalent in material dried by the higher primary drying shelf temperature, so it is likely that they are produced during primary drying. The extent of holes observed in the structure of dried material, increasing with temperature and also in the formulation sequence rhuMAb HER2−trehalose−sucrose, is correlated with lower mass transfer resistance. This agreement suggests that the holes can be an important contributor to the conductance of water vapor through the dried layer. The gradual decrease in mass transfer resistance as a function of temperature seen for rhuMAb HER2 (in the absence of observed holes) suggests that other factors may also play a role.

DSC analysis of the material prepared for microscopic evaluation showed glass transition temperatures (T_g) of 76

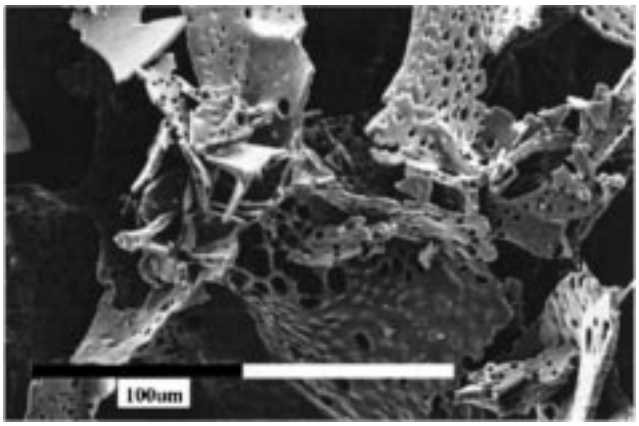

Figure 9—Structure of lyophilized sucrose formulation (10 °C shelf). Note the appearance of small holes (diameter 2–20 μm) in the "plates." Larger holes and smoothed structure suggests increased material flow over that seen in the rhuMAb HER2 and trehalose formulations. SEM, 270X magnification.

Table 2—Transition Temperatures for Frozen Aqueous Formulations Determined by Freeze-Drying Microscopy and DSC

	freeze-drying microscope		DSC: phase transition temp (°C)
formulation[a]	collapse temp (°C)	comment	
rhuMAb HER2	–20	"liquid" phase very viscous	–22
trehalose	–34		–38, –30
sucrose	–40	"liquid" phase flows readily	–43, –33

[a] The composition of each formulation is described in the text.

°C for the sucrose formulation and over 110 °C for the rhuMAb HER2 and trehalose formulations (data not shown). The high T_g values suggest that the materials were thermally stable at the conditions used in the sample preparation and microscopic analysis. In addition, similar structural characteristics were observed by the two methods of microscopy, suggesting that the structures observed were not induced by the evaluation methods. Although the resolution of the fluorescence microscopy technique is lower than that of SEM, it is sufficient to show the presence or absence of holes in the cake structure. In addition, the wax embedment involved in the fluorescence microscopy technique may be useful in protecting samples from atmospheric moisture. This method is under investigation in other freeze-drying studies.

Collapse Temperature Assessment Using Freeze-Drying Microscope—The frozen sample, as observed in the freeze-drying microscope, was composed of branched ice crystals separated by thinner freeze-concentrate regions. Ice crystal growth during cooling was generally from the nucleation site at the center of the stage toward the edges of the sample. Upon evacuation of the chamber, ice sublimation was observed to take place from the edge toward the center of the sample. For each formulation, the structure of the freeze-concentrate was retained at the ice sublimation front at lower stage temperatures but was lost at higher temperatures, as the freeze-concentrated material achieved greater mobility.

The approximate collapse temperature (T_c) and phase transition temperatures (obtained by DSC) for formulated rhuMAb HER2, trehalose, and sucrose are given in Table 2. The formulated rhuMAb HER2 gave the highest T_c, while the sucrose formulation gave the lowest T_c. In our tests, a solution of neat sucrose gave a collapse temperature of −31 to −32 °C, which matches the value reported previously by MacKenzie, −32 °C.[19] For the two protein-free formulations, DSC showed two transitions, possibly corresponding to the glass transition and collapse phenomena. The DSC phase transition temperatures are similar to the T_c data and show the same formulation dependence; we emphasize the T_c results because of their connection to ice sublimation.

For the formulations tested, lower T_c was correlated with lower mass transfer resistance (Figure 6). The data in Table 2 and Figure 6 also suggest that there may be a relationship, for each formulation, between T_c and the temperature dependence of resistance.

The mass transfer resistance data, structure observed by the two microscopy techniques, and collapse temperature results provide a consistent description of ice sublimation and water vapor transport through the dried layer. Increased product temperature during primary drying resulted in lower resistance to vapor flow and, in some cases, the formation of the holes in the dried cake. Between formulations, lower collapse temperature was correlated with lower resistance and more holes. These observations support the theory, set forth by Milton et al. and supported with data for lactose lyophilization,[9] that the alteration in material structure accompanying small-scale collapse results in decreased resistance to water vapor flow in primary drying.

Conclusions

The resistance to water vapor flow through the dried cake layer, as determined from ice sublimation rate and product temperature data, was observed to decrease with increases in temperature. Resistance was also found to depend on formulation, with values following the series: rhuMAb HER2 > trehalose > sucrose. At many process conditions, different formulations were observed to have similar sublimation rates but differing product temperatures. Mass transfer resistance variation between formulations appears to account for these differences. The structure of the dried cake was evaluated by SEM as well as with a newly developed fluorescence microscopy technique. The presence of a dense layer at the top of the dried cake, which may be responsible for the higher resistance determined for this region, was observed. Temperature and formulation affected the microstructure of the cakes. Some of the formulations tested were found to possess small (2−20 μm) holes in their structure after lyophilization. The extent of the holes was observed to increase with the processing temperature, as well as in the formulation series, rhuMAb HER2−trehalose−sucrose. The collapse temperature (T_c), determined by freeze-drying microscopy, was found to decrease over the same formulation series. For the materials studied, lower resistance was correlated with a greater extent of holes and lower T_c. The data obtained in this study support the view that lower resistance to water vapor flow in the primary drying stage of lyophilization may be the result of small-scale product collapse.

Received November 6, 1998. Accepted for publication April 16, 1999.

Abstract □ A drug–excipient compatibility screening model was developed by which potential stability problems due to interactions of drug substances with excipients in solid dosage forms can be predicted. The model involved storing drug–excipient blends with 20% added water in closed glass vials at 50 °C and analyzing them after 1 and 3 weeks for chemical and physical stability. The total weight of drug–excipient blend in a vial was usually kept at about 200 mg. The amount of drug substance in a blend was determined on the basis of the expected drug-to-excipient ratio in the final formulation. Potential roles of several key factors, such as the chemical nature of the excipient, drug-to-excipient ratio, moisture, microenvironmental pH of the drug–excipient mixture, temperature, and light, on dosage form stability could be identified by using the model. Certain physical changes, such as polymorphic conversion or change from crystalline to amorphous form, that could occur in drug–excipient mixtures were also studied. Selection of dosage form composition by using this model at the outset of a drug development program would lead to reduction of "surprise" problems during long-term stability testing of drug products.

Introduction

Excipients are integral components of almost all pharmaceutical dosage forms. What emerges from a drug discovery program is only a new chemical entity or drug substance. It becomes a drug product after formulation and processing with excipients. However, the general principles of selecting suitable excipients for dosage forms are not well-defined, and excipients are often selected without systematic drug−excipient compatibility testing.

Acceleration of drug development and optimization of dosage form stability are two major goals of any drug development program. Identification of dosage form composition at the outset of a drug developmental program, especially during the design of Phase I clinical formulations, based on thorough drug−excipient compatibility testing is a key step in accelerating drug development. This is because subsequent changes in formulation during Phases II and III as a result of unexpected stability problems usually lead to increases in time and cost of drug development. In addition, the stability of a formulation can be maximized and "surprise" problems during its formal stability testing for regulatory submissions can be minimized through drug−excipient compatibility testing.

Despite the importance of drug−excipient compatibility testing, no generally accepted method is available for this purpose. Most of the methods reported in the literature have poor predictive values.[1] They are labor-intensive and time-consuming, and the number of variables studied are limited. As a result of frustration over this situation, Monkhouse and Maderich[1,2] suggested that one should do away with drug−excipient compatibility testing and, instead, select excipients on the basis of physical and chemical characteristics of drug substances and literature data on excipients. They recommended that the final composition should be selected on the basis of accelerated stability testing of one or more target formulations at high temperature and high humidity. This latter approach may, however, have the disadvantage that it could prolong the time necessary for selecting dosage form compositions. Development of various target formulations for the purpose of screening different drug−excipient combinations is time-consuming and may require larger quantities of bulk drug substances than are generally available early in drug development. Additionally, meaningful differences in stability of different target formulations of a particular drug stored at high temperature and humidity (for example, 40 °C/75% RH) may not be observed within a short period of time, unless the compound degrades very rapidly in these formulations. Therefore, a rapid method for selection of excipients for dosage form design is essential for a practical drug−excipient compatibility screening method.

In this paper, we report a method that was used successfully to identify relative influences of different excipients on drug stability. The primary objective of developing this method was to identify in a short period of time excipients that would have low potential for adverse effects on chemical and physical stability of drug substances.

Materials and Methods

Materials—All drug substances used in this study were synthesized by Bristol-Myers Squibb, and their chemical structures are given in Table 1. The excipients, procured from commercial sources, were released by Bristol-Myers Squibb for use in drug manufacturing.

Preparation of Samples—The basic model used in the present study consists of multicomponent blends of drug substances with excipients, which were mixed with 20% added water and stored in closed vials at 50 °C for specific periods of time. Samples were analyzed for chemical and physical (appearance, color, etc.) stability after 1 and 3 weeks of storage.

Only a general method of preparation of samples is described here, because it evolved over the long time during which the studies reported in this paper were conducted. Accurately weighed amounts of drug substances were placed in 4-mL glass vials, each vial was labeled with the amount of drug to determine mass balance during chemical analysis, and weighed amounts of excipients were then added to the vials. The total weight of drug−excipient blend in a vial was usually kept at about 200 mg. The

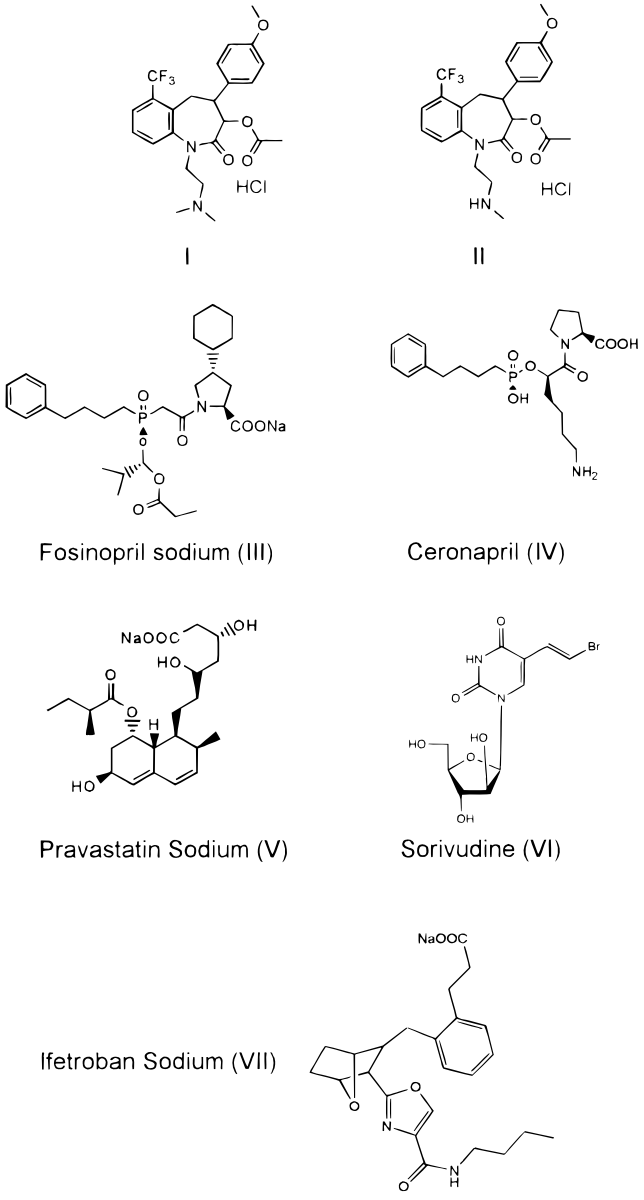
Table 1—Names and Chemical Structures of Drugs Used



amount of drug substance in a blend was determined on the basis of the expected drug-to-excipient ratio in the final formulation. The highest expected drug-to-excipient ratio was usually used. Both the highest and the lowest drug-to-excipient ratios were occasionally used to bracket drug concentrations in a formulation. The amount of the drug–excipient blend per vial sometimes differed as a result of practical reasons; a smaller amount was used when the drug supply was limited. The powder in each vial was mixed with the tip of a disposable Pasteur pipet or a thin glass rod and 20% water (40 μL per 200 mg blend) was then added using a microsyringe. The blend was further mixed, and to prevent any loss of material, the tip of the stirrer (Pasteur pipet) was usually broken and left inside the vial. Each vial was sealed tightly using a Teflon-lined screw cap.

The total number of drug–excipient blends for each study may be selected by statistical design. However, because it might be necessary to screen many diluents, lubricants, binders, disintegrants, coloring agents, coating agents, and so forth for a particular formulation, the number of blends selected this way becomes very high. To limit the number of samples, the drug–excipient compatibility testing may be conducted in two phases. In the first phase, the compatibility of drug with diluents and lubricants is tested, and on the basis of the results, one primary diluent and one primary lubricant are selected. Table 2 provides the design of such a study for one of the compounds (**I**) tested in the present investigation. Using one drug–diluent–lubricant mixture selected in the first phase, the compatibility of other excipients, such as binders and disintegrants, may then be tested in the second phase. Because capsule formulations, which do not require coating agents and coloring agents, are generally used during initial clinical studies, compatibility testing of such agents may be conducted later with the drug–excipient blend used in capsules.

Storage and Analysis of Samples—Closed vials containing drug–excipient blends with added water were stored in ovens at 50 °C. In some cases, samples were also stored as unwetted powders in closed vials at 50 °C or in open vials at 50 °C/75% RH for comparison with those stored in closed vials with added water. Drug–excipient blends without added water stored in a refrigerator or at room temperature served as controls for samples stored at 50 °C with added water or at 50 °C/75% RH. When the drug was photodegradable, clear glass vials containing certain drug–excipient–water mixtures, especially those with coloring agents, were also exposed to light (room light or high-intensity fluorescent light). In this case, identical vials wrapped in aluminum foil and stored side by side with exposed vials served as controls for light stability.

Duplicate samples of drug–excipient blends were analyzed after 1 and 3 weeks by using HPLC methods. Because the drug–excipient compatibility testing was conducted at an early drug developmental stage when fully validated HPLC methods were generally not available, it was not uncommon to use more than one isocratic HPLC method or a gradient HPLC method to distinguish as many degradation products as possible. The HPLC conditions used are recorded under tables and figures in the Results and Discussions section. Whenever feasible, the degradation products were identified by mass spectral, NMR, and other relevant analytical techniques.

To investigate physical changes in drug substances, for example, polymorphic transition or formation of an amorphous phase due to dissolution of the drug in granulating fluids and subsequent drying, drug–excipient–water mixtures stored in closed vials at 50 °C for a suitable period of time were dried overnight at 40 °C and then analyzed by powder X-ray diffraction, solid-state NMR, FTIR, and other appropriate methods. The techniques were described earlier.[3] To maximize the detection of possible physical changes in drug substances during analyses by these techniques, drug concentrations in the mixtures were usually kept at 25% or higher. It was also advantageous to limit the excipient to one that would have the least interference with the analysis of drug substances. Identical blends stored refrigerated or at room temperature without the addition of water served as controls.

Estimation of Microenvironmental pH—The microenvironmental pH of a drug–excipient blend was estimated by adding 1 mL of water to 200 mg of blend in a vial, mixing the suspension with a vortex mixer, and then recording the pH with a pH meter. It was necessary that the solid remained in equilibrium with the liquid phase; variation in pH was observed if filtered solutions were used.

Results and Discussion

Model—Some factors which may have critical influences on the stability of drug substances in the presence of excipients are the chemical nature of the excipient, drug-to-excipient ratio, moisture, microenvironmental pH of the drug–excipient mixture, temperature, and light. The model allowed identification of the potential roles of all of these factors on dosage form stability. Additionally, certain physical changes, for example, polymorphic conversion and the change from crystalline to amorphous form due to dissolution of drug by the sorption of water or during wet granulation and subsequent drying, that could occur in drug–excipient mixtures were also studied.

One important feature of the model is the incorporation of water in the drug–excipient mixture. Although purely solid-state degradation of drug substances is feasible, such instances are rare, and most drug degradation reactions in solid dosage forms involve moisture.[4,5] The presence of moisture is, therefore, essential in establishing the compat-

ibility of drugs with excipients. Although the moisture may be incorporated in the system by exposing samples to high humidity, it has been our experience that the drug–excipient interaction at high humidity conditions always depends on the amount of free moisture present and on relative hygroscopicities of drug substances and/or excipients. Variability in degradation of drugs as a result of differences in the hygroscopicity of excipients has been reported in the literature.[6] Addition of a predetermined amount of water removes this unpredictability from the system. It facilitates intimate mixing of drug substances with excipients and establishes around undissolved drug particles aqueous layers saturated with drugs, excipients, and any impurities that may be present in the system. Such saturation layers also provide a microenvironmental pH to the system. The use of 20% water ensured that a sufficient amount of water would still remain in contact with the drug–excipient blend after evaporation of a certain fraction of added water to saturate the headspace inside the 4-cc vial. The model also works efficiently with lower or higher than 20% water; addition of water ranging from 5% to 20% was reported in the literature.[7–9]

Another important aspect of the model is that the dissolution of drugs and excipients in the added water facilitates the formation of their disordered or amorphous phases. Zografi and co-workers[10] demonstrated that water absorbed in such amorphous phases accelerates drug degradation. Any possible drug–excipient interaction would therefore be facilitated in the amorphous phase as a result of the presence of water and the intimate mixing of drug with excipients. However, it might be argued that the amount of water used in the protocol (20%) might be in excess of what is required to change the glass transition temperature of an amorphous phase and may indeed dissolve the drug in an aqueous solution, thereby increasing its degradation rate. Although this is a possibility for highly water-soluble drugs, most drugs are relatively water-insoluble and amounts dissolved in the added water are usually very small. Also, in the presence of certain excipients, such as cellulose- and starch-derived excipients[11] and poly(vinylpyrrolidone),[12] a large part of the water may be tightly or partially bound with excipients and thus unavailable to dissolve the drug. Even for highly water-soluble drugs, the model is capable of determining relative influences of different excipients of a particular class on the drug degradation. It has been our experience that the absence of a drug–excipient interaction in the present model leads to drug products with long shelf lives. However, if an interaction is observed and no suitable alternative excipient is available, additional studies are needed to determine the impact of such an interaction on the product shelf life and to ascertain whether any restrictive manufacturing and packaging conditions to increase the stability of the drug product would be necessary.

Case Histories—Case histories of the interaction of selected drug molecules with excipient and how such interactions influenced dosage form design decisions are given below.

*Calcium Channel Blockers (**I** and **II**)*—Compounds **I** and **II** are the hydrochloride salts of two calcium channel blockers of the benzazepine series discovered by Bristol-Myers Squibb.[13] They are structurally similar, except for the side chains with amine groups: **I** is a tertiary amine, whereas **II** is a secondary amine. Each compound contains an O-acetyl group that undergoes hydrolysis in aqueous media, forming one degradation product. No degradation product other than the hydrolysis product was observed in aqueous solutions. The formation of hydrolysis products was, therefore, studied during the drug–excipient compatibility testing. Additionally, possible interactions of the compounds with lactose were considered because it has been reported in the literature that amine drugs react with lactose.[14] However, most published reports were for compounds containing primary amines, and it was important to determine how tertiary and secondary amines would behave in the presence of lactose.

The 3-week results of the compatibility screening of **I** with the four diluents and the three lubricants used are shown in Table 2. Since the hydrolysis product **VIII** was the only degradation product formed and there was a good mass balance in all the samples, the results are expressed as the intact drug remaining and the amount of the hydrolysis product formed. As shown in Table 2 and also represented by the chromatograms in Figure 1, the degradation of **I** in the neat drug and in drug–lactose and drug–mannitol mixtures was low and practically similar, indicating that there was no significant interaction of **I** with lactose and mannitol. The degradation of **I**, however, increased in the presence of microcrystalline cellulose (Avicel, FMC) and dicalcium phosphate (DCP, DiTab, Rhone-Poulenc). Among the three lubricants used, stearic acid had the least influence on the degradation of **I**, followed by sodium stearyl fumarate and magnesium stearate in the increasing order of degradation. The HPLC chromatograms of drug–diluent–magnesium stearate mixtures are shown in Figure 2 to indicate that the hydrolysis product **VIII** was the only product formed even when the degradation was high. In a separate study, the compound was observed to have the maximum stability in solution at pH 4, and the stability decreased with an increase or decrease in pH. The maximum stability of **I** in the presence of stearic acid may, in part, be explained by the microenvironmental pH of the systems. The microenvironmental pH of drug–lactose and drug–mannitol mixtures in the

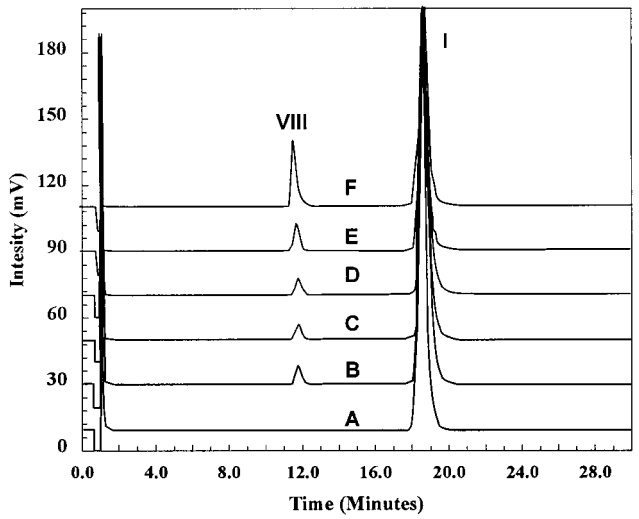

Figure 1—HPLC chromatograms of compound **I**–excipient mixtures (1:7) exposed to 50 °C for 3 weeks with 20% added water. Key: A, reference standard; B, neat drug without excipient; C, drug–lactose mixture; D, drug–mannitol mixture; E, drug–microcrystalline cellulose mixture; and F, drug–dicalcium phosphate dihydrate mixture. Chromatograms were recorded using a 15 cm Novapak C_{18} column and a mobile phase containing 55% aqueous solution (sodium acetate, 14 g/L, and sodium hexane sulfonate, 1.98 g/L) and 45% acetonitrile (flow rate, 1.0 mL/min; UV detection wavelength, 229 nm).

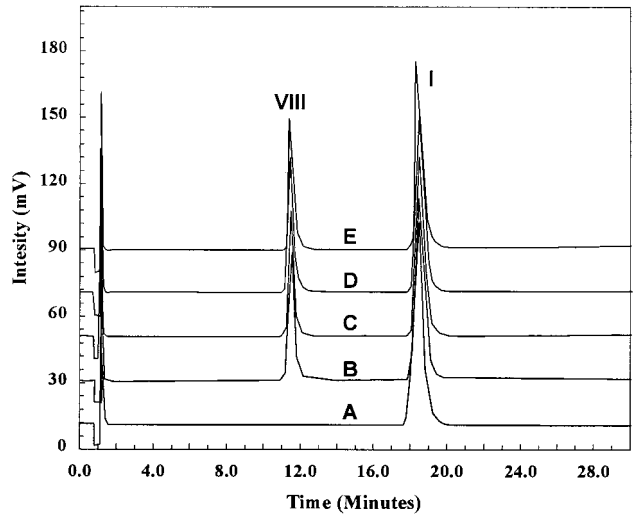

Figure 2—HPLC chromatograms of compound **I**–diluent–magnesium stearate mixtures (25:170:5) exposed to 50 °C for 3 weeks with 20% added water. Key: A, reference standard; B, neat drug without excipient; C, drug–lactose–magnesium stearate mixture; D, drug–mannitol–magnesium stearate mixture; and E, drug–microcrystalline cellulose–magnesium stearate mixture. Chromatographic conditions are the same as in Figure 1.

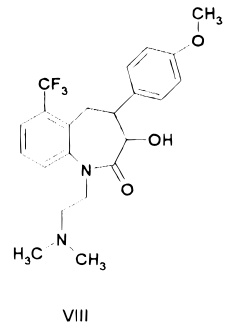
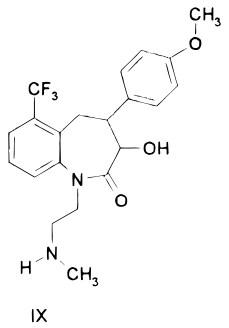
presence of stearic acid was 3.8, whereas sodium stearyl fumarate and magnesium stearate raised the microenvironmental pH to ~5.5. Mixtures of **I** with DCP gave an initial pH of 6.2−6.5. Additionally, its surface acidity[15] and propensity for forming H_3PO_4 upon its hydrolysis in the presence of water would contribute to the acid-catalyzed degradation of the ester bond in **I**. Thus, there appears to be a good agreement between the microenvironmental pH of the excipient blends and the hydrolysis of the drug. From this phase of the study, it was concluded that mixtures of **I** with either lactose or mannitol as the diluent and stearic acid as the lubricant would provide maximum stability of the drug. The microcrystalline cellulose was also considered to be an acceptable diluent because the extent of drug degradation in its presence was not much higher.



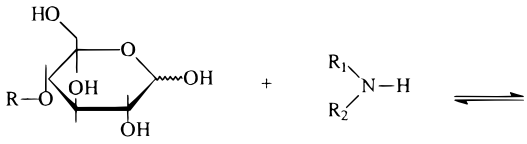
VIII



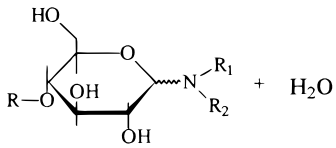
IX

During compatibility screening of the hydrochloride salt of the secondary amine, **II**, it was observed that the drug did not have any significant interaction with lactose and mannitol in binary mixtures (Figure 3). The only significant degradation product formed was the hydrolysis product **IX**. As in the case of **I**, the influence of stearic acid on the compatibility of **II** with lactose and mannitol was minimal; the chromatograms remained similar to those in Figure 3, with hydrolysis being the only drug degradation product. In contrast, both sodium stearyl fumarate and magnesium stearate adversely influenced the drug stability. Figure 4 shows that the hydrolysis product, **IX**, was the major degradation product in the presence of both sodium stearyl fumarate and magnesium stearate. As with **I**, the hydrolysis of **II** was higher with magnesium stearate. Additional peaks at the elution times of 2−3 min were obtained when lactose was present in the mixture, possibly a result of the interaction of lactose with the secondary amine groups of **II** and the hydrolysis product, **IX** (Figure 4, chromatograms B and C). Unidentified degradation products with the elution time of ~1 min were also observed in the presence of magnesium stearate (Figure 4, chromatograms B and D).

The tertiary amine is expected to be nonreactive toward lactose, because the product of such a reaction would lead to unstable ionic species that would revert back to reactants, and for this reason, compound **I** was compatible with lactose. In the case of a secondary amine, a glycosylamine would be formed:



Lactose



Glycosylamine

For the above reaction to occur in the solid state, optimal microenvironmental conditions of humidity and pH would be required. Under acidic conditions, the reactivity was reduced as a result of the protonation of the amine and the consequent decrease in its nucleophilicity. The observed lack of interaction of the hydrochloride salt of **II** and lactose could thus be rationalized. However, in the presence of magnesium stearate and sodium stearyl fumarate, the microenvironmental pH of the system was expected to rise because of the basicity of the excipients. This would liberate the nucleophilic free base of the drug from the salt to react

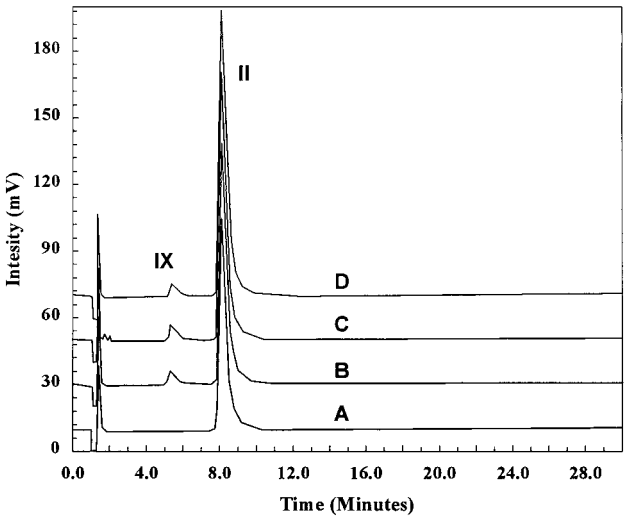


Figure 3—HPLC chromatograms of compound **II**–diluent–stearic acid mixtures (25:170:5) exposed to 50 °C for 3 weeks with 20% added water. Key: A, reference standard; B, neat drug without excipient; C, drug–lactose–stearic acid mixture; and D, drug–mannitol–stearic acid mixture. Chromatographic conditions are the same as in Figure 1.

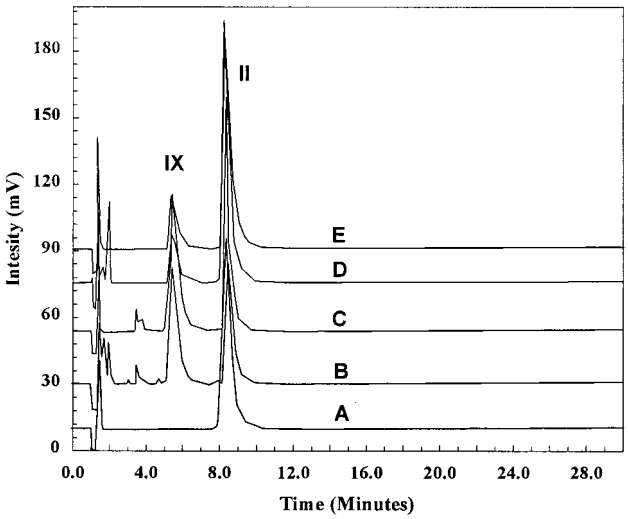

Figure 4—HPLC chromatograms of compound **II**–diluent–lubricant mixtures (25:170:5) exposed to 50 °C for 3 weeks with 20% added water. Key: A, reference standard; B, drug–lactose–magnesium stearate mixture; C, drug–lactose–sodium stearyl fumarate mixture; D, drug–mannitol–magnesium stearate mixture; and E, drug–mannitol–sodium stearyl fumarate mixture. with lactose and form an adduct. A second adduct due to the interaction between the hydrolysis product, **IX**, and lactose could also be formed. A similar reaction between a secondary amine and lactose, which was catalyzed by magnesium stearate, was reported in the literature.[16] The lack of interaction with lactose in the presence of stearic acid is also consistent with this explanation. As shown in the scheme above, the equilibrium of the interaction will be dependent on the moisture content of the system. In the absence of moisture, very little glycosylamine formation would occur because the reaction is postulated to occur in the sorbed layer of water between excipient and drug. In an excess of water, however, the equilibrium will be shifted to the left. Thus, the proposed model attempts to optimize conditions for the observation of the potential interaction between lactose and amine drugs in a relatively short period of time.

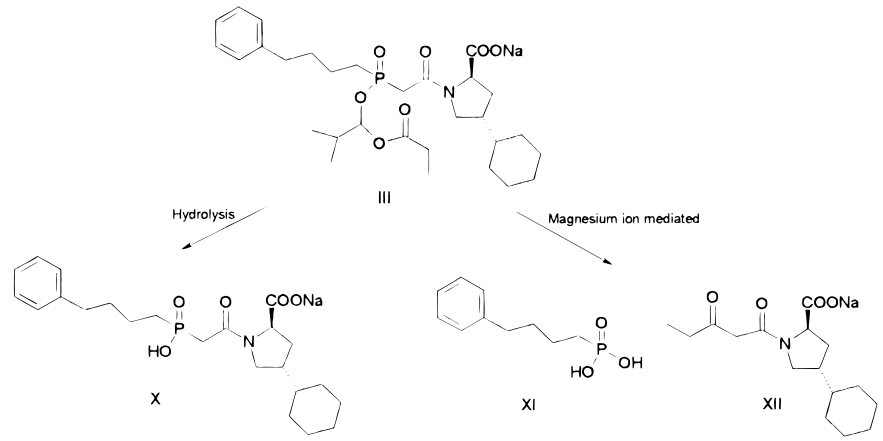
On the basis of the above studies, drug−lactose−stearic acid and drug−mannitol−stearic acid mixtures were selected for the solid dosage forms of **I** and **II**, respectively. The compatibility of these mixtures with various binders and disintegrants were studied in the second phase of the screening, in which the compatibility of povidone, crospovidone, and pregelatinized starch with the drugs was established. Because these studies also indicated that the stability of both drugs was susceptible to moisture, their exposure to moisture during processing and storage was minimized to ensure prolonged stability of the solid dosage forms.

*Fosinopril Sodium (**III**)*—Compound **III** is the prodrug form of an angiotensin-converting enzyme inhibitor which produces in vivo the active moiety fosinoprilat (**X**) by hydrolysis of the phosphinic acid ester side chain. Compound **X** was the only degradation product observed in aqueous media during preformulation testing, indicating that the compound would require protection from moisture during processing and storage. In drug−excipient compatibility testing using 20% added water, **X** was also the only degradation product observed, except in the case of interaction with magnesium stearate. Interaction with magnesium stearate not only accelerated the formation of **X**, it also produced two other major degradation products, **XI** and **XII** (Scheme 1). This is shown with the HPLC chromatograms in Figure 5, which indicate that ~90% of the drug degraded in 1 week when tested according to the model. Although the conditions of the model may appear to be very drastic with such a rapid degradation of **III**, it was by this model that the unexpected interaction with magnesium stearate could be discovered within such a short period of time. The mechanism of this magnesium-mediated reaction was later elucidated.[17]

In a separate study, when a 1:1 mixture of **III** and magnesium stearate was exposed to 75% RH at 50 °C, the degradation of **III** after 3 weeks was less than 1% (Figure 6). This is because both **III** and magnesium stearate were nonhygroscopic, although the interaction between them is mediated by water. This, however, would not be the case in capsules and tablets where other formulation components, such as microcrystalline cellulose, starch, gelatin shell, and so forth, would result in moisture sorption. Therefore, a model in which a limited amount of water is added to a system is often more predictive of drug−excipient compatibility because it does not depend on the hygroscopicity of individual components.

From the above study, it was concluded not only that **III** requires protection from moisture in dosage forms, but also that magnesium stearate should be excluded from formulations. This was later confirmed by accelerated stability testing of the tablet formulation of **III**, where **XI** and **XII** were detected only in a formulation lubricated with magnesium stearate.[17] Thus, the elimination of magnesium stearate from a formulation through drug−excipient compatibility screening maximized product stability and eliminated the necessity of monitoring the formation of two extra degradation products during stability testing.

*Ceronapril (**IV**)*—Compound **IV** is an ACE inhibitor with a primary amine group in its structure. Its interaction with lactose was, therefore, expected. What was unexpected was an interaction with DCP. Figure 7 shows representative HPLC chromatograms of the mixtures of **IV** with three diluents, lactose, DCP, and mannitol. In 3 weeks, **IV** degraded 8.4% and 2.5% in the presence of lactose and DCP, respectively, whereas no degradation was observed in the presence of mannitol or any other excipient. By LC-MS and LC-MS-MS studies, the degradation products formed in the presence of lactose and DCP were identified to be **XIII** and **XIV**, respectively. The formation of **XIV** was oxidative in nature, which could not be predicted on the basis of initial preformulation testing. The model served



Scheme 1

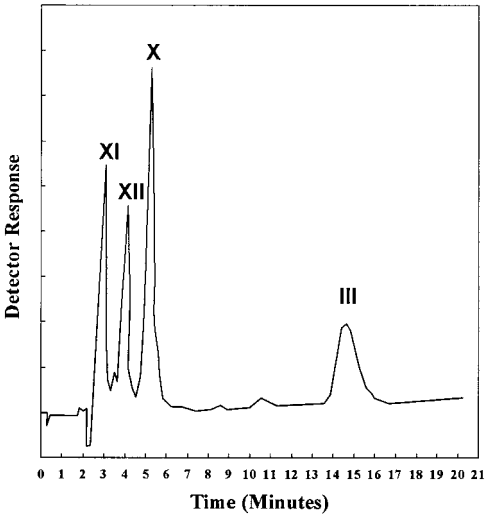


Figure 5—HPLC chromatogram of a fosinopril sodium **(III)**–lactose–magnesium stearate mixture (40:150:10) containing 20% added water stored at 50 °C for 1 week. Compounds **X**, **XI**, and **XII** were the major degradation products formed. A phenyl column (Type C-402, 4.6 mm × 30 cm, 10 μm packing, Column Resolution, Inc., San Jose, CA) using a mixture of methanol and aqueous 0.2% phosphoric acid (72:28) as the mobile phase was utilized (flow rate, 1.5 mL/min; UV detection wavelength, 220 nm).

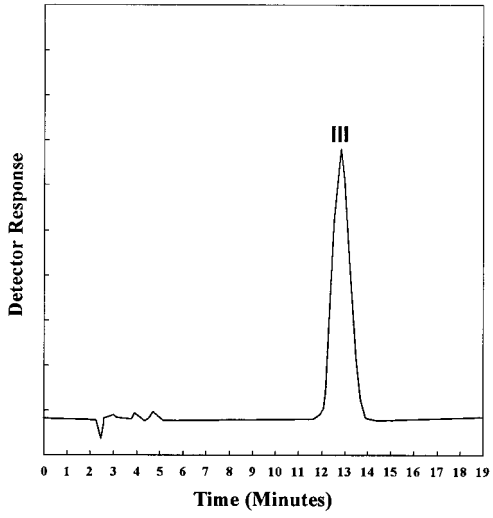

Figure 6—HPLC chromatogram of fosinopril sodium **(III)**–magnesium stearate (1:1) mixture stored at 50 °C under 75% RH for 3 weeks. Chromatographic conditions are the same as in Figure 5.

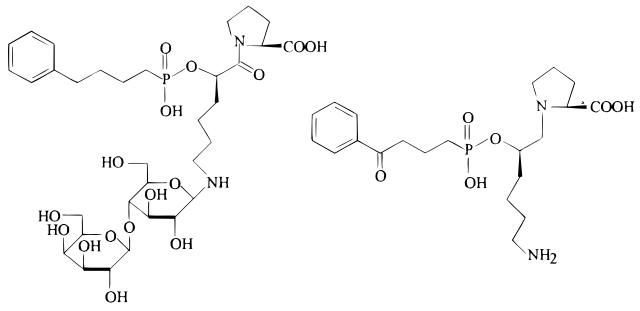
as a powerful tool in identifying this interaction between **IV** and DCP.



On the basis of the above results, lactose and DCP were excluded from the primary tablet formulation of **IV**. However, because DCP is a commonly used excipient for the direct compression of tablets and the degradation of **IV** in its presence was relatively low, a back-up formulation containing this excipient was also prepared and subjected to accelerated stability testing. For a 20-mg potency tablet with the total weight of 200 mg, the extent of degradation of **IV** upon exposure to 40 °C and 75% RH in an open container for 1, 4 and, 6 months was <1%, 2%, and 5%, respectively. The compound **XIV** was the principal degradation product. These findings indicate that an interaction between **IV** and DCP would possibly have been overlooked if, instead of using the model described in this paper, the drug–excipient blends or miniformulations were exposed to high temperature and humidity for up to 1 month. In closed vials stored at 25 °C, it took about 6 months for the concentration of **XIV** in DCP-based tablets to reach the threshold level of 0.1%. Although such a low concentration of a degradation product may be acceptable in a formulation, it is important that all potential degradation products are detected by drug–excipient compatibility testing prior to dosage form design instead of "discovering" them during formal long-term stability testing. Decisions regarding the potential liability of the presence of any degradation product in a formulation must be made during the dosage form design.

*Pravastatin Sodium (**V**)*—The model described in this paper was also used to study the effects of different excipients on the degradation pattern of **V** in solid dosage forms. An optimal degradation product profile was then selected on the basis of such studies. Figure 8 shows the relative amounts of degradation products formed in two blends of pravastatin sodium containing microcrystalline cellulose, lactose, and magnesium stearate; compositions

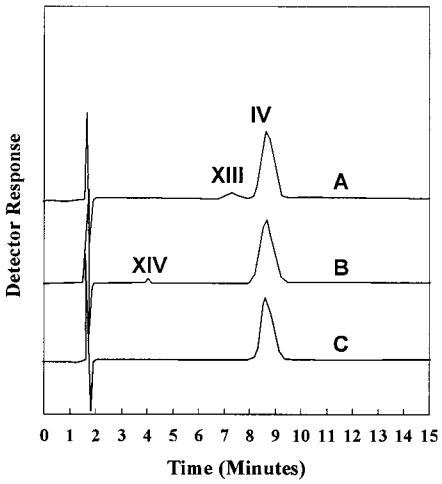


Figure 7—HPLC chromatograms of ceronapril (**IV**)–diluent–magnesium stearate mixtures (40:150:10) containing 20% added water stored at 50 °C for 3 weeks. Diluents used were (A) lactose, (B) dicalcium phosphate dihydrate, and (C) mannitol. Compounds **XIII** and **XIV** are the degradation products formed in mixtures with lactose and dicalcium phosphate dihydrate, respectively. Waters Novapak C_{18} column heated to 30 °C was used. A mixture of acetonitrile and aqueous 0.1% phosphoric acid (19:81) at a flow rate of 1.3 mL/min was used as the mobile phase (detection wavelength: 210 nm).

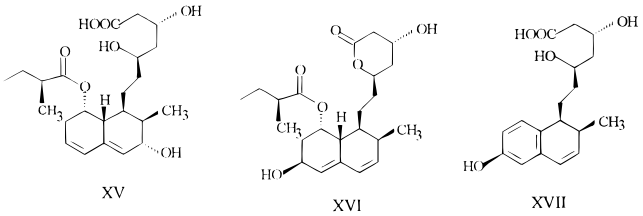
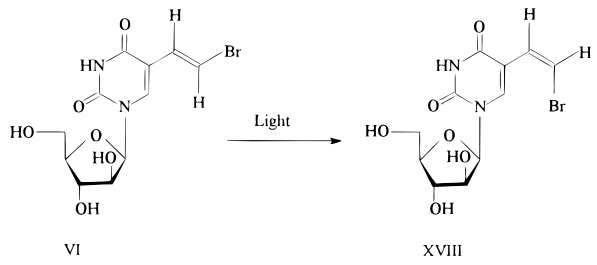
of the two blends were identical, except for the presence of 3.3% magnesium oxide in Blend 2. The difference in microenvironmental pH values of the two blends (6.5 for Blend 1 vs 9.9 for Blend 2) was responsible for the difference in degradation product profiles; the lower pH favored the formation of **XV** and **XVI**, whereas the higher pH favored the formation of **XVII**. Long-term stability testing of the dosage forms of **V** containing magnesium oxide was in agreement with these results. Thus, by selecting the excipient to adjust microenvironmental pH, the solid dosage form composition of pravastatin sodium was optimized.[18]



*Sorivudine (**VI**)*—Drug–excipient compatibility testing led to the stabilization of **VI**, an antiviral drug, against photodegradation. When exposed to light, the compound forms its Z-isomer (**XVIII**). The initial compatibility testing



with excipients was, therefore, conducted by protecting samples from exposure to light. This and other preformulation studies suggested that a tablet formulation of the compound would require opaque film coating to protect it from photodegradation. In a later drug–excipient screening study to select coloring agents for the tablet, it was noticed

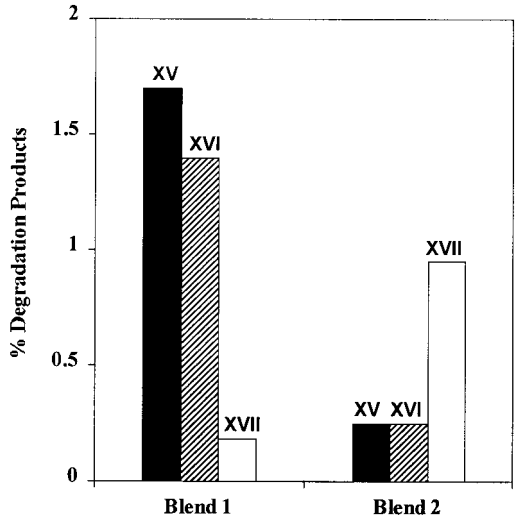


Figure 8—Amounts of degradation products **XV**, **XVI**, and **XVII** formed when pravastatin sodium formulations without magnesium oxide (Blend 1) and with 3.3% magnesium oxide (Blend 2) containing 20% added water were stored at 50 °C for 3 weeks. Products were extracted with a 1:1 mixture of methanol and pH 5.5 aqueous phosphate buffer and analyzed by HPLC using a Waters μ-Bondapak column. A 500:500:1:1 mixture of methanol, water, triethylamine, and acetic acid was used as the mobile phase (flow rate, 1.3 mL/min; UV detection wavelength, 238 nm).

Table 3—Conversion of Sorivudine (VI) to its Z-isomer (XVIII) upon Exposure of Dry and Wet Drug–Excipient Blends Containing Iron Oxides to 900 ft-c Light for 7 Days

	% Z-isomer (**XVIII**) formed[b]	
composition[a]	dry blend	wet blend
no coloring agent	21.1	9.0
red iron oxide	3.4	0.7
yellow iron oxide	2.6	0.7
black iron oxide	2.6	1.3

[a] A 100 mg portion of each blend containing 12.5 mg of drug, 5 mg of iron oxide, and 82.5 mg of other excipients (87.5 mg when no coloring agent was present) was sealed in a 4-mL clear borosilicate glass vial. Each wet blend contained 20 μL of water. The vials were exposed to light from the side by placing them flat. [b] Assayed by HPLC using a 5 μm Lichrosorb RP-18 column (250 mm × 4 mm) using a 15:5:80 mixture of acetonitrile, triethyl ammonium acetate aqueous solution (14% v/v, pH adjusted to 7.0 with acetic acid), and water as the mobile phase (flow rate, 1 mL/min; detection wavelength, 250 nm).

that the formation of **XVIII** was relatively low when drug–excipient blends containing iron oxide dyes were exposed to light. A systematic compatibility testing with iron oxides was therefore conducted by exposing the samples to light, and the results, as shown in Table 3, indicated that iron oxides can greatly reduce the formation of photodegradation product. On the basis of this study, a tablet formulation of **VI** was developed in which iron oxides were admixed with the drug and other excipients to provide color. The tablet did not require any film coating; its stability upon exposure to light was as good as a film-coated tablet which did not contain any iron oxide.[19]

Other Physicochemical Changes—The applications of the model described in this paper are not limited to the testing of the chemical interaction between drugs and excipient. We have used it for many other purposes, including the investigation of (a) dissolution instability of drugs in dosage forms due to conversion of salts to free acid or base forms, (b) changes in crystal forms, such as polymorphic conversion, the formation of an amorphous phase due to dissolution of the drug in granulating fluids and subsequent drying, and so forth, and (c) relative stability of various salt forms during the final form selec-

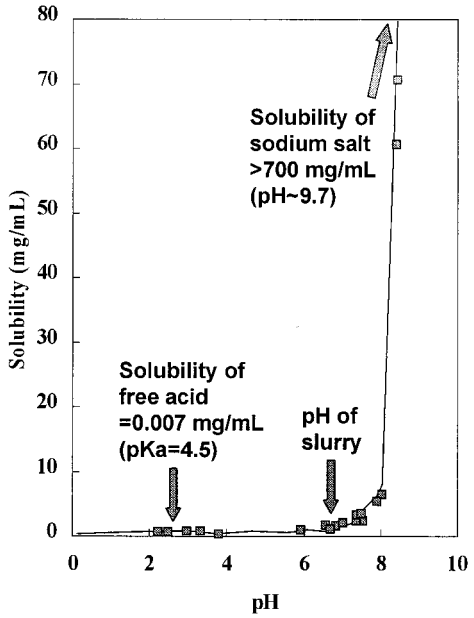

Figure 9—Partial pH-solubility profile of ifetroban sodium (**VII**) at 23 °C. Drug was analyzed by HPLC using a Zorbax Stablebond Cyano column heated to 40 °C. A 35:65 mixture of acetonitrile and 0.005 M KH_2PO_4 aqueous solution, pH adjusted to 3.0 with H_3PO_4, was used as the mobile phase (flow rate, 1.5 mL/min; UV detection wavelength, 215 nm).

tion of a drug. Brief descriptions of some of these studies are given below.

Dissolution Instability—During drug–excipient compatibility testing, ifetroban sodium **(VII)** showed excellent chemical stability in the presence of all excipients tested. However, its capsule formulations exhibited a decrease in dissolution rate during accelerated stability testing.[20] This was most pronounced in formulations containing DCP. When the drug–excipient compatibility testing was repeated, the microenvironmental pH values of various dosage form compositions were observed to be between 6.2 and 6.6, where the sodium salt form of the drug could convert to the insoluble free acid form. This is apparent from the pH-solubility profile of the compound as shown in Figure 9. When a mixture of **VII** and DCP containing 20% water was stored at 50 °C for 1 week, almost complete conversion of the sodium salt to free acid was observed.[21] Liberation of H_3PO_4 from DCP at high temperature[22,23] served as the source of hydrogen ions for the salt-to-acid conversion. Indeed, it was observed that the microenvironmental pH of the mixture decreased with time. The conversion of **VII** to the water-insoluble free acid form in a formulation containing DCP is described by Scheme 2.

It is now a common practice in our laboratory to measure the microenvironmental pH values of drug–excipient blends initially and after exposure to 50 °C, with 20% added water, for various intervals of time. If salt forms of drugs are used, any propensity for their conversion to free acid or base forms can be ascertained from such studies. Adjustment of microenvironmental pH with an appropriate excipient can eliminate any such conversion and the consequent drug dissolution problem. For **VII**, alkalizing agents were added to formulations to keep microenvironmental pH above 9, where the compound has high solubility and would not convert to the free acid form.[23]

Crystal Form Changes—Polymorphic and other crystal form changes may lead to dissolution instability of drugs, especially for compounds with low aqueous solubilities. They also cause various physical stability problems in solid dosage forms, including changes in appearance, hardness, disintegration time, and so forth.[24]

Any propensity for polymorphic change was investigated by recording powder X-ray diffraction patterns and solid-state ^{13}C NMR spectra of drug–excipient mixtures initially and after subjecting them to 50 °C with added water for up to 1 week. The wet samples were dried before analysis. If there is any potential for polymorphic conversion, it would be facilitated by the "pressure cooker" effect of the experimental condition and the presence of excipients that could serve as nuclei for recrystallization. In the absence of any chemical degradation, significant change in powder X-ray diffraction patterns or solid-state NMR spectra would indicate polymorphic transformation.

If the drug substance is water-soluble, instead of a polymorphic conversion the drug substance may convert partially or completely to an amorphous form due to wet granulation with the excipient and subsequent drying. This may affect dosage form stability because an amorphous form may be less stable than a crystalline one. The amorphous form thus produced may, in turn, recrystallize into the original or a different crystal form,[25] leading to dissolution or other physical instability problems if this occurs during stability testing of dosage forms. We have studied such changes by recording powder X-ray diffraction patterns of a drug–excipient blend initially and after mixing with water and drying.[3]

Salt Selection—The model was also applied to determine the relative stability of different salt forms of a compound.[26] Inorganic and organic acids and bases used to prepare salts may interact with drug molecules. The tromethamine salt of ketorolac was found to partially convert to the 1-keto analogue and an amide on exposure to high humidity and temperature.[27] Schildcrout et al.[28] reported 1,4-Michael adduct formation between seproxetine and maleic acid in a maleate salt, and Stahl[29] reported the covalent addition of a secondary amine to fumaric acid in a fumarate salt. Different counterions used in salt formation may also provide different microenvironmental pH values to a compound. When the stability of a compound is sensitive to a change in pH, the stability of salts may differ as a result of such a difference. The salt form of a compound with optimal chemical stability may be selected in less than 1 month by stress stability testing according to the model.

Conclusions

In the present health care economic climate, acceleration of the drug development process and optimization of dosage form stability are two major goals of any drug development program. One key step in achieving these goals is the identification of optimal dosage form compositions at the outset of a drug developmental program, which is generally during the design of Phase I clinical formulations. Subsequent changes in formulation during Phases II and III usually lead to increases in time and cost of drug development. In this paper, a practical drug–excipient compatibility screening model to identify potential chemical and physical stability problems with a drug substance in the presence of different excipients has been presented. Case histories described in the paper demonstrate that the

stability of drug products can be optimized by selecting the excipient according to this model. Selection of dosage form composition based on such drug−excipient compatibility testing reduces "surprise" problems during long-term stability testing of drug products.

Received October 28, 1998. Final revised manuscript received March 9, 1999.
Accepted for publication March 24, 1999.

Abstract □ PNU-107859, an important representative structure in a novel class of matrix metalloproteinases (MMP) inhibitors known as thiadiazoles, was found to be quickly eliminated from rats. A major metabolite (approximately 10% of total dose) was found to be present in the bile of rats. The metabolite in question was isolated and purified from the bile fluids collected from six cannulated rats. From a total of approximately 75 mg of PNU-107859 administered to rats, 3.3 mg of the metabolite was recovered. The NMR and mass spectrometry results indicated that the metabolite is a glucuronide conjugate (1-deoxy-1β-substituted D-glucopyranosiduronic acid) of the intact drug. Furthermore, the UV, MS, and NMR data established that the conjugate is located at the nitrogen α to the thiocarbonyl of the thiadiazole ring.

Introduction

The matrix metalloproteinases (MMPs) are a family of zinc endopeptidases which are capable of degrading the extracellular matrix of connective tissues and basement membranes.[1] Overactivation or increased synthesis of the MMPs has been implicated in several disease pathologies, including arthritis, cancer progression, and related connective tissue disorders[2], periodontal disease,[3] atherosclerotic plaque rupturing,[4] and aortic aneurysms.[5] There are currently at least 18 members of this family of proteinases which can be roughly associated into three groups depending on their native substrates. Thus, the gelatinases are effective proteinases of Type IV collagen, the collagenases degrade interstitial collagen, and the stromelysins are effective as protoglycanases. The discovery and characterization of the MMPs is summarized in several recent reports. Recently several research groups have shown that related metalloproteinases are also involved in the conversion of inactive tumor necrosis factor-I (TNF-I) into active TNF.[6,7] Usually this inflammatory cytokine plays a beneficial role in physiological defense responses; however, overproduction of TNF-I can lead to systemic toxicity. Therefore, MMP inhibitors may be indirectly involved in diseases for which TNF-I has been implicated, such as Crohn's disease, MS, cachexia, sepsis, and rheumatoid arthritis.[8] PNU-107859[9] is a member of a novel class of MMP inhibitors known as thiadiazoles. During a preliminary pharmacokinetic study of PNU-107859, it was observed that this experimental drug has rather short half-life (≅40 min) in rats. To investigate the nature of the unfavorable pharmacokinetics, the bile samples from rats treated with this drug were collected and found to contain the intact drug and a metabolite as the only other major thiadiazole-containing component. It was estimated that this putative metabolite represented about 10% of the total drug 3 h after iv administration. A study was therefore initiated to isolate enough metabolite for spectroscopy experiments to elucidate its structure unambiguously.

Experimental Section

Materials—PNU-107859 was synthesized by Pharmacia and Upjohn. All other chemicals were analytical or HPLC grade.

Dosing and Collection of Bile—The jugular veins of six male Sprague−Dawley rats were cannulated using a variation of the Week's chronic jugular vein cannulation technique. The same animals were anesthetized after eight or 9 days and the bile ducts cannulated using PE-10 polyethylene tubing. The free end of the tubing was placed in a test tube to collect draining bile. Animals (230−290 g) were given a 50 mg/kg dose of PNU-107859 (50 mg/mL in a 50% PEG/50% saline vehicle) iv via the chronic jugular vein cannula. The cannulas were flushed with 100 μL of 50% PEG/50% saline followed by 300 μL of 100% saline. Bile was collected hourly for 3 h postdosing. After pooling samples from all animals, a total of 15 mL of bile was collected.

Cation Exchange Methods—One milliliter of pooled bile was passed over one Varian Bondelut SCX cartridge (1 mL) to remove impurities with a UV absorption maximum at 270 nm. The metabolite was not retained by this resin. The resin was washed with water until HPLC showed no presence of the metabolite in the eluent. Fractions containing the metabolite were collected and used directly for prep-HPLC.

Preparative HPLC Methods—The cation-exchange-purified samples were divided into six samples, and each of these was purified by preparative HPLC employing a Waters μBondapak cartridge (2.5 × 10 cm). Elution at 15 mL/min for 5 min at 10/90 ACN/H_2O plus 0.1% TFA was followed by a 15 min gradient to 25/75. These conditions were maintained for 5 min, followed by an elution at 90/10 to wash the column. Detection was at 220 nm. Fractions were collected with a Foxy collector in the peak detect mode. A second run using the same conditions was performed on the pooled fractions from the six initial runs.

Analytical HPLC Methods—Sample was injected onto a Zorbax Rx-C8 column (4.6 × 250 mm) and eluted isocratically with 25/75 ACN/H_2O plus 0.1% TFA at 1 mL/min with detection performed by a Varian 9065 diode array detector at 311 or 220 nm.

FAB-MS Method—The low resolution positive ion fast atom bombardment (FAB) mass spectrum of the glucuronic acid product isolate was obtained on a VG70-SE Nier-Johnson double-focusing mass spectrometer equipped with an OPUS-2 data system. A cesium ion gun operating at 25 kV was used as the source of the ionizing beam, while the instrument was operated at 8 kV accelerating voltage. The instrument was calibrated at selected masses using a mixture of CsI and NaI. A small portion of the isolate as a methanol solution was mixed with the 2-hydroxyethanol disulfide (2-HED) matrix and introduced into the ion source on a stainless steel tip via a direct insertion probe. The sample

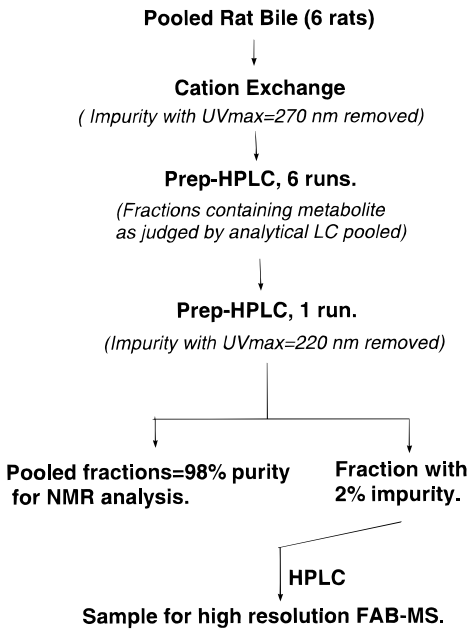

Scheme 1—Purification steps.

spectrum was recorded by scanning the magnetic field from *m*/*z* 2500 to *m*/*z* 15. The results were further analyzed using the mass spectral processing software on the Harris Nighthawk computer system.

The accurate mass of the isolate, as the protonated adduct ([M + H]$^+$), was determined by the peak matching technique relative to the known matrix adduct ion mass of 2-HED at *m*/*z* 463.0445. The mass spectrometer was operating at a mass resolution of approximately 4000 (m/Dm, 10% valley definition).

NMR Methods—^{1}H NMR spectra were recorded at 400.13 MHz using a Bruker ARX-400 spectrometer. Data were processed on an SGI Indy computer using Bruker UXNMR software. Samples were dissolved in 500 μL of DMSO-d_6 in a 5-mm NMR tube. Spectra were recorded at a temperature of 300K (27 °C). One-dimensional proton spectra were recorded as free induction decays of 32K complex points with a spectrum width of 6024 Hz. Four dummy scans were used. The receiver gain and the number of pulses were optimized for each sample. Free induction decays were Fourier transformed with no zero-filling after application of a resolution-enhancing Gaussian window function (LB = −1, GB = 0.2). Two-dimensional homonuclear COSY spectra were recorded in the magnitude mode using 1K × 1K data table (after transformation), with 256 increments in F1 and no zero filling in F2. Unshifted sinebell windows were applied before transformation.

^{13}C NMR spectra were obtained on a Varian XL-300 spectrometer operating at 75.43 MHz. The spectral window was 17391 Hz, and 32K data points were used with an acquisition time of 0.942 s and a pulse delay of 1.00 s. The free induction decays were Fourier transformed using standard sensitivity enhancement parameters.

Heteronuclear Multiple Bond Correlation (HMBC)—NMR spectra were recorded on a Bruker ARX-400 Spectrometer equipped with a 9.4 T magnet, operating at 400.13 MHz for ^{1}H and 100.62 MHz for ^{13}C. A Bruker 5 mm broadband inverse gradient probe was used for these experiments. HMBC data was acquired using the a gradient pulse sequence. 2D transformations were accomplished using Bruker UXNMR software on an SGI Indy computer. Spectra were recorded in the magnitude mode using a 1K by 512 data table with 160 pulses per 256 increments in F1 domain and no zero-filling in F2 domain. All spectra were acquired at 300K. Relaxation delays typically were 1.1 s.

Results

A brief outline of the purification methods is summarized in Scheme 1. Briefly, cation exchange procedures were used to remove some impurities. The pooled fractions containing the metabolite were then processed by preparatory reverse-phase HPLC. Fractions containing the metabolite were dried and redissolved in perdeuterated methanol or DMSO to obtain structural information by NMR. The HMR spectra also revealed a peptidic impurity partially coeluted with the metabolite. This was confirmed by reanalyzing the fractions by HPLC with detection at 220 nm. This peptide has a slightly longer retention time than the metabolite peak. The fractions containing the metabolite were therefore combined and rechromatographed using the same HPLC conditions. The final preparation was judged to be pure by HPLC analysis employing a diode array detector and by HMR spectroscopy. A total of 3.3 mg of the pure metabolite was obtained. Since approximately 70 mg of PNU-107859 was administered to rats and the average conversion rate was 10%, a recovery of nearly 50% of the metabolite present in bile was obtained.

The purified metabolite was then subjected to NMR, FAB-MS, and UV studies. The 1D NMR chemical shift data are summarized in Table 1. The 2D NMR results are summarized graphically in Figure 2. The FAB-MS results are summarized graphically in Scheme 2.

Discussion

1. The Nature of the Conjugate—The main features of the HMR spectra of the metabolite collected during the purification stage were the extra resonance signals ob-

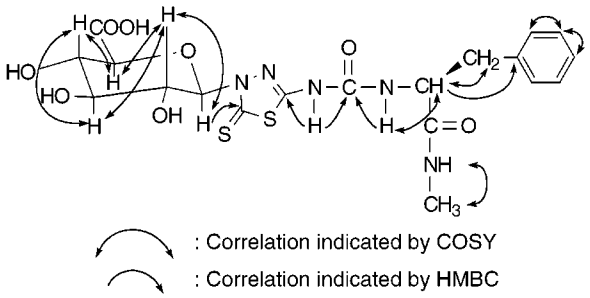

Figure 2—2D NMR results of U-107859 metabolite.

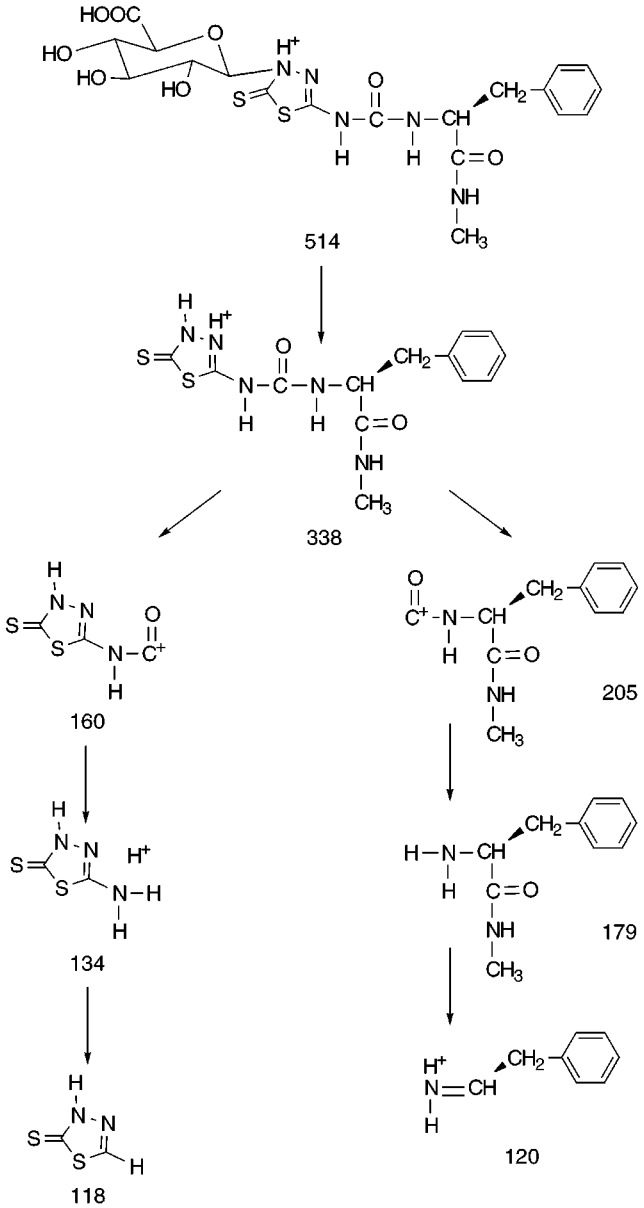

Scheme 2—Major ions observed by FAB-MS.

served between 3 and 6 ppm, suggesting the presence of carbinols, when compared to the parent drug. Integration of these extra signals resulted in a total of five nonexchangeable protons. However, two of the five protons were not resolved in methanol. Resolution of these five signals was attempted with a number of solvents. It was found that DMSO-d_6 provided the best resolution for those five protons. All following experiments, including $^1H-^1H$, $^1H-^{13}C$ COSY, CMR, and $^1H-^{13}C$ HMBC were therefore conducted in DMSO solution. The results are summarized in Table 1 and Figure 2 and discussed below.

The assignments of NMR signals of PNU-107859 are based on various 2D NMR experiments and will not be discussed in this report. Comparison of chemical shift values listed in Table 1 revealed that the major differences were the extra signals (vide infra) obtained for the metabolite when compared to the parent compound. Another important observation was that the conjugate most likely contained a carboxylic acid functional group, as evidenced by the new broad peak at 12.9 ppm and a new carbon signal at 169.7 ppm in the CMR spectrum. The 2D COSY spectrum, the size of $^1H-^1H$ coupling constants (9 Hz), and the HMBC spectrum indicated that the conjugate was a 1-deoxy-1β-aminated-glucopyranuronate. Specifically, the 2D COSY spectrum sequentially linked the five carbinols and connected each of them to an exchangeable hydroxyl proton. The fact that all the carbinols had 9 Hz coupling constants dictated that they adopted a diaxial relationship with their coupled neighbors. Assuming the bulky hydroxyl groups are at the equatorial positions leads to the conclusion that the conjugate is a modified β-D-glucopyranose. Analysis of the HMBC spectrum further connected the 12.9 ppm proton of the pyranoglucoside to the carboxyl carbon, establishing that the conjugate is a glucopyranuronate. Finally, the chemical shift value of the anomeric carbon (84.3 ppm) strongly implied that the conjugate is a 1-deoxy-1β-aminated-D-glucopyranuronate.[10]

2. The Site of Conjugation—There are five possible nitrogens, two on the thiadiazole ring and three on the backbone, that could be linked to the pyranose. Comparison of chemical shift values listed in Table 1 revealed that the 9 N−H signal is missing in the metabolite, suggesting that this position is the site of conjugation. Also, the HMBC spectrum gave a cross-peak between the anomeric proton and the carbon of the thiocarbonyl. Since this experiment will only detect C−H couplings with 2 or 3 bond linkages, the attachment must be on the nitrogen adjacent to the thiocarbonyl. Supporting this conclusion is the observed 3 ppm upfield shift of the C-8 carbon signal caused by the γ gauche effect. Other supporting evidences are the almost identical chemical shift values and the almost identical UV absorption for the metabolite and its parent.

3. Confirmation by Mass Spectrometry—The purified metabolite was subjected to low and high-resolution FAB-mass spectrometry studies. The low resolution FAB-MS results produced the expected molecular ions at 514 $(M + H)^+$ and 536 $(M + Na)^+$ for the glucuronic conjugate. Subsequent high resolution FAB-MS studies unambiguously identified the molecular formula of the metabolite as $C_{19}H_{23}N_5O_8S_2$. The major fragment ions can be rationalized as in Scheme 2. Thus, the FAB-MS results are in total agreement with the conclusions reached by NMR.

Glucuronidation is the most common pathway of conjugation in mammalian metabolism and excretion of xenobiotics.[11] It can be classified as O-, S-, N-, and C-glucuronidation on the basis of the type of atoms to which the glucuronic acid moiety is transferred by a group of inducible UDP-glucuronosyltransferases.[12] We have clearly demonstrated in this study that PNU-107859 is partially cleared by N-glucuronidation. Although N-glucuronidation is a much less commonly observed and a not well understood pathway compared to O-glucuronidation, its participation in the metabolic transformation of xenobiotics has gained increasing recognition in recent years. Examples reported in the literature are of wide structural classes of nitrogen-bearing aglycones, including primary through tertiary amines, and various classes of heterocycles, such as imidazole, hydantoin, pyrimidine, piperidine, tetrahydroiso-

quinoline, triazine, and tetrazole.[13−17] Our result extends this list to include thiadiazole.

Abstract □ In the early progression of atherosclerosis, LDL migrates in the subendothelial space of the artery and plays an important role in foam cell formations of macrophages. LDL may serve as a carrier of site-specific delivery of drugs to atherosclerotic lesions. In this exploratory study, dexamethasone palmitate (DP) was incorporated in LDL, and an inhibitory effect of this complex on foam cell formations was examined. LDL was isolated from human plasma, and the DP–LDL complex was prepared by incubation in the presence of Celite 545. No degradation nor modification of LDL was observed. The DP/LDL molar ratio of the complex was 35-50:1. Foam cell formations of murine macrophages were induced by incubation with oxidized LDL. When macrophages were pretreated with the DP–LDL complex, accumulation of cholesterol ester in the macrophages induced by oxidized LDL, i.e., an index of foam cell formation, was decreased. These findings indicated that the DP–LDL complex showed similar characteristics to LDL, and the DP–LDL complex inhibited foam cell formations of macrophages in vitro. This study provides the basis for further study of the DP–LDL complex as a drug–carrier complex for treatment of atherosclerosis.

Introduction

In an early stage of progression of atherosclerosis, atherosclerotic plaques are developed by accumulation of foam cells derived from macrophages or fibroblasts.[1] Recent studies indicate that LDL migrates under the epithelium of the vascular smooth muscle and is modified to be incorporated into macrophages in early atherosclerotic lesions.[2−4] In fact, macrophages can be converted to foam cells containing large amounts of cholesterol esters when incubated with modified LDL, mainly oxidized, in vitro.[5,6] Modified LDL and macrophages interact to form foam cell formations at atherosclerotic lesions. Prevention of foam cell formations of macrophages by reducing cholesterol esters accumulated in the foam cells is thought to be antiatherogenic.

It is well known that the process of plaque formation in atherosclerotic lesions possesses a number of features in common with inflammation.[7] Several studies have reported that anti-inflammatory drugs suppress the development of atherosclerosis in New Zealand White rabbits and Watanabe heritable hyperlipidemic rabbits.[8−11] Asai et al. reported that dexamethasone inhibits the formation of foam cells in atherosclerotic lesions.[12]

Plasma lipoproteins are a carrier of not only water-insoluble lipids but also lipophilic compounds such as certain vitamins, hormones, toxins, and others in the circulatory system. Recently, it has been demonstrated that lipoproteins, especially LDL, can be used as a carrier to deliver drugs to specific sites in the body.[13,14] In most studies, LDL is used as a carrier to deliver antineoplastic drugs to cancer cell.[15,16]

In the present study, to assess the feasibility of LDL as a drug delivery system for atherosclerosis, we prepared a complex of dexamethasone palmitate (DP), a steroidal anti-inflammatory drug, and LDL and examined its inhibitory effects on cholesterol ester accumulation in macrophages induced by oxidized LDL.

Materials and Methods

Animal—Male ICR mice were obtained from Japan SLC, Inc. (Hamamatsu, Japan) and used for experiments at 6−8 weeks of age.

Materials—Dexamethasone palmitate (DP) and dexamethasone nonadecanoate were supplied by Green Cross Co. (Osaka, Japan). Celite 545 was purchased from Kanto Chemical Co. Inc. (Tokyo, Japan), dexamethasone and FAT RED 7B from Sigma Chemical Co. (St. Louis, MO), and cholesterol esterase, oxidase, and peroxidase from Toyobo Co. (Tokyo, Japan). All other chemicals were of analytical grade.

Isolation of LDL—LDL (d = 1.019−1.063 g/mL) was isolated by sequential ultracentrifugation (100 000g) from normolipidemic human plasma.[17] The LDL fraction was dialyzed sufficiently against phosphate-buffered saline (PBS, pH 7.4) and then filtered through a MILLEX-HV filter (pore size; 0.45 μm, Millipore Co., Bedford, MA). The LDL fraction was stored at 4 °C under the darkness and used for experiments within a week.

Preparation of the Drug−LDL Complex—The DP−LDL complex was prepared by the method of Seki et al.[18] with minor modification. Briefly, Celite 545 (100 mg) and 1 mL of DP solution (1 mg/mL in MeOH) were agitated by a vortex mixer. The mixture was evaporated under the vacuum for 30 min, and then the residues were pulverized adequately. The residue and 2 mL of LDL suspension (300−400 μg protein/mL) were mixed gently and packed with N_2 gas. The mixture was incubated for 20 h with shaking at 37 °C. After incubation, the mixture was centrifuged at 2000g for 10 min, and the supernatant was dialyzed with PBS. The complex obtained was passed through a MILLEX-HV filter and stored at 4 °C until experiments were performed (<1 week).

Oxidation of LDL and the DP−LDL Complex—Each LDL and DP−LDL complex was diluted to 100 μg protein/mL with PBS and incubated with 5 μM $CuSO_4$ at 37 °C for 20 h. The oxidized LDL (ox-LDL) and the oxidized DP−LDL complex (ox-DP complex) suspensions were dialyzed against PBS. Confirmations of oxidation were obtained by electrophoresis.

Preparation of Macrophage—Peritoneal cells from unstimulated ICR mice were washed with PBS by centrifugation (800*g*). The cells were suspended to 10^6 cells/mL in RPMI1640 medium (Gibco BRL, Life Technologies, Rockville, MD) supplemented with 10% fetal bovine serum (Gibco BRL), 50 μM 2-mercaptoethanol, and 10 μg/mL of gentamicin. The cell suspensions were distributed (1 mL each) to wells of a 24-well culture plate (Becton Dickinson, Lincoln Park, NJ), and the plate was incubated for 90 min at 37 °C in a CO_2 incubator. After incubation, nonadherent cells were removed by washing with RPMI 1640 medium, and then the macrophage monolayers were placed in fresh RPMI 1640 medium for 20 h at 37 °C in a CO_2 incubator.

Cholesterol Accumulation Assay in Macrophages—Cholesterol accumulation in macrophages was assayed according to the methods of Miyazaki et al.[19] Macrophage monolayers were incubated with ox-LDL or ox-DP complexes for the periods indicated at 37 °C in a CO_2 incubator. After incubation, the macrophage monolayers were washed twice with RPMI 1640 medium and then PBS. Lipids and proteins were extracted directly from the macrophage monolayers. Briefly, 1 mL of a hexane/2-propanol (3:2) mixture was added to macrophage monolayers in the wells, and the macrophage monolayers were incubated for 30 min at room temperature. The solvent of the mixture was collected and extracted again. The extracts were combined, evaporated under the vacuum, dissolved in 500 μL of EtOH, and used for cholesterol measurements. After lipid extraction, 500 μL of a 0.1 M NaOH solution was added into each well and incubated for 15 min at 37 °C. The extracts were collected, and the extraction was repeated. The combined extracts were used for determination of cell protein.

Measurement of Cellular Cholesterol—The cellular concentration of cholesterol was measured by a fluorometric enzymatic method.[20] Briefly, 200 μL of cellular lipid extract and 2.5 mg of Triton X-100 were mixed and evaporated under the vacuum. The residue was suspended with 200 μL of the enzyme mixture and incubated for 30 min at 37 °C. The enzyme mixture for free cholesterol (F-ch) contained 0.12 units/mL of cholesterol oxidase, 45 units/mL of peroxidase, 0.5 mg/mL of homovanillic acid (Wako Pure Chemical Industries Ltd.), and 2 mg/mL of Triton X-100 in 100 mM sodium phosphate buffer (pH 7.0). The enzyme mixture for total cholesterol (T-ch) contained 0.36 units/mL of cholesterol esterase in the enzyme mixture for F-ch. Following incubation, 2.8 mL of a 0.1 M NaOH was added to stop the reaction, and each fluorescence intensity was measured with excitation at 323 nm and emission at 420 nm using a spectrofluorophotometer (Model FP-770, JASCO, Tokyo, Japan). Cellular cholesterol ester (CE) was determined by subtracting F-ch from T-ch.

Electrophoresis—The electrophoretic mobilities of LDL and DP−LDL complexes were determined by the Pol-E-Film System (Ciba-corning Diagnostics Co., Palo Alto, CA). The samples were loaded at 4.0 μg/well of agarose gel film (Universal Gel/8, Ciba-Corning) and run at 90 V for 40 min. After drying, the gels were stained with FAT RED 7B (Sigma) to visualize lipoprotein bands.

Measurement of LDL and Complex Particle Size—Particle size of LDL and DP−LDL complexes was determined by photon correlation spectroscopy using Coulter N4 plus a submicron particle analyzer (Coulter Co., Miami, FL). All samples were suspended with PBS to 100 μg protein/mL, filtered through an HLC disk (pore size 0.2 μm, Kanto Chemical), and then measured at 20 °C.

HPLC Analysis—DP concentration in the complexes was measured by HPLC as follows: a mixture of samples of the complexes (50 μL) and dexamethasone nonadecanoate (as an internal standard, 50 μL) was extracted by dichloromethane (4 mL). A part of the organic fraction (3 mL) was evaporated under the vacuum at 30 °C. The residue was dissolved in 120 μL of acetonitrile−water (95:5), and a 50 μL of aliqot was injected into the HPLC system (Shimadzu Co., Kyoto, Japan) possessing a 7-μm LiChrosorb RP-18 column (4 × 250 mm, Cica-Merck, Kanto Chemical). The mobile phase was acetonitrile−water (95:5), and flow rate was 2.0 mL/min. The eluate was monitored at 236 nm and quantified on a model C-R6A chromatopac integrator (Shimadzu). The concentrations were determined with resect to a standard curve of DP.

Other Determinations—Proteins were measured by Coomassie Protein Assay Reagent (Pierce Chemical Company, Rockford, IL)[21] using bovine serum albumin as a standard. Each level of cholesterol in LDL or DP−LDL complex suspensions was measured by using commercial kits (Wako Pure Chemical).

Statistical Analysis—Data are expressed as means only or means and SDs ($n = 3$). Statistical analysis was done using nonpaired Student's *t*-test or Fisher's PLSD test. A p value of 0.05 or less was considered a significant difference between the sets of data.

Table 1—Lipids and Proteins Compositions in LDL and the DP–LDL Complex[a]

	LDL	DP–LDL complex
T-ch[b] (mg/100 mL)	103.7 ± 4.18	83.39 ± 2.56*
F-ch[c] (mg/100 mL)	29.84 ± 0.50	23.42 ± 1.02*
CE[d] (mg/100 mL)	73.86 ± 3.71	59.97 ± 2.06*
protein (mg/100 mL)	34.89 ± 1.25	25.99 ± 0.33*
F-ch/T-ch	0.29 ± 0.01	0.28 ± 0.01
T-ch/protein	2.97 ± 0.09	3.21 ± 0.13

[a] Values were mean ± SD ($n = 3$), *: significant difference from LDL, $p < 0.001$. [b] Total cholesterol. [c] Free cholesterol. [d] Cholesterol ester.

Table 2—Particle Size and DP Concentration of the DP–LDL Complex[a]

	particle size (nm)	DP concentration (μg/mL)
LDL	22.43 ± 0.65	–
DP–LDL complex	23.67 ± 0.25	14.19 ± 0.75 [47.60 ± 1.92]

[a] Values were mean ± SD ($n = 3$). Bracketed/values indicate the DP contained in the DP–LDL complex (mol of DP/mol of LDL).

Results

Characteristics of LDL and the DP−LDL Complex—Table 1 shows the concentrations of cholesterols and protein in LDL and the DP−LDL complexes. The T-ch, F-ch, and CE concentrations in the complexes were 83.39, 23.42, and 59.97 mg/100 mL, respectively, and the protein concentration in the DP−LDL complexes was 25.99 mg/100 mL. These values of the DP−LDL complexes were about 75−80% of the corresponding values of LDL, and these percentages were indicated as the yields after the complex preparation. However, the ratios of F-ch/T-ch and T-ch/protein in the DP−LDL complexes were similar to those of LDL (0.28 and 3.21 in the DP−LDL complexes, and 0.29 and 2.97 in LDL, respectively). Furthermore, in the case of oxidized LDL and DP−LDL complexes, these ratios were not different between ox-LDL and ox-DP complexes (data are not shown).

Particle size and DP concentration in the DP−LDL complexes are shown in Table 2. Although several studies have reported that particle size of the drug-LDL complexes is larger than that of LDL,[22,23] the particle size of the DP−LDL complexes in this study (23.67 nm) was not significantly different from that of LDL (22.43 nm). The DP concentration in the DP−LDL complexes was 14.19 μg/mL, and DP contained in the DP−LDL complex was 47.6 mol of DP/mol of LDL (LDL molecular weight of 5.5×10^5 based on protein concentration). The DP concentrations in the complex and those in the LDL particle were not altered by oxidation or dialysis with PBS. DP was not detected in a preparation which was prepared with PBS instead of LDL suspension (data are not shown). Neither aggregation of the DP−LDL complexes nor decrease in DP contained in the DP−LDL complex was recognized after 4 weeks of storage at 4 °C.

LDL is unstable in a buffer after isolation and easily modified by negative ions, air, and other stimuli. To examine whether LDL could be modified by the addition of DP, electrophoresis of the DP−LDL complexes was compared with that of LDL. As shown in Figure 1, electorophoretic mobility and the lipid band of the com-

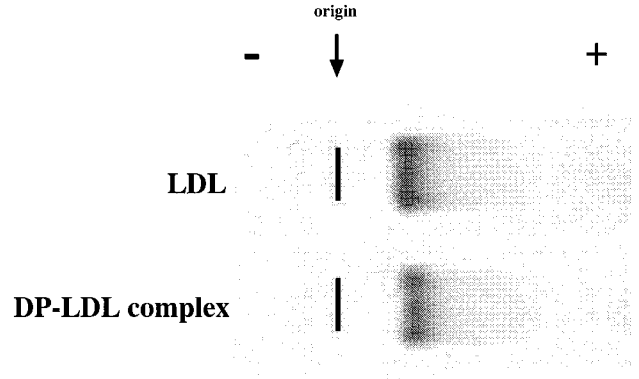

Figure 1—Electrophoretic mobilities of LDL and the DP–LDL complexes. Samples were loaded on agarose gel film at 2 μg/well and run at 90 V for 40 min. The agarose gel film was dried and stained with Fat red 7B.

plexes were similar to those of LDL. Moreover, the concentration of apo-B protein, which is the main protein in the LDL, was over 90% of the total protein concentration in the DP−LDL complexes, and the value was not different from that in LDL (data are not shown). These findings indicate that DP−LDL complexes can be prepared without any transposition and modification.

Cholesterol Accumulation in Macrophages during Incubation with ox-LDL or ox-DP Complex—It is well known that the macrophages are converted to foam cells with lipid droplets consisted of cholesterols during incubation with ox-LDL.

The T-ch and F-ch concentrations in macrophages were increased by incubation with ox-LDL about 2.9- and 2.3-fold of the control value (without ox-LDL), respectively (Figure 2A). The CE concentration in macrophages after incubation with ox-LDL was also increased markedly from 9.2 to 82.4 μg/mg cell protein (Figure 2 B). This increase in CE was associated with conversion of macrophages to foam cells during incubation with ox-LDL. On the other hand, when the macrophages were incubated with ox-DP complexes, CE concentration increased slightly as compared with that with ox-LDL (Figure 2B), while either T-ch or F-ch concentration was increased to the same extent as those in ox-LDL-treated macrophages (Figure 2A).

Effects of the ox-DP Complex on CE Accumulation in Macrophages—Figure 3 shows the changes in cholesterol concentrations in macrophages incubated with ox-LDL alone or ox-LDL together with ox-DP complexes. The concentrations of T-ch, F-ch, and CE in macrophages were increased predominantly by the incubation with ox-LDL alone at 100 μg protein/well rather than those at 50 μg protein/well. The increases in T-ch, F-ch, and CE in macrophages incubated with ox-LDL and ox-DP complexes (total ox-LDL concentration should be 100 μg protein/well) were significantly attenuated as compared with those with ox-LDL alone at 100 μg protein/well. However, the smaller concentration of ox-DP complexes (5 μg protein/well) showed no effects on the increased concentrations of cholesterols in macrophages incubated with ox-LDL at 50 μg protein/well.

Figure 4 shows the changes in cholesterol concentrations in macrophages preincubated with ox-DP complexes at 5 μg protein/well and then incubated with ox-LDL after removing of the ox-DP complexes. Preincubation with ox-DP complexes inhibited the accumulation of T-ch and F-ch in macrophages induced by incubation with ox-LDL. The CE concentration in macrophages preincubated with ox-DP complexes and then incubated with ox-LDL (50.37 μg/mg cell protein) was significantly lower than that in macrophages incubated with ox-LDL alone (83.23 μg/mg cell protein).

Figure 5 shows the changes in cholesterol concentrations in macrophages preincubated with dexamethasone at 0.4 μM in medium and then incubated with ox-LDL after removing of dexamethasone. The CE concentration in macrophages incubated with ox-LDL alone was 62.5 μg/mg cell protein, and the CE concentration in macrophages preincubated with dexamethasone and then incubated with ox-LDL was 39.5 μg/mg cell protein. Therefore, similar to that of the ox-DP complexes, preincubation with dexamethasone inhibited the CE accumulation in macrophages induced by incubation with ox-LDL.

Discussion

Recently, drug−LDL complexes have been examined for use as carriers in site-specific delivery systems.[13−16,22,23] Anticancer drugs have been examined in this drug delivery system. In this study, to study the feasibility of site-specific drug delivery for use in atherosclerosis, the DP−LDL complexes were prepared, and effects of the DP−LDL com-

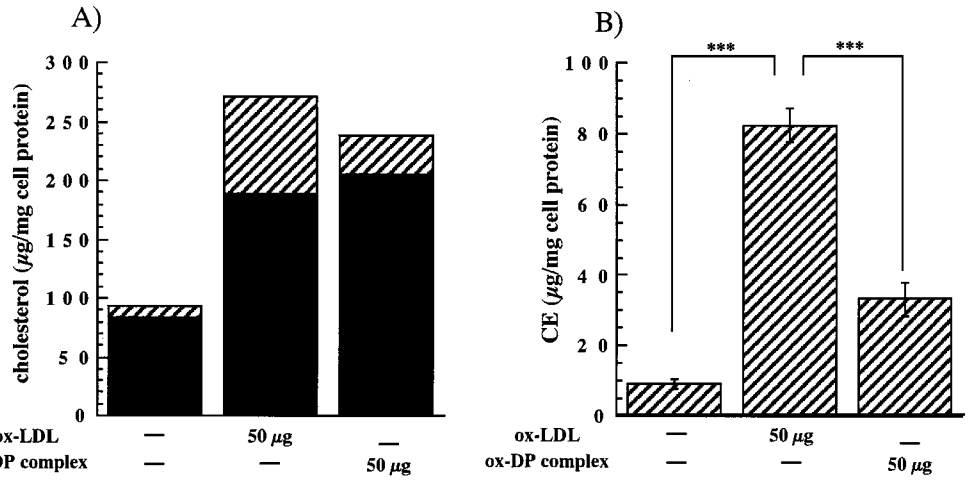

Figure 2—Cholesterol accumulations in macrophages caused by incubation with ox-LDL and the ox-DP complex. Macrophage monolayers were incubated with either ox-LDL or the ox-DP complex (50 μg protein/well, respectively) for 6 h at 37 °C. Final DP concentration in the ox-DP complex medium was 4 μM. After incubation, lipids and protein were extracted, and those levels were measured. In panel A, closed columns and slushed columns are F-ch and CE values, respectively (n = 3), and combined columns' heights indicate T-ch values. In panel B, slushed columns show CE values (mean ± SD, n = 3). The amount of ox-LDL or the ox-DP complex is indicated under the column as protein contents, and "–" indicates the addition of PBS instead of ox-LDL or the ox-DP complexes. Significant differences between groups were determined using a Fisher's PLSD test and are indicated as *** $p < 0.0001$.

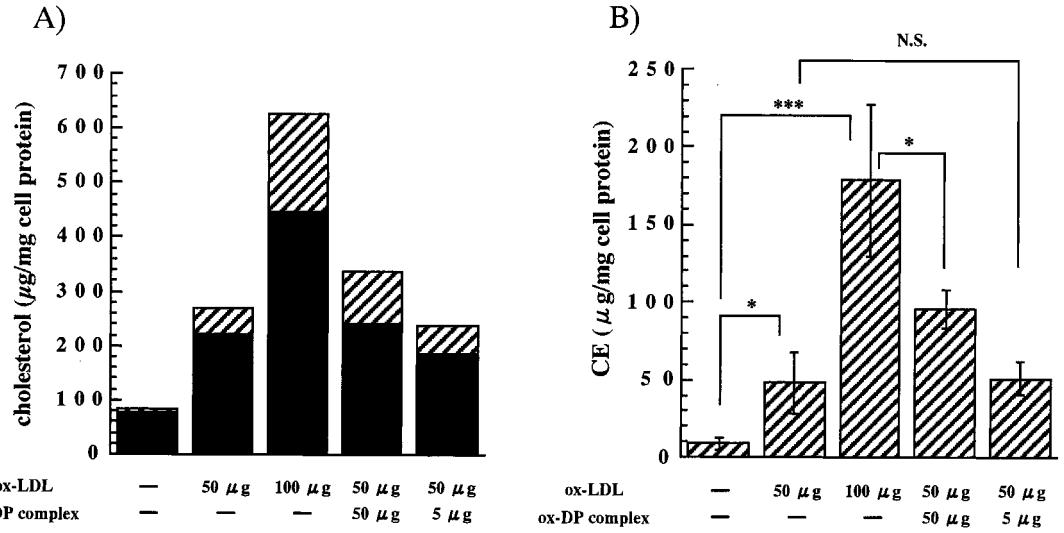

Figure 3—Effect of the ox-DP complex on cholesterol accumulation in macrophages caused by incubation with ox-LDL. Macrophages were incubated with ox-LDL (50 or 100 μg protein/well), or with ox-LDL (50 μg protein/well) and ox-DP complexes (5 or 50 μg protein/well) for 6 h. Final DP concentration in the ox-DP complex medium (5 or 50 μg protein/well) was 0.4 or 4 μM, respectively. Other details are the same as those in Figure 2. *** $p < 0.0001$; * $p < 0.01$. N.S. indicates a difference that is not significant.

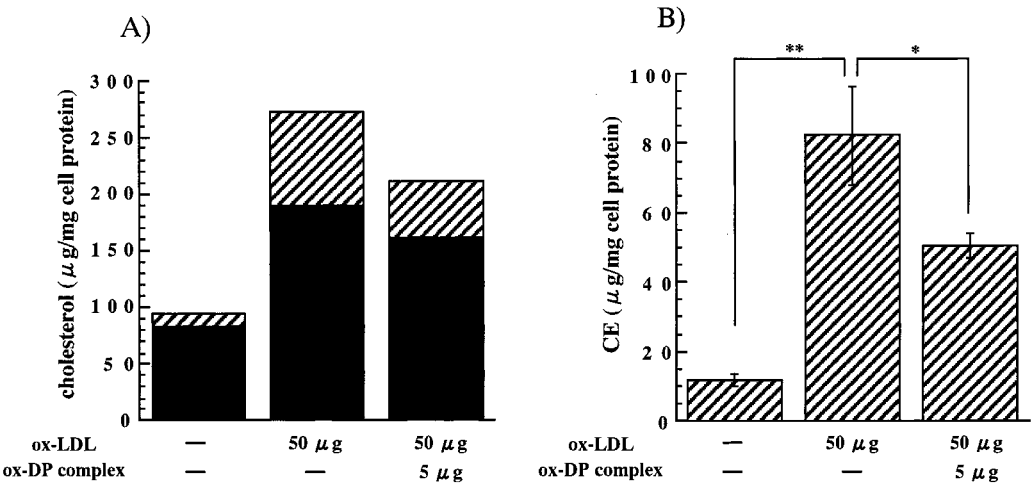

Figure 4—Effect of preincubation with the ox-DP complex on cholesterol accumulation in macrophages caused by incubation with ox-LDL. Macrophages were preincubated with ox-DP complex (5 μg protein/well) for 6 h and then washed with warm medium three times to remove the ox-DP complex. These macrophages were incubated with ox-LDL (50 μg protein/well) for 6 h. Other details are the same as those in Figure 2. ** $p < 0.001$; * $p < 0.01$.

plexes on CE accumulation in macrophages induced by ox-LDL were examined. Because LDL is unstable and easily modified, it was most important to prevent degradation and oxidation of LDL while preparing the DP−LDL complexes. Physiological characteristics and electrophoretic mobilities of the DP−LDL complexes were similar to those of LDL (Table 1 and Figure 1), indicating that the DP−LDL complex can be prepared without degradation, oxidation, and other modifications.

Eley et al.[22] have reported that the particle size (105 nm) of the complex of prednimustine, a steroidal anticancer drug, and LDL is 4 times larger than that of LDL (24.7 nm), and the prednimustine/LDL molar ratio of the complex is 163:1. Lundberg[23] has also demonstrated that the particle size of the prednimustine−LDL complexes is proportional to the concentration of a drug contained in the complex. In this study, however, no significant difference in particle size was observed between the DP−LDL complexes and LDL (Table 2). The reasons for this may be the lower drug concentration contained in our complexes (35−50 mol of DP/mol of LDL) and that the method for complex preparation in our studies was different from that in other studies, in which Celite 545 was not used.

Incubation of macrophages with ox-LDL markedly increased T-ch, F-ch, and especially CE in the cells (Figure 2). Because the accumulation of CE is a good indicator of conversion of macrophages to foam cells,[5,6] the macrophages treated with ox-LDL in this study may be susceptible to foam cell conversion. The accumulation of CE in the macrophages caused by incubation with ox-LDL, however, was significantly attenuated when the macrophages were incubated with ox-LDL containing DP (ox-DP complex). The reduction of CE accumulation may be due to inhibition of CE synthesis or enhancement of CE hydrolysis by DP itself or dexamethasone derived from DP. Asai et al.[12] have reported that dexamethasone can suppress foam cell formations of murine peritoneal macrophages by inhibiting uptake and degradation of lipoproteins.

The T-ch value of macrophages treated with ox-DP complexes was similar to that treated with ox-LDL (Figure 2). This result suggested that ox-DP complexes were incorporated into macrophages by scavenger receptors. Therefore, it is likely that the ox-DP complex can be incorporated into macrophages as well as ox-LDL, and then dexamethasone derived from DP inhibits CE synthesis or enhances CE hydrolysis in macrophages.

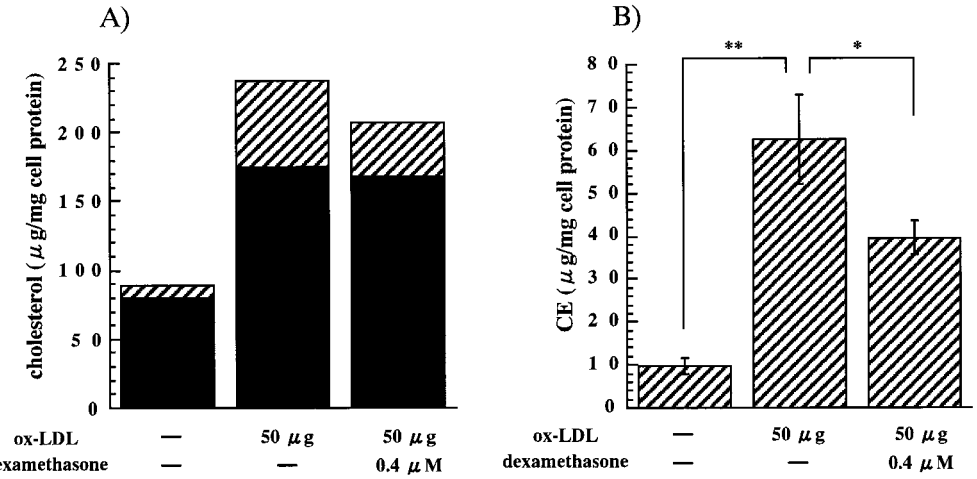

Figure 5—Effect of preincubation with dexamethasone on cholesterol accumulation in macrophages caused by incubation with ox-LDL. Macrophages were preincubated with dexamethasone (0.4 μM) for 6 h and then washed with warm medium three times to remove dexamethasone. These macrophages were incubated with ox-LDL (50 μg protein/well) for 6 h. The amount of ox-LDL (as protein content) or dexamethasone concentration in the well is indicated under the column, respectively. Other details are the same as those in Figure 2. ** $p < 0.001$; * $p < 0.01$.

To confirm the effect of the DP−LDL complex on ox-LDL-induced CE accumulation in macrophages, the cells were incubated with ox-DP complexes together with ox-LDL (Figure 3). Both T-ch and CE contents in macrophages significantly decreased when incubated with 50 μg protein/well of ox-LDL and 50 μg protein/well of ox-DP complexes as compared with those incubated with 100 μg protein/well of ox-LDL alone. This finding indicates that DP or dexamethasone released from ox-DP complexes can reduce the CE accumulation even when the ox-LDL exists simultaneously. However, the lower concentration of ox-DP complexes (5 μg protein/well) showed no effect on the CE accumulation in macrophages incubated with 50 μg protein/well of ox-LDL alone. We considered in this series of experiments that the presence of ox-LDL in 5 μg protein/well of ox-DP complexes is negligible. As shown in Figure 4, we detected a significant attenuation of ox-LDL-induced CE accumulation in macrophages even at 5 μg protein/well (0.4 μM of DP in medium) of the ox-DP complexes, when the cells were incubated with the ox-DP complexes prior to incubation with ox-LDL. Because steroid hormones require a certain period of time to express their effects, the macrophages should be incubated with the ox-DP complexes before incubation with ox-LDL when the concentration of the ox-DP complexes is small. In addition, we examined the effect of free dexamethasone on the CE accumulation in the macrophages induced by ox-LDL. Because free DP was not dissolved in the medium, we used free dexamethasone. The CE accumulation in macrophages incubated with 50 μg protein/well of ox-LDL was significantly inhibited by the pretreatment of the free dexamethasone at 0.4 μM in medium that is the same concentration as that of DP in the ox-DP complexes (Figure 5).

The inhibitory effect of free dexamethasone on the foam cell formation was the same extent as that of the ox-DP complex in the in vitro experiment. This result indicates that ox-DP complexes as well as free dexamethasone can exert a beneficial effect on atherogenic response in vitro. If the DP−LDL complex delivers DP to the atherosclerotic lesions, this complex acts more effectively than free dexamethasone in vivo.

In conclusion, the DP−LDL complex can be prepared by incubation of DP and LDL in the presence of Celite 545, and this complex shows the same lipid composition and electrophoretic mobility as that of LDL. Although this complex is easily oxidized like LDL, the ox-DP complex inhibits CE accumulation in macrophages induced by the ox-LDL. These findings indicate that the DP−LDL complex can be potentially useful as a drug−carrier to atherosclerotic lesions, and reduce foam cell formation in patients with atherosclerosis.

Received September 30, 1998. Accepted for publication April 19, 1999.

Abstract □ A general spectroscopic method is described that might be applied to validating amino acid sequences in peptides and protein fragments with a view to it becoming a routine procedure with which to characterize biotechnology drug products. The tripeptides are the L-enantiomers of GGA, GGH, GGI, GGL, GGF, GHG, LGG, and YGG. The simple procedure calls for their complexation with Cu(II) ion in strong aqueous base. Binding the first three residues in the sequence, beginning at the amine terminus, completes the coordination sphere of the Cu(II) ion, so duplication of the initial sequence from peptide to peptide could be an important limiting factor in determining the extent of differentiation that is possible. The analytical focus is the selectivity associated with the chirality properties of the peptides. Detection is by circular dichroism operating in the visible range. The eight analytes were chosen as representative of a series where the sequences are most similar and therefore potentially the most difficult to discriminate spectroscopically. All have just one chiral center. Using ellipticity data at all ($n = 1500$) wavelengths in the measured spectra, and two novel data reduction procedures, total discrimination among all eight analytes is achieved. The method has considerable potential for use in quality control of peptide and protein biotechnological drug forms, especially their enantiomeric purities.

Introduction

Modern pharmaceutical and biotechnology conglomerates are committed to the production of chiral drug substances.[1,2] Manufacturers have the option to prepare chiral drugs either as pure single substances (enantiomers) or as racemic mixtures. While racemates are easier to make, many good reasons exist for choosing to manufacture enantiomerically pure forms, not the least of which are considerations of the relative therapeutic values and relative toxicity levels of each enantiomer either by itself or as half of a racemate. All of this means that there is a need for simple routine analytical methods that are adaptable to all chiral drug forms which can be used for regulatory control of their chemical and enantiomeric purities (EP), whether it is done by the manufacturer or by a federal agency.

Analytical options currently applied to these tests generally involve simultaneous derivatization of both enantiomers in a partial racemic mixture to their corresponding diastereoisomers by selective reactions with a third chiral species. Unlike enantiomers, diastereoisomers can be differentiated by physical properties other than just the direction of rotation of linearly polarized light.[3] Chiral chromatography is a major player in the development of these methods. The chiral third party is introduced either in the mobile phase or immobilized on the stationary phase.[4,5] Since diastereomers elute after different retention times, achiral detectors, e.g., absorbance, electrochemical, and mass spectrometry, are sufficient to effect quantitative distinctions, within the limit of the detection capabilities of the chosen methods.

If the experimental preference is to determine chemical purities without a prior separation step, spectroscopic procedures generally call for the use of two detectors, one of which is a chiral detector such as polarimetry or circular dichroism (CD).[6−8] By combining CD with absorbance detection, measuring spectral differences or spectral ratios are different strategies that can be applied to handling the data. Generally speaking most of these methods are based on single wavelength detection data.

By combining multiple wavelength detection with modern chemometric methods for data analysis, a third alternative procedure was described.[9,10] The procedure exploits the best characteristics of both of the other methods, namely a single chiral detector, bulk in situ derivatizations, and no separations. Results obtained for the determinations of chemical and enantiomeric impurities using visible CD detection for binary mixtures of the four ephedrine stereoisomers complexed to Cu(II) ion were an improvement over what was capable at that time by either the chiral chromatographic or two-detector methods.

A major new frontier in the pharmaceutical industry is the focus on the therapeutic properties of peptide and protein drug forms. Because the number of chiral centers has virtually no limit, the magnitude of the chirality regulatory control problem is increased almost exponentially. Since derivatizations will not produce a single diastereoisomer, even the very best chiral chromatographic methods face what are probably insurmountable challenges unless the peptides are first cleaved enzymatically.

Problems that are associated with chirality detection also increase. The total CD signal for a metal−peptide complex is not determined by just the number and sequence of chiral centers in the primary peptide structure. It also includes contributions from longer range chiral interactions between side-chain substituents that modify the ternary structure when peptides are coordinated to metal ions. Experimental conditions must be very carefully controlled, otherwise these very pH-sensitive structural modifications would give false information about the analyte to the detector. On the other hand the simple accumulation of these additive chiral properties could conceivably produce a level of analytical selectivity that is unmatched by other detectors and might even approach specificity. Enzymatic cleavage followed by CD detection is also an option. What chirality detection contributes that the others do not is a direct look at the enantiomeric form. This ability will increase in value as long as manufacturers continue to use D- for L-enantiomeric substitutions as a strategy in peptide drug design.

Eight tripeptides were chosen for the study. Common to all eight are two glycine residues which occupy positions 1,2-, 1,3-, and 2,3- in the sequence. The remaining residues are L-enantiomers of aliphatic and aromatic amino acids. The tripeptides have no stable ternary structure to speak of, so variability in the sequence is really the only parameter affecting the chiral response of the CD detector. The order of residues in short peptides is crucial to the extension of the study to peptides and proteins as a whole because coordination of the latter to Cu(II) involves the first

10.1021/js980393o CCC: $18.00
Published on Web 05/20/1999

three amino acids from the amine terminus. If there is no CD selectivity associated with changes in the initial sequence, the method has no value in the study of oligopeptides and proteins where too frequently the same initial sequence is common to several potential analytes.

The experimental procedure is a combination of the methods that were used to discriminate among related dipeptides[11] and insulins[12] and to measure EP's for glycyl-L-alanine and ephedrine mixtures.[9−11] Data reduction and spectral differentiations are done using variations on standardized mathematical algorithms and principal component analysis (PCA).

Experimental Section

Chemicals—Tripeptides used in the study were glycylglycyl-L-alanine (GGA), glycylglycyl-L-histidine (GGH), glycylglycyl-L-isoleucine (GGI), glycylglycyl-L-leucine (GGL), glycylglycyl-L-phenylalanine (GGF), glycyl-L-histidylglycine (GHG) and its D-enantiomer (GhG), l-leucyl-glycylglycine (LGG) and its D-enantiomer (lGG), and L-tyrosylglycylglycine (YGG) and its D-enantiomer (yGG). All eight L-enantiomers were supplied by Sigma Chemical Co. which reported an EP in excess of 99.8%. The D-enantiomers GhG, lGG, and yGG of GHG, LGG, and YGG were prepared by Multiple Peptide Systems (MPS), San Diego, CA. Certificates of Analysis described them as unpurified off white powders. Percent purities as determined by RP-HPLC analyses were reported as 86.57, 99.10, and 97.86, respectively. The low value for GhG is explained as being due to two elution peaks that correspond to the same compound. The percentage is based on the relative area of the first peak which corresponds with most of the material eluting with the void volume peak. The second peak is related to the hydrophobicity of the molecule that causes it to stick to the column to be eluted later. D-Histidine was also a Sigma Chemical Co. product with an EP reported at better than 99.8%. Reagent grade $CuSO_4 \cdot 5H_2O$ was obtained from Fisher Scientific.

Solution Preparations—The chemistry of the derivatization reaction is a simple chiral variation of the classical biuret "color reaction" for the determination of total serum proteins in which the reagent is a solution of [Cu(II)] = 2.0 mM and [tartrate] = 8.0 mM in 0.1 M NaOH. Racemic NaK-tartrate is the solubilizing ligand for Cu(II) and is completely exchanged by protein in the test. The chemistry for the reaction is well understood and relatively uncomplicated.[13] Determinations were done based upon absorbance spectrophotometric detection. Being relatively insensitive and not sufficiently selective, the biuret reaction is no longer the method of choice for serum proteins.

In this instance, aqueous stock solutions at pH 13 were prepared for Cu(II)−D-histidine and each of the Cu(II)−L-tripeptide complexes in which the Cu^{2+} concentration was always 0.020 M. Ligands were present at 0.080 M concentrations, a 4:1 excess over the Cu(II) ion. KI at a concentration of 0.03 M was added as a stabilizer.[9,10] Spectra were measured for working solutions prepared by diluting stocks by a factor of 10 with 0.10 M NaOH. Spectra for the working solutions are the bases for testing the extent of the qualitative analytical selectivity accessible to CD detection.

Quantitation tests were done on two kinds of mixtures. For the first kind, GGA was arbitrarily selected as an enantiomerically pure "reference" material. Aliquots from the stock were spiked with "chemical impurities", i.e., smaller volume aliquots of the other L-tripeptide stocks to cover the impurity range from 1 to 10%, prior to dilution with NaOH. For the second, "enantiomeric purity" tests, aliquots of YGG, LGG, and GHG stocks were spiked with smaller volume aliquots of the corresponding D-enantiomer stocks, yGG, lGG, and GhG, over the same 1−10% impurity range.

Measurements—CD spectra were measured using a Jasco 500-A automatic recording spectropolarimeter coupled to an IBM-compatible PC through a Jasco IF-500 II serial interface and data processing software. Experimental parameters: wavelength range 400−700 nm; sensitivity 100 mdeg/cm; time constant 0.25 s; scan rate 200 nm/min; path length 5.0 cm; ambient temperature.

Calibration of the day to day reproduciblity of the system was done by measuring the CD spectrum for the Cu(II)−D-histidine complex. Statistical data for reproducibilities of the maximum ellipticities measured at wavelengths 487 nm and 682 nm were 7.42 ± 0.07 mdeg and −214 ± 0.60 mdeg, respectively.

Results and Discussion

Cu(II)−Peptide and D-Histidine Complexes—The local microsymmetry of the Cu(II) ion in aqueous solution is essentially square-planar due to axial elongation of the typical octahedral symmetry, assumed by most first row transition metal ions, by Jahn−Teller distortion.[14] Complexation serves to keep the Cu(II) ion in solution at high pH conditions. At pH 13, D-histidine and the amide-nitrogen protons are fully ionized,[15] which essentially eliminates competitive complex formation equilibria when partially protonated anions are present in solution at lower pH.

D-Histidine, the ligand used for instrument calibration, binds via the amine N-atom, the carboxylate functional group, and a pyrimidine N-atom in an equatorial three-coordinate arrangement. Stoichiometry for the complex is 1:1.[15] Complexing a peptide to Cu(II) at pH > 12 involves first attachment through the N-atom of the terminal amine followed by ring closure(s) through bonding with the N-atoms of successive amide bonds until maximum thermodynamic stability is achieved.[15] Side chain substituents on the amino acid residues lie out of the coordinate plane and are factors only in inter- and intramolecular interactions within the inner coordination sphere, unless a potential Lewis base is present, e.g., a histidine residue. Axial positions might be occupied by hydroxide ions which is the only feature that might complicate the stoichiometry of the generic metal−peptide, $(MP)_n$, equilibrium.[16]

By analogy with the Cu(II)−D-histidine equilibrium reaction, the stoichiometry of the Cu(II)−tripeptide complexes is also believed to be 1:1. If the only purpose of the study were to develop analytical selectivity, the question of the stoichiometry of the metal−tripeptide complexes is not relevant. If the stoichiometry were to change from one ligand to another, the analytical selectivity might very well be enhanced. It is only when making an analytical determination by conventional mathematical procedures that knowledge of the stoichiometry is a prerequisite.

CD activity in the visible range for chiral Cu(II) complexes is a result of disymmetric perturbations of ground and excited state ligand field orbitals by the chiral ligands. Bands in the UV range, attributable to only the chirality in the ligands, bound and unbound, are typically very intense but quite insensitive to the environment of the coordinating metal ion. The lack of selectivity is the major reason for not exploiting the obvious analytical sensitivity that is inherent in the intense UV bands.

Visible CD Spectra for Cu(II)−Tripeptide Complexes—Spectra for all eight copper−L-tripeptide complexes, in which [Cu(II)] = 2.0 mM and ligand concentrations are 8.0 mM, are shown in Figure 1. Only GGH, GHG, LGG, and YGG are uniquely differentiable by their zero order CD spectra. Spectra for the histidyl-containing ligand complexes, GGH and GHG, are blue shifted compared with the Cu(II)-D-histidine complex itself which has an intense negative band with a maximum at 689 nm and a weaker positive maximum at 570 nm. The magnitude of the shift is greatly dependent upon the position occupied by the histidyl residue. The sensitivity of the CD spectral response to the histidine position is a significant first result in the context of possibly sequencing short peptides by this spectroscopic method.

Of the five GGX peptides, only the spectrum for GGH is unique, which might be attributable to a special involvement of the pyrimidine N-atom in binding to Cu(II). The remaining four have but one broad negative band that

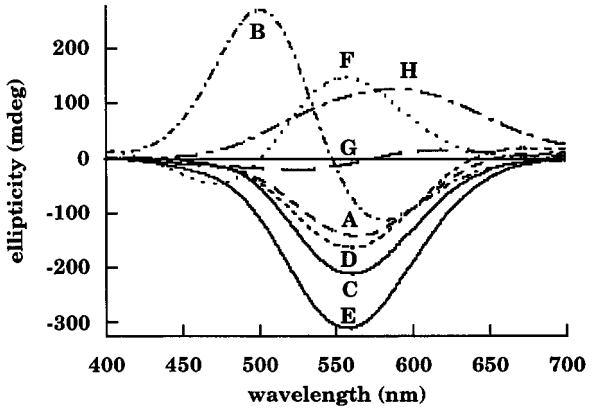

Figure 1—Visible CD spectra for the Cu(II) complexes of (A) GGA, (B) GGH, (C) GGI, (D) GGL, (E) GGF, (F) GHG, (G) LGG, and (H) YGG. Similarities are greatest for the GGA, GGI, GGL, and GGF complexes over the entire wavelength range.

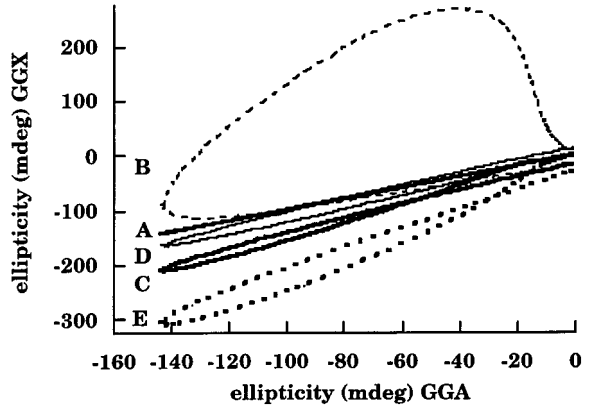

Figure 2—Correlation plots of ellipticity for the Cu(II)GGA complex versus the ellipticities for the analogous complexes with equimolar amounts of (A) GGA, (B) GGH, (C) GGI, (D) GGL, and (E) GGF.

maximizes around 550 nm. Aromaticity in the side chain may (YGG) or may not (GGF) induce a spectral change, which with further developments, might be exploited for short range sequencing. There is ambiguity in differentiating among GGA, GGI, GGL, and GGF unless the solution concentrations are carefully controlled.

The L-leucine structural isomers can ostensibly be differentiated in a quality control context. The lack of band intensity for the LGG is a potential problem in quantitation. Although the glycyl residue is achiral, the relative positions that it occupies affect the CD spectra quite

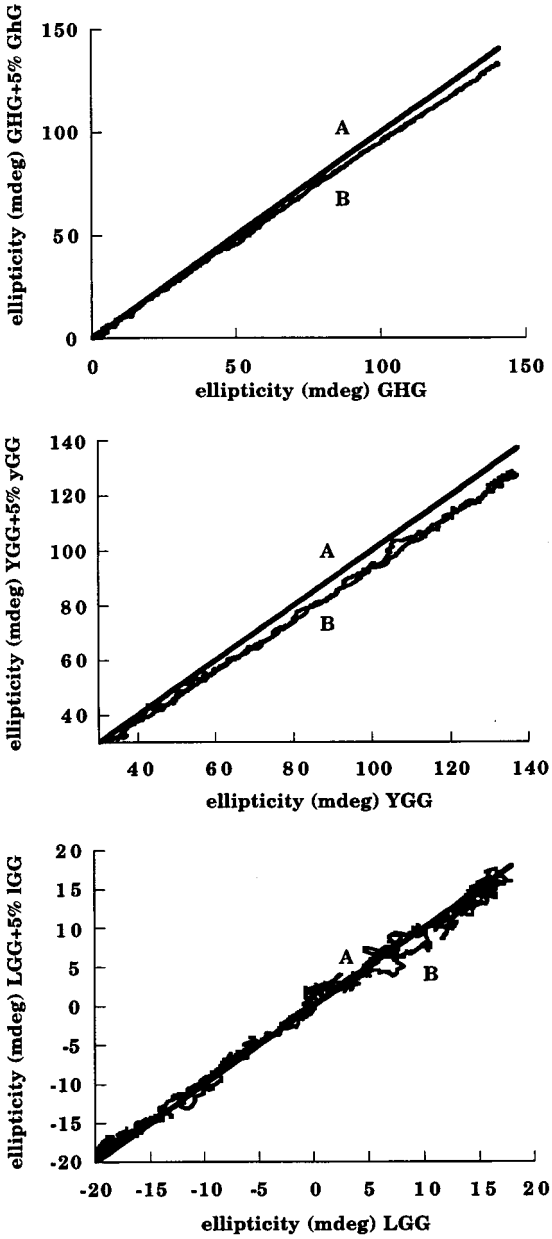

Figure 4—Correlation plots of ellipticities for the Cu complexes of L-GHG, L-YGG, and L-LGG versus ellipticities for 5% racemic mixtures with GhG, yGG, and lGG. In each case line A is for the L-enantiomer against itself and line B is for the L-enantiomer against the mixture.

dramatically, which is good reason to believe that specific interligand interactions occur within the first coordination sphere of the complex.

It is quite clear at this point that total differentiation among all eight analytes is not possible.

Alternative Algorithms for Data Reduction and Enhancing Selectivity—Conventional algorithms typically deal with data measured at just the wavelength of the maximum signal; unless a chemometrics approach is employed.[17] The intent of the algorithms described here was to start with ellipticity data measured at all 1500 wavelengths and, using novel mathematical procedures, reduce the data to a single variable (or factor) upon which selectivity decisions are made. Having a simple numerical means for making selectivity judgments is superior to relying upon subjective graphical superpositions of the CD spectra. Furthermore, if that same numerical factor were to correlate linearly with ligand concentration, then quantitative differentiations might also be accomplished. As a

Table 1—Determination of Enantiomeric Purities for Prepared Binary Mixtures of GHG/GhG, LGG/lGG, and YGG/yGG

% L-form in prepared solution	regression slope (enantiomeric excess)	regression coefficient

95	0.9359	0.9996
90	0.8854	0.9995

final consequence, resultant analytical determinations will be more accurate since experimental uncertainties are significantly reduced when 1500 data points are used rather than only one.

A 2-D Data Reduction Algorithm for Enhancing Selectivity—To illustrate this data reduction procedure, GGA is arbitrarily assigned the status of an enantiomerically pure standard reference material. In a pharmaceutical context, GGA might represent a commercial drug product. The others fill the roles of potential "chemical" and "enantiomeric" impurities.

The simple concept is to plot the 1500 data points for the 8.0 mM GGA spectrum (on the *x*-axis) against analogous data for 8.0 mM solutions for each of the others (on the *y*-axis). To get a baseline reference check for the absolute enantiomeric purity of GGA, its CD spectrum is plotted on both axes. The correlation is a straight line of unit slope and zero intercept. Spectra for the remaining seven tripeptide complexes are plotted against GGA in Figure 2 for the GGX subseries and in Figure 3 for the other sequences.

Plots are decidedly nonlinear and individually distinct from one another. The ellipsoidal shapes for GGI and GGL might appear similar but the best-fit lines do have different slopes. On enlargement, however, the ellipse for GGI is seen to "fold over" on itself in a partial figure 8, implying a latent three-dimensional property in these plots. The same phenomenon can be seen more clearly for the plot of the GGH analogue vs GGA in Figure 3. Differentiation among enantiomerically pure forms of the tripeptides has apparently been achieved at least when the number of possibilities is limited to a small closed set, as they are here. It should be emphasized that in order to reproduce these curves exactly the concentrations must be carefully controlled.

The only other possible correlation line of unit slope (but opposite in sign) and zero intercept is the plot of GGA vs the D-enantiomer, GGa, if their purities are equivalent. This is a consequence of their being chemically identical. The feature that is common to all cases where spectra for chemically dissimilar compounds are correlated is splitting of the correlation line relative to the ideal reference line. Some splittings are extreme, Figures 2 and 3. Conversely, if the correlation plot of the CD spectrum for a newly manufactured lot of GGA vs the reference is linear with a slope less than one, and shows no evidence of splitting, this

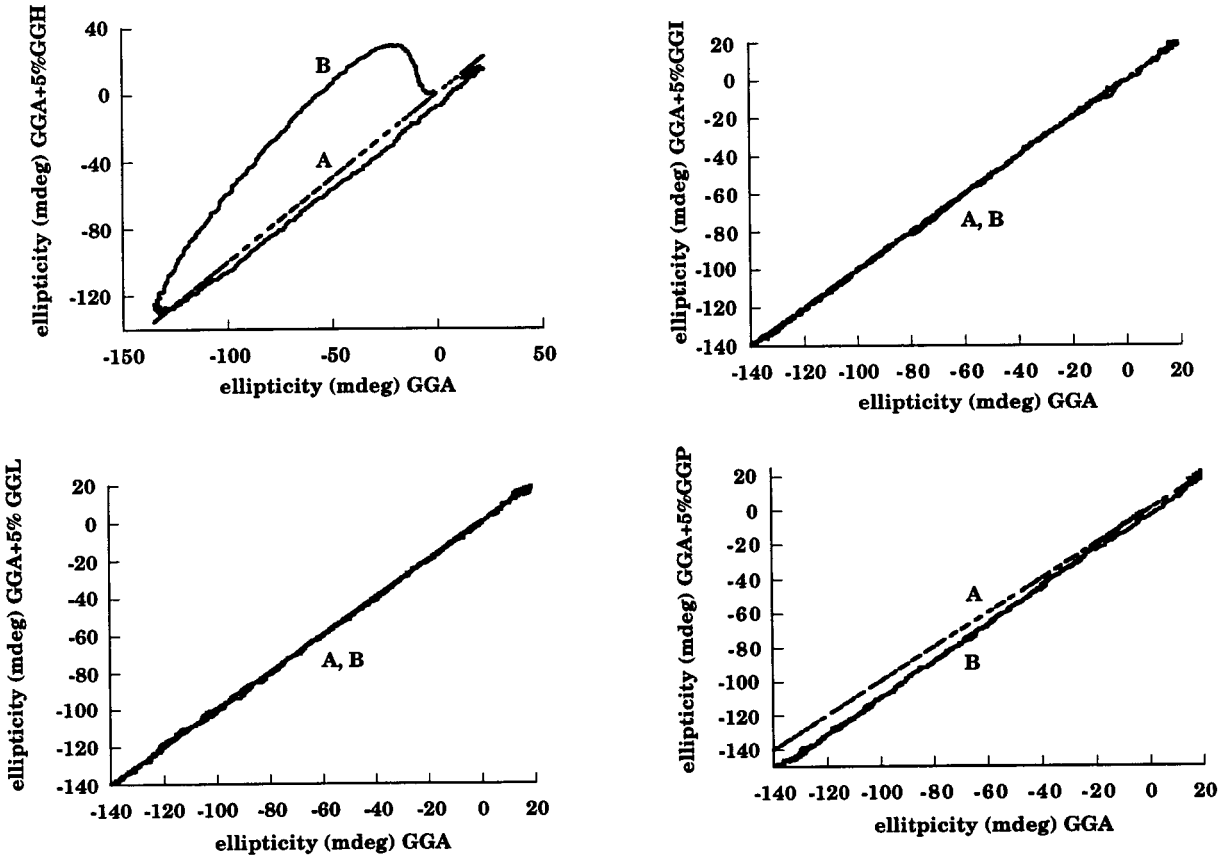

Figure 5—Correlation plots of ellipticity for the Cu(II)–(GGA) complex versus ellipticities for 5% chemical mixtures with GGH, GGI, GGL, and GGF. In each case line A is for GGA against itself and line B is for GGA against the mixture.

is evidence for the presence of the enantiomer. Splitting is instant evidence for the presence of a chemical impurity.

Nonlinear plots, typical of Figures 2 and 3 do not yield easily to quantitation of the "chemical impurities".

(a) Quantitation of Enantiomeric Mixtures—Enantiomeric purity tests were made on three analyte pairs, GHG/GhG, LGG/lGG, and YGG/yGG. As the D-enantiomers were added in increasing amounts, over the range 1, 3, 5, 10% of the L-enantiomer concentration, the slopes of the correlation lines decreased. Data are shown for 5% "impurity" levels only, Figure 4.

Judging by the regression coefficient of 0.9998 for the GHG vs GhG plot, there is no significant loss of linearity compared to the reference baseline, meaning that the EP of GhG is equivalent to that of GHG. The explanation given in the Experimental Section for the low percent purity for GhG, as described in the MPS Certificate of Analysis, is apparently vindicated by the results of this spectroscopic method. Splitting of the YGG/yGG correlation line is consistent with the MPS reported purity level of 97.86% or total impurity of 2.14%. Noise on the LGG/lGG correlation line conceals whether there is splitting of the line or not. A poor S/N ratio is expected since the CD spectral intensity for LGG is the weakest, Figure 1,being approximately one-tenth of the band intensities for the other tripeptides.

Enantiomeric excess, defined for example as:

$$\{[Cu(II)(GHG)] - [Cu(II)(GhG)_x]\}/\{[Cu(II)(GHG)] + [Cu(II)(GhG)_x]\}$$

is given by the correlation slope for each mixture. Calculated values for spiked GHG solutions are in excellent agreement with the measured values for prepared mixtures, Table 1. Imprecisions based on data from three to five repeat measurements are an improvement by almost a factor of 10 over results obtained from the analyses of binary ephedrine mixtures in which a chemometric analysis method was applied to data at five wavelengths.[9] Despite the splitting of the YGG/yGG and the noise in the LGG/lGG plots, by using best-fit correlation lines, the agreements between calculated and measured EP's are still very good. The method is quantitatively valid over the full range of enantiomeric ratios from 100% L to 100% D.

(b) GGA +"Chemical Impurity" Levels for All Other Tripeptides—The question with respect to "chemical impurities" that needs to be addressed is not how great the differences are between the curve for an 8.0 mM solution of GGA and curves for the other tripeptides at equimolar concentrations, Figures 2 and 3, but rather, are the differences sufficient enough to identify and quantitate anonymous chiral "chemical impurities" when these amount to only a few percent of the total composition of a binary mixture? The answer to the question lies in how sensitive the CD detector is in discovering splitting of the correlation line when spectra for "impure" samples are plotted against the spectrum for the primary reference standard.

Spectra were measured for mixtures in which GGA solutions were spiked with small volumes of the other L-tripeptides at levels of 1, 3, 5, and 10%. Data for only the 5% mixtures are plotted in Figure 5 for the GGX subseries and in Figure 6 for GHG, LGG, and YGG. Splittings range from being very small, where they are barely discernible, e.g., for GGI, GGL, and GGF, to extreme, for GGH, GHG, and LGG. Where they are small, the best-fit lines, determined by simple linear regression, are seen to deviate from the unit slope of the reference line. Because of the "absence" of splitting at the lowest concentrations, the plots fail to confirm the presence of GGI, GGL, or GGF at a level of 5% or less, Figure 5. In general the extreme nonlinearity of the split correlations associated with chemical impurities makes it very difficult to determine the amount of impurity.

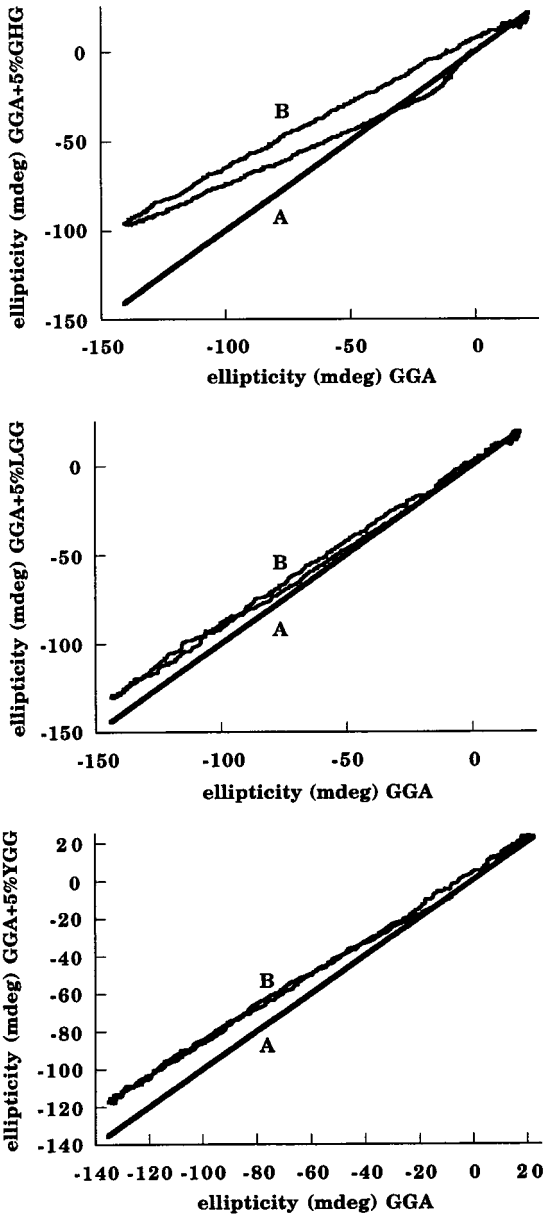

Figure 6—Correlation plots of ellipticity for the Cu(II)–(GGA) complex versus ellipticities for 5% chemical mixtures with GHG, LGG, and YGG. In each case line A is for GGA against itself and line B is for GGA against the mixture.

Briefly recapping the results, the 2-D algorithm has effectively reduced the 1500 spectral data points to one number (the correlation slope), from which EP's can be determined with excellent accuracy over the complete range. Recognition that a potential "chemical impurity" is present is elementary for a limited number of cases, but its analytical determination is not easily done.

A 3-D Data Reduction Algorithm for Enhancing Selectivity—The objectives that relate to this second data reduction algorithm were to discover if the GGA, GGI, GGL, and GGF series can be completely differentiated both qualitatively and quantitatively. The same objectives were achieved when the 3-D algorithm was applied to a series of dipeptides all of which had just one chiral center.[11]

In the 2-D presentations of Figures 2, 3, 5, and 6, wavelength is an implied variable. For the evolution of the 3-D algorithm, wavelength is the third dimension. Since

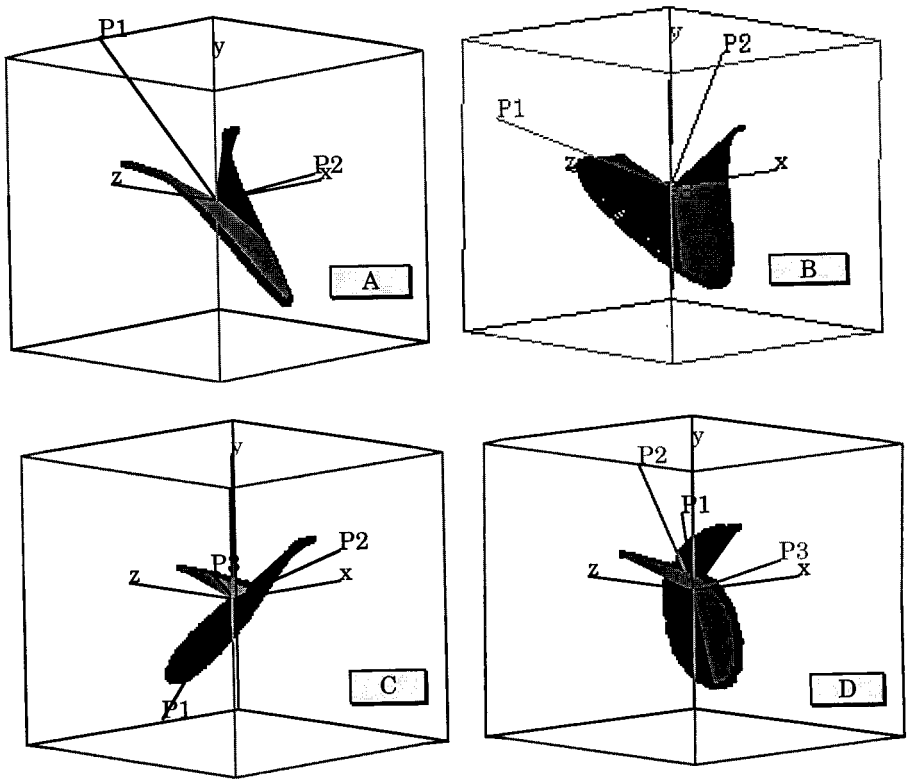

Figure 7—Spinning Plots for the presentation of wavelength (*x*-coordinate), spectral data for the GGA complex (*y*-coordinate), and spectral data for (A) GGA, (B) GGH, (C) GHG, and (D) LGG complexes. The lines P1, P2, and P3 are the principal component axes from the PCA solutions. Dark and light areas distinguish the front four quandrants of the cube from the rear four quadrants.

the experimental parameter measured in CD detection is an absorbance difference, observed signals are positive, negative, and zero. When two CD spectra are plotted against each other, four sign combinations are possible at any wavelength. Repeats of coordinate points, e.g., zero crossover points, can occur at wavelength values that are not adjacent to one another in the spectra. When that occurs, 2-D plots "wrap around" and become three-dimensional. In retrospect what are observed as 2-D plots are simple projections of the 3-D plots on to the $x-y$ coordinate plane, which explains why some of the plots in Figures 2 and 3 appear to have a 3-D character. The added value of the third dimension is that there should be an increase in the overall analytical selectivity.

The algorithm used for the visual presentation of the three-parameter plot was Spinning Plot[18] which is an integral part of a number of commercially available statistical analyses software packages. The software used for these calculations was JMP 3.1 produced by SAS Institute Inc. Four 3-D plots of wavelength (nm) vs ellipticity data for GGA vs ellipticity data for GGA, GGH, GHG, and LGG are shown in Figure 7. By analogy with the 2-D algorithm procedure, GGA plotted against itself is included to provide a baseline for comparison. Front and back quadrants are distinguished by dark and light shading to enhance the 3-D presentation. Discriminations are clearly more evident than they were in Figures 5 and 6.

Factor Analyses of Spinning Plot Data—To derive a quantitative mathematical algorithm, data reduction was done using a Principal Component Analysis (PCA) procedure on the Spinning Plot data.[18] Eigenvalues and eigenvectors for the three principal components, P1, P2, and P3, calculated for the GGA/GGH combination plot are given in Table 2. Spatial projections of these same principal components are superimposed on the coordinate axes of Figure 7.

Table 2—**Principal Components Calculated for the GGA versus GGH System**

		P1	P2	P3
eigenvalues		+1.9603	+0.9798	+0.0599
eigenvectors	nm	+0.19154	+0.97273	–0.13080
	GGA	–0.68522	**+0.22794**	+0.69175
	GHG	+0.70270	–0.04287	+0.71019

Of the twelve resultant eigenfactors, the one that is most sensitive to variations in the identity of the analyte is P22, highlighted in bold type in Table 2. The 22 tag indicates the entry is in the second row of the second column of the eigenvector matrix. Comparative P22 values for all combinations with GGA are as follows: 0.04519 (vs GGA); 0.88194 (vs GGH); 0.13171 (vs GGI); − 0.01932 (vs GGL); 0.10312 (vs GGF); 0.22794 (vs GHG); 0.89248 (vs LGG); 0.57491 (vs YGG). Standard deviations in P22 determined for data from three to five independent repeat measurements are ±0.002, meaning that total analytical selectivity is accomplished. The 3-D algorithm effectively reduced the 1500 original spectral data points to a single discretionary number, P22. The test sets up well in a quality control environment for proving that a chiral substance is or is not a single chemical.

The remaining question is whether the test has the potential to be quantitative. If P22 values were to correlate linearly with the amount of "chemical impurity", then EP's can be determined by difference. Representative plots of P22 vs percent impurity for solutions of GGA spiked with GGH, GGF, LGG, and YGG are shown in Figure 8. The plots cease to be linear when the impurity concentration approaches 2.0 mM, the concentration of the Cu(II) ion. Differences in the slopes of these lines assist in the identification of the chiral impurity. With the exceptions of GGI and GGL, correlation slopes are greater than two

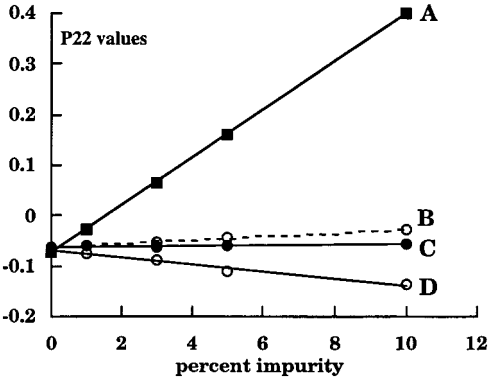

Figure 8—Linear plots of the percent chemical impurity versus the eigenvector P22 for the Cu complex of GGA at a concentration of 8.0 mM spiked with increasing amounts of (A) GGH, (B) GGF, (C) LGG, and (D) YGG.

times the ±0.002 SD in the mean for P22 values, which means that impurity levels as little as 1−3% can be measured with confidence provided the impurity is a single chiral substance. Analytical sensitivities are at least 10 times more accurate than analogous plots in which maximum ellipticity values measured at a single wavelength are plotted against concentration. Why this is so is easily understood when one sees changes in maximum ellipticity values at a single wavelength over the 1−10% impurity range that are less than the best resolution of ± 2.0 mdeg for the CD instrumentation used in this study. The additional accuracy comes from the ability to conveniently include data at 1500 wavelengths.

Where the 2-D method succeeded in providing a means to get accurate values for EP's, the 3-D method provides a way to get a quantitative measure of nonenantiomeric chiral impurities.

Summary and Application of the Method

By the simple chiral modification of the biuret reagent, combined with two novel data reduction algorithms for the handling of visible CD data, a potentially useful QC regulatory procedure for peptides, oligopeptides, and proteins has been developed.

A typical procedure begins with the measurement of the visible CD spectrum for the Cu(II) complex of the chromatographically purest available form of the substance being regulated. Data are archived in a computer file onboard the spectrometer and are updated each time the reference material is measured. Spectra for aliquots taken from each newly manufactured product lot are plotted against the standard and successive on-screen visual comparisons are made.

Deviation from a slope of 1.0 in the 2-D test is an instant indication that the purity is less than that of the reference standard. If the value of the regression coefficient indicates an enantiomeric "impurity", the EP is readily calculated from the regression slope. Splitting of the correlation line for the standard reference material gives instant recognition that a "chemical impurity" is present whose identity may be confirmed by the P22 value calculated from the Spinning Plot algorithm. The percent impurity is calculated from the correlation slope of the P22 vs impurity line.

The two algorithms are complementary in the sense that whereas the 2-D model is capable of measuring EP's with excellent accuracy but only capable of differentiating qualitatively among the eight tripeptides, the 3-D model was capable of quantitatively measuring the compositions of binary mixtures of dissimilar compounds, but incapable of measuring EP's. The latter was not discussed in detail, but is a consequence of the fact the P22 values for an enantiomeric pair are invariant with concentration.

The method is quick, rugged, uses stable inexpensive reagents, requires no specific precautions, and a minimum of technical expertise for a potential operator. Derivatization reactions are instantaneous and data collection is done in a matter of minutes. Spectral data are stored on an onboard computer that is programmed to perform all the mathematical comparisons and quantitative analyses in situ.

All of these advantages point to a very satisfactory and very competitive routine alternative to chromatographic and mass spectrometry methods for the quality control of small peptides. Its successful applications to oligopeptides and proteins[12] are the subjects of subsequent articles.

Predicting the Total Entropy of Melting: Application to Pharmaceuticals and Environmentally Relevant Compounds

ROSE-MARIE DANNENFELSER*† AND SAMUEL H. YALKOWSKY‡

Contribution from *Novartis Pharmaceutical Corporation, 59 Route 10, East Hanover, New Jersey 07936, and College of Pharmacy, University of Arizona, Tucson, Arizona 85721.*

Received August 31, 1998. Accepted for publication April 21, 1999.

Abstract □ Experimental entropy of melting values for physical property estimation schemes, such as solubility and vapor pressure, are not readily available. In this study a semiempirical equation, which contains two molecular parameters, is used to estimate the total entropy of melting for a variety of pharmaceutically and environmentally relevant compounds. A database of experimental entropy values consisting of over 370 different compounds was compiled from literature. A molecular rotational symmetry number and a molecular flexibility number for each compound were defined. The simple equation does very well in predicting the total entropy of melting for the complex set of molecules with an average error of 21%.

Introduction

The physicochemical properties of compounds are important in many fields, including the pharmaceutical and environmental sciences. Property estimations can help to minimize time and cost in drug formulation development. They are also useful in assessing exposure limits for new chemical entities. Aqueous solubility and vapor pressure are among the most important of these properties. These properties can be estimated by the rearrangement of the Clausius−Clapeyron equation. For instance, the following equation can be used to predict the ideal mole fractional solubility:[1]

$$\log X_i = [-\Delta H_m(T_m - T)/(2.3RT_mT)] - \Delta C_p/R[\Delta H_m (T_m - T)/(2.3T) + \log(T_m/T)] \quad (1)$$

where ΔH_m is the enthalpy of melting, ΔC_p is the heat capacity difference between the crystalline and the molten form, R is the gas constant, T and T_m are temperature and the melting point in Kelvin. This equation can be simplified to:

$$\log X_i = -\Delta S_m(T_m - T)/(2.3RT) \quad (2)$$

by replacing $\Delta H_m/T_m$ with ΔS_m, the entropy of melting, and assuming that ΔS_m is large compared to ΔC_p.

As can be seen from eqs 1 and 2, the melting point and either the enthalpy of melting or the entropy of melting are required. Unfortunately, the values of the two latter parameters are usually not readily available. The entropy of melting can either be assumed to be a constant (by Walden's rule or Richard's rule) or estimated from structure. Walden's rule is based on aromatic hydrocarbons while Richard's rule is applicable to small, spherical molecules. There are two types of structure-based estimation schemes found in the literature: group contribution methods such as those of Chickos and co-workers[2,3] and Domalski and Hearing,[4] and the semiempirical equation of Yalkowsky and co-workers.[5−8] The group contribution methods which employ tables of values for each group or fragment are cumbersome to use and some times have missing group fragments, whereas the semiempirical equation which uses two nonadditive molecular descriptors is easy to use and can be employed for all nonelectrolytes.

The following semiempirical equation was shown to work quite well in estimating the total entropy of melting for nonelectrolytes:[5,8]

$$\Delta S_m^{tot} = 50 - R \ln \sigma + R \ln \phi \ J/deg{\cdot}mol \quad (3)$$

where R is the gas constant in J/deg·mol, and σ and ϕ are the molecular symmetry and flexibility numbers which are defined below. The total entropy of melting includes entropies associated with solid−solid transitions, as well as the solid−liquid transition. In this paper the above equation is applied to a complex set of data for a wide range of pharmaceutical and environmental compounds.

Methods

Data—Experimental entropy of melting data, including the transitional entropies when reported, for pharmaceutically and environmentally relevant compounds are compiled from literature[9−11] and entered into a database using dBASE IV. The database contains 413 entropy of melting values for 376 different compounds.

The database contains multiple entropy of melting values for some compounds. Since these values are reported by different authors they are treated as individual data points and are not averaged. Entropy of melting values that are less than 9 J/K·mol are considered to be unreasonably low and therefore omitted from the average calculations. Only five compounds consisting of six entropy of melting values have been omitted from the database based on this criteria.

The error associated with the prediction of the entropy melting in this paper is calculated by:

$$\text{error} = (|\Delta S_m^{obsd} - \Delta S_m^{pred}|)/\Delta S_m^{obsd} \times 100 \quad (4)$$

where ΔS_m^{obsd} and ΔS_m^{pred} are the observed and predicted entropies of melting.

There is some overlap between the data set used in the earlier studies[5,6] and the present data set. Only 48 of the 371 different compounds in the present data set were used in the previous studies. They are included here because of their biological relevance.

Molecular Flexibility Number—Increasing molecular flexibility increases the total entropy of melting. To account

decane	0	8	0	7.3
glycerol tristearate	3	54	0	57.1

for the effects of flexibility on entropy of melting Dannenfelser and co-workers[5,8] have defined a molecular flexibility number, ϕ, for flexible molecules. A flexible molecule contains at least one twist angle, which consists of a string of four non-hydrogen atoms that are not rotationally restricted. The number of twist angles can be calculated by subtracting 1 from the total number of chain atoms present in the molecule. Radially symmetrical end groups such as halogens and carbonyl oxygens are not counted as chain atoms because their rotation does not contribute to the molecule's flexibility. Methyl, primary amine, and hydroxy groups are assumed to be freely rotating and effectively radially symmetrical.

In calculating the molecular flexibility number, sp^2 and sp^3 chain atoms are assigned values of 0.5 and 1.0, respectively. Since the bonds between sp chain atoms do not contribute to flexibility, these atoms are assigned a value of zero. Ring systems, whether single or fused, are counted as a single group and assigned a value of 0.5 per system.

The molecular flexibility number for all molecules is given by:

$$\phi = 2.85^{[SP3 + 0.5SP2 + 0.5RING - 1]} \quad (5)$$

where SP3 is the number of sp^3 chain atoms, SP2 is the number of sp^2 chain atoms, and RING is the number of single or fused ring systems. It is important to note that the exponent is never less than zero. An exponent of zero indicates a rigid, nonflexible molecule so that ϕ equals unity and ln ϕ equals zero, i.e.,

$$\ln 2.85° = 0 \quad (6)$$

Examples of some molecular flexibility numbers (shown as ln ϕ) for some pharmaceutical and environmental compounds are listed in Table 1 along with the values for the SP3, SP2, and RING designations.

Molecular Rotational Symmetry Number—Highly symmetrical molecules are known to have a lower entropy of melting than unsymmetrical molecules. Yalkowsky and co-workers[6,7] have accounted for the effects of symmetry on entropy by defining a molecular symmetry number, σ. The following describes how these numbers are defined for individual molecules.

Since there are many ways in which a molecule can be oriented, one of these ways is arbitrarily chosen as the reference orientation. The number of orientations that are identical to the reference that are produced by rigid rotation, up to 360° about its center of mass, in both of the two spherical angles is defined as the molecular rotational symmetry number or σ. In assigning a value to σ, some groups, such as the halogens, carbonyl oxygen, and cyano, are assumed to be radially symmetrical. Again hydrogens are assumed to be freely rotating and not to contribute to molecular symmetry. Thus methyl, hydroxyl, mercapto, and primary amine groups are treated the same as halogens. Since every molecule has at least one identical

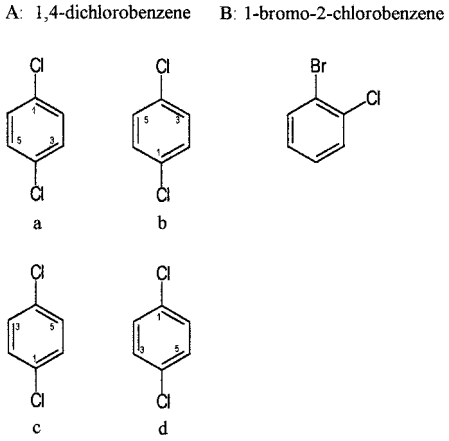

Figure 1—Examples of defining molecular symmetry numbers.

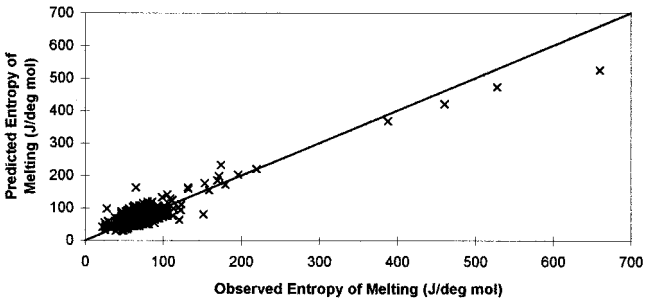

Figure 2—

orientation (produced by a 360° rotation about any axis), the molecular symmetry number is never less than unity (i.e., $\sigma \geq 1$). Thus flexible molecules are assigned a symmetry number of unity.

Molecules with one infinite rotational axis (i.e., cones and cylinders) and molecules with an infinite number of infinite rotational axes (i.e., spheres) have been empirically assigned effective symmetry numbers of 10 and 100, respectively.

Figure 1 shows how 1,4-dichlorobenzene and 1,2-bromochlorobenzene are assigned σ values. Assuming that "a" in Figure 1A is the reference orientation, three other orientations are identical to "a". These can be achieved by rotating "a" 180° about its horizontal axis to obtain "b" and by a 180° clockwise rotation of "a" and "b" to obtain orientations "c" and "d", respectively. Thus 1,4-dichlorobenzene has a molecular symmetry number of four ($\sigma = 4$). As shown in Figure 1B, 1-bromo-2-chlorobenzene, an unsymmetrical molecule, has a molecular symmetry number of unity ($\sigma = 1$) since only a 360° rotation about any axis results in an identical image.

Results and Discussion

The current model to predict the entropy of melting is limited to nonelectrolytes and assumes that the molecules do not self-associate to form dimers or other small aggregates. Only molecular symmetry and flexibility are accounted for in this model. Other factors can effect the entropy of melting, such as eccentricity.

Equation 3 with the molecular parameters, σ and ϕ, was used to predict the total entropy of melting for each compound. No additional parameters or coefficients are used. Figure 2 shows the observed versus predicted entropies of melting. Perfect fit is represented as the solid line with a slope of unity in the graph. As can be seen from the graph, eq 3 does well in predicting the total entropy of

Table 2—Total Entropy of Melting for Highly Flexible Compounds: Walden's Rule versus Eq 3

average ratio	4.52	0.96

melting for the complex set of compounds. The average error in predicting the entropy of melting is 21%. This is well within experimental error seen in the reported entropy of melting data. Experimental errors associated with measuring entropy of melting are reflected in the error of the calculated entropy of melting which are based on the measured values. Whenever possible, experimental values are preferred to calculated values.

A constant to estimate the total entropy of melting cannot be utilized well for those compounds that lie at extremes, i.e., molecules that are small and spherical and those that are highly flexible. Richard's rule was based on small, spherical molecules with an average entropy of melting of 10.5 J/deg mol. While Walden's rule, 56.5 J/deg mol, is an average of 17 entropies of melting for petroleum byproducts or aromatic hydrocarbons. All compounds of interest would have the same estimated entropy of melting when one of the constants are used. Since most pharmaceutical and environmental compounds are not small and spherical, Walden's rule would be chosen to predict the entropy of melting. To see the effect of using eq 3 versus a constant, the ratio of the observed over the predicted entropy of melting values are given in Table 2. A ratio of 1 indicates that the prediction is the same or very close to the observed value. Since the average ratio for eq 3 is close to 1, it predicts the total entropy of melting better than using Walden's rule, which has an average ratio of 4.5. The difference between eq 3 and Walden's rule is more dramatic for molecules with a high degree of flexibility.

Conclusion

Equation 3 which uses only two molecular parameters, σ and ϕ, does very well in predicting the total entropy of melting for more than 370 complex pharmaceutical and environmental compounds. This equation results in an average error of 21% for 407 data points.

Abstract □ Compressibility properties of pharmaceutical materials are widely characterized by measuring the volume reduction of a powder column under pressure. Experimental data are commonly analyzed using the Heckel model from which powder deformation mechanisms are determined using mean yield pressure (P_y). Several studies from the literature have shown the effects of operating conditions on the determination of P_y and have pointed out the limitations of this model. The Heckel model requires true density and compacted mass values to determine P_y from force-displacement data. It is likely that experimental errors will be introduced when measuring the true density and compacted mass. This study investigates the effects of true density and compacted mass on P_y. Materials having different particle deformation mechanisms are studied. Punch displacement and applied pressure are measured for each material at two compression speeds. For each material, three different true density and compacted mass values are utilized to evaluate their effect on P_y. The calculated variation of P_y reaches 20%. This study demonstrates that the errors in measuring true density and compacted mass have a greater effect on P_y than the errors incurred from not correcting the displacement measurements due to punch elasticity.

Introduction and Background

At the present time and for the foreseeable future, most pharmaceutical forms are oral dosage forms, mainly tablets. The measurement of volume reduction of the particle bed under pressure is one of the most commonly used methods to evaluate particle deformation mechanisms. The powder and granule consolidation is often studied on cylindrical compacts, and the measurement of the compact height is an indication of particle bed volume reduction. This method, currently used for ceramic or metal powders, has been applied to pharmaceutical materials since the 1970s.

There are two methods to obtain density−pressure profiles: the "in-die" and "out-die" (or "ejected tablets") methods.[1,2] The "out-die" method calculates the compact volume by measuring its dimensions when it is ejected from the die after compression at pressure P_a. The "in-die" method measures the compacts dimensions in the die, by evaluating punch displacement(s). The "in-die" method is commonly used because it is quicker to operate and consumes less material than the "out-die" method which requires a new compact for each compression pressure of interest. The "in-die" density measurements contain an elastic component leading to falsely low mean yield pressure which is a disadvantage when using the information for tablet formulation.[3]

Several attempts have been made to fit experimental data from powder or granule bed deformation under load to a universal mathematical model. A large number of empirical models have been developed[4] (Kawakita and Lüdde, Cooper and Eaton, Heckel...) and are based on the compact relative density under pressure.

New models are being developed[5] based on physical assumptions and chemical models. The models studied in the literature to date are not a good representation of particle deformation under pressure. The most universally accepted model used to describe the volume reduction of a particle bed is the Heckel model:[6]

$$\ln\left(\frac{1}{1-\rho_r}\right) = KP_a + A \qquad (1)$$

where, ρ_r is the relative density of the compact and the constants K and A are determined by the slope and intercept of the extrapolated region.

Heckel considered the volume reduction of a plastically deforming particle bed as a first-order kinetics phenomenon, where the pores are the reactant. This is not the case for organic powders, especially pharmaceutical materials, when subjected to low pressure (B zone) (Figure 1). However, converting force-displacement data points into a relative density−pressure relationship shows that most pharmaceutical powders exhibit a linear region (C zone) between two intermediate pressures (Figure 1). The linear part (C zone) is generally accepted to be representative of particle plastic deformation. Heckel[7] suggested that the slope of the linear part of the curve is equal to the reciprocal of $3Y$, Y being the yield strength of the material, and that constant A is a function of the initial volume of the particle bed. Hersey and Rees[8] demonstrated that the mean yield pressure of a material is equal to $1/K$. It is well accepted that the slope, K, of the linear region of the Heckel model is the reciprocal of the mean yield pressure P_y and is a measure of its ability to deform plastically. Since 1961, the Heckel representation has been widely used to interpret the consolidation mechanism. It is not a surprise given the number of different techniques used to measure the compression event that discrepancies in results and disagreements between researcher's conclusions have appeared in the literature. Several parameters influence the calculation of P_y, especially operating conditions:[9] type of compression (a uniaxial press, a rotary press, an alternative press, a compaction simulator...), compression speed,[10,11]

contact time, type and amount of lubricant,[12,13] punch diameter,[14] maximum compression pressure, amount of powder tested and filling method (manual, automatic, constant mass or volume),[15] accuracy of the measurement of displacement for the "in-die" method, accuracy of the measurement of the compact volume after ejection for the "out-die" method, accuracy of the strain gauges or piezoelectric transducers for pressure measurements, initial particle size, type of particle being compressed (powder, granules, mixed powder or granules,[16] true density measurement[17]...).

Researchers traditionally agree that the curvature at very low pressure (B zone) is due to particle packing, rearrangement, and fragmentation in the die while some disagreement occurs when considering the curvature at very high pressure (D zone). For example, negative relative density values can be calculated toward high compression pressures when using the "in-die" method. Some researchers suggested that an increase in the true density value (i.e., polymorphic transformation[18,19]), during compression could explain the abnormal negative values. Small errors in punch displacements or true density measurements may lead to large variations in the calculation of relative density. Therefore, one should be careful when interpreting relative density data and also when comparing results which are obtained under different operating conditions.

The objective of this study is to demonstrate the effects of true density and compacted mass on the mean yield pressure (P_y). In addition, other contributing factors such as compression speed, pressure, and correction of punch displacement for elastic deformation are identified. This study was approached in three steps. In the first step, one set of force and displacement data was collected for each material at two compression speeds. In the second step, Heckel plots were generated following eq 1 using the software provided and a fixed true density and compacted mass value. P_y was then calculated from the Heckel plots. For each set of experimental data measured in the first step, five values of P_y are calculated using different true density and compacted mass values (see Table 1). The third step involved comparing the errors in the P_y values obtained by varying true density, compacted mass, and compression speed with the errors in the P_y values obtained for which no correction for elastic deformation of the punches was made.

Material and Methods

Five materials were used in this study. Three materials are classical pharmaceutical excipients: Avicel PH 102 (filler and dry binder supplied by FMC); Starch 1500 (Disintegrant supplied by Colorcon); Pharmatose DCL 21 (filler supplied by DMW). The other two materials consisted of a drug substance (DS) and its formulated drug product (DP). The DS and DP were supplied by the Pharmaceutical Sciences Department of Sanofi Recherche (patented products).

Table 2—True Density Measured with an Helium Pycnometer and Bulk Density

	starch	avicel	lactose	DS	DP
D_{v_0} (g/cm^3)	1.506	1.594	1.576	1.500	1.526
$n = 3$ (deviation)	(0.003)	(0.001)	(0.002)	(0.001)	(0.000)
D_{bulk} (g/cm^3)	0.643	0.341	0.645	0.270	0.722
$n = 3$ (deviation)	(0.001)	(0.004)	(0.008)	(0.012)	(0.003)

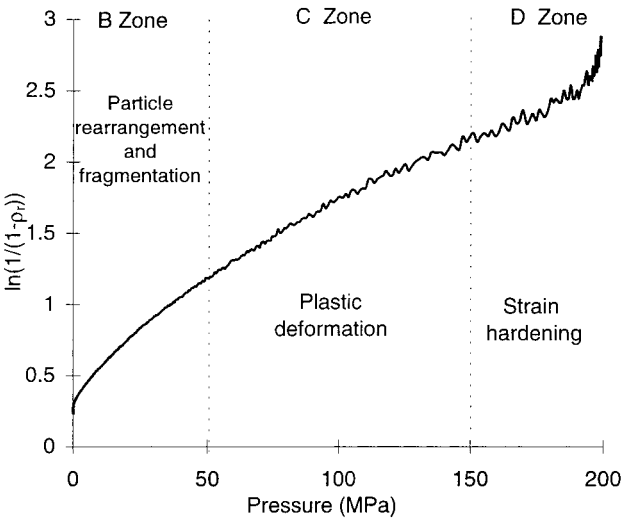

Figure 1—Determination of the linear part in the Heckel treatment.

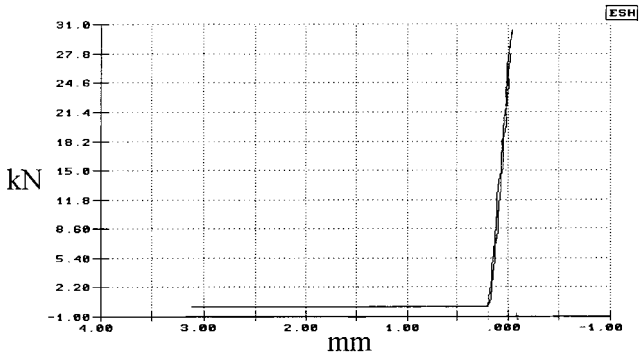
The true density was measured with a helium pycnometer (Micromeritics, Accupyc 1330), which is accurate to within 0.03% of reading values. Powders were weighed on a Mettler Toledo balance (model AG204), accurate to the nearest 0.1 mg.

The bulk density was measured in a volumenometer following European Pharmacopoeia recommendations (3rd edition, 2.9−15, "Volume apparent"). However, DS had a very low density which did not allow 100 g of powder to be placed in a 250 mL cylinder. The amount of material used for each measurement and each material was 50 g to allow a comparison between products. The measurements were done in triplicate.

Compression experiments were performed on an ESH compaction simulator at two compression speeds (16 and 166 mm·s^{-1}) using linear displacement profiles and a dwell time of zero. The amount of material required to fill a 1 cm^3 die (1 cm^2 × 1 cm) (Table 2) was calculated based on its bulk density (D_{bulk}). The die was manually lubricated with magnesium stearate. The elastic component of the punches was measured. The punch displacements were calibrated and data corrected using polynomial fitting (Figure 2, parts a and b). The punch displacements were measured by Linear Variable Displacement Transducer (LVDT), directly connected to the punches. LVDTs were a RDP Group, type D5/500/392. The accuracy of the upper punch LVDT was 99.91% while the accuracy of the lower punch LVDT was 99.98%. The load cells used to measure force were made by Veccer (U.K.), type s.1333 with a range of 0 to 50 kN. The maximum error of the upper load cell is 0.7% while the maximum error of the lower load cell is 0.2%.

The software allowed for data to be corrected or not corrected for elastic deformation of the punches. Force-displacement data were analyzed using the software provided with the ESH compaction simulator and required the true density and mass of material compacted. The software calculated the mean yield pressure (P_y) using the Heckel model (eq 1). P_y is the inverse of the slope of the C zone shown in Figure 1.

This software was used to generate Heckel plots using three different true density values and three different compacted mass values in order to estimate the effect of true density and compacted mass errors on the mean yield pressure. Experimental errors related to compression itself (i.e., filling the die, measurement of punch displacements and upper punch pressure) were not included.



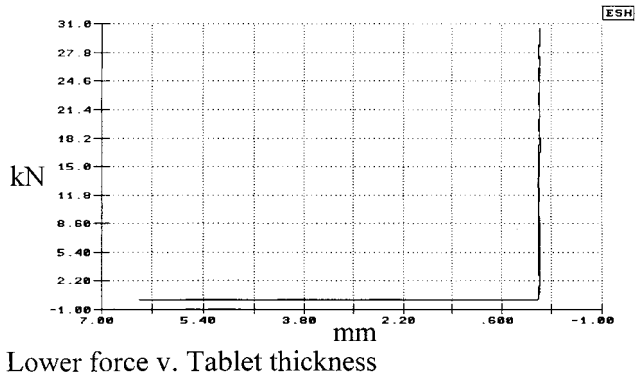


Figure 2—(a) Uncorrected data for punch displacements only. (b) Corrected data for punch displacements only.

Results and Discussion

There are three methods commonly utilized to measure the true density of a material: helium pycnometry, mercury porosimeter, and air pycnometry. True density values will differ according to the measurement method used. In this study, helium pycnometry was utilized because it is the method of choice. Helium pycnometry uses helium atoms which are smaller than both mercury and the atoms composing air. Therefore, helium atoms are able to penetrate pores and interstitial spaces more readily. One of the disadvantages of helium pycnometry is that volatile impurities or adsorbed water may cause a scatter in the measurement. We have found this variation to be up to 3%.

Even when filling material into the die is carried out manually at constant weight and not considering flow properties of materials, a significant source of error can be made on the compacted mass measurement. The amount of material weighed before compressing may differ from the real compressed value because of material losses due to poor flowability, static electricity, sticking, etc. The weight of the compact obtained after ejection may differ from the real weight of the product compacted because of sticking to punches and die walls, capping, lubrication of the die (which will smear onto the tablet and add weight), etc. For some materials such as drug substances which may be very difficult to handle, the error may be up to 10 mg (that is up to 4%, depending on the filling weight). However, for products which are more easily compressed like drug products and direct compression excipients, the weight error may be lower. The difference between the weight of the material before compression and the weight of the compact after ejection is an identification of the error made in the experimental measure. The accuracy of the balance has to be taken into account even though the experimental error made at this stage is negligible.

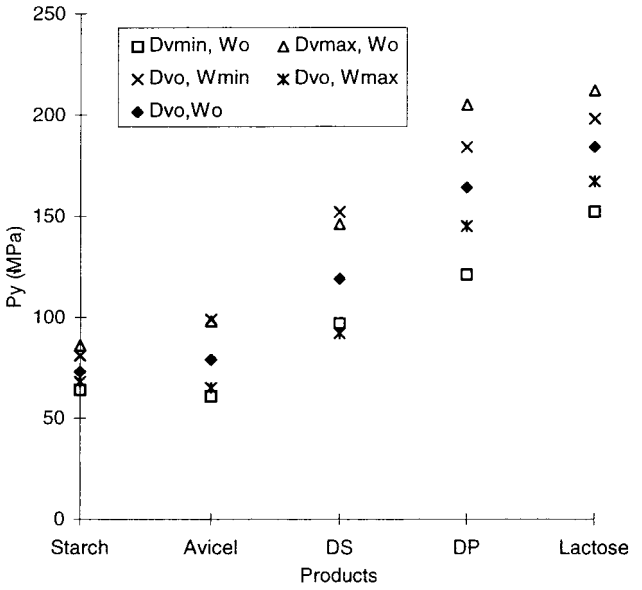

Figure 3—Error due to D_{v_i} and W_i on the mean yield pressure values (P_y, MPa) at V_c = 16.6 mm/s.

For this study, we calculated the mean yield pressure using three different values for the true density (D_{v_0}, $D_{v_{min}}$, and $D_{v_{max}}$) and three different weights for the compacted particles (W_0, W_{min}, and W_{max}) where:

$$D_{v_{min}} = 0.97D_{v_0} \quad \text{and} \quad D_{v_{max}} = 1.03D_{v_0} \qquad (1)$$

$$W_{min} = W_0 - 10\ (\text{mg}) \quad \text{and} \quad W_{max} = W_0 + 10\ (\text{mg}) \qquad (2)$$

The slope of the zone C in Figure 1 has been determined at each simulation test with a good correlation (the correlation coefficient r^2 of the linear regression is greater than 0.99) and the linear zone has been considered to be in the same pressure range [$P_1 - P_2$] for each product.

The value given by the helium pycnometer is assumed to be the best approximation of the true density (designated D_{v_0}, Table 2), and the weight of the compact after ejection (designated W_0) the closest value from the real weight of compacted particles.

Values (D_{v_i}, w_i) used for the mathematical simulations are shown in Table 1.

Figure 3 details the P_y values obtained by varying the true density by ±3% and the compacted mass by ±10 mg for the materials in this study at a compression speed of 16.6 mm·s^{-1}. Materials have been classified according to their increasing $P_{y(0)}$ value. Figure 3 demonstrates that true density exhibits a larger effect on P_y than does weight variation, except for DS. This is because DS has a low bulk density (0.270 g/cm^3). Besides, mean yield pressure decreases when the true density decreases and when the compacted weight increases. The mean yield pressure is calculated in order to determine the particle deformation mechanism(s) of a new product to help understand its compression behavior and to aid in formulation development. How do we characterize a product in such terms if the accuracy of the measurements is not adequate? Considering drug substance and drug product, the mean yield pressure varies at its maximum from 90 to 150 MPa and from 120 to 200 MPa, respectively. Therefore, according to the material deformation classification scheme presented by Roberts and Rowe's[11] (presuming the operating conditions are identical), it is difficult to classify products as plastic or brittle deforming materials.

If the true density varies from ±3% or if the mass of particles compacted varies from approximately ±10 mg, the

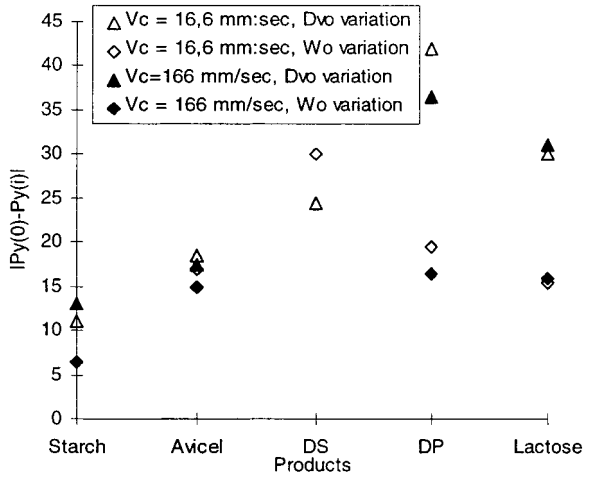

Figure 4—Influence of compression speed on the mean yield pressure variation (MPa).

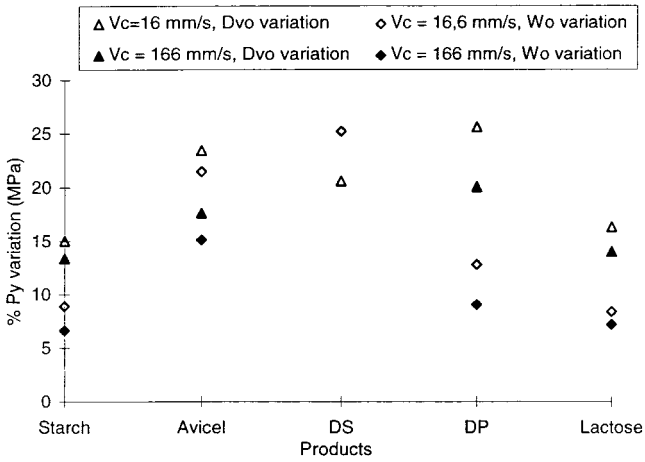

Figure 5—Influence of compression speed on the mean yield pressure relative variation (%).

mean yield pressure differs by approximately the same amount. The P_y variation can be expressed in both directions (either positive or negative) as the absolute value of the difference between $P_{y(0)}$ and $P_{y(i)}$. Figure 4 details the mean yield pressure difference $|P_{y(0)} - P_{y(i)}|$ for the materials in this study from which the effects of compression speed can be observed. Considering the small range of compression speed studied, P_y variation depends on the products and less on the compression speed: the effect of the compression speed is larger for DP than for any of the other products. However, the compression speed consequence is not studied on DS mean yield pressure variation: compacts can be produced at 16.6 mm·s^{-1} but not at 166 mm·s^{-1}. Although production of compacts is not necessary to measure the mean yield pressure, this high speed has not been studied for DS.

The mean yield pressure relative variation $\%P_y$ is defined as the percentage of the yield pressure variation relative to $P_{y(0)}$:

$$\%P_y = \frac{|P_{y(0)} - P_{y(i)}|}{P_{y(0)}} \quad (3)$$

Figure 5 details the $\%P_y$ variation for the materials in this study from which the effects of compression speed can be observed. At the lowest speed, the mean yield pressure relative variation reaches a maximum of 25% for DS and DP. When speed increases, $\%P_y$ decreases. In general, it is well-known from literature that the mean yield pressure of materials increases with increasing compression speed[10,11] (except for brittle deforming materials). Figure 4 shows compression speed does not have a considerable effect on $|P_{y(0)} - P_{y(i)}|$. On the other hand, $P_{y(0)}$ increases with compression speed. Therefore, $\%P_y$ decreases with increasing speed. The variation of the true density value and the compacted mass value has a relatively lower effect on $\%P_y$ when materials are compacted at higher speeds.

Even with the experimental errors introduced by true density and compacted mass measurements, it is possible to deduce the deformation mechanism of new pharmaceutical materials by including reference materials of well-known excipients that are measured at the same operating conditions (including an equivalent accurate measure of the true density and weight of particles compacted). Consequently, complete information about the true density measurement and accuracy of the method should be given with the Heckel model results in order for comparisons to be made.

We can estimate the error on the mean yield pressure when there is a subsequent error on the true density or compacted mass measurements by using the same upper punch force and punch displacements values for one material (also considering the linear part to be in the same pressure range $[P_1 - P_2]$).

The compact height is calculated from the punch displacement data, and depending on the true density of the material and weight of the compacted material, the relative density (ρ_i) is calculated at a pressure P_i:

$$\ln(\rho_i) = \ln\left(1 - \frac{w}{S h_i D_v}\right) \quad (4)$$

where S is the compact surface area, h_i the compact height at pressure P_i, w the compact weight, and D_v the true density of the compacted material.

Since the coefficient of regression r^2 is greater than 0.99, the slope of the linear part of the plot $-\ln(\rho_i)$ versus P (MPa) in the pressure range $[P_1 - P_2]$ can be estimated as follows:

$$K = \frac{-\ln(\rho_2) - [-\ln(\rho_1)]}{P_2 - P_1} \quad (5)$$

and the mean yield pressure can be expressed as:

$$P_y = -\frac{P_2 - P_1}{\ln(\rho_2) - \ln(\rho_1)} \quad (6)$$

From eq 6 we can calculate the error made on the mean yield pressure:

$$\Delta P_y = \frac{P_2 - P_1}{[\ln(\rho_2) - \ln(\rho_1)]^2}\left(\frac{\Delta\rho_2}{\rho_2} - \frac{\Delta\rho_1}{\rho_1}\right) \quad (7)$$

where ρ_i is dependent on the weight and true density value.

Therefore, for a weight variation Δw_0:

$$\Delta P_y = \frac{-\Delta w}{S D_v [\ln(\rho_2) - \ln(\rho_1)]^2}\left[\frac{1}{h_2\rho_2} - \frac{1}{h_1\rho_1}\right] \quad (8)$$

and for a true density variation ΔD_{v_0}:

$$\Delta P_y = \frac{w\Delta D_v}{S(D_v)^2 [\ln(\rho_2) - \ln(\rho_1)]^2}\left[\frac{1}{h_2\rho_2} - \frac{1}{h_1\rho_1}\right] \quad (9)$$

Equation 8 indicates that an underestimation of the compacted material mass ($\Delta W_0 < 0$) increases the mean

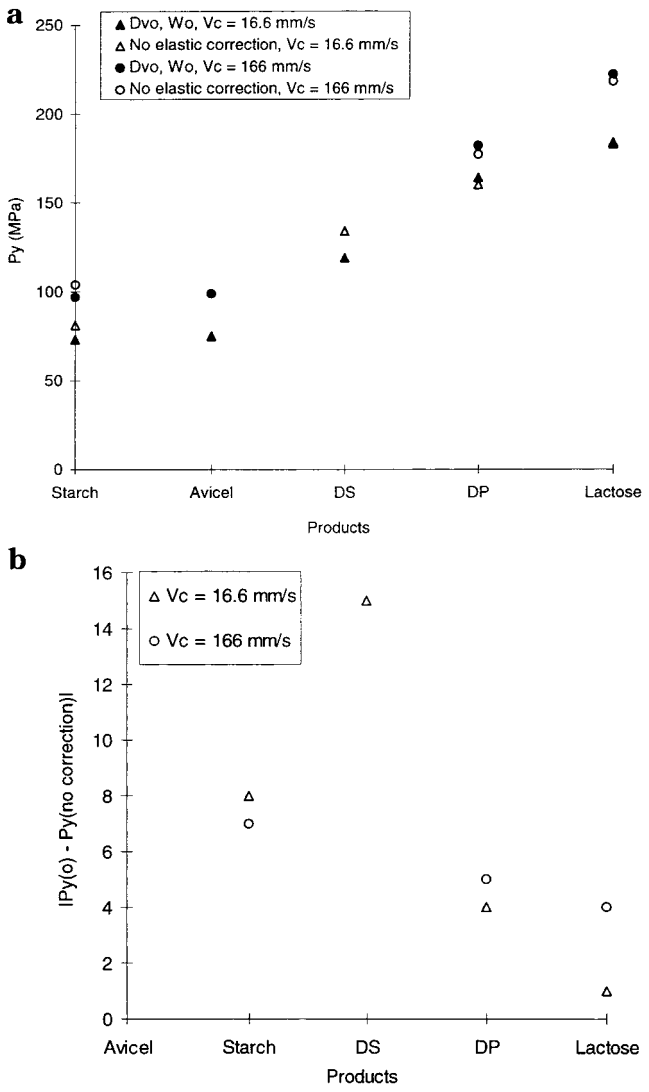

Figure 6—Impact of elastic correction on the mean yield value.

yield pressure value and overestimates the ability of the material to deform by a brittle mechanism. Similarly, eq 9 points out that an underestimation of the true density value ($\Delta D_{v_0} < 0$, which is often the case when it is not measured with a helium pycnometer) decreases P_y value and overestimates the plastic behavior. This reflects the measured variation of mean yield pressure. The two experimental values we studied could have either a complementary effect, i.e., the P_y value error is minimized, or a contradictory effect, i.e., the P_y value error is maximized. Therefore, two extreme cases may appear; if the true density value is minimized and the compacted mass maximized, or, on the other hand, if the true density value is maximized and the compacted mass minimized, the error made on the mean yield pressure would be maximized.

Figure 2, parts a and b, details force versus displacement data for uncorrected (Figure 2a) and corrected (Figure 2b) punch deformation. Most researchers point out that calibration is a significant step for obtaining correct force-displacement profiles.[17,20] The software allows analysis of force-displacement data with or without correction for elastic deformation of the punches. This is useful for comparing the effect elastic deformation of the punches has on P_y while varying the true density or compacted mass values. Figure 6a details P_y for the materials studied for corrected and uncorrected elastic punch deformation at two compression speeds. Figure 6b shows the effect of correction of elastic movement of punches and indicates it is lower than the effect of the true density variation, whatever the compression rate. No calculation of the mean yield pressure without elastic correction of punches has been obtained for microcrystalline cellulose. The greater consequence on P_y variation of the correction of the punches is obtained for DS for which the difference between the two mean yield pressures is 16 MPa. This value is the minimum difference obtained when studying the effect of the true density. The correction of elastic deformation of punches is necessary to improve the accuracy of force-displacement profiles but the consequence on the mean yield pressure is lower than the one which appears when errors occur while measuring true density or compacted mass.

The pressure range used for the Heckel analysis should be as large as possible. Since particle rearrangement and fragmentation often occurs up to 30−50 MPa, it is necessary to compress at least up to 150−200 MPa to increase the accuracy of the mean yield pressure measurement. If the strain-hardening zone[6,7] (D zone in Figure 1) exists when generating the relative porosity of the material column, the maximum amount of data can be used to describe the plastic deformation phase. Then, the mean yield pressure is calculated over a maximum pressure range.

Conclusion

This study showed that the experimental error due to punch displacement accuracy has less effect on the mean yield pressure than the error introduced when measuring the true density or the compacted mass.

Measurements of the force-displacement profiles are quite difficult to interpret according to the literature: Heckel model results are very dependent on the operating conditions. Therefore, it is suggested to analyze well-known pharmaceutical materials with well-known deformation mechanisms such as starch, microcrystalline cellulose, and/or lactose in order to interpret the deformation mechanism of new drug substances and new drug products. To compare the results of P_y between materials, it is important that the operating conditions and measurements methods be extremely accurate and well-defined.

Abstract □ Three classical particle dissolution rate expressions are commonly used to interpret particle dissolution rate phenomena. Our analysis shows that an assumption used in the derivation of the traditional cube-root law may not be accurate under all conditions for diffusion-controlled particle dissolution. Mathematical analysis shows that the three classical particle dissolution rate expressions are approximate solutions to a general diffusion layer model. The cube-root law is most appropriate when particle size is much larger than the diffusion layer thickness, the two-thirds-root expression applies when the particle size is much smaller than the diffusion layer thickness. The square-root expression is intermediate between these two models. A general solution to the diffusion layer model for monodispersed spherical particles dissolution was derived for sink and nonsink conditions. Constant diffusion layer thickness was assumed in the derivation. Simulated dissolution data showed that the ratio between particle size and diffusion layer thickness (a_0/h) is an important factor in controlling the shape of particle dissolution profiles. A new semiempirical general particle dissolution equation is also discussed which encompasses the three classical particle dissolution expressions. The success of the general equation in explaining limitations of traditional particle dissolution expressions demonstrates the usefulness of the general diffusion layer model.

Dissolution phenomena have been studied in a quantitative manner for more than a century. The dissolution of solid particles is more complicated than that of constant surface area tablets because of surface area and/or shape changes during dissolution. Though particle dissolution models have been developed, discrepancies between theory and experimental data are present. It has not been shown whether these discrepancies are due to experimental factors or limitations of the mathematical models.

Two steps are involved in solid particle dissolution: the first step is the detachment of molecules from the solid surface to form hydrated molecules at the solid−liquid interface; the second step is the mass transport from this interface to the bulk solution. Most dissolution processes are controlled by the second step which is diffusion−convection-controlled. The basic diffusion-controlled model for solid dissolution was developed by Noyes and Whitney[1] and later modified by Nernst[2] and Brunner.[3] This model assumes that rapid equilibrium (i.e., saturation) is achieved at the solid−liquid interface and then diffusion occurs across a thin layer of solution, called the diffusion layer, into the bulk solution. Diffusion across this diffusion layer is rate-controlling in most cases, which effectively converts the heterogeneous process of dissolution to a homogeneous process of liquid-phase diffusion. Nernst and Brunner's concept of a diffusion layer being a stagnant or unstirred layer of liquid adhering to the solid surface is naive but allows complex dissolution processes to be analyzed in a tractable fashion. However, as pointed out by King,[4] this layer need not be stagnant and can be a hydrodynamic boundary which has a velocity as well as a concentration gradient.

Three diffusion-controlled models have been reported for single spherical particle dissolution under sink conditions, as shown below:

$$w^{1/3} = w_0^{1/3} - k_{1/3}t \qquad k_{1/3} = \left(\frac{4\pi\rho}{3}\right)^{1/3} \frac{DC_S}{\rho h} \quad \text{(eq 1)}$$

$$w^{1/2} = w_0^{1/2} - k_{1/2}t \qquad k_{1/2} = \left(\frac{3\pi\rho}{2}\right)^{1/2} \frac{DC_S}{k'\rho} \quad \text{(eq 2)}$$

$$w^{2/3} = w_0^{2/3} - k_{2/3}t \qquad k_{2/3} = \left(\frac{4\pi\rho}{3}\right)^{2/3} \frac{2DC_S}{\rho} \quad \text{(eq 3)}$$

where w is particle weight at time t, w_0 is initial particle weight, $k_{1/3}$, $k_{1/2}$, and $k_{2/3}$ are composite rate constants, ρ is the density of the particle, D is diffusion coefficient, C_S is solubility, h is diffusion layer thickness, and k' is a constant. Equation 1 was derived by Hixson and Crowell[5] and is known as the "cube-root law". Equation 2 is the semiempirical expression reported by Niebergall et al.[6] and has a square-root dependency on weight. Equation 3 was derived by Higuchi and Hiestand[7] and has a two-thirds-root dependency on weight. Each of the above equations gives satisfactory fits to certain experimental dissolution data.[6,8,9] These three expressions are still the basis for particle dissolution theories in contemporary dissolution testing.[10] However, the choice of the model to fit experimental data is still somewhat arbitrary. Though they appear different in form, the three equations are difficult to distinguish when applied to experimental data. A particular dissolution profile can often be fitted by at least two of these equations almost equally well.[11] Thus, it seems that dissolution behavior of simple spherical particles is still not theoretically well defined.

Among the three equations, the most commonly used is the "cube-root law". The cube-root law was first derived by assuming that dissolution rate is proportional to particle surface area. Though Hixson and Crowell did not specifically use the diffusion layer model to derive their equation, the cube-root law can also be derived from a simple diffusion layer model. Our further analysis shows that the cube-root law is only an approximate solution to the diffusion layer model, because an assumption used may not be accurate under all conditions for diffusion-controlled particle dissolution.

Below are dissolution rate expressions for the diffusion layer model:

$$\frac{dQ}{dt} = \frac{DA}{h}(C_S - C_b) \quad \text{(eq 4)}$$

$$\frac{dQ}{dt} = -DA\left.\frac{\partial C}{\partial r}\right|_{r=a} \quad \text{(eq 5)}$$

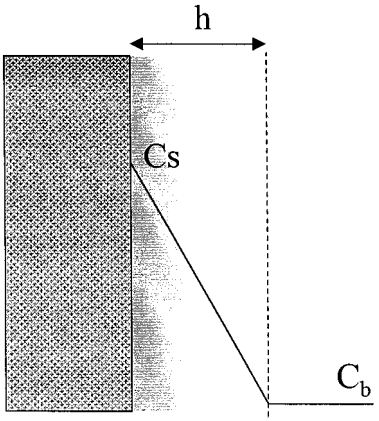

Figure 1—Steady-state concentration gradient around a planar surface.

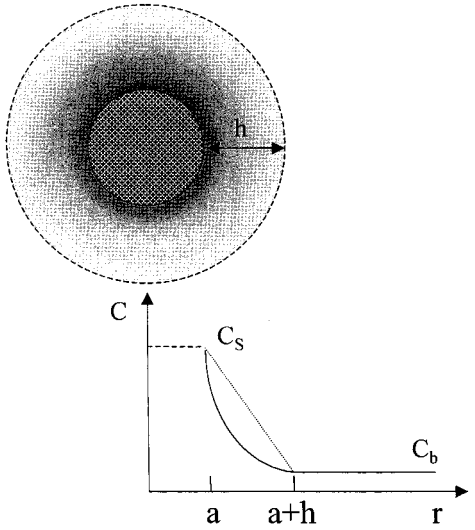

Figure 2—Pseudo-steady-state concentration gradient around a spherical particle (radius = *a*).

where dQ/dt is the rate of dissolution, A is particle surface area, h is the thickness of the diffusion layer, C_b is bulk solution concentration, r is the distance from the center of the particle, and a is particle radius. Equation 4 is exact for planar surface dissolution under sink conditions, because the concentration gradient in the diffusion layer is linear at steady-state (Figure 1). However, for a curved surface, eq 4 is not accurate because the concentration gradient around a spherical particle is not linear under pseudo-steady-state conditions (Figure 2). Particle dissolution rate expressions based on eq 4 will not give accurate solutions to the diffusion layer model for spherical particles. For more accurate results, the derivation should start from eq 5 which is Fick's first law expression for spherical geometry.

For particle dissolution, changing bulk solution concentration complicates the mathematical analysis. Most researchers use sink conditions to make the treatment of experimental data easier. The three traditional particle dissolution expressions are such examples, which is what we emphasize here. A general (and more exact) solution to the diffusion layer model for spherical particle dissolution under sink conditions will be derived, and the relationship between the general solution and the classical expressions will be discussed. A general solution for spherical particle dissolution under nonsink conditions is also included and briefly discussed. Understanding the limitations of the three classical particle dissolution expressions will make it easier to use them appropriately. The availability of the general solution will provide a sound basis for determining whether diffusion layer thickness is dependent upon particle size, which has been a point of discussion.[6,10,12–14] It also provides a sound basis for the investigation of polydispersity effects on particle dissolution.

Theory

The diffusion layer model for single spherical particle dissolution under sink conditions is based on the following assumptions:

(a) The particle is spherical and dissolves isotropically.

(b) The particle is in a well-stirred solution and there exists a boundary layer around the particle of constant thickness (h).

(c) During dissolution, a pseudo-steady-state is established with only minimal solid dissolution, after which the overall mass transport rates across the inner and outer spherical surfaces (at $r = a$ and $a + h$) of the diffusion layer are assumed to be equal.[15]

(d) The concentration at the interface between the solid and the solution is saturated (C_S), and solubility is independent of particle size.

(e) The bulk solution concentration (C_b) is assumed to be zero, and the diffusion coefficient (D) is a constant throughout the diffusion layer.

Since the concentration gradient around a spherical particle is not linear at pseudo-steady-state, it is a function of distance from the center of the particle. The function $G(R)$ can be defined as the concentration gradient at a distance R from the center of the particle and is given by:

$$G(R) \equiv \left.\frac{\partial C}{\partial r}\right|_{r=R}$$

With this definition, eq 5 becomes:

$$\frac{dQ}{dt} = -DAG(a) \qquad \text{(eq 6)}$$

The surface area of a sphere is $4\pi r^2$ and applying the pseudo-steady-state assumption c gives:

$$4\pi a^2 G(a) = 4\pi r^2 G(r) \qquad a \le r \le a + h \quad \text{(eq 7)}$$

and

$$G(r) = \frac{a^2}{r^2} G(a) \qquad \text{(eq 8)}$$

Using assumptions d and e, the total concentration difference across the diffusion layer is C_S, which leads to:

$$\int_a^{a+h} -G(r)dr = C_S \qquad \text{(eq 9)}$$

Substituting eq 8 into eq 9 gives:

$$\int_a^{a+h} -\frac{a^2}{r^2} G(a)dr = C_S \qquad \text{(eq 10)}$$

Integrating eq 10 gives:

$$G(a) = -C_S\left(\frac{1}{a} + \frac{1}{h}\right) \qquad \text{(eq 11)}$$

Substituting eq 11 into eq 6 gives:

$$\frac{dQ}{dt} = DAC_S\left(\frac{1}{a} + \frac{1}{h}\right) \qquad \text{(eq 12)}$$

Using $4\pi a^2$ for area (A) in eq 12 gives:

$$\frac{dQ}{dt} = 4\pi a^2 DC_S\left(\frac{1}{a} + \frac{1}{h}\right) \quad \text{(eq 13)}$$

Considering the change of particle radius during dissolution, the mass balance expression for a dissolving spherical particle is:

$$\frac{dQ}{dt} = -4\pi a^2 \rho \frac{da}{dt} \quad \text{(eq 14)}$$

where ρ is the solid density. Equation 14 is independent from eq 13. Equating eqs 13 and 14 gives:

$$4\pi a^2 DC_S\left(\frac{1}{a} + \frac{1}{h}\right) = -4\pi a^2 \rho \frac{da}{dt} \quad \text{(eq 15)}$$

Rearranging eq 15 gives:

$$\frac{DC_S}{\rho h} dt = \left(-1 + \frac{h}{a+h}\right) da \quad \text{(eq 16)}$$

The integral form of eq 16 is:

$$\int_0^t \frac{DC_S}{\rho h} dt = \int_{a_0}^{a} \left(-1 + \frac{h}{a+h}\right) da \quad \text{(eq 17)}$$

Integrating both sides of eq 17 gives:

$$\frac{DC_S}{\rho h} t = a_0 - a - h \ln \frac{h + a_0}{h + a} \quad \text{(eq 18)}$$

where a_0 is the initial particle radius.

Equation 18 is the general solution (in terms of particle radius) of the diffusion layer model for single spherical particle dissolution under sink conditions. The relationship between particle weight and particle radius is given by:

$$w = \frac{4}{3}\pi a^3 \rho \quad \text{(eq 19)}$$

where w is particle weight and w_0 is initial particle weight.

Substituting eq 19 into eq 18 gives an expression for the change of particle weight with time:

$$\frac{DC_S}{\rho h} t = \left(\frac{3w_0}{4\pi\rho}\right)^{1/3} - \left(\frac{3w}{4\pi\rho}\right)^{1/3} - h \ln \frac{h + \left(\frac{3w_0}{4\pi\rho}\right)^{1/3}}{h + \left(\frac{3w}{4\pi\rho}\right)^{1/3}} \quad \text{(eq 20)}$$

For N monodispersed particles, the total weight (W) of particles is Nw. Using this expression in eq 20 gives eq 21 which describes the dissolution process for N monodispersed particles under sink conditions with total initial weight, W_0.

$$\frac{DC_S}{\rho h} t = \left(\frac{3W_0}{4N\pi\rho}\right)^{1/3} - \left(\frac{3W}{4N\pi\rho}\right)^{1/3} - h \ln \frac{h + \left(\frac{3W_0}{4N\pi\rho}\right)^{1/3}}{h + \left(\frac{3W}{4N\pi\rho}\right)^{1/3}} \quad \text{(eq 21)}$$

Under nonsink conditions, the general dissolution equation can be derived in a similar manner (see appendix II) and is summarized below.

For N monodispersed spherical particles, the general solution in terms of particle size (a) with time is:

$$\frac{D}{\rho h V} t = \frac{1}{\beta - \alpha h^3}\{X + Y + Z\} \quad \text{(eq 22)}$$

$$X = h \ln \frac{a + h}{a_0 + h} - \frac{h}{3} \ln \frac{\alpha a^3 + \beta}{\alpha a_0^3 + \beta}$$

$$Y = \frac{h^2}{\gamma}\left[\frac{1}{2} \ln \frac{(\alpha a^3 + \beta)(\gamma + a_0)^3}{(\gamma + a)^3(\alpha a_0^3 + \beta)} + \sqrt{3} \tan^{-1}\left(\frac{2a - \gamma}{\sqrt{3}\gamma}\right) - \sqrt{3} \tan^{-1}\left(\frac{2a_0 - \gamma}{\sqrt{3}\gamma}\right)\right]$$

$$Z = \frac{\gamma}{3}\left[\frac{1}{2} \ln \frac{(\alpha a^3 + \beta)(\gamma + a_0)^3}{(\gamma + a)^3(\alpha a_0^3 + \beta)} - \sqrt{3} \tan^{-1}\left(\frac{2a - \gamma}{\sqrt{3}\gamma}\right) + \sqrt{3} \tan^{-1}\left(\frac{2a_0 - \gamma}{\sqrt{3}\gamma}\right)\right]$$

where α, β and γ are constants: $\alpha = {}^4/_3\pi\rho N$, $\beta = C_S V - {}^4/_3\pi a_0^3 \rho N$, $\gamma = (\beta/\alpha)^{1/3}$. The above general equation is not applicable when $\beta = 0$ which will lead to an indeterminate condition (i.e., division by zero). Such a situation arises when the initial particle weight (W_0) equals the amount necessary to saturate the solution (i.e., $W_0 = C_S V$). The equation for this condition is:

$$\frac{DC_S}{a_0^3 \rho N} t = \frac{1}{a} - \frac{1}{a_0} + \frac{1}{h} \ln \frac{a(a_0 + h)}{a_0(a + h)} \quad \text{(eq 23)}$$

Results and Discussion

1. Three Classical Particle Dissolution Rate Expressions are Special Cases of the General Solution under Sink Conditions—Two special cases of eq 18 are as follows:

(a) When $a_0 \gg h$ and $a \gg h$, eq 18 becomes (see appendix I):

$$\frac{DC_S}{\rho h} t \approx a_0 - a \quad \text{(eq 24)}$$

This leads to the cube-root expression.[5]

(b) When $a_0 \ll h$, eq 18 becomes (see appendix I):

$$\frac{2DC_S}{\rho} t \approx a_0^2 - a^2 \quad \text{(eq 25)}$$

This leads to the two-thirds-root expression.[7]

It is clear that both the cube-root law and the two-thirds-root expression are approximate solutions to the diffusion layer model at opposite extremes of particle size. Theoretically, the cube-root law is accurate only when the particle size is much larger than the thickness of the diffusion layer, and the two-thirds-root expression is accurate when the particle size is much smaller than the thickness of the diffusion layer.[16] The square-root expression is intermediary between these two limits. It is not surprising that it fits some particle dissolution profiles, but may not describe such profiles exactly. When particle size is comparable to the thickness of the diffusion layer, the general equation provides a more accurate mathematical description.

The above conclusion can also be reached in another way. The concentration gradient at the solid–liquid interface (eq 11) can be considered to be two parts: the particle radius term (C_S/a) and diffusion layer thickness term (C_S/h). When particle size is much larger than diffusion layer thickness ($a \gg h$), the particle radius term can be omitted, we obtain $dQ/dt \approx DAC_S/h$ which will lead to the cube-root

law. On the other hand, when the particle size is much smaller than diffusion layer thickness ($a \ll h$), the diffusion layer thickness term can be omitted and we obtain $dQ/dt \approx DAC_S/a$ which leads to the two-thirds-root expression. It is obvious that both of these expressions underestimate the concentration gradient at the solid–liquid interface.

2. The Ratio between Particle Size and Diffusion Layer Thickness (a_0/h) in Controlling the Shape of a Particle Dissolution Profile—Rearranging eq 18 gives:

$$t = \frac{\rho h}{DC_S}[a_0 - a - h\ln(h + a_0) + h\ln(h + a)] \quad \text{(eq 26)}$$

T can be defined as the time needed for complete dissolution (i.e., at $a = 0$) of a particle as shown below:

$$T = \frac{\rho h}{DC_S}[a_0 - h\ln(h + a_0) + h\ln(h)] \quad \text{(eq 27)}$$

Dividing both sides of eq 26 by eq 27 gives:

$$\frac{t}{T} = \frac{a_0 - a - h\ln(h + a_0) + h\ln(h + a)}{a_0 - h\ln(h + a_0) + h\ln(h)} \quad \text{(eq 28)}$$

Rearranging eq 28 gives:

$$\frac{t}{T} = 1 - \frac{a - h\ln(h + a) + h\ln(h)}{a_0 - h\ln(h + a_0) + h\ln(h)} \quad \text{(eq 29)}$$

Further rearrangement of eq 29 gives:

$$\frac{t}{T} = 1 - \frac{a - h\ln\left(1 + \frac{a}{h}\right)}{a_0 - h\ln\left(1 + \frac{a_0}{h}\right)} \quad \text{(eq 30)}$$

and

$$\frac{t}{T} = 1 - \frac{\frac{a}{a_0} - \frac{h}{a_0}\ln\left(1 + \frac{a}{a_0}\frac{a_0}{h}\right)}{1 - \frac{h}{a_0}\ln\left(1 + \frac{a_0}{h}\right)} \quad \text{(eq 31)}$$

Since $a/a_0 = (w/w_0)^{1/3}$, eq 31 becomes:

$$\frac{t}{T} = 1 - \frac{\left(\frac{w}{w_0}\right)^{1/3} - \frac{h}{a_0}\ln\left[1 + \frac{a_0}{h}\left(\frac{w}{w_0}\right)^{1/3}\right]}{1 - \frac{h}{a_0}\ln\left(1 + \frac{a_0}{h}\right)} \quad \text{(eq 32)}$$

Equation 32 is a dimensionless equation for single particle dissolution under sink conditions where t/T and w/w_0 can be viewed as two variables which range from 0 to 1. Plots of w/w_0 vs t/T give dissolution profiles which are independent of solid and dissolution medium used, but are governed by a_0/h. Theoretical comparisons between the general solution and classical particle dissolution expressions can be made by generating simulated particle dissolution data using eq 32 and comparing the simulated data with the traditional expressions.

If a spherical particle dissolution profile follows one of the three traditional particle dissolution expressions, one of the $(w/w_0)^{1/n}$ vs time plots ($n = 3$, 2, or 3/2) should be linear with a slope of 1. By simulating dissolution profiles using the normalized general equation (eq 32) and plotting the resulting dissolution profiles with these three ordinate axis transformations (Figure 3), it can be seen how well the three approximate particle dissolution rate expressions (eqs 1–3) apply. The dissolution data were simulated with different values of a_0/h. It can be seen from Figure 3 that there are deviations from linearity for some a_0/h ratios no matter what ordinate transformation is used.

It should be pointed out that linearity of such plots is not a sensitive criterion to test whether the dissolution profile is consistent with a certain rate expression. Usually dissolution profiles can be reasonably linear on any of the three transformed axes up to ~80% dissolved (i.e., $[w/w_0]^{1/n} = 0.585$, 0.447, 0.342 for $n = 3$, 2, 3/2, respectively).

3. A New Semiempirical Equation for Single Spherical Particle Dissolution under Sink Conditions—Since there are functional simlarities in the three classical particle dissolution rate expressions, a new semiempirical equation (eq 33) is proposed which incorporates the three classical expressions but the exponent, n, is not limited to values 3, 2, and 3/2. The proportionality constant $k_{1/n}$ is a constant with units of mass$^{1/n}$/time.

$$w^{1/n} = w_0^{1/n} - k_{1/n}t \quad \text{(eq 33)}$$

Single particle dissolution profiles generated from the general equation (eq 32) can be fitted by eq 33 where n ranges from 3/2 to 3 but does not have to be a specific value (i.e., 3/2, 2, or 3). If w is normalized by w_0 and t is normalized by T ($T = w_0^{1/n}/k_{1/n}$), a dimensionless expression is obtained:

$$\frac{w}{w_0} = \left(1 - \frac{t}{T}\right)^n \quad \text{(eq 34)}$$

The two parameters, T and n, can be obtained by fitting eq 34 to dissolution data (w/w_0 vs t). Simulation studies were carried out at six representative a_0/h ratios. For convenience, the w/w_0 values were generated by keeping $a/a_0 = 1.0$, 0.95, 0.90, ..., 0.05, 0 for each a_0/h ratio. The corresponding times (t) for these w/w_0 values were then calculated with eq 32. The values of T and n were obtained by fitting eq 34 to the simulated data and the results are given in Table 1. It can be seen that n depends on a_0/h with the smaller ratio giving a smaller value of n. The other fitted parameter, T, deviates slightly from its theoretical value (1.0) for all a_0/h ratios. Theoretically, it is possible to determine a_0/h from the fitted value of n. However, small variations in n can lead to dramatic changes in calculated a_0/h values making it difficult to obtain an accurate estimation of a_0/h from n.

4. Dependence of Surface-Specific Dissolution Rate upon Particle Size under Sink Conditions—According to Fick's first law,

$$J = -D\frac{\partial C}{\partial r} \quad \text{(eq 35)}$$

J is the diffusional flux and is defined as the amount of substance passing per unit time normal to unit surface area. When applied to dissolution, it may also be defined as the surface-specific dissolution rate. Substituting eq 11 into eq 35 gives:

$$J = DC_S\left(\frac{1}{h} + \frac{1}{a}\right) \quad \text{(eq 36)}$$

Equation 36 demonstrates that the surface-specific dissolution rate depends on particle size, with smaller particles having higher surface-specific dissolution rates (Figure 4). Bisrat et al.[13] and Anderberg et al.[14,17] reported a dependence of surface-specific dissolution rates upon particle size. Their results showed the same trend seen in

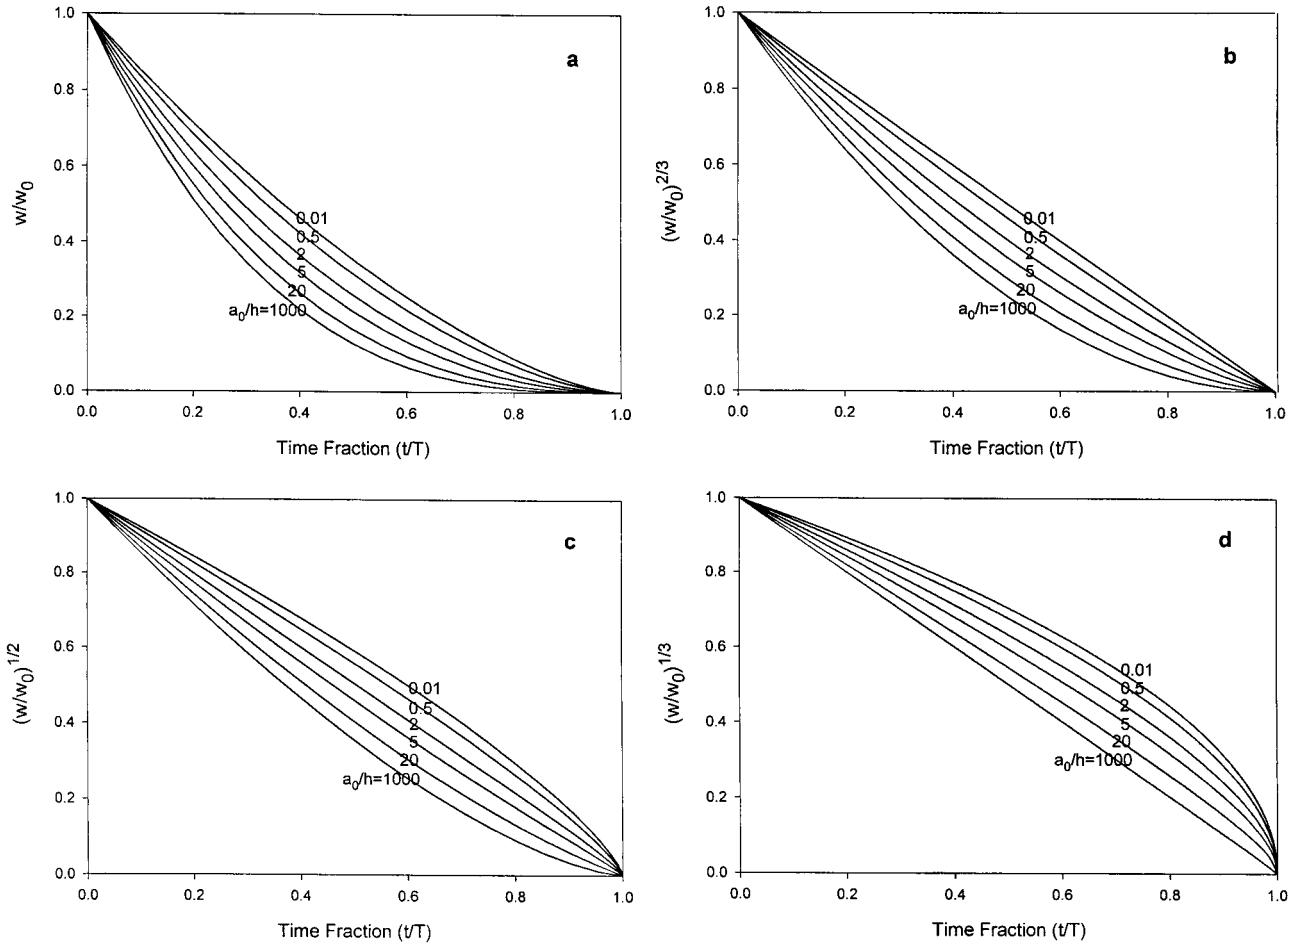

Figure 3—Simulated particle dissolution profiles (eq 32) at representative a_0/h values (0.01, 0.5, 2, 5, 20, 1000) with different $(w/w_0)^{1/n}$ ordinate axes: (a) $n = 1$; (b) $n = 3/2$; (c) $n = 2$; (d) $n = 3$.

Table 1—Fitted Parameters (n, T) for Simulated Data (eq 32) Fitted by eq 34

a_0/h	n	T	r^2
1000	3.00	1.004	1.00000
20	2.80	1.051	1.00000
5	2.43	1.059	0.99999
2	2.09	1.044	0.99998
0.5	1.71	1.016	0.99999
0.01	1.51	1.000	1.00000

Figure 4. The surface-specific dissolution rate increased (after correcting for solubility dependence on particle size) with decreasing particle size. This increase was especially pronounced for particle sizes below ~5 μm.

Harriott similarly reported on mass transfer to particles (i.e., particle growth) for a much wider range of particle sizes.[18] He found that the mass transfer coefficient, k_C (cm/s), was almost independent of particle size for particles larger than 200 μm, but was particle size dependent for smaller particles. Since diffusion layer thicknesses usually range from 10 to 200 μm, it seems that for particles smaller than 200 μm, particle size effects will be significant on particle dissolution.

Equation 36 can be rewritten in a more general form:

$$J = DC_S\left(\frac{1}{h} + \frac{1}{r_c}\right) \qquad \text{(eq 37)}$$

where r_c is the radius of curvature of a dissolving surface and is positive ($r_c > 0$) for a convex surface. For flat surfaces

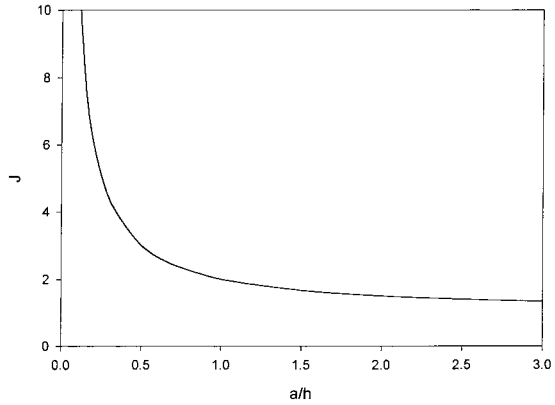

Figure 4—Relative surface-specific dissolution rate dependence (J, $J = 1$ for a flat surface) upon particle radius (a) normalized with diffusion layer thickness (h) using eq 36.

($r_c \rightarrow \infty$), dissolution rate is directly proportional to surface area. However, this simple relationship does not hold for a curved surface. Convex surfaces have larger surface-specific dissolution rates than a flat surface. Hixson and Crowell derived the cube-root law by assuming dissolution rate is proportional to particle surface area. From the above analysis we can see that this assumption is not justified when r_c is comparable to or smaller than h.

5. Particle Dissolution under Nonsink Conditions—The general equation for spherical particle dissolution under nonsink conditions (eq 22) is algebrically complex but can be mathematically simulated. It can also be converted to particle weight (W) which will lead to an

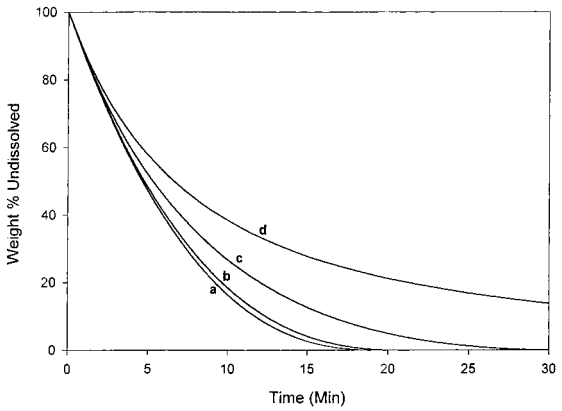

Figure 5—Comparison of particle dissolution under sink conditions (a) and three degrees of saturation: (b) 10%; (c) 50%; (d) 100%.

equally unwieldy equation which we do not show here. The main advantage of such expressions is for dissolution systems in which the drug is quite insoluble where sink conditions are difficult or impossible to maintain.

A simulation was done to compare particle dissolution under sink conditions and different degrees of nonsink conditions using eqs 21−23. Three levels of nonsink conditions were chosen: initial particle weight equal to 10%, 50%, and 100% of the amount necessary to saturate the solution. The initial particle radius was arbitrarily chosen to be 10 times as large as the diffusion layer thickness with $a_0 = 200\ \mu$m, $h = 20\ \mu$m, $D = 1.1 \times 10^{-5}$ cm^2/s, $C_S = 3.4$ mg/mL, $\rho = 1.4$ g/cm^3. A comparison of the dissolution profiles is shown in Figure 5. It can be seen that assuming sink conditions provides good results when initial particle weight is less than 10% of the weight for saturation.

Conclusions

The general solution of the diffusion layer model applied to spherical particle dissolution is derived. The three classical particle dissolution rate expressions, including the cube-root law, are special cases of the general solution to particle dissolution under sink conditions with constant diffusion layer thickness. The ratio between particle radius and diffusion layer thickness (a_0/h) is an important factor in controlling the shape of the dissolution profile. It also controls which classical model can fit a dissolution profile better than the other two models. It is necessary to apply this general equation to typical monodispersed drug powder dissolution data to fit the entire profile. This general equation will be applied to literature and experimental data in future publications.

Nomenclature

a	particle radius
a_0	initial particle radius
A	surface area
C	concentration
C_b	concentration in the bulk solution
C_S	solubility
D	diffusion coefficient
$G(R)$	concentration gradient at distance R from the center of the particle
h	diffusion layer thickness
J	surface-specific dissolution rate, i.e., dissolution rate on unit surface area
$k_{1/3}$	single particle dissolution constant in the cube-root law
$k_{1/2}$	single particle dissolution constant in the square-root expression
$k_{2/3}$	single particle dissolution constant in the two-thirds-root expression
k_n	dissolution rate constant
n	dissolution rate order
N	total number of particles
r	distance from the center of a particle
r_c	radius of curvature
t	time
T	time needed for complete particle dissolution
V	solution volume
w	individual particle weight
w_0	initial individual particle weight
W	total weight of monodispersed particles
W_0	total initial weight of monodispersed particles
ρ	solid density of the particle

Appendix I

The cube-root law and the two-thirds-root expression can be derived from eq 18 using a Taylor series expansion (eq 38).

$$\ln(1+x) = x - \frac{x^2}{2} + \frac{x^3}{3} - \frac{x^4}{4}..... \qquad -1 < x \le 1 \qquad \text{(eq 38)}$$

1. Derivation of the Cube-Root Law from the General Equation (eq 18). Equation 18 can be transformed to:

$$\frac{DC_S}{\rho h}t = a_0 - a + h\ln\left(1 + \frac{a-a_0}{h+a_0}\right) \qquad \text{(eq 39)}$$

To derive the Hixson−Crowell cube-root expression, it is necessary to assume that $h \ll a_0$ and $h \ll a$, so that $|(a - a_0)/(h + a_0)| < 1$. Applying the Taylor series expansion to eq 39 leads to:

$$\frac{DC_S}{\rho h}t = a_0 - a + h\left[\frac{a-a_0}{a_0+h} - \frac{1}{2}\left(\frac{a-a_0}{a_0+h}\right)^2 + \frac{1}{3}\left(\frac{a-a_0}{a_0+h}\right)^3 - \frac{1}{4}\left(\frac{a-a_0}{a_0+h}\right)^4.....\right]$$

$$= a_0 - a + (a-a_0)h\left[\frac{1}{a_0+h} - \frac{1}{2}\frac{(a-a_0)}{(a_0+h)^2} + \frac{1}{3}\frac{(a-a_0)^2}{(a_0+h)^3} - \frac{1}{4}\frac{(a-a_0)^3}{(a_0+h)^4}.....\right]$$

$$= (a_0-a)\left\{1 - \frac{h}{a_0+h}\left[1 - \frac{1}{2}\frac{(a-a_0)}{(a_0+h)} + \frac{1}{3}\frac{(a-a_0)^2}{(a_0+h)^2} - \frac{1}{4}\frac{(a-a_0)^3}{(a_0+h)}.....\right]\right\}$$

$$= (a_0-a)\left\{1 - \frac{h}{a_0+h}\left[1 + \frac{1}{2}\frac{a_0-a}{a_0+h} + \frac{1}{3}\left(\frac{a_0-a}{a_0+h}\right)^2 + \frac{1}{4}\left(\frac{a_0-a}{a_0+h}\right)^3.....\right]\right\} \qquad \text{(eq 40)}$$

Equation 40 can be written as eq 41,

$$\frac{DC_S}{\rho h} = (a_0 - a)(1 - P) \qquad \text{(eq 41)}$$

For the case where $a \geq 0.5a_0$, we have $(a_0 - a)/(a_0 + h) < {}^1/_2$, so,

$$P = \frac{h}{a_0 + h}\left[1 + \frac{1}{2}\frac{(a_0 - a)}{(a_0 + h)} + \frac{1}{3}\left(\frac{a_0 - a}{a_0 + h}\right)^2 + \frac{1}{4}\left(\frac{a_0 - a}{a_0 + h}\right)^3 \ldots\ldots\right]$$

$$< \frac{h}{a_0 + h}\left[1 + \frac{1}{2} \times \frac{1}{2} + \frac{1}{3}\left(\frac{1}{2}\right)^2 + \frac{1}{4}\left(\frac{1}{2}\right)^3 \ldots\ldots\right]$$

$$< \frac{h}{a_0 + h}\left[1 + \frac{1}{2} \times \frac{1}{2} + \frac{1}{2}\left(\frac{1}{2}\right)^2 + \frac{1}{2}\left(\frac{1}{2}\right)^3 \ldots\ldots\right]$$

$$= \frac{3}{2}\frac{h}{a_0 + h} \qquad \text{(eq 42)}$$

Since $a_0 \gg h$, we have $P \ll 1$, so eq 41 can be approximated by:

$$\frac{DC_S}{\rho h} t \approx a_0 - a \qquad \text{(eq 24)}$$

From eq 24, the cube-root law can be derived.

2. Derivation of Two-Thirds-Root Expression from the General Equation (eq 18). Equation 18 can be transformed to:

$$\frac{DC_S}{\rho h} t = a_0 - a - h \ln\left(\frac{h + a_0}{h} \times \frac{h}{h + a}\right) = a_0 - a - h\left[\ln\left(1 + \frac{a_0}{h}\right) - \ln\left(1 + \frac{a}{h}\right)\right] \qquad \text{(eq 43)}$$

In the case of the Higuchi–Hiestand two-thirds-root expression, it is necessary to assume that $h \gg a_0$ which leads to $a_0/h \ll 1$. Applying the Taylor series expansion to eq 43 gives:

$$\frac{DC_S}{\rho h} t = a_0 - a - h\left[\frac{a_0}{h} - \frac{1}{2}\left(\frac{a_0}{h}\right)^2 + \frac{1}{3}\left(\frac{a_0}{h}\right)^3 \ldots\ldots - \frac{a}{h} + \frac{1}{2}\left(\frac{a}{h}\right)^2 - \frac{1}{3}\left(\frac{a}{h}\right)^3 \ldots\ldots\right] \qquad \text{(eq 44)}$$

Since $a_0/h \ll 1$, eq 44 can be approximated by:

$$\frac{DC_S}{\rho h} t \approx a_0 - a - h\left[\frac{a_0}{h} - \frac{1}{2}\left(\frac{a_0}{h}\right)^2 - \frac{a}{h} + \frac{1}{2}\left(\frac{a}{h}\right)^2\right] = \frac{1}{2}\frac{(a_0^2 - a^2)}{h} \qquad \text{(eq 45)}$$

Rearranging eq 45 gives:

$$\frac{2DC_S}{\rho} t \approx a_0^2 - a^2 \qquad \text{(eq 25)}$$

From eq 25 the two-thirds-root expression of Higuchi and Hiestand can be derived.

Appendix II

The general solution for single spherical particle dissolution under nonsink conditions can also be derived in a similar manner as under sink conditions. If the initial bulk concentration is 0 and the solution volume (V) is kept constant, the bulk concentration (C_b) can be described by the following equation for single spherical particle dissolution:

$$C_b = \frac{\frac{4}{3}\pi(a_0^3 - a^3)\rho}{V} \qquad \text{(eq 46)}$$

Under nonsink conditions, eqs 5–8 are still valid, while eq 10 should be modified to give:

$$\int_a^{a+h} -\frac{a^2}{r^2} G(a)\, dr = C_S - C_b \qquad \text{(eq 47)}$$

Integrating eq 47 gives:

$$G(a) = -\left(\frac{1}{a} + \frac{1}{h}\right)(C_S - C_b) \qquad \text{(eq 48)}$$

Substituting eq 48 into eq 6 gives:

$$\frac{dQ}{dt} = 4\pi a^2 D\left(\frac{1}{a} + \frac{1}{h}\right)(C_S - C_b) \qquad \text{(eq 49)}$$

Equating eq 14 and eq 49 and rearranging gives:

$$-\frac{D}{\rho h}\, dt = \frac{a}{(a + h)(C_S - C_b)}\, da \qquad \text{(eq 50)}$$

The integral form of eq 50 is:

$$\int_0^t -\frac{D}{\rho h}\, dt = \int_{a_0}^{a} \frac{a}{(a + h)(C_S - C_b)}\, da \qquad \text{(eq 51)}$$

Substituting eq 46 into eq 51 gives:

$$\int_0^t -\frac{D}{\rho h}\, dt = \int_{a_0}^{a} \frac{a}{(a + h)\left(C_S - \frac{4}{3V}\pi a_0^3 \rho + \frac{4}{3V}\pi a^3 \rho\right)}\, da \qquad \text{(eq 52)}$$

Integrating eq 52 will lead to a relationship between particle radius and time. The integration is complex and only the final form is given below:

$$\frac{D}{\rho h V} t = \frac{1}{\beta - \alpha h^3}\{X + Y + Z\} \qquad \text{(eq 22)}$$

$$X = h \ln \frac{a + h}{a_0 + h} - \frac{h}{3} \ln \frac{\alpha a^3 + \beta}{\alpha a_0^3 + \beta}$$

$$Y = \frac{h^2}{\gamma}\left[\frac{1}{2} \ln \frac{(\alpha a^3 + \beta)(\gamma + a_0)^3}{(\gamma + a)^3(\alpha a_0^3 + \beta)} + \sqrt{3} \tan^{-1}\left(\frac{2a - \gamma}{\sqrt{3}\gamma}\right) - \sqrt{3} \tan^{-1}\left(\frac{2a_0 - \gamma}{\sqrt{3}\gamma}\right)\right]$$

$$Z = \frac{\gamma}{3}\left[\frac{1}{2} \ln \frac{(\alpha a^3 + \beta)(\gamma + a_0)^3}{(\gamma + a)^3(\alpha a_0^3 + \beta)} - \sqrt{3} \tan^{-1}\left(\frac{2a - \gamma}{\sqrt{3}\gamma}\right) + \sqrt{3} \tan^{-1}\left(\frac{2a_0 - \gamma}{\sqrt{3}\gamma}\right)\right]$$

In eq 22, α, β and γ are constants: $\alpha = 4\pi\rho/3$, $\beta = C_S V - 4\pi a_0^3 \rho/3$, $\gamma = (\beta/\alpha)^{1/3}$. For N monodispersed particles, eq

22 is essentially the same except that $C_b = [4\pi(a_0^3 - a^3)\rho N/3]/V$, correspondingly, the values of α and β become $\alpha = {}^4/_3\pi\rho N$, $\beta = C_S V - {}^4/_3\pi a_0^3\rho N$. Weight undissolved ($w$) expressions can be obtained by substituting $a = (3w/4\pi\rho)^{1/3}$ in eq 22.

A special case arises when the initial particle weight (w_0) exactly equals the amount necessary to saturate the solution. In this case, the above equation does not work ($\beta = 0$) and a special equation needs to be derived where:

$$C_S = \frac{4}{3V}\pi a_0^3\rho \qquad \text{(eq 53)}$$

Thus, eq 52 becomes:

$$\int_0^t -\frac{D}{\rho h}\,dt = \int_{a_0}^{a} \frac{1}{\frac{4}{3V}\pi a^2\rho(a+h)}\,da \qquad \text{(eq 54)}$$

Integrating both sides of eq 54 gives:

$$\frac{4D\pi}{3V}\,t = \frac{1}{a} - \frac{1}{a_0} + \frac{1}{h}\ln\frac{a(a_0+h)}{a_0(a+h)} \qquad \text{(eq 55)}$$

Substituting for V using eq 53 into the left-hand side of eq 55 gives:

$$\frac{DC_S}{a_0^3\rho}\,t = \frac{1}{a} - \frac{1}{a_0} + \frac{1}{h}\ln\frac{a(a_0+h)}{a_0(a+h)} \qquad \text{(eq 56)}$$

For N monodispersed particles, $C_S = 4\pi a_0^3\rho N/3V$ and the final equation becomes:

$$\frac{DC_S}{a_0^3\rho N}\,t = \frac{1}{a} - \frac{1}{a_0} + \frac{1}{h}\ln\frac{a(a_0+h)}{a_0(a+h)} \qquad \text{(eq 23)}$$

15. Steady-state and pseudo-steady-state are important concepts in this paper. Dissolution from a planar surface under sink conditions reaches steady-state when the dissolution rate becomes constant; hence, the concentration gradient in the diffusion layer becomes time-invariant. Dissolution of a spherical surface will not reach steady-state because its surface area decreases with time and the concentration gradient is not time-invariant. However, a pseudo-steady-state may exist in which the following approximation is accurate—the overall mass transport rates across the inner and outer spherical surfaces (at $r = a$ and $a + h$) of the diffusion layer are equal. This assumption requires that within the time for an average molecule to cross the diffusion layer, the change of particle surface area is negligible.
16. In the derivation of the two-thirds-root expression (Higuchi and Hiestand), it was assumed that the fluid is perfectly stagnant and the diffusion equation for spherical geometry was solved. This case is mathematically equivalent to assuming a linear concentration gradient in a diffusion layer of thickness equal to the particle radius. This mathematical identity is just a coincidence and does not have any mechanistic significance.

Metabolic Stability of Glutaraldehyde Cross-Linked Peptide DNA Condensates

ROGER C. ADAMI[†] AND KEVIN G. RICE[*,†,‡]

Contribution from *Divisions of Pharmaceutics and Medicinal Chemistry, College of Pharmacy, University of Michigan, Ann Arbor, Michigan 48109-1065.*

Received February 8, 1999. Accepted for publication May 25, 1999.

Abstract ☐ The stability of peptide DNA condensates was examined after introducing glutaraldehyde to cross-link surface amine groups. A 20 amino acid peptide (CWK_{18}) was used to condense DNA into small (70 nm) condensates. The reaction between glutaraldehyde and peptide DNA condensates was indirectly monitored using a fluorescence-based assay to establish reaction completion in 4–5 h when using glutaraldehyde-to-peptide ratios of 1 to 4 mol equiv. Higher levels of glutaraldehyde cross-linking led to significant increases in particle size. The improved stability imparted by glutaraldehyde cross-linking was demonstrated by the increased resistance of DNA condensates to shear stress induced fragmentation. The cross-linked condensates were also significantly more resistant to in vitro metabolism by serum endonucleases. A decrease in the magnitude of transient gene expression was determined for cross-linked DNA condensates which also resulted in a 10-day steady-state expression when cross-linking with 4 mol equiv of glutaraldehyde. The results suggest that cross-linking DNA condensates may provide a means to alter the time course of transient gene expression by inhibiting DNA metabolism.

Introduction

To achieve optimal and prolonged gene expression, carrier molecules are used to protect plasmid DNA from metabolism while en route, and once inside the target cell. Strategies to enhance nonviral DNA delivery have focused on the use of cationic carriers such as lipids, peptides, and polymers that bind DNA through ionic interaction.[1−5] In each case, ion pairing leads to varying degrees of DNA condensation, resulting in cationic particles that internalize into cells and mediate transient gene expression.[6]

To be effective in delivering DNA, carrier molecules must have low toxicity, exhibit low levels of antigenicity or complement activation, and protect DNA from degradation.[7] Simultaneously addressing each of these has been one of the major impediments to developing highly effective in vivo gene delivery formulations.[1,8]

The stability of DNA condensates in serum is dependent on the nature and affinity of a carrier molecule for binding DNA, the ionic strength, the concentration of endonuclease, and the presence of molecules that compete for carrier binding. Dissociation of the carrier molecule in serum exposes DNA to metabolizing endonuclease leading to premature degradation.[9]

Only a few studies have addressed the issue of DNA metabolism despite its obvious relationship to the level and duration of gene expression.[9−13] Early studies by Wu and co-workers concluded that high molecular weight (HMW) polylysines could protect DNA from rapid metabolism in vitro for up to 1.5 h.[13] Subsequent studies by our group determined that a 20 amino acid peptide (CWK_{18}) was sufficient to stabilize DNA condensates from in vitro metabolism.[14] Despite the ability of HMW polylysines to retard metabolism, the associated toxicity of these polymers has prompted the search for LMW carriers for use in vivo.[15]

An alternative strategy to achieve high affinity using LMW carriers is to provide temporary stability through

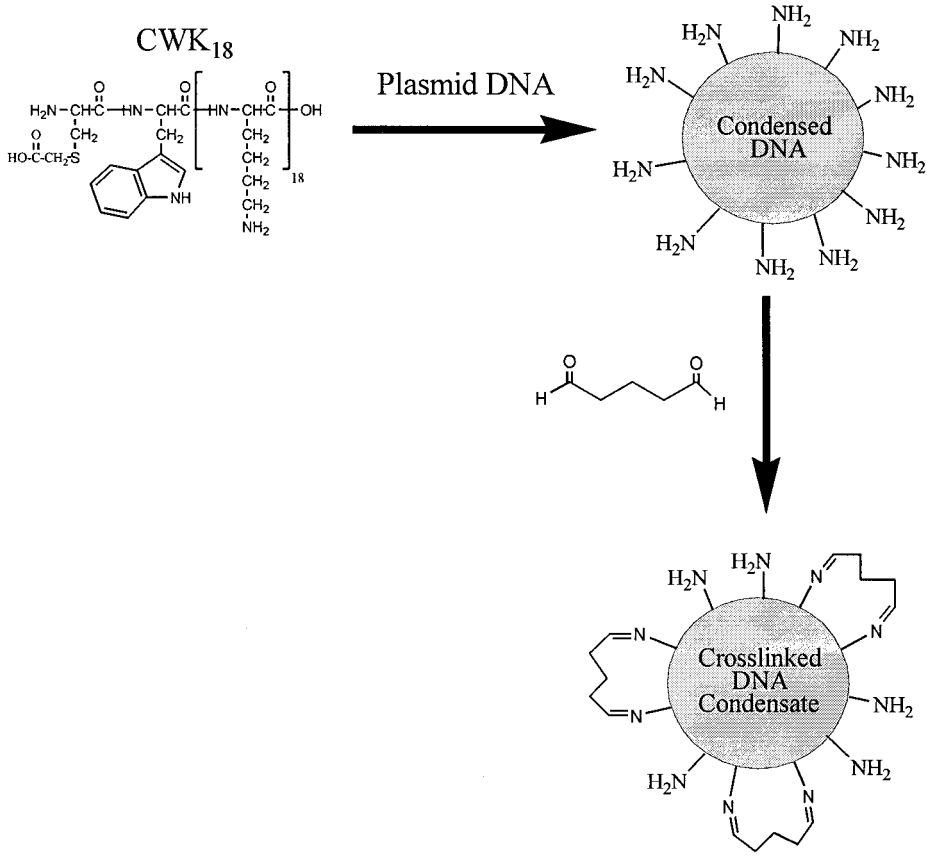

Figure 1—Glutaraldehyde cross-linking DNA condensates. CWK_{18} binds to plasmid DNA to spontaneously form condensed DNA possessing residual surface amines. Glutaraldehdye is reacted with condensed DNA resulting in the formation of two Schiff-bases between neighboring amine groups resulting in cross-linked DNA condensates. The degree of cross-linking is expressed as the mols of glutaraldehyde added relative to mols of CWK_{18}.

molecular cross-linking of carriers on DNA condensates. The unpaired amines on the surface of peptide DNA condensates could potentially be cross-linked with a variety of agents.

Glutaraldehyde is a five-carbon dialdehyde which has long been used as a reagent to increase the tensile strength of transplanted pig heart valves and develop controlled release microspheres for drug delivery.[16−18] The chemical cross-linking of albumin lysines with glutaraldehyde leads to particles which have controlled drug release properties.[19,20] The degree of cross-linking directly affects the particle size, biodegradation, and release properties of drugs encapsulated in glutaraldehyde cross-linked microspheres.[17,18,21]

In the present study, we report the use of glutaraldehyde to cross-link DNA condensates in an attempt to improve their metabolic stability and alter the resulting transient gene expression profiles in vitro. The results indicate that cross-linking can be used to enhance the stability of LMW peptide DNA condensates and leads to steady-state transient gene expression. These attributes may allow the design of nonviral gene delivery carriers that mediate prolonged transient gene expression in vivo.

Materials and Methods

CWK_{18} (alkylated Cys-Trp-Lys_{18}) and dimeric CWK_{18} were synthesized and characterized as described previously.[22] Glutaraldehyde, SDS, ethidium bromide, proteinase K, DNase I (EC 3.1.21.1) from bovine pancreas, and polylysine$_{99}$, polylysine$_{476}$, and polylysine$_{1007}$ were obtained from Sigma. pSEAP (plasmid secreted alkaline phosphatase with SV40 promoter and late polyadenylation sequence) and SEAP chemiluminescent detection kit were obtained from Clontech. pSEAP was grown in *Escherichia coli* and purified using a Qiagen miniprep column (Valencia, CA). TPCK-treated trypsin was obtained from Worthington Biochemicals (Freehold, NJ). Bradford protein assay was obtained from BioRad (Hercules, CA). MEM, fetal calf serum and electrophoresis grade agarose were obtained from Gibco BRL (Gaithersburg, MD). SYBR-Gold was obtained from Molecular Probes (Eugene, OR).

Preparation and Characterization of Cross-Linked DNA Condensates—CWK_{18} DNA condensates were formed by adding 10 μg (100 μL) of pSEAP (4.7 kBp) to 3 nmol of CWK_{18} in 100 μL of 5 mM HEPES, pH 7.4, while vortexing to prepare DNA condensates possessing a calculated charge ratio (amine:phosphate) of 2:1. HMW polylysines$_{99-1007}$ were prepared at 10 mg/mL in HEPES and used to form DNA condensates at a 2:1 amine:phosphate ratio for each.

After 30 min, CWK_{18} DNA condensates were reacted with either 3, 6, 9, or 12 nmol of glutaraldehyde (1 nmol/μL) for 12 h at 4 °C resulting in 1, 2, 3, or 4 mol equiv (mol of glutaraldehyde per mol of CWK_{18}) of cross-linking. The reaction of glutaraldehyde with DNA condensates was studied using a fluorophore exclusion assay. Following the addition of glutaraldehyde, 10 μL aliquots were removed at time intervals ranging from 0 to 5 h and immediately combined with 490 μL of 0.35 M sodium chloride. Prior to measuring fluorescence, 10 μL of SYBR-Gold (diluted 1:200 in DMSO) was added, and the fluorescence intensity (Ex: 495 nm, Em: 537 nm) was measured on a Perkin-Elmer LS-50B fluorimeter.

The particle size of cross-linked DNA condensates was measured using 350 μL of 50 μg/mL DNA condensate in HEPES by quasielastic light scattering (QELS). ζ potential measurements were conducted at the same DNA concentration in HEPES using an average of 10 runs to determine the mean and standard deviation on a Brookhaven ZetaPlus.

Shear Stress Stability of DNA Condensates—Peptide DNA condensates (200 μL) were combined with 0−90 μL of 5 M sodium chloride and normalized with HEPES to a final volume of 300 μL to obtain a final concentration of 0, 0.1, 0.3, 0.5, 0.7, 0.9, 1.2, or 1.5 M sodium chloride. A 100 W Microson XL-2000 ultrasonic

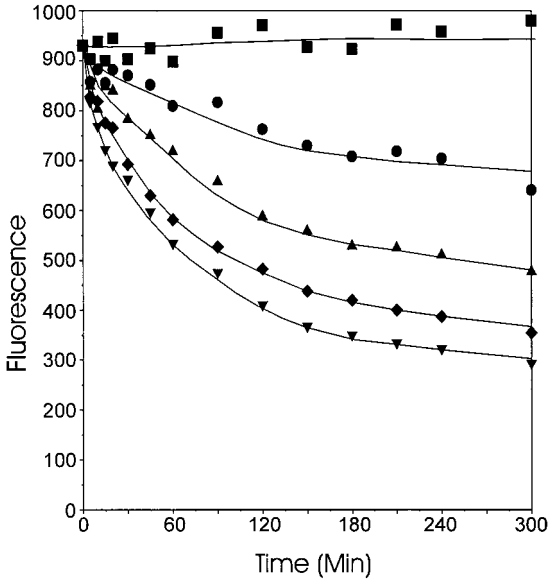

Figure 2—Kinetics of glutaraldehyde cross-linking CWK_{18} DNA condensates. The reaction between glutaraldehyde and condensed DNA was measured indirectly by a fluorescence assay described in Materials and Methods. An inverse relationship between the amount of glutaraldehyde added and fluorescence intensity indicated an increased reaction rate corresponding to increased glutaraldehyde cross-linking. The data represents un-cross-linked (■), 1 mol equiv (●), 2 mol equiv (▲), 3 mol equiv (◆), and 4 mol equiv (▼) cross-linked DNA condensates.

probe homogenizer (Kontes, Vineland, NJ) set at a vibrational amplitude of 5 was used throughout the study. The probe tip was placed $^3/_4$ depth into a 1.5 mL microfuge tube containing 300 μL of sample and then sonicated for 30 s. DNA samples (15 μL) were brought to 1 M sodium chloride by adding 4.6 μL of 5 M sodium chloride and then digested with trypsin (3 μL containing 7 U) for 12 h at 37 °C. The samples were combined with 3 μL of loading buffer, and 18 μL was applied to a 1% agarose gel (50 mL) containing 0.5 μg/mL ethidium bromide. The gel was electrophoresed in TAE buffer at 70 V for 80 min followed by 12 h destaining in deionized water. Transilluminated gels were photographed on polaroid 667 film.

Serum Stability of DNA Condensates—DNA condensates (100 μL) were combined with 100 μL of DNase I augmented mouse serum (0.12 U of DNase I per 100 μL serum) and 3 μL of 5 M sodium chloride to bring the final salt concentration to 150 mM. Samples were incubated at 37 °C for 3 h while withdrawing 20 μL aliquots that were rapidly frozen at time points ranging from 0 to 180 min. Serum samples were processed by adding 3 μL (0.31 U) of proteinase K and then incubated at 37 °C for 30 min to remove endonuclease activity. Sodium chloride was then added (4.6 μL of 5 M) along with trypsin (3 μL containing 7 U) and allowed to digest for 12 h at 37 °C to remove the cross-linked peptide. Samples were applied to a 1% agarose gel containing 0.05% SDS and electrophoresed as described above.

Transient Gene Expression—HepG2 cells (3×10^5) were plated on 6 × 35 mm wells and grown for 48 h to 40% confluence in MEM supplemented with 10% fetal calf serum (FCS). Cross-linked DNA condensates (10 μg of DNA in 200 μL) were transfected in triplicate by dropwise addition to cells in 10% FCS either with or without 80 μM chloroquine followed by 5 h incubation, after which the media was replaced with 2 mL of MEM containing 10% fetal calf serum and allowed to incubate for an additional 19 h. Wells were sampled for 10-days at 24 h intervals by removing and freezing (−20 °C) the media and replacing it with 2 mL of fresh 10% FCS MEM. The amount of heat-stable SEAP in each well was determined using a chemiluminescent kit. Media (50 μL) was combined with 50 μL of dilution buffer followed by incubation at 65 °C for 30 min to denature endogenous alkaline phosphatase. Assay buffer (100 μL) was added and incubated for 10 min at 25 °C followed by the addition of CSPD [(disodium 3-(4-methoxyspiro-{1,2-dioxetane-3,2′-(5′-chloro) tricyclo [3.3.1.1^{3,7}] decan}-4-yl) phenyl phosphate)] substrate in chemiluminescent enhancer. After 30 min, the luminescence was measured with a 10 s integration on a Berthold Lumat LB 9501 luminometer. Light units were converted to μg/mL of SEAP using a standard curve constructed by adding known quantities of SEAP to cell homogenate. Residual endogenous alkaline phosphatase background was determined from a 10-day null control and subtracted from each data set.

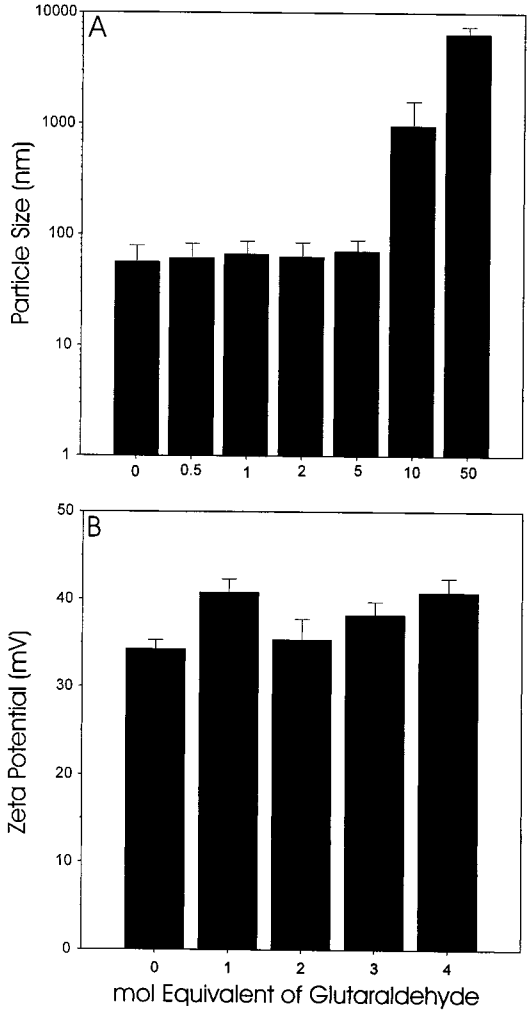

Figure 3—Particle size and ζ potential analysis of cross-linked DNA condensates. CWK_{18} DNA condensates cross-linked with 0–5 mol equiv of glutaraldehyde exhibited particle sizes between 55 and 70 nm as shown in panel A. At concentrations of 10 and 50 mol equiv of glutaraldehyde the particle size increased by 1 and 2 orders of magnitude (panel A). Condensates prepared at 0–4 mol equiv of glutaraldehyde had a ζ potential between +34–41 mV (panel B).

Results

The metabolic stability and transient gene expression was investigated in relationship to the degree of cross-linking applied to peptide DNA condensates. Peptide DNA condensates are colloids that possess primary amines on their surface that can be cross-linked with homobifunctional agents such as glutaraldehyde (Figure 1). The resulting interpeptide cross-links should stabilize condensed DNA from peptide dissociation and from metabolism since it has been previously established that condensed DNA resists endonuclease attack.[13,14]

To establish that glutaraldehyde reacts with DNA condensates to form interpeptide cross-links the time course of the reaction was monitored indirectly using a fluorescent intercalator dye. SYBR-Gold was selected since its intercalation into DNA is not significantly inhibited in sodium chloride up to 1 M. In the absence of sodium

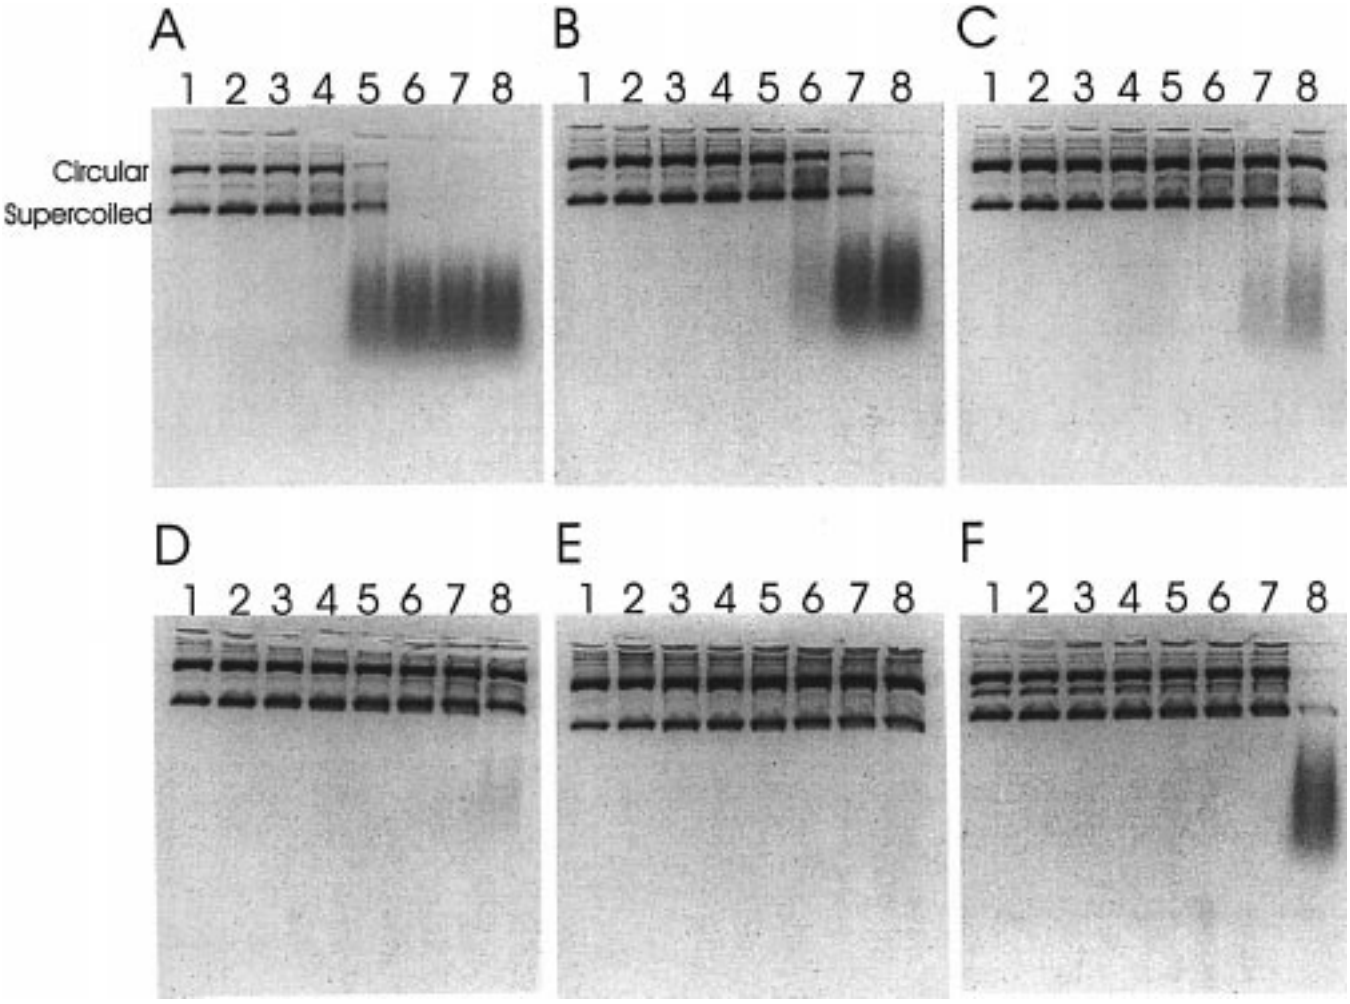

Figure 4—Shear stress stability of cross-linked DNA condensates. The stability of cross-linked DNA condensates was measured by 30 s 100 W sonication in the presence of increasing sodium chloride concentration as described in Methods and Methods. The electrophoretic analysis of CWK_{18} DNA condensates prepared with 0 (A), 1 (B), 2 (C), 3 (D) and 4 (E) mol equiv of glutaraldehyde were compared to $polylysine_{1007}$ DNA condensates (F). Lanes 1 through 8 contain 0, 0.1, 0.3, 0.5, 0.7, 0.9, 1.2, and 1.5 M sodium chloride. The dissociation of CWK_{18} from DNA occurs at 0.7 M sodium chloride (panel A, lane 5) as determined by the formation of fragments during sonication. Alternatively, 1 mol equiv of glutaraldehyde extended the DNA stability to 0.9 M sodium chloride (panel B, lane 6), 2 mol equiv of glutaraldehyde increased the stability to 1.2 M sodium chloride (panel C, lane 7), and 3 and 4 mol equiv of glutaraldehyde resulted in DNA condensates that were stable in 1.5 M sodium chloride (panels D and E). In contrast, $polylysine_{1007}$ DNA condensates dissociate in 1.5 M sodium chloride (panel F, lane 8). Each result was replicated twice.

chloride, the reaction of SYBR-Gold with CWK_{18} DNA condensates produces minimal fluorescence whereas the partial dissociation of condensates that occurred in 0.35 M sodium chloride produced a maximal fluorescence following intercalation (Figure 2). After the addition of glutaraldehyde, the formation of interpeptide cross-links stabilized CWK_{18} DNA condensates from dissociating in 0.35 M sodium chloride, leading to a decrease in the fluorescence intensity as the reaction proceeded over 5 h (Figure 2). Analysis of the reaction profile while varying the stoichiometry of glutaraldehyde from 1 to 4 mol equiv established a progressive decrease in fluorescence intensity that approached reaction completion in 5 h, suggesting that increasing the glutaraldehyde concentration leads to the formation of additional cross-links and further stabilization of DNA condensates (Figure 2).

Since glutaraldehyde could potentially also produce interparticle cross-links leading to larger DNA condensates, the relationship between the degree of cross-linking and the particle size was investigated by QELS analysis. DNA condensates prepared with 1 to 5 mol equiv of glutaraldehyde maintained a particle size of 55−70 nm, whereas stoichiometries of 10 mol equiv or higher caused a significant increase in size suggesting the formation of interparticle cross-links (Figure 3A). At 4 mol equiv of glutaraldehyde or lower, the ζ potential of DNA condensates remained between +34−41 mV, establishing minimal change in the overall charge of DNA condensates (Figure 3B).

The shear stress stability of glutaraldehyde cross-linked DNA condensates was evaluated by gel electrophoresis. CWK_{18} DNA condensates resist fragmentation when subjected to 30 s sonication until the sodium chloride concentration reached 0.7 M or higher, causing dissociation of peptide resulting in DNA fragmentation during sonication (Figure 4A). By comparison, DNA condensates cross-linked with 1 mol equiv of glutaraldehyde resist fragmentation in 0.9 M sodium chloride (Figure 4B). Reaction with 2 mol equiv of glutaraldehyde led to further stabilization resulting in condensates that resist fragmentation in 1.2 M sodium chloride (Figure 4C). Increasing the cross-linking to 3 and 4 mol equiv of glutaraldehyde resulted in DNA condensates that were stable up to 1.5 M sodium chloride (Figure 4D and 4E). Alternatively, $polylysine_{1007}$ DNA condensates were found to be less stable, undergoing fragmentation during sonication in 1.5 M sodium chloride (Figure 4F). These results suggest that the interpeptide cross-links formed with 3 and 4 mol equiv of glutaraldehyde extend the stability of CWK_{18} DNA condensates beyond

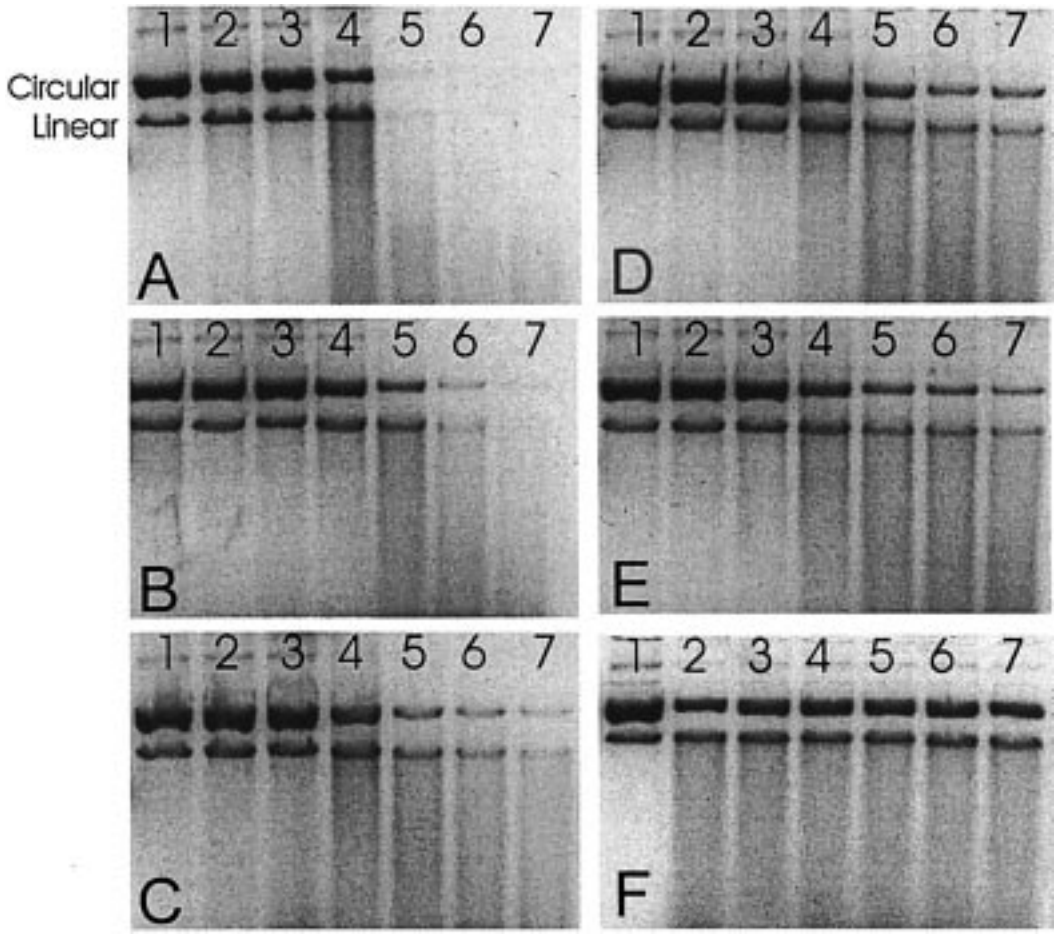

Figure 5—Serum stability of cross-linked condensates. The serum stability of DNA condensates cross-linked with 0 (A), 1 (B), 2 (C), 3 (D) and 4 (E) mol equiv of glutaraldehyde are compared to polylysine$_{1007}$ DNA condensates (F) using gel electrophoresis. Lanes 1 through 7 correspond to 0, 15, 30, 60, 90, 120, and 180 min digestion period. DNA stability was determined by observing a progressive decrease in the intensity of the circular and linear bands during the digestion, ultimately leading to the disappearance of the bands. Metabolism was evident from a decrease in band intensity leading to the complete disappearance of bands after 60 min for un-cross-linked DNA condensates (panel A, lane 4). DNA condensates prepared with 1 mol equiv of glutaraldehyde were delayed in metabolism until 90 min (panel B, lane 5). DNA condensates prepared with 2, 3, and 4 mol equiv of glutaraldehyde were significantly more protected from metabolism during the 180 min digestion, exhibiting only a decrease in the band intensity for circular and linear DNA (panels C–D, lanes 5–7). Polylysine$_{1007}$ was better than cross-linked condensates at protecting DNA throughout the 180 min digestion (panel F). Each results was replicated twice.

that achievable with a HMW polylysine. Control experiments established that plasmid DNA did not change its gel electrophoretic banding pattern when reacted with glutaraldehyde, suggesting that the exocylic amines on plasmid DNA bases are inexcessible to Schiff-base formation.

To be effective in gene delivery, cross-linked DNA condensates should also resist digestion with serum endonucleases. The metabolic stability of DNA was examined by gel electrophoretic analysis of DNA condensates incubated in mouse serum. Since un-cross-linked CWK_{18} DNA condensates proved to be resistant to endogenous serum endonuclease during a 24 h incubation, exogenous DNase I was added to accelerate the metabolism into a 3 h time period. Incubation of CWK_{18} DNA condensates in 50% serum containing 0.12 units of DNase I resulted in metabolism into oligonucleotides after 60 min (Figure 5A, lane 5). A trypsin contaminant produced a single strand nick in the DNA, such that even at time zero only circular and linear forms of DNA were recovered. Cross-linking CWK_{18} DNA condensates with 1−4 mol equiv of glutaraldehyde produced a progressive increase in metabolic stability with even 1 mol equiv of glutaraldehyde extending the stability of DNA condensates from 60 to 90 min (Figure 5B). The addition of 2 to 4 mol equiv extended the stability even further as evidenced by an increase in band intensity at 90 to 180 min (Figure 5C−E). By comparison, polylysine$_{1007}$ DNA condensates demonstrate improved serum stability to that of glutaraldehyde cross-linking at 4 mol equiv (Figure 5F).

The cytotoxicity of both free glutaraldehyde and cross-linked DNA condensates were examined in cell culture. The total protein of cell homogenates harvested 24 h after transfecting cells in the presence of free glutaraldehyde or cross-linked DNA condensates were indistinguishable from control, indicating no toxicity when using 1−4 mol equiv of glutaraldehyde corresponding to 1.5−6 μM.

The ability of cross-linked DNA condensates to release DNA and mediate gene transfer was examined by measuring the alkaline phosphatase secreted from HepG2 cells over a 10-day period. When using chloroquine to augment endosomal escape and increase gene expression, un-cross-linked peptide DNA condensates produced a transient gene expression profile that peaked around day 3−4 and then decreased to near background by day 10 (Figure 6A), with total transgene expression reaching 1.5 μg (Figure 6B). The moderate increase in stability afforded by 1 mol equiv of glutaraldehyde resulted in an expression profile and cumulative SEAP production identical to that afforded by un-cross-linked condensates. Alternatively, cross-linking with 2 mol equiv of glutaraldehyde resulted in a peak expression level that was nearly 2-fold greater than un-cross-linked DNA condensates (Figure 6A). These results are in contrast with those using 3 mol equiv of glutaral-

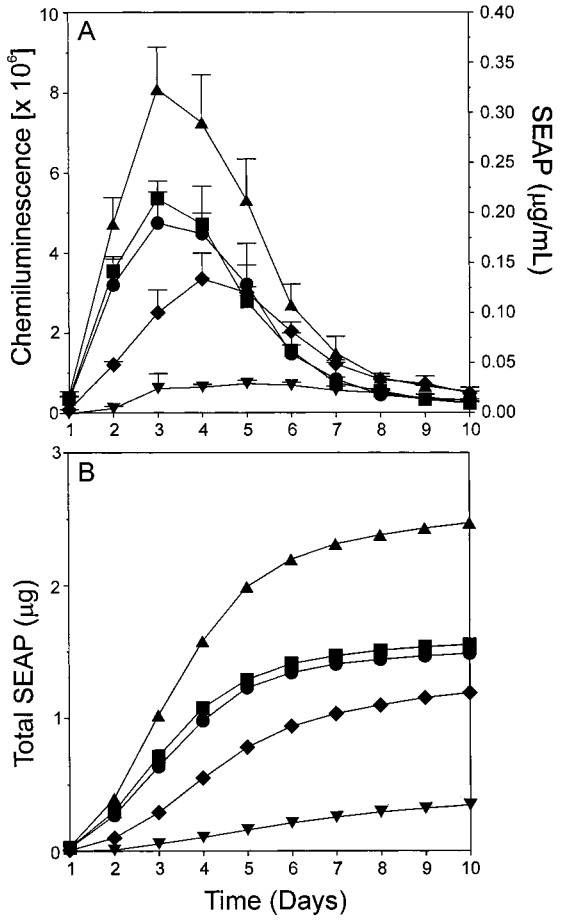

Figure 6—Transient gene expression profiles for cross-linked DNA condensates in the presence of chloroquine. The 10-day HepG2 SEAP expression profiles for cross-linked DNA condensates when including chloroquine in the transfection are shown in panel A. The data represents the mean and standard deviation when using un-cross-linked (■), 1 mol equiv (●), 2 mol equiv (▲), 3 mol equiv (◆), and 4 mol equiv (▼) cross-linked DNA condensates. The cumulative SEAP production for each DNA condensate is plotted in panel B. The slope of the day 7–10 cumulative expression was 28.3 ng/mL ■, 26.8 ng/mL ●, 52.8 ng/mL ▲, and 52.9 ng/mL ◆ with $r^2 \geq 0.965$ for each.

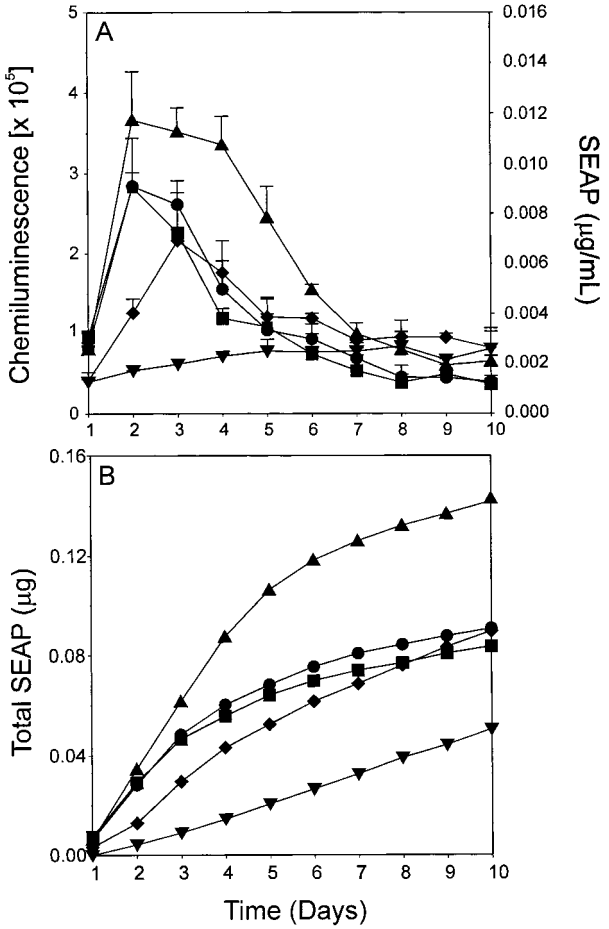

Figure 7—Transient gene expression profiles for cross-linked DNA condensates in the absence of chloroquine. The 10-day HepG2 SEAP expression profile mediated for cross-linked DNA condensates when omitting chloroquine from the transfection are shown in panel A. The data represents the mean and standard deviations when using un-cross-linked (■), 1 mol equiv (●), 2 mol equiv (▲), 3 mol equiv (◆), and 4 mol equiv (▼) cross-linked DNA condensates. The cumulative SEAP production for each DNA condensate is plotted in panel B. The slope of the day 7–10 cumulative expression was 3.3 ng/mL ■, 3.4 ng/mL ●, 5.2 ng/mL ▲, and 7.1 ng/mL ◆ with $r^2 \geq 0.996$ for each.

dehyde which led to a 30% decrease in the maximal expression level. Likewise, the maximal expression determined for 4 mol equiv cross-linked DNA condensate was reduced by approximately 80% compared to CWK_{18} DNA condensates.

Comparison of the cumulative SEAP production for each condensate established a range of 0.3 to 2.2 μg over the 10-day period (Figure 6B). Un-cross-linked condensates and cross-linked condensates possessing 1−3 mol equiv of glutaraldehyde approached a plateau in total SEAP production at day 6. The day 7−10 SEAP production for 2 and 3 mol equiv cross-linked DNA continued at a rate that was 2-fold greater than that of un-cross-linked or 1 mol equiv cross-linked DNA condensates as determined by linear regression of days 7−10. However, the SEAP production mediated by CWK_{18} DNA condensates cross-linked with 4 mol equiv of glutaraldehyde was constant throughout day 1−10 resulting in a linear regression line with a slope of 42 ng/day and $r^2 = 0.986$ (Figure 6B).

When chloroquine was omitted from the assay, the transient gene expression mediated by each peptide DNA condensate was reduced by over 1 order of magnitude (Figure 7A). As was also found for transfection in the presence of chloroquine, the cumulative gene production for 2 and 3 mol equiv cross-linked DNA condensates produced day 7−10 slopes that were 2-fold greater than un-cross-linked or 1 mol equiv cross-linked DNA condensates (Figure 7B). In addition, the cumulative expression for day 1−10 was linear ($r^2 = 0.999$) with a slope of 5.7 ng/day when using 4 mol equiv of glutaraldehyde to cross-link DNA condensates, indicating a steady-state expression of SEAP (Figure 7B).

A possible consequence of glutaraldehyde cross-linking could be the formation of long polylysine chains. To confirm that the expression profiles are not the result of linear polymerization of CWK_{18} the transient gene expression profile was studied using DNA condensates prepared with a panel of HMW polylysines (Figure 8A). The expression of SEAP exhibited a peak intensity correlating directly with the increase in chain length of polylysine, with each peptide DNA condensate mediating a maximum in the gene expression at day 3−4 (Figure 8A). Dimeric CWK_{18} DNA condensates produced approximately 10% more gene product relative to CWK_{18} DNA condensates. $Polylysine_{99}$ resulted in nearly 1.5-fold greater gene expression, whereas the greatest levels of transient gene expression were achieved with $polylysine_{476 \text{ and } 1007}$ DNA condensates which produced 2.1 and 3.2-fold greater gene expression than CWK_{18} DNA condensates (Figure 8B). Likewise, the cumulative SEAP expression for days 7−10 also demon-

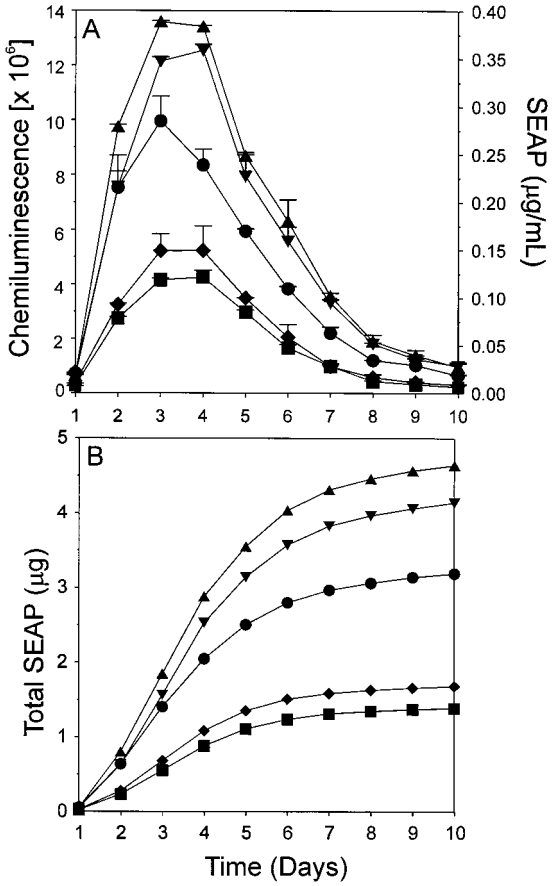

Figure 8—Transient gene expression profiles for HMW polylysine DNA condensates. The 10-day HepG2 SEAP expression profiles are compared for CWK_{18} (■), dimeric-CWK_{18} (◆), polylysine$_{99}$ (●), polylysine$_{476}$ (▼), and polylysine$_{1007}$ (▲) DNA condensates when including chloroquine in the transfection are shown in panel A. The cumulative SEAP production for each DNA condensate is plotted in panel B. The slope of the day 7–10 cumulative expression was 25.5 ng/mL ■, 32.7 ng/mL ◆, 74.7 ng/mL ●, 103.7 ng/mL ▼ and 109.3 ng/mL ▲ with $r^2 \geq 0.978$ for each.

strated a 3-fold increase in slope when comparing CWK_{18} DNA and polylysine$_{1007}$ DNA condensates.

Discussion

The stability of a DNA formulation is fundamental to its successful application in vivo since metabolism results in the generation of fragmented DNA which no longer mediates gene expression.[14] Even though peptide DNA condensates are more resistant to metabolism than naked plasmid DNA[11] or cationic lipid DNA condensates,[10,23] the in vitro stability determined by incubating condensates in serum may not be predictive of the in vivo stability in which the carrier molecules dissociate and are removed during circulation. This is exemplified by earlier studies by Wu and co-workers which showed the prolonged stability of DNA condensates *in vitro*[13] but a more limited stability in vivo.[24]

Even though a short polylysine peptide of 20 amino acids is sufficient to condense DNA into small condensates of approximately 70 nm diameter, HMW polylysines$_{38-1007}$ offer the advantage of binding to DNA with higher affinity, resulting in a greater protection of DNA to metabolism. However, there are also significant drawbacks in using HMW polylysine to create carriers for gene delivery. The polydispersity of HMW polylysine results in batch to batch variation.[25] The derivatization of HMW polylysine with ligands or polyethlene glycol is achieved by random coupling reactions which cannot control the conjugation site along the polylysine chain creating further heterogeneity in the carrier molecule.[26–28] Perhaps most significant, is the known cytotoxicity, complement activation, and inflammation mediated by HMW polylysine.[29] Given these limitations we have focused our efforts on developing LMW DNA carriers that are homogeneous, condense DNA into small condensates, may be selectively derivatized, and are minimal in size to reduce toxicity.

To overcome the limited stability afforded by LMW DNA carriers, we propose to introduce interchain cross-links to preformed DNA condensates to further improve their stability. The advantage of this approach is the ability to vary the degree of cross-linking to create condensates that possess the required stability for different gene therapy applications. Also, a variety of cross-linking agents could potentially be used alone or in combination to create controlled release of the DNA upon hydrolysis and dissociation of the cross-linker and carrier. Control over these events is a prerequisite to achieving delayed or prolonged transgene expression.

The test of this hypothesis was conducted by attempting to cross-link the surface amine groups on CWK_{18} DNA condensates using glutaraldehyde. This cross-linker was chosen because of its prior use in developing cross-linked albumin microspheres for parenteral applications,[20] its safety record when used in a variety of prosthesis,[30] and the Schiff-base that forms is theoretically reversible.[16,31] The results indicate that CWK_{18} DNA condensates undergo cross-linking over a 4–5 h period when very low concentrations of glutaraldehyde (1–4 mol equiv relative to CWK_{18}) are added. This amount of glutaraldehyde is far below the amounts needed to observe toxicity in cells grown in culture. Likewise, the maximum amount of glutaraldehyde used (4 mol equiv) can theoretically cross-link 20% of the amines present, assuming glutaraldehyde distributes equally throughout the DNA condensates. At this low level, the particle size is maintained, the ζ potential of the DNA condensates is unaffected, and trypsin can still be used to enzymatically remove CWK_{18} to quantitatively release the DNA. However, despite numerous attempts, we could not demonstrate the spontaneous reversal of glutaraldehyde cross-linked DNA condensates on prolonged dialysis in the presence of protein.

One measure that establishes the relative stability of peptide DNA condensates is the ability of DNA to resist fragmentation during a 30 s 100 W sonication in a dissociating concentration of sodium chloride. Cross-linked DNA condensates were increasingly stable to sonicative fragmentation at cross-linking levels ranging from 1 to 4 mol equiv of glutaraldehyde and were even found to be more stable than HMW polylysine$_{99-1007}$ DNA condensates. This result suggests that interchain peptide cross-links, and not linear polymerization of CWK_{18}, are responsible for the observed stabilization.

A similar correlation was observed from in vitro metabolism studies that indicated that 4 mol equiv cross-linked DNA condensates were significantly stabilized but still inferior to polylysine$_{1007}$ in their ability to protect DNA from accelerated metabolism. Interestingly, DNA condensates with and without cross-linking appeared to be directly metabolized into fragments without going through the linear form (Figure 5). This is in contrast to the catabolism of naked DNA which is converted completely into linear DNA prior to the formation of fragments.[14] It is also evident that intracellular proteolysis must somehow be involved in the release of DNA from cross-linked condensates since it less likely that the spontaneous reversal of Schiff-base is the major route of DNA release prior to gene expression.

Clearly, the ability of cross-linked DNA condensates to

mediate gene expression is an important measure of their ability to be useful in gene therapy applications. Since cross-linking could delay the release of DNA inside cells, it was important to study the transient gene expression as opposed to a single 24 or 48 h expression level. However, this was also technically challenging due to the doubling rate of cells in culture which slows as they reach confluence. At an optimal seeding density, cell cultures could be maintained for 10 days, and the gene expression occurring each day was determined using secreted alkaline phosphatase. The most significant effect of cross-linking DNA condensates, in addition to stabilization to metabolism, was an apparent flattening of the expression profile such that 4 mol equiv cross-linking of DNA condensates resulted in a low level of steady-state expression over the 10-day transfection which could not be extended in cell culture. Omitting chloroquine more closely models in vivo conditions and further confirmed that cross-linking could produce a steady-state rate of expression.

Analysis of the transient gene expression profile for HMW polylysine$_{38-1007}$ DNA condensates indicated a correlation between the cummulative gene expression and the degree of polymerization. We interpret these results as partial validation of the hypothesis that increasing the DNA condensate stability will result in greater gene expression.

Future studies will examine the influence of cross-linking to prolong the survival of DNA in vivo and to stabilized DNA condensates prepared with more than one LMW carrier to endow the delivery system with specific targeting. The methods developed and used in this study have established the principle of cross-linking DNA condensates using glutaraldehyde and should allow testing of other cross-linkers to stabilize peptide DNA condensates from metabolism leading to prolonged gene expression in vivo.

Accepted for publication May 18, 1999.

Abstract □ Previous studies in rats and humans demonstrated poor oral bioavailability of potent in vitro 2-aminobenzimidazole inhibitors of rhinovirus replication due to significant first-pass elimination and possibly also to poor aqueous solubility. Estimations of aqueous solubility, as well as measurements of caco-2 permeability and NADPH dependent compound loss in rat liver microsomal incubations were employed alongside traditional in vivo experiments in rats to guide subsequent chemistry efforts. Retention of activity upon replacement of the metabolically labile vinyl oxime in the lead molecule with a vinyl carboxamide was a major breakthrough; however, oral bioavailability among the latter compounds was variable. Based on the ability to independently measure solubility, permeability, and metabolic stability of new compounds, variable solubility across the series (ranging from approximately 1 to 10 μg/mL) was identified as the cause of the inconsistent performance. Subsequent efforts to improve solubility led to the discovery of highly soluble (>10 mg/mL) and potent dessulfonyl vinyl carboxamide benzimidazoles. Determination of the metabolic stability of these compounds as a surrogate of the extent of their first-pass elimination supported a prediction of excellent oral bioavailability. In comparison to the sulfonyl-containing vinyl carboxamides, caco-2 permeabilities were reduced 5 to 10-fold; however, these were considered to be in the range of well-absorbed compounds based on comparison to a series of reference compounds of known percentage absorption in humans. Subsequent experiments in the rat verified the oral bioavailability of these *N*-alkyl compounds, with one compound (368177) having an absolute oral bioavailability of 89.4%. The application of solubility and caco-2 permeability as surrogates for oral absorption potential, in conjunction with the use of microsomal incubations as a surrogate for first-pass metabolism, was shown to augment a rational chemistry approach to discover orally bioavailable inhibitors of rhinovirus replication. Future expanded use of these surrogates is planned.

Introduction

The discovery and development of new drugs that are orally bioavailable continues to be a tremendous challenge in the pharmaceutical industry. In the discovery setting, increased reliance on genomics and high throughput screening to identify pharmacologically active lead compounds,[1,2] as well as reliance on combinatorial chemistry to increase molecular diversity and achieve desired activity through structural optimization,[3−6] can result in drug candidates having pharmaceutical properties that are not conducive to oral bioavailability.[7] Realization of this problem has led to a desire for earlier and even parallel consideration in the discovery process of pharmaceutical properties influencing oral bioavailability.[8] In response to the challenge of supplying structure−absorption and structure−metabolism information simultaneous with structure−activity relationships on an increasing supply of new chemical entities, scientists in preclinical drug disposition are increasingly relying on in vitro techniques and more sophisticated analytical methods such as LC-MS and LC-NMR.[9−11] For example, the insightful use of a computational alert approach and turbidimetric solubility measurements to identify compounds with potential for poor oral absorption has recently been employed.[7] With respect to drug transport, caco-2 monolayers have demonstrated potential as a predictive model of human intestinal absorption.[12−15] Coupled with their higher throughput capacity relative to traditional animal experiments, theoretical models of permeability across caco-2 cells show promise to provide additional structure−transport relationship throughput capacity.[16−18] Estimates of drug metabolism using in vitro techniques as a surrogate for first-pass elimination are also being suggested.[19−22]

The objective of the work reported herein was to apply such in vitro approaches to the discovery of orally bioavailable 2-aminobenzimidazoles that inhibit RNA replication in rhinoviruses and enteroviruses.[23] Previous studies demonstrated that, while analogues of this template possessed potent and broad-spectrum inhibition of virus replication in vitro, upon oral administration to both rats and humans these compounds underwent extensive first-pass elimination.[24] An additional objective was to gain experience integrating the results from the various drug absorption and metabolism in vitro techniques, as well as integrating these with in vivo results stemming from traditional bioavailability experiments in animals. This experience could then represent the initial installment of an iterative process to maximize drug discovery and development through parallel potency and bioavailability structural optimization efforts.

Materials and Methods

Materials—2-Aminobenzimidazoles were synthesized and characterized at the Lilly Research Laboratories as previously reported.[25,26]

Culture medium components and reagents for cell culture were obtained from GIBCO Life Technologies, Inc. (Grand Island, NY).

Fetal bovine serum for caco-2 culture was obtained from Hyclone Corp. (Logan, CT). Sulforhodamine 101, used as a marker for caco-2 monolayer integrity,[27] was from Molecular Probes (Eugene, OR). All other reagents were purchased from Sigma Chemical Co. (St. Louis, MO) or Fisher Scientific, Inc. (Fair Lawn, NJ) and were used as received.

Inhibition of Rhinovirus Replication—Human rhinovirus 14 strain 1059 and H-1 HeLa cells were received as a gift from R. Rueckert, University of Wisconsin, Madison. Virus stocks were amplified and diluted as previously described.[23] Plaque reduction assays were conducted by inoculating confluent cell monolayers grown in a 60-mm dish using minimum essential medium, 1% nonessential amino acids, and 10% new born calf serum with 0.2 mL of growth medium containing approximately 150 plaque-forming units of RV14. Following a 30 min attachment period at room temperature, 5 mL of medium containing the desired concentration of an inhibitor was added. Virus-infected cultures were incubated for 48 h at 35 °C, fixed with 10% formalin, and stained with 0.5% crystal violet (which stains only noninfected cells). Results from duplicate flasks at each inhibitor concentration were averaged and compared to nondrug control flasks. The inhibition of plaque formation by 50% (IC_{50}) was calculated from the linear region of the inhibition−concentration curve using the standard method of Reed and Muench as previously described.[23]

Physicochemical Properties—*Solubility*—A rapid throughput solubility screen was implemented to determine if there were gross differences in solubility across the SAR. This assay was based on visual observation 24 h after placing different amounts of compound (0.1, 1, 10, and 100 mg) in 1.0 mL of water. Water was selected as the solvent in this assay because of its fundamental importance in drug solubility for purposes of oral absorption[28] and because of limited compound availability and time in the early stages of an SAR to evaluate the effects of pH, ionic strength, and biological surfactants. In a more detailed evaluation of the solubility of compounds 341908 and 354400, determinations were made in 0.05 M phosphate buffers prepared over the pH range 1.7 to 8.0. Preliminary studies with 341908 indicated that bile salts were unlikely to improve solubility. Namely, the solubility of this compound was not improved in the presence of sodium deoxycholate. Type I flint glass amber vials containing a known quantity of either compound (approximately 5 mg) and 5 mL of buffer were tumbled end-over-end at ambient temperature for up to 7 days. Aliquots of approximately 2 mL were removed on days 3 and 7 and passed through a 0.45 μm Teflon filter. The first 1 mL was discarded and the remaining filtrate assayed by HPLC with UV detection. A Zorbax SB-phenyl column (25 cm × 4.6 mm maintained at 35 °C) was used along with a mobile phase consisting of an equal volume mixture of 0.1% (v/v) trifluoroacetic acid in water and acetonitrile. The flow rate was 1 mL/min and detection was at 244 nm.

Determination of pK_a—Ionization constants were measured using the Sirius PCA 101 Potentiometric System. Compounds were dissolved in various proportions of methanol and 0.15 M KCl, and adjusted to pH 6 or lower. For a given titration, an approximately 0.5 mM solution of each compound was titrated from a low to a high pH. The acid used was 0.5 N HCl, and the base, 0.5 N NaOH. The acid and base were standardized to four decimal places using NIST traceable standards. For a given compound, titrations were performed in triplicate for each of three different proportions of methanol and 0.15 M KCl. These titrations were done under an argon atmosphere at a constant temperature of 25 °C. Estimate of pK_a in 100% water was made using the Yasuda−Shedlovsky method of extrapolation.[29,30]

Caco-2 Permeability—Caco-2 cells were obtained from the Memorial Sloan-Kettering Cancer Center and were cultured at 37 °C in a humidified atmosphere of 5% CO_2 in air. They were grown in DMEM:F12 (3:1) media supplemented with 5% fetal bovine serum and 50 μg/mL tobramycin. Monolayers at 75−90% confluency were either subcultured on a weekly basis using a 1:10 split ratio, or seeded onto Millicell-PCF polycarbonate inserts (30 mm diameter, 0.4 μm pore size; Millipore Corp., Bedford, MA) at a density of 600 000 cells per filter. The culture medium was replaced with fresh medium every other day. For transport studies, cells from passages 43−56 were used at 21−30 days postseeding. Measurement of transepithelial electrical resistance was made immediately prior to an experiment using a Millicell-ERS system (Millipore Corp.). Cells with a net resistance less than 300 $\Omega \cdot cm^2$ were not used.

Measurements of transepithelial flux of the various inhibitors were made at 37 °C using a side-by-side diffusion chamber described previously.[31] This system has now been coupled to a robotics arm to increase throughput capacity.[32] The transport medium consisted of 25 mM HEPES (pH 7.4) or 25 mM MES (pH 6.0) as buffering agents along with 125 mM NaCl, 5.2 mM KCl, 1.2 mM $CaCl_2$, 1.2 mM $MgCl_2$, and 10 mM glucose. To initiate an experiment, a stock solution of an inhibitor in DMSO was added to either the apical or basal side of the monolayer. The final concentration of DMSO was 1.4% (v/v). Samples (200 μL) were taken from the contralateral compartment at various times up to 120 min and replaced with an equal volume of fresh transport buffer. Rates of transport under initial rate conditions (<10% transport) were determined by linear regression analysis; these were divided by the initial donor concentration and filter surface area to calculate the corresponding permeability coefficients. Experiments were conducted in duplicate or triplicate and under limited lighting conditions to minimize light catalyzed *Z*-isomer to *E*-isomer transformation. At the end of an experiment, integrity of each monolayer was assessed by evaluating the percentage transport of sulforhodamine 101 in 30 min. Monolayers with greater than 0.2% transport in this time period were not included in the analysis of permeability (there were never fewer than two monolayers used in the estimation of a given permeability coefficient). Analysis of the various inhibitors via HPLC−UV was conducted as previously described for solubility measurements.

Microsomal-Mediated Metabolism—Using standard techniques,[33] microsomes were prepared from fresh livers obtained from male F344 rats weighing approximately 250 g. Microsomes were diluted to 1 mg protein/mL in 0.1 M sodium phosphate buffer, pH 7.4. Inhibitors were dissolved in either ethanol or acetonitrile to a concentration of 1 mM and spiked into the microsomal suspension such that the final concentration was 10 μM. This concentration was selected based on analytical sensitivity requirements and the desire to keep the concentration in the low micromolar, pharmacologically relevant, range. To start the reaction, either NADPH or, in the case of controls, buffer without NADPH was added. After 30 min, the reaction was stopped with an equal volume of acetonitrile, and the incubation mixture was centrifuged and analyzed for parent compound using HPLC−UV as described previously for measurement of solubility. The integrated peak areas from the HPLC chromatograms were compared for an inhibitor in the presence or absence of NADPH, and the amount of loss of parent compound was calculated.

***In Vivo* Studies**—Pharmacokinetic profiles and absolute oral bioavailability in 24 h fasted male F344 rats weighing approximately 200 to 250 g were determined for select inhibitors in the series. Plasma concentrations of an inhibitor following either an intravenous (iv) dose ($n = 2-3$ rats) or an oral dose ($n = 3$ rats) were quantitated by HPLC−UV analysis as described for solubility measurements. For iv dosing, compounds 341908 and 354400 were prepared in poly(ethylene glycol) PEG-400, ethanol, water mixtures (30%, 30%, 40%; w,v,v), and dosed via the tail vein. Compounds 366094 and 368177 were dissolved in saline and administered similarly. The latter two compounds were also dosed orally as solutions; whereas compounds 341908 and 354400 were dosed orally either as aqueous suspensions (10% acacia/0.5% polysorbate 80) of controlled particle size (5−25 μm), or as solutions (85% PEG-400/0.5% polysorbate 80). Precipitation of formulated solutions of 341908 and 354400 (10 mg/mL) was not observed upon 1:10 dilution with either 0.1 N HCl or 0.1 μ (ionic strength) pH 7.4 buffer. Pharmacokinetic parameters were obtained using model independent methodology. With respect to estimation of $AUC_{0-\infty}$, percent extrapolated areas were never greater than 10%. Percent oral bioavailability was calculated by comparison of dose normalized $AUC_{0-\infty}$ values for iv and oral doses (the equation used is summarized in Table 4B).

Results

In Vitro Potency and Metabolic Stability—Table 1 shows the structures of the compounds evaluated according to structural class. Also included are the potency and metabolic stability of the compounds. Enviroxime, a compound that was tested in Phase II clinical trials in the early 1980s, is included for comparison. Replacing the hydroxyl-

containing oxime in enviroxime at R2, which was extensively conjugated following oral administration of a 10 mg/kg dose in the rat (unpublished results from studies conducted to support enviroxime IND), with a vinylcarboxamide conferred resistance to metabolism by a primary conjugative mechanism. Specifically, incubation of enviroxime and 153186 in rat and human liver microsomes in the presence of UDP-glucuronic acid resulted in a 21% and an 11% loss of enviroxime from rat and human sources, respectively; whereas there was no loss of 153186 from either source. In addition, fluorine substitution at R1, which was a site of aromatic hydroxylation in enviroxime, was expected to provide a further increase in metabolic stability. The percent loss of enviroxime under oxidative conditions was 39% in 30 min. By comparison, the mean percent loss in 30 min of the sulfonamide containing vinylcarboxamides was 11 ± 7.3% (± 1 sd, $n = 17$ compounds). The nonsulfonyl *N*-alkyl compounds were similarly relatively resistant to oxidative metabolism, having a mean percent loss in 30 min of 7 ± 3.0% ($n = 3$ compounds). Importantly, while these structural modifications increased metabolic stability in vitro, they had no effect on antiviral potency relative to enviroxime (Table 1). Mean percentage loss of the sulfonylureas was 26 ± 11.0% ($n = 5$ compounds).

Permeability—Permeability coefficients across caco-2 monolayers relative to several marker compounds of known and varying percentage absorption in humans provided an estimate of the absorption potential of the novel antirhinovirus compounds. These results are shown in Figure 1 according to the three structural classes. The *N*-alkyl compound, 366853, had the lowest permeability ($0.5 \pm 0.05 \times 10^{-5}$ cm/s) while the sulfonamide, 366092, had the highest ($9.3 \pm 0.16 \times 10^{-5}$ cm/s). By comparison to the

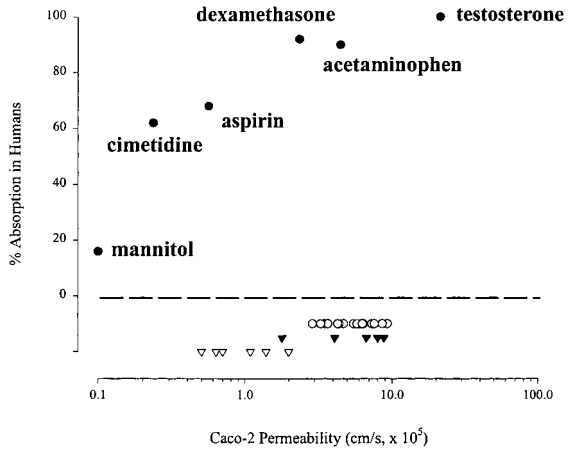

Figure 1—Permeability coefficients of 2-aminobenzimidazoles across caco-2 monolayers in relation to permeability coefficients of reference compounds (●). The three classes of 2-aminobenzimidazoles were sulfonamides, ○; sulfonylureas, ▼; and *N*-alkyls, ▽.

marker compounds, the observed range of permeabilities corresponded to a percentage absorption in humans of approximately 60% to 100%, thus indicating that these compounds should be well absorbed in vivo notwithstanding any potential dissolution or solubility limitations. Since, with a limited set of structurally different compounds, there was no asymmetry with respect to permeability (Table 2), the transport mechanism appeared to be passive. Table 3 indicates the pH dependent permeability of the *N*-alkyl compounds and the lack of pH dependence on the permeability of a sulfonamide. These results were expected due to pK_a differences (Table 1). Indeed, the lower permeability

366853	*N*-alkyl	0.5 ± 0.05	0.7 ± 0.03[b]
368177	*N*-alkyl	0.7 ± 0.01	2.0 ± 0.13[b]

[a] Results are expressed as mean ± one standard deviation; $n = 3$ filters. [b] Indicates significantly different from pH 6 result at $p \leq 0.05$ based on an unpaired Student's *t*-test.

of the *N*-alkyl class compared to the sulfonamides and sulfonylureas is attributed to the significant fraction of protonated amine at pH 6.0 for the *N*-alkyl compounds. The fraction present in the ionized form at this pH was estimated to be about 80% for the three *N*-alkyl compounds.

Solubility and Biopharmaceutics of Oral Solution and Suspension Formulations—The equilibrium solubility of enviroxime in water at ambient temperature was approximately 2 μg/mL. The water solubility of compound 341908, one of the earliest compounds in the current SAR, was 1 μg/mL. Based on this finding, there was concern that insufficient solubility in vivo would result in poor bioavailability of the sulfonamide vinyl carboxamide series. These concerns were realized upon administration of compound 341908 to rats. As shown in Figure 2A and summarized in Table 4, systemic exposure from a suspension was substantially lower than from a solution formulation. Interestingly, replacing the fluorine at the 3 position of the phenyl ring at site R1 (compound 341908) with fluorines at positions 2 and 5 (compound 354400), a seemingly minor modification, resulted in a 10-fold enhancement in water solubility (compound 354400 had a solubility of 10 μg/mL in water). As shown in Figure 3, the pH-solubility profiles of these two compounds demonstrate that, over the pH range of 1.75 to 7.9, 354400 solubility in 0.05 M phosphate buffer was consistently 5 to 7 times greater than that of 341908. The cause for this difference may be related more to differences in the interaction of the two compounds with solvent than to crystal lattice energy differences because of the similar melting points of the two compounds, ca. 210 °C. Importantly, as shown in Table 4, the absolute bioavailability of 354400 was similar from both solution and suspension dosage forms and was markedly greater compared to 341908 bioavailability from a suspension. The lower absolute bioavailability of 354400 compared to 341908 bioavailability from solution dosage forms may be due to greater first-pass elimination of 354400. This interpretation is supported by the approximate 6-fold higher systemic clearance of 354400 (Table 4A). While loss in liver microsomes was similar for the two compounds (17% for 354400 versus 11% for 341908, Table 1), as previously indicated, this assay was not scaled to in vivo clearance, nor does it take into account the possibility for conjugative metabolism. The possibility for biliary elimination was also not evaluated. Thus, the cause for the greater clearance of 354400 is not known.

Given the lack of predictability in the solubility properties of the sulfonamides, efforts were made to identify compounds of consistently greater solubility. These efforts led to removal of the sulfonyl group resulting in direct attachment of various alkyl groups to the benzimidazole nitrogen in the R3 position. This modification resulted in conversion of the primary amine to a significantly more basic functional group, as shown by the pK_a values (Table 1). Importantly, this modification had no impact on antiviral potency (Table 1). The water solubility of these so-called *N*-alkyl vinyl carboxamides was consistently greater than 10 mg/mL. As shown in Figure 2C and Table 4, systemic exposure of compound 368177, dosed as neat drug dissolved in water, was excellent, resulting in an absolute bioavailability of 89%.

Discussion

Evaluation of enviroxime disposition in rats demonstrated that glucuronidation of the hydroxyl containing oxime at position R2 was the major metabolic pathway, accounting for 60% to 70% of an oral dose in 24 h and up to 80% in 48 h (unpublished results). Hydroxylation of the phenyl moiety (R1) also significantly contributed to loss of parent. Identification of strategies to obviate these two metabolic pathways while simultaneously preserving or enhancing antiviral potency were the two most important goals of the current structural optimization effort. Discovery of the potent vinyl carboxamide series was a major breakthrough due to the resistance of the acidic primary amide to direct conjugation. Subsequently, attempts to achieve a balance between structural effects on potency and susceptibility to oxidative metabolism became the focus of our optimization work. A 30 min incubation in the presence of rat liver microsomes was used to rank order the compounds with respect to their susceptibility to metabolism, measured as percent loss of parent compound, and was placed after the initial potency screen. No attempt was made to correlate this screen with an in vivo measure of elimination; rather, the intent of the screen was to look for gross effects of structure on susceptibility to metabolism. Although the number of compounds was few, it seemed that the cyclic sulfonylurea compounds 362898, 359353, and 368288 were metabolized to a greater extent than the noncyclic sulfonylureas and sulfonamides. On the basis of loss of parent compound, aromatic fluorine substitution at R1 did not appear to reduce metabolism. However, to conclude that fluorine substitution had no effect is equivocal because metabolites were not identified; also, if fluorine did not have an effect, whether this would translate to the in vivo situation is also not known. Fortunately, fluorine substitution had no effect on antiviral potency.

On the basis of experience with enviroxime, a poor dose to aqueous solubility ratio of the benzimidazoles was considered a potential barrier to achieving adequate and reproducible systemic exposure following oral administration.[34] With a solubility of 2 μg/mL, complete dissolution of a therapeutic dose of enviroxime as low as 10 mg would require 5 L of fluid, which approximates the entire volume consumed and produced by secretions in the human gastrointestinal tract in a 24 h period.[35] The water solubility of compound 341908, one of the earliest vinyl carboxamides made, was 1 μg/mL. Concern that poor solubility of vinyl carboxamide sulfonamides and sulfonylureas would result

Table 4—Summary Single Dose Pharmacokinetics of Vinyl Carboxamide 2-Aminobenzimidazoles in Male F344 Rats

A. Intravenous Bolus Administration

compd no.	structural class	dose (mg/kg)	$AUC_{0-\infty}$[a] (ng·hr/mL)	clearance (L/h/kg)	$T_{1/2}$ (mean ± se) (h)
341908	sulfonamide	3	7703.6	0.37	0.8 ± 0.14
354400	sulfonamide	3	1211.9	2.42	1.8 ± 0.02
366094	*N*-alkyl	5	4042.5	1.18	1.0 ± 0.05

[a] Extrapolated areas were less than 10% in all cases. [b] Absolute bioavailability = $(AUC_{0-\infty,po}/AUC_{0-\infty,iv}) \times (dose_{iv}/dose_{po}) \times 100$.

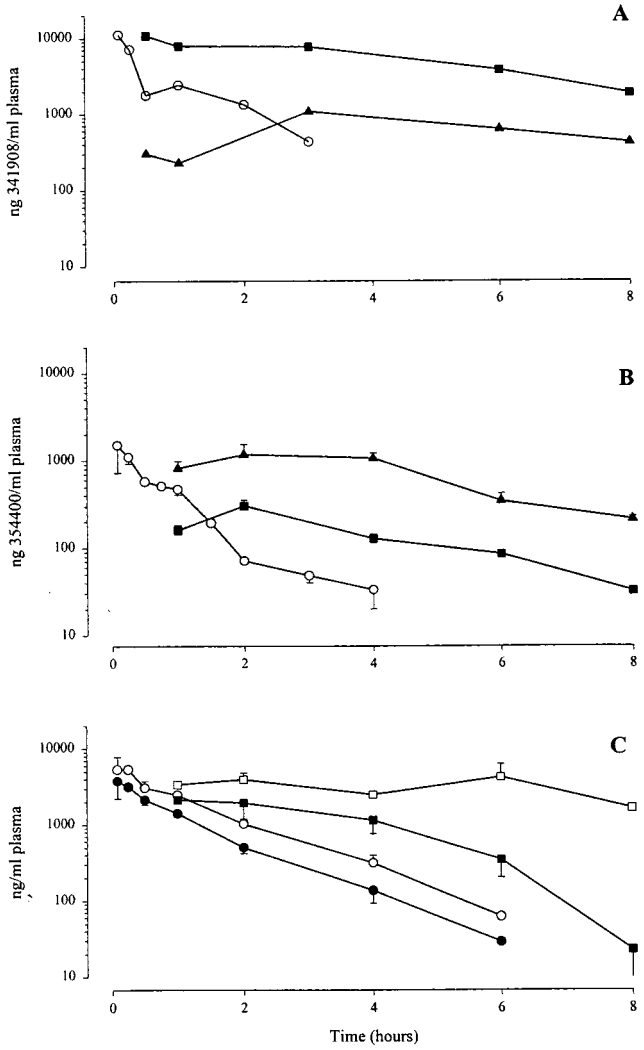

Figure 2—Rat plasma concentration versus time profiles of rhinovirus inhibitors following either intravenous (○ or ●), oral solution (□ or ■), or oral suspension (▲) administration. (A) Compound 341908. (B) Compound 354400. (C) Compounds 366094 (●, ■) and 368177 (○, □). Refer to Table 4 for actual doses administered. For consistency of presentation, 24 h levels following oral administration of compounds 341908, 366094, and 368177 have been omitted; these were <100 ng/mL.

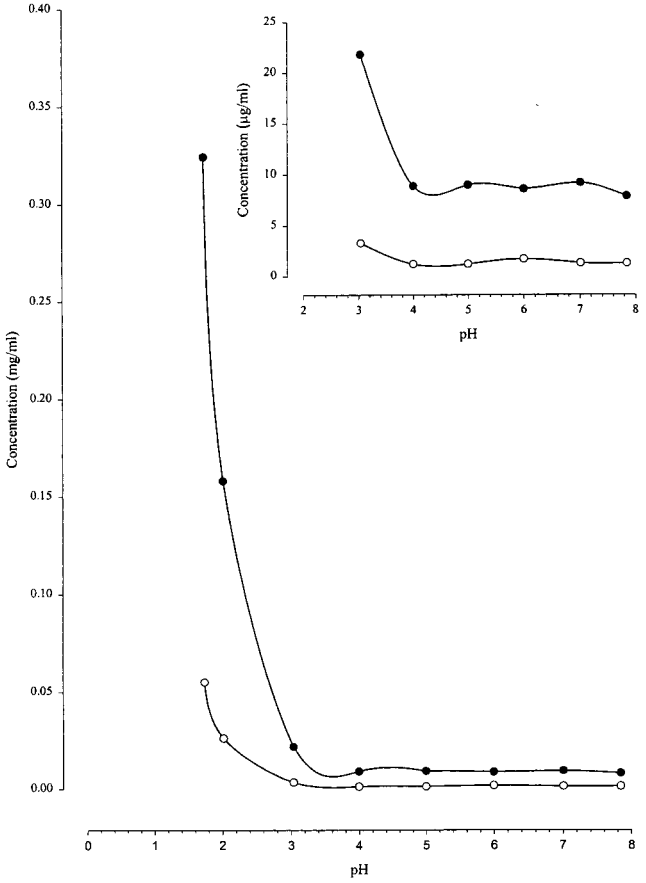

Figure 3—pH versus solubility profiles for compounds 341908 (○) and 354400 (●). Phosphate buffers, 0.05 M, were prepared over the pH range 1.7 to 8.0. Inset graph is of the same results, but expressed in μg/mL over the pH range 3 to 8.

in poor systemic exposure was verified upon oral administration of compound 341908. As shown in Table 4B, absolute bioavailability of this compound when dosed as an aqueous suspension was approximately 10%. In contrast, administration of a solution of 341908 prepared using a mixture of PEG-400, ethanol, and water resulted in a bioavailability of 80%. These results, as well as dose/solubility ratios based on projected human doses and gastrointestinal volumes, indicated that solubility could be problematic in relation to the clinical development of this therapeutic class.

A simplified solubility screen in water was consequently implemented; this was based on visual observation following incubation at room temperature for 24 h. Samples of a given compound were prepared in 10-fold increments of

concentration ranging from 0.1 mg/mL to 100 mg/mL. On the basis of this assay, all compounds tested had a solubility in water less than 0.1 mg/mL (data not shown). Compound 354400 was one of these compounds. HPLC analysis of its pH dependent solubility versus that of compound 341908 indicated a 5- to 7-fold higher solubility throughout the pH range of 1.7 to 7.9 (Figure 3). For the two compounds, an approximate 20-fold increase in solubility was observed at pH 2 relative to pH 4; this is attributed to protonation of the primary amine at the 2 position of the benzimidazole ring, which had a measured pK_a of 3.4 (Table 1). Importantly, the absolute bioavailability of a suspension of 354400 was 49.8%, which was similar to the bioavailability of a solution formulation, 48.5% (Figure 2, Table 4B). On the basis of the physical stability of the solution formulation of 354400 to a 10-fold dilution in either 37 °C 0.1 N HCl, pH 1.2 or pH 7.4 buffer, these results suggested that dissolution of the suspension was sufficient to produce a comparable bioavailability. Furthermore, given the excellent permeabilities of the two compounds (7.3 and 3.5 $\times$ 10^{-5} cm/s, for 341908 and 354400, respectively) and the greater systemic clearance of 354400 (Table 4A), greater solubility of 354400 was the attributed cause of its superior bioavailability from a suspension dosage form. The different effects of the two formulations on the bioavailability of these two compounds suggested that, under the experimental conditions tested, systemic exposure was acutely dependent on solubility and dissolution. Considering the less than 10-fold difference in the solubility of these two compounds, the similar solubilities of the compounds that had thus far been synthesized and the aforementioned unfavorable dose/solubility ratios applicable to human dosing, an effort to identify more soluble compounds was made.

Elimination of the R3 sulfonyl portion of these compounds significantly increased the pK_a of the primary amine at the 2 position of the benzimidazole ring (Table 1). Improvement in aqueous solubility to greater than 10 mg/mL was a consequence of this modification. Importantly, these so-called *N*-alkyl compounds had similar potency and metabolic stability compared to the sulfonamides and sulfonylureas. Given that these compounds had pK_a values in the range of small intestinal pH, it was expected that the *N*-alkyls would have a pH dependent permeability influenced by the ratio of protonated to unprotonated species. As shown in Table 3, *N*-alkyl permeability at pH 7.4 was significantly greater than at pH 6.0. Furthermore, as expected, permeability of compound 354400 was not similarly influenced by pH. It was also expected that the permeability of the *N*-alkyls in general would be less than that of the sulfonylureas and sulfonamides. While this was the case, the permeability of the *N*-alkyls was still in the range of what would be considered moderately well-absorbed compounds (Figure 1). Oral administration of aqueous solutions of compounds 366094 and 368177 to rats resulted in absolute bioavailability estimates of 33.2% and 89.4%, respectively (Table 4B). The approximate 3-fold greater bioavailability of 368177 may be due to either greater absorption, which is consistent with a larger permeability coefficient relative to 366094, or to reduced first-pass elimination, which is supported by the approximate 2-fold lower clearance compared to 366094, or to a combination of these two factors. According to the testing conditions used, both compounds exhibited prolonged absorption behavior, with absorption-rate limited kinetics indicated for compound 368177 (oral terminal half-life was 3.9 h vs 1.0 h following iv administration). The cause of this apparent slow absorption is not known, but may be due to prolonged absorption throughout the rat gastrointestinal tract, possibly including colonic absorption. This possibility is consistent with the known progressive increase in pH along the longitudinal axis of the intestinal tract and the observed increase in permeability of these compounds from pH 6 to 7.4. However, precipitation of drug in the stomach or in the duodenum with subsequent dissolution along the tract cannot be ruled out. The high caco-2 permeability coefficients of these compounds, even at pH 6, are indicative of excellent absorption, but are by no means definitive for novel compounds such as these for which a definitive in vitro/in vivo correlation has not been established.

In conclusion, this work has demonstrated the ability through structural modifications to independently influence potency, solubility, permeability, and metabolism in order to achieve oral bioavailability of potent inhibitors of rhinovirus replication. This positive experience has enabled this laboratory to move forward with a broader implementation of bioavailability surrogates to achieve a more expeditious discovery and development process.

Accepted for publication May 14, 1999.

Abstract □ Individuals who consume cocaine illegally have long since adopted or explored the nasal route of administration. This study was designed to determine in an animal model whether nasally applied cocaine could be transported directly from the nasal cavity to the central nervous system. Male Sprague–Dawley rats were used in the study. The nasal cavity was isolated to prevent drainage of nasally applied dosing solution to nonnasal regions. Cocaine was then administered, either by intranasal (in) administration or by intravenous (iv) injection. At different times post dose, blood and tissues from different regions of the brain were collected. Cocaine concentrations in plasma and tissue samples were analyzed by HPLC. After iv administration, similar cocaine contents in different brain regions were observed. Following in administration, cocaine content in samples collected within 60 min post dose were found to differ considerably in different brain regions. The highest content was observed in the olfactory bulb, followed by the olfactory tract and then the remaining part of the brain. To allow comparison of brain cocaine content after iv and in administration, brain cocaine contents were normalized by plasma cocaine concentrations. The ratios of the area under the cocaine concentration–time curve (AUC) between the olfactory bulb and plasma at early times following in administration were significantly higher than those obtained after the iv dose (13.4 ± 5.56 vs 6.16 ± 0.94, $p < 0.05$, for AUC ratio up to 2 min post dose; 9.39 ± 1.47 vs 7.34 ± 0.59, $p < 0.05$, for AUC ratio up to 4 min post dose). At 1 min post dose, the olfactory bulb-to-plasma cocaine concentration ratios following in administration was three times those obtained after iv administration. After 1 min, the olfactory bulb-to-plasma concentration ratios following in administration were found to be similar to or smaller than those obtained after iv administration. The tissue-to-plasma concentration ratios in other brain regions following in administration were found to be smaller than those obtained following iv dosing. We conclude that nasally administered cocaine was transported directly from the nasal cavity to the brain but that only a very small fraction of the dose was transported via the direct pathway.

Introduction

Over the past decade, the possibility that intranasal drug administration might be useful has received a great deal of attention. Some relevant research efforts have been reviewed comprehensively.[1] The extensive network of blood capillaries under the nasal mucosa seems to facilitate effective systemic absorption and, because venous blood drains directly into the systemic circulation, this route thereby avoids first-pass metabolism of the drug in the gastrointestinal tract and the liver. For a number of drugs, systemic drug exposure following intranasal administration is comparable to that obtained from intravenous or intramuscular injections.[2−4]

Interestingly, individuals who consume cocaine illicitly have either long ago adopted or have explored this route of administration. It often has been noted that a rise in the physiological and behavior effects of cocaine precedes a rise in the plasma cocaine concentration following intranasal "snorting".[5−7] A clockwise hysteresis loop was consistently observed when behavior or physiological responses were plotted against plasma cocaine concentrations. This indicates that the same plasma cocaine concentration corresponds to a higher response at an earlier time after dosing than that at a later time. Development of acute tolerance can be used to explain such a concentration−response relationship. However, there is no evidence that tolerance would develop rapidly following administration of a single dose of cocaine. To exert CNS activity following nasal drug application, it is typically believed that the drug needs to be absorbed into the systemic circulation via the capillary network under the nasal mucosa and subsequently distributed into target regions in the brain. If this is the only pathway of CNS entry, there will be a time delay in the distribution of cocaine to the brain tissues following nasal administration. A rise in the pharmacological response should therefore occur after a rise in the plasma cocaine concentration. Nevertheless, this outcome is not in agreement with the concentration−response relationship observed following intranasal cocaine snorting.

Evidence exists that substances applied nasally may enter the brain directly from the nasal cavity via the olfactory system.[8−10] If nasally applied cocaine can distribute into the brain directly via this alternative CNS entry pathway, an increase in the brain cocaine concentration could occur prior to a rise in the plasma drug levels following nasal application. This hypothesis would be consistent with the clockwise hysteresis loop observed in the plasma concentration−response relationship following nasal cocaine snorting.

In this study, we determined plasma and brain cocaine concentration−time profiles following intravenous and intranasal administration of cocaine in rats in an effort to determine whether cocaine could be transported directly from the nose to the brain following intranasal application.

Materials and Methods

Chemicals and Reagents—Cocaine and tropacocaine were provided by the Research Triangle Institute (Research Triangle Park, NC) through the National Institute on Drug Abuse. All other reagents were of HPLC grade or of the highest grade commercially available.

Animal Experimentation—Male Sprague−Dawley rats (250−350 g) were anesthetized with an ip injection of pentobarbital (50 mg/kg) and kept anesthetized throughout the experiment. The anesthetized animals were placed on a warm pad to maintain

normal body temperature. The nasal cavity was isolated from the respiratory and gastrointestinal tracts using a procedure described by Hussain et al.[11] Briefly, an incision was made in the neck, the trachea was severed, and the upper tracheal segment was tied off with a suture. The lower trachea was cannulated with polyethylene tubing (PE 260; o.d.: 2.8 mm, i.d.: 1.77 mm) to provide a patent airway. Another piece of PE 260 tubing with the ends sealed was inserted from the esophagus to the posterior part of the nasal cavity. The nasopalatine opening was closed with cyanoacrylate glue. This surgical procedure was performed to prevent drainage of nasally applied dosing solution to nonnasal regions.

Following nasal cavity isolation, animals received a cocaine dose over 30 s, either by intranasal administration or by intravenous injection. For intranasal administration, 50 μL of cocaine solution (16.7 mg/kg) was injected via a silastic tubing (o.d.: 1.19 mm, i.d.: 0.64 mm) inserted 2 cm into one of the nares toward the roof of the nasal cavity. For intravenous administration, cocaine dosing solution (5 mg/kg) was injected via an indwelling jugular vein cannula. At 1, 2, 4, 8, 15, 60, and 120 min following the end of the 30-s dosing period, a terminal blood sample was collected from the inferior vena cava. Plasma was separated and immediately stored at −70 °C in tubes containing NaF. The blood collection was generally completed within 15 s. Following the completion of blood collection, the skull of the animals was opened and the brain tissues collected in the following order: the whole brain with the exception of the olfactory tract and olfactory bulb (RB), olfactory tract (OT), and olfactory bulb (OB). The collection of all brain tissues was typically completed within 1 min following the blood collection. The tissue samples were weighed and immediately homogenized in 200 mM NaF solution. An aliquot of the homogenate was stored at −70 °C before analysis. The addition of NaF protected cocaine from undergoing hydrolysis during processing and storage. Four or five rats were used at each collection time. The sample collection process always involved two laboratory personnel: one responsible for dosing and sample collection and the other for tracking the time and sample handling.

Analytical Methods—Plasma and brain cocaine concentrations were determined within 48 h of collection by a published HPLC procedure.[12] Briefly, the plasma (200 μL) and brain homogenates (100−200 μL) were mixed with 50 μL of the internal standard (tropacocaine, 1 μg/mL) and 200 μL of 0.5 M carbonate buffer (pH 9.1). The mixture was extracted with 2 mL of ethyl acetate, and the organic phase was back-extracted with 150 μL of 0.05 M HCl. The final acidic aqueous phase was evaporated with a centrifugal evaporator (Savant, Farmingdale, NY) at room temperature. The residue was reconstituted with the mobile phase (see below) and then injected onto a C_8 column (Nova-Pak, 15 cm × 3.9 mm i.d., 4 μm; Waters, Milford, MA). A mobile phase composed of a mixture of 100 mM pentanesulfonic acid and 50 mM monobasic potassium phosphate (pH 6.0) and acetonitrile in an aqueous-to-organic ratio of 76:24 at a flow rate of 1.3 mL/min was used. The UV absorbance of the effluent was monitored (Waters 486 UV detector) at a wavelength of 235 nm.

Data Analysis—The area under the cocaine concentration versus time curve (AUC) was estimated by the trapezoidal rule. The variance for the AUC was estimated by the method of Yuan.[13] The variance (var) for the AUC ratio was approximated using the statistical method described previously,[14]

$$\mathrm{var}\left(\frac{\mathrm{AUC_{in}}}{\mathrm{AUC_{iv}}}\right) \cong \left(\frac{\overline{\mathrm{AUC_{in}}}}{\overline{\mathrm{AUC_{iv}}}}\right)^2 \cdot \left(\frac{\mathrm{var(AUC_{in})}}{(\overline{\mathrm{AUC_{in}}})^2} + \frac{\mathrm{var(AUC_{iv})}}{(\overline{\mathrm{AUC_{iv}}})^2}\right)$$

where $\overline{\mathrm{AUC}}$ denotes the mean AUC value.

A one-way ANOVA followed by a Student−Newman−Keuls test was used to compare the measurements in different brain regions. An unpaired two-sided *t*-test was used to compare the measurements for intravenous and intranasal administration.

Results

Figure 1 illustrates the cocaine concentration versus time profiles in plasma and in different brain regions following intravenous and intranasal administration. Following intravenous administration, plasma and brain cocaine concentrations reached peak levels at 1−2 min after dosing

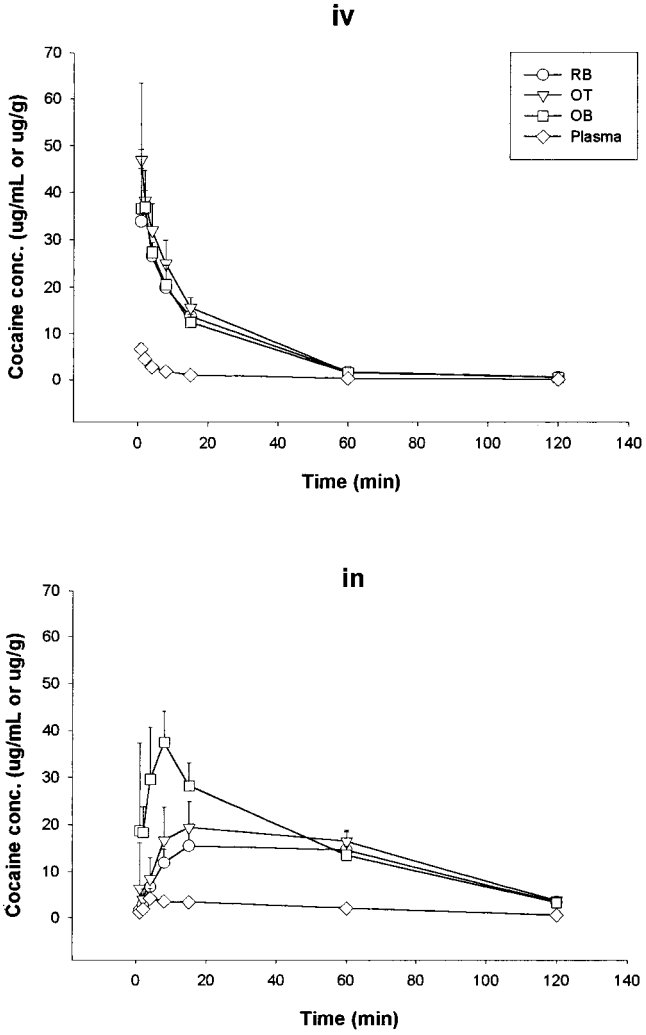

Figure 1—Plasma and brain cocaine concentrations versus time profiles following intravenous (iv) and intranasal (in) administration in rats. Each point represents the average of 4–5 rats and the cross-vertical bars represent one standard deviation of the mean. Key: OT, olfactory tract; OB, olfactory bulb; RB, remaining part of the brain.

and declined exponentially as a function of time. Except for samples collected at 1 min post dose, similar cocaine contents were observed in different brain regions. Following intranasal administration, plasma and brain cocaine concentrations increased gradually to peak levels and started to decline as a function of time. Cocaine contents in samples collected within 60 min post dose were found to differ considerably in different brain regions. The highest content was observed in the olfactory bulb, followed by the olfactory tract and then the remaining part of the brain.

Table 1 summarizes the brain tissue-to-plasma cocaine AUC ratios as a function of time following intravenous and intranasal administration. Following intravenous administration, the tissue-to-plasma AUC ratios in different brain regions increased consistently toward plateau levels as a function of time. Following intranasal dosing, the RB-to-plasma AUC ratios also increased toward plateau levels as a function of time. The OT-to-plasma AUC ratios decreased initially and then started to increase. The OB-to-plasma AUC ratios were high initially and decreased as a function of time. Up to 2 and 4 min following intranasal administration, the cumulative OB-to-plasma AUC ratios were significantly higher than those obtained after the intravenous dose (13.8 ± 6.29 vs 6.06 ± 1.02, $p < 0.05$, for AUC ratio up to 2 min post dose; 9.62 ± 1.77 vs 7.17 ± 0.67, $p < 0.05$, for AUC ratio up to 4 min post dose). At

[a] Significantly different from that after intravenous dosing, $p < 0.05$. [b] Significantly different from OB, $p < 0.05$. [c] Significantly different from RB, $p < 0.05$. [d] Significantly different from OT, $p < 0.05$.

later times, the OB-to-plasma cocaine AUC ratios obtained following intranasal administration were similar to or smaller than those obtained after intravenous dosing. The tissue-to-plasma cocaine AUC ratios in other brain regions following intranasal administration were smaller than those obtained after intravenous dosing.

Figure 2 illustrates the brain-to-plasma cocaine concentration ratios following intravenous and intranasal administration as a function of time. There were no significant differences in these ratios among different brain regions following intravenous administration. The tissue-to-plasma ratios of cocaine in OB following intranasal administration were found to be significantly higher than those in other brain regions before 60 min post dose. At 1 min post dose, the tissue-to-plasma ratios in the olfactory bulb following intranasal administration were found to be three times those obtained after intravenous administration (15.0 ± 4.1 vs 5.5 ± 1.1, $p < 0.05$). After 1 min, the olfactory bulb-to-plasma concentration ratios in samples collected following intranasal administration were found to be similar to or smaller than those obtained after intravenous administration. The tissue-to-plasma concentration ratios in other brain regions following intranasal administration were found to be smaller than those obtained following intravenous administration.

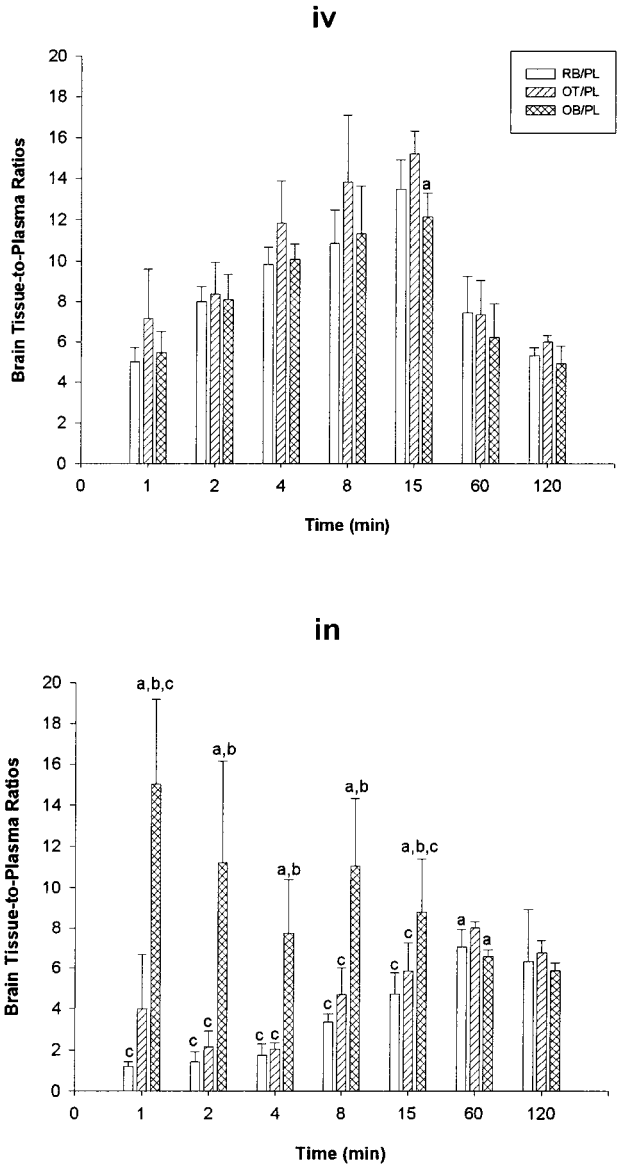

Figure 2—Brain tissue-to-plasma cocaine concentration ratios as a function of time following intravenous (iv) and intranasal (in) administration in rats (mean ± SD, $n = 4–5$ per time point). See legend for Figure 1 for definitions of the abbreviations. a: significantly different from OT/PL cocaine ratio, $p < 0.05$; b: significantly different from RB/PL cocaine ratio, $p < 0.05$; c: significantly different from the corresponding ratios obtained following intravenous administration, $p < 0.05$.

Discussion

Intranasal drug administration has received considerable recent attention, because it is an attractive noninvasive alternative route that can be used for the systemic delivery of compounds with poor oral bioavailability. Individuals who consume cocaine illicitly have long ago adopted and explored this route of administration. Because of the fear of HIV or other types of infection, there has been a recent shift among drug addicts away from intravenous injection to intranasal use. For inexperienced drug users in particular, the intranasal route has been preferred over intravenous injection. Although some evidence exists that substances may enter the brain directly from the nasal cavity, little attention has been paid to addressing the possibility that nasally applied abused substances could be transported directly from the nasal cavity to the central nervous system (CNS). Using a pharmacokinetic study design, we have obtained results suggesting that, when applied intranasally, a small fraction of the cocaine dose can be transported directly from the nasal cavity to the olfactory bulb. Whether the direct entry of nasally applied substances from the nasal cavity to the brain could result in increased abuse potential of nasally applied neurologically active drugs requires further study.

The olfactory system begins peripherally with the olfactory epithelium that is located on the roof of the nasal cavity. The olfactory receptors are bipolar neurons, one end of which is located in the nasal olfactory epithelium and the other end extending through the holes in the cribriform

plate of the ethmoid bone and ending in the olfactory bulb.[15,16] It has been suggested that there is free communication between the nasal submusocal interstitial space and the olfactory perineuronal space, which appears to be continuous with a subarachnoid extension that surrounds the oflactory nerve as it penetrates the cribriform plate.[17,18] Previous studies in mammals have demonstrated transport of protein tracers such as albumin labeled with Evans blue,[19] horseradish peroxidase,[20−22] and conjugated wheat germ agglutinin−horseradish peroxidase[20−22] from the nasal cavity to the olfactory bulb and its connected structures. Studies examining the transport of metals in the olfactory system have reported the movement of colloidal gold,[23] manganese,[24] and cadmium[25,26] within the olfactory system following intranasal administration. A series of recent studies performed by Sakane and co-workers have demonstrated significant increases of drug concentrations in the cerebrospinal fluid following intranasal administration of a variety of model substances, which have been shown to have low permeability to the CNS following systemic administration.[8,27−30] In contrast, enhanced brain delivery of a number of drugs was not always observed when results of nasal administration were compared with those obtained after intravenous dosing.[2,9,31]

One major limitation of the cited work is that brain and CSF drug concentrations usually were determined at a single time following dosing. Depending on the time of sampling, the brain drug concentration obtained following intravenous administration could have passed the maximal level and already have been in the declining phase, while the brain drug concentration obtained following intranasal administration could have been right around the maximal level. One could then incorrectly conclude that enhanced drug exposure in the brain had been observed following intranasal administration, implying the existence of direct nose−brain drug transport. In this research, a more complete pharmacokinetic examination of drug levels in plasma and different regions of the brain in the rat has been used as a tool to determine the existence of the direct nose−brain drug transport of nasally applied cocaine.

Cocaine is known to be a potent vasoconstricting agent commonly used to constrict nasal blood vessels during rhinologic procedures. This unique property of cocaine could prevent or delay its own systemic absorption following local application. Comparison of the dose−normalized plasma data collected from intravenous and intranasal administration indicates that nasally applied cocaine was rapidly and completely absorbed into the systemic circulation. This suggests that because of its high lipophilicity, movement of cocaine from the nasal mucosa to the blood was not limited by the reduction in the nasal blood flow. The detection of cocaine in the brain following intranasal dosing could have been due to the systemic absorption of the drug via the capillary network under the nasal mucosa and the subsequent distribution from the systemic blood into the target regions in the brain. The brain cocaine content was therefore normalized by the plasma cocaine concentration to allow comparisons of data collected following different routes of administration. The brain-to-plasma cocaine AUC or concentration ratios obtained after intravenous administration should represent the distribution of cocaine from systemic circulation into different brain regions (passing through the blood brain barrier). Because nasally applied cocaine does not appear in the systemic circulation instantaneously, the brain-to-plasma cocaine ratios after intranasal dosing should be similar to or smaller than those obtained after intravenous administration if nasally applied cocaine enters the brain only via the systemic blood. In this study, the cumulative OB-to-plasma cocaine AUC ratios obtained up to 4 min following nasal application was 1.5 to 3 times higher than that obtained after intravenous dosing. At 1 min post dose, the OB-to-plasma cocaine concentration ratio following intranasal administration was 3 times those obtained after intravenous dosing. These results support the existence of an alternative brain entry pathway for cocaine. Furthermore, following intravenous administration, no significant differences in cocaine content were observed among different brain regions whereas cocaine content was found to be region specific (olfactory bulb > olfactory tract > the remaining part of the brain) following intranasal administration. If the substance can be transported directly via the olfactory system, the first anatomical brain region of contact is the olfactory bulb. The olfactory tract connects the olfactory bulb to the remaining part of the brain. The brain cocaine content gradient observed following intranasal dosing but not after intravenous dosing further supports the existence of a direct pathway.

Because nasally applied cocaine was extensively and rapidly absorbed into the systemic circulation, the amount available for the direct nose−brain pathway is small. Therefore, the OB-to-plasma cocaine AUC ratios after intranasal administration were higher than those after intravenous administration only at early times after dosing. The distribution of this small amount of cocaine into other brain regions is counteracted by their large masses, thus leading to the insignificant increase in cocaine content in other brain regions. Consequently, the tissue-to-plasma AUC ratios in other brain regions obtained after intranasal administration were not higher than those after intravenous dosing. Similar to the tissue-to-plasma AUC ratios in different brain regions after intravenous dosing, the RB-to-plasma AUC ratios after intranasal administration increased as a function of time. The OT-to-plasma AUC ratios after intranasal dosing were high initially, decreased as a function of time, and subsequently increased as a function of time. The OB-to-plasma AUC ratios after intranasal dosing were high initially and decreased as a function of time. These results suggest that directly transported cocaine also was distributed into the OT regions but, because the amount entered via this pathway was not substantial, the OT-to-plasma AUC ratios after intranasal dosing were not higher than those after intravenous dosing. Similar results were obtained when the data were analyzed in nonaccumulated fashion (brain tissue-to-plasma cocaine concentration ratios).

Mechanisms responsible for the direct nose−brain transport of nasally applied substances are not clear. One suggested anatomical pathway for the direct transport of foreign compounds from the nasal cavity to the brain theorizes that foreign compounds enter into the olfactory sensory neurons by endocytosis or by binding to surface receptors and subsequently undergoing adsorptive endocytosis. The compounds could thereafter be transported within the olfactory sensory neurons by the axoplasmic flow, but whether they could be transported beyond the olfactory system is a question that remains to be answered. Neuronal transport is generally believed to be a slow process and seems to be consistent with the results from studies on heavy metals[23−26] and protein tracers.[19−22] However, this pathway is not likely to explain the observed increase in OB-to-plasma cocaine AUC or concentration ratios within 1−2 min following nasal application.

Another plausible explanation is that foreign substances can diffuse into the nasal submucosa and subsequently travel into the olfactory perineuronal channels because no morphological barrier between the loose submucosal connective tissue and the perineuronal space has been identified.[17,18] Large molecular weight markers injected into the lateral ventricles can be observed to flow down from the

central nervous system and reach the nasal submucosal extracellular space via the open pathway in the perineuronal space.[18] However, an intriguing question to us is the following: How could foreign compounds be transported from the nasal cavity to the brain through this open channel against the direction of flow of the cerebral spinal fluid? More studies are needed to define the exact mechanism(s) responsible for the direct transport of cocaine to the olfactory bulb.

We conclude that nasally administered cocaine can be transported directly from the nasal cavity to the olfactory bulb. Due to rapid and extensive systemic absorption of nasally applied cocaine, only a small fraction was transported to the CNS via the direct pathway. Further studies are necessary to investigate the pharmacological/toxicological consequences of direct nose−brain transport of nasally applied cocaine and other abuse substances.

Accepted for publication June 2, 1999.

Abstract □ The UV absorbance and bitter taste of oxyphenonium bromide (OB), an antiacetylcholine drug, in cyclodextrin (CD) solutions are measured, and the local environment of the binding site and the reduction of the bitter taste intensity are quantitatively estimated from the UV data. The UV spectrum of OB is changed with the addition of α-, β-, and γ-CD, because the phenyl group of OB is included into the CD cavity. The maximum wavelength, λ_{max}, senses environmental changes of OB best among several spectral characteristics. From comparison of λ_{max} between a CD solution and the reference ethanol–water and dioxane–water systems, the dielectric constant of the binding site is evaluated. This value leads us to estimate the microenvironment and structure of the binding site. The suppression of the bitter taste of 4 mM OB by CDs is in the increasing order α-CD < γ-CD < β-CD. The extent of this suppression can be quantitatively predicted from the UV absorbance by assuming that the free OB molecule alone exhibits the bitter taste, regardless of the kind and concentration of CD. Some implications and limitations of the present approach are discussed.

Introduction

Cyclodextrins (CDs) have homogeneous toroidal structures of different sizes. One side of the torus contains primary hydroxyl groups, whereas the secondary groups are located on the other side. The toroidal structure has a hydrophilic surface resulting from the 2-, 4-, and 6-position hydroxyls, making them water-soluble. The cavity is composed of the glucoside oxygens and methylene hydrogens, giving it a hydrophobic character.[1,2] CDs can give beneficial modifications of guest molecules not otherwise achievable: solubility enhancement, stabilization of labile guests, control of volatility and sublimation, and physical isolation of incompatible compounds. Because they are practically nontoxic, they are added into pharmaceuticals and foods for stabilization of labile compounds and long-term protection of color, odor, and flavor.[2,3] Furthermore, cyclodextrins can mask bitter tastes of drugs,[2,3] e.g., propantheline bromide[4] and oxyphenonium bromide.[5]

The effect of solvents on the ultraviolet (UV) spectra of aromatic molecules, particularly benzene, has been studied extensively. UV spectra are often sensitive to the nature of the local environment in solution.[6] Medium sensitive spectral characteristics can in turn be useful for studying the microenvironments of molecules and, indeed, a great variety of spectroscopic methods in solutions of small molecules and macromolecules as also in micelle and membrane research.[7] Many such studies have the objective of estimating the polarity of the microenvironment by comparison with a number of reference solvents. Many times relatively small changes with CD inclusion can be observed on UV spectra of guest.[2,3] At least an approximate estimation of the polarity of the internal CD cavity enables us to understand the inclusion of the various guests and to predict the type of the potential guests. Various and different estimates have been published. One estimate is based on the fact that the spectral shift shown by the *N*,*N*-diphenylamine (DPA) fluorescence probe depends on the polarity of ethanol−water mixtures. The fluorescence spectra of DPA show that the polarity of β-CD seems to be identical with that of a 40% ethanol/water mixture. Of course, this value cannot be considered to be an absolute one, but probably only as a lower level. The DPA molecule in solution is completely surrounded by solvent molecules, while the extent of penetration of the DPA guest into the CD cavity is probably only a partial inclusion.[3] From measurements of fluorescence quantum yields, Kondo et al. estimated the dielectric constant of 6-*p*-toluidinylnaphthalene-2-sulfonate in the CD cavity.[8]

Sensory tests generally depend on individuals. Some instrumental methods, therefore, are desired for such tests. In this work we develop a UV method for the quantitative estimation of the bitter taste intensity of oxyphenonium bromide (OB, Figure 1), an antiacetylcholine drug, in aqueous solutions of α-, β-, and γ-CDs. The UV absorbance can be used for the determination of the binding constants of OB with the CDs. Those constants enable us to estimate the concentration of the free OB molecule in the CD solutions. Bitter compounds are generally hydrophobic,[9] but their CD complexes are rather hydrophilic, because of the hydrophilicity of CDs.[4] Thus we can expect that the bitter taste of OB in a CD solution is estimated from the free OB concentration alone.[4,5] The other research interest is that OB has two possible hydrophobic groups for CD inclusion, phenyl and cyclohexyl groups. The incorporation of the phenyl group into the CD cavity should result in UV spectral changes, because of the change of its microenvironment. Thus, we can expect to determine which group of OB is entrapped into the CD cavity.

Experimental Section

Materials—A sample of OB was purchased from Sigma Chemical Co. Because this sample was analyzed to be pure by reversed-phase liquid chromatography, it was used without purification. Sodium bromide of analytical grade and α-, β-, and γ-CDs from Nacalai Tesque Co. (Kyoto) were used as received. The ion-exchanged water was used after double distillation.

UV Measurements—All UV spectra were recorded with a Hitachi U-3000 spectrophotometer at 36.5 ± 0.1 °C. The absorbance was determined at an interval of 0.5 nm between 220 and 300 nm and at an interval of 0.1 nm between 240 and 280 nm. The first and second derivative spectra of OB were recorded at an interval of 0.1 nm between 240 and 280 nm. All sample and reference cuvettes contained 154 mM NaBr, unless specified. The sample cuvette contained 4 mM OB and CD, whereas the reference cuvette contained CD of the same concentration as the sample. The difference spectra were obtained by subtracting the spectra of a 4 mM OB solution from those of sample solutions. The maximum wavelength, λ_{max}, was determined from the first deriva-

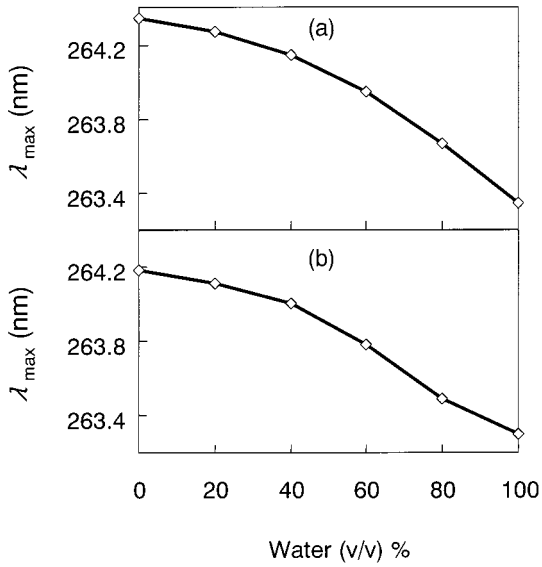

Figure 2—UV maximum wavelength of OB vs volume percent of water in binary mixtures of (a) ethanol and water and (b) dioxane and water. The smooth lines are hand-drawn through the observed data at 36.5 °C.

tive spectrum. The CD concentrations in the sample were changed up to 50 mM, 10 mM, and 50 mM for α-CD, β-CD, and γ-CD, respectively. For each CD system the difference spectra were obtained at about seven concentrations, and those absorbance data were used for the determination of the binding constant of OB and CD.

The effects of ethanol and dioxane on the spectrum of 4 mM OB were investigated at several compositions without NaBr.

Test of Bitter Taste—Five volunteers were involved in the sensory test. These panelists tasted aqueous 154 mM NaBr solutions containing OB alone and a mixture of 4 mM OB and CD. Each volunteer categorized the bitter taste intensity of a solution as one of the following scores: 0 = no bitter taste; 1 = very slightly bitter taste; 2 = slightly bitter taste; 3 = appreciably bitter taste; 4 = very bitter taste; 5 = extremely bitter taste. The bitterness score for the solution was averaged over the five individuals, so that the averaged score of the solution was a continuous variable smaller than 5.

Data Treatments—Absorbance data were transferred to tables in Microsoft Excel 97 to be subject to further analysis. The nonlinear least-squares method available in Microsoft Excel 97 was used.

Results and Discussion

UV Spectra of Oxyphenonium Bromide—The aromatic chromophore absorbs the UV light. The water spectrum of benzene, for example, exhibits a bathochromic shift, a reduction in the peak intensity, and a broadening of the bands.[6] Similar spectral changes were observed for OB in water, dioxane, ethanol, and their mixtures. The maximum wavelength (λ_{max}), minimum wavelength (λ_{min}), and absorbance ratio (A_{max}/A_{min}) at λ_{max} and λ_{min} in original spectra and corresponding spectral parameters in the first and second derivative spectra depend on the solvents. The peak around 263 nm is the most sensitive to the solvent among these spectral parameters. As Figure 2 shows, this band shifts toward the longer wavelength side with the addition of ethanol and dioxane.

Table 1—Absorption Maximum Wavelengths, Dielectric Constants, and Binding Constants of OB in CD Solutions at 309.7 K

CD	λ_{max} (nm)	D_{ETOH}	$D_{ETOHcor}$[a]	D_{DIO}	D_{DIOcor}[a]	K_1 (M^{-1}) UV	K_1 (M^{-1}) emf[b]
none	263.30	74.5	74.5	74.5	74.5	–	–

[a] Dielectric constant at full binding. [b] Electromotive force measurements.[5]

As Table 1 shows, the CDs also cause red shifts. This result indicates that OB is bound to these CDs. Comparison between these λ_{max} values and the results of Figure 2 enable us to estimate the local microenvironments of OB in the CDs. The dielectric constants of the water–ethanol[10] and water–dioxane[11] systems at 37 °C are available in the literature. The estimated dielectric constants are shown at columns labeled D_{ETOH} and D_{DIO} in Table 1. The dielectric constant in a 10 mM β-CD solution is smaller than that of ethanol (22.7).[10] These dielectric constant values do not accurately correspond to the true microenvironments of the binding sites, because all of the OB molecules are not incorporated into the CDs under the present conditions. To correct this partial binding, we need the binding constants of OB with the CDs.

Binding Constants of Oxyphenonium Bromide for Cyclodextrins—On the basis of electromotive force data, we have shown that OB (P) does not self-associate below 10 mM and that it forms the 1:1 complexes (PD) alone with α-CD, β-CD, and γ-CD (D).[5] The equilibrium constant of this complexation is defined as

$$K_1 = [PD]/[P][D] \quad (1)$$

The total concentrations of OB and CD are written as

$$C_P = [P] + [PD] \quad (2)$$

$$C_D = [D] + [PD] \quad (3)$$

From eqs 1–3, we can obtain the concentration of free OB:

$$[P] = \{K_1C_P - K_1C_D - 1 + [(K_1C_P - K_1C_D - 1)^2 + 4K_1C_P]^{1/2}\}/2K_1 \quad (4)$$

Figure 3 shows typical difference spectra of OB in solutions of α-CD, β-CD, and γ-CD containing 154 mM NaBr. At a given wavelength the absorbance difference, ΔA, can be expressed as

$$\Delta A = l(\epsilon_{PD} - \epsilon_P)[PD] \quad (5)$$

$$= l(\epsilon_{PD} - \epsilon_P)\{K_1C_P + K_1C_D + 1 - [(K_1C_P - K_1C_D - 1)^2 + 4K_1C_P]^{1/2}\}/2K_1 \quad (6)$$

where ϵ_P and ϵ_{PD} denote the molar absorptivities of OB and the equimolar complex of OB and CD, respectively, and l stands for the optical path length of the cuvette. The ϵ_P value was determined from the spectrum of a 4 mM OB solution.

From eq 6 we can calculate a theoretical absorbance difference value for a given set of C_P and C_D. The values of ϵ_{PD} and K_1 were regarded as adjustable parameters to be best fitted to the observed absorbance difference by nonlinear least-squares method. The best fit binding constants are shown in Table 1. These values are close to those

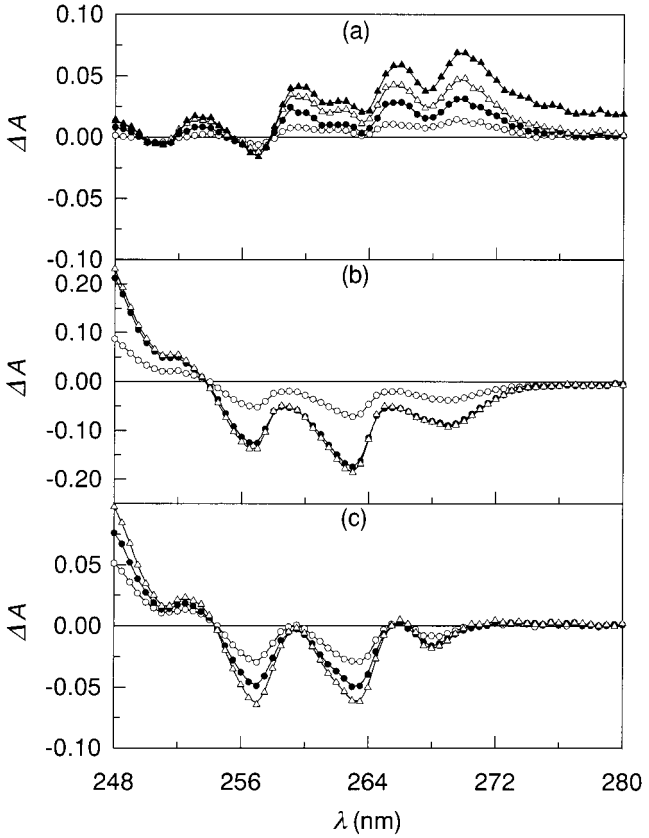

Figure 3—Typical UV difference spectra of 4 mM OB in 154 mM NaBr solutions of (a) α-CD, (b) β-CD, and (c) γ-CD. The CD concentrations (mM) were at 5 (○), 10 (●), 20 (△), and 30 (▲) for α-CD, 1.5 (○), 4.5 (●), and 9.0 (△) for β-CD, and 5 (○), 10 (●), and 15 (△) for γ-CD.

Table 2—Molar Absorptivities (cm^{-1} mM^{-1} at Two Wavelengths) of OB and the Equimolar Complex, the Number of Data, and the SS Value for the OB–CD Systems at 309.7 K

CD	ϵ_P	ϵ_{PD}	λ_1 (nm)	ϵ_P	ϵ_{PD}	λ_2 (nm)	n	SS × 10^4
α-CD	0.1596	0.1752	265.5	0.0821	0.1001	269.5	12	7.79
β-CD	0.2277	0.1945	257.0	0.1886	0.1418	263.0	13	2.49
γ-CD	0.2277	0.2030	257.0	0.1917	0.1669	263.5	13	2.15

determined by electromotive force measurements.[5] For α-CD the observed absorbance differences at 265.5 and 269.5 nm were used simultaneously, because these values exhibited the greatest changes. By the same reasons the wavelengths at 257.0 and 263.0 and at 257.0 and 263.5 nm were employed for β-CD and γ-CD, respectively. The extent of fitting was measured by the SS value defined as

$$SS = \sum^{n} (\Delta A_{obsd} - \Delta A_{calcd})^2 \qquad (7)$$

The number, n, of data and the SS value were shown in Table 2, together with the molar absorptivities for the equimolar complex of OB and CD.

Now we can estimate the dielectric constants at the binding sites of OB in CD by using the binding constants obtained by the UV method. The binding percent of OB is 81.5% for 50 mM α-CD, 97.8% for 10 mM β-CD, and 86.8% for 50 mM γ-CD. We assumed that the estimated dielectric constant is the sum of the free OB and bound OB. Thus, we can estimate the dielectric constants, D_{cor}, at full binding for the ethanol and dioxane systems. As Table 1 shows, these dielectric constants for CD are rather close to one another for the two solvent systems. This fact

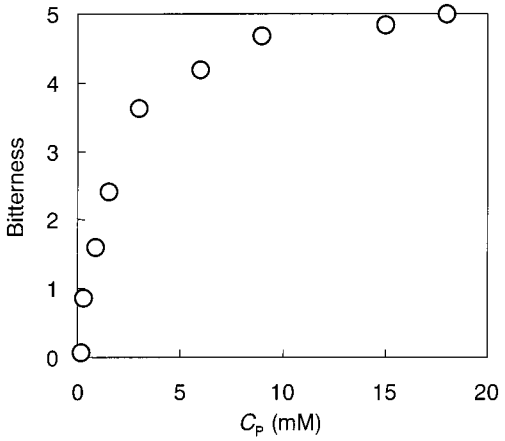

Figure 4—Scores of bitter tastes of aqueous OB solutions plotted against the OB concentrations.

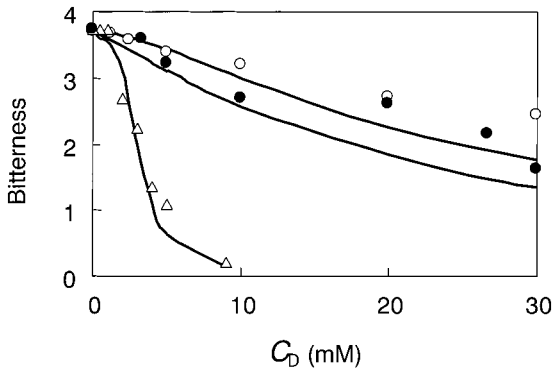

Figure 5—Effects of CDs on the bitter taste intensity of a 4 mM OB solution: α-CD (○), β-CD (△), and γ-CD (●). The solid lines are calculated from eqs 4 and 8 by using the equilibrium binding constants shown in Table 1.

demonstrates the validity of the present estimation. The dielectric constant for α-CD suggests that the phenyl group of OB is outside of the α-CD cavity or is shallowly penetrated into the cavity. The phenyl group of OB will be deeply incorporated into the β-CD cavity, because an estimated dielectric constant of $D_{DIOcor} = 2.9$ is very close to 2.1 of dioxane.[11] Because this group is snugly incorporated in the γ-CD cavity, the cavity has room enough to contain some remaining water molecules. Therefore, OB senses the γ-CD cavity to be a mixture of dioxane and water with $D_{cor} = 30.7$.

Thus, we can estimate the microenvironments of OB in the CDs from the UV spectra.

Effects of Cyclodextrins on the Bitter Taste Intensity of OB—The intensity of bitter taste of an OB solution is shown as a function of OB concentration in Figure 4. As Figure 5 shows, the bitter taste intensity of a 4 mM OB solution is remarkably reduced by the addition of CDs. This reduction by the kind of CD is in the increasing order of α-CD < γ-CD < β-CD, consistent with the magnitude of the binding constant.

Bitter compounds have a variety of chemical structures including alkaloids and terpenes. These compounds, however, are generally hydrophobic and easily absorbed to the receptor of bitter sites.[9] OB tastes bitter, but CD is not a bitter compound, because of its hydrophilicity. We have shown that the complexes of CD with surfactants[12] and propantheline bromide[4] are surface-inactive. Similarly, the complex of OB and CD is rather hydrophilic and would not taste bitter.[4,5] Thus we can assume that the free OB molecule alone exhibits the bitter taste, regardless of its CD complex and CD. On the basis of this assumption, the bitter taste intensity of an aqueous solution of OB and CD

will be determined by the concentration ([P]) of uncomplexed OB in the solution, irrespective of the kind and concentration of CD:

$$\text{bitter taste intensity} = g\{[P]\} \quad (8)$$

Actually we did not attempt to fit any empirical equation to the observed bitter scores shown in Figure 4, but drew a smooth line through these data, albeit not shown therein. This line was used for reading a bitter score at a free concentration of OB and is expected to hold true for all solutions of OB and CD.

To verify this assumption, we calculated a theoretical bitter taste intensity by using eqs 4 and 8 for a solution containing 4 mM OB and CD. Here the binding constant estimated by the UV method was employed in eq 4. The solid curves in Figure 5 show such theoretical values. These values are close to the observed ones. Thus, eq 8 holds true for all solutions containing OB and CDs. This important result enables us to predict the intensity of bitter taste of an OB and CD solution from the observed UV absorbance of their mixed solution.

Implications and Limitations of the Present Work—The present UV approach for estimating the microenvironment of the binding site will apply for CD inclusion of other chromophores. OB exclusively forms the 1:1 complexes with α-, β-, and γ-CD.[5] Other guests often form ternary and quaternary complexes.[12] For such complicated inclusion systems, the present approach will not provide clear information on their microenvironments, though other spectroscopic methods, such as NMR and circular dichroism, can give more detailed information. Such spectroscopic data will generally provide a basis of the present UV method for estimating the binding site.

The UV method for predicting the bitter taste of OB reduced by CDs will apply to other bitter aromatic compounds. This enables us to determine the kind and concentration of CD to suppress the bitter taste of drug from a few and reproducible experiments. The UV method, however, does not apply for the self-associating or multiple complexing systems, because the UV absorbance senses all of the monomer and polymers of guest and its CD complexes. For the same purpose we have proposed the surface tension[4] and electromotive force[5] methods. Many drugs self-associate in aqueous media by hydrophobic interactions,[13] though OB does not self-associate.[5] Guest generally forms multiple complexes with CD.[12,14] The surface tension and electromotive force methods can apply to such self-associating or multiple complexing systems,[4,5] because these methods sense the free drug molecule alone. The UV method, however, has the advantage of convenience over these methods. This method would apply to bitter blockers with characteristics similar to CD. A kind of lipoprotein can specifically inhibit bitter taste by masking the receptor site for bitter substances.[15] The present method will be inapplicable to such masking systems.

Received December 30, 1998. Accepted for publication June 3, 1999.

Abstract □ The in vitro release of a drug from topical formulations depends on the concentration of the drug in the formulation, the solubility of the drug in the base, the diffusion coefficient of the drug in the vehicle, and the partition coefficient of the drug between the vehicle, and the release medium. Incorporation of both complexing agents and cosolvents into such formulations has been used to enhance the in vitro release of a drug from topical formulations. In this investigation, a novel approach to enhance the in vitro release of benzocaine from different ointment formulations has been introduced. In this study, benzocaine was microencapsulated using gelatin–acacia complex coacervation technique. Various weight fractions of the coacervate, 5, 10, and 20% (w/w), were incorporated into both oleaginous and absorption bases. The in vitro release characteristics of benzocaine from the resulting ointments were studied using a modified USP Dissolution Apparatus 2. A plot of the cumulative amount of drug released (7–8%) per unit surface area versus $(\text{time})^{1/2}$ was linear. Microscopic studies of the formulations revealed that the coacervates maintained their integrity in the formulation during the preparation and storage of the dosage form. Differential scanning calorimetric (DSC) studies indicated that the drug existed in the crystalline state in all formulations including those at a low drug load (0.5% w/w). DSC was also used to determine the solubility of the drug in the formulation. The rate and extent of drug release was higher in the absorption base as compared to the oleaginous base.

Introduction

When striving to achieve therapeutic effectiveness in a topical formulation, two important factors are generally considered during the design of such formulations including (i) the rate of drug release from the vehicle used in the formulation and (ii) the ease or difficulty with which the drug will penetrate the skin barrier after its release from the base. Different mathematical models have been utilized in the literature to describe the in vitro release characteristics of a drug from topical dosage forms.[1−3] The rate of drug release from such formulations depends on various physicochemical factors including the solubility of the drug in the vehicle, the concentration of the drug in the formulation, and the diffusion coefficient of the drug in the topical vehicle.[1] However, when two-phase emulsion type topical formulations are utilized, one must consider the type of emulsion used in the formulation of the ointment and also the effect of micellar solubilization on the thermodynamic activity of the drug in various phases.[3−6] When the topical formulation matrix is an emulsion or suspension type, the effective diffusion coefficient of the drug must be used instead of diffusion coefficient.[3] In general, the rate of drug release from topical formulations has been enhanced by increasing the drug load, by changing the diffusivity of the drug in the vehicle, and by changing the drug's solubility in the vehicle. The solubility of a drug in the vehicle has been modified by incorporation of other components into the base, the addition of a cosolvent, changing the pH of the medium, and addition of a complexing agent.[7−9] The diffusivity of the drug has been altered by changing the microscopic viscosity of the vehicle.[1] In essence, the effect of different bases and their composition on the release of benzocaine from topical formulations has been extensively studied.[10−14] The present study attempts to enhance the release rate of a model drug benzocaine from ointments prepared from two different bases using a novel gelatin−acacia coacervation technique.

The gelatin−acacia complex coacervation method has been widely used for the microencapsulation of many hydrophobic drugs.[15−20] During the microencapsulation process, the coacervates formed are usually cross-linked and hardened by the addition of a dehydrating agent.[21] Aldehydes are generally used for this purpose. Cross-linking of the gelatin−acacia coacervate occurs through either a dimethylene ether bridge or methylene bridge.[21] In contrast, this investigation has used gelatin−acacia complex coacervates (without cross-linking) containing benzocaine in topical formulations to modify the release characteristics of this drug. In this study, benzocaine microcapsules prepared using the gelatin−acacia complex coacervation method were incorporated directly into the ointment bases by levigation prior to the hardening process of the microcapsule wall. Therefore, the objectives of this investigation were (i) to modify the release characteristics of benzocaine from various topical formulations by incorporation of the gelatin−acacia coacervate of the drug into base, (ii) to evaluate the effect of various base-types on the release characteristics of the drug, and (iii) to elucidate the mechanism of release from the resulting formulations.

Materials and Methods

Materials—Benzocaine and *n*-butyl PABA (Sigma Chemicals, Milwaukee, WS); gelatin, acacia, chloroform, *n*-octanol, hydrochloric acid (Fisher Scientific, Fairlawn, NJ); white petrolatum (Dayton Hudson, Minneapolis, MN); Aquaphor (Beiersdorf, Norwalk, CT) were used as received.

Preparation of the Benzocaine Microcapsules and the Ointments—Benzocaine (2 g) was dispersed in 100 mL of 1% (w/v) acacia solution in water, and the resulting suspension was then mixed with 1% (w/v) gelatin solution at 40 °C while stirring the solution. The pH of the 1% acacia solution was 4.5 and that of the 1% (w/w) gelatin solution was 4.0. The pH of the gelatin−acacia mixture (50:50 v/v) was 4.3. The pH of this mixture was adjusted to 3.9 with 0.1 N HCl and stirred for an additional 30 min. The coacervates were then centrifuged at 2000 rpm for 5 min in a IEC HN-II model centrifuge (International Equipment Company, Needham Hts, MI), and the supernatant was discarded. Different weight fractions of the coacervate were then incorporated into an oleaginous base (Petrolatum) and an absorption base

(Aquaphor). Empty gelatin–acacia coacervates were prepared without benzocaine using the similar procedure described earlier for the benzocaine microcapsules. Physical mixtures of both bases with blank coacervate (microcapsules without drug) were prepared by mixing the coacervates with base by levigation. The resulting mixture will be described as the "physical mixture" in the text, hereafter. Ointments were prepared using the levigation method on an ointment slab. The water content of the coacervate without benzocaine and with benzocaine, prior to incorporation into ointment bases was determined using Karl Fisher titrimetry.

Analysis of Benzocaine—Benzocaine was analyzed by two methods. An HPLC method was used to study the in vitro release kinetics of the drug and its stability in the formulation. A Spherisorb C18, pH stable column (Phase Separations, Norwalk, CT), 15 cm in length was used. The column effluents were monitored at 254 nm (Shimadzu SPD-6A UV detector, Shimadzu. Koyoto, Japan), and the flow rate was maintained at 1 mL/min (Shimadzu LC-6A pump). The mobile phase consisted of methanol: phosphate buffer (58:42 v/v, pH 8.0). A UV/vis spectrophotometer (Perkin-Elmer, Lamda 400, Perkin-Elmer, Norwalk, CT) was operated at a wavelength of 290 nm. This method was used to determine the drug load in the formulation.

Drug Content in the Ointments—A known amount of the ointment was dissolved in chloroform, and the concentration of benzocaine in solution was determined using a calibration curve of the drug in chloroform. Standard curves were linear over the concentration range (0.5–40 μg/mL).

In Vitro Release Studies—The in vitro release of benzocaine from the ointments was carried out in a modified USP Dissolution Apparatus 2 (Hanson Research Corp., Chatsworth, CA). Five hundred milliliters of Sorensen's phosphate buffer pH 7.4 was used as the release medium, and temperature of the medium was maintained at 32 °C. The ointments (3.6–4.0 g) were placed in a specially designed aluminum cell (made in-house) with a diameter of 4.5 cm. The aluminum cells containing the ointments were carefully placed in the bottom of the dissolution medium. The paddles were rotated at 50 rpm. The release of drug from the surface (surface area = 15.90 cm^2) to the bulk of the release medium was studied. At predetermined time intervals, 1 mL of the release medium was collected and replaced with 1 mL of fresh buffer. The concentration of benzocaine in the solution was determined using the HPLC method described earlier. The data presented are the average of three formulations prepared independently.

Phase Contrast Microscopic Studies—The ointment samples were carefully smeared on glass slide and examined under a phase contrast microscope (Olympus, model CK2). This microscope was attached to a camera (OM-10) and used a Kodak Plus-X-Pan film with an ASA 125 automatic exposure.

Differential Scanning Calorimetry—DSC curves were obtained using a Shimadzu (DSC-50) differential scanning calorimeter attached to a Shimadzu (model C-R49) Chromatopac integrator. Samples (2–5 mg) were placed in the aluminum pans and heated at a rate of 10 °C/min with nitrogen purge at a rate of 20 mL/min.

Determination of Solubility of the Drug in the Ointment—The solubility of the drug in the ointment at its melting point was determined by DSC using a method described by Theeuwes et al.[22] The ointment sample (2–5 mg) was crimped into a nonhermatically sealed aluminum pan and heated in a DSC at a controlled rate (10 °C/min) with nitrogen purge. The enthalpy of fusion of the drug was determined and plotted against the known drug load.

Results and Discussion

The phase contrast microscopic studies of the petrolatum base containing benzocaine, empty microcapsules, and microencapsulated benzocaine is shown in Figure 1. Benzocaine crystals were evident in the ointment even at the lowest drug load (0.5% w/w) as shown in Figure 1a. Figure 1b depicts the micrograph of an ointment containing a physical mixture of 20% (w/w) of empty gelatin–acacia coacervate (without benzocaine) and 80% (w/w) of petrolatum after one month of storage in a refrigerator. Figure 1c represents the micrograph of ointment prepared from microencapsulated benzocaine in petrolatum. This study

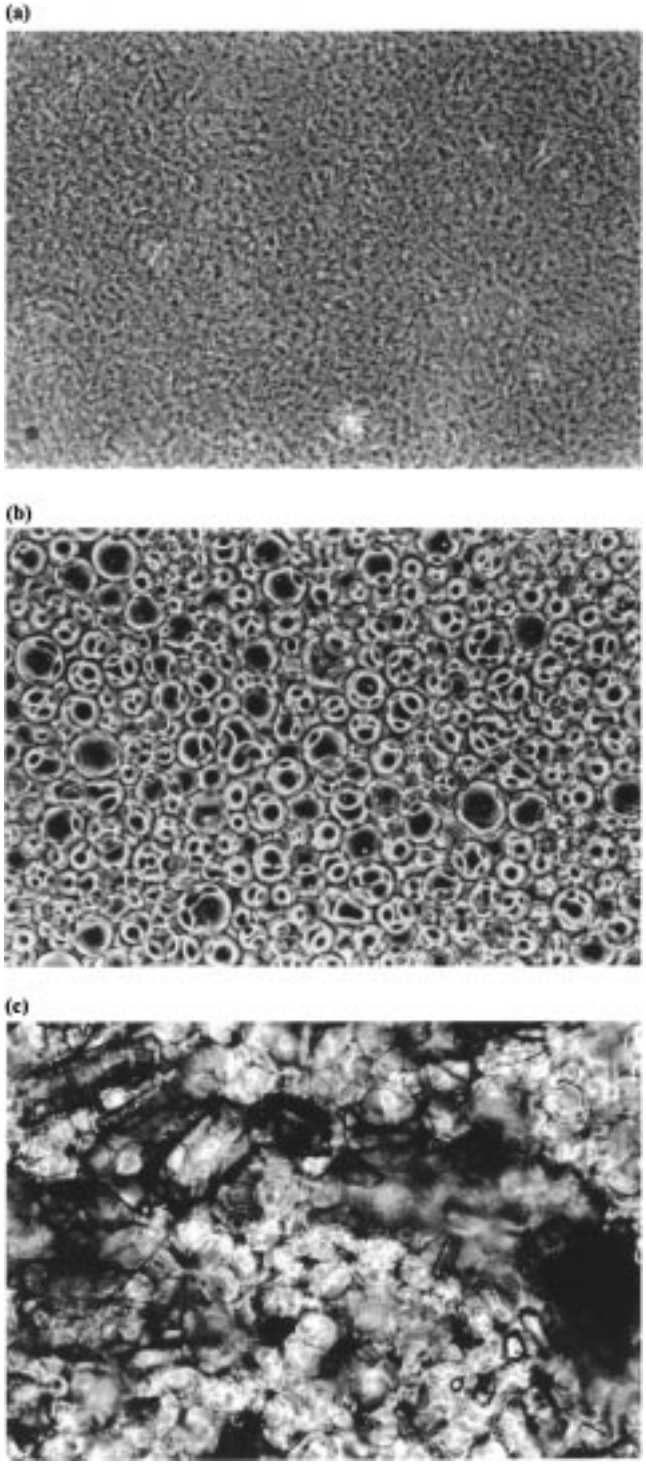

Figure 1—Photomicrographs of (a) benzocaine ointment in Petroatum (0.5% w/w); (b) physical mixture of empty microcapsules 20% (w/w) and Petrolatum 80% (w/w); (c) microencapsulated benzocaine in Petrolatum.

revealed that the coacervate maintains its integrity during preparation of the ointments and storage over a period of at least one month. The physical state of drug in the topical formulation is an important parameter, which in turn affects the drug's release rate from the topical vehicle. The rate of release of a drug from a formulation is always higher if the drug is present in the dissolved state rather than the dispersed state.[3,11] In this investigation, the physical state of the drug was determined by two independent methods. DSC was used to measure the enthalpy of fusion, if any, of the free crystalline drug in the formulation. No melting peak in the formulation indicated the drug was

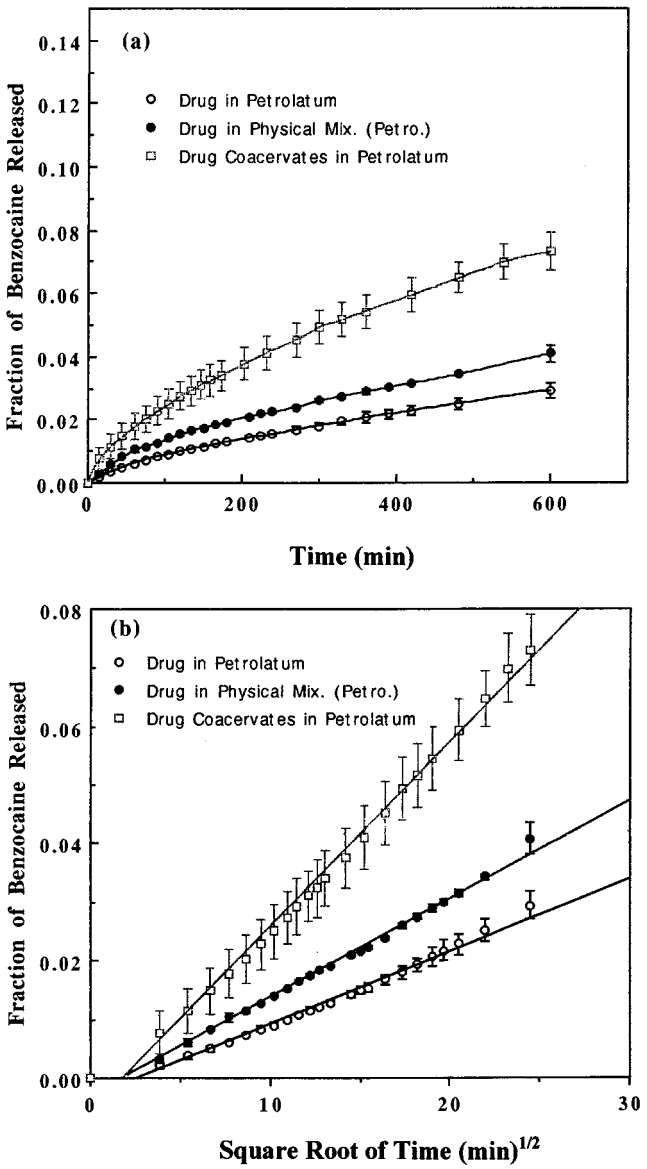

Figure 2—In vitro release of benzocaine from oleaginous (Petrolatum) ointments containing 2.9% (w/w) of benzocaine: (a) plot of cumulative amounts of benzocaine released versus time, and (b) plot of cumulative amounts of benzocaine released versus square root of time.

present in a molecularly dispersed state. The physical state of the drug in the formulation was further confirmed by visual inspection of the free crystalline drug in the formulation under a phase contrast microscope. DSC studies revealed that at even an extremely low drug load (0.5% w/w), an endothermic peak at 88 °C was observed in the DSC thermogram. This endothermic peak was attributed to the melting of benzocaine. Therefore, some of the drug was present in the crystalline state in the formulation at a drug load of 0.5% (w/w).

The fraction of benzocaine released from the ointments prepared from Petrolatum base is shown in Figure 2. In this study, benzocaine was incorporated into the petrolatum base as follows: (i) directly into Petrolatum, (ii) into a physical mixture of the empty microcapsules and Petrolatum (20:80 w/w), and (iii) microencapsulated benzocaine into Petrolatum. The benzocaine load was kept the same in all formulations. The cumulative amount of drug released from ointments containing microencapsulated benzocaine was found to be higher than the physical mixture or Petrolatum alone. A linear relationship was observed when the cumulative amount of drug released was plotted against the square root of time. The results of this study suggest that the release of benzocaine from these formulations occurred by a matrix diffusion control mechanism as described by Higuchi.[1] The slope of the lines (Figure 2b), which is a measure of the rate of drug released from the formulation, was then determined. In the case of the ointment containing coacervated benzocaine in Petrolatum, the release rate was found to be 2.5 times faster than the petrolatum ointment containing benzocaine alone. However, in case of the physical mixture the rate was only 1.4 times higher under similar test conditions.

Also of interest was the determination of the release kinetics of benzocaine from an absorption base. Aquaphor was selected for this study. Three different formulations were prepared in a similar manner as described earlier for Petrolatum. Interestingly, the ointment containing microencapsulated benzocaine also showed a higher rate and extent of benzocaine release. A plot of the cumulative amount of drug released vs the square root of time also showed a linear relationship indicating matrix diffusion control release. The rate of release of benzocaine from Aquaphor containing the coacervated drug was found to be 2.1 times faster than the Aquaphor containing the benzocaine alone. In the case of the physical mixture, the rate of drug release was approximately 1.4 times higher than the base containing benzocaine alone. Comparison of in vitro release profiles of benzocaine from these two bases revealed that in all three types of formulations studied, the release of benzocaine was always higher in Aquaphor than Petrolatum. The in vitro release profiles of benzocaine from Aquaphor and Petrolatum bases containing a similar drug load of benzocaine were then studied. Comparison of the slope of the cumulative amount of benzocaine released versus square root of time for these release profiles revealed that the rate of benzocaine release from the Aquaphor base is approximately 2.6 times higher than that of the Petrolatum base. The increase in drug release from Aquaphor as compared to Petrolatum is possibly explained by the fact that the solubility of the drug in petrolatum is higher than in Aquaphor, thereby held firmly by the vehicle, and the rate of release of drug was slow.[12] The presence of water in the formulation due to the incorporation of the coacervate could also contribute to the rate of release of the drug from these ointments. The water content of the empty coacervates and coacervate containing benzocaine prior to incorporation into the ointments were determined by Karl Fisher Titrimetry and found to be 82.5 and 78.5% w/w, respectively. Therefore, water content of the ointments was approximately 15 to 17% w/w (assuming 20% w/w of the coacervate in the ointment). Presence of water will provide rapid diffusion pathways of drug to get into the dissolution medium. Although benzocaine has very low solubility in water,[23] diffusion through the water pathway or aqueous coacervate pathway would be much faster than through the high viscosity, gellike Petrolatum or Aquaphor. This may explain the increased rate of drug release from ointments containing coacervates or from the physical mixtures.

The solubility of the drug in both bases and the physical mixture was determined by DSC. As mentioned earlier, the solubility of the drug in the matrix is determined by this method at the drug's melting point (approximately 88 °C). As such, the solubility of the drug in the Petrolatum base was determined from the intercept of the line obtained after plotting the drug-load in the formulation versus the heat of fusion. After heating, some samples were allowed to cool to room temperature and again reheated. Melting was observed at the same temperature during reheating indicating the drug was in the same crystalline form. Using this method, the solubility of benzocaine in the Petrolatum

was found to be 0.06 (w/w) (at 88 °C). Unfortunately, the determination of the solubility of benzocaine in Aquaphor, as well as in the physical mixtures, was not possible due to other thermal activity interference near the melting point of the drug from the matrix material.

Conclusions

(1) Gelatin−acacia coacervation method was used in the microencapsulation of benzocaine.

(2) Incorporation of the coacervate (without cross-linking) into Petrolatum or Aquaphor base substantially enhanced the rate of drug release from both bases.

(3) This enhanced release is possibly due to the increased diffusivity of the drug in the base, change in solubility, and the thermodynamic activity of the drug in base by inclusion of coacervates in the formulations.

(4) The release of benzocaine (7−8%, w/w) from all of the formulations occurred via a matrix-controlled diffusion mechanism.

(5) The absorption base showed a higher rate and extent of benzocaine release as compared to the oleaginous base.

Multivariate Parameter Evaluation of Pharmaceutically Important Cellulose Ethers

BENGT PERSSON, HANS EVERTSSON,* ROLF BERGMAN,† AND LARS-OLOF SUNDELÖF

Contribution from *Physical Pharmaceutical Chemistry, Uppsala University, Uppsala Biomedical Centre, Box 574, 751 23 Uppsala, Sweden, and SPOC, UF3A1, Pharmacia & Upjohn, 751 82 Uppsala.*

Received February 24, 1998. Accepted for publication April 22, 1999.

Abstract □ A set of nonionic cellulose ethers with varying hydrophobicity and molecular weight has been investigated by principal component analysis (PCA). Several experimental variables such as dynamic surface tension, diffusion coefficient, microviscosity as monitored by a fluorescence probe technique, and intrinsic viscosity are included in the analysis. The experimental variables and observations (polymer fractions) are analyzed in models with good predictive capacities. The apparent equilibrium surface tension correlates to the cloud point and to the critical aggregation concentration in the presence of surfactant. The microviscosity is shown to be a predictive parameter for the degree of hydrophobic substitution. The irreversible process of dynamic surface tension is dependent on the diffusion coefficient but to an even larger degree on the polymer concentration, which is well illustrated by the PCA models.

Introduction

Cellulose ethers of amphiphilic nature such as hydroxypropyl(methyl)cellulose (HPMC) and ethyl(hydroxyethyl)-cellulose (EHEC) are widely used in various pharmaceutical dosage forms. These polymers are used as swelling agents, binders, emulsifiers, rheological stabilizers, and for film coating, etc.[1] Cellulose ethers can be obtained in a variety of fractions (samples) with different physicochemical properties, since the molecular weight and degree of substitution can vary considerably. Furthermore, large batch to batch variations are common which may alter the final pharmaceutical product in which they occur. Interaction between these high molecular weight amphiphiles and low molecular weight active substances, which often are hydrophobic or even amphiphilic in nature,[2] will affect, for example, the release rate of drug from pharmaceutical formulations based on cellulose ethers. The strength of such associative polymer−drug interaction is in turn dependent on the physicochemical properties of the cellulose ether used. Thus, it is of importance to map the influence of the chemical structure of the polymer on its physicochemical properties in aqueous solution.

A set of cellulose ethers differing in hydrophobicity has previously been thoroughly examined in this laboratory by time dependent surface tension determination, viscosity measurements, fluorescence probe techniques, solubilization measurements, light scattering techniques, and size exclusion chromatography. Most of these experimental results have been published elsewhere.[3−5] Some qualitative relationships between the observed variables were seen. However, the interplay between a large number of variables is difficult, if at all possible, to reveal without the aid of mathematical tools capable of handling many, even correlated, variables simultaneously.

Multivariate analysis[6] (MVA) has, over the last couple of decades, become more and more important as the amount of data available on chemical systems increases steadily. This branch of science, today named chemometrics when applied on chemistry, involves a number of multivariate methods[6] and is used in various branches of chemistry and chemical processing[7,8] to find optimum conditions. The present polymer systems have been investigated by principal component analysis[6] (PCA), a method based on linear algebra involving a matrix decomposition. Special emphasis has been put on finding models as simple as possible with which to describe the systems, to find predictive parameters for the physicochemical properties of the polymer fractions (samples). Since the experimental data available on these polymer fractions are quite extensive, the paper also presents a validation of the usefulness of principal component analysis on complex aqueous polymer systems.

Experimental Section

Most of the data used in the analysis are published elsewhere.[3−5] The different polymer samples (observations) are six different ethyl(hydroxyethyl)cellulose (EHEC) fractions, CST-103, DVT-87014, E230G, E411G, PR, OS, varying in molecular weight and degree of substitution, and one fraction each of hydroxypropyl-(methyl)cellulose (HPMC), hydroxypropylcellulose (HPC), hydroxyethylcellulose (HEC), and methylcellulose (MC). All EHEC fractions were obtained from Akzo Nobel AB, Stenungssund, Sweden. HEC and MC were obtained from Aldrich Chemie, Steinham, Germany, HPMC from Colorcon., West Point, PA, and HPC from Hercules Inc., Wilmington, DE. The abbreviations of the variables studied are explained in the Glossary.

The determinations of molecular weight, diffusion coefficient, microviscosity, and the rest of the parameters are presented elsewhere.[3−5] The microviscosity of the mixed sodium dodecyl sulfate−polymer micelles was determined with the fluorescent probe 1,3-di(1-pyrenyl)propane, P3P. The intramolecular excimer formation of P3P is dependent on the local microfluidity around the probe, and the monomer to excimer intensity ratio, I_M/I_E, is a qualitative measure of the microviscosity.[9]

Method

Principal component analysis (PCA) was performed using the SIMCA software package.[10] The data matrix was normalized and centered by an autoscaling procedure, before the principal components (PC:s) were calculated. This is a least-squares method producing principal components which are orthogonal to each other. The first principal component represents the largest variation in the data, and the second component describes the second largest variation orthogonal to the first and so forth. The observations (polymer fractions) are in some sense sum-

Table 1—Summary of Some of the Experimental Data Used in the Principal Component Analysis. The Variables Are Explained in the Experimental Section

Polymer	M_w (×10^5 g/mol)	MS_{ao}	DS_{alkyl}	CP (°C)	C1 (mM SDS)	IM/IE-max	[η] (mL/g)	D (×10^{-12} m^2/s)	γ (mN/m)
EHEC Fractions									
CST-103	1.89	0.7	1.5	28	1.5	13.2	455	6.59	37
DVT-87014	1.33	0.9	1.4	28	1.5	8.1	290	7.55	40
E230 G	5.35	0.9	0.9	65	3.9	3.2	410	7.65	48
E411 G	7.85	1.7	1.2	58	3.7	3.2	1000	6.3	52
OS	13.2	1.5	1.6	24	1.5	10.0	1400	–	37
PR	12.4	1.75	1.4	48	2.5	4.0	1500	–	42
Other Cellulose Ethers									
HPMC	3.01	0.4	2	55	3.9	5.2	740	6.48	47
HPC	1.06	0.4	–	42	2.0	6.6	134	12.22	42
MC	1.62	–	2	65	4.1	3.1	400	8.37	47
HEC	1.89	3	–	100	7.0	2.4	237	7.55	63

marized in the score vectors, which are linear combinations of the variables, and the corresponding summary of the variables is named loadings. In other words, the original experimental variables are decomposed into fewer new variables (PC:s) onto which the observations are projected. A multiplication of the score (**T**) and loading (**P′**) matrixes plus a residual (**R**) will regain the original normalized and centered data matrix (**X**) according to

$$\mathbf{X} = \mathbf{T}\cdot\mathbf{P}' + \mathbf{R} \qquad (1)$$

The original, unscaled data matrix is given in Appendix 1. The accuracy of the least squares models is expressed as R^2, the explained variance of the model. R^2 is the comparison between the squared sum of the experimental observations (y_{obsd}) and the squared sum of the values calculated by the model (y_{calcd}) according to

$$R^2 = (\sum y_{obsd}{}^2 - \sum (y_{obsd} - y_{calcd})^2)/\sum y_{obsd}{}^2 \qquad (2)$$

where the sums range from 1 to n observations. R^2 increases with the number of PC:s used in the model since more variation in the experimental data can be explained as the number of "new" variables used increases, and hence the residual decreases. The idea with the PCA, however, is to use as few PC:s as possible in order to get a simpler model. Q^2 describes the relation between the squared sum of observed values and the sum of squares of the values as determined from cross validation (y_{cv}):[8]

$$Q^2 = (\sum y_{obsd}{}^2 - \sum (y_{obsd} - y_{cv})^2)/\sum y_{obsd}{}^2 \qquad (3)$$

Cross validation is a process where the data themselves are used. A few data points are left out at a time of the consecutive model-calculations. Each data point is left out of the calculation once. The closer to 1 that Q^2 is, the better the model. The predictive capacity can never be higher than the explained variance and will reach a maximum when increasing the number of PC:s used. Thus, the optimum model has a high R^2 as well as Q^2 and a small difference between the two. It follows that the model only is valid within the experimental domain. All models presented here contain two principal components. The R^2 value for each component is noted in percent on the axes in the figures. The cumulative R^2 and Q^2 for each model are as follows: Figures 1a and 1b (model 1), 0.882 and 0.536; Figures 2a and 2b (model 2), 0.733 and 0.325; Figures 3a and 3b (model 3), 0.769 and 0.648, respectively. The ellipse in each figure describes the 95% confidence region.[10]

Results and Discussion

The characterization of water soluble polysaccharides is far from trivial, involving a number of physically different methods such as in this case dynamic light scattering, fluorescence probe techniques, and dynamic surface tension. Some, but far from all, qualitative relationships can be deduced just by looking at Table 1 and Appendix 1. Principal component analysis, however, gives a much more objective picture of the complex interplay between the variables. The extensive knowledge of the polymer fractions from this laboratory gives the possibility to construct models containing the appropriate parameters, a critical step in the analysis which is always subjective to some degree. The data set has been divided into two subsets; one containing observations of some of the polymer systems at equilibrium (Figures 1a and 1b (model 1)), and one containing observations describing the irreversible process of dynamic surface tension before equilibrium together with part of the equilibrium responses (Figures 2a and 2b (model 2), Figures 3a and 3b (model 3)). The a-figures give the loading plot (experimental variables in relation to the principal components) of each model, and the b-figures give the score plot (polymer samples in relation to the principal components) of each model.

Equilibrium Parameters—Only the EHEC fractions were chosen for the equilibrium parameter model since complete substituent-information exist for these fractions, and the substituents are of the same types ethyl (hydrophobic) and hydroxyethyl (hydrophilic) groups. This makes the EHEC subgroup straightforward to compare. Figure 1a shows the loadings of the experimental variables for two significant principal components (PC:s, denoted p1 and p2 in the figure) for all EHEC fractions. If a variable is located close to and far along a PC axis, this variable "strongly loads" into that PC. Such an experimental variable then correlates with the new variable, or PC. Original experimental variables lying close to each other correlate in the hyper plane (the two-dimensional window provided by p1 and p2). The model shows four groupings of experimental variables located far along the positive and negative sides on the two principal component axes p1 and p2. The first PC monitors the largest variation in the data. It can be interpreted from the figure that the surface tension γ (measured after 11.7 h on 500 ppm polymer solutions) is strongly correlated to the surfactant concentration corresponding to the onset of polymer–surfactant interaction C1, as well as the cloud point CP, since these variable vectors lie close to and far out on the first principal component axis. Also, these variables are negatively correlated to the microviscosity indices and the surface pressure as these variables are grouped close to and far along the negative side of the first principal component. The negative correlation between the microviscosity and CP/C1/γ is in accord with the earlier reports.[4,5] These correlations can be qualitatively deduced from Table 1. Furthermore, CP, C1, the surface tension, and the micro-

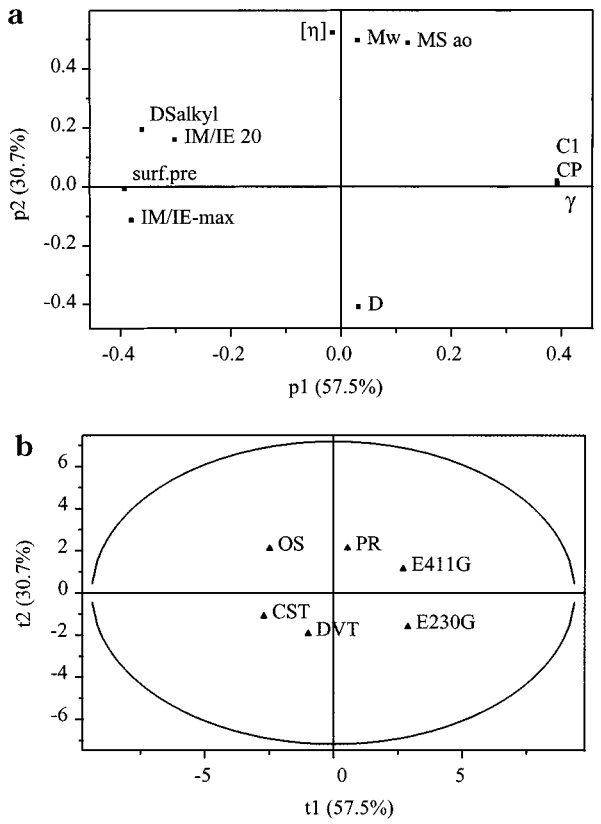

Figure 1—(a) Loading plot of all EHEC fractions of the equilibrium model, showing the first (p1) and second (p2) PC. The cumulative R^2 and Q^2 are 0.882 and 0.536, respectively. (b) The corresponding score plot of all EHEC fractions of the equilibrium model, showing the first (t1) and second (t2) PC.

viscosity are mainly governed by the hydrophobicity of the EHEC fractions, as can be seen by the degree of hydrophobic substitution, DS_{alkyl}, which is located in the group of variables at the negative side of the first principal component axis, and thus correlates with the microviscosity and the surface pressure. A high surface tension, close to that of water, is coupled to a high cloud point as both variables monitor the hydration properties of the polymer. A high surface tension also gives a low surface pressure, or surface activity, since the latter is the difference between the surface tension of water (73 mN/m) and the surface tension of the polymer.

The microviscosity of mixed polymer−surfactant micelles is hence strongly correlated to the hydrophobic substitution of the polymer, as well as the surface activity, which earlier has been discussed[9] in terms of the ability of the polymer to form densely packed mixed polymer−surfactant micelles. This principal component model verifies that the microviscosity of the ternary system EHEC/sodium dodecyl sulfate/water can be used to predict the solubilization properties of the corresponding binary cellulose ether/water system, with the additional information that DS_{alkyl} is the structure-related parameter with the highest influence on the ability to form densely mixed polymer micelles with SDS.

The second PC p2 monitors the second largest variation in data, 30.7%, as compared to the first PC, 57.5%. As expected, the diffusion coefficient D is negatively correlated to the molecular weight and the intrinsic viscosity, which follows directly from the Stokes−Einstein equation $D = kT/(6\pi\eta r)$, where k is the Boltzmann constant, T is the temperature, η is the viscosity of the solvent, and r is the radius of a small hard sphere immersed in the viscous solvent. It should be pointed out that D is obtained by dynamic light scattering, $[\eta]$ from capillary viscometry, and M_w from size exclusion chromatography—that is, from independent methods. The molecular weight correlates as expected with the intrinsic viscosity in accord with the Mark−Houwink equation $[\eta] = KM^a$. These variables, however, do not explain the variation of data along the first PC and hence neither to the surface tension nor to the microviscosity. An interesting feature is that the intrinsic viscosity is correlated to MS_{ao}, the degree of hydrophilic substitution. This is not too surprising since a polymer with a higher hydrophilicity tends to swell in an aqueous solution. MS_{ao} does not occur directly opposite to DS_{alkyl} in the plot. Whereas the degree of hydrophobic substitution has a strong influence on the steady state surface tension and microviscosity, the degree of hydrophilic substitution is important for the intrinsic viscosity. This of course, is not entirely true since DS_{alkyl} and MS_{ao} in combination give the polymer its specific amphiphilic nature. For example, CST-103 is partly self-aggregated in aqueous solution due to the uneven distribution of large hydrophobic substituents,[5,11] a feature originating in the hydrophobic−hydrophilic balance and clearly affecting the hydrodynamics of the polymer. Nonetheless, the degree of hydrophobic substitution DS_{alkyl} seems to affect the microviscosity of polymer/surfactant micelles to a larger extent than the degree of hydrophilic substitution MS_{ao}.

Figure 1b shows the score plot corresponding to the loading plot of Figure 1a. The PC:s are denoted t1 and t2 to signify that the vectors plotted in this space are observables (polymer samples)—not original variables as in the loading plot of Figure 1a, where the PC:s are denoted p1 and p2. The observation vectors in Figure 1b are separated with an even distribution. Such a score plot thus gives a good overview of the observations or polymer samples in relation to the new variables (PC:s), which carry about 88% of the information of the original experimental variables. The two EHEC samples having the highest molecular weight, OS and PR, are located above the others in accord with Figure 1a. The fractions having the higher microviscosities and lower surface tensions, OS and CST-103, are located to the left, also in accord with the loading plot, cf. the original data matrix in Table 1 and Appendix 1. This score plot separates CST from DVT in accord with previous investigations[3−5] even though these two fractions have very similar degree and balance in substitution. The difference is thought to originated in a more separated distribution of substituents and hence longer substituents on the CST fraction, making it effectively more hydrophobic.

The above presented model makes it possible to predict (to 54% using only these six EHEC samples) the solution properties of an unknown EHEC sample by just knowing its DS_{alkyl} and MS_{ao}. If, in addition, some easily measured variable as CP is determined, the other experimental variables can be predicted more precisely and optimum conditions for these determinations might be chosen. Any of the experimental variables along p1 should be useful for the prediction of the strength of amphiphilic polymer−drug interaction, which is important when designing advanced controlled release formulations.

Dynamic Parameters—The irreversible process of surface tension decrease to equilibrium is considered here for all of the cellulose ethers investigated. Figure 2a shows the loadings of the surface tension from time zero to equilibrium at an initial homogeneous polymer concentration of 3 ppm, the lag time, t_{lag}, and the time it takes to reach $(\gamma H_2O - \gamma)/2$, t. t_{lag} is the time from time zero to the point where the surface tension curve shows a negative second derivative. The major variation in data is illustrated along the horizontal first PC axis p1, where the diffusion coefficient is negatively correlated to the surface tension

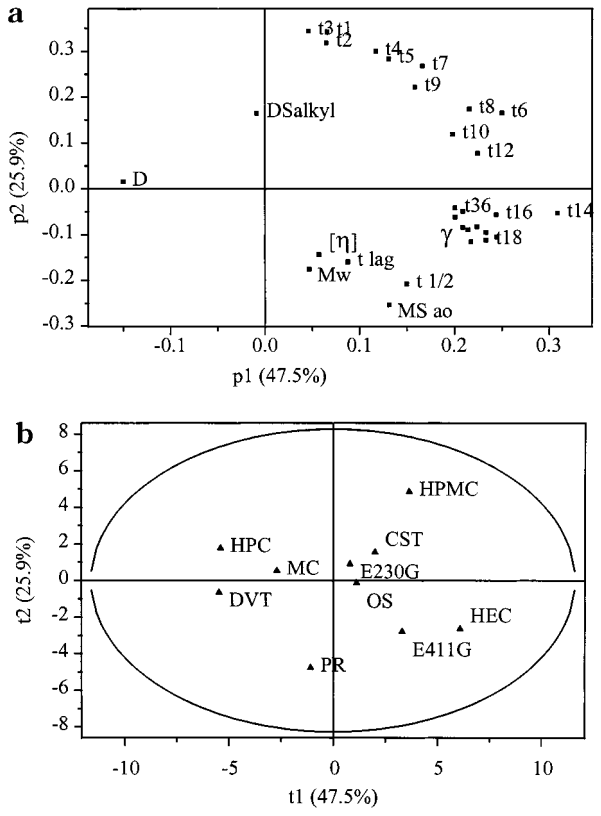

Figure 2—(a) Loading plot of all polymer fractions of the first dynamic model, showing the first (p1) and second (p2) PC. The polymer concentration in the surface tension measurements is 3 ppm. The cumulative R^2 and Q^2 are 0.733 and 0.325, respectively. (b) The corresponding score plot of all polymer fractions of the first dynamic model, showing the first (t1) and second (t2) PC.

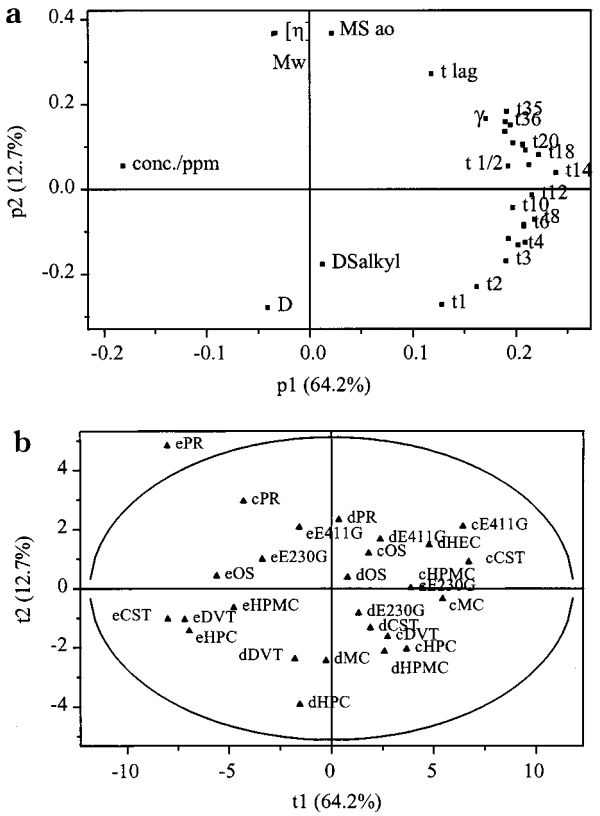

Figure 3—(a) Loading plot of all polymer fractions of the second dynamic model, showing the first (p1) and second (p2) PC. The polymer concentrations in the surface tension measurements are 2, 3, and 10 ppm. The cumulative R^2 and Q^2 are 0.769 and 0.648, respectively. (b) The corresponding score plot of all polymer fractions of the second dynamic model, showing the first (t1) and second (t2) PC. The prefix of each observation corresponds to the polymer concentrations of the surface tension measurements: c = 2 ppm, d = 3 ppm, e = 10 ppm.

at ascending times, meaning that a large diffusion coefficient gives a low surface tension after a certain time. A clear trend within the surface tension variables at ascending times is seen. The early times are located at the top of the plot and a movement downward of the second PC and to the right is seen as the time increases. At very early times the surface tension vectors are totally random due to randomness (a low signal-to-noise ratio) in the measurements, and as time evolves, the discrepancy between the scalars (numerical values) constituting the vectors becomes more stable as the surface tension is lowered by polymer adsorption, which tends to relocate the vectors in the hyper plane (the two-dimensional window provided by p1 and p2). The variable vectors t14 (after about 100 min) to γ (measured at 11.7 h) are located as one cluster indicating they are similar. At these longer times the surface tension has reached the lower plateau of the sigmoidal relationship between the surface tension and time[4] for most of the polymers, and the surface tension does not change very much with time in this time interval. The loading plot thus expresses an excellent overview of the irreversible surface tension build up process.

DS_{alkyl} and MS_{ao} span the second principal component p2 in this model as DS_{alkyl} is located in the upper and MS_{ao} in the lower half of the plot. MS_{ao} is still located quite close to the molecular weight and the intrinsic viscosity in accord with the equilibrium model. The molecular weight and the hydrodynamic volume (proportional to $[\eta]$) are also correlated to the lag time and to some extent to the time it takes to reach $(\gamma H_2O - \gamma)/2$, which seems logical; a long lag time should be coupled to a high molecular weight and to slow diffusion. These times also seem to be dependent on the amount of hydrophilic substitutents in accord with Figure 1a and the discussion above.

The corresponding score plot is given in Figure 2b. The more hydrophilic fractions PR, HEC, and E411 G are located far down in the plot, and the fast-diffusing substances DVT, HPC, and MC to the left, cf., the original data matrix in Appendix 1, and Table 1. The position of each observation in this score plot thus represents a fingerprint of the dynamic behavior of each polymer fraction, since all experimental variables are decomposed into these two principal components t1 and t2.

A conclusion from the dynamic model of Figures 2a and 2b is that the time dependence of the surface tension process is dependent on the molecular weight of the polymer samples to a large extent, which in turn is easily determined from the intrinsic viscosity.

The speed of the irreversible process of dynamic surface tension will, of course, also be dependent on the polymer concentration initially present in the bulk. To determine the effect of the polymer concentration, a second model containing the dynamic parameters is given in Figures 3a and 3b. This model is based on the same data set as above, with time dependent surface tension data at two additional polymer concentrations, 2, 3, and 10 ppm. Hence, the influence of polymer concentration on the irreversible time dependent surface tension process is presented here. In the loading plot of Figure 3a, the main variation in data along the first PC p1 is strongly governed by the polymer concentration. An increase in the polymer concentration results in a decrease in the surface tension after a certain time since the two quantities are negatively correlated. For example: for CST at t2 (100 s after the start of the experiment) the surface tension is 72.55 mN/m at an initial

polymer concentration of 2 ppm, 71.86 mN/m at 3 ppm, and 64.10 mN/m at 10 ppm.

The polymer concentration affects the dynamics to a much larger extent than what the diffusion coefficient does.[12,13] This is logical in the sense that the net mass transport increases to the surface with increasing polymer concentration, assuming a constant diffusion coefficient. According to Fick's first law of diffusion, the mass flux J of a substance per unit area and time is proportional to the diffusion coefficient and to the concentration gradient of the substance, $J = -D\partial c/\partial x$. This implies the amount of the concentration gradient to increase as the polymer concentration increases. It must be remembered though that the process of polymer adsorption to the water/air interface is more complex than free diffusion, involving different states of chemical potential of the polymer in solution compared to the same polymer at the surface, and a negative concentration gradient at longer times.[12,13] The effect however, is a faster lowering of the surface tension if the mass transport to the surface increases.

This second dynamic model of Figures 3a and 3b shows the same general trends concerning the position of the rest of the variable vectors as the dynamic model of Figures 2a and 2b presented above. The second PC p2 in Figure 3a is dominated by the hydrophobicity of the polymer. The apparent equilibrium surface tension γ is located in the upper half of the plot as is the degree of hydrophilic substitution MS_{ao}, in agreement with the discussion above. Furthermore, this model monitors a difference between t and t_{lag}. While the former is governed by the polymer concentration, the latter is more influenced by the hydrophobic balance of the polymer. In the ideal case this is supported by the experimental data, interpreted as follows: An increase in the polymer concentration lowers both the lag time and the time it takes to reach $(\gamma H_2O - \gamma)/2$, but t_{lag} is also in model 3 independently significantly affected by the amphiphilic character of the polymer, with higher lag times for more hydrophilic, slower diffusing polymer fractions. The lag time thus contains valuable structure-information which, in relation to $t_{1/2}$, helps to interpret the hydrodynamics and surface-related thermodynamics of the polymer. The time it takes to lower the surface tension to $t_{1/2}$, on the other hand, is strongly governed by the mass flux J. In conclusion, t_{lag} is more sensitive to the diffusion coefficient which in turn is decided by the hydrodynamic volume, while $t_{1/2}$—governed by the mass flux J—is more sensitive to the polymer concentration.

Turning next to the score plot in Figure 3b, this plot at first looks more "crowded" and complex to deduce. The main variation in data along the first PC t1 due to different polymer concentrations can be seen to be quite structured, however. The prefix of each observation vector corresponds to a certain polymer concentration; c = 2 ppm, d = 3 ppm, and e = 10 ppm. The observations at 10 ppm is located to the left of the figure in accord with the loading plot. CST spans the first PC more than any other polymer fraction, as eCST is located to the far left, and cCST to the far right of the plot. The dynamic surface tension process of CST is in other words more affected by an increase in the polymer concentration than any of the other polymer fractions, e.g., E411 G or DVT. This is most likely due to a more complex adsorption process and reorientation of CST at the surface, which might be attributed to the tendency for self-aggregation.[11] For most of the polymers, the observation with prefix d (= 3 ppm) is located both below the one with prefix c (= 2 ppm) and e (= 10 ppm). This "minimum" in the majority of the observations suggests 3 ppm to be an optimum concentration for the polymer-characterization using dynamic surface tension, since the correlation to the diffusion coefficient and the hydrophobic substitution reaches a maximum—that is, the influence of diffusion on the surface tension process is best described at 3 ppm.

Summary

In summary, the principal component analysis gives an excellent overview of the complex interaction pattern of nonionic cellulose ethers in aqueous solution and verifies the earlier stated qualitative relationships in a more quantitative manner. However, the good models are obtained from the extensive information and knowledge available on these polymer fractions, which enables choice of the appropriate variable settings. The polymer fractions analyzed constitute a heterogeneous group of substances with polydisperse molecular weights ranging from about one hundred thousand to over a million, large differences in the degree of substitution, and documented complex hydrodynamic behavior such as self-aggregation (CST-103[11]) and intermolecular aggregation—formation (E230 G[3]). Despite this and a few missing data, the models obtained have good predictive capacities and manifest the importance of accurate data handling for the characterization of pharmaceutically important polymer fractions. The influence of hydrophobic balance and molecular weight on the experimental variables is clearly illustrated, making the models useful for synthesis of desirable nonionic cellulose ether fractions. For example, the study displays some important differences between the influence of hydrophobic and hydrophilic substitution on the thermo- and hydrodynamics of the polymer samples.

Glossary

DS_{alkyl}	degree of hydrophobic substitution by alkyl groups (the mean number of alkyl groups per anhydroglucose unit of the polymer) as given by the producer. DSalkyl can be 3 at most, as there are three hydroxyl groups on each anhydroglucose unit of cellulose to etherificate
MS_{ao}	degree of hydrophilic substitution (molar substitution) by alkylene oxide groups (the mean number of alkylene oxide groups per anhydroglucose unit of the polymer) as given by the producer. MS_{ao} can theoretically be larger than 3 due to formation of oligo(alkylene oxide) substituents, but is practically only a small number
M_w	molecular weight as determined by size exclusion chromatography with LALLS/RI detection[3]
D	diffusion coefficient as determined from dynamic light scattering[3]
$[\eta]$	intrinsic viscosity as determined from capillary viscometry[3]
γ	apparent equilibrium surface tension as determined by the pendant drop method[4] measured after 11.7 h
surf. press.	the surface tension of water (γH_2O) minus γ
t1—t35	dynamic surface tension before equilibrium at ascending times. The real times in seconds are regained taking (index number × 5)[2], e.g., for t2: $(2 \times 5)2 = 100$ s
t_{lag}	lag time of surface tension, defined as the time it takes to visually detect a negative second derivative of γ

Appendix 1— The Original Data Matrix Used in the Analysis. The Abbreviations of the Experimental Variables and Observations Are Explained in the Experimental Section

$t_{1/2}$	the time it takes to reach ($\gamma H_2O - \gamma$)/2
concn/ppm	the polymer concentration in ppm. Because the low concentrations and measurements carried out at room temperature, 1 ppm = 1×10^{-4} (w/v)%
CP (°C)	the cloud point temperature[3]
C1 (mM)	the surfactant (SDS) concentration at onset of polymer−surfactant interaction[5]
$I_{M/IE-max}$	the maximum monitored value of the microviscosity of polymer−surfactant mixed micelles as monitored by the fluorescent probe P3P[5] in SDS/0.2% polymer/water solutions
$I_{M/IE20}$	an asymptotic value of $I_{M/IE}$ for 20 mM SDS/0.2% polymer/water solutions

Abstract □ Some physicochemical properties of *N*-acyloxyalkyl prodrugs of phenytoin were reported previously.[1,2] It was shown that despite their lower aqueous solubilities relative to phenytoin, these lower-melting prodrugs with apparently disrupted crystalline structures gave either comparable or enhanced in vitro solubility and dissolution rate in simulated intestinal media made up of bile salts and lecithin (SIBLM).[2] The current objective was to compare the in vivo behavior of two of these prodrugs to phenytoin in dogs and attempt to correlate the in vitro behavior to their in vivo behavior. The oral bioavailability of phenytoin after administration of phenytoin (**1**) and the selected prodrugs, 3-pentanoyloxymethyl 5,5-diphenylhydantoin (**2**) and 3-octanoyloxymethyl 5,5-diphenylhydantoin (**3**), in fed and fasted beagle dogs were compared to intravenously administered phenytoin. Phenytoin and its prodrugs showed improvement in fed-state phenytoin bioavailability relative to the fasted state indicating that food enhanced the delivery of phenytoin from phenytoin and its prodrugs. The increased bioavailability in the fed state may be due to stimulation of bile release by food and, for the prodrugs, possible catalysis of their dissolution by lipases.[3] In both, fasted and fed states, prodrugs **2** and **3** gave higher AUC values of phenytoin than the parent compound. The enhanced bioavailability of phenytoin after oral administration were more obvious in fed dogs. Although enhanced, AUC values of phenytoin from the prodrugs relative to phenytoin were not statistically different (at 95% confidence level) in fasted state, but were different in fed state. Although the aqueous solubilities and dissolution of both prodrugs were lower than phenytoin, dissolution of **2** and **3** was equivalent and greater, respectively, relative to phenytoin in SIBLM. As expected, the in vivo behavior correlated better with the in vitro SIBLM dissolution behavior. These results indicate that aqueous solubility per se does not adequately predict in vivo behavior.

Introduction

Phenytoin has a high melting point and poor aqueous and lipid solubility resulting in erratic and sometimes incomplete oral availability. The probable cause of this high melting point is strong intermolecular hydrogen bonding between the hydrogen atom on the N_3 of one molecule and a carbonyl oxygen of a neighboring molecule in the crystal packing.

N-Acyloxyalkyl prodrugs of phenytoin were synthesized to lower the melting point and alter the physicochemical properties.[1] Properties such as melting points, solubilities, dissolution rates, and partition coefficient were reported previously.[2] Of all the prodrugs studied, two prodrugs **2** and **3** (Figure 1) showed the most interesting physicochemical properties compared to phenytoin (**1**).[2] It was shown that the solubility and dissolution rate of the prodrugs in a simulated bile−lecithin mixture (SIBLM) was significantly enhanced relative to phenytoin even though their aqueous properties were significantly inferior to phenytoin (Table 1). These properties could not be correlated with the respective values in water, suggesting that water solubility could be a poor predictor of dissolution and bioavailability in vivo. It was therefore hypothesized that this increased solubility and dissolution rate in SIBLM should translate to a significant improvement in bioavailability of the prodrugs over the parent compound, phenytoin. Presented here are the results of an in vivo oral bioavailability study in dogs in both the fasted and fed state.

Experimental Section

Prodrugs **2** and **3** used in this study were prepared by procedures described earlier.[1] All other chemicals were of analytical grade.

Enzymatic Hydrolysis of Prodrugs—The conversion rates of the ester prodrugs to the parent compound, phenytoin, were studied in dog plasma. The plasma was obtained by centrifuging fresh whole blood from a male beagle dog. Sodium ethylenediamine tetraacetate (Na EDTA) was added as an anticoagulant. Centrifugation was carried out in a Dynec I centrifuge (Beckon and Dickinson) for 10 min at 2000 rpm. A stock solution of each prodrug having a concentration of ~2 mg/mL phenytoin equivalent was prepared in acetonitrile. The plasma was equilibrated in a water bath at 37 °C for at least 10 min before the addition of an aliquot of the stock solution. Twenty microliters aliquot of stock solution was added to 2 mL of plasma. All the kinetic studies were followed to completion by monitoring the appearance of phenytoin. At appropriate time intervals 100 μL samples were withdrawn and added to 250 μL of acetonitrile which was then vortexed for 10−15 s. The mixture was then centrifuged at 2000 rpm for 5−10 min, and the supernatant was collected and analyzed by HPLC. No attempt was made to correct for pH drift in plasma samples. Conversion studies of these prodrugs in other animal species and tissues were reported earlier.[1,3]

3	0.03	5.4	1800	0.04[c]	55.9	1379

[a] Data reproduced from previously reported work from our laboratory.[2] [b] All the dissolution rate experiments were conducted at a rotation speed of 200 rpm. [c] The dissolution rates were estimated using the Levich equation.

Intravenous Administration—Four adult male beagle dogs (11−12.8 kg) were used in an iv administration study. The dogs were fasted overnight prior to administration of the drug, but they were allowed water ad libitum during the study. Each dog received a 5.5 and 10 mg/kg phenytoin dose as sodium phenytoin (Dilantin, Parke-Davis), and a two-week washout period was allowed between doses. The drug was injected into the femoral vein over a period of 2−3 min. After dosing, serial venous blood samples of 1.5−2 mL were taken at appropriate time intervals from the alternate femoral vein. The blood samples were then placed into 2 mL Vacutiners (Becton-Dickinson, Ruthford, NJ) containing 3 mg of ethylenediaminetetraacetic acid as the anticoagulant. The samples were shaken and centrifuged for 5 min at 2000 rpm. Two hundred microliters of the separated plasma sample was added to 500 μL of acetonitrile and vortexed for 10−15 s and centrifuged at 2000 rpm for 5−10 min, and the supernatant was collected and analyzed by HPLC.

Oral Administration—A dog model was chosen to study the oral bioavailability of phenytoin, **2** and **3**. The same four adult male beagle dogs used for the iv study were used for a 4 × 6 random crossover study. A two-week washout period was allowed between dosing.

The dogs were fasted overnight prior to drug administration, but were allowed water ad libitum during the study. The prodrugs and phenytoin used in this study were administered without any excipients in hard gelatin capsules which were placed in the back of the mouth cavity. To help ensure particle size homogeneity, the compounds were passed through a 100-mesh sieve and collected on a 200-mesh sieve resulting in a particle size distribution range of 149 to 74 μm.

In the case of the dogs in the fed state, the capsules were given 30 min after feeding the dogs. The food used consisted of 250 g of dry dog food, 5 g of canned-dog food, and 12 mL of water. Once again, the dogs were allowed water ad libitum during the study. After dosing, the same procedures as described under the iv administration section were followed.

HPLC Analysis of Phenytoin—Reverse phase chromatography was used for the quantitative analysis of phenytoin and its prodrugs. A 15 cm long CPS hypersil column (i.d. 4.6 mm, particle size 5 μm) was used. The mobile phase consisted of acetonitrile: phosphate buffer (0.025 M, pH 6.0)/(25:75 v/v), and the samples were detected at 214 nm by Spectroflow 757, Kratos Analytical. The standard reference curve was obtained by spiking blank plasma with phenytoin and then treating the samples as for the plasma samples. Phenytoin concentration in plasma samples obtained from the bioavailability studies were calculated from the peak area by reference to the standard curve.

Statistical Analysis—Statistical comparison of AUC values obtained after oral administration of phenytoin and its prodrugs in both fed and fasted states was performed by analysis of variance method. A posthoc Bonferroni/Dunn test was conducted using STATVIEW 2.0 (Abacus Concepts, Inc., CA) to determine which of the AUC values were significantly different from each other ($p < 0.0033$).

Results and Discussion

Enzymatic Hydrolysis of 2 and 3 to Phenytoin—The enzymatic hydrolysis of the phenytoin prodrugs (**2** and **3**) to phenytoin in dog plasma exhibited pseudo-first-order kinetics. Both the prodrugs completely hydrolyzed to phenytoin presumably by the action of plasma esterases. The hydrolysis of the prodrugs to the parent compound is a two-step reaction. The first step, which is rate-limiting, involves the cleavage of the ester group resulting in the formation of an *N*-hydroxymethyl phenytoin. The second step involving the dehydroxymethylation of *N*-hydroxymethyl phenytoin to phenytoin has been shown to be rapid (half-life < 2 s)[4] at pH 7.4 and 37 °C. The apparent first-order rate constants for compounds **2** and **3** were found to be 7.5×10^{-2} min^{-1} ($t_{1/2}$ = 9.2 min) and 0.9×10^{-2} min^{-1} ($t_{1/2}$ = 74.4 min), respectively. The half-lives of these prodrugs were adequate to ensure that phenytoin would be quantitatively produced from these prodrugs in vivo, and that the enzymatic conversion was probably not a limiting factor.

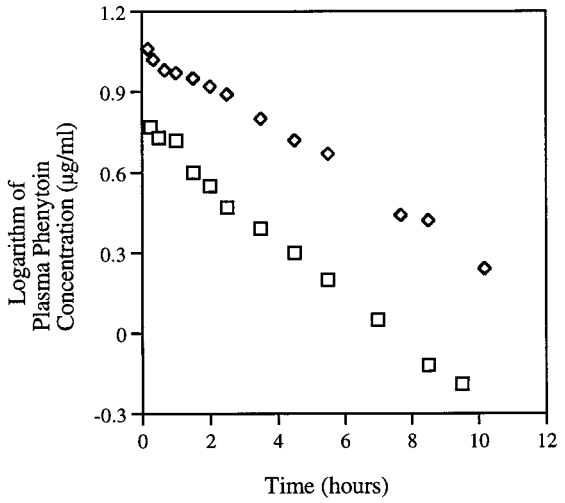

Figure 2—Plots of logarithm of plasma phenytoin concentrations versus time obtained after intravenous administration of 5 mg/kg (□) and 10 mg/kg (◇) of sodium phenytoin to dog no. 4.

Following oral administration, the conversion of the prodrugs to phenytoin could occur in presystemic tissues such as the intestinal lumen, the brush border, the enterocytes, blood, liver, etc.[5] It has also been shown that prodrugs **2** and **3** undergo lipolytic cleavage by pancreatic lipases.[3] Moreover, intact prodrugs were not detected following oral administration of the prodrugs, indicating that the enzymatic conversion is not a limiting factor in the absorption process after oral administration of these prodrugs.

Intravenous Administration of Sodium Phenytoin—Figure 2 is a representative plot of plasma phenytoin concentration versus time curve obtained after intravenous administration of sodium phenytoin (doses 5.5 and 10 mg/kg) to a dog. Phenytoin followed an apparent two-compartment model with a rapid but short distribution phase allowing the overall kinetics to be effectively modeled as a one-compartment model with saturable metabolism since the clearance and the elimination is dose-dependent.[6−8] These findings were in agreement with previously reported studies showing that phenytoin exhibited dose-dependent kinetics in dogs.[6,9] The possible cause for the dose-dependency may be due to the capacity-limited, saturable enzymatic conversion of phenytoin to aromatic hydroxylated metabolites.[10] Such a capacity-limited elimination

process can be described by the Michaelis Menten equation.

$$\frac{dC}{dt} = -\frac{V_m C}{K_m + C} \quad (1)$$

V_m, theoretical maximum velocity of the capacity-limited process and K_m, Michaelis−Menten constant were calculated using a nonlinear, least-squares iteration of eq 1 as reported previously by Varia et al.[11] The apparent volume of distribution (V_d) was determined as the ratio of dose administered and C_0, obtained by extrapolating the elimination phase of the plot of the logarithm of plasma concentration versus time neglecting the short distribution phase (see Figure 2). The area under the plasma concentration versus time curves $[AUC]^{0\rightarrow\infty}$ were calculated using the trapezoidal rule and the apparent half-lives obtained from the linear, terminal slopes and are given in Table 2 along with apparent K_m and V_m values for each dog. The values obtained for both K_m and V_m were comparable to that obtained by Varia et al.[11]

Oral Administration of Phenytoin—The oral administration of **1**−**3** to the dogs in fasted and fed states was carried out in a 4 × 6 crossover study design. Figures 3 and 4 show plots of the mean plasma concentration versus time following the oral administration of 10 mg/kg phenytoin equivalent dose of **1**−**3** to the four dogs in both the fasted and the fed states, respectively. The AUCs were calculated using the trapezoidal rule. The apparent elimination half-lives of phenytoin and phenytoin from its prodrugs after oral administration were calculated using the linear, terminal slopes of the logarithm of plasma

phenytoin concentration versus time assuming a simple first-order elimination model. These pharmacokinetic parameters are summarized in Table 3. The in vivo regeneration of phenytoin from its prodrugs appeared to be rapid as intact prodrugs were not detected in the plasma. On the basis of the in vitro half-life of **3** in dog plasma (74 min), one would expect to observe this prodrug with phenytoin in plasma samples. The absence of prodrug in the plasma samples perhaps suggested that the regeneration of phenytoin from **3** was also occurring by the lipase-catalyzed hydrolysis in the lumen or conversion in the brush border, enterocyctes, or liver.[1,3] For example, the half-life for the conversion of **2** and **3** to **1** in rat intestine homogenates was been reported to be less than 2 min.[1]

A two-way ANOVA indicated that both the prodrugs and food had an overall significant effect on phenytoin AUC values. To determine which of the treatments significantly differed from each other, a posthoc Bonferroni/Dunn test was conducted (95% confidence interval, number of comparisons =15, $p < 0.0033$). A portion of the results which are useful for this discussion are presented in the Table 4. In the fasted state, the phenytoin AUC values for phenytoin and its prodrugs were not statistically significant from each other at the 95% confidence level. Qualitative differences were seen, however. The phenyotin AUC values for the dogs in the fed state were significantly different with **2** and **3**, providing higher levels compared to phenytoin per se.

The ratio of $[AUC]^{0\rightarrow\infty}$ after oral dosing to $[AUC]^{0\rightarrow\infty}$ after iv dosing gives an "apparent" absolute bioavailability because the absorption rate and subsequent plasma levels of phenytoin due to the nonlinearities in phenytoin clearance. This can affect bioavailability estimates.[11] Therefore, a correction to the "apparent" absolute bioavailability was

Table 4—Multiple Comparison of AUCs after Oral Administration of Phenytoin (1) and Its Prodrugs 2 and 3 to Fasted and Fed Dogs[a] Using Posthoc Bonferroni/Dunn Test

comparison between treatments	significance[b] (95% confidence, $p < 0.0033$)[c]

2 (fasted), **2** (fed)	S
3 (fasted), **3** (fed)	S
1 (fasted), **2** (fasted)	NS
1 (fasted), **3** (fasted)	NS
1 (fed), **2** (fed)	S
1 (fed), **3** (fed)	S

[a] The values shown are the mean values with their standard deviations in parentheses ($n = 4$). [b] S means significantly different and NS means significantly different. [c] A total of 15 comparisons were conducted at a 95% confidence level making. $p < 0.05/15 = 0.0033$.

needed to obtain a more accurate estimate of the absolute bioavailability. One method of calculating bioavailabilities of drugs possessing dose-dependent elimination due to enzyme saturation was to assume a one-compartment model with a constant (dose-independent) volume of distribution and a capacity-limited pathway of elimination.[11–13] Assuming a rapid conversion of prodrugs to phenytoin, the rate of change of phenytoin concentration in the body after administration of phenytoin or its prodrugs may be written as

$$\frac{dC}{dt} = \frac{k_a F D_{iv} \exp(-k_a t)}{V_d} - \frac{V_m C}{(K_m + C)} \qquad (2)$$

where k_a is the apparent first-order absorption constant, F is the fraction of the total administered dose that is absorbed, D_{iv} is the equivalent iv dose. The true or corrected absolute bioavailability is given as

$$F = \frac{\left(\int_0^\infty \frac{V_m C}{K_m + C}\, dt\right)}{\left(\frac{D_{iv}}{V_d}\right)} \qquad (3)$$

The specific V_m and K_m values for each dog were obtained from the iv data.

The numerator of the above equation was evaluated by applying the trapezoidal rule on $V_m C/(K_m + C)$ versus time curve between time limits $t = 0$ to $t =$ last time point. The contribution of the integral from the last time point to infinity is assumed to be negligible as the concentration at the last time point is small.

Apparent relative bioavailabilities of phenytoin after oral administration of **2** and **3** were calculated as

$$F_{app,rel} = \frac{[AUC]_{prodrug}^{0\to\infty}}{[AUC]_{phenytoin}^{0\to\infty}} \qquad (4)$$

where the AUC are the mean values.

Phenytoin apparent absolute bioavailability, corrected absolute bioavailability and apparent relative bioavailability after oral administration of phenytoin and **2** and **3** are given in Table 5. In the fasted state, the apparent relative bioavailability of prodrugs **2** and **3** was 2.3 and 2 times, respectively, compared to phenytoin. In the fed state, the apparent relative bioavailability of prodrugs **2** and **3** compared to phenytoin were 2.6 and 2.4. The corrected absolute bioavailabilities in the fed state were found to be 84.2 (±16.5)% and 77.5 (± 22.1)%, respectively. These values appear to be close to quantitative suggesting that

Table 5—Calculated Percent Bioavailabilities of Phenytoin after Oral Administration of Phenytoin (1) and Its Prodrugs 2 and 3 to Beagle Dogs[a] ($n = 4$)

state	compd	apparent absolute % bioavailability[b]	apparent relative % bioavailability[c]	corrected absolute % bioavailability[d]
fasted	**1**	15.5 (3.3)	100	21.0 (6.9)
	2	36.5 (11.9)	232	44.2 (16.2)
	3	30.7 (13.5)	197	40.7 (19.8)
fed	**1**	30.4 (4.2)	100	37.8 (9.3)
	2	79.0 (11.4)	262	84.2 (16.5)
	3	73.0 (22.4)	239	77.5 (22.1)

when administered in the fed state, **2** and **3** perhaps overcome the dissolution limitations observed with phenytoin.

The accuracy of F depends on the accuracy of the estimates of K_m and V_m. In this study the K_m and V_m values were determined by nonlinear curve fitting of limited iv data (only two doses). A wider range of drug dosage would enable one to determine the Michaelis–Menten constants with more accuracy. The purpose for presenting these "corrected" values was simply to point out that the apparent absolute bioavailabilties based on AUC comparisons alone can lead to undersestimates of the true bioavailability values due to the nonlinear elimination behavior of phenytoin. Note, as pointed earlier, the V_m, K_m, and V_d values obtained here are within the range of values reported for phenytoin in dogs in an earlier study.[11]

Correlation between in Vitro Dissolution Studies and in Vivo Bioavailability—The larger AUC values in the fed state were found to be significantly different from those in fasted state from **2** and **3**. In the fasted state, the AUC values for phenytoin and its prodrugs were not statistically significant from each other at the 95% confidence level. However, the AUC values in the fed state were significantly different.

On the basis of solubility and dissolution characteristics in water alone, **2** and especially **3** were expected to give a lower bioavailability relative to the parent compound.[2] A portion of the results published previously are reproduced in Table 1 for the present discussion. It was obvious from the bioavailability studies that the in vitro dissolution studies in water do not predict the in vivo results. If the dissolution and solubility characteristics in SIBLM were considered, the prodrugs were expected to give higher or equivalent bioavailabilities with respect to the parent compound, phenytoin. In the fed state, the contents of gastrointestinal tract (GIT) will be influenced by the byproducts of food digestion as well as an increased level of bile acids, lecithin, and the lipase/colipase complex. The ratio of dissolution rate of all the compounds in SIBLM to that in water indicates the probable sensitivity of these compounds to changes in the GIT contents. On the basis of the ratio of the dissolution rates in SIBLM to those in water, the bioavailability of phenytoin from **2** and **3** were expected to be much more sensitive to changes in the GIT content than phenytoin itself. This was consistent with the in vivo observation that the bioavailabilities of phenytoin from **2** and **3** were qualitatively superior to phenytoin in the fasted state, and that the differences were quantitatively superior in the fed state animals. When administered in fed state, the prodrugs appeared to have overcome dissolution rate limitations as the corrected absolute bioavailabilities were close to 100%.

The reasons for the altered bioavailability of orally administered drugs in the fed state have been described earlier.[14,15] The most plausible explanation for the effect of food on the bioavailability of phenytoin from phenytoin and phenytoin from its two prodrugs was that the dissolution rates of the drugs may be increased due to the food-induced stimulation of bile flow.[14,16]

This enhanced dissolution rate in the presence of food may be the reason for the improved bioavailability observed after oral administration of several lipophilic drugs such as danazol,[17] itracanazole,[18] phytonadione,[19] 5-methoxypsoralen.[20] The importance of physiologically relevant dissolution media in predicting the effect of food on the oral bioavailability of poorly soluble drugs has been emphasized in a recent review.[21] From the present study, it was clear that the inferior aqueous solubilities of **2** and **3** do not have as great an influence on their in vivo behavior, while their relative behavior in the presence of SIBLM reasonably predicted their in vivo behavior.

Conclusions

Despite possessing poor aqueous solubilities, prodrugs **2** and **3** showed superior qualitative bioavailability of phenytoin relative to phenytoin in the fasted state and a significant enhancement in the fed state. Physicochemical properties such as aqueous dissolution rate or aqueous solubility did not correlate with the in vivo performance in this homologous prodrug series. The in vitro dissolution rates correlated better with the in vivo results when SIBLM was used as the dissolution medium.

Abstract □ Three different powder preparations of the drug disodium 9-ethyl-4,6-dioxo-10-propyl-4*H*,6*H* pyrano[3,2-*g*]quinoline-2,8-dicarboxylic trihydrate, Nedocromil sodium (trade name Tilade), have been fully dehydrated in a vacuum and their water vapor adsorption characteristics quantitatively assessed at different water vapor pressures over a temperature range 20 to 40 °C. At saturated vapor pressures, 100% RH, rates of adsorption are around 0.1 $s^{-1/2}$. Graphs of square root of time against reduced mass during uptake of water vapor at vapor pressures in the range 20 to 47 mm of Hg, all equivalent to 100% RH, indicate control by a diffusion mechanism with activation energies in the range 8 to 24 kJ mol^{-1}, dependent on the powder preparation method. In two of the powders nonlinear Arrhenius-type plots are interpreted as showing that control of the process is dependent on the surface's ability to hold water molecules at the experimental temperature. The variation in activation energies and the calculated values for diffusivities, around 1×10^{-13} m^2 s^{-1}, are used to explore structural involvement in the overall water adsorption process. The measured values of water vapor diffusivity into the structure have been used to predict the water solubility of nedocromil sodium trihydrate, and the results show good agreement to reported solubilities. This approach to solubility prediction is an alternative to the Noyes and Whitney method where ions leaving the surface are monitored.

Introduction

Some 15 years ago a drug, $C_{19}H_{15}NO_7 \cdot 2Na \cdot 3H_2O$, disodium 9-ethyl-4,6-dioxo-10-propyl-4*H*,6*H* pyrano[3,2-*g*]quinoline-2,8-dicarboxylic trihydrate, was found to have potential for the treatment of asthma.[1] This proved to be the most promising member of a series of salts of nedocromil acid and was simply named as nedocromil sodium (NS), now marketed as Tilade, a registered trade name. NS has been extensively characterized by chemical means[2]. Its behavior has been compared to its acid form[3] and several hydrate forms containing divalent cations.[4] A focus of the investigations has been the relationship between water adsorption and relative humidity of finely powdered crystalline forms of the compounds together with characterization of hydrates using physical techniques. In the case of NS trihydrate a full crystallographic analysis has been achieved[5] which shows the position of water molecules in the trihydrate form. This has led to the description of loosely bound and strongly bound water in the salt.[5] Surprisingly, only limited information exists on rates of water uptake.[4] Most of the experiments involved hydrates and not the anhydrous form. Reaction kinetics, from which activation energies and diffusivites can be found, do not appear to have been studied. This paper reports practical work on the uptake of water vapor by anhydrous NS using thermogravimetric analysis techniques. Restrictions imposed by the fixed water vapor pressure meant that work was done at various relative humidities (RH) in a conventional Cahn balance system. This subsequently led to the development of a sensitive thermobalance housed in a controlled temperature chamber with computer-aided measuring techniques. All work with this system is done at 100% RH from which diffusivities of water in the crystal of anhydrous NS and activation energies of the controlling mechanism have been established.

Table 1—Forms of the Nedocromil Sodium Trihydrate Used in This Work[a]

sample code	form	supplier's code no.[b]	preparation note
A	amorphous A	Bx1909R	atm at 100% RH
B	amorphous B	B-93%RH	atm at 93% RH
C	crystalline	ZBB3W	atm at 100% RH

[a] All samples were of particle size 2.5 ± 0.5 μm except sample C which had a wider spread of ±0.8 μm. [b] The supplier's code number indicates the manufacturer's batch number.

Experimental Procedures

NS was supplied in various forms by Fisons Pharmaceuticals plc., Loughborough, U.K. (prior to various amalgamations), details of which and specimen codes are given in Table 1. The water was double-distilled in glass apparatus in house.

Before the experiments, each sample was dried using a standard procedure: The powders were totally dehydrated by heating to 200 °C in a vacuum to remove both the loosely and tightly bound water in the crystal structure. All samples were cooled in a vacuum of approximately 10^{-4} mm of Hg to room temperature before experiments were performed. The above process was carried out in situ on the balance so that samples were not exposed to air after drying.

Some samples were recycled through several dehydration−hydration−dehydration sequences in order to limit variability from physical features, such as particle size and surface area, and so produce more consistent comparative data. Constant mass changes were a control mechanism to show that the sample was cycling between anhydrous and trihydrate forms. Any variation in this pattern caused the sample to be rejected. As a further control, experiments were performed on repeat samples from the same batch. No differences could be detected in the results whether the NS was recycled several times or fresh samples were used for each temperature point.

Exploratory work was performed using an all-glass system connected to a Cahn microbalance[6,7] with water vapor being delivered via a liquid water reservoir kept at 21 °C, i.e., a water vapor pressure of 18.65 mm of Hg. This constraint meant that RH's were in the range 100 to 39.6% RH. Experiments were timed from opening the water reservoir tap and lasted approximately 4 h. This experimental arrangement produced a fixed water vapor pressure within the system. The sample was heated by a resistance element around the sample holder capable of controlling the temperature to ±1 °C. Results were of limited value due to the range of RH. This led to the development of a new system based on a modified Cahn balance manufactured by Combustion Instrument (CI) which allowed the water reservoir to be thermostatically

controlled along with all itinerant connections. Control of the sample temperature was improved to ±0.1 °C from just above room temperature up to 50 °C. A block diagram is shown in Figure 1. The mass and temperature of the specimens were measured and recorded every 5 s and could be reproduced graphically or the data processed numerically as required.[8] Both balances are sensitive to changes in mass of 1 μg.

Powder X-ray diffraction films were taken from the powders as supplied which confirmed differences in the degree of crystallinity. A sensitive focusing Hägg–Guinier camera was used, capable of high resolution; this showed that samples classed as amorphous were not totally amorphous because some broad, very weak Bragg lines were present.

Results

(a) Reaction at Fixed Water Vapor Pressure, Cahn Balance—The first trial experiments were conducted at a constant water vapor pressure of 18.65 mm of Hg, corresponding to a temperature of 21 °C, on the crystalline sample C, over the temperature range 22 to 40 °C. The crystallinity was qualitatively confirmed by the sharp appearance of the X-ray diffraction lines. The results were obtained graphically as time in minutes against changes in mass in micrograms. The data were represented as square root of time, t, in minutes, against $\Delta W/W_\infty$, the increase in mass at time t divided by the total mass gain. The decision to use the square root function came from the view that the rate most likely would be determined by a diffusion process. Several possible control mechanisms are described and investigated in a theoretical paper in preparation.[9] Changing control processes are indicated as the graphs change from a sigmoidal curve, to linear, to two linear parts and back to sigmoidal curves as the sample temperature was increased. None of the graphs are included because a clearer view of changing control mechanisms is given in Figure 2, where the sample temperature is plotted against total mass gained after 4 h exposed to the constant water vapor pressure. These results are for

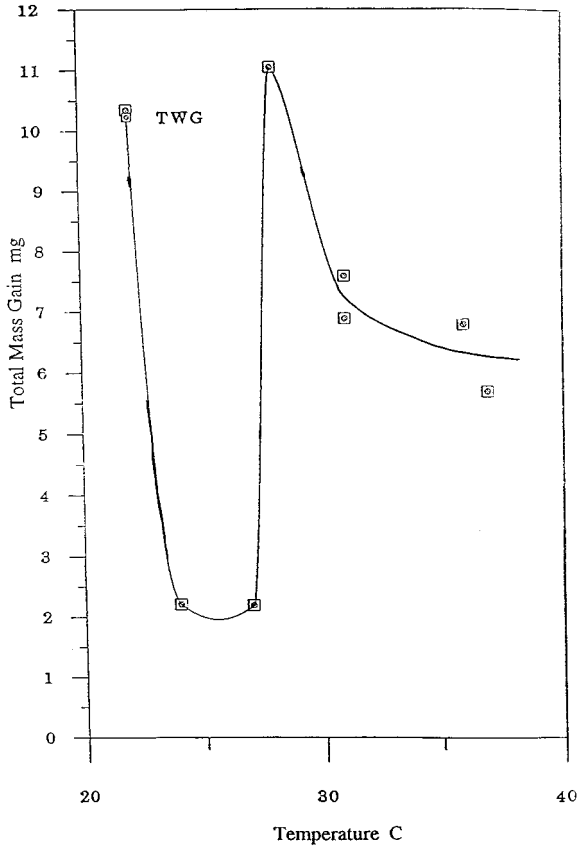

Figure 2—Plot of temperature against total mass gained after 4 h for sample C on the Cahn balance.

the same sample dehydrated by heating to 200 °C under vacuum between each water adsorption experiment. Experiments of this type are useful in delineating temperature intervals where different physicochemical processes

are important and hence where more detailed experiments can be made. It is particularly useful when combined with a theoretical analysis of a model system. More detailed investigations were made at 100% RH for each temperature on the system with improved control and sensitivity.

(b) Experiments at Controlled Water Vapor Pressures, Isothermal Environment—The three samples of NS, A, B, and C, were used in the new thermogravimetric apparatus. Some of the adsorption curves are shown in Figures 3–5, which are plots of square root of time against normalized mass. All the plots are sigmoidal to a greater or lesser degree, and to proceed the rate was determined as the slope of the best fit to a straight line which fitted the experimental points between 0.2 and 0.8 normalized mass. It can be seen that considerable similarities exist between the various forms of the drug. Table 2 contains data for sample C using both balance techniques from which some points can be drawn:

(i) When 100% RH is maintained as the sample temperature is increased (CI system), the time to achieve 60% of the total adsorption decreases with increasing temperature, i.e., the reaction rate increases with temperature throughout the temperature interval studied. These results allow activation energies to be determined.

(ii) When the water vapor was allowed to enter the sample chamber, the balance underwent a brief settling period. Following this period, in the CI system, the square root time function then produced linear adsorption curves up to at least 80% of the total adsorbed mass for all temperatures studied. This supports the view that a diffusion mechanism controls the process in these conditions. The results from the Cahn balance produce a variety of different shaped water uptake curves for a square root time function with only an intermediate temperature range being linear.

(iii) The CI balance results show that when the water vapor pressure was at saturation value the reaction rates were from 4 to 16 times faster than the Cahn balance results obtained with the restricted water vapor pressure. This was true for all the temperatures studied.

Repeat experiments involving all three forms of the drug produced similar curves to those for sample C. Forms A and B showed decreasing rates with increasing temperature over a small range, 26–31 °C. For all the results a reaction rate constant was calculated from the slope of the linear part of the square root time versus the normalized mass plots. This produced much data concerning reaction rate at specific temperatures. A plot of the reciprocal of the absolute temperature against the natural logarithm of the rates was made to extract activation energies. Figures 6–8 are examples of these plots and strongly suggest that even at 100% RH there is a temperature at which a controlling mechanism change occurs for samples A and B. The error bars shown on data points were calculated from the square root time, reduced mass curves by the binomial error expansion technique. Even with the wide uncertainty this produces, it can be seen that two lines

must be drawn through the Arrhenius data, in the cases of samples A and B, while form C gives an almost normal Arrhenius plot throughout the temperature range. This seems to imply a feature of the reaction which involves the physical form of the sample.

From Figure 8, an Arrhenius plot for the crystalline sample C, the line XY corresponds to an activation energy of 8.2 kJ mol^{-1}. The two samples, A and B, show increased activation energies from lines XY in Figures 6 and 7, of 23.6 and 18.7 kJ mol^{-1}, up to temperatures of 26 and 31 °C, respectively. After these temperatures, a negative activation energy is indicated by the lines YZ in Figures 6 and 7. Hence, an interesting feature of the results is the way the form of the drug appears to influence both the activation energy and the temperature at which there is an apparent negative activation energy, see Table 3.

Discussion

The data reported here are supported by earlier indications in the literature as to the rates of water vapor uptake of the anhydrous acid form of nedocromil.[3] Our results for NS show that a second or more elapses before any adsorption is recorded on a sensitive system, and then adsorption rates are modest, around 0.1 $s^{-1/2}$. The literature shows that nedocromil magnesium hydrates also do not appear to absorb water rapidly because Zhu et al.[4] noted that several months in environments saturated with water vapor are needed to increase the crystal water content of the salt to saturation values. In both the acid and magnesium forms of nedocromil, dissolution of the solid into liquid water was reported as a slow process, and this was rationalized using forms of the Noyes–Whitney equation[10] of dissolution kinetics.

Khankari et al.[2] have reported gravimetric experiments performed on anhydrous NS in different relative humidities. The importance of the RH parameter was demonstrated but no indication of the actual time taken to adsorb water at critical relative humidities was given; hence, no conclusions about rates of adsorption can be made from that work.

Why and where the critical temperature for reaction rate changes at 100% RH, seen in this research, occurs need

more detailed investigation using a wider range of techniques. This question is presently being probed using desorption studies from fully hydrated samples as a means to a better understanding of the mechanisms of hydration.

When the humidity is controlled so that vapor phase diffusion is not rate-limiting, diffusion of water in the solid can be the controlling feature, and the mostly linear graphs of square root time against normalized mass suggest that this situation applies here. The rate constants derived from the linear slopes for experiments done at 100% RH allow activation energies to be obtained. The values found here for activation energies, for the adsorption process when availability of water molecules is not limiting, show that the lowest energy barrier is associated with the crystalline form of NS, see Table 3. The answer to questions regarding the activation energy changes might at first seem to be associated with total surface area i.e., the amorphous forms of the drug having a greater surface area, and surface energy and so having the potential to hold more water on the surface. Clearly this is less important than crystal perfection because the crystalline samples have the lowest activation energy values. The Arrehnius-type plots that can be made for the effect temperature has on the absorption rate, Figures 6 and 7, reveal, from the negative activation

energy line, YZ, that two processes at least are involved in water uptake.

The physical form of the salt, whether crystalline or less-so, does affect the activation energy of the hydration process; when well-formed crystals are used, a smaller barrier to the process is encountered, compared to the poorly crystalline or amorphous forms. This suggests that the surface area is of less importance than some other feature in the mechanism, and if diffusion of water molecules into the solid is indeed dominant in controlling the rate of hydration, then the role of the crystal structure must be considered. Freer et al.[9] have published the results of a single-crystal analysis of NS trihydrate, from which, in the structure features of sodium zeolites, can be seen in that sodium ions are accommodated within tunnels formed by cage like molecules. Diffusion as an activated process in such a structure is approached through a logarithmic analysis of the data.[11,12] Given several assumptions, quoted in the references, a standard analysis leads to eq 1:

$$\frac{\Delta W}{W_\infty} = \frac{6(Dt)^{1/2}}{\pi r_c} \tag{1}$$

where D is the intracrystal diffusivity, r_c is the mean particle radius, assuming spherical particles and t is the elapsed time. Equation 1 predicts an essentially linear plot for square root time against $\Delta W/W_\infty$, and since most of the data presented here is linear between 20% and 80% reaction, the importance of diffusion is confirmed. Further analysis gives:

$$D = \frac{(\pi r_c \text{slope})^2}{36} \tag{2}$$

where the slope is that from the linear part of the $t^{1/2}$ against $\Delta W/W_\infty$ graphs and r_c is the average particle radius, taken here to be 2.5 μm, as supplied by the manufacturers.

From eq 2, diffusivities at a range of temperature can be found from all the original experimental results, such as those shown in Figures 3−5. These data are given in Table 4 and show values at the lower end of the range reported for such systems as hydrocarbons diffusing into zeolites,[12] where values range between 10^{-8} to 10^{-13} $m^2 s^{-1}$. This is evidence for a structurally related feature to be critically involved in the water absorption mechanism.

Data from Table 2 in Zhu et al.'s [4] paper on dissolution of nedocromil magnesium enables us to compare both sets of experimental results in the following way:

An equation derived from the Noyes and Whitney's equation[10] of dissolution from a solid surface into a liquid, is given as:

$$J = \frac{k'DS}{h} \tag{3}$$

where J is the intrinsic dissolution rate, S is the solubility, D is the diffusivity into the solution, and h is the diffusion layer thickness.

Using the data for the nedocromil magnesium heptahydrate solubility[4] and the diffusivity values for water vapor into NS crystals found in this work, k' has a value of 20. It is a constant with no units and the value 20 comes from using SI units. Then using this value for k' and a diffusion layer thickness of 1×10^{-6} m, with diffusivity data from Table 4 in this paper, we are able to predict a solubility for nedocromil magnesium decahydrate of 9.6 mol m^{-3}. This compares to 9.77×10^{-3} mol L^{-1}, that is 9.77 mol m^{-3}, measured by Zhu et al.,[4] which is in very close agreement and gives some confidence for the low values for diffusivity we have measured in the NS structure. Furthermore, for dissolution of the solid, it points to a situation where diffusion of water molecules into the crystal structure is as important as the Noyes and Whitney's approach involving diffusion of ions and molecules off the solid surface into the solution. This suggestion is given more credence by using the k' value, already quoted above, with the diffusivity coefficient for 22 °C in Table 4 and applying them to eq 3, using $J = 0.0074$ mol s^{-1}/m^{-2}, derived from data in Khankari et al., to predict the solubility of NS. A value of 3.7×10^3 mol m^{-3} is obtained. This value is in the same order of magnitude as that found experimentally by Khankari et al.; as 1.3×10^3 mol m^{-3}. Furthermore, this model predicts an increased solubility for the anhydrous form of the drug, compared to the hydrates, because diffusivity into the crystal decreases as the degree of hydration increases. This is the order of solubility shown in Khankari et al.'s paper.

Resolution of Ephedrine in Supercritical CO_2: A Novel Technique for the Separation of Chiral Drugs

A. KORDIKOWSKI,*,† P. YORK,†,‡ AND D. LATHAM§

Contribution from *Drug Delivery Group, School of Pharmacy, University of Bradford, Bradford, West Yorkshire, BD7 1DP, UK, Bradford Particle Design, 49 Listerhills Science Park, Campus Road, Bradford, West Yorkshire, BD7 1HR, and Medicines Research Centre, Glaxo Wellcome R&D, Gunnels Wood Road, Stevenage, Hertfordshire, SG1 2NY, UK.*

Received November 30, 1998. Accepted for publication May 11, 1999.

Abstract □ Racemic ephedrine has been resolved by diastereomeric salt formation with mandelic acid using supercritical CO_2 as precipitating agent. Crystallizations were performed using the Solution Enhanced Dispersion by Supercritical Fluids (SEDS) technique. Temperature was varied between 35 and 75 °C, and pressures ranged from 100 to 350 bar. Resolution, determined by chiral capillary electrophoresis, is described as a function of temperature and density of the supercritical fluid. A comparison of SEDS-produced material with a conventional resolution method shows that SEDS-crystallized material exhibits identical properties to conventionally crystallized material.

Introduction

Pharmacologically active substances containing chiral centers can exist as pairs of enantiomers, which exhibit the same physical properties but show a different molecular conformation. Since, in general, only one of the enantiomers is biologically active or possesses pharmacological relevance,[1−3] the resolution of enantiomers is of great importance for the pharmaceutical industry.[4−6] Pure enantiomers can be obtained either from chiral starting materials or by asymmetric synthesis.[7] While chiral natural products always exhibit very high enantiomeric purity, only a few natural products show a desired pharmacological activity. By contrast, synthetic drugs are often produced as racemates. It is therefore necessary to have a simple but powerful technique to resolve racemates.

Racemates have been resolved by a variety of methods. If the racemate exists as racemic conglomerate, it will resolve spontaneously when crystallized.[8] In 1850, Pasteur discovered the resolution of sodium ammonium tartrate[9] and was able to separate the enantiomers by sorting them under a microscope. Another method of resolving conglomerates is by seeding a supersaturated solution with crystals of one enantiomer.[10] Additional methods for the resolution of racemates have involved either crystallization by entrainment,[11] or optically active solvents.[12] A detailed description of resolution techniques in terms of thermodynamics is given by Jacques et al.[13]

If the compound of interest is either a carboxylic acid or an organic base, resolution can be achieved by diastereomeric salt formation.[13−16] In many cases a racemate of a chiral carboxylic acid has been resolved using a naturally occurring chiral amine.[17] However, resolution is usually not complete after a single crystallization, and the partially resolved material has to be recrystallized. A classical example is the resolution of racemic ephedrine with (*R*)-mandelic acid, a procedure reported almost 70 years ago.[18] The authors separated diastereomeric (*R*)-mandelates by crystallization from ethanol, but the initial crop had to be recrystallized several times to achieve a pure product.

Conventional crystallization from organic solvents can often lead to solvent inclusion in the crystal. However, it is known that organic substrates crystallized from supercritical CO_2 produce crystals with solvent levels below 25 ppm.[19] Additionally, supercritical CO_2 has been used to produce a variety of materials of defined crystal size.[20,21] Supercritical CO_2 might therefore provide an alternative method for the resolution of racemates. This possibility was briefly investigated by Fogassy et al.,[22] who precipitated diastereomeric mixtures of several similar chiral carboxylic acids onto glass beads and extracted them with supercritical CO_2. Although partial resolution was achieved and both enantiomers were recovered, the degree of resolution was poor. Although resolution was explained in terms of acid−base molecular recognition, no attempt was made to exploit the benefits of the supercritical phase.

We present a simple and reliable method to resolve racemic ephedrine with (*R*)-mandelic acid by crystallization from supercritical CO_2. We show that a high degree of resolution can be achieved within a single crystallization. Furthermore, the product is highly crystalline unlike the conventionally resolved material.

Experimental Section

Chemicals—(1*R*,2*S*)-ephedrine, (1*S*,2*R*)-ephedrine, and (*R*)-mandelic acid had a purity of >99% and were supplied by Aldrich (Gillingham, UK). Methanol was >99.9% and was supplied by BDH Chemicals (Poole, UK). CO_2 was 99.99% and supplied by BOC (Manchester, UK). All chemicals were used without further purification.

Equipment—Experiments were carried out in a SEDS (Solution Enhanced Dispersion by Supercritical Fluids) apparatus for crystallization in supercritical fluids. A scheme of the equipment is given in Figure 1. HPLC pumps P_{1-3} (Jasco, model 880) were used to feed CO_2, solute solution, and additional solvent to the crystallization vessel. Pressure pulses, originating from the pumps, were eliminated by a pulse dampener PD, made from a $^1/_4$ in. stainless steel tube. CO_2 was supplied from a high-pressure cylinder GC, cooled to approximately −10 °C (*T*), and then pumped into the vessel. Simultaneously, solute solution SS was pumped into the crystallization vessel, through a specially designed nozzle N, consisting of two coaxial concentric tubes.[23] The crystallization vessel V (Keystone, 32 mL) was placed inside an oven O (ICI Instruments, TC1900), which controlled the temperature. Pressure was maintained with a backpressure regulator BPR (Jasco, model 880-81). A small additional stream of solvent (0.2 mL·min^{-1}) was introduced at the bottom of the crystallization vessel AS to dissolve material soluble in supercritical CO_2, preventing precipitation in the backpressure regulator. The used solvent was collected SC

after the back pressure regulator BPR. A more detailed description of the equipment and its operating procedure has been given elsewhere.[19,24,25]

Procedure—The general experimental procedure was as follows: 0.261 g (0.79 mmol) of (1*R*,2*S*)-ephedrine, 0.261 g (0.79 mmol) of (1*S*,2*R*)-ephedrine, and 0.239 g of (*R*)-mandelic acid (0.79 mmol) were dissolved in 40 mL of methanol (1.93 w/v%) and the solution was pumped at 0.2 mL·min^{-1} together with 9 mL·min^{-1} CO_2 into the vessel. During the experiment, the solvent dissolved in the supercritical CO_2, leaving the solute behind. The precipitated solid was collected on a filter plate at the bottom of the vessel. After all solute solution had been fed into the vessel, the apparatus was flushed with CO_2 for 15 min. to remove solvent traces present in the vessel. Temperatures for the crystallization ranged from 35 to 75 °C, and pressures varied between 100 and 350 bar. Temperature during the crystallization was constant to ±0.5 °C, and pressure was constant within 1 bar. Densities of CO_2 were obtained from the IUPAC tables.[26] The small variations in temperature and pressure during any experiment result in a small error in density of the supercritical CO_2, which is reflected in the error bars.

Analysis—Samples were analyzed using capillary electrophoresis (CE), using a Beckman P/ACE 2210 system with a fused silica column 27 cm length and an inner diameter of 50 μm. The buffer consisted of a 25 mM solution of dimethyl-β-cyclodextrin in 100 mM triethanolamine at pH 2.5. A voltage of 10 kV was applied producing a current around 50 μA. Separation temperature was 25 °C at a detection wavelength of 200 nm. Sample concentration was typically around 0.1 mg·mL^{-1} in water. Experimental error for the resolution was 0.3 mol %.

Selected samples were investigated by differential scanning calorimetry (DSC) using a Mettler M3 system. A temperature program with a ramp of 2 °C·min^{-1} from 80 to 200 °C was used for all samples. Error in melting point (T_m) was ±0.5 °C. The enthalpy of fusion (ΔH_f) was determined by integration of the melting peak with an error of ±1.5 kJ·mol^{-1}.

Results and Discussion

Pure Diastereomers—The diastereomeric salts (1*S*,2*R*)-ephedrinium-(*R*)-mandelate ((+)-E-(−)-MA) and (1*R*,2*S*)-ephedrinium-(*R*)-mandelate ((−)-E-(−)-MA) were prepared with the SEDS equipment to obtain reference material for the separation. Experimental parameters for the crystallization of the pure diastereomers are summarized in Table 1. From Table 1 it can be seen that (−)-E-(−)-MA was crystallized at the high pressure of 300 bar using methanol as solvent. In contrast, (+)-E-(−)-MA was not obtained under these conditions, due to greater solubility in CO_2 than (−)-E-(−)-MA. For crystallization of (+)-E-(−)-MA, the pressure had to be lowered to 100 bar, and THF used as solvent, because no precipitation occurred in CO_2 with methanol. (+)-E-(−)-MA is less soluble in THF; the same solution concentration is therefore more saturated and precipitates easier when CO_2 is added as an antisolvent.

Table 1—Experimental Parameters for SEDS Crystallizations

The differences in crystallization between the diastereomers can be explained by their different solubility in CO_2. Solubility of a solid in a liquid can be expressed with the enthalpy of fusion and the isobaric heat capacity. Neglecting the influence of the heat capacity and assuming that in the SEDS process both diastereomers are infinitely diluted, differences in solubility between them can solely be related to their heat of fusion. From the melting points and enthalpies of fusion of both salts shown in Table 2, it can be seen that their T_m differ by more than 50 °C and ΔH_f by 20 kJ·mol^{-1}.[27] The low ΔH_f for (+)-E-(−)-MA explains why it is difficult to crystallize from supercritical CO_2. Table 2 also shows T_m and ΔH_f for the diastereomers produced by SEDS. In comparison to the literature data, the SEDS-produced materials have almost identical melting points. The difference in enthalpy of fusion observed might either be due to small amorphous regions within the SEDS product, or to the minute crystal size of the SEDS material. Supersaturation and subsequent precipitation in the SEDS process occur within milliseconds; therefore, particles can be produced which give rise to the possibility of amorphous regions within the crystal.

SEM photographs were taken as reference of both diastereomeric salts. From the SEM photograph in Figure 2a it can be seen that (−)-E-(−)-MA produced by SEDS is comprised of very thin plates, which were shown to have an average size of 100 × 200 μm. The plates are also translucent, as can be seen from Figure 2b. The SEM photograph in Figure 3a shows the crystal shape of SEDS produced (+)-E-(−)-MA. It is distinctively different to the other diastereomer and consists of needlelike structures with an average length of 300 μm. From Figure 3b, it can be seen that individual needle pieces are "grafted" on top of each other.

Resolution by SEDS—As discussed above, the difference in enthalpy of fusion between the diastereomers results in a large difference in solubility in supercritical CO_2. (−)-E-(−)-MA possesses the higher enthalpy of fusion and should therefore crystallize preferentially making resolution of the racemate in supercritical CO_2 possible. For the separations, racemic ephedrine and (*R*)-mandelic acid were dissolved in methanol, and the solution was pumped into the crystallization vessel simultaneously with the supercritical CO_2. Experimental parameters are sum-

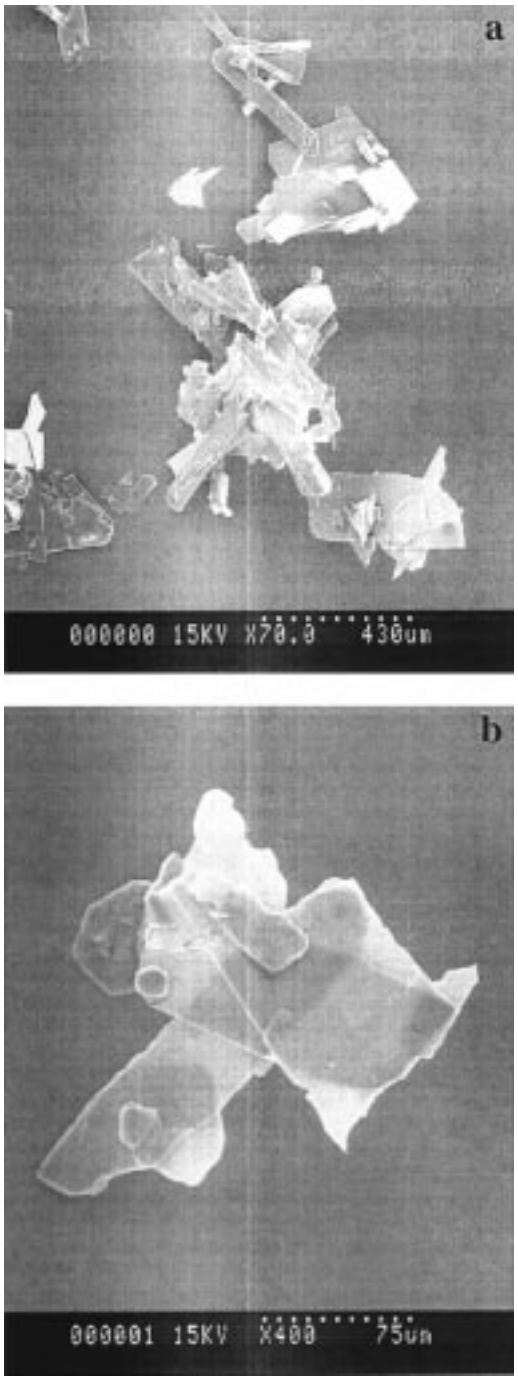

Figure 2—SEM photograph of pure (1*R*,2*S*)-ephedrinium-(*R*)-mandelate crystallized with SEDS from methanol at 35 °C and 300 bar with a CO_2 flow rate of 9 mL·min^{-1} and a solution flow rate of 0.2 mL·min^{-1}.

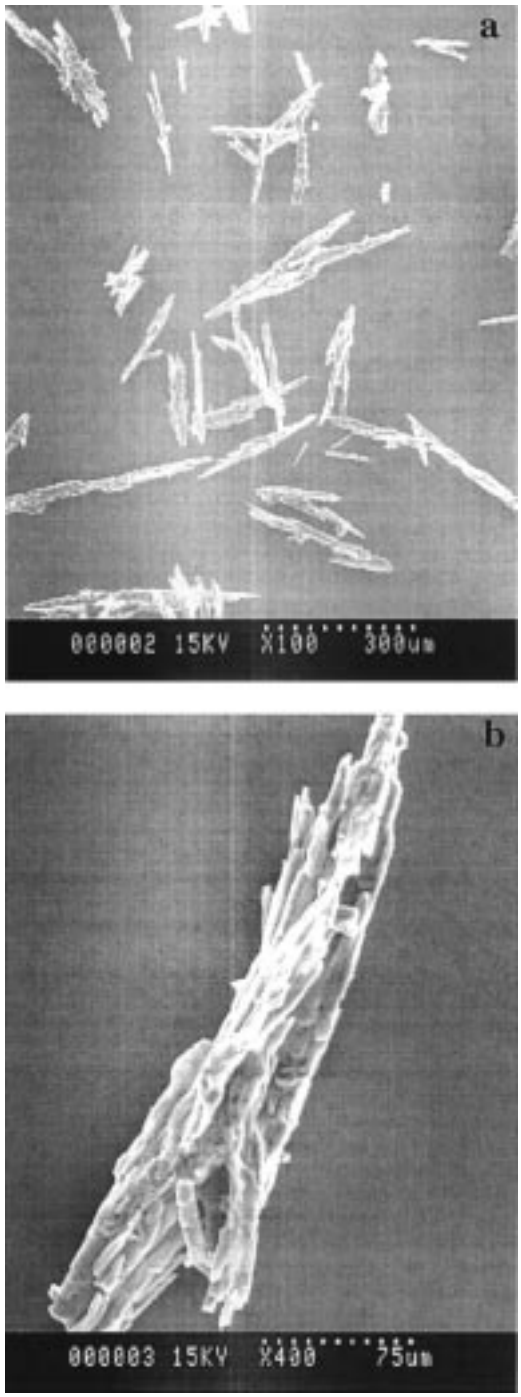

Figure 3—SEM photograph of pure (1*S*,2*R*)-ephedrinium-(*R*)-mandelate crystallized with SEDS from tetrahydrofuran at 35 °C and 100 bar with a CO_2 flow rate of 9 mL·min^{-1} and a solution flow rate of 0.2 mL·min^{-1}.

marized in Table 3. Pressure was varied between 100 and 350 bar at a constant temperature of 35 °C, ensuring that a wide range of densities of CO_2 was covered. Additionally, the temperature was changed between 35 and 75 °C keeping the density of the supercritical CO_2 at a constant value. From Table 3 it can be seen that the achieved resolutions range from 89 to 92%, as expected from the large difference in ΔH_f. In Figure 4, the achieved resolution is plotted against the density of CO_2. Bidirectional error bars are given, reflecting the experimental uncertainties. Within experimental error, a linear relationship between resolution and density of CO_2 can clearly be seen. Resolution rises with increasing density of the supercritical fluid at constant temperature. As explained, (+)-E-(−)-MA is much more soluble in CO_2 than (−)-E-(−)-MA. Thus, at higher pressures the corresponding density of the super-

critical CO_2 is increased supplying more "solvent" in which (+)-E-(−)-MA can be dissolved, resulting in higher enantiomeric excess. As shown, density plays the key role for the resolution, and a higher degree of resolution could therefore be obtained by increasing the density even further. Unfortunately, the density of the supercritical CO_2 rises approximately logarithmically with pressure and, significantly higher densities can only be achieved by applying practically excessive pressures.

As density is an important factor in the resolution of the ephedrinium mandelates, a second series of crystallizations was performed to investigate the temperature dependence of the resolution. In these experiments, the density of the supercritical CO_2 was kept virtually constant (±1.7%) at different temperatures, applying a consecutively higher pressure at elevated temperatures. Results are summarized in Table 3. A linear relationship is obtained in Figure 5 for resolution plotted against temperature with resolution decreased from more than 90% to less than 88% as temperature rises from 35 °C to 75 °C. Bidirectional error bars are included in Figure 5 for the uncertainty in temperature and resolution. The loss in resolution can be explained by changes of ΔH_f with temperature for both diastereomers. Although the difference in ΔH_f between the diastereomers is large, this difference becomes smaller with increasing temperature, causing less efficient resolution. Furthermore, the methanol solution of the solute is less saturated at elevated temperatures, making it more difficult to crystallize the diastereomers. This results in a lower yield in crystalline product at elevated temperatures.

Chiral separations are an extreme case of impurity removal. Considering one of the enantiomers as an impurity, up to 50% has to be removed to obtain an enantiomerically pure product. Yields for each SEDS crystallization lie between 40 and 45%, meaning that 80−90% of the theoretical yield is obtained. Furthermore, highest yields are achieved at low densities of CO_2, because overall solubility of the diastereomeric salts is at a minimum.

SEDS versus "Classic" Resolution—In order, to compare the SEDS products with conventionally obtained enantiomers, a classical resolution of ephedrine with mandelic acid was performed according to the method of Manske and Johnson.[18] For this model resolution, racemic ephedrine and (*R*)-mandelic acid were dissolved in boiling ethanol, and on cooling a diastereomeric salt mixture precipitated. Part of the initial crop was recrystallized twice from boiling ethanol. The first crop had a resolution of 88%, with a yield of 70%. Consecutive recrystallizations with identical yields increased the resolution to 95.3% and finally after another recrystallization to more than 99% with an overall yield of 34%.

SEDS samples produced at 35 °C were recrystallized under identical experimental parameters as for their initial crystallization to determine the efficiency of further purification. The yields for each crystallization was 80% resulting in an overall yield of 64%. Table 4 compares the achieved resolution of the SEDS and classical material and data show that the initial resolution of all SEDS material is higher than for the conventional material. An ANOVA test[28] of the obtained resolutions on a 95% confidence level shows that all samples are significantly different. A summary of the statistical analysis is given in Table 5. Furthermore, after only one recrystallization, the resolution of the SEDS product has risen to more than 99% with no peak of (+)-E-(−)-MA detected by CE. Although the initial resolution of the individual SEDS samples differed by several percent, the recrystallized samples have an identical purity within the error of analysis. Thus it is proposed that also less-resolved material can be resolved to >99% after a recrystallization in supercritical CO_2.

Figure 6 shows a SEM photograph of ephedrinium mandelate that has been crystallized twice from supercritical CO_2. The material exhibits the same very thin plate morphology as pure (−)-E-(−)-MA, as seen in Figure 1. It is known that small amounts of the second enantiomer influence the habit of the crystal[29] and resolution can

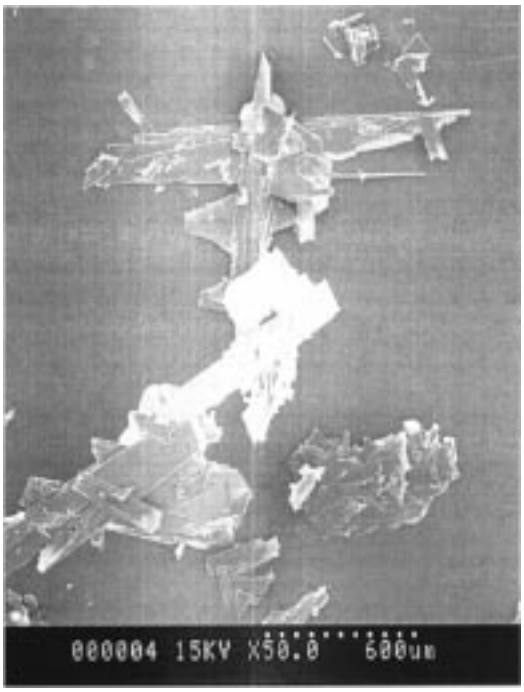

Figure 6—SEM photograph of SEDS-recrystallized ephedrinium-mandelate from methanol at 35 °C and 300 bar with a CO_2 flow rate of 9 mL·min^{-1} and a solution flow rate of 0.2 mL·min^{-1}.

therefore be qualitatively monitored by looking at particle shape. If the crystal habit does not resemble that of the desired diastereomer, it can be assumed that the resolution is not complete. In addition to the crystal shape, T_m and ΔH_f are also almost identical to values for pure (−)-E-(−)-MA. Small differences in T_m and ΔH_f between the individual samples are likely to result from variations in the HPLC-pumps efficiency over the long run periods of the experiment and not from differences in resolution under different conditions. Table 4 also shows that the SEDS-recrystallized samples exhibit T_m comparable to conventionally recrystallized material. The difference in ΔH_f between SEDS and conventional samples is again due to the smaller crystal size, as explained earlier. In contrast to conventionally obtained (−)-E-(−)-MA the material produced by SEDS has the melting point of the pure product after only one recrystallization.

Conclusions

Crystallization by the SEDS process using supercritical CO_2 has been shown to be a versatile method for the resolution of ephedrine racemates via diastereomeric salt and produce material of high enantiomeric purity. Starting from the racemate, crystals with more than 90% resolution can easily be obtained in one crystallization. Resolution has been shown to be a function of density of the supercritical CO_2 and temperature. At constant temperature resolution increased with increasing density of the supercritical CO_2, whereas raising the temperature under isopycnic conditions had a detrimental effect on the degree of resolution. Temperature and density effects were explained by the difference of enthalpy of fusion between enantiomers. After one recrystallization, the SEDS product is indistinguishable from material obtained from enantiomerically pure ephedrine samples. Crystals produced with the SEDS technique exhibit enhanced purity and smoother crystal habits compared to conventionally obtained material. Ease of use and ability to produce highly resolved material make the SEDS process a viable alternative to conventional resolution of chiral compounds.

Abstract □ Differential scanning calorimetry (DSC) was employed to characterize the distribution of water in gels produced from a series of hydroxypropylmethylcelluloses (HPMC, Methocel K-series) of different molecular weights (i.e., different viscosity grades). The presence of loosely bound water was characterized as pre-endothermic events occurring at temperatures below the main melting endotherm of free water. Both the magnitude and occurrence of these pre-endothermic events were affected by polymer molecular weight and gel storage time. In addition, the amount of water bound to the polymer depended on polymer molecular weight and gel storage time. The temperature at which frozen water melted within the gels was dependent on polymer concentration, with a depression of extrapolated endothermic melting peak onset occurring with an increase in polymer concentration. The addition of propranolol hydrochloride or diclofenac sodium, as model drugs, affected both the occurrence of pre-endothermic events and the distribution of water within the gels.

1. Introduction

Hydrophilic cellulose ether polymers commonly used in controlled release matrices form a gel-like structure when hydrated. Different types of water have been reported to exist within such gel systems.[1] The rate at which water diffuses into hydrophilic matrices and forms a barrier gel layer,[2] followed by water diffusion through this gel layer, both modify the rate at which a drug is released from such systems.[3] Detailed study on the gel layer and more specifically on the types of water which exist is fundamental to the optimization of the use of cellulose ethers in sustained release formulations.

Thermal techniques, including differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA), have been employed to study the states of water within some hydrophilic polymer gel systems.[1] The majority of workers have identified three classes of water within hydrophilic polymer gels which may be defined in terms of their thermal analysis as: (a) free water, i.e., unbound water whose transition temperature enthalpy and peak shape in DSC curves are equal to those of pure (bulk) water;[4] (b) nonfreezing water, i.e., bound water which is attached directly to the polymer and does not undergo a detectable phase transition;[5] (c) freezing bound water, which is characterized as having a phase transition temperature lower than that of bulk water due to a weak interaction with the polymer chain.[6]

There have been many studies comparing drug release from hydroxypropylmethylcelluloses (HPMCs) of different molecular weights with some debate existing within the literature regarding the influence of HPMC viscosity grade on drug release.[7−12]

The presence of a drug in a matrix tablet may influence the way water is bound to or taken up by the cellulose ether. The influence of drugs such as propranolol hydrochloride (a water soluble drug) on the interaction of water with polymer has been studied by DSC[13] and in thermal gelation or cloud-point studies.[14] The presence of free water within the barrier gel layer plays an important part in drug movement across this barrier. Increased availability of free water (i.e., not bound to the polymer) may lead to increased drug diffusion across the gel layer. The effect of diclofenac sodium (a sparingly water soluble drug) on polymer hydration within hydrophilic polymer matrices was studied using cryogenic scanning electron microscopy (SEM) and revealed that internal gel structure was modified by drug addition.[15,16] In addition, it has been reported that diclofenac sodium decreases the hydration of HPMC polymers, causing the polymers to precipitate at elevated temperatures.[2]

The distribution of water within HPMC K15M gels has been characterized.[1,17] Nokhodchi et al.[18] characterized the water distribution in powders of different viscosity grades of the HPMC K-series using DSC and concluded that viscosity grade had no significant effect on the amount of water bound to HPMC polymers.

In this paper, the water distribution within gels of a range of HPMC polymers of different molecular weights but with similar substitution types and levels is characterized using DSC. Furthermore, the influence of drug addition on water distribution within the gel systems is also examined.

2. Experimental Section

2.1 Materials—Hydroxypropylmethylcellulose (HPMC) is a cellulose ether with methoxyl and hydroxypropoxyl substituents on the cellulose backbone. Methocel K-series (22% methoxyl and 8.1% hydroxypropoxyl substitutions) with different viscosity grades, i.e., HPMC K100LV, HPMC K4M, HPMC K15M, and HPMC K100M were obtained from Dow Chemical Co., Midland, MI.

Propranolol hydrochloride and diclofenac sodium were obtained from Becpharm, Harlow, Essex, England and Profarmaco, Milan, Italy, respectively.

2.2 Gel Preparation—HPMC gels (5−25% w/w) (sample size 20 g) were prepared by heating the full quantity of distilled water to ~80 °C and adding in two aliquots to the previously weighed HPMC powder in a mortar and pestle. The mixture was triturated vigorously to ensure thorough wetting before adjusting to weight. Gels containing propranolol hydrochloride (50 mM) or diclofenac sodium (50 mM) were prepared by dissolving the drugs in distilled water by mixing with the aid of gentle heat on a hot plate stirrer (Griffin & George, England) prior to gel preparation. Both drugs

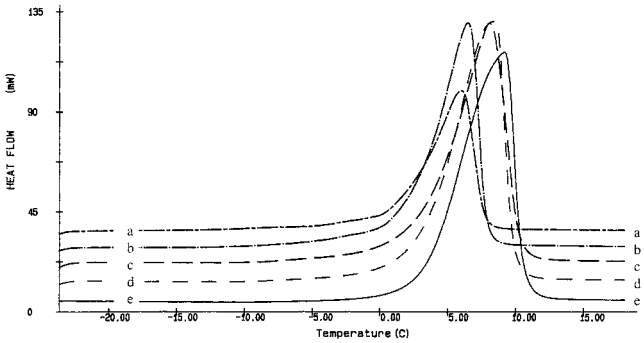

Figure 1—DSC scans of HPMC K15M (5–25% w/w) gels obtained by heating at +10 °C min^{-1} after cooling at –10 °C min^{-1} following storage for 24 h. (a) 5%, (b) 10%, (c) 15%, (d) 20%, (e) 25% (w/w) HPMC K15M.

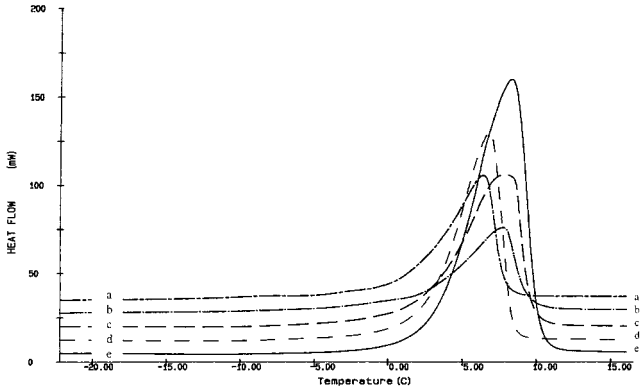

Figure 2—DSC scans of HPMC K15M (5–25% w/w) gels obtained by heating at +10 °C min^{-1} after cooling at –10 °C min^{-1} following storage for 96 h. (a) 5%, (b) 10%, (c) 15%, (d) 20%, (e) 25% (w/w) HPMC K15M.

were fully soluble in warm water at the chosen concentration. Gels were transferred to Pyrex storage vessels which were sealed and stored at 4−6 °C for 24 h before use. Water losses during preparation and storage were taken into account when determining the final polymer concentrations of all gels.

Gel samples >25% w/w were made by preparing gels initially as detailed above in the 10−20% w/w range and storing at 4−6 °C for 24 h. A series of samples (10−16 mg) of the gels were weighed into DSC sample pans (40 μL, Perkin-Elmer) and held at 55 °C in a moisture extraction oven (Townsend & Mercer Ltd., Croydon, England). The samples were removed after defined periods of time to obtain a measurable % weight loss from which the exact polymer:water ratios were calculated.

2.3 Thermal Analysis—A Perkin-Elmer DSC7 (Beaconsfield, UK) with an attached liquid nitrogen based cooling accessory controlled by a Perkin-Elmer TAC-7 was employed. Calibrations with indium (mp onset 156.60 °C) and zinc (mp onset 419.47 °C) were carried out each time the heating rate was changed. Gel samples (5−15 mg) were analyzed in sealed aluminum sample pans (40 μL, Perkin-Elmer, Beaconsfield, UK) by cooling from +20 °C to −35 °C at a cooling rate of −10 °C min^{-1} and then heating from −35 °C to +20 °C at a heating rate of +10 °C min^{-1}.

For gel samples >25% w/w, 5−15 mg of each gel was placed in a DSC pan, sealed, and stored for 24 h at ambient temperature to allow equilibration and uniform water distribution in the gels, before DSC analysis.

3. Results and Discussion

3.1 Characterization of HPMC Gels Using DSC Analysis—Figures 1 and 2 show typical DSC scans for HPMC K15M gels after 24 and 96 h storage time. The exothermic enthalpy (from cooling scans) is the energy released when water within the gels freezes. The endothermic enthalpy (from heating scans) is the energy that is required for melting of frozen water within the gels. Increasing the concentration of HPMC K15M resulted in a decrease in both exothermic (cooling) and endothermic (heating) enthalpies (J/g) after gel storage for both 24 or 96 h (Table 1). Assuming that both exothermic and endothermic peaks are attributable mainly to the crystallization and melting of free water, respectively, it is apparent that there is a decrease in the amount of free water present with an increase in HPMC K15M concentration. As the concentration of the polymer increases, the amount of water required to hydrate the polymer increases and thus less free water is available.

Table 1—Effect of HPMC K15M Concentration (% w/w) on the Extrapolated Exothermic and Endothermic Peak Onsets, the Exothermic and Endothermic Crystallization/Melting Enthalpies (Jg^{-1}) ($n = 3$; ± SD)

HPMC K15M (% w/w)	extrapolated exothermic peak onset (°C)	exothermic enthalpy (J/g)	extrapolated endothermic peak onset (°C)	endothermic enthalpy (J/g)
		After 24 h Storage		
5	–13.4 ± 1.4	259.9 ± 13.9	3.4 ± 0.2	334.7 ± 8.0
10	–16.5 ± 3.0	213.4 ± 21.1	2.9 ± 0.2	289.8 ± 11.3
15	–11.7 ± 2.4	248.2 ± 12.1	2.8 ± 0.3	289.7 ± 14.0
20	–16.0 ± 3.4	208.2 ± 31.7	2.4 ± 0.3	263.6 ± 15.8
25	–13.5 ± 3.4	205.0 ± 18.1	1.8 ± 0.5	228.3 ± 15.4
		After 96 h Storage		
5	–14.2 ± 1.9	218.1 ± 78.3	3.6 ± 0.9	343.3 ± 12.5
10	–15.3 ± 4.7	217.0 ± 33.7	2.8 ± 0.3	304.0 ± 13.9
15	–18.1 ± 0.7	216.7 ± 8.4	2.6 ± 0.2	281.6 ± 15.5
20	–11.3 ± 1.1	209.2 ± 26.8	2.0 ± 0.4	246.3 ± 13.7
25	–14.9 ± 3.8	202.2 ± 9.1	1.5 ± 0.1	231.1 ± 6.6

Increasing HPMC K15M concentration from 5 to 25% (w/w) caused a decrease in the extrapolated endothermic melting peak onset. The extrapolated endothermic melting peak onset is defined as the temperature where the extrapolation of the baseline meets the extrapolation of the ascending melting peak.[19] For example, Table 1 and Figures 1 and 2 show a decrease of extrapolated endothermic melting peak onset from 3.4 ± 0.2 to 1.8 ± 0.5 °C for 5 and 25% w/w gels, respectively, after 24 h hydration, and a decrease from 3.6 ± 0.9 to 1.5 ± 0.1 °C for 5 and 25% w/w gels, respectively, after 96 h hydration. This decrease in the extrapolated endothermic melting peak onset may be related to an increase in the quantity of loosely bound water which melts at a lower temperature than free water due to a stronger interaction with the polymer.[20] This phenomena has previously been reported for HPMC K4M gels.[18] Increasing HPMC K15M concentration has no quantifiable effect on the position of the extrapolated exothermic peak onset (Table 1). This may be because crystallization occurs via nucleation which is an uncontrolled phenomena.[21,22] This lack of control during crystallization was also apparent in HPMC K100LV, HPMC K4M, and HPMC K100M gels (data not shown), where increase in polymer concentration had no effect on the position of the extrapolated exothermic peak onset.

Depression of melting point (extrapolated endothermic peak onset) with increasing concentration of polymer was observed in all HPMC polymers studied here (data not shown). HPMC K100LV (−0.2 ± 0.3 to −2.0 ± 0.1 °C; 5 & 25% w/w gels, respectively, 24 h), HPMC K4M (−2.6 ± 0.1 to −3.4 ± 1.2 °C; 5 & 25% w/w gels respectively, 24 h) and HPMC K100M (−0.2 ± 0.3 to −2.0 ± 0.4 °C; 5 & 25% w/w gels respectively, 24 h), all display this depression in melting point. However, there is no apparent trend between polymer molecular weight and extent of melting point depression with increase in polymer concentration. Similar findings were obtained for HPMC K100LV, HPMC K4M and HPMC K100M gels after 96 h storage.

The presence of endothermic events on low temperature side of the main endotherm for the melting of free water

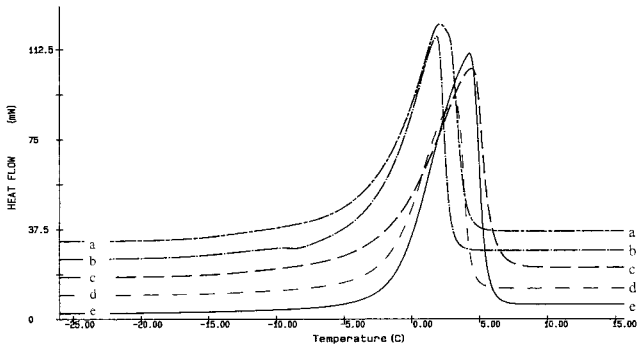

Figure 3—DSC scans of HPMC K100LV (5–25% w/w) gels obtained by heating at +10 °C min^{-1} after cooling at –10 °C min^{-1} following storage for 96 h. (a) 5%, (b) 10%, (c) 15%, (d) 20%, (e) 25% (w/w) HPMC K100LV.

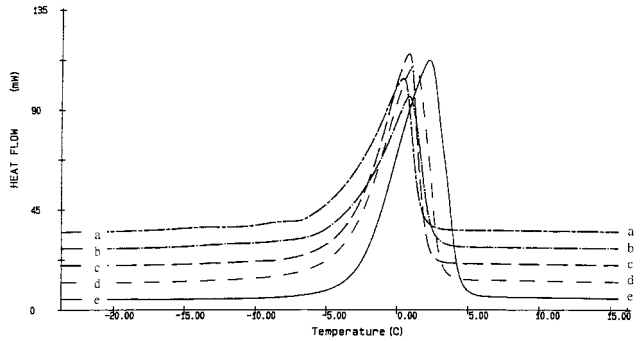

Figure 4—DSC scans of HPMC K4M (5–25% w/w) gels obtained by heating at +10 °C min^{-1} after cooling at –10 °C min^{-1} following storage for 24 h. (a) 5%, (b) 10%, (c) 15%, (d) 20%, (e) 25% (w/w) HPMC K4M.

in DSC scans for HPMC K15M gels was discussed previously.[17] Their occurrence were dependent on polymer concentration, storage time, and scanning rates during DSC analysis. These events were related to the presence of different states of water in the polymer gels. Alternative explanations for similar pre-endothermic events in other systems have been considered in the literature where they were attributed to overlapping ice melting (first-order) and glass transition (second-order) phase transitions.[23] Ratto et al.[24] attributed pre-endothermic events present in water/chitosan systems to cold crystallization. This occurs in systems where only nonfreezing and freezing bound water are present. Upon heating, some of the nonfreezing water becomes mobile, comes into contact with solid freezing bound water, and forms ice. A crystallization exotherm is subsequently visible.

Similar events were also visible prior to the main DSC melting endotherms in gels containing HPMC K100LV, HPMC K4M, or HPMC K100M. Their appearance was dependent on both polymer molecular weight and gel storage time. In HPMC K100LV and HPMC K15M, pre-endothermic events were only visible in 20% w/w and 25% w/w gels after storage for 24 and 96 h (Figures 1−3). In the case of HPMC K15M, pre-endothermic events were more pronounced after 96 h storage.

Gels of HPMC K4M or HPMC K100M showed pre-endothermic events at 15, 20, or 25% w/w polymer content after storage for both 24 and 96 h (Figure 4 and Figure 5). In both these cases, the appearance of such events was unaffected by storage time. It appears that the occurrence of endothermic events varied between HPMCs of different molecular weights.

3.2 Quantitative Analysis of the Effect of Molecular Weight on Water Distribution within Cellulose Ethers—The number of moles of bound (nonfreezing) water per polymer repeating unit (PRU) was calculated for HPMC

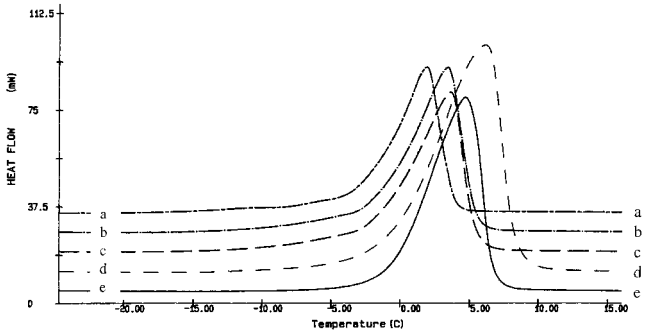

Figure 5—DSC scans of HPMC K100M (5–25% w/w) gels obtained by heating at +10 °C min^{-1} after cooling at –10 °C min^{-1} following storage for 24 h. (a) 5%, (b) 10%, (c) 15%, (d) 20%, (e) 25% (w/w) HPMC K100M.

Table 2—Effect of HPMC Molecular Weight and Equilibration Time on the Bound (nonfreezing) Water (BW) Content per Polymer Repeating Unit (PRU) As Calculated by the Method Proposed by Ford and Mitchell[1]

polymer	viscosity (cP)[a]	PRU value	moles BW per PRU (24 h)	R^2 (24 h)[b]	moles BW per PRU (96 h)	R^2 (96 h)
HPMC K100	93	189	2.4	0.994	4.4	0.973
HPMC K4M	4 196	188	7.1	0.996	4.5	0.973
HPMC K15M	15 825	189	4.5	0.978	6.5	0.934
HPMC K100M	119 768	192	6.0	0.970	6.6	0.963

[a] Values were taken from certificate of analysis provided by the manufacturer of the products. [b] R^2 is the regression coefficient.

K100LV, HPMC K4M, HPMC K15M, and HPMC K100M gels according to the method outlined by Ford and Mitchell[1] and have been reported previously.[17] Enthalpy of fusion of ice (J g^{-1}) was plotted against HPMC concentration (% w/w), and the plots were extrapolated to zero enthalpy through the lines of best fit. The concentration at zero enthalpy was taken as being the minimum ratio of water: HPMC that is required for complete hydration of the polymer. A linear relationship was assumed to exist between enthalpy and polymer concentration. The bound water content was calculated using values for the PRU listed in Table 2 that were calculated for each HPMC viscosity grade based on their % methoxyl and % hydroxypropoxyl substitution on the cellulose ether backbone.

HPMC K4M showed a decrease in bound water content from 24 to 96 h storage, whereas all other polymers showed an increase in their bound water content during this equilibration period (Table 2). The largest change in bound water content occurred in HPMC K100LV (the lowest viscosity grade polymer within the K-series), which shows a 58% increase in the bound water content from 24 to 96 h. Allowing 96 h equilibration, which should be ample time for uniform equilibration in all gel samples, an increase in the bound water content is apparent with an increase in polymer viscosity within the HPMC K-series (Table 2).

3.3 Effect of Drug Addition on Water Distribution in Cellulose Ether Gels—In the absence of a drug, pre-endothermic events were present in 15, 20, and 25% w/w HPMC K4M and HPMC K100M gels and in 20 and 25% w/w HPMC K100LV and HPMC K15M gels after 24 h storage (section 3.2). Incorporation of 50 mM of propranolol hydrochloride did not affect the appearance of such events in HPMC K100LV, HPMC K4M, and HPMC K15M gels. However, in HPMC K100M gels, pre-endothermic events were visible only in 20 and 25% w/w gels after 24 h.

Figure 6 shows the influence of diclofenac sodium on the appearance of pre-endothermic events in 5−25% w/w HPMC K4M gels which is representative of other polymers studied. After 24 h equilibration, pre-endothermic events

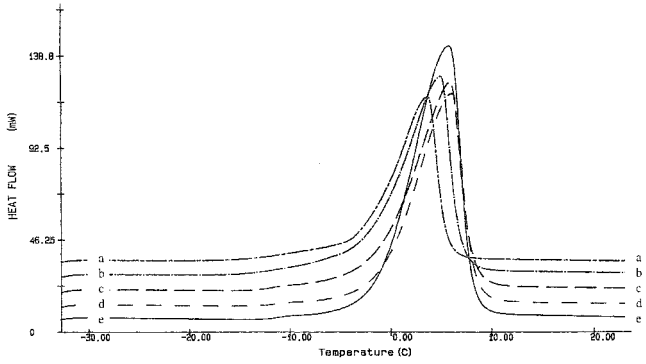

Figure 6—DSC scans of HPMC K4M (5–25% w/w) gels containing 50 mM of diclofenac sodium obtained by heating at +10 °C min^{-1} after cooling at –10 °C min^{-1} following storage for 24 h. (a) 5%, (b) 10%, (c) 15%, (d) 20%, (e) 25% (w/w) HPMC K4M + 50 mM diclofenac sodium.

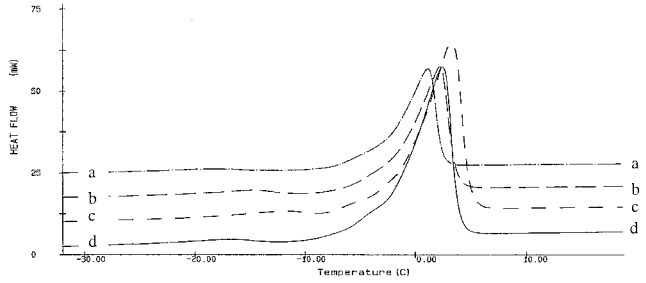

Figure 7—DSC scans of 26.7–32.4% (w/w) HPMC K15M gels in the absence and presence of 50 mM of diclofenac sodium obtained by heating at +10 °C min^{-1} after cooling at –10 °C min^{-1} following storage for 24 h. (a) 26.7% K15M, (b) 30.5% K15M, (c) 29.2% K15M + 50 mM diclofenac sodium, (d) 32.4% (w/w) K15M + 50 mM diclofenac sodium.

were visible in all HPMC K-series studied here, at each concentration (5−25% w/w). It is hypothesized that diclofenac sodium causes the polymer to "salt out", making it less soluble and requiring more water to bind to the polymer to keep it in solution. Therefore, there is more loosely bound water in the system. It is possible that this loosely bound water appears in DSC scans and may explain the appearance of these pre-endothermic events.

Pre-endothermic events in HPMC K15M gels were previously found to be exaggerated in the 25−35% w/w concentration range in comparison to the events observed with 20 and 25% w/w HPMC K15M gels.[17] The influence of each drug on the DSC scans of gels containing 25−40% w/w HPMC K15M was examined.

Following the inclusion of 50 mM of propranolol hydrochloride into HPMC K15M gels, pre-endothermic events were visible at 29.0% w/w but they were not present at the higher concentrations studied (30.7−40.1% w/w). The pre-endothermic events became quite pronounced in the HPMC K15M gels in the 25−35% w/w concentration range when diclofenac sodium (50mM) was added. However, they were not apparent in HPMC K15M gels at concentrations >35% w/w. Figure 7 shows that in 25−33% w/w HPMC K15M gels, secondary events were clearly visible both in the presence and absence of diclofenac sodium.

Increasing HPMC K15M concentration from 5 to 25% w/w caused a decrease in the extrapolated endothermic melting peak onset from 3.4 ± 0.2 to 1.8 ± 0.5 °C after 24 h storage. With the addition of a drug, this depression of melting onset may be expected regardless of polymer molecular weight. For HPMC K15M gels, increasing polymer concentration from 5 to 25% w/w in the presence of 50 mM propranolol hydrochloride caused a depression of the extrapolated endothermic melting peak onset from 3.2 ± 0.7 °C to 0.8 ± 0.2 °C. Similarly, increasing polymer concentration in HPMC K15M gels from 5 to 25% w/w in the presence of 50 mM diclofenac sodium caused a depression of the extrapolated endothermic melting peak onset from 2.9 ± 0.5 °C to 1.3 ± 0.2 °C.

Table 3—The Effect of Addition of 50 mM of Propranolol Hydrochloride or Diclofenac Sodium on the Water Distribution within a Range of Cellulose Ether Gels after 24 h Storage

polymer	viscosity (cP)[a]	polymer (% w/w)	water (% w/w)	R^{2b}	moles bound water per PRU
HPMC K100LV	93	81.2	18.8	0.994	2.4
+ propranolol		80.3	18.3	0.976	2.4
+ diclofenac		70.0	28.5	0.986	4.3
HPMC K4M	4 196	59.6	40.4	0.996	7.1
+ propranolol		79.4	19.2	0.997	2.5
+ diclofenac		65.4	33.1	0.987	5.3
HPMC K15M	15 825	70.2	29.8	0.978	4.5
+ propranolol		76.6	21.9	0.975	3.0
+ diclofenac		71.8	26.8	0.992	3.9
HPMC K100M	119 768	64.1	35.9	0.970	6.0
+ propranolol		81.4	17.2	0.982	2.3
+ diclofenac		65.1	33.4	0.981	5.5

[a] Values were taken from certificate of analysis provided by the manufacturer of the products. [b] R^2 is the regression coefficient.

The number of moles of bound water per PRU (average molecular weight of one polymer repeating unit) were calculated as previously described using the Ford and Mitchell[1] method (section 3.2), and the values chosen for the PRU were as listed in Table 2. In HPMC K4M, HPMC K15M, and HPMC K100M gels, propranolol hydrochloride reduced the amount of water bound to the polymer (Table 3). In effect, less water was required to fully hydrate the polymer, most likely due to the "salting-in" effect of the drug which increases polymer solubility.[25] The ability of propranolol hydrochloride to reduce the amount of water required to fully hydrate HPMC K15M gels has been previously reported.[13]

Addition of propranolol hydrochloride to HPMC K100LV gels did not reduce the amount of bound water. The bound water content initially was very low in these gels. When diclofenac sodium was added to cellulose ether gels, with the exception of HPMC K100LV, the amount of water bound to the polymer was reduced in comparison with that bound in the absence of drug. More water was required to fully hydrate the polymer compared to when propranolol hydrochloride was added. Diclofenac sodium "salts out" cellulose ether polymers making them less soluble. Therefore, more water will be required to hydrate the polymer, and thus the bound water content should increase. For HPMC K100LV, addition of propranolol hydrochloride did not change the bound water content, while addition of diclofenac sodium caused an increase in the amount of water binding to the polymer. Addition of diclofenac sodium would certainly seem to make the polymer less soluble, causing an increase in water required to hydrate the polymer, as reflected in an increase in bound water. In the case of propranolol hydrochloride, the expected reduction in bound water content due to the "salting in" effect of the drug did not occur. It may be that a certain minimum level of water is required to maintain the gel structure and remains tightly bound to the polymer. This amount of tightly bound water cannot be removed even with the addition of a drug like propranolol hydrochloride.

4. Conclusions

The water distribution within cellulose ether polymer gels was found to be dependent on polymer molecular

weight and gel equilibration (or storage) time. The presence of loosely bound water was characterized as pre-endothermic events occurring to the left of the main melting endotherm of free water. The occurrence and magnitude of these pre-endothermic events were affected by polymer molecular weight. The melting of frozen water within the gels, as characterized by the extrapolated endothermic melting peak onset, was dependent on polymer concentration. No apparent trend was found to exist between polymer molecular weight and extent of melting point depression with increase in polymer concentration.

The amount of water tightly bound to the polymer, as calculated by the method proposed by Ford and Mitchell,[1] was dependent on polymer molecular weight. This was further affected by drug addition to the polymer gels. Diclofenac sodium had a marked effect on the appearance of pre-endothermic events in cellulose ether polymer gels; however, a negligible effect was observed with the addition of propranolol hydrochloride.

Received October 26, 1998. Accepted for publication May 18, 1999.

Abstract □ The distribution of water within gels composed of a range of cellulose ether polymers of similar molecular weights (viscosity grades of 4000–6000 cP) but varying substitution types and levels was assessed by differential scanning calorimetry (DSC). Water loosely bound to the polymer was detected as one or more events appearing at the low-temperature side of the main endotherm for the melting of free water in DSC scans. Polymer substitution types and levels, and added drugs (50 mM propranolol hydrochloride or 50 mM diclofenac sodium) influenced the appearance of these melting events. Hydroxypropylcellulose (HPC) and hydroxypropylmethylcellulose (HPMC F4M) gels showed behavior different to that of the other polymers studied. It is thought that any water binding to HPC gels is tightly attached and is not visible as pre-endothermic events on DSC scans. The amount of water bound per polymer repeating unit (PRU) was influenced by and related to the degree of hydrophilic and hydrophobic substitution on the polymer backbone and by the inclusion of either drug. HPC gels had the highest bound water content after 96 h and this was probably related to the high percentage of hydrophilic hydroxypropoxyl substitutions in this polymer. In contrast, methylcellulose (MC A4M) had the lowest bound water content after 96 h storage, and this was explained by the lack of hydrophilic hydroxypropoxyl substitutions in the polymer.

1. Introduction

The formation of a barrier gel layer in hydrophilic controlled release matrices containing cellulose ethers, and the subsequent water diffusion through this gel layer determine the rate and mechanism of drug release.[1] Different polymer properties have been reported to be responsible for the rate of polymer hydration including polymer viscosity grade,[2−4] polymer particle size,[5−8] polymer concentration,[2] and polymer substitution type.[5]

It was initially proposed by Alderman[5] that cellulose ethers of different substitution levels hydrate at different rates, and this factor may be used to optimize the formulation of sustained release matrices. However, Mitchell et al.,[9] using a combination of differential scanning calorimetry (DSC) and dissolution studies, have shown that the differences in drug release rates from HPMCs with different substitution levels are not due to differences in their hydration rates. Further studies using thermomechanical analysis[9] have shown that gel layer thickness (which will affect the diffusional path length) is similar in HPMCs of different substitution levels. Using NMR imaging, Rajabi-Siahboomi et al.[10] showed that gel layer development in HPMC tablets occurred to the same extent in both axial and radial directions and was similar in HPMCs with different substitution levels.

Differences in drug release patterns between the three HPMC substitution types (Methocels K, E, and F) were found in matrices containing low quantities of the polymers.[11] In addition, Bonferoni et al.[12] reported differences in drug release profiles from HPMC E4M and the other two substitution levels (HPMC K4M and HPMC F4M) at low polymer concentrations. Rajabi-Siahboomi et al.,[1] using NMR imaging, showed that water mobility in the gel layer of hydrated HPMC tablets varied with substitution levels. They found that the lowest value for water mobility was for HPMC K4M. Although no specific reason was given for the differences in water mobility, this differential water mobility may explain the different drug release profiles observed from their matrices.[1] In this article, the water distribution within a range of polymer gels containing cellulose ethers with different substitution types and levels but similar molecular weights are characterized using differential scanning calorimetry (DSC). The influence of drug addition on the distribution of water within these gel systems is also characterized.

2. Experimental Section

2.1 Materials—Methocel cellulose ethers, HPMC K4M, HPMC E4M, HPMC F4M, and methylcellulose (MC) A4M, were obtained from Dow Chemical Co., Midland, MI. Hydroxypropylcellulose (HPC) was obtained from Hercules Limited, Aqualon Division, U.K.

Propranolol hydrochloride and diclofenac sodium were obtained from Becpharm, Harlow, Essex, England, and Profarmaco, Milan, Italy, respectively.

2.2 Gel Preparation—HPMC gels of 5−25% w/w (sample size 20 g) were prepared as described previously[13] and stored for 24 or 96 h before use. Gels containing propranolol hydrochloride (50 mM) or diclofenac sodium (50 mM) were prepared by dissolving the drugs in distilled water by mixing with the aid of gentle heat on a hot plate stirrer (Griffin and George, England) prior to gel preparation. Gel samples greater than 25% w/w were made by preparing gels initially as above, followed by moisture extraction from the gels as described previously.[13]

2.3 Thermal Analysis—A Perkin-Elmer DSC7 (Beaconsfield, UK) with an attached liquid nitrogen based cooling accessory controlled by a Perkin-Elmer TAC-7 was employed as described previously.[13] For gel samples >25% w/w, 5−15 mg of each gel was placed in a DSC pan, sealed and stored for 24 h at ambient temperature to allow equilibration and uniform water distribution in the gels, before DSC analysis.

3. Results and Discussion

3.1 Effect of Polymer Substitution Type on the Nature of Water Distribution within Cellulose Ethers—Cellulose ether polymers of varying substitution types and levels possess different degrees of hydrophilic and hydrophobic substituents (Table 1). HPMC E4M and HPMC F4M both have a higher percentage of hydrophobic methoxyl substituents (about 29%) compared to HPMC K4M (22.2%). HPMC E4M has a similar percentage of hydrophilic hydroxypropoxyl substituents to HPMC K4M (about 8%), unlike HPMC F4M which has a lower hydroxypropoxyl percentage content (6%). Methylcellulose (MC A4M) possesses no hydrophilic hydroxypropoxyl substituents whereas hydroxypropylcellulose (HPC) possesses no methoxyl substituents. Therefore, it may be anticipated that water distribution within cellulose ether polymers would be dependent on substitution types and levels.

Table 2 shows the DSC data for HPC gels stored for 24 and 96 h respectively, and they are representative of the data seen for HPMC E4M, HPMC F4M, HPMC K4M, and MC A4M gels. In all cases, as seen in HPMC K-series,[13] increasing the concentration of the polymer from 5 to 25% w/w resulted in a decrease in the temperature of the extrapolated endothermic peak onset. For example, HPMC E4M (−2.1 ± 0.3 to −3.8 ± 0.3 °C; 5 and 25% w/w gels, respectively, 96 h), HPMC F4M (−3.1 ± 0.6 to −5.5 ± 0.3 °C; 5 and 25% w/w gels, respectively, 96 h), HPMC K4M (−2.7 ± 0.2 to −4.2 ± 0.3 °C; 5 and 25% w/w gels, respectively, 96 h), MC A4M (−2.0 ± 0.5 to −4.2 ± 0.4 °C; 5 and 25% w/w gels, respectively, 96 h) and HPC (−1.5 ± 0.6 to −3.7 ± 0.5 °C; 5 and 25% w/w gels, respectively, 96 h) all show a decrease in the temperature of the extrapolated endothermic peak onset. In addition, a decrease in temperature of the endothermic peak and a decrease in the endothermic melting enthalpy with increasing polymer concentration were observed.

There was no specific trend between polymer substitution type and the extent of melting peak depression with increase in polymer concentration.

The existence of events present at the low-temperature side of the main endotherm for the melting of free water

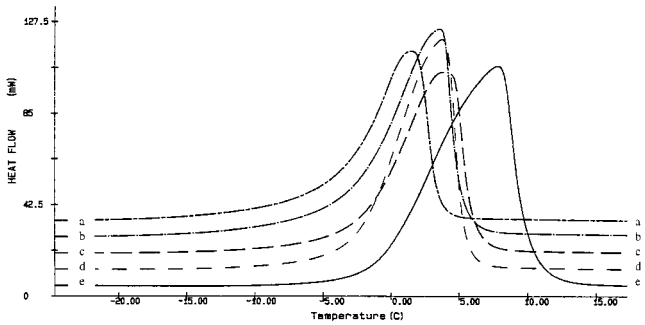

Figure 1—DSC scans of HPC (5–25% w/w) gels obtained by heating at +10 °C min^{-1} after cooling at –10 °C min^{-1} following storage for 96 h: (a) 5%, (b) 10%, (c) 15%, (d) 20%, (e) 25% (w/w) HPC.

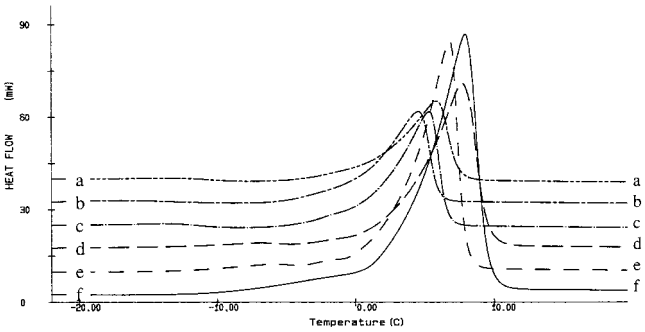

Figure 2—DSC scans of HPMC F4M (19.10–37.80% w/w) gels obtained by heating at +10 °C min^{-1} after cooling at –10 °C min^{-1} following storage for 24 h: (a) 19.10%, (b) 22.49%, (c) 27.14%, (d) 31.71%, (e) 34.07%, (f) 37.80% (w/w) HPMC F4M.

in DSC scans for HPMC K − series gels was discussed previously.[13,14] Such events were related to the presence of different types of water bound to varying degrees to the hydrophilic HPMC polymer and were dependent on polymer molecular weight.[13] Such events were barely visible in HPMC F4M gels, after 24 h storage, but became more pronounced in 20 and 25% w/w gels after 96 h storage. In HPMC E4M, pre-endothermic events were visible in both 20 and 25% w/w gels after 24 and 96 h storage. In the case of methylcellulose, these events were visible in both 20 and 25% w/w gels after 24 h storage, however, they were only visible in 25% w/w gels after 96 h storage. Finally, in all HPC gels, there were no pre-endothermic events visible after either 24 or 96 h (Figure 1). These results indicate that the nature of water distribution within these polymer gels is dependent on substitution types and levels.

Previously, the pre-endothermic events in HPMC K15M gels were found to be exaggerated by an increase in polymer concentration.[14] Therefore, the presence of these events was examined in gels containing higher concentrations of HPC and HPMC F4M.

A series of HPMC F4M 19.10−37.8% w/w and HPC 27.3−48.2% w/w gels were prepared, and their DSC scans were recorded after 24 h storage. Pre-endothermic events were visible in HPMC F4M gels at the higher concentrations studied of >25% w/w (Figure 2). In contrast, in HPC gels, only a small secondary event became visible at concentrations >30% w/w (Figure 3).

Hydroxypropylcellulose gels clearly behaved differently in comparison to the HPMC and MC gels. HPC contains a high percentage of hydrophilic hydroypropoxyl groups and therefore it may be expected to have a larger amount of bound water which is not visible as pre-endothermic events on DSC scans. It is possible that after 96 h storage, the water is tightly attached to the polymer and does not freeze upon cooling. This would explain the nonappearance of pre-endothermic events which have been attributed to loosly

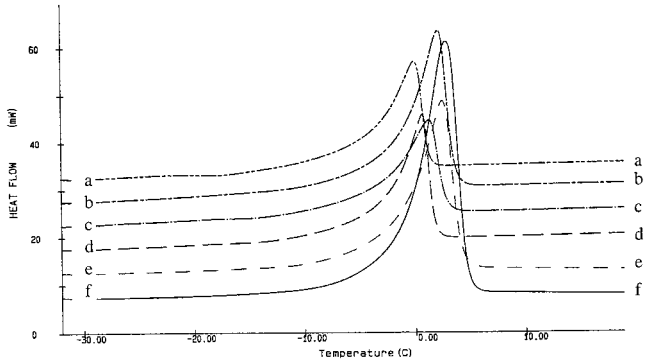

Figure 3—DSC scans of HPC (27.3–35.5% w/w) gels obtained by heating at +10 °C min^{-1} after cooling at –10 °C min^{-1} following storage for 24 h: (a) 27.3%, (b) 29.2%, (c) 30.1%, (d) 31.3%, (e) 32.9%, (f) 35.5% (w/w) HPC.

Table 3—Effect of Polymer Substitution Type and Equilibration Time on the Bound (nonfreezing) Water (BW) Content per Polymer Repeating Unit (PRU) As Calculated by the Method Proposed by Ford and Mitchell[15]

polymer	viscosity (cP)[a]	PRU value	moles BW per PRU (24 h)	R^2 [b] (24 h)	moles BW per PRU (96 h)	R^2 [b] (96 h)
HPMC K4M	4196	188	7.1	0.996	4.5	0.973
HPMC F4M	5218	187	3.2	0.968	5.4	0.993
HPMC E4M	3970	190	6.2	0.974	5.6	0.966
MC A4M	3811	177	5.3	0.999	3.8	0.988
HPC	5950	171	5.5	0.983	6.1	0.990

bound water. If this theory is indeed correct, the amount of nonfreezing bound water in HPC gels would be quite high.

3.2 Quantitative Analysis of the Effect of Substitution Type on Water Distribution within Cellulose Ethers—The number of moles of bound (nonfreezing) water per polymer repeating unit (PRU) was calculated for HPMC K4M, HPMC E4M, HPMC F4M, MC A4M, and HPC according to the method outlined by Ford and Mitchell.[15] The PRU value for each polymer was calculated as previously decribed,[13] and they are in Table 3 along with the values for bound water after both 24 and 96 h storage.

HPMC K4M, HPMC E4M, and MC A4M all showed a decrease in their bound water content from 24 to 96 h storage, whereas HPMC F4M and HPC showed an increase in their bound water content during this equilibration period. Considering the bound water content after 96 h to be the equilibrium of the water distribution within these gels, MC A4M has the lowest bound water content compared to other substitution types. This may be due to the fact that MC A4M contains a high hydrophobic methoxyl (29.9%) with no hydrophilic hydroxypropoxyl substitution. A high methoxyl substituent content will not favor large amounts of water binding to the polymer. Previous studies have shown that methoxyl substituent levels are the major factor in causing an apparent decrease in cellulose ether solubility and causing precipitation of the polymer in cloud-point studies.[9]

After 96 h equilibration time, HPC had a high bound water content. HPC contains only hydroxypropoxyl substituents, and a large value for bound water content after equilibration would be expected. This was thought to be the reason for the nonappearance of pre-endothermic events in the DSC scans of HPC gels (Figure 3), indicating that only tightly bound water was present which were not detectable by DSC.

It is reported that HPMC K4M, having a similar hydroxypropoxyl constituent to HPMC E4M, but with smaller

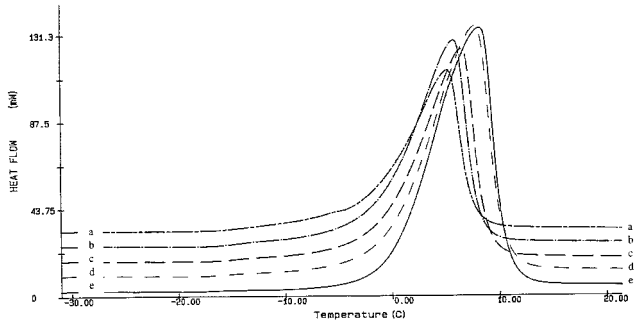

Figure 4—DSC scans of HPMC F4M (5–25% w/w) gels containing 50 mM of propranolol hydrochloride obtained by heating at +10 °C min^{-1} after cooling at –10 °C min^{-1} following storage for 24 h: (a) 5%, (b) 10%, (c) 15%, (d) 20%, (e) 25% (w/w) HPMC F4M + 50 mM propranolol hydrochloride.

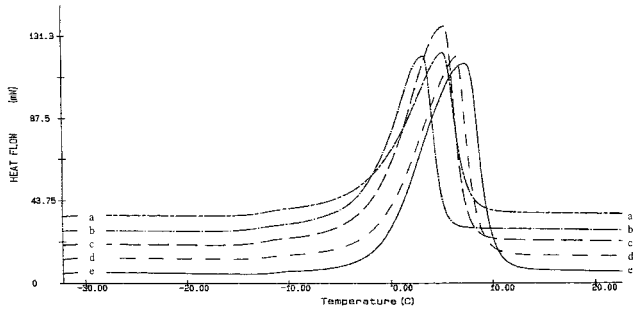

Figure 5—DSC scans of MC A4M (5–25% w/w) gels containing 50 mM of diclofenac sodium obtained by heating at +10 °C min^{-1} after cooling at –10 °C min^{-1} following storage for 24 h: (a) 5%, (b) 10%, (c) 15%, (d) 20%, (e) 25% (w/w) MC A4M + 50 mM diclofenac sodium.

methoxyl substituent levels than HPMC E4M, HPMC F4M, or MC A4M, is more water soluble[5] and undergoes precipitation at higher temperatures than polymers of other substitution types.[9] This may explain the high value for bound water content (7 mol BW per PRU) for HPMC K4M after 24 h storage. However, this high bound water content is not reflected after 96 h storage.

3.3 Effect of Drug Addition on Water Distribution in Cellulose Ether Polymer Gels—In the absence of drug, pre-endothermic events were very slight or not visible in 5−25% w/w HPMC F4M and HPC gels after 24 h equilibration (section 3.2). Figure 4 shows that incorporation of propranolol hydrochloride (50 mM) resulted in the appearance of such events in HPMC F4M gels at concentrations of 15, 20, and 25% w/w. However, no pre-endothermic events were visible in 5−25% w/w HPC gels after incorporation of propranolol hydrochloride (50 mM).

Propranolol hydrochloride addition had no effect on pre-endothermic events in HPMC K4M, HPMC E4M and MC A4M gels after 24 h equilibration with such events being visible in 20 and 25% w/w gels both in the absence or presence of the drug.

Figure 5 illustrates how incorporation of diclofenac sodium into gels resulted in the appearance of pre-endothermic events in 5−25% w/w MC A4M gels. Pre-endothermic events were visible in 5−25% w/w HPMC K4M, HPMC E4M and HPMC F4M gels at all concentrations studied. In HPC gels, however, no pre-endothermic events were visible after addition of diclofenac sodium at any gel concentrations between 5 and 25% w/w.

DSC analysis of 27.3−48.2% w/w HPC gels (with no drug addition) revealed that, even at high concentrations, only a small secondary event was visible at concentrations greater than 30% w/w (section 3.1). In addition, in HPC gels greater than 25% w/w, containing 50 mM of propranolol hydrochloride, pre-endothermic events were barely visible and were similar to the events observed in HPC gels

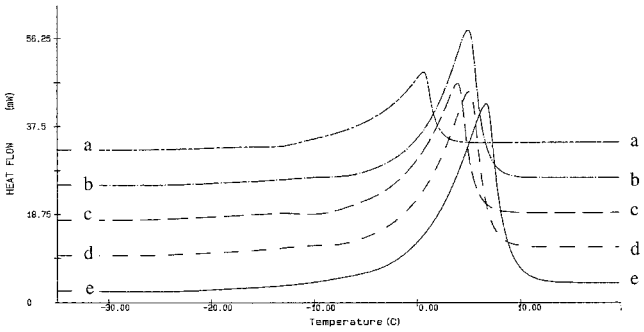

Figure 6—DSC scans of HPC (23.1–32.8% w/w) gels containing 50 mM of diclofenac sodium obtained by heating at +10 °C min^{-1} after cooling at −10 °C min^{-1} following storage for 24 h: (a) 23.1%, (b) 24.9%, (c) 25.3%, (d) 30.0%, (e) 32.8% (w/w) HPC + 50 mM diclofenac sodium.

Table 4—The Effect of Addition of 50 mM of Propranolol Hydrochloride or Diclofenac Sodium on the Water Distribution within a Range of Cellulose Ether Gels after 24 h Equilibration

polymer	viscosity grade (cP)	polymer (% w/w)	water (% w/w)	regression coefficient (R^2)	moles bound water per PRU
HPMC K4M	4196	59.6	40.4	0.996	7.1
+ propranolol		79.4	19.2	0.997	2.5
+ diclofenac		65.4	33.1	0.987	5.3
HPMC F4M	5218	76.4	23.6	0.968	3.2
+ propranolol		76.3	22.2	0.986	3.0
+ diclofenac		83.3	15.3	0.992	1.9
HPMC E4M	3970	63.1	36.9	0.974	6.2
+ propranolol		71.3	27.2	0.951	4.0
+ diclofenac		67.9	30.6	0.958	4.8
MC A4M	3811	65.1	34.9	0.999	5.3
+ propranolol		77.4	21.2	0.995	2.7
+ diclofenac		71.8	26.8	0.998	3.7
HPC	5950	61.6	38.4	0.983	5.5
+ propranolol		67.4	31.1	0.981	4.4
+ diclofenac		63.4	35.2	0.984	5.3

in the absence of drug over a similar concentration range. In contrast, Figure 6 shows that pre-endothermic events are clearly visible in HPC gels containing diclofenac sodium in the 25−35% w/w concentration range. These pre-endothermic events may indicate the presence of loosely bound water which has resulted from the "salting-out" effect of diclofenac sodium.

The number of moles of bound water per PRU were calculated as previously described using the Ford and Mitchell[15] method, and the values chosen for the PRU are as listed in Table 3. In all cases, propranolol hydrochloride reduced the amount of water bound to the polymer (Table 4), i.e., less water was required to fully hydrate the polymer, most likely due to its "salting in" effect. No particular trend was apparent in the extent to which the amount of bound water was reduced by propranolol hydrochloride among the polymers studied. In contrast, diclofenac sodium has a "salting out" effect on cellulose ether polymers. With the exception of HPMC F4M, more water was required to fully hydrate the polymer compared to when propranolol hydrochloride was added.

Differences in the bound water content of polymer gels of different substitution types were previously explained by the degree of substitution of hydrophilic and hydrophobic substituents on the polymer backbone (section 3.2). The bound water content of HPMC F4M in the absence or presence of drug did not follow the pattern shown by other polymer gels studied here. HPMC F4M would be expected to have a fairly low bound water content on the basis that it has a high methoxyl substitution level (28.9%) combined with a low hydroxypropoxyl substitution level (6.1%). This is found to be the case; however, while propranolol hydrochloride exhibits its "salting in" effect, diclofenac sodium does not show its "salting out" properties as in other polymers. A different mechanism may be operating in this case which requires further exploration.

4. Conclusions

Polymer substitution type is an important factor in the distribution of water within cellulose ether polymer gel systems. Polymers of different substitution types possess different degrees of hydrophilic and hydrophobic substitution, and it is thought that these substituents influence the way water attaches itself to the polymer. Pre-endothermic events occurring to the left of the main melting endotherm for the melting of free water in DSC scans, thought to be due to the melting of water loosely bound to the polymer, were dependent on polymer substitution type. HPC gels behaved differently in comparison to the HPMC and MC polymers studied.

The amount of water tightly bound to the polymer, as calculated by the Ford and Mitchell[15] method, was dependent on polymer substitution type. Drug addition influenced both the amount of water bound to the polymer and the appearance of pre-endothermic melting events.

Abstract □ Drug partitioning to liposomes has been suggested as a model for partitioning to biomembranes but has been lacking a rapid analytical assay useful for drug screening. A fast pH-metric titration method for the determination of liposome partitioning of ionizable drugs using small unilamellar phosphatidylcholine vesicles prepared by sonic homogenization has been successfully developed, enabling the use of high lipid-to-drug ratios. Liposome–water partition coefficients of diclofenac and propranolol were determined to study the impact of varying titration parameters, temperature, equilibration time, lipid, and liposome types on the partitioning. To validate this method, the results were compared to literature values generated with different techniques and to pH-metric titration results with large unilamellar vesicles. The rapid pH-metric assay gave liposome partitioning data for the two model compounds which were consistent with other analytical techniques and liposome types.

Introduction

Partitioning between phospholipid bilayer vesicles and water has been suggested as a better model for predicting the passive diffusion of drug molecules through biomembranes than partitioning between organic bulk solvents and water.[1−4] In contrast to octanol and other water-immiscible solvents no bulk phase separation between aqueous and organic component occurs in liposome systems. Therefore, standard spectrophotometric techniques cannot be routinely applied to measure drug partitioning in liposomes. The combination of equilibrium dialysis with radiotracer assays has been successfully used to measure partitioning at drug concentrations far below saturation of the lipid and can therefore be regarded as a gold standard for the determination of liposome partitioning.[5] However, this method fails to be useful as a routine method.

Approximately 75% of all drugs are bases, 20% are acids, and less than 5% are nonionic.[6]

The Sirius semiautomated pH-metric logP titration equipment offers a less cumbersome means of generating liposome partitioning data on a routine basis.[7] The impact of titration variables on pH-metric partitioning results with liposomes has been largely unknown and is studied here (e.g., temperature, titration direction, equilibrium time, pH-range). The liposomes are tested for titratable impurities as could, for example, be generated by hydrolysis of phospholipids.

The choice of lipid is studied together with the impact of different liposome preparation techniques and resulting vesicle sizes.

The major components of biomembranes such as intestinal brush border membranes are phospholipids, neutral lipids, and proteins. The bilayer has been suggested to be the primary barrier to passive transcellular drug absorption. A contribution of membrane-based proteins to this mode of absorption has not been reported. The molar ratio of rabbit brush border membrane lipids is reported to be 1:1:1 (neutral:phospholipid:glycolipid).[8] The distinct bilayer configuration of the zwitterionic phosphatidylcholine in vesicles appears to mimic the interfacial character as well as the ionic, H-bond, dipole−dipole, and hydrophobic interactions which may define partitioning in real biomembranes. The impact of cholesterol, the most important neutral membrane lipid, is discussed later on.

Small unilamellar vesicles are prepared by sonication, allowing for particularly high lipid concentrations (e.g., 100 mg phospholipid/mL) and consequently for high molar phospholipid/drug ratios (above 100), avoiding saturation of phospholipid with drug. The minimal vesicle size should provide for a maximum surface area, allowing for minimal partitioning equilibrium times. Also, this type of liposome can be prepared with simple lab equipment in sufficient quality and in short time. pH-metric partitioning data from sonicated small unilamellar vesicles (S-SUV) are compared to reference values from small unilamellar vesicles as prepared by equilibrium dialysis (ED-SUV) and other published data. Furthermore, they are compared with other partitioning data obtained by the Sirius pH-metric technique with large unilamellar vesicles prepared by a freeze and thaw technique (FAT-LUV).

Experimental Section

Materials—Diclofenac sodium and propranolol hydrochloride were obtained from Sigma. Cholesterol was obtained from Fluka (Sigma Chemie Vertriebs GmbH Deisenhofen, Germany). Epikuron200 (Soy-PC: >92% glycerophosphocholine esters with various mainly unsaturated fatty acids, <3% lyso-phosphatidylcholine, <2% other phospholipids, <0.8% water, <2% oil, and <0.2% α-tocopherol) was provided by Lucas Meyer GmbH (Hamburg, Germany). Linoleic acid was the predominant fatty acid of the 70−80% of unsaturated fatty acids. Lipoid PC 18:1; 18:1 containing 98.5% dioleoylphosphatidylcholine (DOPC) was obtained from Lipoid GmbH (Ludwigshafen, Germany). Potassium chloride, HCl−Titrisol, and KOH−Titrisol were purchased from Merck KGaA (Darmstadt, Germany).

Liposome Preparation—S-SUV Liposomes were prepared as follows: 1.6 g of phospholipid was dissolved in a small amount of methanol in a 200 mL round-bottom flask. A solid phospholipid film was formed by vacuum evaporation of methanol at 50 °C using a rotary evaporator. As determined by thermogravimetry, the resulting film contained less than 5% volatiles after 30 min of vacuum drying. The phospholipid film was dispersed with 14.4 mL of a 0.15 M potassium chloride solution resulting in a phospholipid concentration of 100 mg/mL. A 15 mL aliquot of this phospholipid dispersion was sonicated for 20 min in a Sirius-titrator vial using a Bandelin Sonopuls HD70 sonifier equipped

with a TT13 sonotrode (Bandelin Electronic GmbH, Berlin, Germany) at 50% amplitude setting with argon purge and cooling with ice−water.

Vesicle Size—The size of the SUV liposomes was measured by photon correlation spectroscopy with a Coulter N4 Plus at 90° angle and 600 s sample time. The evaluation of the results could be limited to a range from 5 to 500 nm. Samples were diluted with 0.2 μm filtered 0.15 M KCl solution to reach 10^5 to 10^6 counts per second. Liposomes were not filtered to avoid artifacts.

Determination of Partition Coefficients—Titrations were performed on PCA101 and GLPKA automatic titrators (Sirius Analytical Instruments Ltd., Forest Row, UK). All titrations were carried out in the pH range between 3.5 and 10.5. Alkalimetric titrations from pH 3.5 to 10.5 were called "up-assay", and acidimetric titrations from pH 10.5 to 3.5 were called "down-assays" and differed only with respect to titration direction. In this pH range drug concentrations >0.4 mM were required. After sonication, the liposome dispersion was added manually to the weighed diclofenac sodium or propranolol hydrochloride samples in 20 mL vials. Different volume ratios of lipid dispersion and water were adjusted according to the scheme in Table 1 by automatic addition of 0.15 M KCl solution. A partial density of 1.0 g/mL for aqueous KCl solution and for the phospholipid[9] in the liquid-crystalline state was used for the calculation of the lipid to water volume ratio. For the comparison of S-SUV and FAT-LUV vesicles, the mixtures were constituted according to Table 2. Samples were stirred until complete dissolution of the drug. The resulting diclofenac−liposome solutions had a pH of 7, and the propranolol−liposome solutions a pH between 5.6 and 6.6. Then the pH was adjusted automatically to the start pH of the titration at pH 10.5 or 3.5. The maximum titrant volume increment for one titration step was limited to 0.01 mL. The pH change per titrant addition was limited to 0.2 pH units. Typically, more than 30 pH readings were collected from each titration. The pH values were recorded when the pH-drift was lower than 0.01 pH per minute. The titration time was between 20 and 60 min for low and high lipid concentrations, respectively. Argon purge was applied to all titrations. Processing of titration data was carried out using the PKALOGP version 5.01 software (Sirius Analytical Instruments Ltd., Forest Row, UK). Final partitioning results log $P_{neutral}$ and log P_{ion} were calculated from titrations at different lipid concentrations including at least the two extremes of the lipid-to-drug ratio. A detailed description of the pH-metric log P method can be found elsewhere.[7,10,11]

Results and Discussion

The impact of assay conditions on drug partitioning into small unilamellar soybean phospholipid bilayer vesicles was studied in detail and is discussed in the following paragraphs. Table 3 shows the impact of different assay parameters on the partitioning of neutral and anionic diclofenac and neutral and cationic propranolol. Table 4 shows the results of a study on titratable lipid impurities measurable at the assay conditions. Table 5 shows the comparison of results as generated with the preferred titrimetric assay conditions (see line 2) with results of different liposome and lipid types and analytical techniques. Table 6 shows the results of a reproducibility study.The chemical structures and pK_a values of the neutral species of the two model drugs are shown in Figure 1.

Direction of Titration—The neutral species of diclofenac and propranolol showed no significantly different partitioning for down-titrations. The partitioning of the propranolol cation was found to be reduced by 0.5 log units for the down-titration while no different partitioning was found for the diclofenac anion (see Table 3, columns 1 and 2). The data quality of the results obtained from the down assays was generally better and resulted in smaller errors for the calculated partition coefficients. For this reason the down-assay was selected for routine measurements.

Lipid−Drug Ratio—Columns 2−4 of Table 3 show the differences of partitioning results when calculated based on four titrations covering lipid−drug ratios from 3 to100 or based on three titrations at lipid−drug ratios 3−40 or 10−100. We found no significant differences in the final results when ratios as small as 3 were used together with high ratios.

Temperature—The application of the pH-metric technique to liposome partitioning did not show any evidence for analytical problems or critical liposome instabilities at 37 °C so that this physiologic temperature can be used for routine application. Also, the higher temperature should accelerate the adjustment of the partitioning equilibrium. No significant partitioning differences were found for the different ionic species of the two model drugs at standard laboratory temperature 25 °C and physiologic temperature 37 °C (see Table 3, columns 2 and 5). The pK_a of propranolol was shifted to a significantly lower basicity at the higher temperature, which is typical for many bases, and points out the necessity to evaluate the partitioning and pK_a at the same temperature (see Figure 1).

Equilibration Time—The results of titrations with 3 h extra equilibration time before starting the titration are shown in Table 3. The partitioning of the propranolol species remained unchanged. The partition coefficients of diclofenac acid and anion rose by 0.4 and 0.5 log units, respectively. Another assay variation included a 2-min delay time after each titration step. The additional equilibration time during the assay led to nonsignificant changes of partitioning results. The minimal impact of the additional delay time suggests such a prolongation of the assay is not necessary for a rapid and continuous titration.

Titration pH-Range—The usable pH-range for titrations with phospholipids is limited by ionizable functions in the liposomes and degradation of phospholipids at extreme pH-values. It was found that the ionization of the lipid phosphate disturbs the assay at a pH lower than 3.5. The upper limit of the titration pH-range is defined by increasing hydrolytic degradation of phosphatidylcholine to titratable free fatty acids. Typically, the pH of the sample dissolved in liposome dispersion is approximately neutral. The automatic titration program quickly approaches the acidic or alkaline start pH and approaches the neutral region again after 10 to 30 min depending on the lipid and sample concentration. Consequently, the liposome stressing conditions at extreme pH-values prevail only shortly. With start pH-values not higher than 10.5, assays could be evaluated without major disturbance by generated degradation products or other artifacts.

[a] The pH-titration was performed either from pH 3.5 to 10.5 "up" or in the opposite direction "down". "Range [lipid]:[drug]" gives the range of lipid ratios of Table 1 which were used for the multiset calculation of final log *P* results as listed in the lower section of the table.

Table 4—Titratable Impurities[a]

lipid (g)	total volume (mL)	approx pK_a of impurity	concn (mM)	mol % (impurity/total lipids)
0.025	20	6.4	0.042	2
0.1	15	6.8	0.074	1
0.2	8	6.7	0.192	0.6
1.0	20	6.8	0.185	0.3

[a] The molar fraction of titratable impurity was calculated as oleic acid (mw 282).

Titratable Impurities—An impurity, probably a fatty acid with an apparent pK_a at 6.8,[12] could be detected in blank titrations containing only the phospholipid vesicles without any drug compound. Blank titrations were carried out at 37 °C as down-assays (see Table 4). The calculated concentrations of impurity for the assays with high phospholipid concentrations were more reliable than those at lower phospholipid concentrations since concentrations of impurities below 0.1 mM were likely to be too low to be determined exactly. Partitioning of drugs into phospholipid bilayers has been reported to be influenced by concentrations of free fatty acids above 10%.[13] The direct influence of acidic impurities on the titration curves can be corrected by the refinement of data. Although the start of the titrations at pH 10.5 may increase the formation of these hydrolysis products, the measured free fatty concentration was still below the concentration reported for biological membranes.[8] High free fatty acid values should be interpreted carefully as membrane preparation techniques could also lead to phospholipid decomposition. Generally nonsaturated phospholipids such as soybean phospholipids are susceptible to autoxidation and might form peroxides. For minimizing oxidation, the sonication was carried out under argon at low temperature, and the titration was performed under argon. The titration of an aged liposome dispersion (8 h at 25 °C) did not show additional titratable impurities so that oxidation of the phospholipid is regarded to be insignificant.

Lipid Selection—The liposomes in this study were prepared from a purified soybean phosphatidylcholine so that titratable biomembrane constituents such as free fatty acids, phosphatidylethanolamine, and phosphatidylserine were minimized. The pattern of predominantly unsaturated fatty acids in soy-phospholipids provides for a fluid bilayer structure at 25 °C or higher temperatures. Compared to pure, chemically defined phospholipids such as dioleoylphosphatidylcholine (DOPC), which consists of >98.5% DOPC, phospholipids of natural origin have the advantages of a fatty acyl chain composition similar to biomembranes and low price. No significant differences were found for the partitioning of neutral propranolol and diclofenac to Soy-PC and DOPC liposomes. In contrast, the difference (Soy-PC-DOPC) was up to 0.8 for the diclofenac anion and 0.5 for the propranolol cation. However, the partitioning results for propranolol in Soy-PC/S−SUV were found to be closer to the reference results based on Egg-PC/ED-SUV than those based on DOPC/S−SUV or DOPC/FAT-LUV.

Influence of Cholesterol—Small unilamellar vesicles with cholesterol were made from a 1:1 molar mixture of Soy-PC and cholesterol.[14] The presence of cholesterol in liposomes decreased partitioning for all species, but the decrease for the diclofenac anion may not be significant (see below). The difference between log $P_{neutral}$ and log P_{ion} (Δ (neutral−ion)) was not significantly changed compared to cholesterol-free liposomes (see Table 3). A similarly significant decrease of partitioning with raising cholesterol concentrations in a bilayer was reported for nimodipine by Mason et al.[15] The titrimetric measurement of partitioning to cholesterol containing vesicles appears to be viable and may lead to further refined assay procedures.

Effect of Vesicle-Size—The size determination of the Soy-PC-S-SUV liposomes yielded a mean diameter of 32 ± 2 nm resulting in a vesicle surface area of approximately 35 m^2 per 100 mg of lipid. In contrast, the FAT-LUV technique leads to larger liposomes with a diameter of approximately 100 nm.[7] For the neutral species, no significant changes in partitioning were observed for different vesicles sizes (see Table 5). The diclofenac anion partitioning was decreased in small vesicles by 0.4 log units in DOPC and Soy-PC. The propranolol cation partitioning was decreased by. 0.5 log units in DOPC. The decrease of ion partitioning with lower vesicle size was found to be slightly smaller for Soy-PC based vesicles compared to DOPC. Small vesicles with their stronger curvature have been regarded as a less celllike membrane model than larger liposomes. On the other hand, the measurement in highly concentrated small vesicle dispersions allows for measuring at higher lipid concentrations, higher lipid/drug ratios, and maximum interfacial surface area. This benefit may outweigh the impact of higher artificial curvature.

Reproducibility—The reproducibility of titrimetric liposome partitioning results was assessed at 25 °C based on down-titration results at four different lipid concentrations according to Table 1 which were generated by three operators in two different labs. The results of each four-titration set were fitted to obtain one weighted average partition coefficient for the different ionic species of the two test compounds as listed in Table 6. The high reproducibility of the partitioning results could be achieved despite some differences in equipment, e.g., new versus old sonifier. The standard deviation (SD) was highest for the neutral diclofenac and minimal for its anionic species. We estimate that partitioning differences between two datasets as

calculated from four titrations at different lipid concentrations may not be significant if they do not exceed ±0.3 log units.

Comparison with Available Partitioning Data—The results obtained with the S-SUV in potentiometric titrations were in good agreement with literature results of membrane partitioning. Equilibrium dialysis results for propranolol liposome partitioning were used as the reference of the first choice. Good agreement could be achieved at 37 °C without any extra equilibrium time (see lines 2 and 6, Table 5). For these experimental conditions, the same partition coefficient was determined for the neutral species of propranolol. The partition coefficient of the cation determined by titration was 0.3 log units lower compared to the equilibrium dialysis result which may not be significant. In ref 16, partitioning results were given for pH 7.4 where propranolol is almost completely present in the cationic form. In the octanol–water partitioning system, drastically smaller partition coefficients have been determined for the ionic species of diclofenac and propranolol.

Conclusions

The use of sonicated small unilamellar vesicles made of soybean-PC as a biomembrane partition model in a pH-metric titration assay was studied with various assay settings. The titrimetric results for the partitioning of propranolol to sonicated small vesicles were in good agreement with results generated with an equilibrium dialysis/radiotracer method at a high lipid-to-drug ratio. Titrimetric partition results measured with S-SUV were also comparable to those obtained with large unilamellar vesicles made by an extrusion technique.

Small unilamellar vesicles made by sonication combine several advantages for its use as a rapid partitioning assay. The production process allows testing at lipid concentrations as high as 100 mg/mL. Therefore partitioning assays can be run at high lipid-to-drug ratios to avoid saturation of lipid with drug. They can also be prepared with simple lab equipment in a short time. Furthermore, partitioning to small vesicles of soybean-PC differed only slightly for minimally from large vesicles despite their more pronounced curvature. The use of pure DOPC instead of soybean-PC did not lead to more relevant partitioning results or other advantages. Since soybean-PC consists of a mixture of acyl-glycerophosphocholines, it should be closer to the composition of biological membranes than pure DOPC. On the basis of the results discussed above, partitioning data to small unilamellar soybean-PC vesicles can be utilized as a potential membrane model and may have advantages over other vesicles. Higher possible lipid concentrations, simple preparation, and low cost of phospholipid make this method attractive as a standard screening procedure. Data generated by this titrimetric assay have been successfully utilized for a correlation of intestinal drug absorption with dose, solubility, and liposome partitioning.[16]

Glossary

S-SUV	Small unilamellar vesicles generated by sonication
ED-SUV	Small unilamellar vesicles generated by equilibrium dialysis
FAT-LUV	Large unilamellar vesicles generated by equilibrium dialysis
Soy-PC	Soybean phosphatidylcholine, purified
MLV	Multilamellar vesicles
DOPC	Dioleoylphosphatidylcholine

Accepted for publication April 30, 1999.

Abstract □ A method for the rapid computation of polar molecular surface area (PSA) is described. It is shown that consideration of only a single conformer when computing PSA gives an excellent correlation with intestinal absorption data—as good as previously reported methods employing multiple conformers. Circumventing a time-consuming conformational analysis opens the possibility of computationally screening large numbers of compounds for problems relating to absorption prior to synthesis. The robustness of the criterion for identifying poorly absorbed compounds (PSA $\geq$ 140 Å^2) is illustrated through its application to a diverse test set of 74 drugs. The PSA-based method is also compared to an experimental method for absorption prediction recently described in the literature.

Introduction

In recent years, the pharmaceutical industry has come under increasing pressure to reduce the time that is required for the discovery and development of novel therapeutics. The advent of combinatorial chemistry and high-throughput screening methodologies has brought with it the ability to synthesize and evaluate orders of magnitude more compounds than has been possible using traditional means. However, these new high-throughput techniques alone do not provide the means to faster drug discovery. Increasingly, researchers have become aware that it is not merely the *number* of compounds made and tested that is important; the *nature* of those compounds is just as vital.

In particular, the focus of drug discovery is now not simply on achieving the best possible potency against the biological target of interest, but also on seeking favorable ADME (absorption, distribution, metabolism, and excretion) properties and performing these two tasks in parallel, rather than in sequence.[1−4] The emphasis is now on "failing fast", i.e., weeding out compounds with poor physicochemical properties early in the drug discovery phase, thereby saving both time and expense.

To this end, a battery of in vitro experimental methods has arisen to help screen candidate molecules for their ADME characteristics.[1,5] Of particular note are Caco-2 monolayers for predicting in vivo intestinal absorption[6,7] and systems for the evaluation of metabolic susceptibility employing human liver microsomes, hepatocytes, or recombinant P450 isozymes.[8] The use of artificial membranes for evaluating absorption processes has also been recently reported.[9] More rapid in vivo tests are also being developed such as "cassette" dosing protocols in which multiple compounds are administered in a single dose to a single animal.[10] However, all these techniques require the synthesis of the compounds to be tested. Even more time and effort could be saved if it were possible for computational techniques to assess reliably compounds for ADME properties prior to synthesis and to identify those likely to be problematic. Such problem compounds could then be rejected or assigned a reduced priority for synthesis. For this reason, several groups have developed computational screening methods seeking to distinguish between druglike and nondruglike compounds in a general sense.[11−13]

For most drugs, the preferred route of administration is by oral ingestion. Researchers have therefore sought to delineate the physicochemical properties that favor intestinal absorption[14,15] and to develop computational methods for its prediction. The so-called "rule-of-5" has proved very popular as a rapid, if approximate, screen for compounds likely to be poorly absorbed.[16] This rule states that if a compound satisfies any *two* of the following rules, it is likely to exhibit poor intestinal absorption:

- Molecular weight > 500
- Number of hydrogen bond donors > 5 (a donor being any O−H or N−H group)
- Number of hydrogen bond acceptors > 10 (an acceptor being any O or N including those in donor groups)
- Calculated log P > 5.0 (if ClogP[17] is used) or > 4.15 (if MlogP[18] is used)

Wessel et al.[19] recently reported the generation of a QSPR (quantitative structure−property relationship) model from a training set of 76 compounds with human fractional absorption (%FA) data using a genetic algorithm with a neural network scoring function. The errors (RMSE) in prediction from this model were 9.4% for the training set and 16.0% for the test set of 10 compounds. Another regression-based approach was described by Hirono et al.;[20] however, their work used oral bioavailability data which may include metabolism effects and so cannot be compared directly to intestinal absorption.

Polar Surface Area

The use of molecular surface areas in the modeling of solvation and partitioning processes has a long history.[21,22] More recently, approaches to absorption prediction have been developed that involve a quantity derived from the molecular surface known as the *polar surface area* (PSA). The PSA of a molecule is defined as the area of its van der Waals surface that arises from oxygen or nitrogen atoms or hydrogen atoms attached to oxygen or nitrogen atoms. As such, it is clearly related to the capacity of a compound to form hydrogen bonds. One study relating PSA to

10.1021/js9804011 CCC: $18.00
Published on Web 06/22/1999

intestinal absorption was that of van de Waterbeemd et al.,[23] in which a quantitative structure−absorption relationship was derived for the passage of 17 compounds across a Caco-2 monolayer:

$$\log P_{app} = 0.008(\pm 0.002)\mathrm{MW} - 0.043(\pm 0.008)\mathrm{PSA} - 5.165(\pm 0.605) \quad (1)$$

where $\log P_{app}$ is the logarithm of the apparent permeability through the monolayer (in cm/s), and MW is the molecular weight of the compounds. The standard errors of the regression coefficients are given in parentheses. The correlation coefficient for this equation was $r = 0.833$ ($r^2 = 0.694$).

The method used by van de Waterbeemd et al.[23] to calculate PSA considered only a single conformation of the molecules concerned. By contrast, Palm and co-workers employed a measure termed the "dynamic" PSA (PSA_d), which is a Boltzmann-weighted average value computed from an ensemble of low-energy conformers obtained by a detailed conformational search.[24] This kind of Boltzmann averaging of molecular surface areas seems to have been used first by Hermann in the modeling of hydrocarbon solubility[21] and has been applied more recently by Lipkowitz et al.[25] in a study of weakly bound diastereomeric complexes. In their work, Palm et al. showed that PSA_d correlated well with intestinal absorption, in terms of both measurements of Caco-2 monolayer permeability[24] and the fraction absorbed (%FA) in humans.[26] In the former case, the correlation between PSA_d values and Caco-2 absorption was $r^2 = 0.99$. In the latter study on 20 carefully selected drugs, a sigmoidal fit with an $r^2 = 0.94$ (RMSE = 9.2%) was obtained. From this sigmoidal curve, Palm et al.[26] suggested that molecules with a PSA_d of ≥ 140 Å^2 should exhibit a %FA of < 10% and that this PSA_d value could therefore be used to identify poorly absorbed compounds prior to synthesis. Conversely, completely absorbed molecules (%FA > 90%) exhibited PSA_d values of ≤ 60 Å^2.

Palm et al.[24] argued that their PSA_d measure, by taking account of multiple low-energy conformations, should give a better description of molecular surface properties than methods that consider only a single conformer. A similar argument has been advanced recently by Krarup and co-workers[27] who developed a PSA_d measure similar to that described by Palm et al.,[24] but using the solvent-accessible, rather than the van der Waals, molecular surface. The difficulty with these "dynamic" methods from a practical point of view is that they are very computationally expensive. To carry out a conformational search with energy minimization for even a moderately flexible small molecule can take several hours of CPU time on a modern workstation. Clearly, a dynamic PSA calculation becomes impractical if one wants to consider more than just a few molecules on a routine basis. Furthermore, from a theoretical viewpoint, the use of gas-phase conformational energies to calculate the Boltzmann-averaged PSA_d value might be questioned on the grounds that, in solution, solvation effects could significantly alter the relative energies of the conformers. To counter this latter argument, it should be noted that a recent paper by Palm et al.[28] showed that, for most of the set of nine beta-blockers studied, the simulation environment (gas phase, water, or chloroform) had only a small effect on the value of PSA_d.

Despite being advocates of a "dynamic" approach, it is noteworthy that both Palm et al.[24] and Krarup et al.[27] concede that good correlations with absorption can be obtained by just considering a single conformation. To quote from the former: "Surprisingly, the correlations between the surface properties of the global minimum conformations and the permeability were *only slightly poorer* [my italics] than the correlations obtained with the dynamic properties".[24] In the work of the latter group,[27] an excellent correlation ($r^2 = 0.98$) with absorption was discovered using just the (extended) starting conformation for the molecular dynamics simulation. These observations accord with earlier work by Pearlman[22] who demonstrated that single conformation-based surface areas could be as effective as the Boltzmann-averaged areas described by Hermann[21] for the modeling of the free energy of cavity formation. These results encouraged us to investigate in more detail the use of calculations of PSA, from just a single conformer, for the prediction of intestinal absorption. If reliable predictions could be made on this basis, it would open the way for the rapid prescreening of large compound collections or combinatorial libraries to eliminate molecules likely to show poor absorption characteristics. These compound sets might already be in existence, perhaps being considered for purchase from an external source, or they could be *virtual*, i.e., not yet synthesized but represented in a computer-readable form. In either case, a computational procedure for assessing absorption in a reasonable time scale would be of great utility in the drug discovery process.

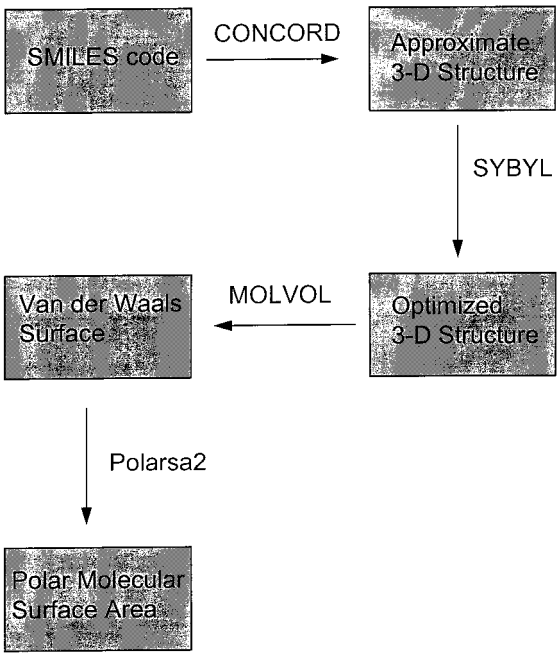

Figure 1—Flowchart of computational procedures.

In the remainder of this paper, the computational methods we have developed will be detailed. Following that, we shall demonstrate their performance first on the training set used by Palm et al.[26] and then on a larger test set drawn from the work of Wessel et al.[19] We shall also compare the results of our method with those of the experimental system developed by Kansy and co-workers.[9] After a discussion of the results obtained to date, some future directions for research in this area will be postulated. The paper immediately following this one will describe the further use of PSA calculations for the prediction of blood-brain partitioning.

Computational Methods

A flowchart of the computational processes employed in this work is given in Figure 1. In detail, the steps are as follows:

1. The molecule is encoded as its neutral species in SMILES[29] format with appropriate stereochemical designations where the stereochemistry is known.

Table 1—Data for the Set of Compounds from Palm et al[26]

compound	PSA/Å^2	PSA$_d$/Å^2	%FA	rule-of-5 status
metoprolol	57.2	53.1	100	pass
nordiazepam	47.5	45.1	99	pass
diazepam	34.5	33.0	97	pass
oxprenolol	53.2	46.8	97	pass
phenazone	28.0	27.1	97	pass
oxazepam	55.6	66.9	97	pass
alprenolol	41.8	37.1	96	pass
practolol	77.2	73.4	95	pass
pindolol	60.9	56.5	92	pass
ciprofloxacin	80.1	78.7	69	pass
metolazone	95.9	94.5	64	pass
tranexamic acid	71.5	69.2	55	pass
atenolol	93.3	90.9	54	pass
sulpiride	101.4	100.2	36	pass
mannitol	129.6	116.6	26	pass
foscarnet	117.3	115.3	17	pass
sulfasalazine	148.6	141.9	12	pass
olsalazine	147.0	141.0	2.3	pass
lactulose	197.8	177.2	0.6	warning
raffinose	266.8	242.1	0.3	warning

2. The program CONCORD[30,31] is used to convert the SMILES representation into an approximate 3-D structure.

3. This conformation is then energy-minimized to relieve any close steric contacts using the maximin2 minimizer in SYBYL.[32] Minimization is terminated after either 1000 iterations or when a gradient of less than 0.05 kcal/(mol.Å) is attained.

4. The minimized conformation is passed to the MOLVOL program developed by Dodd and Theodorou.[33] MOLVOL computes the van der Waals molecular surface area for the conformation and outputs the contributions of the individual atoms to the surface area.

5. Finally, an in-house Fortran program, Polarsa2, sums the contributions of the polar atoms (N, O, and H attached to N or O) and outputs the PSA value.

It should be noted that this procedure is entirely automated by means of a C-shell script and so large numbers of molecules can be processed in batch. An intranet-based interface is also available for medicinal chemists to calculate PSA-based predictions of absorption and blood-brain barrier penetration on single molecules. Typically, the CPU time required to process a compound is of the order of 10−15 CPU seconds (SGI R10000 workstation), most of this time being required for the energy minimization step (which can be curtailed if very large numbers of molecules are to be processed). This efficiency of calculation enables the processing of large sets of compounds, particular virtual combinatorial libraries, in a realistic time frame.

Results

Training Set—The 20 drug molecules studied by Palm et al.[26] were encoded as SMILES and processed in batch using the procedure described above. The CPU time required for this was 138 s (SGI R10000 processor). The resulting PSA values are shown in Table 1, along with the PSA$_d$ and %FA values taken from Palm et al.[26] and the status of the compounds according to the rule-of-5. The fit of the single conformer PSA values to the %FA data using a Boltzmann sigmoidal curve[34] is shown in Figure 2. The statistics for this fit ($r^2 = 0.94$, RMSE = 9.1%) are almost identical to those quoted by Palm et al.[26] ($r^2 = 0.94$, RMSE = 9.2%). Reading from the curve, the PSA value corresponding to a fractional absorption of 10% is 139.4 Å^2 and for 90% absorption, the value is 61 Å^2. Again, these figures are almost identical to those quoted by Palm et al.[26] The correlation coefficient between the values of PSA and PSA$_d$ presented in Table 1 is $r = 0.996$. As might be expected, the agreement in absolute terms is worse for the more-flexible, more-polar compounds such as mannitol, lactulose, and raffinose. Of the more rigid compounds, oxazepam also shows quite a large absolute difference between PSA and PSA$_d$. This difference probably reflects an instance where the use of different computational methods between this work and that of Palm et al.[26] (e.g., for 3-D structure generation and molecular mechanics optimization) has a significant effect on the results.

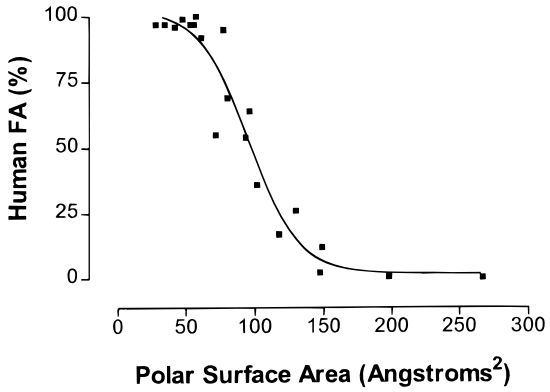

Figure 2—Boltzmann sigmoidal fit of single conformer PSA values to human %FA data for Palm et al.[26] compounds.

From these results, we concluded that, for this set at least, the use of a rapid, single-conformer-based calculation of PSA is sufficient for determining molecules likely to exhibit poor intestinal absorption. It is important to note that all the compounds in the Palm set were chosen on the basis of their being absorbed primarily by passive processes. Thus, the PSA criterion cannot be expected to apply to compounds that are substrates for active transporters.

Applying the value of 140 Å^2 to this set picks out four compounds as being poorly absorbed: sulfasalazine, olsalazine, lactulose, and raffinose. These all show %FA of ≤ 13%. The rule-of-5 only generates warnings for the latter two compounds, suggesting that the PSA value may be a better discriminator of poorly absorbed molecules.

Test Set—To test further the PSA ≥ 140 Å^2 criterion for poor absorption, a further set of compounds was compiled from a recent publication.[19] After removing compounds that are also in the Palm et al. set,[26] 74 compounds remained. PSA values were computed for these compounds and are presented in Table 2 (plotted as a graph in Figure 3) together with the predicted classification of the molecules as "good" (PSA ≤ 61 Å^2), "poor" (PSA ≥ 140 Å^2) or "OK" (140 Å^2 > PSA > 61 Å^2). The rule-of-5 status of each compound is also included, and the %FA values are taken from Wessel et al.[19]

From a practical point of view, when testing this measure, we were most concerned about any *false negative* predictions that might arise from the application of the PSA ≥ 140 Å^2 criterion, i.e., compounds which are predicted to be poorly absorbed but which in fact are well absorbed. False negatives are worrisome because, were the compounds to be discarded on the basis of the prediction, their true absorption would never be discovered. On the other hand, false positive predictions would always be discovered and, while wasteful, would not be serious in the long term. The seven apparent false negatives are highlighted in Table 2 and shown as crosses (×) in Figure 3. Each of these compounds is commented on below.

• Methotrexate has a very high PSA value (225 Å^2), and yet it is still reported as being 100% absorbed. The reason for this is that it is absorbed by a carrier-mediated process which is responsible for folate absorption.[35,36]

• Zidovudine (AZT) just transgresses the PSA limit (142.9 Å^2) while exhibiting 100% absorption. Again, this absorption is made possible by active transport, the carrier in

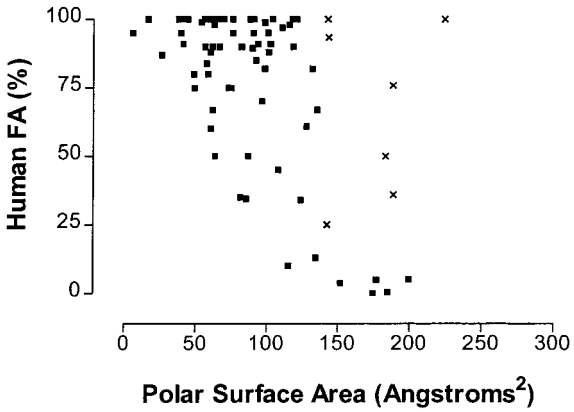

Figure 3—Plot of single conformer PSA values to %FA data for 74 compounds from Wessel et al.[19] set. Seven compounds apparently violating the PSA ≥ 140 Å^2 criterion for poor absorption are shown as crosses (×).

question being a recombinant nucleoside transporter which is responsible for the absorption of pyrimidine nucleosides.[37]

• Amoxicillin and cefatrizine are both amino-β-lactam antibiotics that show good intestinal absorption despite high PSA values. The explanation for this behavior is that both are absorbed via dipeptide carriers.[38,39]

• Cefuroxime axetil shows moderate absorption (36%)—more than would be predicted from its PSA value of 188.6 Å^2. It appears that absorption of this compound takes place by a specialized transport mechanism that obeys Michaelis−Menten kinetics.[40]

• Like zidovudine, lisinopril is a little over the PSA limit and shows a greater than expected absorption. In common with other dipeptide ACE inhibitors, lisinopril is absorbed in a nonpassive process via the dipeptide carrier system.[41]

Thus, all the above compounds are actively transported by one means or another and so are not true false negatives within the scope of the PSA predictions, which only apply to passively transported molecules. The remaining compound, etoposide, is more problematic. To our knowledge, there is no evidence in the literature for any active processes being involved in its intestinal absorption although a recent paper[42] suggests that etoposide distribution into the brain is partly controlled by an active transport process. In any case, etoposide does show very erratic oral bioavailability which has been attributed to low aqueous solubility, slow intrinsic dissolution rate, and chemical instability at pH 1.3[43] and attempts to improve its bioavailability have been unsuccessful.[44] Etoposide, therefore, while apparently a false negative, is not an ideal representative of small molecule oral drugs.

If the above compounds are ignored, the distribution of the remaining points in Figure 3 is roughly sigmoidal; however, there is considerably more scatter than in Figure 2. The reason for this is most likely that the compounds in the Wessel et al. set[19] were not chosen so carefully as those in the Palm et al. set,[26] particularly with regard to the mode of absorption. Even after eliminating the seven "problem" compounds, it is likely that the set contains compounds that are absorbed at least partially by active processes (e.g., acyclovir, cephalexin), and these will tend to add noise to the data.

Nevertheless, the (non)absorption of the remaining 67 compounds is successfully predicted when the PSA value of 140 Å^2 is used to partition the set. These results bolster our confidence that, when passive absorption processes are being considered, the criterion of PSA ≥ 140 Å^2 is a reliable predictor of poorly absorbed compounds and certainly more reliable than the rule-of-5, which only identifies two out of the five compounds showing <10% absorption in this set.

Comparison with a High-Throughput Experimental Method—Recently, Kansy et al.[9] reported the application of a system (called PAMPA − Parallel Artificial Membrane Permeation Assay) for the prediction of passive absorption. PAMPA estimates absorption by measuring the "flux" of a compound through an artificial membrane and is capable of processing large numbers of compounds in parallel by means of 96-well plates. Using the PAMPA system, Kansy et al. classified each member of a set of 25 compounds as being either:

- Highly absorbed (h): %FA ≥ 70, PAMPA flux > 25%
- Moderately absorbed (m): <30 %FA < 70, PAMPA flux 5−25%
- Poorly absorbed (l): %FA ≤ 30, PAMPA flux < 5%

From the curve in Figure 2, the PSA values corresponding to %FA values of 70 and 30 can be determined to be 83 Å² and 112 Å², respectively. Using these limits, it was decided to compare the classification of the compounds based upon PSA values to that arising from the experimental PAMPA system. Of the 25 compounds comprising the test set for the PAMPA, one (cephalexin) was excluded as it is known to be actively transported (for this reason it was poorly predicted by the PAMPA system). PSA values and rule-of-5 status were calculated for the remaining 24 compounds, and the compounds were classified according to their PSA values. The results are shown in Table 3 where the classifications of the compounds from experiment (human %FA), the PAMPA system, and PSA are collated.

The instances where the PAMPA or PSA predictions are correct are highlighted. From this, it can be seen that the PAMPA makes six classification errors, particularly underestimating compounds likely to be transported by a paracellular route, e.g., theophylline and salicylic acid.[9] The PSA classification system makes only three errors, although one of these (chloramphenicol) is a serious one: the compound being predicted to be in the low absorption class, but in fact having a high absorption (i.e., a false negative). The two other errors in the PSA classification are both steroids (dexamethasone and hydrocortisone) which are predicted to have moderate absorption but which are actually well-absorbed. If the original criterion for poor absorption of 140 Å² is applied, all three poor compounds are correctly identified (although two of these are present in the original training set of Palm et al.[26]) and no false negatives are predicted.

Discussion

The results presented above suggest that using single conformer-based calculations to identify compounds with a PSA of ≥ 140 Å² provides a rapid and reliable means of eliminating candidates that are likely to be poorly absorbed in the human intestine. This criterion would seem to be more discriminating than the popular rule-of-5[16] and of similar predictive ability to a high-throughput experimental system.[9] The speed of the method makes it suitable for screening large compound sets, and the fact that it does not require the synthesis of the compounds being assessed means it is especially applicable in the design of combinatorial libraries. For example, we are already using PSA values as an additional constraint in our programs for product-based reagent selection.[45]

Our method is rather different in philosophy from the QSPR-type approach adopted by Wessel et al.,[19] inasmuch as we seek simply a rough classification of compounds whereas their model seeks to predict accurate values across the whole range of absorption. While the results of Wessel et al. seem quite reasonable (RMSEs in predicted %FA: training set 9.4%, cross-validation set 19.7%, and external prediction set 16.0%), there are a number of questions about their work, in particular concerning the data set employed. First, as the authors concede, the data set is heavily skewed toward well-absorbed compounds—only 15 of the 86 compounds have %FA values of less than 50. This bias tends to cause their model to be less accurate in predicting %FA values for less-well-absorbed compounds. For instance, enalaprilat is predicted to have %FA of 47.68, whereas its real value is 10%; conversely, lisinopril is predicted to have a %FA of 0, whereas its true value is 25%. Second, and more fundamentally, we would question the constitution of the data set used by Wessel et al. because it contains compounds that are absorbed by active transport processes as well as passively absorbed compounds. To our minds, it seems unrealistic to expect to find a single model that will accurately predict such different physical processes: passive absorption being diffusion controlled while each active transport mechanism requires more specific molecular recognition.[46] It is for this reason that other workers have striven to use only passively absorbed compounds in their studies.[26] Finally, some of the descriptors used in the model require the use of semiempirical molecular orbital (MO) calculations to generate partial charge information, and these can be moderately time-consuming. A more high-throughput model not including the MO-based descriptors was developed for processing combinatorial libraries, but this was found to give less accurate predictions.[19] Nonetheless, it is interesting to examine the six descriptors used in the model described by Wessel et al. Three seem to code for size, flexibility, and shape while the remainder could be related to PSA: SAAA-2 (surface area of hydrogen bond acceptor atoms), SCAA-2 (surface area × charge of hydrogen bond acceptor atoms), and CHDH-1 (charge on donatable hydrogen atoms). This would seem to provide additional evidence of the validity of polar surface measures in the prediction of absorption.

This begs the question: why should PSA be a useful predictor of passive absorption? Two of the key physicochemical determinants of passive absorption are lipophilicity and hydrogen bonding potential,[47] so it would seem

Table 4—Atomic Radii Used in Molecular Surface Calculations

atom	radius/Å
C	1.9
O	1.74

P	2.05
F	1.65
Cl	2.03
Br	2.18
I	2.32

likely that PSA describes one of these in some way. However, PSA is not simply related to lipophilicity. This can be clearly shown by considering, for instance, a homologous series of monoalcohols: MeOH, EtOH, PrOH, etc. In this series, the PSA is constant, while the lipophilicity increases with increasing carbon chain length. More generally, for the 86 compounds in the Wessel et al. set,[19] there is only a poor correlation between PSA and ClogP ($r = 0.56$). PSA is more closely related to hydrogen bonding potential as shown by Palm et al.[25] who found a correlation of $r = 0.92$ between PSA_d and a count of the total number of hydrogen bonds capable of being formed by a molecule (H_t). However, PSA is a more subtle descriptor of hydrogen bonding potential than H_t because it can account for 3D effects such as shielding or burial of polar groups by other parts of a molecule, perhaps because of internal hydrogen bonding. Given that calculations of lipophilicity, at least for neutral species, are readily available,[48] combining these with PSA predictions should help to guide drug design toward orally available compounds.

There are a number of factors affecting the PSA value for any given compound. First, it is incontrovertible that PSA will vary with conformation as shown by Palm et al.[24] However, for the large range of compounds studied here, it seems that using a single low-energy conformer as a representative of the ensemble of conformers likely to be present in vivo is a reasonable approximation. While this approximation will tend to hold best for more rigid compounds, more flexible compounds also pose problems to a "dynamic" approach in terms of the increased CPU time required for a thorough conformational search. Second, for compounds with more than one stereocenter, the choice of absolute configuration can also affect the PSA value although, in general, unless the stereochemistry is complex, this is only a minor effect. Finally, the atomic radii and algorithm used for the molecular surface calculation will also have an effect, as will the method of generating the 3-D structure and the particular force field used for any geometry optimization. In this work, we have used the same radii as Palm et al.,[26] with the exception of not distinguishing between sp^2 and sp^3 carbon atoms. The radii used in this work are given in Table 4.[49]

While the PSA criterion for poor absorption seems robust in avoiding false negative predictions, it is not immune from making false positive assessments. A good example of this is pyridostigmine (**1**, Figure 4), which has a very low PSA value but is poorly absorbed. This indicates that a PSA of <140 Å^2 is a necessary, but not sufficient, criterion for absorption. In the case of pyridostigmine, the cause of the poor absorption is the presence of the positively charged quaternary nitrogen which inhibits partitioning into the intestinal membranes. Likewise, the pK_a of a compound is also a key determinant of its absorption; a point well

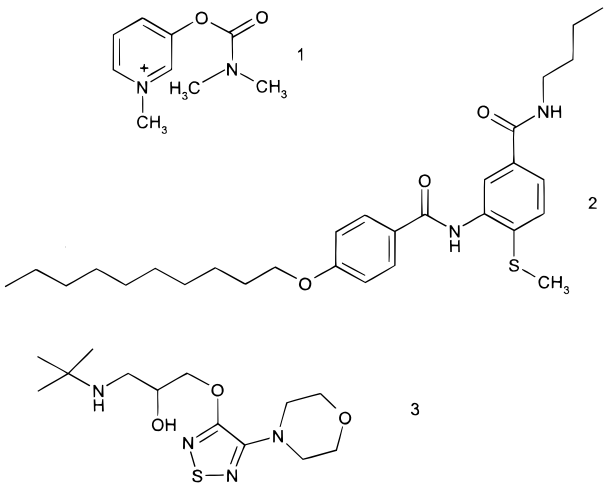

Figure 4—Pyridostigmine (**1**), RP64477 (**2**), and timolol (**3**).

illustrated by a recent publication on 5-HT_{1D} agonists.[50] As indicated above, the lipophilicity of a compound must also be considered. For instance, RP64477 (**2**, Figure 4) has a PSA value of 67.9 Å^2 and on this basis would be expected to be well-absorbed. The fact that it is, in fact, poorly orally available has been attributed to its high log *D* (5.2 at pH 7.4).[51] Finally, aqueous solubility also affects absorption and should be an additional consideration early in compound design.[16] In summary, it is important not to use PSA naively as a guide to absorption but to couple it to existing medicinal chemistry knowledge and intuition. Future work will seek to incorporate some of these factors in an attempt to reduce the number of false positive predictions while avoiding false negatives. Other workers are also exploring these avenues: in a recent article, Winiwarter and coworkers showed that, in addition to PSA, a count of hydrogen bond number and log *D* (octanol/water, pH 5.5 or pH 6.5) were helpful in accurately predicting drug permeability across the human jejunum.[52] Stenberg et al.[53] have also shown recently in a study of a set of peptides that consideration of the nonpolar, as well as the polar, surface area can lead to improved predictions of permeability.

Another interesting avenue of future research is the investigation of refinements to the definition of what constitutes the polar surface area of a molecule. For instance, Krarup et al.[27] reported that for timolol (**3**, Figure 4) and its ester prodrug, a correction was needed to the definition of the polar surface in order to obtain the excellent reported correlation with Caco-2 permeability. The correction was to omit the two nitrogens in the thiadiazole ring from the definition of the polar surface, on the grounds that they are only weak acceptors. When this was done, the correlation between the predicted and actual log P_{app} values improved significantly. The idea of refining the polar surface area so that it takes account of the strength of the hydrogen bonds formed by the groups that comprise it is intriguing. Certainly, the reported improvement in the predictions for timolol and its ester is striking. However, if Krarup et al. were to be consistent, they should also have omitted the non-carbonyl ester oxygen from the polar surface of the timolol prodrug as such oxygens are also known to be extremely infrequent hydrogen-bond acceptors from crystal structure surveys and ab initio calculations.[54–56] The effect of this modification upon their correlation has not yet been investigated. Nonetheless, this idea is certainly worthy of further investigation to see if it helps to improve the accuracy of PSA-based predictions of absorption.

Conclusion

A method for the rapid computation of polar surface area has been described. It has been shown that excellent correlation between polar surface area and intestinal absorption can be obtained without the time-consuming procedure of examining multiple conformations.[57] The use of such rapid calculations in conjunction with the criterion for poor absorption of PSA ≥ 140 Å^2 appears to be an efficient and robust method of computationally screening large numbers of compounds prior to synthesis. It should thus be a valuable tool in both lead generation and optimization.

57. During the revision of this paper, van de Waterbeemd et al. published a paper describing the use of single conformation PSA values in the classification of drug compounds as CNS active or CNS inactive: van de Waterbeemd, H.; Camenisch, G.; Folkers, G.; Chretien, J. R.; Raevsky, O. A. Estimation of Blood-Brain Barrier Crossing of Drugs Using Molecular Size and Shape, and H-bonding Descriptors. *J. Drug Target.* **1998**, *6*, 151−165. In their experience, the conformational effect in low molecular weight molecules represents a variation of about ±10% in the polar surface area which they do not consider as critical when making first estimates of BBB uptake.

Acknowledgments

I am indebted to my colleagues from Rhône-Poulenc Rorer for many helpful discussions during the work described in this paper. In particular, Drs. Stephen Pickett, Andrew Ratcliffe, and Christopher Newton gave much encouragement and made constructive comments upon the manuscript while it was in preparation. Drs. Nicola Wilsher, Martin Barrett, and Ken Page gave advice on matters relating to absorption while Drs. Richard Lewis (now Eli Lilly, UK) and Paul Bamborough (now GlaxoWellcome, UK) helped in the development of the intranet interface to the calculations. I am grateful to Drs. Kristina Luthman (University of Tromsø, Norway) and Larry Dodd (Polytechnic University, New York) for the kind provision of values for atomic radii (Table 4) and the MOLVOL program, respectively. Prof. Peter Jurs (Pennsylvania State University) and Dr. Inge Christensen (Royal Danish School of Pharmacy) are thanked for providing preprints of refs 19 and 27, respectively. Finally, the comments and suggestions of the anonymous referees were greatly appreciated; particularly regarding the history of the use of molecular surface areas in modeling of transport and partitioning processes (refs 21 and 22) and issues concerning Boltzmann averaging of molecular surface areas.

Accepted for publication April 30, 1999.

Abstract □ This paper describes the derivation of a simple QSAR model for the prediction of log BB from a set of 55 diverse organic compounds. The model contains two variables: polar surface area (PSA) and calculated logP, both of which can be rapidly computed. It therefore permits the prediction of log BB for large compound sets, such as virtual combinatorial libraries. The performance of this QSAR on two test sets taken from the literature is illustrated and compared with results from other reported computational approaches to log BB prediction.

Introduction

The blood−brain barrier (BBB) is a complex cellular system whose purpose is to maintain the homeostasis of the central nervous system (CNS) by separating the brain from the systemic blood circulation.[1] In drug discovery, it is important to determine whether a candidate molecule is capable of penetrating the BBB. For drugs targeted at the CNS, BBB penetration is a necessity (unless invasive or intranasal delivery routes are being considered[2]), whereas for drugs aimed at other sites of action, passage through the BBB may lead to unwanted side-effects.

A common measure of the degree of BBB penetration is the ratio of the steady-state concentrations of the drug molecule in the brain and in the blood, usually expressed as $\log(C_{brain}/C_{blood})$ or, more simply, log BB. Experimental values of log BB published to date cover the range about −2.00 to +1.00. Within this range, compounds with log BB > 0.3 cross the BBB readily, while compounds with log BB < −1.0 are only poorly distributed to the brain.[3] The determination of log BB is difficult and time-consuming, requiring animal experiments and the synthesis (sometimes in radiolabeled form) of the compounds to be tested. Although *in vitro*[4] and artificial membrane-based methods[5] for studying BBB penetration are being developed, it would be desirable if log BB could be predicted computationally with enough accuracy to allow the early rejection of unsuitable candidates.

In this paper, we review existing computational approaches for the prediction of log BB and then describe the derivation and validation of a novel, simple QSAR (quantitative structure−activity relationship) model allowing the rapid and accurate prediction of blood-brain barrier penetration.

QSAR Models for log BB Prediction—The first purely computational approach to log BB prediction was that of Kansy and van de Waterbeemd[6] who developed the following QSAR from a set of 20 compounds taken from the work of Young et al.:[7]

$$\log BB = -0.021(\pm 0.003)PSA - 0.003(\pm 0.001)Mol\_Vol + 1.643(\pm 0.465) \quad (1)$$
$$n = 20,\ r = 0.835,\ s = 0.448,\ F = 19.5$$

where PSA is the polar surface area, Mol_Vol is the molecular volume, n is the number of compounds, r is the correlation coefficient, s is the standard error, and F is the Fisher value, a measure of the statistical significance of the equation. The standard errors of the correlation coefficients are given in parentheses.

However, subsequent application of this equation to compounds outside its training set showed it to be poorly predictive,[8] suggesting that the 20 compound training set was insufficient to derive a generally applicable QSAR for predicting log BB.[9] Thus, Abraham and co-workers[9] constructed a larger training set of 65 compounds from which (after the removal of various outliers) they derived the following two models which they denoted ACM-II and log Pplus, respectively:[10]

$$\log BB = -0.038(\pm 0.064) + 0.198(\pm 0.100)R_2 - 0.687(\pm 0.125)\pi_2^H - 0.715(\pm 0.334)\Sigma\alpha_2^H - 0.698(\pm 0.107)\Sigma\beta_2^H + 0.995(\pm 0.096)V_x \quad (2)$$
$$n = 57,\ r = 0.952,\ s = 0.197,\ F = 99.2$$

$$\log BB = +0.055 + 0.023 \log P_{oct} - 0.507\Sigma\alpha_2^H - 0.500\Sigma\beta_2^H \quad (3)$$
$$n = 49,\ r = 0.949,\ s = 0.201,\ F = 136.1$$

No standard errors of the correlation coefficients were given for eq 3.[10] In both of these equations, the various parameters (excepting the experimental quantity, log P_{oct}) are solute descriptors, specifically: R_2 is an excess molar refraction, π_2^H is a dipolarity/polarizability parameter, $\Sigma\alpha_2^H$ and $\Sigma\beta_2^H$ are the solute hydrogen-bond acidity and basicity, respectively, and V_x is the characteristic volume of McGowan.[11]

There are a number of difficulties when applying either of these equations to more than a handful of compounds. First, to estimate log BB using either of these equations, it is necessary to calculate a value for each of the descriptors for the compound in question. The descriptor values in turn are calculated by summing the contributions from the molecule's constituent fragments. While research is ongoing to automate this process, at present, manual calculations require several minutes (at least) to make an

10.1021/js980402t CCC: $18.00
Published on Web 06/24/1999

appropriate dissection of the molecule under study and retrieve the relevant fragment values. If values for a particular fragment cannot be found, they must be calculated. Equation 3, while more compact, requires experimental values for the partition coefficient log P_{oct}, although it is conceivable that computed estimates of log *P* could be substituted for this quantity. Finally, a close examination of the descriptor values used to construct eq 2 reveals that a number of the descriptors are very highly correlated (the pairs R_2 and π_2^H, R_2 and $\Sigma\beta_2^H$, R_2 and V_x, π_2^H and $\Sigma\beta_2^H$, and π_2^H and V_x are all correlated with $r > 0.9$). Such collinearity among the descriptors may cause the regression coefficients to become unreliable.[12] For these reasons, although the above equations appear statistically impressive, other approaches have been sought.

Lombardo et al.[13] started with a set of 57 compounds drawn from the Abraham training set[9] mentioned above. Detailed conformational analyses and semiempirical calculations were used to arrive at this simple model, denoted here as LBC, which omits two outliers from the original set of 57 compounds:

$$\log BB = 0.054(\pm 0.005)\Delta G^{o}_{W} + 0.43(\pm 0.07) \quad (4)$$
$$n = 55,\ r = 0.82,\ s = 0.41,\ F = 108.3$$

where ΔG^{o}_{W} is the computed free energy of solvation of a compound in water. As described by Lombardo et al., the determination of this quantity is rather computationally expensive, making this approach unsuitable for screening large numbers of compounds. However, recent work has led to faster methods for the calculation of solvation free energies.[14]

Most recently, Norinder and co-workers[15] have developed models for log BB prediction using their computed MolSurf parameters together with statistical analysis by the Partial Least Squares to Latent Structures (PLS) method. The model from their work with the largest training set (56 compounds − model 2 in ref 15, denoted here as NSO) contained three significant PLS components with the following statistics: $n = 56$, $r = 0.913$, $s = 0.312$, $F = 86.95$. Here again, however, the computational methods employed required conformational analysis and computationally intensive semiempirical and ab initio calculations which render the approach too slow for high-throughput applications.

In what follows, we describe the derivation of a simple QSAR model for the prediction of log BB that is automatic and rapid to calculate and therefore applicable to the screening of large compound sets, such as virtual combinatorial libraries. The performance of this QSAR on two test sets taken from the literature will be illustrated and compared with the methods above where such results are available.

Computational Methods—*Training Set*—A set of 57 compounds previously studied by Lombardo et al.[13] was used as a training set. These compounds are illustrated in Figure 1 and listed in Table 1 along with experimental log BB values taken from ref 13.

Test Set 1—This set consists of the seven compounds (shown in Figure 2) used as a test set by Abraham et al.[10] The experimental log BB values listed in Table 2 for these compounds were taken from ref 10 as were the predicted log BB values from eqs 2 and 3.

Test Set 2—This test set was used by Lombardo et al.[13] and also by Norinder et al.[15] It comprises six compounds whose structures are shown in Figure 3. Table 3 shows the log BB values from the various equations and experiment.

Polar Surface Area Calculations—PSA values for the molecules under study were calculated using the methods described in the previous paper.[16]

Calculations of log *P*—Two computational methods for logP prediction were used. ClogP was calculated using the Daylight software.[17] MlogP values were computed using an implementation of the method developed by Moriguchi et al.[18] encoded in the Sybyl Programming Language and executed within the Sybyl Molecular Modeling package.[19]

Regression Analysis—All multiple linear regressions were carried out within the Tsar program.[20]

Results

Training Set—Despite the limitations found with the Kansy and van de Waterbeemd approach,[6] we decided to investigate the possibility of using PSA values to derive a generally applicable QSAR for log BB. Starting from the 57 compounds used by Lombardo et al.,[13] we first tried correlating PSA with log BB and obtained the following equation:

$$\log BB = -0.016(\pm 0.001)PSA + 0.547(\pm 0.050) \quad (5)$$
$$n = 57,\ r = 0.819,\ s = 0.455,\ F = 112.4$$

This initial result was encouraging and, incidentally, suggested a relationship between PSA and ΔG^{o}_{W}. An investigation showed the two quantities were indeed closely correlated ($r = 0.962$). However, a purely PSA-based model failed to distinguish the varying BBB-penetrating abilities of nonpolar compounds. For example, benzene and 3-methylpentane have log BB values of −0.69 and 2.01 respectively, but both have a PSA of zero. Thus, we began to search for an additional descriptor that would differentiate between the nonpolar compounds in the set. Molecular weight, molecular volume, and nonpolar surface area were tried, but none led to a significant improvement in the model.[21] Finally, calculated logP values were tried with more success generating a model we denote DEC-I:

$$\log BB = -0.0148(\pm 0.001)PSA + 0.152(\pm 0.036)ClogP + 0.139(\pm 0.073) \quad (6)$$
$$n = 55,\ r = 0.887,\ s = 0.354,\ F = 95.8$$

where ClogP is the calculated logP.[17] The two compounds omitted from the original set of 57 were N_2, for which ClogP cannot calculate an accurate value, and compound 12 which, if included in the model, shows an error of 1.5 log units in the prediction of its experimental log BB value (data not shown). Compound 12 has also been found to be an outlier by other groups.[13,15] One difficulty with using ClogP values is that there are compounds for which it cannot generate accurate values. For this reason, some workers[22] have proposed the use of the MlogP[18] approach in such circumstances. If MlogP values are substituted for ClogP values, the following model (DEC-II) is generated:

$$\log BB = -0.0145(\pm 0.001)PSA + 0.172(\pm 0.022)MlogP + 0.131(\pm 0.033) \quad (7)$$
$$n = 55,\ r = 0.876,\ s = 0.369,\ F = 86.0$$

To allow a direct comparison of these two equations with a purely PSA-based model, eq 5 was rederived based on the same 55 compounds as were used in the derivation of eqs 6 and 7 giving:

$$\log BB = -0.0156(\pm 0.001)PSA + 0.548(\pm 0.048) \quad (8)$$
$$n = 55,\ r = 0.841,\ s = 0.410,\ F = 128.4$$

When the statistics are compared, eqs 6 and 7 show superior *r* and *s* values to eq 8, and the *F* values for the three equations indicate that all are significant at the 95%

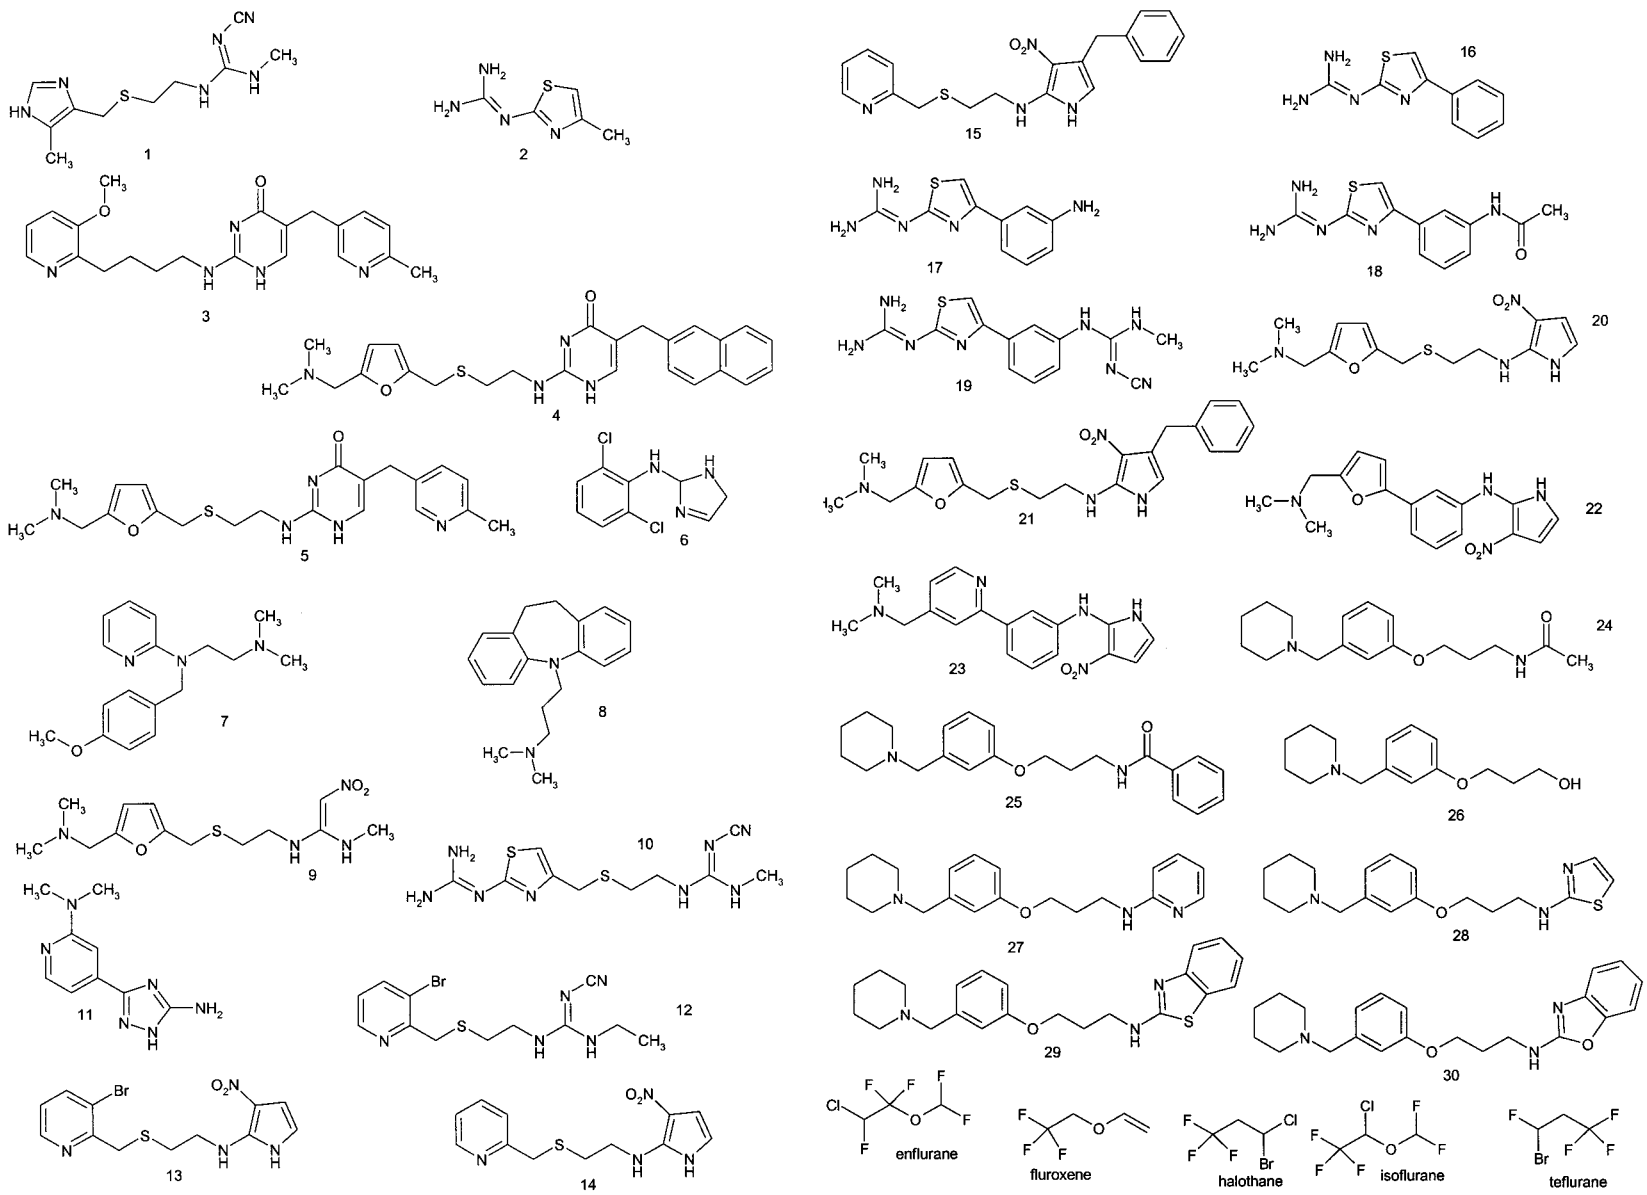

Figure 1—Compounds **1**–**30** and less familiar compounds from the training set.

[a] Compounds not included in final training set for eqs 6 and 7. [b] ClogP could not calculate an accurate value for this compound. DEC-I is the predicted set of values using eq 6 and DEC-II is the predicted set of values using eq 7.

confidence level. It is apparent that the inclusion of a calculated log *P* value has improved the model for log BB prediction. Thus, eqs 6 and 7 were preferred for log BB prediction over the simple PSA-based model of eq 8.

The quantities comprising eqs 6 and 7 are rapidly calculable, and, furthermore, the descriptors involved are not significantly correlated with one another: the correlation coefficient *r* being 0.15 for PSA and ClogP, and 0.23 for PSA and MlogP. The predicted log BB values from eqs 6 and 7 are tabulated in Table 1, and plots of computed versus experimental values are shown in Figure 4. However, the real test of any QSAR equation is how well it predicts values for compounds outside its training set. Accordingly, we have applied our equations to two test sets that are available in the literature.

Test Set 1—Looking at Table 2, if all seven compounds are considered, the mean absolute errors in the log BB predictions are: ACM-II: 0.30, log Pplus: 0.54, DEC-I: 0.37 and DEC-II: 0.40. However, it can be seen that all the models overpredict log BB for compounds Y-G19 and Y-G20. This is in accord with the findings of Abraham et al.[10] who considered them as outliers. They suggested that

Table 2—Data and Results from Test Set 1[a]

compound	PSA/Å^2	ClogP	MlogP	expt log BB	ACM-II log BB	log Pplus log BB	DEC-I log BB	DEC-II log BB

[a] ACM-II is the predicted set of values from eq 2, log Pplus is the predicted set of values from eq 3, DEC-I and DEC-II are the predicted set of values from eq 6 and eq 7, respectively.

Table 3—Data and Results from Test Set 2[a]

compound	PSA/Å^2	ClogP	MlogP	expt log BB	LBC log BB	NSO log BB	DEC-I log BB	DEC-II log BB
31	46.7	1.980	3.139	0.00	–0.14	–0.58	–0.25	–0.01
32	62.7	0.260	2.408	–0.34	–0.28	–1.11	–0.75	–0.37
33	76.1	1.907	3.446	–0.30	–0.46	–0.75	–0.70	–0.38
34	98.5	0.380	2.698	–1.34	–0.64	–0.99	–1.26	–0.83
35	120.4	–0.932	1.959	–1.82	–0.82	–1.35	–1.77	–1.28
36	5.4	4.641	4.369	0.76–0.98	0.28	1.03	0.76	0.80

[a] LBC is the predicted set of values from eq 4, NSO is the predicted set of values from model 2 of Norinder et al.,[15] DEC-I and DEC-II are the predicted set of values from eq 6 and eq 7, respectively.

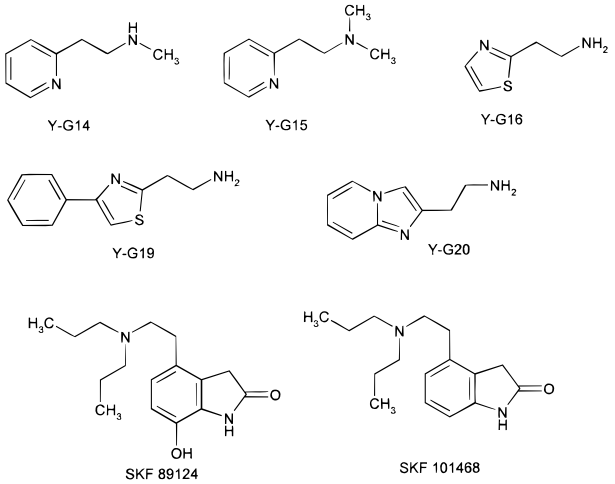

Figure 2—Structures for test set 1.

such outliers might be caused by factors such as inaccurate data due to experimental difficulties or metabolic effects not accounted for in log BB measurements.[10] The fact that our independently derived models also find large deviations for these compounds, while treating the remainder quite well, adds some weight to the argument to consider Y-G19 and Y-G20 as outliers. If this is done, for the remaining five compounds, the mean absolute errors in the log BB predictions are as follows: ACM-II: 0.02, log Pplus: 0.28, DEC-I: 0.14, and DEC-II: 0.13. Thus, whether the outliers are included or excluded, ACM-II is the best predictor for this set, and DEC-I and DEC-II perform about as well as each other and better than log Pplus.

Test Set 2—Considering the results in Table 3, it can be seen that compound **36** (amitryptyline) has a large uncertainty in its experimental log BB value; however, DEC-I and DEC-II predict log BB values within the given range. In so doing, they perform better than LBC, which underpredicts log BB, and NSO which predicts too high a value. Calculating the mean absolute errors over compounds **31**–**35**, we obtain: LBC: 0.41; NSO: 0.52; DEC-I: 0.24; DEC-II: 0.23.

In this case, the equations based on PSA and calculated log *P* perform substantially better than the more computationally expensive methods of Lombardo et al.[13] and Norinder et al.[15]

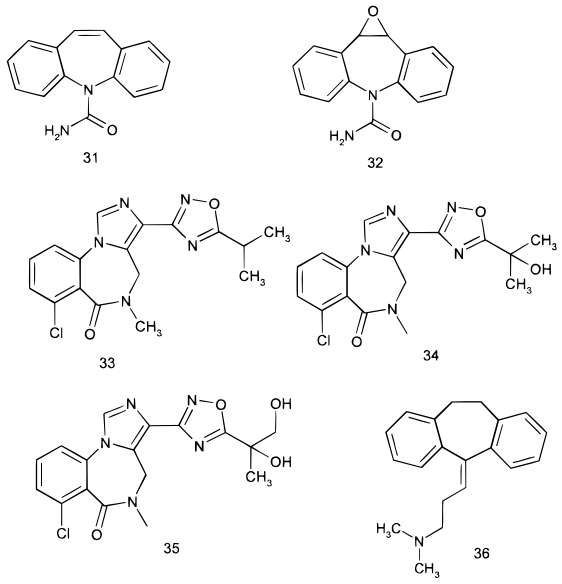

Figure 3—Structures for test set 2.

Discussion

It has been suggested by Lennernäs[23] that purely passive diffusion is universal for membranes with different physiological functions and physicochemical properties. Thus, the factors that determine a compound's intestinal absorption should also, to some extent, model its BBB permeability. Therefore, it is not surprising that PSA, which has been found to be useful in modeling intestinal absorption (see the preceding paper[16] and references therein), together with a direct estimate of lipophilicity, widely acknowledged as an important factor in transport across membranes,[24] should yield a predictive model for log BB. It would seem from our results that, with this set of compounds, quantities such as molecular weight, molecular volume, or nonpolar surface area do not correlate strongly enough with

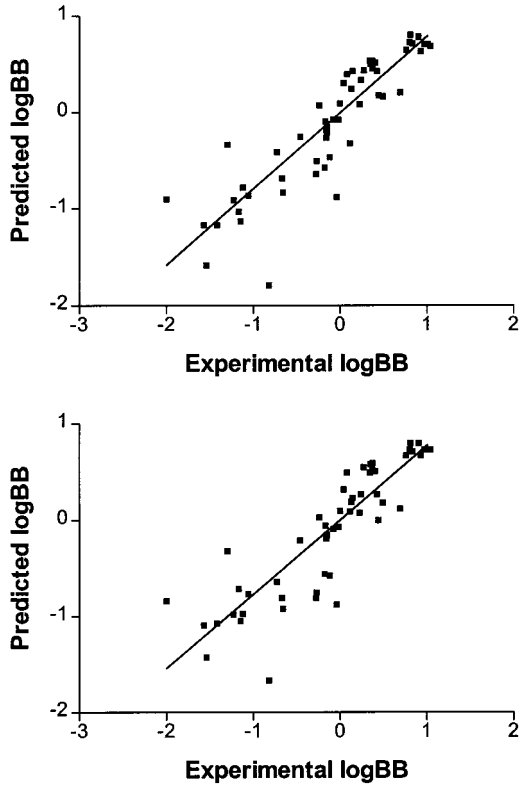

Figure 4—(a) Plot of computed (DEC-I) versus experimental log BB values. (b) Plot of computed (DEC-II) versus experimental log BB values.

lipophilicity to be useful (when combined with PSA) for modeling BBB penetration. An analysis of the 55 compounds used in the training set in this paper bears this out. The correlation coefficients, *r*, for the relationships between ClogP and molecular weight, molecular volume, and nonpolar surface area are 0.386, 0.468, and 0.599, respectively.

It is interesting to note the similarity between the models derived in this paper (DEC-I and DEC-II) and the log Pplus equation of Abraham et al.[10] In the latter (eq 3), the two parameters, $\Sigma\alpha_2^H$ and $\Sigma\beta_2^H$, denote the solute hydrogen-bond acidity and basicity, respectively. The fact that these have negative coefficients while log *P* has a positive coefficient accords with the expectation that membrane permeation will be more facile for compounds that form fewer (and weaker) hydrogen bonds with solvent and with the observation that the brain is more lipophilic than the blood, making lipophilic compounds more likely to penetrate the brain. Similar findings were reported by Norinder et al.[15] who reported that high brain/blood partitioning was favored by an absence of atoms capable of hydrogen bonding together with high lipophilicity. The same may be said for DEC-I and DEC-II, where better brain penetration is predicted for compounds with high calculated log *P* and low PSA (the polar surface area being an indication of a compound's capacity to form hydrogen bonds). In addition, van de Waterbeemd et al.[25] recently showed that, of a set of 125 drugs, all those showing CNS activity could be found within the ranges: $0 \le \text{PSA} \le 90$; $-1 \le \log D$ (pH 7.5) ≤ 4 with the likelihood of CNS activity appearing to increase with decreasing PSA and increasing log *D*. Thus, the models derived in this paper would seem to be sensible from a physiological point of view and are also in agreement with insights from other models into the factors facilitating blood−brain barrier penetration.

As with the model for intestinal absorption described previously (see the preceding paper[16] and references therein), it is likely that the simple model described here is only valid for passive diffusion processes across the BBB. There are active transport systems for both influx and efflux in the brain and compounds which are affected by these are not likely to be well-predicted. Another factor influencing BBB transport is the binding of drugs by plasma proteins.[26] This too is not directly accounted for in the PSA/calculated log P-based model, although plasma binding within a given series may be correlated with log *P*.[27]

Finally, other experimental measures of blood−brain barrier permeability are now becoming available. Eddy et al.[4] have reviewed various in vitro models, and Lombardo et al.[13] showed that, for a small set of 10 compounds, it was possible to correlate permeability across a monolayer composed of endothelial cells from bovine brain microvessels with free energy of solvation. Gratton et al.[28] have reported permeability−surface area measurements (denoted log PS) using a short-duration vascular perfusion method for 18 compounds and correlated the values with Abraham's solute descriptors. A relatively new technique for measuring brain penetration in vivo is microdialysis.[29] This offers the potential for observing drug disposition between the extracellular and intracellular space in the brain, something not possible with traditional log BB measurements.[30] As more data emerge from these various novel techniques, it will be interesting to see how well computational techniques can adapt to predict new measures of blood−brain barrier penetration.

Conclusion

In summary, the equations (DEC-I and DEC-II) described in this paper for log BB prediction show a good predictive ability. Their utility is enhanced by the fact that they comprise only two simple, noncorrelated variables, values for which may be rapidly computed for almost any structure. (As described in the preceding paper,[16] PSA values can be computed in about 10−15 s on a modern workstation, and ClogP and MlogP calculations are very fast.) The procedure for log BB estimation is fully automated, allowing the prescreening of virtual libraries and other compound sets prior to synthesis or purchase. For this reason, it should be of use in drug discovery projects where blood−brain barrier penetration is an issue.

Acknowledgments

I am very grateful to my colleagues at RPR for many helpful discussions and invaluable advice. I would especially like to thank Dr. Iain McLay for proposing the investigation of PSA values in log BB prediction and Dr. Stephen Pickett for suggesting the inclusion of ClogP as a variable in eq 6. Dr. Ulf Norinder kindly supplied a preprint of ref 15. Dr. James Blake (Pfizer, US) is thanked for making his SPL script for MlogP calculations available and the technical support of Drs. Jon Swanson and Gareth Wilden (Tripos, Inc.) in relation to this code is acknowledged.

Accepted for publication June 1, 1999.

Abstract □ Quantitative tools to assess vascular macromolecular distributions have been limited by low signal-to-noise ratios, reduced spatial resolution, postexperimental motion artifact, and the inability to provide multidimensional drug distribution profiles. Fluorescence microscopy offers the potential of identifying exogenous compounds within intact tissue by reducing autofluorescence, the process by which endogenous compounds emit energy at the same wavelength as fluorescent labels. A new technique combining fluorescence microscopy with digital postprocessing has been developed to address these limitations and is now described in detail. As a demonstration, histologic cross-sections of calf carotid arteries that had been loaded endovascularly with FITC-Dextran (20 kD) ex vivo were imaged at two different locations of the electromagnetic spectrum, one exciting only autofluorescent structures and the other exciting both autofluorescent elements and exogenous fluorescent labels. The former image was used to estimate the autofluorescence in the latter. Subtraction of the estimated autofluorescence resulted in an autofluorescence-corrected image. A standard curve, constructed from arteries that were incubated until equilibrium in different bulk phase concentrations of FITC-Dextran, was used to convert fluorescent intensities to tissue concentrations. This resulted in a concentration map with spatial resolution superior to many of the previous methods used to quantify macromolecular distributions. The transvascular concentration profiles measured by quantitative fluorescence microscopy compared favorably with those generated from the proven *en face* serial sectioning technique, validating the former. In addition, the fluorescence method demonstrated markedly increased spatial resolution. This new technique may well prove to be a valuable tool for elucidating the mechanisms of macromolecular transport, and for the rational design of drug delivery systems.

Introduction

The appeal of local pharmaceutical administration is that specific tissues and organs can be targeted for therapy without adverse systemic effects.[1−4] Yet, implementation of local delivery strategies has been limited by a whole new set of pharmacologic issues.[5] Local delivery systems impart large dynamic concentration gradients across tissues that can be difficult to identify, characterize, and control.[6] Because drug levels are not uniform, the concept of dosing takes on another level of complexity.[5] For example, cells near the point of release experience a very different concentration of drug in their extracellular milieu than do cells far away, and these levels are not static in time. The dose a cell sees depends on both time and space as well as administered drug mass. Thus, the successful implementation of local drug delivery systems requires accurate, high resolution techniques to assess drug deposition, and as proof that therapeutic levels are achieved rapidly and persist long enough for biologic effect to emerge. These very issues are especially important in considering the potential of local vascular drug therapy. The scale of the blood vessel wall dimensions, the importance and prevalence of vascular diseases, and the promise of increasingly novel vasoactive compounds make for quantification of local administration all the more essential.

We now describe the development of a new method for visualizing and quantifying drug distribution in vascular tissue. This technique utilizes fluorescence microscopy with digital postprocessing[7−10] and avoids the experimental hazards and disposal costs associated with radiolabeled compounds, while providing spatial resolution superior to conventional radioactive techniques. A nonaqueous method is used to immobilize drug and prevent postexperimental diffusion of soluble molecules. Vessel cross-sections are imaged with fluorescence microscopy, and digital postprocessing algorithms are used to reduce autofluorescence, a prior obstacle to quantitative interpretation. Autofluorescence compensation is accomplished by acquiring images at two different excitation wavelengths, one consisting of only nonspecific autofluorescence and the other containing both the specific fluorescence of markers and autofluorescence.[8,9] The former image is then used to estimate the autofluorescence in the latter image. This estimated autofluorescence could then be subtracted from the latter image to yield an autofluorescence-free image containing only the signal from the fluorescent tags. Fluorescent intensities are then converted to tissue concentrations, yielding a high-resolution map of macromolecular distribution. As a demonstration, the transvascular concentration gradient of an endovascularly applied model drug, 20 kD FITC-dextrans, is measured in the calf carotid artery. This compound was chosen for its inert properties, relative availability, and similarity in size to several vasoactive growth factors. High-resolution transvascular concentration profiles provided by this technique will yield improved understanding of macromolecular transport and deposition in vascular tissue and insight into the special pharmacologic issues raised by local delivery systems.

Experimental Protocol

Calibration Standards—Calf carotid arteries were obtained from a slaughterhouse and stored on ice for no more than 2 h. The arteries were submerged in phosphate-buffered saline with

calcium and magnesium (PBS^{2+}; Sigma PBS Catalog no. 1000-3, 0.01 M phosphate buffer salts, 0.120 M NaCl, 0.0027 M KCl with 0.01 M $CaCl_2$ and 0.01 M $MgCl_2$ added) throughout the preparation process to prevent dehydration and maintain tissue viability. Excess fascia and fat were gently teased away using forceps and scissors prior to sectioning vessels into cylindrical segments, 8−12 mm long and 4−8 mm in diameter. These segments were placed into separate vials containing 10 mL of 20 kD dextrans labeled with fluorescein isothiocyanate (FITC-Dx, 0.006−0.007 mol FITC per mol glucose, Sigma) in PBS^{2+} at 0, 0.02, 0.05, 0.1, 0.15, 0.2, 0.25, 0.5, 1, 2, and 2.5 mg/mL. Specimens that were incubated without any FITC-Dx will be referred to as unloaded arteries. The arteries were incubated in the dark, to prevent photobleaching, for 24 h at 4 °C. This duration was determined to be sufficient for FITC-Dx to achieve chemical equilibrium between the tissue and the bulk phase by incubating arterial segments in a single bulk phase and measuring the resulting tissue concentrations after different incubation periods. The data suggest that the tissues were fully saturated in less than 24 h, supporting the claim that 24 h is sufficient to fully load arterial segments with FITC-Dx. Incubation also did not result in any tissue swelling which would cause the calibration standards to not accurately reflect the tissue specimens. In pilot studies, the thickness of the arterial media was measured from histologic cryosections prepared both on arrival from the slaughterhouse and after incubation in PBS^{2+} for 65 h. There was no statistical difference in medial thickness at time zero (459 ± 17 μm) and at 65 h (477 ± 23 μm, $n = 3$, avg ± sd), suggesting that the tissues did not swell significantly.

Drug Immobilization and Tissue Sectioning—To immobilize drug within the tissue and limit diffusion during storage and handling, tissues were snap frozen in embedding medium (OCT, Tissue-Tek) with liquid nitrogen. Specimen blocks were stored at −20 °C prior to being cut into 20-μm-thick axial cross-sections using a precooled cryostat (CM 3050, Leica). Section thickness was previously measured to vary by less than 0.5 μm between slices. Three histologic sections were taken from each tissue standard. Frozen OCT around the tissue was gently removed to facilitate mounting onto glass slides (Superfrost Plus, VWR Scientific). The histologic sections were freeze-dried in the dark at −50 °C in a lyophilizer (Labconco) for 24 h, and stored at room temperature in a dark, dry environment prior to imaging. Freeze-drying of the tissue sections ensured that the FITC-Dx was immobilized throughout subsequent storage and processing.

Image Acquisition System—The histologic sections were imaged without any mounting medium or cover slip. Diffusion of drug from its location within the blood vessel wall was significantly reduced by snap freezing, which does not require applying a liquid phase to the tissue. 24-bit color images were acquired using a CCD video camera system (Optronics) attached to a fluorescence microscope (Optiphot-2, Nikon). The system resided on a pneumatic optical table (Technical Manufacturing Corporation) to minimize vibrations. Video images were captured on a computer (Power Computing) via a frame grabber (LG-3, Scion) using a commercial imaging software package (IPLab Spectrum, Signal Analytics). The frame grabber was calibrated by displaying a test image consisting of color bars generated from the video camera system. The gain and offset of the frame grabber were adjusted to match its dynamic range (0 to 255 units for the red, green, and blue channels) to the dynamic range of the video camera system. Magnification was provided by a 10× ocular and a 10× objective, resulting in 640 by 480 pixel images with pixel dimensions of 1.326 μm by 1.326 μm. Illumination was provided by a super high-pressure mercury lamp (Nikon) which was allowed to warm for at least 2 h prior to imaging for consistent illumination. This duration was previously determined to adequately stabilize the imaging system. Ultraviolet (UV) and FITC filter sets were used to examine tissue specimens. The UV filter set consisted of an excitation filter of 330−380 nm, a dichroic filter (beam splitter) of 400 nm, and a barrier filter of 420 nm. The FITC filter set consisted of an excitation filter of 465−495 nm, a dichroic filter of 505 nm, and a barrier filter of 515−555 nm. Images of each histologic section were acquired at 0.25, 0.5, 1.0, and 2.0 s exposure times for both UV and FITC filters. The image with the maximal signal that did not contain any saturated pixels was used. In this way each section was exposed to less than 4 s at each wavelength. In pilot studies, the impact of photobleachning was found to be negligible by continuously exposing a histologic section with drug signal to the excitation beam and acquiring sequential images. No reduction in intensities was found over one minute.

Hence forth, UV and FITC images refer to images taken with the UV and FITC filter sets, respectively. The fluorescent tag used in these experiments, FITC, is maximally excited around 490 nm so UV images contain only autofluorescence and FITC images contain both autofluorescence and specific signal from the fluorescent labels.

Initial Processing—Images were acquired using 8-bit RGB (red, green, and blue) color components and converted to the HSI (hue, saturation, and intensity) color model.[11] The HSI color model decouples luminance and chrominance in an image, with the intensity image representing the luminance information, and the hue and saturation images representing the chrominance information. Both UV and FITC images were decoupled in this manner, and the hue and saturation images were discarded leaving only the intensity image (Figure 1). Intensities in these images range from 0 (absolute black) to 255 (absolute white).

Autofluorescence Compensation—Since UV images contain only autofluorescence and FITC images contain both autofluorescence and the specific signal of interest, each pixel in a UV image can be used to estimate the autofluorescence present in the corresponding pixel in the counterpart FITC image.[8,9] A 50 pixel wide region that spanned the media but excluded the adventitia and intima was defined on both the UV and FITC images of an unloaded artery. Corresponding pixels from this region of the UV and FITC images were correlated, which allows estimation of the autofluorescence component in each pixel of this region in a FITC image, using the corresponding pixel in the counterpart UV image (Figure 1). The estimated autofluorescence was subtracted from the original FITC image yielding an autofluorescence compensated FITC image that contains only the signal from fluorescent markers (Figure 1).

Conversion of Fluorescent Intensities to Tissue Concentrations—Fluorescent intensities were converted to tissue concentrations using a standard calibration curve obtained from tissue standards incubated until equilibrium in known concentrations of FITC-Dx in PBS^{2+}. A 50 pixel wide region that spanned the media, but excluded adventitia and intima, was selected from each autofluorescence corrected FITC image (three histologic sections each with one image per standard). The average fluorescent signal in this region was correlated with the bulk phase concentration of FITC-Dx that the tissue standard was incubated in.

Whereas in bulk solutions dextrans are free to access an entire unit of volume, compounds in tissue are excluded from areas by steric interactions. Thus, the fractional accessible space in which hydrophilic drugs can distribute in tissue (ϵ) must be less than one.[6] Drug in the accessible space in a tissue is in chemical equilibrium with the bulk phase, and therefore the concentration in the accessible space is known for each tissue standard. This definition of accessible space is dependent not only on the tissue examined, but also on the specific compound of interest. The fluorescent microscopy image, however, contains contributions from both accessible and nonaccessible spaces, and concentrations are detected on a per tissue volume basis. The bulk phase concentrations of tissue standards can be converted to tissue concentration by multiplying the former by the fractional space (ϵ),[12−14]

$$c_T = \epsilon c_{Bulk} \quad (1)$$

which was measured independently (see below).

Measurement of Fractional Space Available for Distribution—To measure the fractional space available for distribution in arterial media, 1 cm long segments of calf carotid arteries were incubated for 24 h to equilibrium in 10 mL of 20 kD FITC-Dx in PBS^{2+} at concentrations (c_{Bulk}) of 0.1, 0.5, 1, and 3 mg/mL. Four arteries were incubated at each concentration. Tissue concentrations in "isolated" arterial media were measured after the intima and adventitia were removed by an *en face* cryosectioning technique (see below).[15,16] The fractional space was determined from the correlation between the bulk phase and the tissue concentrations (eq 1).

En Face Cryosectioning—Carotid artery segments were removed from incubation and cut longitudinally, unfolded, placed on a microscopy slide with the intima face down and covered in OCT. A second slide was placed on top of the specimen with two 1-mm

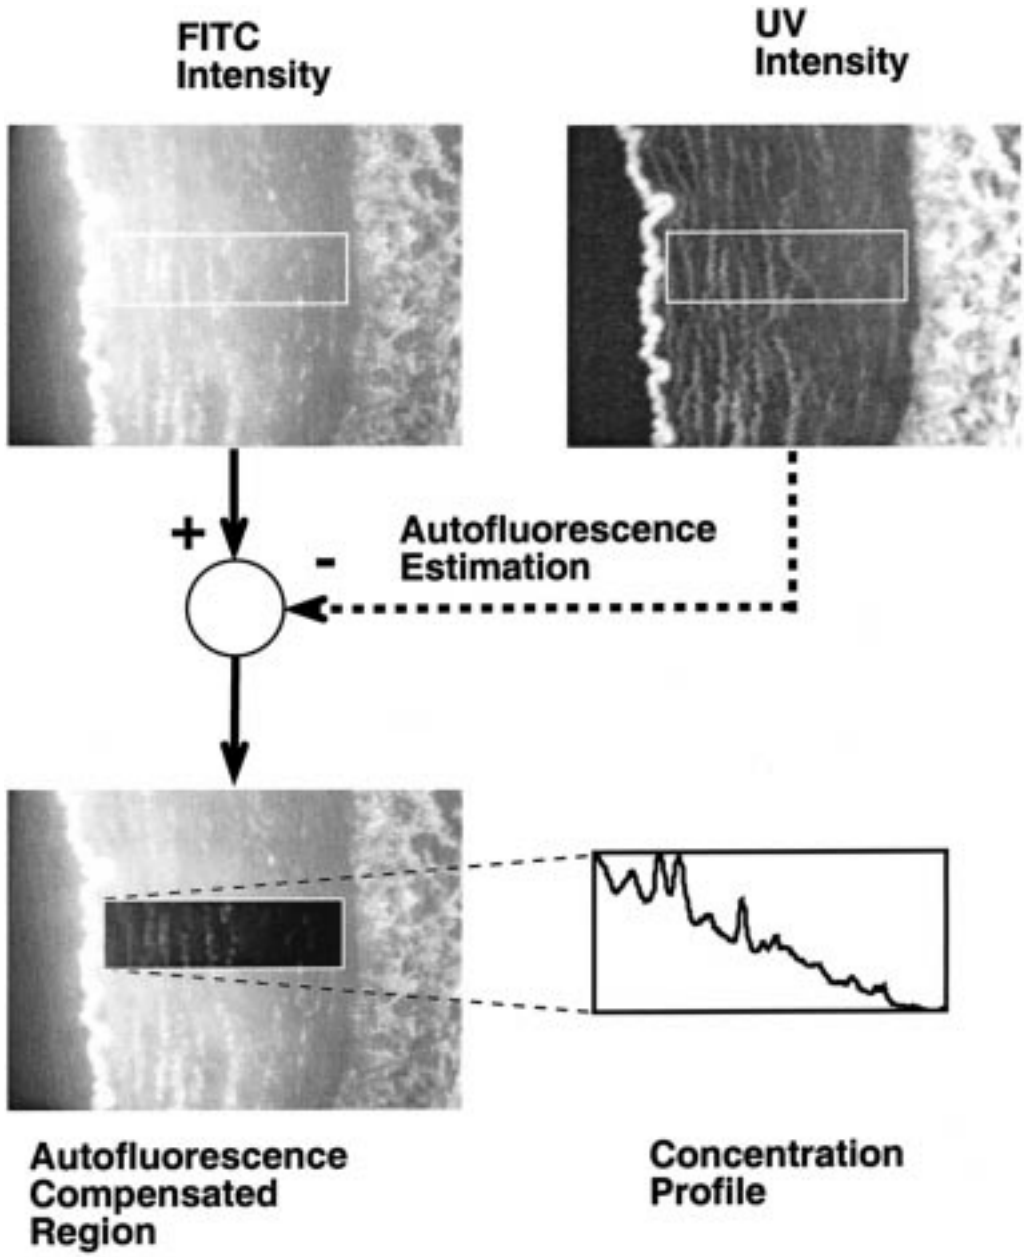

Figure 1—Image processing algorithm to compute concentration profiles. A cross-section of a calf carotid artery is imaged with the FITC and UV filter sets. A 50-pixel wide region corresponding to the media is defined from each intensity subimage. The UV region is used to estimate autofluorescence in the medial region. Pixel intensities are converted to tissue concentrations using a calibration curve. This example shows the transmedial concentration profile of fluorescent-labeled compound 2 h after endovascular application ex vivo.

spacers placed around the specimen. The glass slides were clamped together to ensure that sectioning was parallel to the intimal surface, and the tissue was snap frozen with a freezing aerosol (Cytocool II, Stephens Scientific). The frozen specimen was wrapped in aluminum foil and stored at −20° C prior to sectioning. A frozen block of OCT was mounted in the cryostat to serve as a chuck for the specimens, and was cut until the resulting surface was parallel to the blade. The cryostat was retracted so that the artery could be mounted. Arteries were separated from the slides by gently rubbing a lightly heated spatula against the slide until the specimen easily slid off. The specimens were mounted flat onto the chuck with the intima toward the blade and then trimmed into a rectangle with a razor blade. The length and width of the rectangle were measured so that the volume of each 20-μm-thick slice (V_{Slice}) could be calculated. Additional OCT was frozen around the specimen for support during sectioning.

The artery was sectioned from the intima toward the adventitia. Eighteen slices corresponding to the carotid media were pooled and reincubated in 24 mL of fresh PBS^{2+} for 48 h. This time has been shown to be more than sufficient to release more than 96% of the FITC-Dx from whole arteries. The reincubation bath volume (V_{Bath}) was more than 1000-fold greater than the volume of all the combined tissue slices, permitting the small amount of residual drug in the tissue at the end of reincubation to be neglected. The concentration of the reincubation bath was measured with a spectrofluorimeter (Fluorolog 1681, SPEX), using a standard curve of known concentrations of FITC-Dx in PBS^{2+}. This reincubation concentration ($c_{Release}$) was used to calculate the original tissue concentration of FITC-Dx in PBS^{2+} (c_T) with the following formula:

$$c_T \approx \frac{c_{Release} V_{Bath}}{n V_{Slice}} = \frac{\text{mass of released drug}}{\text{volume of tissue slices}} \qquad (2)$$

where n is the number of tissue slices in each reincubation bath. Thus, the tissue concentration was measured, and the slope between the tissue and bulk phase concentrations was taken to be the fractional space of the media.[12−14] This method of measuring the fractional space assumes that binding between the compound and the tissue is insignificant.

Quantitative Fluorescence Microscopy vs *en Face* Cryosectioning—To demonstrate the validity of this technique, FITC-Dx was applied to the endovascular aspect of an artery, and the resulting transmural concentration profile was determined both through the proposed quantitative fluorescence microscopy technique and the standard method of *en face* serial cryosectioning.[15–18] Calf carotid arteries were obtained and cleaned of adventitia as described above. Arterial segments about 1.5 cm long without visible branches were cannulated at both ends and tested for leaks by visually inspecting the vessel after connecting one end to an elevated bag of Ringer's solution and closing off the other end. The intact artery was then placed in an in vitro perfusion apparatus that has been described elsewhere.[19,20] Briefly, the apparatus recirculates PBS^{2+} through the artery, simulating plasma flow, and allows control of the drug concentration in both the endovascular and perivascular compartments, which are separated by the arterial wall. 20 kD FITC-Dx (5 mg/mL) was applied to the endovascular compartment, and the continuously stirred perivascular compartment contained PBS^{2+}. Throughout this study, the hydrostatic head was set to zero, so that the transarterial pressure gradient and subsequent convective effects on molecular transport were eliminated.

Three arteries were perfused for 2 h and were then removed from the apparatus and cut in longitudinal segments, one for analysis with quantitative fluorescence microscopy, and the other with *en face* cryosectioning. Specimens for quantitative fluorescence microscopy were immediately snap frozen, sectioned onto histologic slides, freeze-dried, and imaged, as described above. Snap freezing and freeze-drying deprives the drug of an aqueous phase to diffuse and therefore significantly reduces post experimental motion artifacts. The image was autofluorescence corrected, and a 50 pixel wide region was defined which spanned the arterial media (Figure 1). The intensity values were averaged across the 50-pixel width to reduce the circumferential variance of drug distribution and were converted to FITC-Dx concentration in tissue using the standard calibration curve. Eight such transmedial regions were defined around the circumference of the artery, and their resulting transmural concentration profiles were averaged.

Specimens for *en face* cryosectioning were splayed open and frozen between two glass slides, stored, mounted, and trimmed as described above. The length and width of the opened and trimmed artery was measured with a ruler so that the volume of each 20-μm slice (V_{Slice}) could be calculated. The slices were transferred in groups of three into a 4 mL PBS^{2+} bath (V_{Bath}) and stored in the dark at 4° C for 48 h to allow drug to diffuse into the bulk phase. Three slices were used in each bath to increase the fluorescent signal into the dynamic range of the spectrofluorimeter, which was used to measure the concentration of drug in the reincubation bath ($c_{Release}$). The tissue concentration (c_T) was determined through eq 2.

Results

Autofluorescence Compensation—UV and FITC images of an unloaded artery were examined to determine the correlation between the autofluorescence with the UV and FITC filter sets. A 50-pixel wide region that spanned the arterial media was defined. The pixel intensities in this region of an UV image were linearly correlated to the corresponding intensities in the FITC image (Figure 2):

$$FITC_{autofluorescence} = 0.073UV_{total} + 44.9 \qquad (R^2 = 0.629) \quad (3)$$

The 50% confidence intervals (dashed lines) for the linear regression of eq 3 (solid line) are shown. The gray scale shading reflects the number of times data appears at the same pair of specific UV and FITC intensity values. The range of FITC values that correspond to specific UV intensities are shown in two sample histograms, which indicate limited scatter about the fitted value. This linear relationship allows the estimation of the autofluorescence component in one pixel of a FITC image using the corresponding pixel in the counterpart UV image. Assuming that the autofluorescence and specific fluorescence from the markers add linearly, the estimated autofluorescence can then be subtracted from the original FITC image yielding only the specific signal of fluorescent markers:

$$FITC_{specific} = FITC_{total} - FITC_{autofluorescence} \quad (4)$$
$$= FITC_{total} - (0.073UV_{total} + 44.9)$$

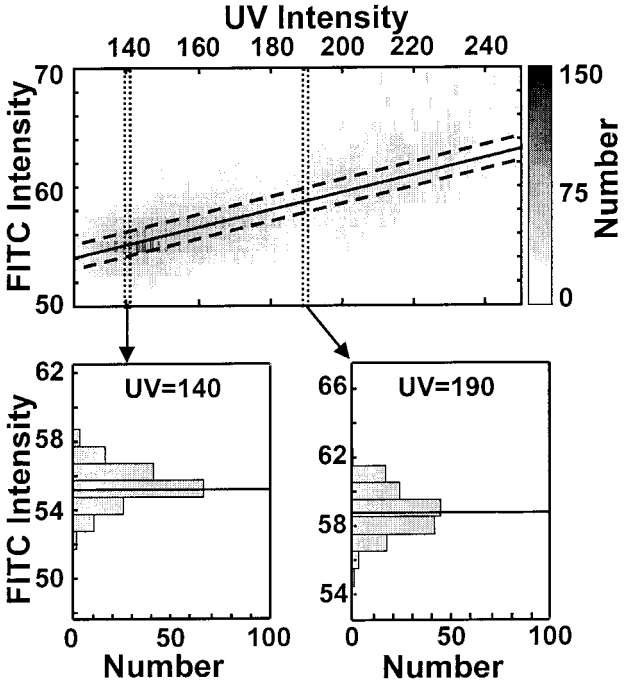

Figure 2—Correlation between autofluorescence with the UV and FITC filter sets. The media of an unloaded artery (devoid of FITC-Dx) was extracted after being imaged with the UV and FITC filter sets. Pixel intensities in the FITC image are plotted as a function of the intensity of the corresponding pixel in the counterpart UV image ($n = 9990$). The gray scale shading reflects the number of times data appears at the same pair of specific UV and FITC intensity values. The linear fit (solid line) can be used to estimate the autofluorescence in a FITC image from the corresponding UV image. The 50% confidence intervals are shown surrounding the linear fit (dashed line). Histograms are shown at two sample UV intensities and demonstrate limited scatter of FITC intensity about the fitted value.

The correlation between UV and FITC autofluorescence (eq 3) was verified by examining three other unloaded arteries subjected to the same processing. When eq 4 was used to subtract autofluorescence in histologic sections of these arteries, the resulting signal in the media hovers close to zero intensity (data not shown).

Conversion of Fluorescent Intensities to Tissue Concentrations—The conversion of fluorescent intensities to tissue concentrations requires two relations. Fluorescent intensities must first be converted to the bulk phase concentrations of tissue standards (c_{Bulk}). Three histologic axial sections were prepared and autofluorescence corrected. Regions were defined that were 50-pixel wide regions and spanned the arterial media. The mean intensity of each of these regions was fit to its corresponding bulk phase incubation concentration using a power relation (Figure 3):

$$\text{mean intensity} = 93.7c_{bulk}^{0.732} \qquad (R^2 = 0.966) \quad (5)$$

The range of this mapping is bounded by two factors. The lower concentration bound of 0.02 mg/mL is determined by the sensitivity of the image acquisition system, and low fluorescent emissions from dilute concentrations

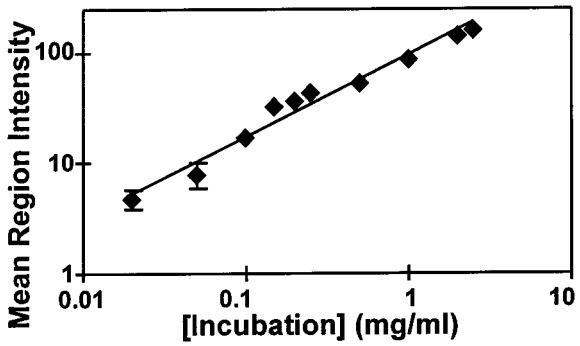

Figure 3—Fluorescent intensity as a function of incubation concentration (mean of three histologic sections from one artery ± standard deviation, $n = 3$). Tissue standards were created by incubating arteries in varying concentrations of FITC-Dx in PBS^{2+} until chemical equilibrium, and the mean intensity of a 50-pixel wide transmedial region in autofluorescence compensated images were calculated.

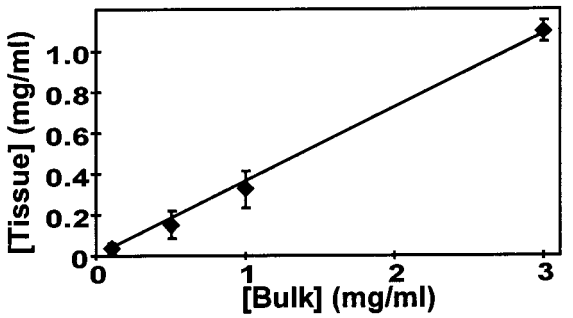

Figure 4—Tissue concentration as a function of bulk phase concentration (mean ± standard deviation, $n = 4$). Arterial segments were incubated to equilibrium in varying concentrations of FITC-Dx in PBS^{2+} until chemical equilibrium. The adventitia and intima were removed through *en face* cryosectioning, and the amount of drug in the remaining arterial media was extracted and quantified to yield the tissue concentration. The slope of the linear fit is a measure of the fractional space available for distribution in the tissue (ϵ).

of the fluorescent marker. The upper concentration bound (2.5 mg/mL) is determined by saturation of the image acquisition system. The bulk phase concentrations and the average tissue concentrations of arteries incubated to equilibrium were fit to a linear equation passing through the origin (eq 1). The slope of this line is an estimate of the fractional space accessible to the drug (ϵ). The data shows that 36.1% ($R^2 = 0.996$) of a unit volume is available for FITC-Dx distribution in the tissue (Figure 4). Equation 5 can then be rearranged and combined with eq 1:

$$c_T = \epsilon(\text{mean intensity}/93.7)^{1.37} \qquad (6)$$

This relationship was used to convert medial regions of autofluorescence corrected images from intensity to tissue concentration.

Comparison of Quantitative Fluorescence Microscopy with *en Face* Cryosectioning—Transvascular concentration profiles were obtained with the new quantitative fluorescence microscopy technique and the established method of *en face* cryosectioning (Figure 5). Three calf carotid arteries were perfused for 2 h with an endovascular bath concentration of 5 mg/mL of 20 kD FITC-Dx, a perivascular bath concentration of 0, and no transvascular pressure gradient. Each artery was cut transversely into two halves, one-half for quantitative fluorescence microscopy, the other for *en face* cryosectioning. The latter measures the average concentration in 60-μm-thick transmural divisions and this curve is depicted as a step function for one of the three arteries (Figure 5). Similar transmural

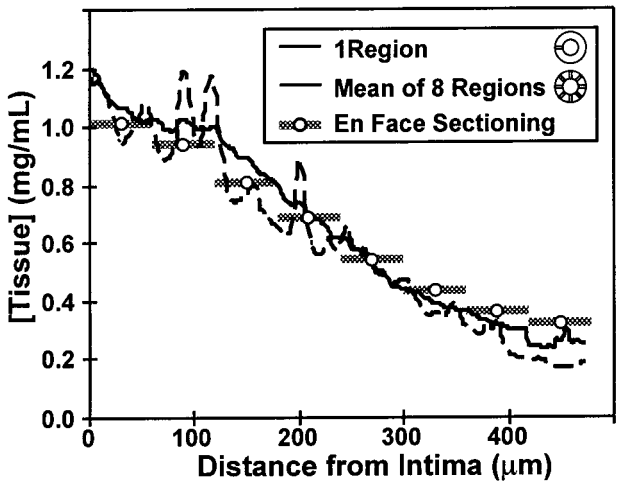

Figure 5—Transvascular concentration profiles obtained with quantitative fluorescence microscopy and *en face* cryosectioning techniques. The transmural concentration profile was obtained from a 50-pixel wide transmedial region. At each transmural location the concentration was averaged across the 50 pixels (dashed line). Another smoother transmural profile was the mean from 8 such regions, approximately equidistant around the circumference of the artery (solid line).

concentration profiles were measured for the other perfused arteries. Superimposing the profiles obtained with the two techniques demonstrates that the quantitative fluorescence microscopy technique provides higher resolution data in the form of measurements between neighboring points obtained with *en face* cryosectioning (Figure 5). For example, the quantitative fluorescence microscopy method shows peaks and valleys superimposed on a gradual transmural profile, whereas *en face* cryosectioning neglects these fine details and loses this potentially important data. Furthermore, the fluorescence technique shows a profile at a specific location about the artery and does not average the signal about the entire circumference. When transmural profiles from eight locations about the circumference of the artery are averaged, the agreement between these two methods increases (Figure 5).

Discussion

A new technique has been developed to obtain arterial concentration profiles combining fluorescence microscopy and digital image processing. Fluorescence microscopy offers several advantages over other techniques (such as higher spatial resolution and smaller marker size) that have been developed to quantify arterial concentrations of compounds, but also introduces additional limitations such as autofluorescence and the difficulty in converting fluorescent intensities to physical concentrations.

Comparison with Other Techniques—Vascular deposition studies have utilized radioactive nucleotides, which minimally change the physical structure of a compound and its transport properties, but these experiments often have limited spatial resolution and are fraught with experimental hazards and disposal costs. Early studies measured the radioactivity in grossly dissected sections providing low detection limits, but questionable repeatability as well as limited spatial resolution.[21] Measuring radioactivity in *en face* serial sections parallel to the intimal surface provides resolution down to 10 μm, but can only assess the macromolecular distribution in one direction and by necessity provides only an average concentration in the plane of sectioning.[15,16,18] The radiolabeled drug content in a specimen can also be visualized by allowing the emitted energy to expose specially prepared photographic film or a silver

emulsion applied to a histologic section.[12,22–24] Silver grain counting or optical densitometry methods can then quantify the density of exposed silver grains. These autoradiographic techniques offer increased resolution (down to ~2 μm), but may be hampered by inaccurate localization, inconsistent background radiation, and postexperimental diffusion of soluble macromolecules in the emulsion.[12,22–24] In addition, the exposure time of the film or emulsion may take months.

Nonisotopic techniques, including biochemical and fluorescent labels, offer higher spatial resolution and avoid the hazards of radioactivity, but may be limited by marker size. Large labels can affect the physicochemical and transport properties of the macromolecules under investigation. For example, the transport of horseradish peroxidase (HRP) has been quantified in arteries using a colored reaction product.[13,17,25,26] Specimens were examined with a light microscope which provided HRP concentration profiles with spatial resolution superior to radioactive techniques. Similar studies could be adapted for study of local delivery systems, however, the large size of HRP (40 kD) prevents its utility as a molecular tag on much smaller drugs. In addition, the aqueous tissue processing required to fix and embed the tissues, and to create the colored reaction product, may also allow for postexperiment diffusion of smaller or more soluble molecules. Fluorescent labels such as FITC and rhodamine isothiocyanate are smaller (~400 D), permitting their use in studies on smaller compounds. Though fluorescence microscopy offers the advantages of high spatial resolution, as in HRP studies, and smaller label size, quantitative studies have been complicated by autofluorescence and the proper application of calibration standards. This digital image processing technique seeks to address these limitations.

Autofluorescence Compensation—Constituent arterial components, such as elastin, fibronectin, and lipofuscin, exhibit autofluorescence, the emission of energy at the same wavelength as exogenous fluorescent labels.[8] The fluorescence spectra of these compounds are often very broad and autofluorescence cannot be avoided by selecting a probe with excitation and emission spectra outside their range. While uniform autofluorescence with small variability has been effectively corrected for by subtracting a constant intensity,[7,10] autofluorescent structures are often distributed inhomogeneously throughout the tissue, resulting in nonuniform artifact that is difficult to compensate for. In addition, autofluorescence may be very intense, masking the fluorescent signals of interest. Counterstaining tissue sections with solutions derived from flow cytometry such as crystal violet[27] or pontamine sky blue[28] to eliminate background autofluorescence may be impractical as aqueous processing can produce postexperimental drug diffusion. Time-resolved fluorometry, which utilizes the different decay times between autofluorescent molecules and fluorescent tags, has also been used to compensate for autofluorescence,[29,30] but utilizes a sophisticated fluorescence microscopy system and lengthy excitation times. In addition, this technique may require special fluorescent tags such as lanthanide chelates,[31] which may not be readily available individually or conjugated to compounds of interest.

Fluorescent labels have narrower excitation and emission spectra than constituent molecules of the arterial wall. Digital image processing methods have been developed that take advantage of this principle and have reduced autofluorescence, in flow cytometry studies[32] and in histologic preparations.[8,9] Images are captured at two wavelengths with one image consisting only of autofluorescence and the other image possessing both autofluorescence and the specific fluorescence signal of interest. The former image is then used to estimate the autofluorescence in the latter image. Assuming that autofluorescence and the fluorescence from the labels are simply additive, the estimated autofluorescence can be subtracted from the latter image to yield an autofluorescence-compensated image. These concepts form the basis of our quantitative fluorescence microscopy method.

Conversion of Fluorescent Intensities to Tissue Concentrations—Fluorescence microscopy is usually used as a binary tool to determine the presence or absence of a compound by qualitatively assessing the fluorescence from markers. The relation between the fluorescent intensity and tissue concentration of the tagged compound is rarely measured in histologic sections. Quantitative analysis requires the development of a reliable calibration curve to convert fluorescent intensities to physical tissue concentrations. Calibration curves have been constructed by measuring the intensity of various concentrations of FITC solution in a hemocytometer[33,34] or capillary tubes.[35] The photoabsorptive properties of solutions, however, may be very different from those of tissues. In addition, the difference in thickness of a section of tissue compared to a hemocytometer or capillary tube may cause calculated tissue concentrations to not accurately represent the actual tissue concentration.[36] Thus, calibration standards for fluorescent compounds should be created from the same substrates and conditions used in experiments and mimic the experimental samples as closely as possible to obtain reliable calibration data. In this study, this was accomplished by incubating calf carotid arteries in different concentrations until equilibrium. The transmural concentration profiles were measured in identical arteries. These calibration standards were then used to construct a relationship between fluorescent intensity and bulk phase concentration. The corresponding tissue concentration of each standard was determined through the fractional volume accessible to the compound, measured in separate experiments.

Comparison of Quantitative Fluorescence Microscopy and *en Face* Cryosectioning—The quantitative fluorescence microscopy technique described in this paper was compared to the established *en face* serial cryosectioning method (Figure 5).[15,16] This new technique performed well at predicting the complex drug distribution pattern imparted by an in vitro perfusion apparatus. Transvascular concentration profiles obtained with quantitative fluorescence microscopy have higher resolution than those obtained with *en face* cryosectioning. The resolution of the former technique is that of the light microscope, about 0.5 μm. The peaks and valleys exhibited using the technique described could not have been appreciated with en *face* cryosectioning.

The high spatial resolution of this quantitative fluorescence microscopy technique provides insights into the mechanisms of drug deposition and distribution. For example, the peaks in the tissue concentration may indicate binding or sequestration to specific arterial elements such as thin connective tissue layers. The height of these peaks are greatest in regions of increased tissue concentration and lowest away from the endovascular source of dextran, suggestive of a small degree of binding that is proportional to the local drug concentration and hence likely to be of first-order kinetics. Recent data has shown that FITC-dextran binds weakly to isolated elastin networks (data not shown). Thus, the high resolution of the quantitative fluorescence microscopy method offers insights into vascular drug deposition and distribution that could not be appreciated by traditional means.

The normalized mean square error (NMSE) between *en face* cryosectioning and the new quantitative fluorescence

microscopy technique was computed to demonstrate the statistical agreement between these two methods. The resolution of the profile from the quantitative fluorescence microscopy technique was first reduced to that of the cryosectioning profile. Data points from the profile generated with the quantitative fluorescence microscopy technique were grouped in sequential sets of 60 μm and then averaged for comparison with the cryosectioning profile. The NMSE was then computed as the sum of the squared differences between every pair of data points over the sum of the squared magnitude of every point in the cryosectioning profile. The NMSE was normalized to the cryosectioning data since cryosectioning is the standard that the new technique is being compared to. The NMSE was equal to 0.0109 for the profile obtained with one region and 0.0060 for the profile obtained by averaging across eight regions. The low NMSE demonstrates the validity and accuracy of the new fluorescence method and is not surprising given the visual similarity of the profiles in Figure 5.

There are significant differences between the transmural concentration profiles generated by quantitative fluorescence microscopy and *en face* cryosectioning (Figure 5). However, when eight concentration profiles from different locations about the circumference of a single artery generated with quantitative fluorescence microscopy were averaged, the agreement between these two methods was greatly increased. This example demonstrates that techniques such as *en face* cryosectioning, which inherently average about the circumference, gloss over important subtleties in the deposition of compounds that quantitative fluorescence microscopy can detect. Furthermore, although the potency of the fluorescence microscopy technique has been illustrated with a one-dimensional transmural concentration profile, it examines histologic sections and therefore is capable of examining drug concentration gradients in any two dimensions within a plane in which a tissue is sectioned.

Summary

This work describes a fluorescence microscopy technique to visualize and quantify drug deposition. It consists of laboratory techniques that immobilize drug in its postexperimental position, digital postprocessing to eliminate autofluorescence, and the appropriate calibration standards to convert fluorescent intensities to drug concentrations. This technique offers spatial resolution superior to conventional radioactive techniques and is adaptable to many compounds and tissues. The complex and dynamic drug deposition patterns imparted by local drug delivery systems might be defined in this manner and may ultimately allow for their rational design.

Nomenclature

c_T	Concentration of drug in a volume of tissue
c_{Bulk}	Bulk phase concentration of drug in first incubation bath
$c_{Release}$	Concentration of drug released from tissue into reincubation bath
ϵ	Fractional space in which drug can distribute through a tissue
V_{Bath}	Volume of the reincubation bath
n	Number of slices of tissue in a reincubation bath
V_{Slice}	Volume of each slice of tissue
$FITC_{Autofluorescence}$	Autofluorescence intensity of tissue imaged under FITC filter set
UV_{Total}	Autofluorescence intensity imaged under UV filter set
$FITC_{Total}$	Total intensity imaged under FITC filter set
$FITC_{Specific}$	Autofluorescence-compensated intensity under FITC filter set
FITC	Fluorescein isothiocyanate
UV	Ultraviolet

Accepted for publication May 27, 1999.

Abstract □ The in vitro uptake study was performed using the isolated cells of human oral mucosa, buccal and the dorsum of the tongue, to investigate the mechanisms of glucose uptake. The uptake of D-glucose was much larger in cells of the dorsum of the tongue than in buccal cells and was inhibited more extensively by 2-deoxy-D-glucose, a substrate of facilitative glucose transporters, than by α-methyl-D-glucoside, a specific substrate of SGLT1, suggesting the larger contribution of a facilitative transporter than Na^+/glucose cotransporter. Furthermore, from the results of inhibition studies by several sugar analogues including maltose and D-mannose, GLUT1 and/or GLUT3 were suggested to take part in the glucose uptake by oral mucosa. Therefore, we have attempted to confirm the expression of glucose transporters on the oral mucosa by employing Western blotting. As a result, it was suggested that SGLT1, GLUT1, GLUT2, and GLUT3 are expressed in the epithelial cells of human oral mucosa.

Introduction

Oral mucosa has been used as a site for drug delivery, because the drug thus administered reaches systemic circulation circumventing both intra-alimentary canal and hepatic first-pass eliminations.[1−3] Generally, the mechanism of drug absorption from the oral cavity is passive diffusion.[4,5] On the other hand, not only some nutrients, D-glucose,[6] amino acid,[7] glutathione,[8] thiamine,[9] and nicotinic acid,[10] but also an aminocephalosporin antibiotic cefadroxil[11] were reported to be absorbed by specialized transport mechanisms from the human oral cavity, using a buccal absorption test method.[4] Recently, we developed perfusion cells, which can be applied on five regions in the human oral cavity, the dorsum of the tongue, ventral surface of the tongue, labial mucosa, floor of mouth, and buccal mucosa,[12] and could show the presence of the specialized transport system for D-glucose in the dorsum of the human tongue.[13] D-Glucose is transported into the enterocytes across the brush border membrane by a Na^+/glucose cotransporter (SGLT1), and then the hexose is transported out across the basolateral membrane by a facilitative sugar transporter (GLUT2).[14,15] Furthermore, some glucose transporters have been found in mammalian tissues.[16] However, details of sugar transporters present in oral epithelial cells have not been clarified.

In the present study, the mechanism of D-glucose uptake by epithelial cells isolated from human buccal mucosa and the dorsum of the tongue was examined to clarify the glucose transport system in the human oral cavity.

Materials and Methods

Materials—^{3}H-D-Glucose, ^{14}C-L-glucose, and ^{14}C-2-deoxy-D-glucose were purchased from Amersham International (Buckinghamshire, England). A liquid scintillator, Clear-Sol I, was purchased from Nacalai Tesque (Kyoto, Japan). D-Glucose (Ishizu Pharmaceutical Co., Osaka, Japan), L-glucose (Tokyo Kasei Kogyo Co., Tokyo, Japan), 2-deoxy-D-glucose, and fluorescein isothiocyanate dextran (FITC-dextran, MW 35600, Sigma Chemical Co., St. Louis, MO) were used as supplied. Iatro-Chrom GLU-L_Q and Glucose-Test Wako were purchased from Iatron Laboratories, Inc. (Tokyo) and Wako Pure Chemical Industries (Osaka), respectively. Rabbit anti-SGLT-1, rabbit anti-GLUT-1, rabbit anti-GLUT-2, and rabbit anti-GLUT-3 were obtained from Chemicon International (Temecula, CA). Prestained molecular weight markers for SDS-polyacrylamide gel electrophoresis (PAGE) used in this study were phosphorylase (102 kDa), bovine serum albumin (BSA) (78 kDa), ovalbumin (49.5 kDa), carbonic anhydrase (34.2 kDa), soybean trypsin inhibitor (28.3 kDa), and lysozyme (19.9 kDa) (Bio-Rad Laboratories, Hercules, CA). All other chemicals were regent grade and commercially available.

Subjects—Ten healthy volunteers, aged 22−25 years, participated in this study. Written informed consent, in accordance with the principles of the Declaration of Helsinki, was obtained from each volunteer prior to the study.

Preparation of Oral Mucosal Cells—Epithelial cells were isolated from the buccal mucosa or the dorsum of the tongue of volunteers using a mouthwash technique.[17] Briefly, mucosal cells were obtained on the morning of assay. Subjects swirled high-purity water around their mouth for a short period of time in conjunction with molar scraping action for buccal mucosa or the dorsum of the tongue. This procedure was repeated several times. The pooled expectorate containing mucosal cells was filtered through three layers of 250 μm nylon mesh, centrifuged at 3000 rpm for 10 min, and gently resuspended in the incubation buffer. The composition of the incubation buffer was 100 mM mannitol, 80 mM NaCl, 20 mM Tris-HCl (pH 7.4), 3 mM K_2HPO_4, 1 mM $MgCl_2$, 1 mM $CaCl_2$ and 1 mg/mL bovine serum albumin (BSA). The cell suspension was centrifuged again at 3000 rpm for 10 min and resuspended in the incubation buffer at the concentration of 1×10^6 cells/mL.

Uptake Experiments—The uptake of the substrate was determined by a rapid filtration technique.[18] Uptake studies were initiated by the addition of 0.4 mL of a buffer solution containing a labeled substrate to 0.1 mL of the cell suspension, which was preincubated at 37 °C for 30 min. At the desired times, 4 mL of ice-cold stop solution (100 mM mannitol, 100 mM $MgCl_2$, 8 mM HEPES, 4 mM Tris and 1 mM NaCl, pH 7.4) was added to the mixture. The resulting mixtures were immediately filtered through prewetted 0.45 μm filters (Fuji Photo Film, Tokyo). The filters were quickly rinsed with 4 mL of the ice-cold stop solution three times and transferred into a counting vial for the determination. Background value or nonspecific adsorption to the filter was determined by using the incubation buffer without mucosal cells. This value was subtracted from the uptake data.

Absorption Experiments (Buccal Absorption Test)—The experiments were carried out according to the method of Kurosaki et al.[11] which was originated by Beckett and Triggs.[4] Briefly, a 2-deoxy-D-glucose solution (10 mL) containing an unabsorbable marker, FITC-dextran (1 μM), was placed in the mouth. The

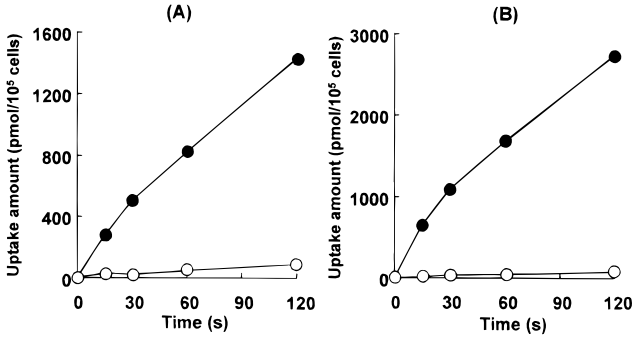

Figure 1—Uptake of D- and L-glucose by isolated cells of human buccal mucosa (A) and dorsum of tongue (B). Initial concentration of glucose was 0.1 mM. Key: ●, D-glucose; ○, L-glucose. Results are expressed as the mean with a vertical bar showing the SE of four experiments. The bars are hidden behind symbols.

solution in the mouth was vigorously agitated using the cheeks and tongue for 5 min, and then the solution was expelled as completely as possible. The subject quickly rinsed his mouth three times with the same buffer solution (total volume, 20 mL) and expelled the rinsing. The expelled solutions were combined and were adjusted to 50 mL with the buffer solution. From the values of the initial and final concentrations of 2-deoxy-D-glucose and the marker, percentage of 2-deoxy-D-glucose absorbed during a period of 5 min was calculated.

Analytical Methods—For uptake studies, radioactivity was measured by a Beckman LS-232 liquid scintillation counter. For absorption studies, D-glucose and 2-deoxy-D-glucose were determined using commercially available assay kits, Iatro-Chrom GLU-L_Q (glucose oxidase method). L-Glucose was determined using commercially available assay kits, Glucose-Test Wako (*o*-toluidine-boric acid method). FITC-dextran was determined spectrofluorometrically (ex 495 nm, em 514 nm).

SDS–Polyacrylamide Gel Electrophoresis and Western Blot Analysis—SDS–PAGE was performed using a 12% polyacrylamide gel for protein separation. Cells suspended in 10 mM Tris-HCl buffer (pH 7.4) containing 1 mM EDTA and 1 μM aprotinin were disrupted by Ultrasonic Generator US300 (Nissei, Tokyo) for 30 min, and the suspension was centrifuged at 200*g* for 30 min. The supernatant fraction was centrifuged at 27000*g* for 1 h. The precipitate was resuspended in 10 mM Tris-HCl buffer (pH 7.4) containing 2% SDS, 2% Triton X-100, and 2 mM EDTA to dissolve membrane proteins. The protein samples were loaded on top of a 4.5% stacking gel. After electrophoresis, proteins were transferred onto nitrocellulose membranes. Remaining active sites on the nitrocellulose membranes were blocked with 5% nonfat dry milk in phosphate-buffered saline for 1 h at room temperature on a flat bed shaker. Membranes were incubated overnight at 4 °C with rabbit anti-human antibodies against SGLT1, GLUT1, GLUT2, or GLUT3 under constant agitation, and then incubated further for 1 h at room temperature with horseradish peroxidase-conjugated goat anti-rabbit immunoglobulin G. Horseradish peroxidase activity was revealed using ECL Western blotting detection reagents (Amersham International).

Statistical Analysis—Statistical significance was evaluated using Student's *t*-test or analysis of variance. Results are expressed as mean ± SE of more than three experiments.

Results

Isolated Mucosal Cells—The photomicroscopic observation of the mucosal cells stained with hematoxylin–eosin revealed that cells isolated from the dorsum of the tongue contain cornified cells, but cells from buccal mucosa do not. The specific character of both sites was observed. The viability of the cells was maintained as 80–90% even 3 h after the isolation.

Uptake of Glucose by Isolated Mucosal Cells—Figure 1 shows the time course of glucose uptake by the cells isolated from buccal mucosa (A) and the dorsum of the tongue (B). As is evident from the figure, the uptake

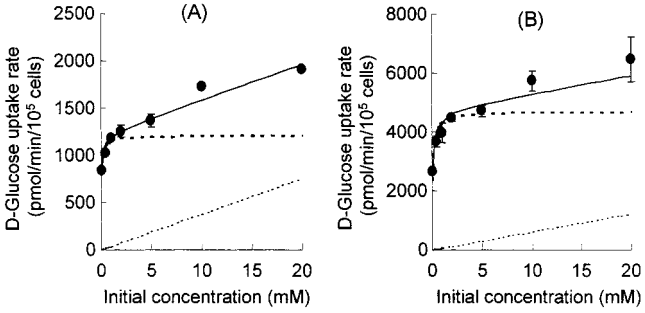

Figure 2—Concentration dependency of D-glucose uptake by isolated cells of human buccal mucosa (A) and dorsum of tongue (B). Results are expressed as the mean with a vertical bar showing the SE of three experiments. —, fitting curve; ••••, uptake via carrier-mediated system; ----, uptake via passive diffusion (uptake rate of L-glucose).

of D-glucose was much greater than that of L-glucose in both cells, and stereospecificity was observed. Furthermore, the uptake by cells from the dorsum of the tongue was greater than that from buccal mucosa.

Figure 2 shows the concentration dependency of the initial rate (in 1 min) of D-glucose uptake by the cells isolated from buccal mucosa (A) and the dorsum of the tongue (B). The kinetic parameters for D-glucose uptake were calculated by fitting these data to the eq 1.

$$v = V_{max}C/(K_m + C) + k_dC \qquad (1)$$

where v is the initial uptake rate at the concentration C, V_{max} and K_m are the maximum uptake rate and Michaelis constant for the specialized transport system, respectively, and k_d is the first-order rate constant for the uptake by simple diffusion. The initial uptake rate constants for L-glucose were used as k_d values: they were 37.7 ± 6.7 nL/min/10^5 cells for cells of buccal mucosa and 61.8 ± 7.8 nL/min/10^5 cells for cells from the dorsum of the tongue. The kinetic parameters for D-glucose uptake thus obtained were as follows: V_{max} and K_m values for cells of buccal mucosa are 1207.4 ± 124.2 pmol/min/10^5 cells and 51.2 ± 47.8 μM, respectively; on the other hand, those for cells from the dorsum of the tongue are 4696.3 ± 132.0 pmol/min/10^5 cells and 97.7 ± 19.8 μM, respectively. The statistical analysis by ANOVA clarified that V_{max} and k_d values in the two cells are significantly different while K_m values are not.

To investigate the characteristics of the glucose transport system, the effect of some transport inhibitors and specific conditions on the uptake by isolated oral mucosal cells were examined, and the results are shown in Table 1. In both mucosal cells, D-glucose uptake at the concentration of 0.05 mM was markedly reduced in the ice-cold condition or by 0.5 mM *p*-chloromercuribenzoic acid (PCMB), suggesting that the uptake is a carrier-mediated process. Since D-glucose uptake was significantly reduced in the Na^+-free condition, it is suggested that a part of this uptake system is Na^+-dependent. The significant inhibition by 1 mM 2,4-dinitrophenol and the slight inhibition, but not statistically significant, by 1 mM phlorizin were observed. These results suggest that a Na^+-dependent D-glucose transport system is operating, at least partly, in the uptake process. To further clarify the carrier system, the effect of various sugars (50 mM) on D-glucose uptake (1 mM) was examined, and the results are also shown in Table 1. α-Methyl-D-glucoside, a specific substrate of SGLT1, significantly inhibited the D-glucose uptake in both mucosal cells. The uptake of D-glucose was inhibited more extensively by substrates of facilitative transporters, 2-deoxy-D-glucose, D-mannose, and maltose. Figure 3 shows the comparison of the inhibitory effects on D-glucose uptake by isolated mucosal cells between α-methyl-D-glucoside and 2-deoxy-

[a] Concentration of D-glucose was 0.05 mM. Control values for buccal cells and cells of dorsum of the tongue were 121.3 ± 5.0 and 250.2 ± 4.3 pmol/min/10^5 cells, respectively. Results are expressed as the mean± SE of 3–8 experiments. * $p < 0.05$; ** $p < 0.01$; *** $p < 0.001$, compared with each control value.

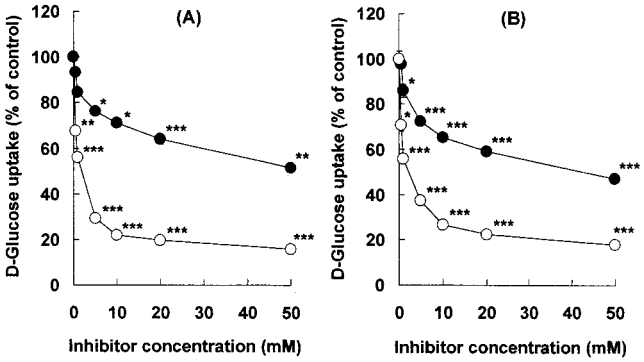

Figure 3—Effect of specific sugars on D-glucose uptake by isolated cells of human buccal mucosa (A) and dorsum of tongue (B). Initial concentration of D-glucose was 0.1 mM. Key: ●, with α-methyl-D-glucoside; ○, with 2-deoxy-D-glucose. Results are expressed as the mean with a vertical bar showing the SE of four experiments. The bars are hidden behind symbols. *** $p < 0.001$; ** $p < 0.01$; * $p < 0.05$, compared with the control.

D-glucose. As is evident from the figure, the inhibitory effect of 2-deoxy-D-glucose is greater than that of α-methyl-D-glucoside, suggesting that the contribution of the facilitative glucose transporters to D-glucose uptake by oral mucosal cells is larger than that of active Na^+/glucose cotransporter.

To further analyze the facilitative glucose transport system, similar uptake studies by isolated cells from buccal mucosa and the dorsum of the tongue were performed for 2-deoxy-D-glucose. Figure 4 shows the concentration dependency of the initial rate of 2-deoxy-D-glucose. Kinetic parameters for 2-deoxy-D-glucose were similarly calculated using the eq 1 shown above, and the results are as follows: V_{max}, K_m, and k_d values for cells of buccal mucosa are 417.9 ± 167.8 pmol/min/10^5 cells, 0.555 ± 0.705 mM, and 29.3 ± 11.2 nL/min/10^5 cells, respectively; on the other hand, those for cells from the dorsum of the tongue are 965.0 ± 115.7 pmol/min/10^5 cells, 0.619 ± 0.263 mM, and 69.1 ± 4.6 nL/min/10^5 cells, respectively. The k_d values thus obtained were similar to the initial uptake rate constants of L-glucose, which were shown above, in both cells. The statistical analysis by ANOVA clarified that both V_{max} and k_d values are significantly different between the two cells, while the difference of K_m value was not statistically significant. Table 2 shows the effect of ice-cold conditions, PCMB, or other sugars on 2-deoxy-D-glucose uptake by oral

with 10 mM mannitol	94.8 ± 2.9	97.5 ± 3.0
with 10 mM 2-deoxy-D-glucose	1.6 ± 1.2***	5.2 ± 1.2***
with 10 mM D-mannose	11.1 ± 1.5***	26.2 ± 1.8***
with 10 mM maltose	16.8 ± 1.0***	66.5 ± 0.7***
with 10 mM D-allose	35.5 ± 2.9***	43.1 ± 4.2***

[a] Concentration of 2-deoxy-D-glucose was 0.1 mM. Control values for buccal cells and cells of dorsum of tongue were 152.5 ± 1.8 and 211.8 ± 2.2 pmol/min/10^5 cells, respectively. Results are expressed as the mean± SE of three experiments. *** $p < 0.001$, compared with each control value.

mucosal cells. In both mucosal cells, 2-deoxy-D-glucose uptake at the concentration of 0.1 mM was markedly reduced in ice-cold conditions or by 0.5 mM PCMB. D-Mannose, maltose, and D-allose, sugars transported by the facilitative transporters, inhibited the uptake of 2-deoxy-D-glucose, suggesting that this sugar can be transported by multiple facilitative transporters.

2-Deoxy-D-Glucose Absorption from Oral Cavity—Oral mucosal epithelium is a stratified squamous epithelium with the polarity. In our previous study, we showed that D-glucose is absorbed from oral cavity by carrier-mediated mechanism, a part of which is Na^+-dependent.[13] To investigate whether the facilitative transport system operates on the apical surface of the mucosal cell or not, the absorption of 2-deoxy-D-glucose was examined by buccal absorption test. At the concentration of 1 mM, the absorption rates for 2-deoxy-D-glucose, D-glucose, and L-glucose were 630.9 ± 122.0, 3026.1 ± 91.3, and 198.9 ± 28.4 nmol/5 min, respectively. Although the absorption rate of 2-deoxy-D-glucose is lower than that of D-glucose, the inhibition by D-allose was observed: the absorption rate of 2-deoxy-D-glucose at 0.5 mM (443.2 ± 56.4 nmol/5 min) was inhibited to 267.7 ± 30.6 nmol/5 min ($p < 0.05$) by 5 mM D-allose. Although it was difficult to determine the kinetic parameters for 2-deoxy-D-glucose due to very low absorption (%) of this sugar at the high initial concentration, the expression of the facilitative transporter for D-glucose on the apical surface of the oral mucosal cells was suggested.

Western Blot Analysis of Glucose Transporters Present in Oral Mucosal Membrane—To identify glucose transporters present in oral mucosal membrane, Western blot analysis of the membrane protein was per-

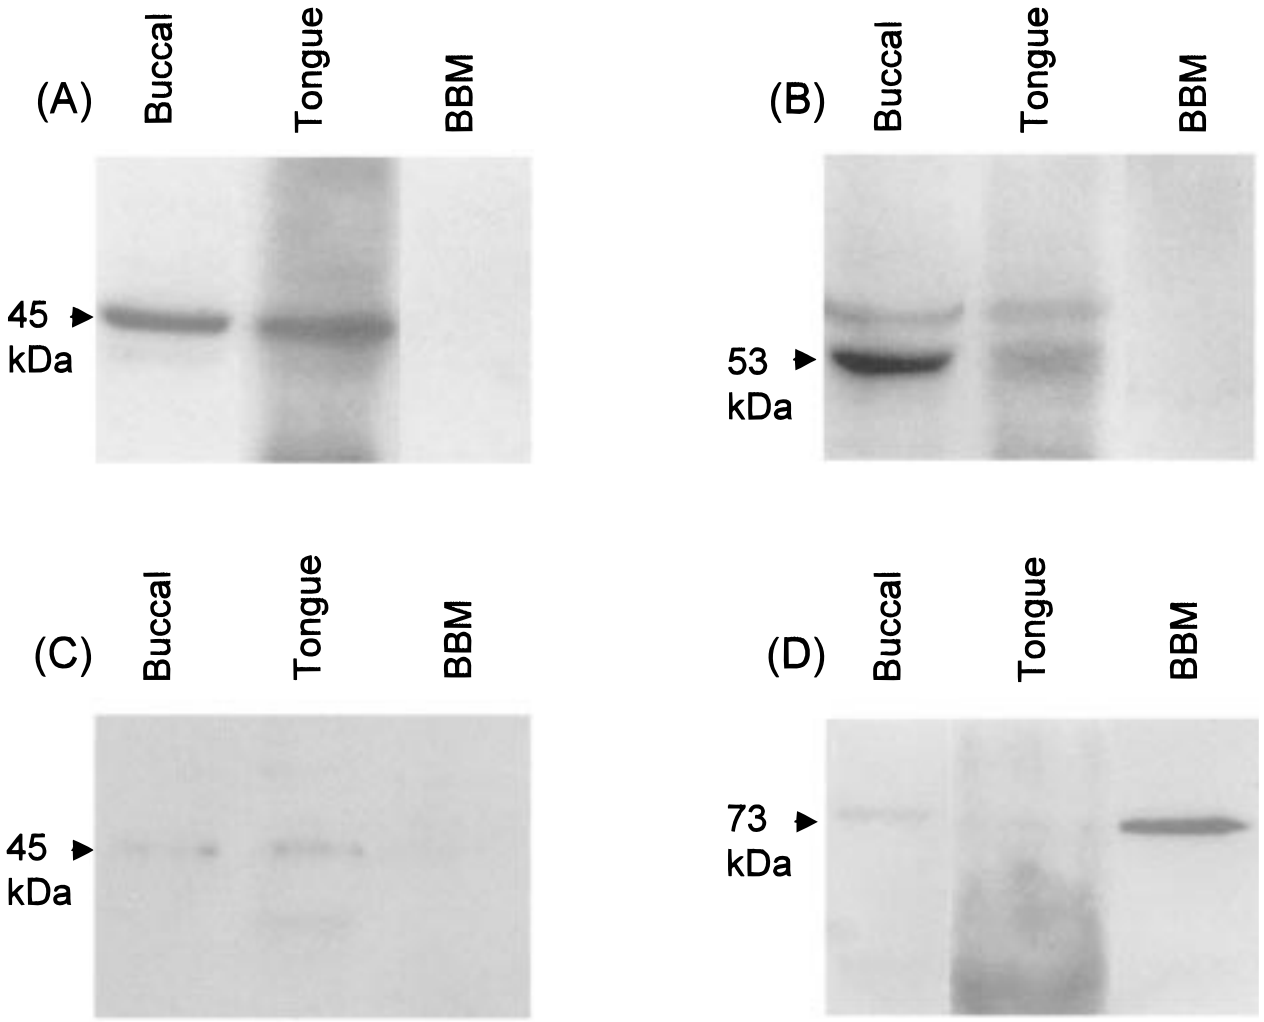

Figure 5—Western blot analysis of glucose transporters in isolated cells of human buccal mucosa, dorsum of the tongue, and brush border membranes of rat small intestine. Protein samples (20–50 μg) were electrophoresed through a SDS–PAGE gel, transferred to a nitrocellulose membrane and incubated with rabbit anti-human antibodies against GLUT1 (A), GLUT2 (B), GLUT3 (C), and SGLT1 (D). The membranes were incubated further with horseradish peroxidase-conjugated goat anti-rabbit immunoglobulin G. Horseradish peroxidase activity was revealed using ECL Western blotting detection reagents.

formed. The brush border membrane prepared from rat small intestine (BBM) was used as the positive control of SGLT1. The results are shown in Figure 5. Although there are some unidentified bands, not only the band for GLUT1 (45kDa[19]) but also the bands for GLUT2 (53kDa[15]), GLUT3 (45kDa[20]) and SGLT1 (73kDa[15]) are found in both buccal mucosal cells and cells of the dorsum of the tongue.

Discussion

D-Glucose is one of the nutrients that can be absorbed from oral cavity by the carrier-mediated mechanism.[6,13] In our previous study, we showed using perfusion cells for human oral mucosa that the carrier-mediated absorption of D-glucose is predominant in the dorsum of tongue.[13] However, details of glucose transporters present in the oral mucosal cells were remaining to be clarified. In the present study, oral mucosal cells were isolated from human buccal mucosa and the dorsum of tongue using a mouth-wash technique[16] and glucose transport systems present in these cells were examined. Lee et al. reported that buccal cells thus obtained containing superficial, intermediate and prickle cells, but not basal cells, are osmotically very stable and did not undergo any discernible swelling.[17] We confirmed that the viability of oral mucosal cells thus prepared was maintained as 80−90% over 3 h after the isolation.

As shown in Figures 1 and 2, stereospecific uptake of D-glucose was observed in both buccal mucosal cells and cells of the dorsum of the tongue. In the perfusion cell study described previously, we could not find the specialized transport mechanism for D-glucose in the buccal mucosa.[13] However, this isolated cell study could clarify that the specialized transport system for D-glucose is present not only in the dorsum of the tongue but also in the buccal epithelium. This discrepancy may be caused by difference in the surface area; that is, the large surface area of isolated mucosal cells could enable them to take up D-glucose more efficiently via the specialized transport mechanism. The result of the inhibition study (Table 1) suggested that, in addition to Na^+/glucose cotransporter, the facilitative glucose transporter is expressed in the oral epithelial cells. Furthermore, it was shown that the contribution of the facilitative transport mechanism to overall D-glucose transport in the oral mucosal cells is more predominant than Na^+-dependent active transport mechanism. The facilitative transport system present in the oral mucosal cells was suggested by the 2-deoxy-D-glucose uptake study (Figure 4, Table 2). D-Mannose, maltose, and D-allose inhibited the uptake of 2-deoxy-D-glucose. D-Mannose is transported by GLUTs1−4.[21,22] Maltose is an inhibitor of glucose transport by GLUT3, but not by GLUT2 or 4.[22] On the other hand, D-allose is an effective inhibitor

of glucose transport by GLUT2, but not by GLUT1, 3, or 4.[22] Thus, multiple facilitative transporters are suggested to be present in the oral mucosal cells. In addition, it was clarified by the buccal absorption test of 2-deoxy-D-glucose that the facilitative transport system is expressed on the apical surface of the stratified squamous epithelium. It has been reported that GLUT1, but not GLUT4, is expressed in human oral mucosa.[23,24] Finally, the result of the Western blot analysis suggested that GLUT1, GLUT2, GLUT3, and SGLT1 are expressed in the oral epithelial membrane (Figure 5). Further studies are necessary to elucidate how the active and facilitative transporters are operating in the stratified squamous epithelium of oral cavity.

As to the kinetic parameters for D-glucose uptake by isolated oral mucosal cells, V_{max} value for the dorsum of the tongue was 2.5 times larger than that for buccal mucosa, while K_m values for both cells were not significantly different. Although these values are pooled parameters of parallel Michaelis−Menten equations, the larger V_{max} value in the dorsum of the tongue suggests that transporters for D-glucose are more abundant in this site. The parameters obtained by 2-deoxy-D-glucose uptake experiments are also pooled values for multiple facilitative glucose transporters, but the larger transport capacity of the facilitative transport system in the dorsum of tongue than in the buccal is suggested, while K_m values in both cells were not significantly different. The reduction of D-glucose uptake rate in the Na^+-free medium and the inhibition of D-glucose uptake by α-methyl-D-glucoside were similar in degree in both mucosal cells, suggesting that Na^+/glucose cotransporter is also expressed more predominantly in the dorsum of tongue than in the buccal.

In conclusion, the in vitro uptake study using the isolated cells of human oral mucosa, buccal and the dorsum of the tongue, revealed that not only the Na^+/glucose cotransporter but also facilitative glucose transporters are expressed in the oral mucosal cells and that the transport system is more abundant in the dorsum of tongue than in the buccal. The glucose transporters were confirmed by the Western blot analysis.

Accepted for publication May 28, 1999.

Abstract □ The electrotransport transdermal fentanyl system (ET [fentanyl]), uses a small electrical current to enhance delivery of fentanyl to systemic circulation. Intermittent doses can be administered by periodic application of the current. The purpose of this study was to compare the effects of the frequency of intermittent drug delivery by ET (fentanyl) and compare the drug delivery to systemic circulation by ET (fentanyl) with intravenous administration. The topical safety was also determined for the ET (fentanyl) system. Nine adult male volunteers completed this three-treatment, randomized, 24-h, crossover study. ET (fentanyl) treatments with 200 μA direct current applied for 30 min at frequent (hourly) or infrequent (4-hourly) intervals over a 24-h period were compared. Also, the drug delivery to systemic circulation from ET (fentanyl) was compared with intravenous fentanyl 75 μg infused over 30 min every 4 h over a 24-hour period. The mean serum fentanyl concentration achieved with the hourly ET (fentanyl) regimen was higher than that for the 4-hourly ET (fentanyl) regimen as expected from the higher frequency of drug doses. The amount of fentanyl delivered estimated per dose from the ET (fentanyl) system using the iv fentanyl treatment as the reference was similar for the two ET regimens throughout the dosing period. This indicates consistent drug delivery regardless of the frequency of ET dosing. The majority of subjects reported either no, or barely perceptible, erythema 24 h after removal of the system.

Introduction

Fentanyl is a short-acting synthetic opioid analgesic. When administered by a passive transdermal system (Duragesic [U.S.]/Durogesic [outside U.S.]), fentanyl is effective for the treatment of moderate to severe chronic pain.[3] Compared to intravenous or oral routes for delivering analgesia, the passive transdermal system has the advantages of being a noninvasive, nonoral route that maintains adequate serum concentrations for the duration of application (for Duragesic, a patch has to be applied every 72 h).[4,5] The fentanyl passive transdermal system has proven effective for control of chronic pain; however, it is not suitable for managing postoperative pain and other acute or intermittent pain conditions.[4]

Analgesic delivery systems that are controlled by the patient (patient-controlled analgesia or PCA) provide better pain control than standard modes of delivery because they allow continuous patient access to pain medication within predetermined limits.[1] Such PCA systems are both efficacious and well accepted. The PCA systems are fully computerized portable syringe pumps with a reservoir for the drug solution. The pump delivers the drug into an intravenous access site on the patient via microbore tubing.

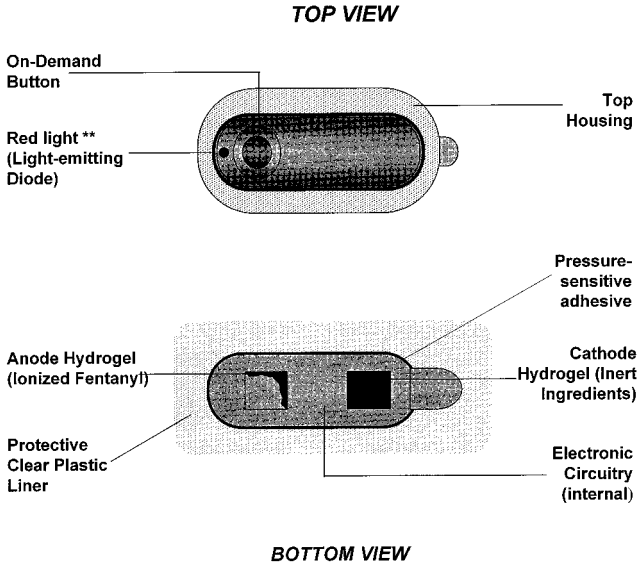

Figure 1—Schematic diagram of ET (fentanyl) system (**indicates when a dose is being delivered, as well as the approximate number of doses the patient has received since application of the particular system).

These pumps have visual displays providing information on patients drug consumption minute by minute. From the PCA systems, the drug can be either administered as a bolus injection, continuous infusion over a period of time, or continuous background infusion plus bolus whenever needed.[2] The economic advantages of PCA include lower cost due to the decreased need for medical intervention and, potentially, earlier release from the medical facility. Unfortunately, PCA equipment is costly, cumbersome, and invasive, and it requires maintenance and sterilization.

An electrotransport (ET) transdermal system for fentanyl has been developed which combines the advantages offered by PCA and the passive transdermal system. The ET system enhances the delivery of drug by means of an electrical current. Application of an electrical field facilitates the transport of charged compounds across the skin. A number of comprehensive reviews on the subject of electrotransport or iontophoresis have been written.[6–8] The pathways of molecular transport through the skin during iontophoresis have also been extensively studied.[19,20] The commercial ET system is a lightweight, self-contained system, worn on the patient's upper outer arm or chest. The system contains internal electronic circuitry, a battery, anode and cathode hydrogels, and an external button to activate delivery of fentanyl. The system is backed with a pressure-sensitive adhesive which allows it to stick to the skin (Figure 1). As with PCA, the drug delivery rate can be set by adjusting the current; as the current is increased, the rate of drug delivery is increased.[9] Intermittent doses

can be administered by switching the current on for a predetermined period of time (dosing period). This system can, therefore, effectively manage acute or intermittent pain conditions.

The purpose of this randomized crossover study was to compare fentanyl delivery to systemic circulation from frequent intermittent doses administered hourly to infrequent doses administered every 4-hours by an ET (fentanyl) system. An additional objective was to compare serum concentrations achieved from ET (fentanyl) treatments with the reference intravenous (iv) treatment, and estimate the fentanyl dose delivered to systemic circulation from ET (fentanyl) treatments using this reference treatment. The study also evaluated the topical safety of fentanyl delivered by ET (fentanyl) system.

Materials and Methods

The study enrolled 10 healthy adult male volunteers (all Caucasian, aged 20−37 years [mean 27.3, SD 4.8]) to ensure that nine subjects would complete the study. Subjects were within 10% of ideal weight, nonsmokers with no history of drug or alcohol abuse, and they had abstained from recreational drug use within the past 30 days. Subjects also agreed to abstain from alcohol from 48 h before the study started until the end of the study. Exclusion criteria included active skin disease that precluded application of the system; a history of CO_2 retention, asthma or other lung disease; other clinically significant medical problems or organ abnormalities; hemoglobin <13 g/dL; or a history of allergic reaction to fentanyl, other opioids, or naltrexone. The subjects were also screened for physical dependence on opioids by Narcan (Naloxone hydrochloride: Endo Pharmaceuticals, Wilmington, DE) challenge test.[10] The protocol and consent form were reviewed and approved by the Institutional Review Board of Inveresk Clinical Research Ltd. (Edinburgh, Scotland) before the study started.

This was a randomized, open-label, three-treatment, three-period, crossover study. Each subject received three 24-h fentanyl treatments separated by 6-day washout periods. The ET (fentanyl) system (E-TRANS [fentanyl], ALZA Corporation, Palo Alto, CA), using direct current at 200 μA over a 30-min interval, was compared with 75 μg of fentanyl iv delivered over the same interval. The prototype ET (fentanyl) system used in this study consisted of a custom-built current source (Medtronic Model 6443) attached to the wrist and connected by a cable to a patchlike drug unit. The drug unit was composed of two poly(vinyl alcohol) hydrogels: one contacting a silver anode (2 cm^2) and containing fentanyl hydrochloride (10 mg) with polymeric buffer, the other contacting a silver chloride cathode (6.5 cm^2) and containing a biocompatible buffered electrolyte. The hydrogels and electrodes were housed in a medical-grade polyethylene foam with a peripheral acrylic adhesive. The ET (fentanyl) application site (upper arm) was wiped with an alcohol swab as is normally done for cleansing purposes and then either wiped dry or allowed to air-dry. The drug unit was placed on the upper arm after the peel-off protective liner was removed from the adhesive layer.

Fentanyl was delivered for the first 30 min of each hour (regimen A) or for the first 30 min of every fourth hour (regimen B). Fentanyl solution (50 μg/mL) was administered intravenously by a portable, battery-operated, syringe driver pump (Model MS2000; Graseby Medical Ltd., Watford, Hertfordshire, UK) at a rate of 1.5 mL (75 μg) over the first 30 min of every fourth hour (total dose over 24 h, 525 μg; regimen C). To minimize the opioid effects of fentanyl, five doses of naltrexone 50 mg were administered at 12-h intervals, starting 14 h before the first fentanyl dose.

Blood samples were drawn immediately before the initial fentanyl administration and periodically throughout the treatment: 10, 20, 30, 45, 60 min post 0, 12, and 24 h dosing, and also at 25, 26, 28, 32, 36 and 48 h posttreatment initiation. Serum samples were assayed for fentanyl at Janssen Research Foundation (Beerse, Belgium) using a radioimmunoassay method with a quantification limit of 0.1 ng/mL.[11]

Pharmacokinetic Analysis—The average maximum serum fentanyl concentration (C_{max} in ng/mL) and corresponding time (T_{max} in hours) observed during the entire 24-h treatment regimen were calculated. Serum fentanyl elimination rate constants (k) were estimated by linear regression of log-transformed (natural log) serum fentanyl concentrations during the terminal log-linear phase of the data after system removal. Apparent half-life ($t_{1/2}$) values were calculated as 0.693/k.

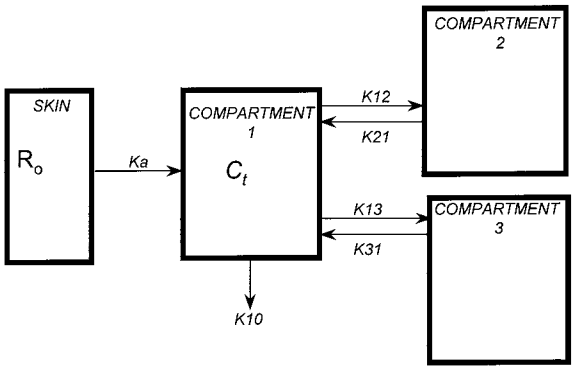

Figure 2—Three-compartment model for fentanyl administered by ET (fentanyl) system and by intravenous infusion (C_p = serum fentanyl concentrations).

For all three regimens, the area under the fentanyl concentration−time curve [$AUC_{(n-n+1)}$] was calculated by the linear trapezoidal method for doses administered during hours 0−1, 12−13, and 24−25, when frequent blood sampling was performed. For the two 4 h regimens (ET and iv), the $AUC_{(24-28)}$ (AUC for one dosing interval) was also estimated.

Statistical Analysis—An analysis of variance (ANOVA) was used to (i) compare $AUC_{(0-1)}$ among the three treatments and (ii) compare steady-state AUC over one dosing interval after the last dose ($AUC_{(24-25)}$ for the hourly regimen and $AUC_{(24-28)}$ for the 4 hly regimen) among the three treatments.

Compartmental Modeling—A three-compartment open distribution model was used to describe the observed fentanyl concentration−time profile after iv infusion. Equation 1 defines the three-compartment disposition model for administration of a single dose by iv infusion.[12] For fentanyl administration by the ET system, absorption was described by first-order kinetics (Figure 2).

$$C(_{t'}) = \frac{R_{iv}\,(1 - e^{\alpha\theta})(k_{21} - \alpha)(k_{31} - \alpha)e^{-\alpha t'}}{-V_1\alpha(\beta - \alpha)(\gamma - \alpha)} + \frac{R_{iv}\,(1 - e^{\beta\theta})(k_{21} - \beta)(k_{31} - \beta)e^{-\beta t'}}{-V_1\beta(\alpha - \beta)(\gamma - \beta)} + \frac{R_{iv}(1 - e^{\gamma\theta})(k_{21} - \gamma)(k_{31} - \gamma)e^{-\gamma t'}}{-V_1\gamma(\beta - \gamma)(\alpha - \gamma)} \quad (1)$$

Equation 2 describes the three-compartment disposition model for a single intermittent dose from an ET (fentanyl) system.[12] The absorption rate constant in this equation defines absorption due to both electrotransport and passive diffusion if any from the ET (fentanyl) system. In a previous study[13] the passive delivery of fentanyl from an ET (fentanyl) system was shown to be negligible. Four models for the ET (fentanyl) treatments were evaluated as described below. Model selection was based on residual sum of squares (RSS) and the Akaike information criterion (AIC).[14] A model with lower RSS and AIC values is preferred.

$$C_{(t')} = \frac{R_t k_a(1 - e^{\alpha\theta})(k_{21} - \alpha)(k_{31} - \alpha)e^{-\alpha t'}}{-V_1\alpha(\beta - \alpha)(\gamma - \alpha)(k_a - \alpha)} + \frac{R_t k_a(1 - e^{\beta\theta})(k_{21} - \beta)(k_{31} - \beta)e^{-\beta t'}}{-V_1\beta(\alpha - \beta)(\gamma - \beta)(k_a - \beta)} + \frac{R_t k_a(1 - e^{\gamma\theta})(k_{21} - \gamma)(k_{31} - \gamma)e^{-\gamma t'}}{-V_1\gamma(\beta - \gamma)(\alpha - \gamma)(k_a - \gamma)} + \frac{R_t k_a(1 - e^{k_a\theta})(k_{21} - k_a)(k_{31} - k_a)e^{-k_a t'}}{-V_1 k_a(\alpha - k_a)(\beta - k_a)(\gamma - k_a)} \quad (2)$$

where

t = Time since initiation of the treatment

$C_{(t')}$ = Concentration at time t′

t' = Time since initiation of the last input

α = First disposition rate constant

β = Second disposition rate constant

γ = Third disposition rate constant

k_{21} = Rate constant for transfer from second compartment to the central compartment

k_{31} = Rate constant for transfer from third compartment to the central compartment

V_1 = Volume of distribution of the central compartment

k_a = Transdermal absorption rate constant

R_{iv} = Rate of intravenous infusion (150 μg/h over 0.5 h)

R_o = Rate of fentanyl input after ET system dose at initiation and throughout for model 1

R_t = Rate of fentanyl input after ET system dose at time t:

= R_o (from 0−12 h); R_1 (from 12−24 h); R_2 (from 24−25 h) [stepwise increase in rate of fentanyl input such that $R_o < R_1 < R_2$; model 2

= R_o + st [linear increase in rate of fentanyl input; model 3]

= R_o (2-e^{-st}) [exponential increase in rate of fentanyl input; model 4]

s = Slope constant to account for increase in the input rate

CL = Clearance = $V_1\alpha\beta\gamma/k_{21}k_{31}$

θ = t' when $t' \leq 0.5$ or 0.5 when $t' > 0.5$

The profiles for multiple dose applications were then obtained by superposition of the profile associated with each administration given before t:

$$C_{(t)} = \sum_{j=1}^{M} C^{j}_{(t-(j-1)\tau)} \qquad (3)$$

where

$C_{(t)}$ = Concentration at time t

j = jth administration before t

M = Total number of administrations

τ = Dosing interval

These equations were simultaneously fitted to the all plasma concentration from each subject following all three treatments. Models were fitted to only those serum fentanyl concentration values above the quantification limit (concentrations below limit of quantification were set to missing). Pharmacokinetic disposition parameters and absorption parameters (both amount and absorption rate constants) were estimated by nonlinear regression, using the PROC NLIN procedure in SAS 6.04, with the "power model" weighting function.[15]

Safety Analysis—Safety was evaluated by analysis of pre- and poststudy blood chemistry, hematology, and urinalysis data, as well as physical examination results and electrocardiograms. During each 24-h administration period, and for 24 h after the end of each administration period, vital signs (heart rate, blood pressure, and respiratory rate) were recorded periodically. At 1, 6, and 24 h after system removal, the skin occluded by the system was evaluated visually, and any evidence of local reaction was scored as follows:

Erythema: 0 = none; 1 = barely perceptible redness; 2 = definite redness; 3 = beet redness.

Edema: Extent of erythema, papules, pustules: 0 = none; 1 = <50% occluded area; 2 = >50% occluded area.

Itching: 0 = none; 1 = mild; 2 = moderate; 3 = severe.

Results and Discussion

Ten healthy Caucasian males, aged 20−37 years (mean 27.3, SD 4.8), entered the study, and nine subjects completed. One subject discontinued study participation for a non-drug-related (personal) reason after completing the first regimen (fentanyl delivered by the ET system for 30 min/h). Data from the nine subjects who completed the study are included in the pharmacokinetic analysis, and data from all 10 subjects enrolled are included in the safety analysis. None of the subjects showed any signs or symptoms of withdrawal after administration of the Narcan challenge.

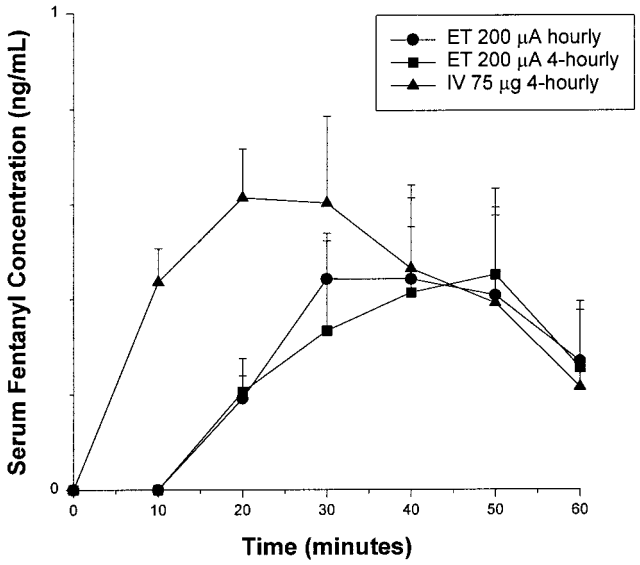

Figure 3—Mean (±SD) serum fentanyl concentrations for the first hour of the three 24-hour fentanyl regimens (n = 9). (Note: Concentrations below limit of quantification are set to zero value).

For three subjects, the duration of fentanyl administration in regimen A (30 min/h) deviated from the approved protocol. One subject received fentanyl for 1 h instead of 30 min, from hour 14 to hour 15 (half-hourly administration was restarted at hour 16). Two subjects received fentanyl for only 20 min during hour 5. The actual duration of drug administration was accounted for in the compartmental analysis.

Fentanyl Pharmacokinetics—Mean serum fentanyl concentrations increased after the first set of intermittent doses at hour 0 for both ET (fentanyl) regimens. However, the rate of increase with the ET (fentanyl) regimens was slower than that of the iv regimen (Figure 3) and serum fentanyl concentration 10 min after the dose was not detectable. Also, the mean serum fentanyl concentration declined rapidly upon termination of the iv infusion at hour 0.5, but when the ET (fentanyl) dosing interval ended, serum fentanyl concentrations did not decline for approximately 10 min (Figure 3). Similar observations were made following intermittent dosing at hours 12 and 24. These observations suggest that the barrier effect of the skin moderates both the rise and fall of serum fentanyl concentrations with ET (fentanyl) administration. Serum concentration profiles for the three regimens are shown in Figure 4. Following the hour 24 dose, the mean serum fentanyl concentration for the ET (fentanyl) hourly regimen was approximately 4-fold higher than that for the ET (fentanyl) 4-hourly regimen, which, in turn, was about twice as high as that for the iv 4-hourly regimen.

The mean fentanyl pharmacokinetic parameters are listed in Table 1. The mean C_{max} value for the ET (fentanyl) hourly regimen (2.6 ng/mL) was higher than those for the ET (fentanyl) 4-hourly or iv 4-hourly regimens (1.3 and 0.9 ng/mL, respectively). The T_{max} values for most subjects were between 24 and 25 h, with median values of 25 h after ET (fentanyl) administration and 24 h after iv administration.

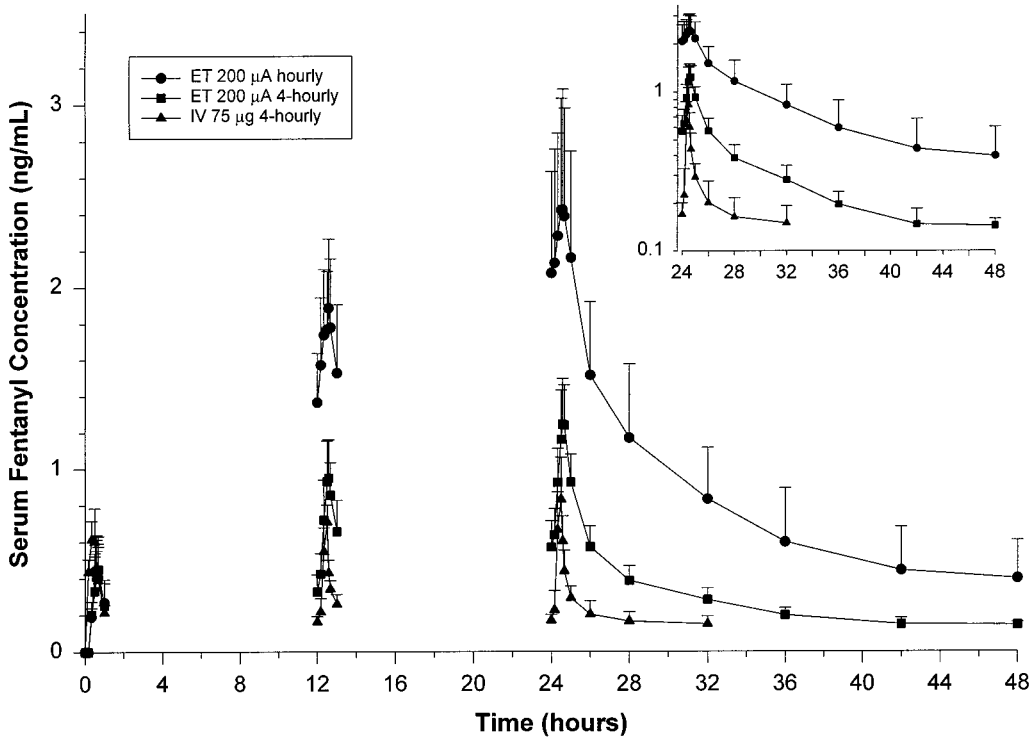

Figure 4—Mean (±SD) serum fentanyl concentrations for the three 24-hour fentanyl regimens ($n = 9$). Serum fentanyl concentrations were measured during hours 0–1, 12–13, and 24–25.

Table 1—Mean (± SD) Fentanyl Pharmacokinetic Parameters in Nine Healthy Volunteers[a]

		regimen		
parameter	units	A ET (fentanyl) hourly	B ET (fentanyl) 4-hourly	C iv 4-hourly
C_{max}	ng/mL	2.6 ± 0.7	1.3 ± 0.3	0.9 ± 0.2
T_{max}[b]	h	23.3 ± 4.0	23.3 ± 4.0	15.2 ± 11.6
K	h^{-1}	0.053 ± 0.029	0.083 ± 0.031	0.308 ± 0.257
$t_{1/2}$	h	22.0 ± 21.0	10.0 ± 5.6	3.4 ± 1.7
$AUC_{(0-1)}$	ng·h/mL	0.25 ± 0.11*	0.24 ± 0.13*	0.39 ± 0.08**
$AUC_{(12-13)}$	ng·h/mL	1.67 ± 0.35	0.75 ± 0.17	0.36 ± 0.04
$AUC_{(24-25)}$ for hourly regimen $AUC_{(24-28)}$ for 4-hourly regimen	ng·h/mL	2.23 ± 0.59*	2.66 ± 0.45*	1.00 ± 0.33**

[a] Abbreviations: C_{max}, peak serum concentration; T_{max}, time to peak concentration; k, apparent elimination rate constant; $t_{1/2}$, apparent half-life; AUC, area under the serum concentration–time curve. [b] The mean value for intravenous administration was skewed downward by three outlying values of <1 h. Median values for the three treatments were 25 h (regimens A and B) and 24 h (regimen C). Note: C_{max} and T_{max} are over the entire treatment period. *Parameters with the same number of asterisks are not significantly different ($p<0.05$).

A polyexponential decline of serum fentanyl concentrations occurred after the last dose in all three regimens (Figure 4). The mean apparent half-life values varied widely among the three regimens; half-lives were longer for the two ET (fentanyl) regimens (regimen A = 22.0 h; regimen B = 10.0 h) than for the iv regimen (regimen C = 3.4 h). Due to the assay sensitivity (0.1 ng/mL), the serum concentrations for all subjects could be quantified to hour 26 for the iv treatment, to hour 32 for the ET (fentanyl) 4-hourly regimen, and to a much longer duration of up to hour 48 for the ET (fentanyl) hourly regimen. This suggests that only the distribution phase, rather than the terminal elimination phase, was observed after the 4-hourly ET (fentanyl) and iv regimens. This probably was the reason for apparent half-life values for these two regimens to be shorter than it would be if the terminal elimination phase could have been quantified. This explanation is further supported by the previously reported terminal elimination half-life of 8 h following iv fentanyl adminsitration.[16] Alternatively, the long mean apparent half-life of the hourly ET (fentanyl) regimen (which was due mainly to two subjects with long apparent half-life values of 49.5 and 65.8 h) may indicate some contribution of the skin to the apparent terminal phase of the ET (fentanyl) regimens. However, if the long apparent terminal half-life observed after ET (fentanyl) administration was the electrotransport absorption half-life value, then the increase in serum fentanyl concentrations after a supplemental fentanyl dose would have been much more delayed than that observed. It appears that for ET fentanyl the depot or the reservoir effect is not as pronounced as seen with the transdermal system. With passive fentanyl transdermal system (Duragesic), the terminal half-life is severalfolds higher than that observed with intravenous fentanyl.[17] In the passive transdermal system, ethanol is incorporated to enhance drug solubility in the system and to enhance drug flux through the skin. Thus, fentanyl flux depends on the ethanol concentration being delivered. Ethanol flux is about 500 times greater than fentanyl flux.[18] After the system is removed, the ethanol in the skin is absorbed into systemic circulation much faster than fentanyl. This causes the rate of fentanyl appearing in systemic circulation to decrease

[a] α = First disposition rate constant. β = Second disposition rate constant. γ = Third disposition rate constant compartment. k_{21} = Rate constant for transfer from the second compartment to the central compartment. k_{31} = Rate constant for transfer from the third compartment to the central compartment. k_{10} = Elimination rate constant from the central compartment to out. k_{13} = Elimination rate constant from the central compartment to the third. k_{12} = Elimination rate constant from the central compartment to the second compartment. k_a = Transdermal absorption rate constant. CL = Clearance = $(V_1\alpha\beta\gamma/k_{21}k_{31})$. V_1 = Volume of distribution of the central compartment. S_a = Slope constant to account for increase in the input rate for treatment A. S_b = Slope constant to account for increase in the input rate for treatment B.

(forms a reservoir in the skin) and the terminal half-life is longer than that observed with intravenous administration.[18]

The $AUC_{(0-1)}$ values for the ET (fentanyl) regimens were similar (0.25 and 0.24 ng·h/mL) and were significantly lower ($p < 0.05$), approximately 60% of the value for the iv regimen (0.39 ng·h/mL). However, a direct comparison of the $AUC_{(0-1)}$ values may not be an exact reflection of the dose delivered to the systemic circulation because the profiles for the ET (fentanyl) regimens are shifted to the right of the iv regimen profile, and the concentrations at hour 1 for the ET (fentanyl) regimens are approximately 10% to 15% higher than that for the iv regimen. In contrast, the steady-state AUC after the last dose − mean $AUC_{(24-25)}$ for the ET (fentanyl) hourly regimen and $AUC_{(24-28)}$ for the ET (fentanyl) 4-hourly regimen were significantly more (2-fold) than that of $AUC_{(24-28)}$ for the iv administration. This is discussed further in the Compartmental Modeling section below.

Compartmental Modeling—Compartmental modeling was used to determine the exact amount of fentanyl delivered by the ET (fentanyl) treatments using iv regimen as the reference. Since the serum fentanyl concentrations declined polyexponentially (Figure 4), a model with first-order absorption and triexponential disposition was fitted to the data for the ET (fentanyl) regimens, and a triexponential disposition model was fitted to the data for the iv regimen (eq 1). This model (model 1) was able describe the iv data well. However, for the ET (fentanyl) treatments, with this model (model 1), the observations near hour 24 were underestimated and those near hour 0 were overestimated, suggesting that the amount of fentanyl delivered to the systemic circulation with the ET system increased with time. Three other models (allowing different amounts of fentanyl input at each dose interval) which were modifications of model 1 were investigated. Model 2 allowed stepwise increase in the input rate in eq 2; results from this model showed that the mean rate of input at hour 24 was nearly twice that for input at hour 0. However, since the input rate change is probably a gradual and continuous change rather than a step function, the model was further modified so that the input increased linearly (model 3) or exponentially (model 4) with time (eq 2). For most subjects, the RSS and AIC values with model 4 were less than model

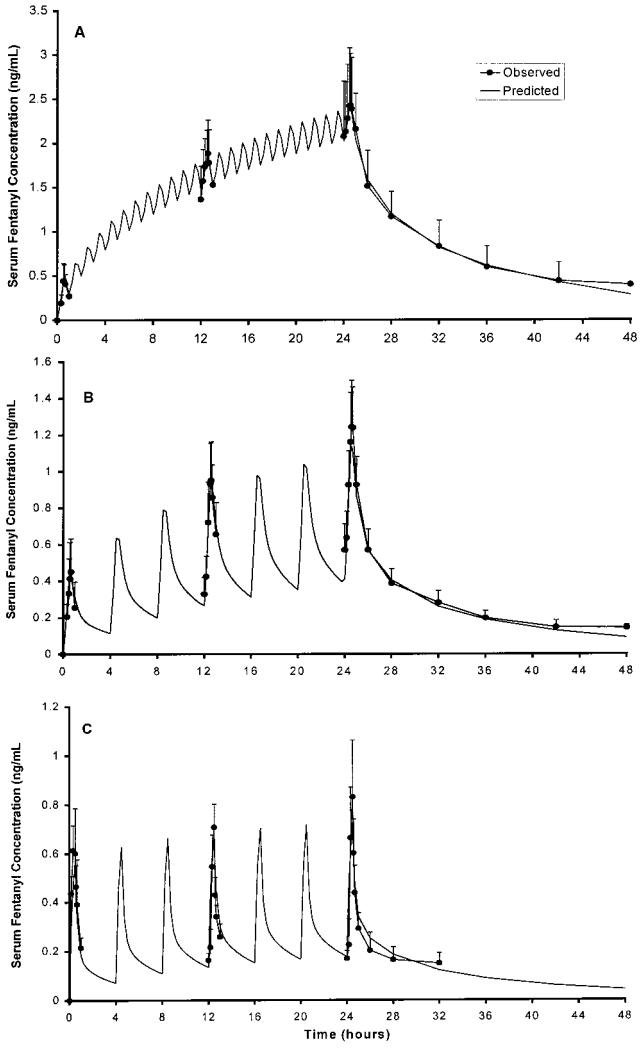

Figure 5—Model predicted and observed (mean ± SD) serum fentanyl concentrations for the three 24-hour fentanyl regimens (n = 9). A = ET (fentanyl) hourly regimen; B = ET (fentanyl) 4-hourly regimen; C = iv (fentanyl) 4-hourly regimen.

3. Figure 5 shows good agreement between the model predicted concentration and the observed concentration. The rate constants for model 4 are shown in Table 2. Using model 4 parameters, the estimated amounts of fentanyl delivered to the systemic circulation at hours 0, 12, and 24 for the ET (fentanyl) hourly regimen and the ET (fentanyl) 4-hourly regimen were determined ($R_t = R_o[2 - e^{-st}]$; eq 2). The estimated amount of fentanyl delivered in 30 min at 0, 12, and 24 h were 84, 126, and 142 μg, respectively, for the hourly treatment, and 84, 142, and 157 μg, respectively, for the 4-hourly treatment. The increase in the amount of fentanyl delivered at the 24 h time point may be due to skin (depot effect, permeability changes, etc.) equilibrating with the delivery system (current, occlusion, etc). However, any conclusion regarding a time-dependent fentanyl input rate phenomenon should be considered tentative because it is highly dependent on the plasma concentration data from the first intermittent delivery period; these concentrations are low and cluster around the detection limit of the assay. Regardless, the mean amount of fentanyl delivered initially and the rate of increase were of similar magnitude irrespective of the frequency of transdermal dosing (i.e., hourly or 4-hourly).

Safety and Tolerability—All subjects received naltrexone to minimize the opioid effects of fentanyl. One subject reported nausea with the ET (fentanyl) hourly regimen. Three subjects reported adverse events during the ET (fentanyl) 4-hourly regimen (two reports of headache, and one each of abdominal pain and dizziness). Five subjects reported adverse effects during iv administration (one each of abdominal pain, constipation, nausea, asthenia, somnolence, erythema, and pruritus). No clinically significant alterations in vital signs were noted.

All the observed topical reactions 1, 6, and 24 h after system removal are summarized in Table 3. Erythema at the active gel site persisting at 24 h after system removal was comparable for both ET (fentanyl) regimens: no, or barely perceptible, erythema was evident for five subjects in the hourly regimen and six subjects in the 4-hourly regimen, while definite erythema was evident for four and three subjects, respectively. "Beet" redness was evident for one subject in the hourly regimen. No erythema was noted at the inactive gel site 24 h after system removal. The active gel site reactions are likely due to both drug and current.

Conclusion

The amount of fentanyl delivered to the systemic circulation per delivery period by the ET (fentanyl) system was estimated to be similar regardless of whether intermittent delivery was hourly or 4-hourly. About half the subjects reported either no, or barely perceptible, erythema at 24 h after system removal. Therefore, electronically controlled fentanyl delivery from the ET (fentanyl) system provided consistent drug delivery with either frequent or infrequent intermittent dosing. The skin reactions were tolerable, although, a larger study would be needed to assess them.

Introduction

In line with the key focus of recent publications[1−3] emerging from the labs of Dressman, Amidon, and Shah, and in conjunction with the aims of both the FDA and US Pharmacopoeial Convention to improve and possibly develop alternative dissolution testing procedures as well as techniques for data analysis, this work considers an overview of the constantly changing areas of in vitro dissolution research in the evaluation of novel oral drug delivery systems. Over the years, dissolution testing has been employed as a quality control procedure in pharmaceutical production, in product development to assist in selection of a candidate formulation, in research to detect the influence of critical manufacturing variables such as binder effect,[4] mixing effect,[5,6] granulation procedure,[7] coating parameters,[8,9] excipient type,[10] and/or in comparative studies of different formulations,[11] in in vitro−in vivo correlations,[12−15] and possibly as an in vivo surrogate under strictly defined conditions.[16,17] It therefore becomes apparent that sensitive and reproducible dissolution data derived from physicochemically and hydrodynamically defined conditions are necessary in order to compare various in vitro dissolution data and be able to use such results as a surrogate for possible in vivo bioavailability, bioequivalence testing, and in vitro−in vivo correlations (IVIVC). However, the influence of technological differences and process variables involved during manufacturing on dissolution rate often complicates the decision making process in selection of the appropriate dissolution method and subsequent data interpretation technique. Moreover, Skoug and co-workers[18] stressed that this consequence is the reason dissolution studies and the defined specifications so often generate strong interest during regulatory review of solid oral dosage forms. As a result, the Center for Drug Evaluation and Research (CDER) at the Food and Drug Administration (FDA) has recently released guidelines called Scale-Up and Post Approval Changes, commonly referred to as SUPAC[19] and Extended Release Solid Oral Dosage Forms: Development, Evaluation and Application of In vitro/In vivo Correlations, commonly known as IVIVC,[20] to be used by the pharmaceutical sponsor in quality assurance and specific postapproval changes and to demonstrate that the "dissolution profiles of prechange product and postchange product are similar". The impact of the process and establishment of an in vitro and in vivo performance (IVIVR) as a critical stage in development of oral controlled release products has been further highlighted in the recent work of Devane and Butler.[21]

The current sophistication in formulation of new modified release drug delivery systems and associated diversity in dosage form design necessitates the development of new procedures or appropriate modification to the existing apparatus as an alternative for dissolution measurements.[22,23] More recently, it has been shown that the complex hydrodynamics and three-dimensional fluid flow pattern produced by the USP paddle[24] within different regions of the dissolution vessel varies significantly with a relatively more stagnant region at the bottom portion of the vessel.[25,26] Consequently, to mimic and more closely reflect the possible in vivo dosage form surface exposure, have reliable dissolution data, and be able to discriminate between release behavior of various modified release formulations, it becomes apparent that a better understanding of the role of hydrodynamics in relation to delivery

system and release mechanisms are necessary for the development of alternative dissolution methods.[22,23]

In general, the design of alternative dissolution methods may be approached in one of two ways or a combination. First, the method might consider the establishment of in vitro testing conditions similar to an actual in vivo setting. This approach may encompass instrumental developments mimicking gastrointestinal peristaltic motion with combination of flow-through methods for ensuring sink condition maintenance. All media used in testing of dosage forms should also be very similar to fluids comprising the gastrointestinal compartment particularly with respect to composition. Furthermore, other technical considerations may incorporate fabrication materials that are in contact with the dosage to possibly behave as pliable, flexible gastrointestinal tissue. Irrespective of the extent to which the ideal testing conditions are achieved, this approach becomes a mammoth task flawed by numerous inconsistencies. The second and more amenable approach is to establish in vitro dissolution conditions that may provide drug release profiles very similar to deconvoluted (i.e., fraction absorbed) blood plasma profiles through different levels of correlation as described in the USP. This entails an establishment of in vitro–in vivo correlation through manipulation of process variables such as selection of appropriate dissolution media systems taking into consideration sink condition maintenance and/or manipulation of fluid flow hydrodynamics by use of additional devices within the standard dissolution vessel. A useful example of the latter suggestion is the reported ring/mesh assembly used for the in vitro enhancement of dosage form positioning and surface area exposure in order to simulate hydrodynamically comparable conditions to that of in vivo.[27,28]

Generally reviews, theoretical papers, and research publications on the subject of dissolution have focused on standardizing, expanding, and developing useful mathematical and physical models principally due to apparent unresolved mechanistic complexities in the thermodynamic sense.[29–34] On the basis of such past in-depth analyses, researchers may presently use those concepts in experimental design of alternative dissolution methods. Therefore, to consolidate the principles governing the dissolution process, this article will attempt to provide a brief theoretical perspective of dissolution theory and associated concepts used in drug release from oral dosage forms. In keeping with the significant research activities with hydrophilic swellable matrixes, priority will be given to the optimization of dissolution studies pertaining to modified/controlled release drug delivery from such systems. A summary of attempts to improve the currently recommended USP, 23 dissolution methodologies for swellable sticking and swellable floatable delivery systems is provided, and the approaches recently used to overcome the associated difficulties are referred to in the text.[27] In addition, aspects relating to the lack of an official in vitro dissolution test method for lipid-filled capsules and the strategy used to solve this dilemma is discussed.[28] A critical review on the advantages and limitations of commonly used mathematical and statistical parameters for comparison of dissolution data, including the newly developed FDA-recommended f_2 similarity factor and f_1 difference factor, also follows. The use of "chemical stabilizers" in dissolution testing of drugs (such as ascorbic acid), normally susceptible to rapid decomposition in solution, is discussed for a gel-based controlled release product. We also briefly examine the problems associated with non-UV responsive drugs and the implications of colorimetric adaptation for the evaluation of release characteristics of both soluble and insoluble active substances.

Fundamental Dissolution Theories

Dissolution of a solute is a multistep process involving heterogeneous reactions/interactions between the phases of the solute–solute, solute–solvent, solvent–solvent, and at the solute–solvent interface. As one of the most commonly known mass transfer rate processes, the component heterogeneous reactions may broadly be categorized into (i) diffusion or convective transport of the solute from the interface to the bulk phase; and (ii) the rate of solute liberation and transport from and across the interfacial boundaries.

Various researchers in the field have developed theories to define the dissolution process and these have been comprehensively reported.[35–37] As three of the pioneering theories in the field, this review will not be complete without a brief description of the diffusion layer model, surface renewal theory, and limited solvation theory.

Table 1 concisely depicts the principal mathematical equations associated with the theories and highlights key points regarding the theory. Selected information is derived from the text of Abdou[35] for diffusion layer and surface renewal theories. The limited solvation theory is presented from the original work of Goldberg and co-workers.[38]

In the diffusion layer theory, the simplest model used to describe dissolution makes use of a single crystal in a nonreactive environment. The initial step in solution of the solid (solute or crystal) at the interface is usually very rapid and results in the formation of a saturated stagnant layer around the particle. This is contrasted by the second diffusion step that is slow and becomes the rate-limiting step in the dissolution process. In particular, the Noyes–Whitney equation (eq 3) illustrates that one of the main factors determining the rate of dissolution is drug solubility.[37] From this it is understood that in vivo the dissolution process may become the rate-limiting step if the rate of solution is much slower than the rate of absorption. This may be the case when the drug in question has a very low solubility at both gastric and intestinal pH.

The surface renewal theory assumes an equilibrium at the solute–solution interface is attained and that the rate-limiting step in the dissolution process is mass transport. The model is thought of as being continually exposed to fresh dissolution medium. The agitating medium consists of numerous eddies or packets into which the solute diffuses and is carried to the bulk medium. Due to the turbulence at the surface of the solute, there is no boundary layer and therefore no stagnant film layer. In other words the surface is continually being replaced with fresh medium.

The limited solvation theory[38] predicts that a crystal undergoes dissolution through an interfacial process in the dissolving medium. The true surface area of the crystal must be considered since each face of the crystal may have a different interfacial barrier. Hence each surface may provide a different contribution to the dissolution process.

Basic Theories of Dissolution Profile Analysis

Table 2 in summary depicts four prominent theories used in dissolution profile analysis, namely Wagner's,[39] Kitazawa's,[40–42] El-Yazigi's,[43] and Carstensen's.[44]

Wagner's theory[39] for the interpretation of percent dissolved–time plots of tablets and capsules relates the apparent first-order kinetics under sink conditions to the fact that a percent dissolved value at a certain time may be equivalent to the percent surface area generated at the same time. Kitazawa's theory[40–42] showed that the biphasic straight lines were obtained from plots of $\ln c_s/(c_s - c)$ vs t. The first segment was due to tablet disintegration or

Table 1—Summary of Fundamental Dissolution Theories[a]

theory[b]	equations		associated characteristics
diffusion layer[35]			
Fick's First Law	$J_{ix} = -D_i (\partial c_i/\partial x)$	(1)	Considers diffusion only under steady-state conditions.
Fick's Second Law	$\partial c/\partial t = D (\partial^2 c/\partial x^2)$	(2)	Used when drug concentration decreases with time; hence, considers non-steady state conditions.
Noyes and Whitney	$dc/dt = K (c_s - c_t)$	(3)	Description of drug dissolution based on constant surface area.
Brunner and Tolloczko	$dc/dt = kS (c_s - c_t)$	(4)	Manipulation of Noyes–Whitney's eq 3 by incorporation of surface area term S. Proposed the formation of a stagnant layer around the dissolving particle, a layer through which solute diffuses through into the bulk.
Nernst	-		
Brunner	$dc/dt = kDS/vh (c_s - c_t)$	(5)	Manipulation of Fick's first law and expansion of eq 4 by incorporation of a diffusion coefficient D, stagnant layer thickness h, and volume of dissolution medium v.
	If $c_t \ll c_s$ (i.e. <10%) $\Rightarrow dc/dt = kDS/vhc_s$	(6)	
	If v and S are constant $\Rightarrow dc/dt = K$	(7)	
Hixson and Crowell Cube Root	$w_0^{1/3} - w^{1/3} = (4\pi\rho\eta/3)^{1/3} (Dc_s/h\rho)t$	(8)	Originally developed for single particles but has been extended to use in multiparticulate systems.
	or $w_0^{1/3} - w^{1/3} = Kt$	(9)	
surface renewal[35]	$Vdc/dt = dW/dt = S(\gamma D)^{1/2} (c_s - c_t)$	(10)	Assumes solid–solution equilibrium is achieved at the interface and that mass transport is the rate-limiting step in the dissolution process.
limited solvation[38]	$G = k_i(c_s - c_t)$	(11)	An intermediate drug concentration less than saturation may exist at the interfacial barrier between the solid surface and solvent. Different faces of a crystal may have different interfacial barriers and therefore make different contributions to the dissolution process.

[a] Key to symbols and abbreviations: J_{ix}: flux (mg/cm^2 s^{-1}); D_i: diffusion coefficient; $\partial c_i/\partial x$: concentration gradient; $\partial c/\partial t$ or dc/dt: drug dissolution rate; K: first-order dissolution constant; c_s: equilibrium drug concentration; c_t: drug concentration at time t; k: dissolution constant; S: surface area; v: volume of dissolution medium; h: thickness of stagnant layer; w_0: initial powder weight; w: powder weight at time t; ρ: particle density; η: viscosity; h: thickness of diffusion layer; γ: interfacial tension; G: dissolution rate per unit area; k_i: effective interfacial transport constant. [b] Superscript numbers in first column denote references.

Table 2—Summary of Basic Theories of Dissolution Profile Analysis[a]

theory[b]	equations		associated characteristics
Wagner[39]	$\log(w^\infty - w) = \log M - k_s/2.303 (t - t^\circ)$	(12)	Relates apparent first-order kinetics under sink conditions to the distribution of available surface area and not dissolution per se. In case of exponential decrease in surface area with time, then first-order kinetics could be related to dissolution data.
	where $M = K/k_sC_sS^\circ$	(13)	
Kitazawa[40−42]	$\ln w^\infty/(w^\infty - w) = K't$	(14)	Assumes constant surface as long as sink is maintained. Under these conditions C^∞ is not always equal to C_s. A plot of $\ln w^\infty/(w^\infty - w)$ vs t yields a straight line with slope as the dissolution rate constant K'.
El-Yazigi[43]	$(100 - f_s) = 100k_d/(k_d - k_s)e^{-k_st} - 100k_s/(k_d - k_s)e^{-k_dt}$	(15)	Disintegration and dissolution are consecutive first-order processes. Because disintegration is usually much faster than dissolution, the semilog plot of $(100 - f_s)$ vs t yields a biexponential curve.
Carstensen[44]	If q is small and $F/q \ll 1$		Considered that the dissolution process in the USP basket proceeds in three steps: some disintegration but particles not dislodged from basket; more disintegration and particles move out of basket; more disintegration and first particles have completely dissolved. These three phases have to be mathematically explained to calculate the mass of solute undissolved at time $t = 0$.
	$\Rightarrow \ln m = -q\theta + \ln m_0$	(16)	
	If q is large		
	$\Rightarrow \ln m = -q\theta + q\theta_2 + \ln m_0\, 6(F/q)^3$	(17)	

[a] Key to symbols and abbreviations: w^∞: amount of drug in solution at infinite time; $(w^\infty - w)$: amount of undissolved drug; K: dissolution constant; k_s: dissolution rate constant; t: time in question; t°: time $t = 0$; C_s: aqueous solubility of drug; S°: surface area at time t°; K': dissolution constant; f_s: cumulative percentage of drug dissolved at time t; k_d: disintegration rate constant; k_s: dissolution rate constant; q: erosion constant; m: mass of undissolved solute; θ: experimentally observed time; F: factor as a function of the intrinsic dissolution rate (either in basket or vessel), drug solubility, and particle density. [b] Superscript numbers in first column denote references.

disruption of the capsule shell, while the second segment was obtained from this point onward to the end of the dissolution. Through multiplication by volume the concentration terms were changed to weight as depicted in eq 14. This theory was seriously criticized because it assumed a sudden increase in surface area rather than a continuous change, as proposed by Wagner. The major difference between the approach of El-Yazigi[43] and Kitazawa is that the former treats disintegration and dissolution as two kinetically distinct processes. The application of the eqs 16 and 17 in Carstensen's approach[44] generated curves that had skewed S shapes and followed Weibull or log-normal distributions when the percent dissolved was plotted against time. This may be attributed to the initial lag phase in the dissolution process (also expected from the proposed theory in terms of the time-dependent phases of disintegration, escape of particles through the basket, and dissolution of initial particles).

Currently Recommended USP 23 Methods

The currently available USP-23 has been one of the most valuable references to pharmaceutical scientists involved in the area of dissolution studies. The available dissolution methods within individual drug monographs with respect to solid oral dosage forms have been divided, where appropriate, into immediate and controlled or extended release products. Irrespective of this division and prominence given to differences in specifications such as tolerance (Q) values between immediate and controlled release products, there are no substantial differences in the methodologies used to test these products. Expected differences in dissolution test methods may include variation in the pH of the buffer medium depending on where the designed controlled release product is to deliver the drug or depending on the drug release rate, drug solubility, and absorption window. In most cases, the monographs are not up to date and the necessary refinements reflecting the recent advances in research findings with respect to both changes in media and methods are not included. With the recent tendencies toward application of hydrophilic floatable and/or sticking materials, new impetus has taken over in drug delivery systems design. Another unspoken reason for this shift in scientific momentum has been due to the "sudden" expiration of drug product patents and concurrent

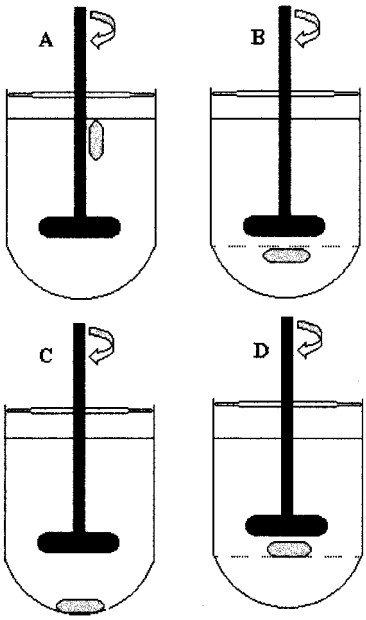

Figure 1—Schematic of drug delivery system positioning within a dissolution vessel: (A) floatable system close to the paddle shaft; (B) floatable system under the ring/mesh assembly; (C) sticking system adhering to bottom of dissolution vessel; (D) sticking system placed over the ring/mesh assembly. (Modified from Pillay and Fassihi[27]).

progress and expansion of "generic" industries. The application of new polymeric materials to enhance drug delivery, particularly in certain aspects of controlled release, has from our experience led to the recognition of limitations in the versatility of the currently recommended USP-23 dissolution methods.[24] This aspect has been adequately demonstrated in the recent publications showing the benefits of alternative dissolution approaches to the currently recommended USP-23 methods applied to swellable sticking and swellable floatable delivery systems, the summary of which is presented in the following sections.

Alternative Dissolution Methods and Examples

(i) Application of Ring/Mesh Assembly for Determination of Release Profiles from Swellable Low- and High-Density Matrices—As pointed out above, new modified release formulation technologies and diversity in dosage form design necessitates the development of new procedures or appropriate modification to the existing apparatus as alternative dissolution measurement methods.[22,23,27,28] For example, in dissolution studies of low-density swellable, floatable controlled release drug delivery systems, often position of the dosage form appears to be close to the paddle shaft and liquid surface as illustrated in Figure 1A (i.e., in schematic). On the other hand, when a sinker such as the USP-recommended[24] "wire helix" is wound around the delivery system, position of the dosage form will vary within the vessel (inconsistent hydrodynamics), and its free three-dimensional swelling process would be adversely affected and difficult to control.[45] Furthermore, and contrary to floatable dosage forms, many drug delivery systems having high density tend to adhere (stick) to the bottom of the dissolution vessel as illustrated in Figure 1C. This problem of sticking is accentuated with the use of swellable polymers such as hydroxypropylmethylcellulose, hydroxypropylcellulose, and poly(ethylene oxide). Under these conditions, the lower surface of the dosage form is not exposed to the dissolution medium, and drug release is limited to the exposed surfaces only. Similar phenomena are unlikely to occur in the human gastrointestinal tract. Furthermore, it may be anticipated that the USP 23 Apparatus 1 (rotating basket method) may be used to surmount this problem by allowing complete immersion of the dosage form and full surface area exposure. However, the early work of Withey and Bowker[46] on fluid flow dynamics clearly show that the rotating basket produces nonreproducible flow patterns with least fluid flow in the axial plane directly above and below the basket as well as within the basket. In addition, our experience has shown that some swellable delivery systems tend to expand greater than the diameter of the basket and often float against the flat base of the rotating shaft. These events will result in restriction of swelling and erosion processes, as well as limited surface exposure to dissolution medium. More recently, it has been shown that the complex hydrodynamics and three-dimensional fluid flow pattern produced by the USP paddle within different regions of the dissolution vessel varies significantly with a relatively more stagnant region at the bottom portion of the vessel.[25,26] Consequently, to mimic and more closely reflect the possible in vivo dosage form surface exposure, have reliable dissolution data, and be able to discriminate between release behavior of various modified release formulations, a better understanding of the role of hydrodynamics, delivery system, and release mechanisms together with the development of alternative dissolution methods is apparent.[22,23]

Recently Pillay and Fassihi[27] have used a new device (ring/mesh assembly) in conjunction with the paddle method to study the influence of the position of various dosage forms on release behavior and evaluated the release profiles obtained with such modification with those derived under standard dissolution conditions including the USP 23- recommended helical wire sinker used for swellable floatable delivery systems (see schematic Figure 1). Model drugs used included theophylline (0.85% water soluble at 25 °C) and diltiazem hydrochloride (>50% water soluble at 25 °C). It was shown that for a low water-soluble drug such as theophylline, full surface exposure was necessary in order to accomplish complete drug release from the delivery system (Figure 2a). This was accomplished by placing the delivery system over the ring/mesh assembly as depicted in Figure 1. This surface area exposure phenomenon was also applicable to a floatable theophylline system. Application of the USP-recommended helical wire sinker to the swellable floatable theophylline delivery system appeared to inhibit the three-dimensional swelling process of the dosage form and consequently suppressed drug release from the formulation (Figure 2b). Such a limitation was alleviated by positioning the delivery system below the ring/mesh assembly (Figure 1). In the case of diltiazem hydrochloride (solubility in water >50% at 25 °C) similar release differences as in the case of theophylline ($p < 0.05$) were also observed when the sticking delivery system was placed either in the vessel as recommended by the USP 23 standard method or when it was positioned over the ring/mesh assembly (Figure 2c). However, in the case of a swellable floatable system containing the highly soluble drug diltiazem hydrochloride, no differences in release were found by employing the helical wire sinker, placing the dosage form in the vessel as such or when the delivery system was fully submerged under the ring/mesh assembly (see Figure 2d). Hence, the nature of drug release behavior from swellable floatable systems depended both on full surface exposure and unhindered swelling as well as drug solubility.

(ii) Evaluation of Drug Release from Lipid-Filled Hardshell or Softgel Capsules—Considerable interest has been shown in the formulation of lipid-filled capsules for the enhancement of either in vivo dissolution rates or

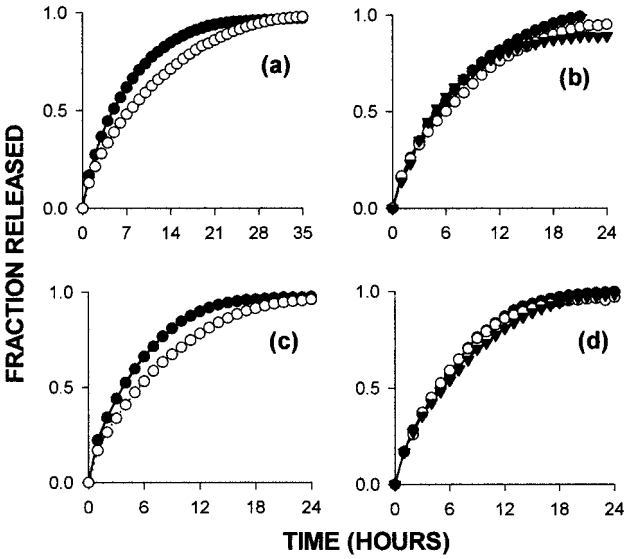

Figure 2—(a) Theophylline release from a swellable sticking drug delivery system. bioavailability of bioactive agents.[28,47,48] To ascertain that drug is completely delivered from its formulation over an appropriate time period and is able to reach and cross the gut wall, an aqueous environment similar to the gut luminal fluid and a sink resembling the lipoidal nature of the gastrointestinal mucosa becomes a necessary condition for the development of a prognostic in vitro test method. Both softgel and hard shell capsules filled with vehicles which are capable of self-emulsification (due to their ability to form fine oil-in-water emulsions) offer great potential for the oral delivery of insoluble hydrophobic and poorly absorbable drugs. However, in vitro evaluation of such dosage forms have thus far been problematic, since no official dissolution method for lipid-based formulations as yet has been established. This may be due to the relative difficulties associated with the evaluation methodology of lipid-based formulations. A greater challenge is presented when poorly soluble drugs in a lipid-based vehicle are presented as lipid-filled capsules for enhancement of solubility. Such matrixes, however, are not soluble in commonly used aqueous dissolution media. With some conventional dissolution methods, the use of surfactants[48–50] or hydro-alcoholic media[47,50] have been recommended. However, it is speculated that exposure of the gelatin shell to such media may induce physical and/or chemical changes, arising either through complex formation or cross-linking reactions. Typically, sodium lauryl sulfate (SLS), an anionic surfactant, is often employed in dissolution media; however, many researchers fail to recognize that SLS will bind to cationic charges of gelatin at pH values equivalent to

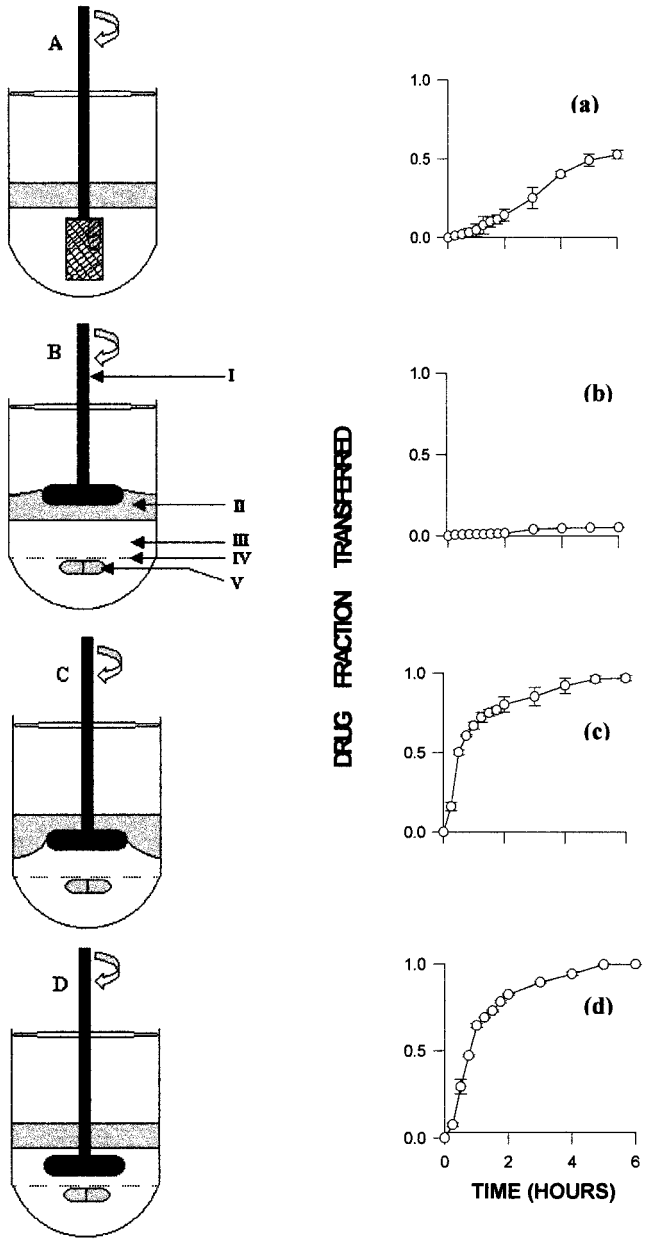

Figure 3—A comparative illustration of the four dissolution designs employed for the induction of different hydrodynamic conditions. Left panel: Key: I = Position of either rotating basket or paddle with hydrodynamic arrangements as follows. Design A: Centrally positioned in aqueous phase between boundaries of organic phase and bottom of vessel. Design B: Halfway at air/organic phase interface. Design C: Halfway at organic/aqueous phase interface. Design D: Centrally positioned in aqueous phase between boundaries of organic phase and ring/mesh assembly. Stirring rate of 75 rpm was used in all designs with exception of design D where in addition 100 rpm was also tested. II = organic phase, i.e., 100 mL 1-octanol. III = aqueous phase i.e., phosphate buffer: 400 mL for design A, 200 mL for designs B and C, 300 mL for design D. Note that 400 and 300 mL of phosphate buffer were employed in designs A and D to ensure that basket and paddle are fully immersed in aqueous phase. IV = ring/mesh assembly. V = Position of capsule either within basket or below ring/mesh assembly. Right panel: Transfer profile of lipid-based nifedipine capsule preparation derived under different hydrodynamic conditions and designs as described above ($N = 3$). (a) Profile obtained using the USP 23 rotating basket method at 75 rpm (dissolution design A). (b) Profile obtained using paddle over ring/mesh assembly halfway at air/organic interface at 75 rpm (dissolution design B). (c) Profile obtained using paddle over ring/mesh assembly halfway at organic/aqueous interface at 75 rpm (dissolution design C). (d) Profile obtained using paddle over ring/mesh assembly in aqueous phase at 100 rpm (dissolution design D). (Modified from Pillay and Fassihi[28]).

gastric pH. These interactions may influence the solubility and disintegration time of the shell and/ or true release potential of the product. Therefore, difficulties that may be experienced include, but are not limited to, exposure of gelatin shell to the organic phase, separation of poorly soluble drugs as metastable liquid crystals, lack of reproducibility in dissolution data, dosage form and lipid flotation in the dissolution vessel, etc.

In a recent report[28,51] a method which encompasses the development, design, and use of a modified two-phase dissolution media system by a novel approach for testing of either soft or hard shell lipid-filled gelatin capsules was proposed. Nifedipine was chosen as the model compound due to its water-insoluble nature (<10 μg/mL at 25 °C) and high octanol–water partition coefficient (10000:1). The experimental design takes advantage of the inherent immiscibility of aqueous phosphate buffer and 1-octanol, as well as the ability to modulate dissolution hydrodynamics and position of the formulation in the aqueous phase within the vessel (see Figure 3, i.e., schematic in left panel). Furthermore, the organic phase will act as a sink for drug removal from the aqueous phase in the dissolution vessels, a concept also recognized and pointed out in the early work of Gibaldi and Feldman[52] on the establishment of in vitro sink conditions in dissolution rate analysis and the merits of using a two-phase dissolution media system.

With USP-23 Apparatus I, it was demonstrated that the standard dissolution basket pores (mesh no. 40) and lack of appropriate hydrodynamic conditions within the basket have a significant limiting effect on drug release from the oleaginous formulation; hence, incomplete release was achieved (maximum of 50% released in 7 h; see profile in Figure 3a in right panel). As depicted in Figure 3, different hydrodynamics and various positionings of the rotating paddle was attempted to afford complete drug transfer to the upper organic 1-octanol phase from the lower aqueous phosphate buffer phase. Note that each design is accompanied by its appropriate release profile as depicted in Figures 3a–d in the right panel. With design C, induction of fluid dilatation at the organic/aqueous interface proved to be effective in encouraging rapid dissolution of the capsule shell and subsequent self-emulsification of the formulation. This essentially enabled complete drug transfer in 6 h (96.84%) (see profile in Figure 3c in right panel). Manipulation of the hydrodynamic conditions in the case of design D proved crucial in determining the rate of drug transfer and reproducibility of such a process (see profile in Figure 3d in right panel).

(iii) Determination of Dissolution Profile under Nitrogen Blanket for Oxidizable or Unstable Substances—A typical example of such substance evaluated in our laboratory will be given below. Ascorbic acid displays very poor stability characteristics in aqueous media in the presence of oxygen. As a result during the release process of ascorbic acid in a typical dissolution study, significant degradation products are simultaneously formed. To suppress the degradation process initially, the dissolution media can be purged with nitrogen gas while the gas flow would continue throughout the dissolution study. To generate a blanket of nitrogen gas over the medium within the vessel, individual vessels were sealed with the exception of allowing enough tolerance for shaft rotation. A typical profile obtained under such conditions is shown in Figure 4. Therefore full stability considerations and utilization of appropriate analytical techniques for determination of degradation and other byproducts is essential.

(iv) Glucosamine Release Study from Swellable Hydrophilic Matrix System—Typically in any dissolution study, UV spectrophotometry measurements are more preferable in terms of simplicity and cost saving. When

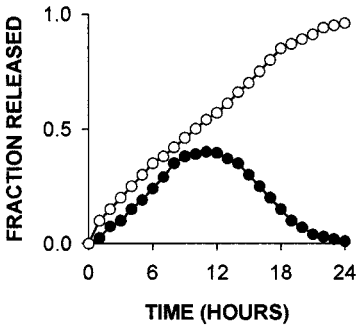

Figure 4—Typical profile for release of ascorbic acid in aqueous medium from a hydrophilic gel-based system ($N = 3$) under standard dissolution conditions showing significant degradation (●) and under modified conditions using a constant nitrogen purge (○). (From Fassihi, unpublished data).

substances do not absorb UV light often derivatization or complexation by addition of specific reagents may be adapted. Glucosamine as such does not absorb UV light. To measure the amount of glucosamine released, sufficient quantity of ninhydrin was added to the dissolution medium and color reduction as a result of glucosamine–ninhydrin complex formation could have been measured. This, however, resulted in the medium penetration into the swellable hydrophilic matrix causing significant peripheral stiffening of the matrix as a result of intragel complexation and suppression of release rate. As a result it was decided to remove samples of glucosamine solution periodically from the medium, adding to standard ninhydrin solution and measuring the color changes spectrophotometrically. Under these conditions, the rate constant of complex formation has to be optimized.

(v) Use of Reverse-Binding Technique for Evaluation of DMP 504, a Water-Insoluble Bile Acid Sequestrant—DMP 504 is a water-insoluble, cross-linked polymeric bile acid used as a nonsystemic cholesterol lowering agent, since it has the ability to bind bile salts with a slow dissociation rate. A film-coated DMP 504 tablet formulation was recently developed.[53] To evaluate the release characteristics of this dosage form, a new dissolution test method was proposed,[53] since direct measurement of drug concentration in the dissolution medium cannot be accomplished due to the water-insoluble nature and the fact that it has a binding function. A sodium cholate–phosphate buffer solution was selected as a dissolution medium. The amount of drug released from the tablet was calculated from the amount of cholate bound by the released drug at various time points using a binding calibration curve. By HPLC analysis, the bound cholate was calculated from the free cholate remaining in the dissolution medium at different time intervals. Through this approach it was determined that DMP 504 was completely released from the film-coated tablets within 15 min. Furthermore, from recovery testing on the bile salt, it was established that the reverse binding technique is robust, and values obtained were representative of complete release/binding.

Elementary and Supac-Based Dissolution Data Analysis

In the past decade many approaches have been proposed for the comparison of dissolution profiles.[54–57] In spite of the development of complicated approaches employing multivariate analysis, time series models, and mathematical models, the main problem persisting in the comparison process was the inability to define an exact measure of quantification, a point strongly acknowledged by Shah et

al. in their recent work on dissolution profile analysis.[2] Over the years, scientists have given much consideration to use of the Weibull function,[58,59] a model-dependent approach, as depicted in eq 18:

$$m = 1 - \exp[-(t - T_1)^{b/a}] \quad (18)$$

where m is the percent dissolved at time t, a is the time scale parameter, b is the shape factor, and T_1 is the location parameter. The shape factor, b, qualitatively defines the curve, i.e., when $b = 1$, the curve becomes a simple first-order exponential. If $b > 1$, the drug release rate is slow initially followed by an increase in release rate. The shape factor also provides qualitative information on diffusion and disintegration processes. The effective surface area for dissolution will be maximum after a certain time at the outset when $b > 1$, while when $b \leq 1$ no disintegration occurs at all, and the rate of dissolution will decrease steadily. The scale factor, a, provides a quantitative evaluation by differentiating the curves along the time axis. As pointed out by Polli and co-workers,[60] the Weibull model becomes fraught with an element of subjectivity because the judgment of the researcher is used in devising criteria for an adequate model fit. This further introduces a lack of metric sensitivity since as with all model-dependent approaches, no acceptance limits have been set as standard. In addition, the success of this approach relies on linearizing the dissolution data. However, a considerable curvature may be found in the upper region of the plot if the accumulated fraction of drug dissolved is not 1.0. In addition, the location parameter, which represents the lag time before the actual onset of the dissolution process, has to be estimated indirectly by a least-squares analysis or a graphical trial and error technique.

Therefore, it may be useful to consider a second category of analyses, i.e., model-independent treatment of dissolution data in order to determine the release profile similarity and concomitant dissimilarity where applicable. In this work we will focus on two classes of model-independency, namely time point or ratio test approaches and pairwise models. Model-independency, previously described by Rescigno,[61] in general would generate results for which the values do not depend on the selection of the specific parameter for fitting the data, but are dependent on the sampling times t_1, t_2,..., t_n and on an appropriate coefficient w_j representing the weight that the sampling time t_j has in the determination of the specific fitted functions.

In the time point/ratio test approach the $t_{50\%}$, $t_{70\%}$, and $t_{90\%}$ values as well as the mean dissolution times ($MDT_{50\%}$, $MDT_{70\%}$, $MDT_{90\%}$) are calculated for each formulation in each of the replicate dissolution measurements. Application of MDT provides more accurate drug release rate as compared to the $t_{x\%}$ approach and is determined as the sum of the individual periods of time during which a specific fraction of the total dose is released.[62]

The following equation (eq 19) may be used to calculate the MDT for each percentage point:

$$\mathrm{MDT} = \sum_{i=1}^{n} \hat{t}_i \frac{M_t}{M\infty} \quad (19)$$

where M_t is the fraction of dose released in time $\hat{t}_i = (t_i + t_{i-1})/2$, and M_∞ corresponds to the loading dose.

In the pairwise approach, determination of a "difference factor, f_1"[63] and "similarity factor, f_2"[19,20,63] (as outlined in the SUPAC and IVIVC guidelines) using the mean percentage released values can be performed by using eqs 20 and 21. To validate the acceptance of the f_1 and f_2 fit factors, calculations should be performed on the individual dissolution data of each formulation, which should reflect no statistical difference ($p > 0.05$) to the mean dissolution values.

The recent guidelines by the CDER at the FDA[20] describes the necessary criteria for granting biowaivers for specific changes in drug product manufacturing such as formulation changes or even changes in manufacturing site. To this end, the guidelines and specific published work[63] on extended release solid oral dosage forms describe the mathematical treatment of dissolution data derived from the pre- and postapproval changes by comparing their release profiles using the "similarity factor, f_2" which may be defined as follows:

$$f_2 = 50 \log\left\{\left[1 + \frac{1}{n}\sum_{t=1}^{n} w_t(R_t - T_i)^2\right]^{-0.5} \times 100\right\} \quad (20)$$

where n is the number of dissolution time points, w_t is an optional weight factor, R_t is the reference assay at time point t, and T_t is the test assay at time point t. Note that the "reference" and "test" products may be identical formulations. Optimization of release profiles may be achieved by the appropriate adoption of standard or alternative dissolution methods. The f_2 value between 50 and 100 suggests that the dissolution profiles are similar. The f_2 value of 100 suggests that the test and reference release profiles are identical, and as the value becomes smaller, the dissimilarity between release profiles increases. Equation 20 is a logarithmic transformation of the sum of squared error. It takes the average sums of squares of the difference between test and reference profiles and fits the result between 0 and 100. It is important to note that eq 20 is for the comparison of dissolution curves in which the average difference between R_t and T_t is <100. The use of the weight factor allows some values to be more important than other values, where w_t will be >1. If all values are treated equally, then $w_t = 1.0$.

In addition, Moore and Flanner[63] in their recent work also describe an f_1 fit factor or "difference factor" as follows:

$$f_1 = \left\{\frac{\sum_{t=1}^{n}|R_t - T_t|}{\sum_{t=1}^{n} R_t}\right\} \times 100\% \quad (21)$$

where f_1 describes the relative error between two dissolution profiles. "It approximates the percent error between two curves. The percent error is zero when the test and reference profiles are identical and increases proportionally with the dissimilarity between the two profiles".

Advantages and Limitations Associated with the Time Point/Ratio Test and Pairwise Approaches Used in Dissolution Data Treatment

The time point approach ($t_{x\%}$) for the interpretation of dissolution data appears to be inadequate for complete characterization of the profiles, since comparison of profiles not following a single path or void of crossover are not uncommon. Consequently, the choice of single data points for the calculation of meaningful dissolution values are questionable in the case of such issues revolving around product bioequivalence. Similarly, the choice of $MDT_{50\%}$, $MDT_{70\%}$, and $MDT_{90\%}$ may not always provide accurate information when profile crossover is too close. In the case of immediate release products such crossover in drug

release profiles may not present a major problem since the time scale of the release event is very short, often in the range of a few minutes to hours. On the contrary, such occurrences with controlled release products may have a significant impact on both quality assurance during product development and establishment of in vitro−in vivo correlations. Therefore, in the characterization of such dissolution profiles, a more in-depth analysis of data could provide a better description of the overall release profile.

Polli and co-workers[60] recently undertook an extensive study to mathematically and statistically evaluate various methods for the comparison of dissolution profiles of conventional metoprolol tartrate dosage forms for the demonstration of IVIVC. One of the selected methods included the application of the "similarity factor, f_2". In this work[60] as well as in studies from our lab,[27,28] it is shown that the similarity factor, f_2" is useful in providing an overall basis for dissolution profile comparisons. In addition, the fit factors evaluate curves that cross without a canceling effect. This effect may be unavoidable when the $t_{x\%}$ and $MDT_{x\%}$ models are used. While the method appears accurate, one of the main difficulties experienced is the "dependence of metric value on length of dissolution profile". When the "similarity−difference factor approach" is employed in data treatment (pairwise procedure), it becomes apparent that the selection and determination of the number of dissolution time points play a critical role in the calculation of the similarity factor value and the subsequent decision as to whether the test and reference profiles resemble each other or not. This observation is in agreement with the latest addition to the CDER document on the dissolution guidance for immediate release products.[64] However, it should be noted that as yet no limit on the selection of the dissolution time points has been released in the case of modified release dosage forms. For example, in the case of the high-density sticking formulation of theophylline (Figure 2a), f_2 values of 49.85 and 51.30 are obtained when time points (i.e., the *n* value) up to 30.5 and 35 h are respectively selected. This is also the case for the high-density sticking system of diltiazem hydrochloride (Figure 2c), i.e., f_2 values of 47.57 and 52.09 are obtained when time points up to 15 and 25 h are selected. Therefore, marginal differences observed in the comparison of dissolution data between the "test" and "reference" products may result in rejection of the test product as it is currently stipulated in the guidelines.

Conclusions

Historically, the theories applied to dissolution have remained unchanged, though to date their application and basic understanding is essential for design and development of sound alternative dissolution methodologies as well as for deriving complementary statistical and mathematical techniques for unbiased dissolution profile comparison. The various approaches described in this review, including intervention with the ring/mesh assembly, application of two-phase dissolution media systems, use of reverse binding technique, chemical stabilization via constant nitrogen gas purge into aqueous dissolution media, and chemical complexation/interaction outside the dissolution vessel as a colorimetric tool for analytical measurements, emphasize the potential of new or alternative methods for both qualitative and quantitative in vitro dissolution analysis. In particular, and as defined by dissolution theories, strict control of sink conditions by possibly mimicking the role played by the lipoidal nature of the gastrointestinal tissue in drug dissolution and absorption is primarily an absolute necessity prior to validating any in vitro−in vivo comparison. Various model-dependent and independent techniques have been used to characterize dissolution profiles for the primary purpose of comparison. With the advent of international harmonization of scientific protocols and implementation of SUPAC guidelines including site-to-site manufacturing conditions, such process comparisons have important regulatory implications. Although not infallible, the most statistically viable approach at this stage appears to be the use of f_2 similarity factor and f_1 difference factor. As outlined earlier, one of the distinct features of these two model-independent statistical measures surpassing all other techniques for profile comparison is their unique ability for complete profile characterization. However, more data on their utility in conjunction with similarity of in vivo drug absorption profiles will provide the ultimate measure of their discerning potential.

UPPER III: Unified Physical Property Estimation Relationships. Application to Non-Hydrogen Bonding Aromatic Compounds

NEERA JAIN AND SAMUEL H. YALKOWSKY*

Contribution from *Department of Pharmaceutical Sciences, College of Pharmacy, 1703 E. Mabel Street, The University of Arizona, Tucson, Arizona 85721.*

Received April 9, 1999. Accepted for publication June 28, 1999.

Abstract □ The UPPER scheme uses four additive and two nonadditive parameters and several well-known equations to calculate 21 physical properties of organic compounds strictly from molecular structure. The scheme allows reasonable estimations of melting and boiling points, aqueous and octanol solubilities, air–octanol, air–water, and octanol–water partition coefficients, vapor pressure, and other properties. In this report non-hydrogen bonding aromatic compounds are used to evaluate a portion of the UPPER scheme.

Introduction

A number of group contribution methods of calculating various physical properties of compounds such as melting point, boiling point, aqueous solubility, octanol solubility, partition coefficients, and vapor pressure have been reported. Some of these have been reviewed by Lyman et al.[1]. The most commonly used schemes for each property are independent of one another and are based on different models and assumptions for the molecule. Two notable exceptions have been presented by Bondi[2] and Joback and Reid.[3] These each use a single molecular fragmentation scheme for the calculation of several physical properties. Recently computational approaches have been used by several groups.[4−12] Unlike most existing schemes, the UPPER (unified physical property estimation relationships) scheme[13,14] uses calculations that are simple, straightforward, and can be performed without a computer. They are also based upon well-known physicochemical relationships. The molecular descriptors used in the UPPER scheme are well defined and highly intuitive. The UPPER scheme is unique in its use of a combination of additive group contribution values and simple nonadditive molecular parameters that account for the effects of the overall molecular geometry.

The UPPER scheme has many applications in the fields of pharmaceutical, environmental, and material sciences. Estimations of the above physical properties can provide important insight regarding the pharmaceutical efficacy, environmental fate, and industrial utility of a compound.

In this study estimated values for eight physical properties calculated by UPPER are compared to experimental values obtained from the literature. Aromatic compounds (benzenes, naphthalenes, anthracenes, phenanthrenes, and biphenyls) substituted with non-hydrogen bonding groups (i.e., methyl, fluoro, chloro, bromo, iodo, nitro) are used for this evaluation.

Theoretical Background

UPPER is used to calculate a number of physical properties directly from molecular structure. Four sets of group contribution values are used to calculate four additive physical properties: heat of boiling, heat of melting, molar volume, and the aqueous activity coefficient. The breakdown of the molecule into its constitutive groups is both simple and uniform for all the calculations. Additionally, two nonadditive molecular descriptors that account for molecular symmetry and flexibility are used to estimate transition entropies. These six parameters are then used to calculate several fundamental physical properties via well-accepted equations.

Additive Molecular Parameters—the change in enthalpy that accompanies a phase transition is the result of the total intermolecular interactions of the molecule. It can be assumed that a group (for example an aromatic CH_3) will make a nearly constant contribution to the molar enthalpy change. On this basis the enthalpies of boiling and melting can each be considered as the summation of group contributions from constituent groups. Thus the contribution of each group toward the molar heat of boiling and melting can be quantitated as the sum of b_i and m_i values, respectively. Simamora et al.[15] and Krzyzaniak et al.[16] used multiple linear regression to generate b_i and m_i values from literature data for thousands of aliphatic and aromatic compounds. The b_i and m_i values[15] used in this study are shown in Table 1.

The molar volume of a liquid is the ratio of the molecular weight to the density. Each group occupies a nearly constant volume in a molecule that is designated as its v_i value. A number of group contribution schemes have been used to estimate the molar volume. In this study the values developed by Fedors[17] are used and are shown in Table 1.

Myrdal et al.[18−20] presented the AQUAFAC (aqueous functional activity coefficients) scheme that considers the group aqueous activity coefficient as an additive property. The AQUAFAC model is based on an extensive database (AQUASOL) of reported solubilities. The q_i values[18−22] that are given in Table 1 are group contributions to the aqueous activity coefficient of the solute.

Nonadditive Molecular Parameters—The two nonadditive molecular descriptors that account for the geometry of the molecule are the symmetry and flexibility numbers. Dannenfelser et al.[23] and Simamora et al.[24] have

Table 2—Molecular Symmetry Numbers (σ) of Some Compounds

σ	Examples
1	2	2	3	4	6	12	
described these parameters in detail. The external rotational symmetry number (σ) is a measure of the rotational degeneracy of the molecule. It is equal to the number of orientations of a molecule that are identical with some reference orientation. The assignment of molecular symmetry number is illustrated in Table 2. The flexibility (ϕ) of a molecule is a measure of the number of stable torsional conformations that it can assume. Since the molecules of this study are considered rigid, they are all assigned a flexibility number of unity. Note, biphenyls can assume more than one conformation; therefore, the entropy of fusion is approximated using the most stable conformation. The ortho substituents on the biphenyl can result in noncoplanarity of the molecule and therefore a correction factor, OBIP, is used as shown in Table 1.

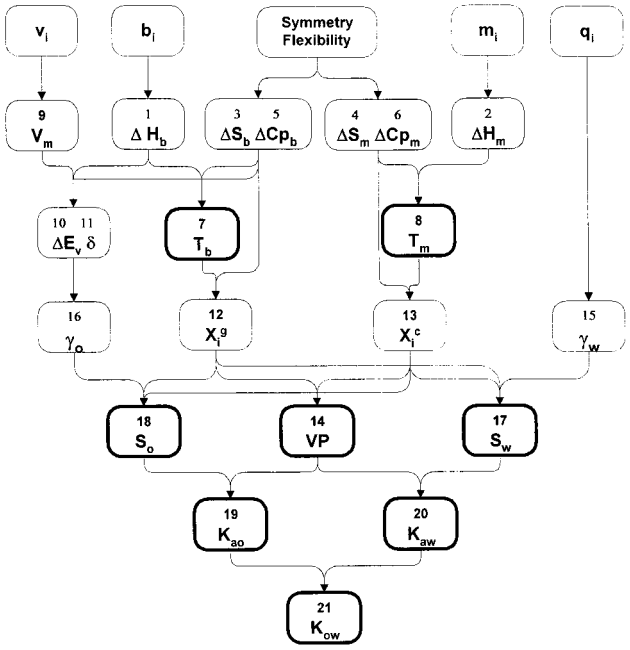

Figure 1—Schematic representation of UPPER.

Calculation of the Physical Properties—The logic of the UPPER scheme is illustrated in Figure 1. Twenty-one physical properties are each calculated from other properties by the use of simple, well-established relationships described below. The eight properties considered in this study are outlined in bold in Figure 1. The numbers in the following brief summary of the UPPER scheme correspond to the numbers in Figure 1.

1. Heat of Boiling (ΔH_b)—The heat of boiling, or the enthalpy of vaporization at the normal boiling temperature (J/mol), is calculated as the summation of the b_i values for the constitutive groups of the molecule. Therefore,

$$\Delta H_b = \sum(n_i b_i) \qquad (1)$$

where n_i is the number of times the group b_i appears in the molecule.

2. Heat of Melting (ΔH_m)—The heat of melting, or the enthalpy of fusion (J/mol) is analogously calculated as the summation of the m_i values for the constitutive groups of the molecule, so that

$$\Delta H_m = \sum(n_i m_i) \quad (2)$$

3. Entropy of Boiling (ΔS_b)—The entropy of boiling, or the entropy of vaporization at the normal boiling point (J/K-mol) is calculated by Trouton's rule, which is applicable to coal tar derivatives, including non-hydrogen bonding aromatic compounds. Trouton's rule states that

$$\Delta S_b = 88 \quad (3)$$

4. Entropy of Melting (ΔS_m)—The entropy of melting, or the entropy of fusion (J/K-mol) is calculated by the Dannenfelser and Yalkowsky equation[23] that accounts for the effects of symmetry (σ) and flexibility (ϕ) upon the probability of a molecule being properly oriented and conformed for incorporation into the crystal lattice. The equation states:

$$\Delta S_m = 56.5 - 19.1 \log \sigma + 19.1 \log \phi \quad (4)$$

For the rigid molecules of this study $\phi = 1$ and eq 4 reduces to

$$\Delta S_m = 56.5 - 19.1 \log \sigma \quad (4a)$$

(Note that for most organic compounds the value of σ is either 1 or 2, and only 2% of compounds have σ exceeding 4.)

5. Heat Capacity Changes on Boiling (ΔC_{p_b})—Myrdal et al.[25] estimated that the heat capacity change on boiling (J/K-mol) is related to the flexibility of the molecule as:

$$\Delta C_{p_b} = -90 - 6.8 \log \phi \quad (5)$$

For the rigid molecules of this study $\phi = 1$, and the above eq 5 reduces to

$$\Delta C_{p_b} = -90 \quad (5a)$$

6. Heat Capacity Changes on Melting (ΔC_{p_m})—Mackay[26] and Yalkowsky and Mishra[27] have shown that the heat capacity change on melting can be approximated to be zero for rigid molecules, i.e.,

$$\Delta C_{p_m} = 0 \quad (6)$$

7. Boiling Point (T_b)—The boiling point (K) is calculated as the ratio of the enthalpy of boiling (from eq 1) to the entropy of boiling (from eq 3). Thus

$$T_b = \frac{\Delta H_b}{\Delta S_b} = \frac{\sum n_i b_i}{88} \quad (7)$$

8. Melting Point (T_m)—The melting point (K) is calculated as the ratio of the enthalpy of melting (from eq 2) to the entropy of melting (from eq 4a).

$$T_m = \frac{\Delta H_m}{\Delta S_m} = \frac{\sum n_i m_i}{56.5 - 19.1 \log \sigma} \quad (8)$$

9. Molar Volume (V_m)—The molar volume (cm^3/mol) is calculated as the summation of the v_i values.

$$V = \sum n_i v_i \quad (9)$$

10. Energy of Vaporization (ΔE_v)—According to the second law of thermodynamics

$$\Delta E_b = \Delta H_b - RT \quad (10)$$

where ΔE_b is the change in energy of boiling at the boiling point. The energy of vaporization, ΔE_v (J/mol) at any temperature is related to its value at the boiling point by

$$\Delta E_v = \Delta E_b - (T_b - T)\Delta C_{p_b} \quad (10a)$$

where ΔH_b, ΔC_{p_b}, and T_b are obtained from eqs 1, 5a, and 7, respectively, R is the gas constant, and T is 298 K. Combining eqs 10 and 10a gives

$$\Delta E_v = \Delta H_b - (T_b - T)\Delta C_{p_b} - RT \quad (10b)$$

11. Solubility Parameter (δ)—The solubility parameter (J/cm^3)$^{0.5}$ is an expression of the cohesion between like molecules. It is calculated from the energy of vaporization (from eq 10b) and the molar volume (from eq 9) by

$$\delta = \sqrt{\frac{\Delta E_v}{V}} \quad (11)$$

12. Ideal Solubility of a Gas (X_i^g)—The ideal mole fractional solubility of a gas is the solubility that it would have in a perfect solvent. It is calculated using the integrated form of the Clausius–Clapyeron equation as

$$\log X_i^g = \frac{\Delta S_b(T_b - T)}{2.3RT} - \frac{\Delta C_{p_b}(T_b - T)}{2.3RT} + \frac{\Delta C_{p_b}}{2.3R} \ln \frac{T_b}{T} \quad (12)$$

where ΔS_b, C_{pb}, and T_b are calculated from eqs 3, 5a, and 7, respectively.

13. Ideal Solubility of a Crystal (X_i^c)—The ideal mole fractional solubility of a crystalline solid is similarly calculated from the van't Hoff equation

$$\log X_i^c = -\frac{\Delta S_m(T_m - T)}{2.3RT} - \frac{\Delta C_{p_m}(T_m - T)}{2.3RT} + \frac{\Delta C_{p_m}}{2.3R} \ln \frac{T_m}{T} \quad (13)$$

According to eq 6, $\Delta C_{p_m} = 0$; therefore, eq 13 can be simplified to

$$\log X_i^c = -\frac{\Delta S_m(T_m - T)}{2.3RT} \quad (13a)$$

where ΔS_m and T_m are calculated from eqs 4a and 8, respectively. Note that when the melting point of a compound is less than 298 K, the logarithm of the ideal solubility of the crystal is zero or in other words it is completely miscible. Also note that for solids of low symmetry the above eq 13a is approximately

$$\log X_i^c = -0.01(T_m - T) \quad (13b)$$

14. Vapor Pressure (VP)—Yalkowsky and Mishra[28] showed that the vapor pressure (atm) can be calculated from the integrated form of the Clausius–Clapeyron equation

$$\log VP = -\frac{\Delta S_m(T_m - T)}{2.3RT} - \frac{\Delta C_{p_m}(T_m - T)}{2.3RT} + \frac{\Delta C_{p_m}}{2.3RT} \ln \frac{T_m}{T} - \frac{\Delta S_b(T_b - T)}{2.3RT} + \frac{\Delta C_{p_b}(T_m - T)}{2.3RT} - \frac{\Delta C_{p_b}}{2.3RT} \ln \frac{T_b}{T} \quad (14)$$

By incorporating eqs 12 and 13 the above equation can be written as

$$\log VP = \log X_i^c - \log X_i^g \quad (14a)$$

If the compound is a liquid, eq 14a is reduced to eq 14b as the crystal term drops out.

$$\log VP = -\log X_i^g \quad (14b)$$

15. Activity Coefficient in Water (γ_w)—The logarithm of the aqueous activity coefficient (mol/L) is equal to the summation of the AQUAFAC substituent group activity coefficients.

$$\log \gamma_w = \sum n_i q_i \quad (15)$$

16. Activity Coefficient in Octanol (γ_o)—The octanol activity coefficient (mol/L) is calculated by applying the Scatchard–Hildebrand relationship to octanol. This gives

$$\log \gamma_o = \frac{V_u(\delta_{oct} - \delta_u)^2 \phi_{oct}{}^2}{2.3RT} \quad (16)$$

where V_u and δ_u are the molar volume and solubility parameter of the solute calculated using eqs 9 and 11, respectively, and ϕ_{oct} is the volume fraction of the solvent, octanol. Using the solubility parameter for octanol as the solvent, eq 16 becomes

$$\log \gamma_{oct} = \frac{V_u(21.1 - \delta_u)^2 \phi_{oct}{}^2}{2.3RT} \quad (16a)$$

Hildebrand and Scott[29] showed that the critical temperature, T_c, at which two liquids are completely miscible, is

$$T_c = \frac{V(\delta_v - \delta_u)^2}{2R} \quad (16b)$$

where V is the arithmetic of the molar volumes of octanol and the solute. If we assume the molar volume of the solute is nearly same as octanol, 138 cm^3/mol, i.e.,

$$V = \frac{V_{oct} + V_u}{2} \approx 138 \quad (16c)$$

then complete miscibility will be achieved if

$$|21.1 - \delta_u| < \sqrt{\frac{2RT}{138}} \quad (16d)$$

which corresponds to $15.1 < \delta_u < 27.1$ in (J/cm^3)$^{0.5}$ at 298 K or higher temperature. As most organic compounds have solubility parameters in this range, they are completely miscible with octanol.

17. Solubility in Water (S_w)—The aqueous solubility (mol/L) for solids is calculated as the ratio of the ideal solubility of the solute to its aqueous activity coefficient. In logarithmic terms this is

$$\log S_w = \log X_i^c - \log \gamma_w \quad (17)$$

where $\log X_i^c$ and $\log \gamma_w$ are calculated from eqs 13a and 15, respectively. For liquids X_i^c is set equal to unity and thus eq 17 reduces to

$$\log S_w = -\log \gamma_w \quad (17a)$$

18. Solubility in Octanol (S_o)—Likewise the octanol solubility (mol/L) is calculated as the ratio of the ideal solubility of the solute to its octanol activity coefficient. For a solid solute this is

$$\log S_o = \log X_i^c - \log \gamma_o \quad (18)$$

where $\log X_i^c$, and $\log \gamma_o$ are calculated from eqs 13a and 16, respectively.

19. Air–Octanol Partition Coefficient (K_{ao})—The air–octanol partition coefficient (atm-L/mol) is calculated as the ratio of the vapor pressure to the octanol solubility.

$$\log K_{ao} = \log VP - \log S_o \quad (19)$$

where $\log VP$, and $\log S_o$ are calculated from eqs 14a and 18, respectively.

Air–Water Partition Coefficient or Henry's Law Constant (K_{aw})—The air–water partition coefficient (atm-L/mol) is calculated as the ratio vapor pressure coefficient to the aqueous solubility.

$$\log K_{aw} = \log VP - \log S_w \quad (20)$$

where $\log VP$ and $\log S_w$ are calculated from eqs 14a and 17, respectively.

21. Octanol–Water Partition Coefficient (K_{ow})—The octanol–water partition coefficient is calculated as the ratio of the aqueous activity coefficient to the octanol activity coefficient.

$$\log K_{ow} = \log \gamma_w - \log \gamma_o \quad (21)$$

where $\log \gamma_w$ and $\log \gamma_o$ are calculated from eqs 15 and 16, respectively. Alternatively $\log K_{ow}$ can be calculated either by

$$\log K_{ow} = \log S_o - \log S_w \quad (21a)$$

$$\log K_{ow} = \log K_{aw} - \log K_{ao} \quad (21b)$$

where $\log S_w$, $\log S_o$, $\log K_{ao}$, and $\log K_{aw}$ are calculated from eqs 17, 18, 19, and 20, respectively.

Data Collection

Four hundred and five rigid, non-hydrogen bonding aromatic compounds including benzenes, naphthalenes, anthracenes, phenanthrenes, and biphenyls substituted with methyl, fluoro, chloro, bromo, iodo, and nitro groups were used in this study. Data for melting and boiling points,[30–33] aqueous,[31,33–37] and octanol[38] solubilities, air–water,[33] air-octanol,[42] and octanol–water[33,43] partition coefficients, and vapor pressure[31,33,39–41] were taken from the literature.

Additive Parameters—Simamora et al.,[15] Fedors,[17] Myrdal et al.,[18,19] and Lee et al.[21] reported the values of the additive parameters used in this study. These are shown in Table 1.

Nonadditive Parameters—Symmetry numbers as described by Dannenfelser et al.[23] and illustrated in Table 2 were assigned to each compound. Since the substituted aromatics considered are rigid molecules ϕ is equal to unity for all compounds.

Results and Discussion

Boiling Point—The observed and predicted boiling points are in good agreement as evidenced by the fit of the data to the line of identity in Figure 2. The average

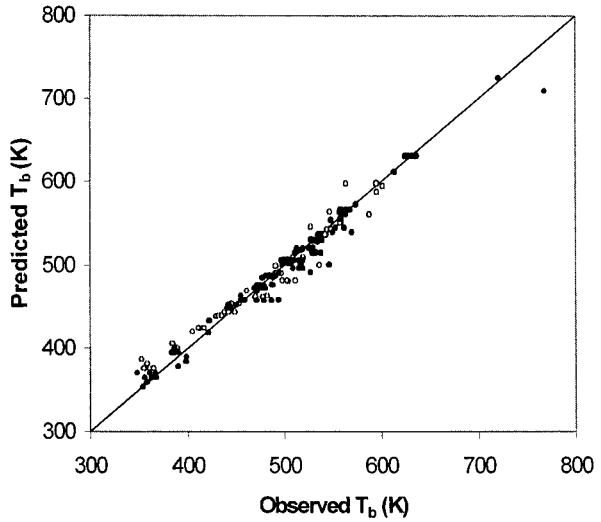

Figure 2—Observed vs predicted boiling point (K). (○) Compounds used in the training set to generate b_i values. (●) Compounds not used in the training set.

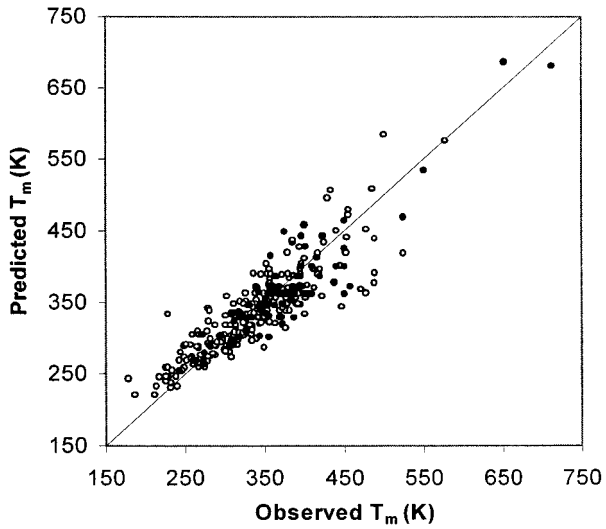

Figure 3—Observed vs predicted melting point (K). (○) Compounds used in the training set to generate m_i values. (●) compounds not used in the training set.

absolute error is 8.67 K for 191 compounds. Only 68 of the 191 compounds were used by Simamora et al.[15] to generate the b_i values. These are denoted by open circles. The remainder of the compounds are a true test and are denoted by filled circles in Figure 2.

Melting Point—The observed and predicted melting points are shown in Figure 3. The average absolute error is 23 K for 338 compounds. Over 85 of these compounds were not used by Simamora et al.[15] to generate m_i values. These compounds are represented by filled circles and are a true test set for the relationship.

As melting point is dependent upon the arrangement of the molecules in the crystal lattice as well as upon the strength of the pairwise group interactions, it is more difficult to predict than boiling point. The importance of incorporating a nonadditive parameter along with the group contributions is evident from the fact that the calculation of the melting points without a symmetry term yields a average absolute error of 30 K. The calculation of the melting point by group contributions alone leads to the same estimated melting point for constitutional isomers while using the symmetry number distinguishes them effectively.

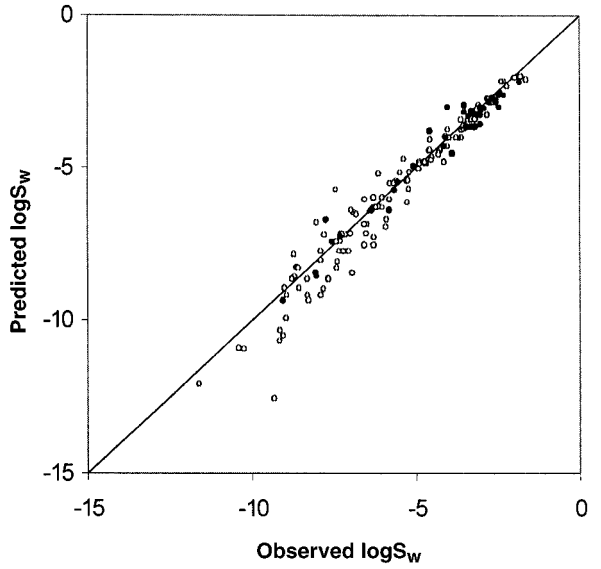

Figure 4—Observed vs predicted logarithm of molar aqueous solubility. (○) Compounds used in the training set to generate q_i values. (●) Compounds not used in the training set.

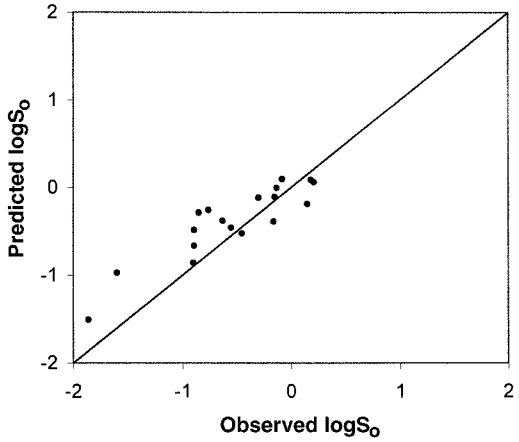

Figure 5—Observed vs predicted logarithm of molar octanol solubility.

Aqueous Solubility—The calculated solubility values agree very well with the experimental data as shown in Figure 4. The average absolute error of 0.38 log units for 165 compounds varying over 10 orders of of magnitude is slightly less than a factor of 2.5. This is well within experimental error of the reported data. One hundred and thirty six compounds were used to generate q_i values by Myrdal et al.[18,19] and Lee et al.[21] using the true melting points. It should be noted that in this study the aqueous solubility was calculated using the calculated melting points. Therefore the filled circles in Figure 4 represent a true test set of melting point in determining solubility.

Octanol Solubility—Although not much data is available for octanol solubility, UPPER appears to be applicable to its prediction. The 22 reported octanol solubilities are in reasonable agreement with the calculated values as shown in Figure 5. The average absolute error is 0.40 log units (or a factor of 2.5) for the 22 compounds. Note that since no values were generated from octanol solubility data, the whole data set represents a true test for eq 18.

Vapor Pressure—Although no vapor pressure data has been used in the generation of the m_i or b_i coefficients in Table 1, the calculated vapor pressures are in very good agreement with the reported values as evident from Figure 6. Of the compounds shown, 27 were used by Myrdal et al.[25] to generate the value of ΔC_{p_b}, the heat capacity change

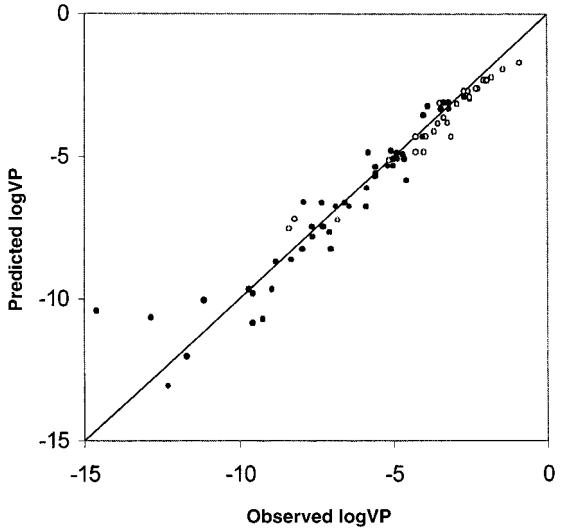

Figure 6—Observed vs predicted logarithm of vapor pressure (atm). (○) Compounds used in the training set to generate ΔC_{p_b}. (●) Compounds not used in the training set.

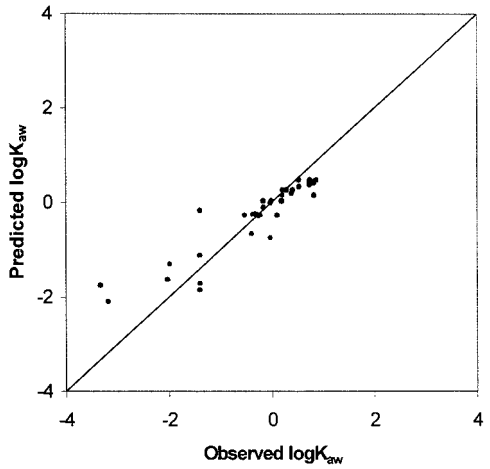

Figure 7—Observed vs predicted logarithm of Henry's Law Constant (atm-L/mol).

on boiling. The average absolute error is 0.38 log units for 73 compounds with vapor pressures covering 11 orders of magnitude. This is well within the error associated with vapor pressure measurements.

Air–Water Partition Coefficient or Henry's Law Constant—Most of the predicted values of the Henry's law constants for 37 compounds show good agreement with the experimentally determined values. However, the error for four compounds is unacceptably large. Because of these points the average absolute error for total test set is 0.49 log units. The data are plotted in Figure 7.

Air–Octanol Partition Coeffficient—The calculated air–water partition coefficients of 25 compounds are in reasonable agreement with the experimental data reported[42] with an average absolute error of 0.45 as shown in Figure 8.

Octanol–Water Partition Coefficient—The agreement between measured and estimated partition coefficients is shown in Figure 9. The average absolute error of 0.40 is primarily due to over estimation of partition coefficients greater than five. The good agreement between the observed and the predicted partition coefficient values below 10^5 (average absolute error of 0.25) is noteworthy since none of the parameters used for the estimations are based upon partitioning data. A note should be made that

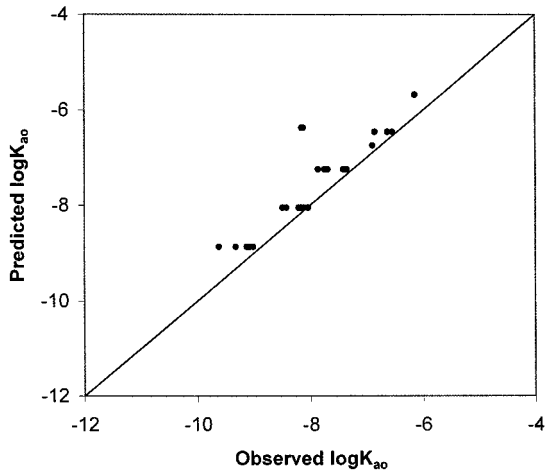

Figure 8—Observed vs predicted logarithm of air–octanol partition coefficient (atm-L/mol).

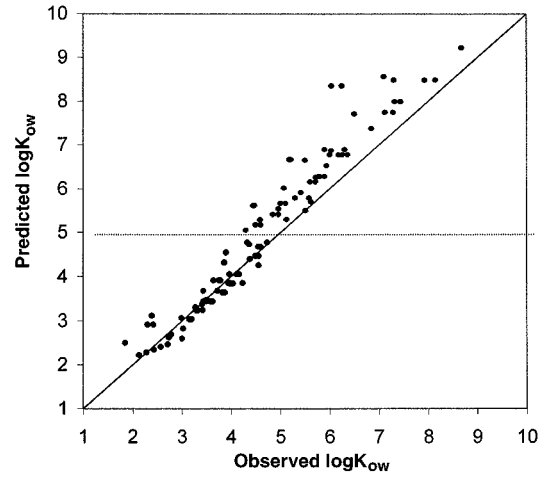

Figure 9—Observed vs predicted logarithm of the octanol–water partition coefficient.

Table 3—Summary of Physical Property Estimation Results

property	*n*	average absolute error	range	
			min	max
T_b	191	8.67	348.00	636.00
T_m	338	23.12	178.00	651.00
log S_w	165	0.38	–11.62	–1.64
log S_o	22	0.40	–2.77	0.21
log *VP*	73	0.38	–12.30	–0.91
log K_{aw}	37	0.49	–1.40	0.88
log K_{ao}	25	0.42	–9.62	–6.14
log K_{ow}	128	0.40	1.85	11.46
log K_{ow} (<10^5)	84	0.25	1.85	5.00

the octanol–water partition coefficient calculated using eq 21 does not take into account the mutual solubilities of octanol and water. This is probably one of the reasons for the overestimations that are especially pronounced with high partition coefficients.

Conclusion

Table 3 summarizes the results of estimating the eight properties considered in this report. For each property it gives the number of compounds studied and the average absolute error of the estimate along with the range of the experimental values. The average absolute error of all the

logarithmic terms are generally of the same magnitude as the error associated with the experimental measurements. On the other hand the errors in estimation of the transition temperatures exceed the accuracy of their measurement. However, these errors are less than those produced by any other predictive method and correspond to relatively small

errors in those logarithmic terms that are dependent upon the melting point. Therefore, since none of the average absolute errors exceeds half an order of magnitude, UPPER can be expected to consistently provide reasonable (order of magnitude) estimations of these properties.

The success of UPPER is due to three factors: its use of well-established physicochemical relationships, its use of a uniform breakdown of molecules into substituents, and its use of nonadditive parameters. Because all property values are calculated strictly from thermodynamically sound relationships, UPPER itself is thermodynamically sound. The use of mathematical relationships, which relate one parameter to another, minimizes the need for approximations and eliminates the need to utilize multiple structural breakdown schemes.

The use of nonadditive parameters to account for those molecular properties that are not simply the sum of group values is the most unique feature of UPPER. In the present study the use of molecular symmetry improves the estimation of melting point and enables the distinction of constitutional isomers. Consequently, it improves the estimation of solubility and vapor pressure which are both calculated from the melting point. Note that although a 30 K error in melting point corresponds to a 0.3 log unit error (i.e., a factor of 2) in either solubility or vapor pressure. An error in the estimation of the melting point has no effect on either air−liquid or liquid−liquid partition coefficients.

There were no new fitted parameters generated or used in this study. About one-third of the data set used in this study is a true test of the group contribution values previously determined by Simamora,[15] Myrdal et al.,[18,19] and Lee et al.[21] A total of 119 boiling points, 86 melting points, 29 aqueous solubilities, and 40 vapor pressures were calculated strictly from the molecular structure as they were not used in generating the group contributions previously. Note that in this study the aqueous solubility and vapor pressure were calculated from the calculated melting and boiling points while both AQUAFAC coefficients and the heat capacity change on boiling were generated using the true melting and boiling temperatures. The excellent agreement of the aqueous solubility and vapor pressure values spanning almost 10 orders of magnitude is noteworthy and suggests that UPPER can be used to estimate values before actual costly experimentation. Even higher accuracy can be achieved with the use of the true melting point, an easily measurable property. For example, the use of the true melting point gives an absolute average error of 0.30.

The agreement of both the calculated air−water and octanol−water partition coefficients reflects the strength of the UPPER scheme as no partitioning data were used in the generation of the group contribution values of Table 1.

Thus the overall UPPER scheme does remarkably well as validated using 974 values for 8 biologically and environmentally relevant properties of 405 rigid, nonhydrogen bonding aromatic compounds. The logarithmic values in Table 3 have average absolute errors that correspond to less than a factor of 3 for all the properties and less than a factor of 2 for most of the properties.

A representative set of 66 compounds is presented in Table 4. All the data for 405 compounds are provided in Supporting Information.

Supporting Information Available— Table of obseved and predicted properties. This material is available free of charge via the Internet at http://pubs.acs.org.

Abstract □ The monomeric analogue, $Lys^{B28}Pro^{B29}$-human insulin (LysPro), has been crystallized using similar conditions employed to prepare extended-acting insulin ultralente formulations. In the presence of zinc ions, sodium acetate and sodium chloride, but without phenolic preservative, LysPro surprisingly forms small rhombohedral crystals with similar morphology to human insulin ultralente crystals with a mean particle size of 20 ± 1 μm. X-ray powder diffraction studies on the LysPro crystals prior to dilution in ultralente vehicle ([NaCl] = 1.2 M) revealed the presence of $T_3R_3^f$ hexamers. Consistent with human insulin ultralente preparations, LysPro crystals formulated as an ultralente suspension ([NaCl] = 0.12 M) contain T_6 hexamers indicating that a conformational change occurs in the hexamer units of the crystals upon dilution of the salt concentration. The pharmacological properties of subcutaneously administered ultralente LysPro (ULP) were compared to ultralente human insulin (UHI) using a conscious dog model ($n = 5$) with glucose levels clamped at basal. There were no statistically significant differences between the kinetic and dynamic responses of ULP compared to UHI [C_{max} (ng/mL): 3.58 ± 0.76, ULP and 3.61 ± 0.66, UHI; T_{max} (min): 226 ± 30, ULP and 185 ± 42, UHI; R_{max} (mg/kg min): 11.2 ± 1.9, ULP and 13.3 ± 2.0, UHI; and T_{Rmax} (min): 336 ± 11, ULP and 285 ± 57, UHI]. Although the Pro to Lys sequence inversion destabilizes insulin self-assembly and greatly alters the time action of soluble LysPro preparations, this modification has now been found neither to prevent the formation of ultralente crystals in the absence of phenolics nor to compromise the protracted activity of the insulin analogue suspension.

Introduction

Extended-acting insulin preparations are microcrystalline suspensions that provide their protracted effect by slow dissolution of the crystals and gradual release of insulin into the blood stream. There are several approaches to formulating extended-acting insulin preparations. One example, ultralente human insulin (UHI),[1] is a zinc−insulin suspension composed predominantly of small rhombohedral crystals and characterized by an intermediate to long time−action profile. Ultralente is one of a series of insulin−zinc suspensions (lente insulins) that were developed by Hallas-Møller and colleagues who determined that the addition of zinc ions in preparations that had neutral pH and no zinc-binding ions (i.e., no phosphate or citrate) led to insulin formulations with protracted effects.[2,3] This series of zinc−insulin suspension formulations includes ultralente (crystalline insulin particles), semilente (amorphous insulin particles), and lente (a mixture of amorphous and crystalline insulin particles). A second approach to making protracted insulin preparations is to depress insulin solubility by adding basic peptides. This approach is exemplified by the product Neutral Protamine Hagedorn insulin (NPH). NPH is an intermediate-acting formulation prepared by cocrystallization of insulin with the basic peptide protamine.[4,5]

A recent study showed that the monomeric insulin analogue, $Lys^{B28}Pro^{B29}$-human insulin (LysPro), can be cocrystallized with the basic peptide protamine to form a microcrystalline suspension having a time action nearly identical to human insulin NPH.[6] The cocrystallization of LysPro with protamine requires the presence of both zinc ions and phenolic preservatives. In other work, the X-ray crystal structure of LysPro was reported.[7] The crystals were grown in the presence of both zinc ions and phenol, and LysPro was found to crystallize as $T_3R_3^f$ hexamers. The quaternary structure of LysPro was described using the T, R^f, and R nomenclature[7,8] for insulin hexamers whereby monomer subunits are named according to the conformation of the first eight amino acid residues of the B-chain. In this notation, T refers to an extended conformation, R to an α-helical conformation, and R^f to an extended conformation for the first three residues and α-helical for the remainder. These recent examples of LysPro crystal forms have demonstrated an apparent requirement for the presence of both zinc ions and phenolic preservatives to initiate crystallization, presumably due to the ability of these ligands to promote self-association. Indeed, numerous studies exploring the solution properties of LysPro have confirmed that the addition of zinc ions and phenolic preservatives overcomes the otherwise destabilizing effect on hexamer self-assembly caused by the sequence modification in the region required for dimer formation.[9−11]

The role of ligand binding and its influence on insulin self-assembly and crystallization is well-known for porcine and human insulin species.[12−16] One notable difference between these insulin species and LysPro is their ability to form discrete hexamers in the presence of zinc ions alone. For example, crystals of porcine insulin grown in the presence of zinc ions but without phenolic preservative have been shown by X-ray crystallography to be composed of T_6 hexamers.[16] Although high-resolution structural analysis of ultralente crystals has been thwarted by poor crystal diffraction characteristics and dimensions, atomic force microscopy studies confirmed the presence of insulin

hexamers in the crystal lattice.[17] Hexamers comprising ultralente crystals likely adopt T_6 or T_3R_3 conformations since these crystallizations are conducted in the presence of both zinc ions and sodium chloride, but in the absence of phenolic preservatives, as this additive will not produce the desired crystal form.[18]

The requirement for zinc ions and phenolic preservatives to induce crystal formation of LysPro offers a unique challenge to preparing an ultralente-type suspension of this analogue. Such a preparation may have a more desirable time−action profile compared to currently available extended-acting insulin suspensions, thus providing the impetus for undertaking the present study to explore the feasibility of producing ultralente LysPro (ULP). A variety of physicochemical techniques were used to characterize the solid material comprising the resulting ULP suspension to determine how the properties compare to authentic UHI. Pharmacological properties of ULP obtained using a conscious dog model are also reported.

Experimental Section

Chemicals—LysPro was manufactured by Eli Lilly and Company using recombinant DNA technology. All chemicals were pharmaceutical grade and were obtained from various suppliers. Humulin U (40 U/mL) (Eli Lilly and Company) was used as a comparator.

Preparation of Crystals and Formulation—A stock solution was prepared containing approximately 22 mg/mL LysPro. The endogenous level of zinc in the LysPro solid was supplemented by the addition of appropriate volumes of an acidic zinc oxide solution (10 mg/mL) to achieve a final zinc ion concentration of 0.24 mg/mL. The pH was lowered to 2.5−3.0 with 10% hydrochloric acid to aid dissolution of the LysPro solid. A separate buffer solution was prepared containing 21.3 mg/mL sodium acetate and 186.7 mg/mL sodium chloride. The pH of the buffer solution was adjusted empirically with 10% sodium hydroxide such that the combination of 62.5% of the LysPro solution and 37.5% of the buffer solution afforded a crystallization mixture having pH 5.5. Combination of the two solutions in the ratio indicated resulted in the immediate formation of a white, flocculent precipitate. The final crystallization mixture contained 14 mg/mL LysPro, 0.15 mg/mL zinc ions, 8.0 mg/mL sodium acetate, and 70 mg/mL sodium chloride. The glass, conical flask containing the crystallization mixture was mounted in a mixing apparatus and stirred continuously with a stainless steel paddle at 100 rpm. A small amount (<1% v/v) of human insulin seed crystals (Eli Lilly and Company) was added to the crystallization mixture shortly after combination. Small, rhombohedral crystals were visible by microscopy within 24 h. Crystallizations were allowed to proceed for 24−96 h at room temperature.

The ultralente LysPro (ULP) preparations used for animal testing were formulated to contain final concentrations of 1.4 mg/mL (40 U/mL) LysPro, 0.084 mg/mL zinc ions, 1.6 mg/mL sodium acetate, 7.0 mg/mL sodium chloride, and 1.0 mg/mL methylparaben at pH 7.3. To make the formulation, a stock diluent solution was prepared containing 1.11 mg/mL methylparaben, 0.89 mg/mL sodium acetate, and 0.077 mg/mL zinc ions. The diluent solution was mixed with the 400 U/mL ultralente LysPro concentrated suspension (ULP C/S) described above in a 9:1 ratio and adjusted to the final pH with 10% hydrochloric acid and/or 10% sodium hydroxide.

Optimization of Crystallization Conditions—The effects of four variables (zinc ion concentration, sodium acetate concentration, sodium chloride concentration, and pH) on ULP crystallization were evaluated using a full-factorial experimental design. All possible combinations of high and low values for each variable were tested, and a total of 16 trials and 4 centerpoints were performed in a randomly assigned order. The high/low concentrations for the four variables in the crystallization were 0.20 versus 0.29 mg/mL zinc ion, 4.0 versus 12.0 mg/mL sodium acetate, 40 versus 100 mg/mL sodium chloride, and pH 5.0 versus pH 6.0. Crystal morphology and time at which crystals formed were used as endpoints.

Analytical Methods—The concentration of LysPro in the solid and solution phases of the suspension was determined by HPLC. An aliquot of suspension was centrifuged and the supernatant decanted and retained for analysis. Distilled water, equal to the original volume of the suspension, was added to wash the pellet. The pellet was suspended and centrifuged, and the supernatant from the wash was discarded. This water wash procedure was repeated three times. After the final wash, the pellet was dissolved in a volume of 0.01 N hydrochloric acid equal to the volume of the original sample and 3 μL of 9.6 N hydrochloric acid per milliliter of solution. The dissolved pellet and supernatant fraction were analyzed with a reversed phase gradient method using a mobile phase of sulfate buffer and acetonitrile (pH 2.3), a C18 column (Spherisorb ODSII, 10 cm × 4.6 mm) temperature controlled at 40 °C and UV detection at 214 nm.

Microscopy and Particle Size Determinations—Crystal morphology was evaluated using a Zeiss Axioskop microscope equipped with a differential phase-contrast accessory. Approximately 5 μL of a resuspended sample was placed on a glass microscope slide and covered with a cover slip. Photographs were taken at 400× magnification. Edge dimensions were estimated with the aid of an ocular micrometer scale graticule subdivided into 10 μm divisions.

Particle size distributions were performed using a Coulter Multisizer and sampling stand (Miami, FL). The aperture tube orifice size was 100 μm. A 0.20 mL aliquot of resuspended sample was pipetted into 100 mL of a solution containing ISOTON II (Miami, FL). Particle size data were collected for 50 s and are reported as volume percent mean diameter ($D_{4,3}$).

Powder Diffraction—Samples were loaded into a 0.8 mm glass capillary along with mother liquor. The capillaries were then centrifuged in order to pack the microcrystals into a pellet at the bottom of the mother liquor, excess mother liquor was removed, and the capillaries were then sealed. Each capillary was placed on a Rigaku R-AXIS II-C image plate system and RU-200 rotating anode generator with graphite monochromated Cu Kα radiation (λ = 1.54178 Å) at 290 K. Following a 10- to 15-h exposure, the plot of intensity versus 2θ of the powder diffraction image was generated with the X12B software.[19] Backgrounds were subtracted from the peaks, and relative intensities were calculated for each diffraction peak. This procedure was employed for the ULP C/S prior to dilution to prepare the ULP preparation, ULP suspension (40 U/mL), and human insulin ultralente (40 U/mL).

Large, single crystals of T_6 human insulin were grown according to published procedures,[16] and a preliminary refinement of single-crystal diffraction data measured from these crystals showed the structure to be identical to that of the published structure.[16] A sample of the single crystals was ground into a fine powder in the presence of mother liquor, and the procedure described above was repeated.

As no powder diffraction data are available for the various $T_3R_3^f$ and R_6 forms of human insulin whose structures have been published,[13−15,20,21] powder patterns were simulated from the single crystal intensity data. Because of the 3-fold symmetry axis in space group *R*3, two or more general and independent reflections will make a contribution to each powder diffraction peak. Since single crystal data from protein crystals frequently have missing data, particularly at very low values of sin θ/λ, multiple sets of data for T_6 porcine[16] and human (unpublished results) insulin, $T_3R_3^f$ human insulin (chloride,[14] 4′-hydroxyacetanilide,[20] p-hydroxybenzamide[21]), and $T_3R_3^f$ LysPro[7] and a second unpublished set of data were merged using SORTAV from the DREAR suite of data reduction program package[22] to minimize missing data. Although the resulting merged data were carefully checked to ensure that there were no missing data which would alter the intensity patterns of the resulting simulated powder diffraction patterns, one strong reflection was absent from the $T_3R_3^f$ human insulin data. The merged squares of the structure factor amplitudes (F^2) were multiplied by the Lorentz and polarization factors ($Lp = (1 + \cos^2 2\theta)/(\sin^2 \theta \cos \theta)$) to give intensities corresponding to powder data. The resulting intensities were plotted as a function of 2θ after applying a broadening function to simulate the powder diffraction pattern as obtained from the R-AXIS image plate system.

$$I_{2\theta} = \sum I_{hkl} \exp - [8.66 \times (2\theta_{hkl} - 2\theta)]^2 \qquad (1)$$

Particular care must be taken in applying the correct unit cell constants in powder patterns from single-crystal intensities. Due to the relationship between the Miller indices (hkl) and the cell constants, small differences in cell constants

$$Q_{hkl} = h^2a^{*2} + k^2b^{*2} + l^2c^{*2} + 2klb^*c^*\cos\alpha^* + 2lhc^*a^*\cos\beta^* + 2hka^*b^*\cos\gamma^* \quad (2)$$

where a^*, b^*, c^*, a^*, β^*, and γ^* are the reciprocal lattice constants and

$$d = 1.0/(Q_{hkl})^{1/2} \quad (3)$$

will displace the position of the powder diffraction peak relative to nearby peaks altering the appearance of the simulated powder diffraction pattern. While single-crystal data are available for $T_3R_3^f$ LysPro human insulin,[7] no data are available for the T_6 form. As a result of the T → R conformational transition in human insulin, the a-dimension in the unit cell decreases from 81.91 to 80.83 Å while the c-dimension increases from 34.13 to 37.76 Å. It should also be noted that due to the sequence inversion in LysPro, the a-dimension in the $T_3R_3^f$ form decreases by 2.29 Å relative to that of human insulin. To a first approximation, it is possible to calculate the expected cell dimensions for T_6 LysPro based upon the observed changes in cell dimensions of human insulin.

$$a(T_6\ \text{LysPro}) = a(T_3R_3^{\,f}\ \text{LysPro}) \times [a(T_6\ \text{human})/a(T_3R_3^{\,f}\ \text{human})] \quad (4)$$

$$c(T_6\ \text{LysPro}) = c(T_3R_3^{\,f}\ \text{LysPro}) \times [c(T_6\ \text{human})/c(T_3R_3^{\,f}\ \text{human})] \quad (5)$$

In this way, a simulated powder pattern can be calculated for T_6 LysPro using expected T_6 cell constants for LysPro and intensities from human insulin.

Pharmacology—The pharmacokinetic and pharmacodynamic properties of UHI and ULP were assessed following previously described procedures.[6] Briefly, five normal conditioned mongrel dogs weighing 15−25 kg each underwent one study with ULP and one with UHI. For each animal, an 18 h fast was followed by three basal samples, a somatostatin infusion (0.3 μg/kg min), and, after a 10 min interval, a 0.5 IU/kg subcutaneous dose of either ULP or UHI. Plasma glucose was monitored at approximately 5 min intervals, and 20% glucose was infused continuously and at a variable rate to maintain near basal fasting glycemia. Additional samples were collected approximately every 5 min for 45 min, every 10 min for 40 min, every 15 min for 30 min, every 20 min for 40 min, every 25 min for 150 min, and then every 30 min until 840 min. Plasma insulin was determined by radioimmunoassay and glucose using the glucose oxidase method.

Interpolated plasma insulin and glucose profiles were compared using analysis of variance with time as a repeated measure. An overall comparison was made between the two groups (ULP and UHI), as well as of the interaction between group and time. Kinetic and pharmacodynamic parameters were compared using paired t-tests. The following parameters were evaluated for the interpolated insulin curves: C_{max}, the maximal insulin or LysPro concentration reached following its subcutaneous injection during the clamp study; T_{max}, the time at which C_{max} was attained; insulin area, the area under the insulin or LysPro curve, deemed to be representative of the total amount of exogenous insulin or LysPro which is absorbed during the course of the study; R_{max}, the maximal rate of glucose infusion which was achieved during the course of the clamp and T_{Rmax}, the time at which R_{max} was achieved. The cumulative rate of glucose infusion was also calculated. All data are reported as means ± SEM.

Results

Preparation and Characterization of ULP—The ULP preparation was prepared following a similar method used to produce ultralente (bovine, human, or porcine) insulin suspensions.[18] The procedure essentially involves preparing two solutions: an acidic protein solution containing excess zinc, and a separate precipitation solution containing sodium acetate and sodium chloride. The precipitation solution pH was appropriately adjusted to achieve crystallization conditions around the isoelectric point of LysPro (pI = 5.5). Upon combination of the protein and precipitation solutions, a flocculated, white precipitate immediately formed. Evaluation of the crystallization mixture by microscopy indicated that small rhombohedral crystals formed within 24 h; however, crystal growth was allowed to continue for up to 96 h to completely transform any remaining amorphous material. Although ULP crystals were observed to form in the absence of seed crystals (data not shown), a small amount of human insulin seed crystals (<1% v/v) were added to the crystallization reaction to improve the uniformity of the crystallization.[23] The addition of seed crystals was also noted to decrease the time required for complete crystallization.

Crystallization was routinely halted after 96 h by diluting the crystallization mixture into a diluent solution containing methylparaben. A dilution to 40 U/mL was prepared to match the concentration of the comparator UHI sample. The size and morphology of the ULP crystals comprising the suspension were evaluated by microscopy and found to be very similar to those contained in the UHI sample (data not shown). The ULP crystals were estimated to have edge lengths of approximately 5−15 μm. Mean particle size for the crystals was determined to be 20 ± 1 μm as measured by the Coulter particle size technique (data not shown). This result is in good agreement with the mean particle size of the commercial UHI sample. The completeness of crystallization in the final formulated preparation was assessed by comparing the amounts of LysPro in the solid and solution phases. Reversed-phase HPLC analysis revealed that the solid phase contained approximately 40 U/mL of LysPro whereas less than 0.05 U/mL of LysPro was found in the soluble fraction.

The conditions for preparing ULP crystals were further evaluated using a standard four-variable, full-factorial experimental design. The effects of zinc concentration, sodium acetate concentration, sodium chloride concentration, and pH were studied, and the results are summarized as follows: (i) pH had a very pronounced effect on ULP crystallization with pH 5.5 being optimal; (ii) no crystals formed at pH 5.0, regardless of the other conditions, and although some crystallization occurred at pH 6.0, these crystals were typically small, slow-growing and of poor quality compared to the crystals grown at pH 5.5; (iii) sodium acetate concentrations had little effect on crystallization within the parameters of the current experiments; (iv) an interaction between zinc and sodium chloride concentration was observed; that is, the effect of zinc concentration on crystallization depends on the sodium chloride concentration; (v) the centerpoint conditions (i.e., those closely matching the procedure for preparing UHI) reproducibly formed the highest quality crystals characterized by rhombohedral morphology with uniform size and well-defined edges forming within 24−48 h.

To characterize further the ULP suspension and possibly identify the nature of the LysPro hexamers comprising the crystals, powder diffraction studies were performed. X-ray powder diffraction has been used for many years as a means of identifying organic and inorganic microcrystalline samples. The d-spacing and intensity can be calculated for each diffraction line, and the resulting information provides an accurate and reproducible fingerprint of the material in question. This method can also be used to distinguish between different crystalline polymorphs of the same compound. While powder diffraction has rarely been applied to proteins due to lack of sufficient microcrystalline material and the requirement that the protein remain

Table 1—2θ and Relative Intensity Data Derived from Powder Diffraction Patterns[a]

[a] 2θ (degrees) and relative intensities (in parentheses) for the four measured powder diffraction patterns and the six simulated powder diffraction patterns. Codes are as follows: **ULP**, observed powder pattern for LysPro Ultralente in the presence of 7 mg/mL NaCl; **UHI**, observed powder pattern for human insulin Ultralente in the presence of 7 mg/mL NaCl; **T_6KP**, simulated powder pattern for T_6 LysPro; **T_6**, observed powder pattern for T_6 human insulin; **T_6HI**, simulated powder pattern for T_6 human insulin; **$T_3R_3^f$KP,** simulated powder pattern for $T_3R_3^f$ LysPro; **$T_3R_3^f$HI**, simulated powder pattern for $T_3R_3^f$ human insulin; **ULP C/S**, observed powder pattern for LysPro Ultralente in the presence of 70 mg/mL NaCl; **R_6R**, simulated powder pattern for the rhombohedral R_6 human insulin; and **R_6M**, simulated powder pattern for the monoclinic R_6 human insulin. A broad peak is designated by the letter b following the intensity; a shoulder on a larger peak by s; and an asymmetric peak by a. [b] Low angle data were not measured for the rhombohedral R_6 human insulin structure. [c] There is a very small broad peak at this value of 2θ, but its intensity is too small to estimate. [d] The (–3,4,2) reflection which comprises 99% of the intensity of this peak was not measured in the human insulin data.

immersed in its mother liquor, it is certainly capable of identifying various polymorphs by changes in *d*-spacings and intensities of the resulting powder pattern. In the case of crystals of hexameric insulin, the low resolution powder lines ($0° < 2\theta < 12°$) provide a definitive way in which to identify the hexamer type within a crystal due to significant differences in the unit cell constants of the three different hexamer types, T_6, $T_3R_3^f$, and R_6.

The powder diffraction results are summarized in Table 1 where the 2θ values and relative intensities are listed for the measured and simulated powder patterns obtained for the various insulin forms. An examination of the simulated powder patterns for the rhombohedral or monoclinic R_6 forms shows no similarity to that of the observed powder patterns for UHI, either of the ULP samples (concentrated or diluted) or T_6 human insulin. Neither is there any similarity of the R_6 forms to the simulated powder patterns for T_6 or $T_3R_3^f$ LysPro or human insulin. Therefore, it is clear that neither of the ultralente forms possess R_6 hexamers in either rhombohedral or monoclinic unit cells.

A comparison of the simulated and observed powder patterns for T_6 human insulin showed that they are in quite good agreement in both 2θ and intensities for each peak, suggesting that preferred orientation is not a serious problem. As noted earlier, some care must be taken in comparing the powder patterns from human insulin to that of LysPro, since the small changes in unit cell constants are sufficient to alter the 2θ values of certain diffraction peaks.

With one exception, a very strong diffraction peak is observed at a 2θ value of approximately 2.20° for all T_6 or $T_3R_3^f$ samples. This strong peak has Miller indices of (−2,1,0) and is a consequence of rows of insulin hexamers spaced 40.2 Å apart and perpendicular to the *a*- and *b*-axes. The presence of this strong peak in the unknown ultralente diffraction patterns is indicative of the presence of hexam-

ers in the crystals. The one exception is that of $T_3R_3^f$ human insulin, but in this case, due to the very low value of θ, a portion of the peak was obscured by the beam stop during the measurement of the data.

While there are similarities in the 2θ values for the crystals containing either T_6 or $T_3R_3^f$ hexamers, there are several peaks which are quite characteristic of one or the other forms. For example, peaks at average 2θ values of 2.66, 3.45, 4.10, and 6.58° are only observed in the simulated powder patterns for $T_3R_3^f$ human insulin or $T_3R_3^f$ LysPro. Likewise, peaks at 2.88, 4.22, 6.06, and 9.32° are only observed in the simulated powder patterns for T_6 human insulin. Therefore, these peaks can be used as a very sensitive indicator of the conformation of the hexamer present in the unknown ultralente samples.

An examination of the observed powder pattern for ULP C/S grown in the presence of 70 mg/mL sodium chloride shows that it contains peaks at 2.71, 3.50, 4.12, and 6.60°, but none at 2.88, 4.22, 6.06, and 9.32° 2θ. Thus, the powder diffraction pattern clearly identifies this sample to be made up of $T_3R_3^f$ hexamers. In contrast, the observed powder patterns for ULP and UHI having sodium chloride concentrations of 7 mg/mL contain peaks at 2.92, 4.30, 6.11, and 9.28°, but none at 2.66, 3.45 or 4.10, or 6.58° 2θ, which is completely consistent with the presence of a T_6 hexamer in the crystal structure.

Pharmacological Characterization—ULP was compared to UHI with respect to both its plasma concentration and glucose requirements following subcutaneous injection. During the study, glucose concentrations were monitored, and its intravenous infusion was adjusted to maintain near-basal concentrations (a clamp procedure). The rate of glucose infusion, in turn, defines the action of insulin administered. For UHI, the basal (fasting, preexperimental) glucose concentration was 109 ± 3 mg/dL. Hourly glucose concentrations thereafter were 116 ± 5, 118 ± 8, 120 ± 7, 117 ± 2, 110 ± 2, 117 ± 4, 112 ± 3, 112 ± 2, 117 ± 3, 115 ± 4, 111 ± 1, 118 ± 3, and 111 ± 5 mg/dL. For ULP, the basal glucose concentration was 105 ± 2 mg/dL with hourly concentrations of 113 ± 6, 110 ± 5, 110 ± 6, 111 ± 5, 105 ± 6, 116 ± 6, 113 ± 6, 113 ± 4, 111 ± 6, 114 ± 5, 114 ± 5, 113 ± 6, and 111 ± 3 mg/dL. There was no difference between the two groups ($F = 0.47$ and $p = 0.51$) or any divergence between them in time ($F = 0.80$ and $p = 0.55$). The stability of the clamp procedure was indicated by the absence of change in the glucose level over time ($F = 1.78$ and $p = 0.15$).

Figure 1 shows the insulin and LysPro concentrations following the subcutaneous injection of the UHI and ULP preparations. The profile of the two curves is similar, and the LysPro concentrations appear to be slightly higher. Analysis of variance, however, indicates that the two curves are not distinguishable ($F = 0.94$ and $p = 0.36$), nor do they diverge in time ($F = 0.31$ and $p = 0.77$). Within the limits of the current study, there are no discernible differences between the responses of the two preparations. The concentration profiles were found to decrease to between 20 and 40% of peak values by the end of the study (14 h after injection). As shown in Table 2, the average maximal concentration (C_{max}) of human or LysPro achieved in these studies is similar (approximately 3.6 ng/mL). The time at which these peaks occur is also not different (approximately 200 min), and the area under the curves remains analogous at ~1500 ng-min/mL. Within the bounds of this comparison, there are no differences in the kinetic parameters examined.

The rate of glucose infusion necessary to maintain fasting glycemia is shown in Figure 2. Inspection of the data reveals an almost identical pattern of glucose infusion over the course of the study. On the basis of statistical

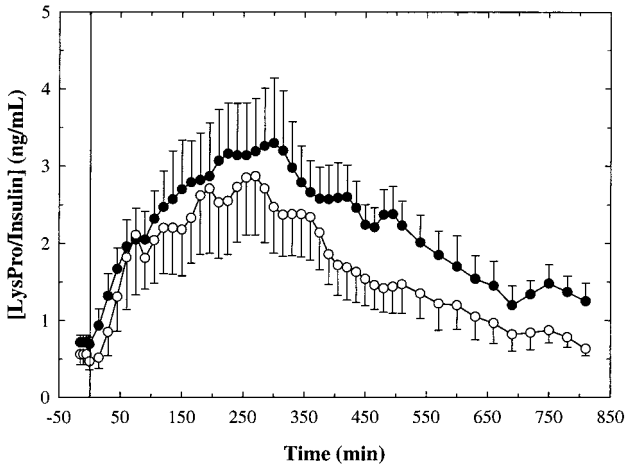

Figure 1—Plasma human insulin or LysPro concentrations following administration of subcutaneous injections of either commercial UHI (○) or ULP suspension (●) at time zero. The dose used was 0.5 U/kg. Concentrations were measured using radioimmunoassays. Error bars represent the average of five test animals.

Table 2—Pharmacokinetic and Pharmacodynamic Parameters Following Subcutaneous Administration of UHI and ULP (means ± SEM)

parameter	UHI	ULP	*T*	*p*
C_{max} (ng/mL)	3.61 ± 0.66	3.58 ± 0.76	0.074	0.94
T_{max} (min)	185 ± 42	226 ± 30	–0.97	0.39
insulin area (ng-min/mL)	1340 ± 257	1760 ± 305	–1.38	0.24
R_{max} (mg/kg-min)	13.3 ± 2.0	11.2 ± 1.9	1.06	0.35
T_{Rmax} (min)	285 ± 57	336 ± 11	–0.94	0.40
total glucose infused[a] (g/kg)	4.95 ± 0.70	4.20 ± 0.70	1.086	0.34

[a] Total glucose infused until $t = 840$ min.

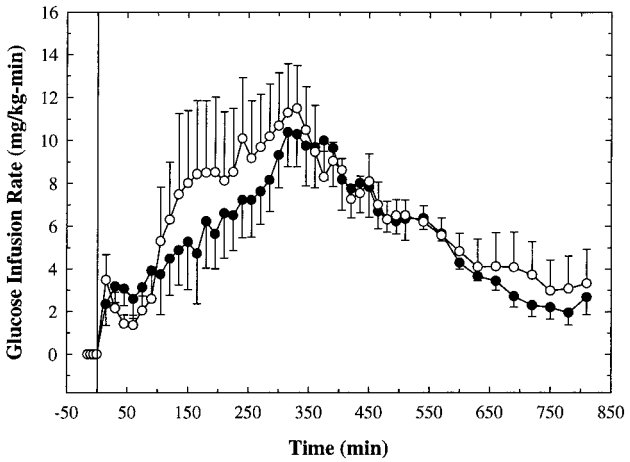

Figure 2—Rates of glucose infusion necessary to maintain fasting glycemia during the glucose clamp imposed following subcutaneous injection of either commercial UHI (○) or ULP suspension (●). The dose used was 0.5 U/kg. Plasma glucose concentrations were measured using a glucose oxidase method. Error bars represent the average of five test animals.

analysis, there is no indication of either an overall group difference or any divergence of the behavior of the groups in time (analysis of variance results: group, $F = 1.77$ and $p = 0.24$; time, $F = 3.81$ and $p = 0.06$; group *x* time, $F = 0.94$ and $p = 0.42$). Both preparations yield very similar peaks approximately 5 h after injection and decrease thereafter until 14 h. The profiles are therefore essentially identical. A plot of the cumulative amount of glucose infused following subcutaneous administration is shown in Figure 3. This cumulative amount is obtained by integrating the glucose infusion curves. Inspection of these data

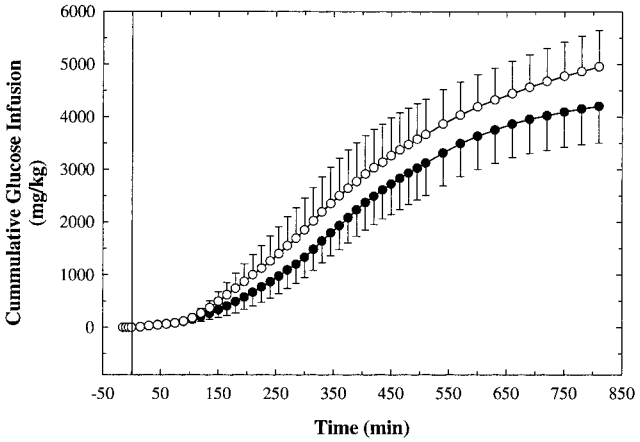

Figure 3—Cumulative glucose infusion following subcutaneous injection of either commercial UHI (○) or ULP suspension (●). Results are based on the integration of the curves shown in Figure 2. Error bars represent the average of five test animals.

show the consistent result that the ultralente preparations of human insulin and LysPro require very similar amounts of glucose to cover their subcutaneous injections. The pharmacodynamic parameters calculated were the maximum rate of glucose infusion (R_{max}), the time at which this was achieved (T_{Rmax}), and the total amount of glucose infused over 14 h and are shown in Table 2. Corroborating the comparison of the curves of glucose infusion, these parameters are all statistically equivalent. Maximal glucose infusion rates are ~12 mg/kg-min and are reached at approximately 5 h after injection of either preparation. A total of about 4.5 g/kg of glucose is infused in each case.

Discussion

LysPro Crystallizes in the Absence of Phenolic Preservatives—On the basis of the wealth of X-ray crystallographic data on wild-type insulins (bovine, human, and porcine), it is clear that the crystals are composed of precisely oriented hexamer units. Studies on the precrystallization stage of 2Zn-porcine insulin further demonstrated that crystal growth proceeds by the addition of hexamers, indicating the importance of solution state self-association to crystallization.[24] Because the wild-type insulin species are known to self-associate into well-defined hexamers in the presence of zinc ions alone, the preparation of ultralente suspensions is straightforward. In contrast, LysPro aggregates nonspecifically in the presence of zinc ions, producing high molecular weight species[11] suggesting that crystallization is unlikely to proceed without modification to the ultralente procedure. We hypothesized that the inclusion of a phenolic preservative in the crystallization media might be necessary, as it is known that LysPro will form well-defined hexamers in the presence of both this ligand and zinc ions.[9,11] Indeed, previous studies describing the preparation of NPH crystals of LysPro demonstrated the necessary requirement of producing LysPro hexamers by the addition of both zinc ions and phenol prior to initiating crystallization.[6]

Contrary to the expected outcome, ultralente crystals of LysPro did form in the absence of phenolic preservative with a procedure similar to that used for wild-type insulins. The fact that LysPro forms crystals with morphology and dimensions indistinguishable from human insulin ultralente crystals suggests that the concentrations of zinc and halide ions override the destabilizing effects of the Pro,Lys amino acid inversion driving the formation of LysPro hexamers. The high sodium chloride concentration (1.2 M) used in the crystallization media may also serve to inhibit nonspecific high-order aggregation by an electrostatic effect.

Evidence for a $T_3R_3^f \rightarrow T_6$ Structural Transformation—Powder diffraction studies revealed that both the ULP and UHI formulations are composed of crystals containing T_6 hexamers. While $T_3R_3^f$ crystals of LysPro have been previously prepared, this is the first report demonstrating the crystallization of LysPro as T_6 hexamers. Furthermore, our studies provide definitive data on the nature of the crystals comprising UHI suspensions. Such information has heretofore been inaccessible due to the poor diffraction quality of the crystals. We also note that the presence of methylparaben in either the ULP or UHI formulations does not affect hexamer conformation (i.e., inducing the T → R transition). In contrast to the T_6 hexamer conformation identified in the ultralente formulations, the ULP C/S sample was found to contain $T_3R_3^f$ hexamers.

While it may appear that the differences between the two LysPro ultralente samples present an anomaly, since one is T_6 and the other $T_3R_3^f$, there is a simple explanation for this behavior. Diffraction quality single crystals of insulin have been transformed from T_6 to $T_3R_3^f$ by reducing the sodium chloride content to less than 0.3 M,[25,26] and a similar transformation can be effected from R_6 to $T_3R_3^f$ by reducing the phenol concentration (unpublished results). Single crystals treated in such a fashion still retain their diffraction properties despite the occurrence of the R → T transition in the crystal structure. In this study, the dilution of the sodium chloride concentration from 1.2 to 0.12 M as formulated for animal testing is sufficient to induce the R → T transition, resulting in a crystalline powder sample made up of T_6 hexamers. Thus, the original ULP C/S crystals grown at 1.2 M sodium chloride contain $T_3R_3^f$ hexamers, and the dilution to 0.12 M sodium chloride transforms these crystals to T_6. These results also show that despite differences in a formulated insulin preparation as compared to the crystallizing media used to prepare diffraction quality single crystals, the formulated microcrystals possess a structure nearly identical to that obtained from single-crystal diffraction studies.

Pharmaceutical Relevance—The primary motivation for exploring the feasibility of preparing a LysPro ultralente formulation was to compare the time–action profile to that of wild-type insulin preparations. A study comparing the activity of bovine, human, and porcine ultralente showed that all preparations evaluated displayed a duration of activity in excess of 30 h.[27] However, bovine ultralente displayed a flat, essentially peakless profile although it was noted that a consistent peak was not evident due to the wide variability between subjects. The authors also concluded that any one of the ultralente formulations is suitable to provide basal insulinemia in clinical practice. Nevertheless, a peakless profile with a time–action greater than 24 h is considered highly desirable in certain diabetes treatment regimens.

Atomic force microscopy studies have provided evidence that the difference in time action between bovine ultralente compared to either human or porcine ultralente may be related to packing and orientation of insulin hexamers at the crystal–solution interface.[17] In bovine ultralente crystals, the hexamers on the predominant faces [(010) and (110)] are oriented "edge-on" to the aqueous medium, limiting solvent penetration into the crystals and consequently further retarding dissolution. Conversely, the predominant exposed crystal surface of human and porcine ultralente crystals is the (001) crystal plane. Hexamer orientation on this face allows for easier penetration of solvent through the crystal surface, contributing to more rapid dissolution. Given this diversity in ultralente crystal

morphology, it is reasonable to evaluate the pharmacological properties of insulin analogue suspensions especially in light of the inherent immunological issues associated with bovine insulin preparations.[28] The pharmacological data collected on ULP indicate that it has a time−action profile that is more consistent with human rather than bovine insulin ultralente. This result is nonetheless interesting considering the perturbed self-association properties of LysPro. Despite the "monomeric" nature of LysPro, crystallization as an ultralente form did not result in any significant decrease in duration of activity compared to UHI.

References and Notes

1. The following abbreviations are used: C_{max}, maximal insulin/LysPro concentration; LysPro, [Lys^{B28},Pro^{B29}]-human insulin analogue; NPH, Neutral Protamine Hagedorn; R_6, insulin hexamers in which the B-chain residues B1−B8 of all monomer subunits are α-helical resulting in a continuous α-helix from B1−B19; R_{max}, maximal rate of glucose infusion; T_3R_3, insulin hexamers in which three of the monomer subunits contain an extended conformation for B-chain residues B1−B8 and B9−B19 are α-helical while the other three monomers contain B-chain residues B1−B8 that are α-helical resulting in a continuous α-helix from B1−B19; $T_3R_3^f$, insulin hexamers in which three of the monomer subunits contain an extended conformation for B-chain residues B1−B8 and B9−B19 are α-helical while the other three monomers have a "frayed" α-helix in which the B-chain residues B1−B3 are extended and only B4−B19 are α-helical; T_6, insulin hexamers in which the B-chain residues B1−B8 of all monomer subunits are in an extended conformation and B9−B19 are α-helical; T_{max}, time at which C_{max} is attained; T_{Rmax}, time at which R_{max} is attained; (UHI), ultralente human insulin; ULP, ultralente LysPro; ULP C/S, ultralente LysPro concentrated suspension.

The Correlation and Prediction of the Solubility of Compounds in Water Using an Amended Solvation Energy Relationship

MICHAEL H. ABRAHAM* AND JOELLE LE

Contribution from *Department of Chemistry, University College London, 20 Gordon Street, London, United Kingdom WC1H OAJ.*

Received March 30, 1999. Accepted for publication June 7, 1999.

Abstract □ The aqueous solubility of liquids and solids, as log S_W, has been correlated with an amended solvation equation that incorporates a term in $\Sigma\alpha_2^H \times \Sigma\beta_2^H$, where the latter are the hydrogen bond acidity and basicity of the solutes, respectively. Application to a training set of 594 compounds led to a correlation equation with a standard deviation, SD, of 0.56 log units. For a test set of 65 compounds, the SD was 0.50 log units, and for a combined correlation equation for 659 compounds, the SD was 0.56 log units. The correlation equations enable the factors that influence aqueous solubility to be revealed. The hydrogen-bond propensity of a compound always leads to an increase in solubility, even though the $\Sigma\alpha_2^H \times \Sigma\beta_2^H$ term opposes solubility due to interactions in the liquid or solid. Increase in solute dipolarity/polarizability increases solubility, whereas an increase in solute excess molar refraction, and especially, volume decrease solubility. The solubility of Bronsted acids and bases is discussed, and corrections for the fraction of neutral species in the saturated solution are graphically presented.

Introduction

The solubility of liquids and solids in water is a very important molecular property that influences the release, transport, and extent of absorption of drugs in the body and that is a key determinant of the environmental fate of agrochemicals and pollutants in the environment. Not surprisingly, numerous methods for the prediction of aqueous solubilities have been suggested. We restrict our discussion primarily to methods that include solid solutes because methods that predict only liquid solubilities are of limited use.

One of the first predictive methods for aqueous solubilities was that of Irmann,[1] who set up a group contribution scheme for liquid hydrocarbons and halocompounds. For solids, Irmann used an additional term, $\Delta S_m(T_m - T)/1364$, where ΔS_m is the entropy of fusion (melting) at the melting point T_m. A value of 13 cal deg^{-1} mol^{-1} was taken for ΔS_m, leading to the following simplified correction term

$$-0.0095(\text{mp} - 25) \qquad (1)$$

In eq 1, mp is the melting point in °C; for liquids, the term (mp − 25) is taken as zero. Irmann[1] gave no statistical analysis, but we have used Irmann's original data, excluding compounds for which the observed solubility was given as approximate, and give details in Table 1. Several other group contribution schemes have been constructed,[2−5] some of which[2] do not require any mp correction term.

The UNIFAC and UNIQUAT methods are also group contribution schemes and have been used to estimate aqueous solubilities.[6,7] Because the reference state for solutes in these methods is the pure liquid, they require a knowledge of the solute enthalpy of fusion or an approximate mp correction term for solids. Another type of group contribution scheme is used in the AQUAFAC program,[8−13] which was applied to 970 compounds.[10] Again, either the entropy of fusion or the mp is needed for solid solutes.

A number of correlations are based on theoretically calculated descriptors.[14−18] None of these require any mp correction term for solids and therefore are capable of predicting aqueous solubilities from structure. Interestingly, there is no discussion[14−18] on why it is not necessary to include a correction for solids.

Quite different types of calculation were initiated by Hansch and co-workers,[19] who showed that there was a relationship (eq 2) between log S_W (the solubility in mol dm^{-3}) and the water−octanol partition coefficient (log P_{oct}) for a training set of 156 liquids

$$\log S_W = -1.339 \log P_{oct} + 0.978$$
$$n = 156,\ \text{SD} = 0.472,\ r^2 = 0.874 \qquad (2)$$

Yalkowsky and Valvani[20] extended the applicability of this relationship by incorporation of similar terms to those used by Irmann[1] for solids. They showed that the entropy of fusion could be estimated and that the entropy of fusion term could be replaced by a mp correction term as in eq 3 (compare eq 1). Several related equations were put forward:[10,21,22]

$$\log S_W = -1.05 \log P_{oct} - 0.012(\text{mp} - 25) + 0.87$$
$$n = 155,\ \text{SD} = 0.308,\ r^2 = 0.979 \qquad (3)$$

$$\log S_W = -1.00 \log P_{oct} - \Delta S_m(\text{mp} - 25)/1364 + 0.87$$
$$n = 873 \qquad (4)$$

$$\Delta S_m = 13.5 - 4.6(\log \sigma) \qquad (5)$$

In eq 3, and elsewhere, n is the number of data points, SD is the standard deviation, r is the correlation coefficient and F is the F-statistic. Values of log P_{oct} in eq 4 were not experimental ones but were calculated by the CLOGP program. The entropies of fusion were a combination of experimental and calculated values, using eq 5 where σ is the rotational symmetry number. However, the compound mp is still needed to apply eq 4, so log S_W values cannot be calculated from structure.

Mobile Order Theory[23−25] has recently been applied to the estimation of aqueous solubility with impressive results.[24] However, the method requires not only the entropy of fusion of solid solutes (or a mp correction term), but also a modified nonspecific solute cohesion parameter. The latter is obtained either from experimental solubilities in hydrocarbon solvents or is "...deduced by analogy to similar compounds."[24]

[a] Model I, that is not too general. A later analysis[4] gives AAE = 0.50 for 694 compounds. [b] Model II, that is very general. A later analysis[4] gives AAE = 0.56 for 614 compounds. [c] Using a neural network with nine descriptors. [d] Using a linear model with nine descriptors.

In Tables 1 and 2 we summarize the methods that have been applied more generally; that is, to large sets of structurally diverse compounds. It is not always easy to compare different methods because some have been constructed using only a training set, others have used both a training set and a test set. In addition, various statistics have been used to describe the goodness of fit between observed and calculated log S_W values in a training set and between observed and predicted log S_W values in a test set. We prefer the SD, given by SD = $\sqrt{[\sum(\log S_W\text{obs} - \log S_W\text{calc})^2/(n - 1 - p)]}$ (where p is the number of parameters), but the average absolute error (AAE) is sometimes used. Defined as AAE = $\sum$(|log $S_W$obs − log $S_W$calc|)/n, the AAE is always much smaller than the corresponding SD value. In addition, some workers list outliers but other workers do not. Because the number of outliers can be very large (42 out of 300 for the general case in ref 16), care has to be taken in judging one model against another. Wherever possible in Tables 1 and 2, we have calculated the SD, as already described, to provide a uniform basis of comparison. Even then, comparisons of the various models is difficult. Bodor and Huang[15] obtain a very low SD value of 0.30 log units for a 331 compound data set, using 18 theoretically calculated descriptors, and Sutter and Jurs[17] find even lower SD values of 0.27 and 0.22 for a 123 compound data set. Myrdal and co-workers,[10] however, find a much larger SD of 0.56 for an 873 compound training set using the AQUASOLVE model. However, the 331 training set[15] includes very few complicated molecules and the 123 compound data set[17] no complicated molecules at all, whereas the 873 training set[10] is much more diverse.

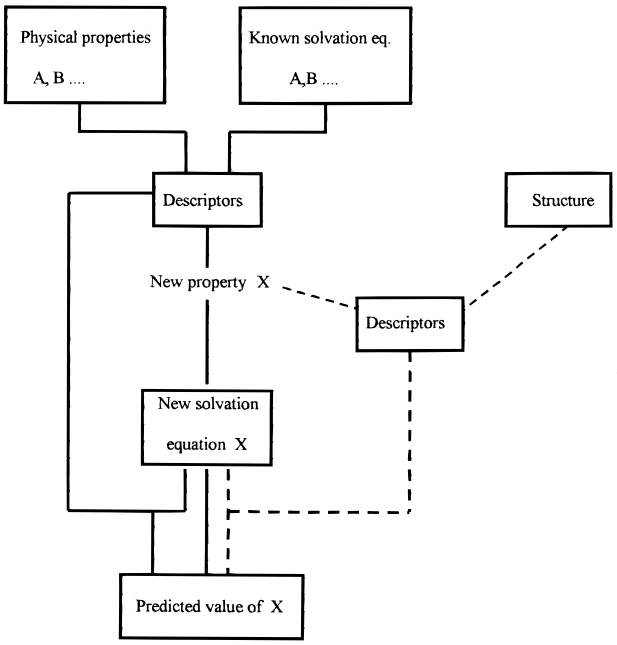

Figure 1—The application of the solvation equation. Full lines show the pathway using experimental descriptors and broken lines show the pathway using calculated descriptors.

Our conclusion is that for training sets that do not contain compounds of complicated structure, SD values as low as 0.30 log units may be obtained, but that for training sets that contain more varied compounds, SD values will not be lower than ~0.50 log units. Myrdal and co-workers[10] point out that the experimental solubilities themselves are a source of considerable error and note that recorded log S_W values for anthracene differ by 1.85 log units, and for fluoranthene by 1.15 log units. Hence, for training sets that contain a reasonable proportion of complicated structures, for many of which only one solubility determination has been made, experimental error probably precludes SD values less than around ~0.50 log units. What is also evident from Tables 1 and 2 is that there is no advantage, as regards SD values, of methods that require additional solute properties. Because there are very considerable advantages in methods that calculate log S_W from structure, especially in view of the importance of high throughput screening, our eventual aim is indeed to calculate aqueous solubility from structure.

Methodology

Our method starts with the following general solvation equation,[26]

$$\log SP = c + rR_2 + s\pi_2^H + a\Sigma\alpha_2^H + b\Sigma\beta_2^H + vV_x \qquad (6)$$

Here, the dependent variable, log SP, is a property of a series of solutes in a given system, such as log P_{oct} or log S_W, and the independent variables are solute descriptors as follows:[26] R_2 is an excess molar refraction in units of (cm^3 mol^{-1})/10, π_2^H is the dipolarity/polarizability, $\Sigma\alpha_2^H$ is the overall or summation hydrogen-bond acidity, $\Sigma\beta_2^H$ is the overall or summation hydrogen-bond basicity, and V_x is the McGowan characteristic volume[27] in units of (cm^3 mol^{-1})/100. The coefficients in eq 6 are found by multiple linear regression analysis, using a set of solutes for which the descriptors are known. There are numerous applications of eq 6 to physicochemical properties, both by ourselves[28–47] and by other workers,[48–59] so that eq 6 can be regarded as a well-established general equation.

The application of eq 6 is summarized in Figure 1 (full lines). Various sets of physical properties, already calibrated through known solvation equations, can be used to assign descriptors, exactly as detailed before.[60] In this way, a database of descriptors for some 3500 compounds has been established. If a new property, X, is to be investigated, the experimental database is used to obtain a correlation equation for the new property, through eq 6. Thus we have recently constructed[47] an equation for water–chloroform partition coefficients, log P_{chl}, for solutes as neutral species.

Once such an equation has been set up, more values of the dependent variable can be predicted from the experimental database of descriptors, as shown by the full lines in Figure 1. However, a further step is to calculate descriptors from structure, so that values of property X may be predicted from structure. This prediction is essential for any fast throughput screening of drugs, agrochemicals, etc. We have just completed a computer program, ABSOLVE, for the calculation of descriptors from structure;[61] this is then tantamount to a method for the prediction from structure of any property, X, for which we have solvation equations, as shown by the broken lines in Figure 1.

The aim of the present work is to obtain an equation for the correlation of log S_W values, without the need for a mp correction, using a large training set and also a reasonably large test set of compounds. Together with the program ABSOLVE, we will then be in a position to predict solubilities from structure.

Results and Discussion

Construction of an Equation for log S_W—We have used a number of databases to set out values of log S_W for 664 solids and liquids. We excluded five compounds from the 664 data set (cyclopropyl-5-spirobarbituric acid, uracil, chlorpheniramine, fentanyl, and adenine) because a preliminary analysis showed that these four were large outliers to all the equations we constructed. In addition we have not included any dicarboxylic acids, such as phthalic acid and succinic acid, partly because we have not yet finalised descriptors for these and partly because preliminary analyses suggest that calculated values of log S_W are always too positive. A total of 659 compounds were left for the final analysis. Every tenth compound in a random order was selected to form a test set, to give 594 compounds as a training set and 65 compounds as a test set. The total set of 664 compounds is given in the Appendix. The smaller test set of 65 compounds is in Table 3. Application of eq 6 to the 594 training set yielded eqs 7 and 8, with SD values of 0.56 and 0.63 log units, respectively; note that fewer compounds were used in eq 7, because of lack of mps. These SD values are not far short of the SD values obtained for models that have been applied to large data sets[3,18] (see Tables 1 and 2).

$$\log S_W = 0.579 - 0.576R_2 + 0.980\pi_2^H + 1.233\Sigma\alpha_2^H + 3.389\Sigma\beta_2^H - 4.079V_x - 0.010(\mathrm{mp} - 25)$$

$$n = 411,\ \mathrm{SD} = 0.564,\ r^2 = 0.915,\ F = 724,\ \mathrm{AAE} = 0.389 \quad (7)$$

$$\log S_W = 0.849 - 1.061R_2 + 0.851\pi_2^H + 0.646\Sigma\alpha_2^H + 3.279\Sigma\beta_2^H - 4.050V_x$$

$$n = 594,\ \mathrm{SD} = 0.630,\ r^2 = 0.895,\ F = 1004,\ \mathrm{AAE} = 0.470 \quad (8)$$

It is somewhat surprising that eq 6 has led to the reasonable eqs 7 and 8, because eq 6 was not set up at all to

[a] All equations are without any mp correction term. [b] (1) Omit very soluble compounds; (2) omit very insoluble compounds; (3) omit both very soluble and very insoluble compounds; (4) eq 10; (5) eq 11.

correlate quantities such as log S_W. There is a fundamental difference between processes such as water−solvent partitions, to which eq 6 has previously been applied, and solubility in water. In the former processes, the thermodynamic standard states are those of unit molar concentration and unit activity in both the aqueous and the solvent phase. For solubility in water, the standard states are unit molar concentration and unit activity in the aqueous phase, but the pure liquid or solid (as the other phase). As pointed out before,[62] the standard state of pure liquid or pure solid is equivalent to a different standard state for each compound. Now eq 6 is constructed for processes in which different solutes have the same standard state in each phase. In chemical terms, this means that a solute in a given phase is surrounded by the phase molecules, whereas for the standard state of pure liquid or solid, the solute is surrounded by itself. Difficulties in application to aqueous solubility of equations similar to eq 6 have previously been encountered; for example, aliphatic and aromatic compounds give rise to quite different correlation equations.[63]

We can amend eq 6 to incorporate terms that reflect interactions in the pure liquid or solid. A term in $\Sigma\alpha_2^H \times \Sigma\beta_2^H$ will deal with hydrogen-bond interactions between acid and basic sites in the solid or liquid, and a term in $\pi_2^H \times \pi_2^H$ with dipole/dipole interactions. The best equations constructed on these lines are

$$\log S_W = 0.403 - 0.484R_2 + 0.814\pi_2^H + 1.956\Sigma\alpha_2^H + 4.018\Sigma\beta_2^H - 1.130\Sigma\alpha_2^H \times \Sigma\beta_2^H - 4.067V_x - 0.010(\text{mp} - 25)$$

$$n = 411,\ \text{SD} = 0.496,\ r^2 = 0.934,\ F = 819,\ \text{AAE} = 0.245 \quad (9)$$

$$\log S_W = 0.510 - 1.020R_2 + 0.813\pi_2^H + 2.124\Sigma\alpha_2^H + 4.187\Sigma\beta_2^H - 3.337\Sigma\alpha_2^H \times \Sigma\beta_2^H - 3.986V_x$$

$$n = 594,\ \text{SD} = 0.562,\ r^2 = 0.918,\ F = 1089,\ \text{AAE} = 0.409 \quad (10)$$

Inspection of eqs 7−10 shows that there is little to be gained by inclusion of the mp correction term (compare Tables 1 and 2). The equations with the cross-term are significantly better than those without this term, and eq 9 is better than eq 10. However, the practical advantages of eq 10 quite outweigh the better fit of eq 9; in any case, eq 10 compares well with the equations listed in Table 2 that cover a wide range of compound type.

We can probe the predictive capability of eq 10 through the test set of 65 compounds given in Table 3, where the observed and calculated log S_W values for eq 10 are given. The SD value for the 65 compound test set is 0.496 log units, AAE = 0.397, and av error = −0.122, which we can take as an estimate of the predictive power of eq 10. Finally, we can combine the training set and test set and obtain eq 11 for the total of 659 compounds.

$$\log S_W = 0.518 - 1.004R_2 + 0.771\pi_2^H + 2.168\Sigma\alpha_2^H + 4.238\Sigma\beta_2^H - 3.362\Sigma\alpha_2^H\Sigma\beta_2^H - 3.987V_x$$

$$n = 659,\ \text{SD} = 0.557,\ r^2 = 0.920,\ F = 1256,\ \text{AAE} = 0.408 \quad (11)$$

We consider eq 11 to be the best equation we have constructed from the general solvation descriptors, and conclude that an amended version of eq 6, containing the extra $\Sigma\alpha_2^H \times \Sigma\beta_2^H$ term, can correlate and predict log S_W values to ~0.56 log units. The calculated values of log S_W from eq 11 are included in the Appendix.

There are particular experimental difficulties with regard to compounds that have very low solubilities. To ascertain if such compounds were exerting any undue influence on the regression, we re-ran the correlation leaving out the very insoluble compounds. We also left out separately the very soluble compounds, and finally omitted both the very insoluble and very soluble compounds. A summary of the resulting equations is given in Table 4, where the coefficient of the product term $\Sigma\alpha_2^H \times \Sigma\beta_2^H$ is denoted as '*k*'. By comparison with eqs 10 and 11, changes in the regression coefficients are not very pronounced and so there is little disrupting effect of compounds with very low or very high solubilities.

More important effects probably arise when the solid in equilibrium with the saturated solution is a hydrate, because the solubility of the hydrate will not be the same as the unhydrated solid, to which all the correlation equations refer. In addition, solubilities may depend on the physical form of a solid, for example whether it is amorphous or crystalline.

The Factors that Influence Aqueous Solubility—Unlike most regression equations for log S_W, eqs 10 and 11 can be interpreted to show the physicochemical properties of the compound that influence aqueous solubility. We have already noted that most studies of aqueous solubility in which correlations are constructed without any correction term for solids do not discuss why a correction term is unnecessary. Neither eq 10 nor eq 11 include a solid correction term, and it seems obligatory to comment on this. The two main properties that lead to an increase in solubility are hydrogen-bond acidity and hydrogen-bond basicity; these properties no doubt reflect the strong hydrogen-bond basicity and strong hydrogen-bond acidity of water as a bulk solvent.[28,29] However, if the compound is itself both a hydrogen-bond acid and a hydrogen-bond base, then intermolecular hydrogen-bond interactions will lead to an increase in mp and to a decrease in solubility. Thus, the product term, $\Sigma\alpha_2^H \times \Sigma\beta_2^H$, takes the place (at least partly) of a solid correction term.

Table 5—Hydrogen-Bond Effects on Solubility (log S_W)

compound	2.124 $\Sigma\alpha_2^H$	4.187 $\Sigma\beta_2^H$	−3.337 $\Sigma\alpha_2^H \times \Sigma\beta_2^H$	resultant

trichloromethane	0.32	0.08	−0.01	0.39

Now all hydrogen-bond acids, with the exception of carbon acids, are also hydrogen-bond bases, so that the effect of hydrogen-bonding on solubility will be a resultant of the two single terms and the product term, as shown in Table 5 for some representative acids. It is quite clear that the net result of the presence of hydrogen-bond acid and hydrogen-bond base groups will increase solubility. The intermolecular acid−base interaction in a solid or liquid, given by the $\Sigma\alpha_2^H \times \Sigma\beta_2^H$ term, reduces the hydrogen-bond effect but still leaves a negative resultant. For the large number of compounds that are hydrogen-bond bases, but not acids, there is a straightforward effect of increased solubility (also shown in Table 5). As already mentioned, there are but few compounds that are hydrogen-bond acids and yet have no or very little hydrogen-bond basicity. Again, there will be virtually no cross-term, and all the effect of hydrogen-bond acidity will be toward an increase in solubility, as shown for trichloromethane. The single terms in the descriptors $\Sigma\alpha_2^H$ and $\Sigma\beta_2^H$ both lead to an increase in solubility. The other 'polar' term in eq 10 is $s.\pi_2^H$ that leads also to an increase in solubility. It might be expected that intermolecular interactions, such as dipole/dipole or dipole/induced dipole would lead to an increase in mp and, again, a decrease in solubility. However, the product term $\pi_2^H \times \pi_2^H$ is not significant, no doubt because it is very well correlated with π_2^H which leads to an increase in solubility. However the coefficient of π_2^H in eq 10 is very much less than for the solubility of gases and vapors, so that dipolar effects within the solid or liquid counteract to some extent the solute/water effects that lead to increased solubility.

Two other terms in eq 10, rR_2 and vV_x, both result in a decrease in solubility; the r and v coefficients in eq 10 are markedly more negative than in the solvation equation for gaseous solubility. The R_2 descriptor refers to the propensity of a solute to interact with surrounding σ and π electrons, the negative r coefficient suggesting that such interaction within the solid or liquid is much larger than the corresponding interaction between the solute and bulk water. Although the V_x descriptor refers to the size of the solute, the vV_x term for the solubility of gaseous solutes will be the resultant of two opposing effects, (i) a cavity effect that arises from the disruption of solvent−solvent interactions and leads to a negative coefficient, and (ii) a general solute−solvent dispersion interaction that leads to a positive coefficient. For the solubility of gaseous solutes in water, the v coefficient is negative (−0.869) so that the unfavorable cavity effect dominates.[29] In solids and liquids, part of the cohesive forces will be general dispersion interactions that help to hold the solid or liquid together. These interactions within the solid or liquid will lead to an increase in mp, to a decrease in solubility, and to a much more negative v coefficient in eq 10, as observed (−3.986).

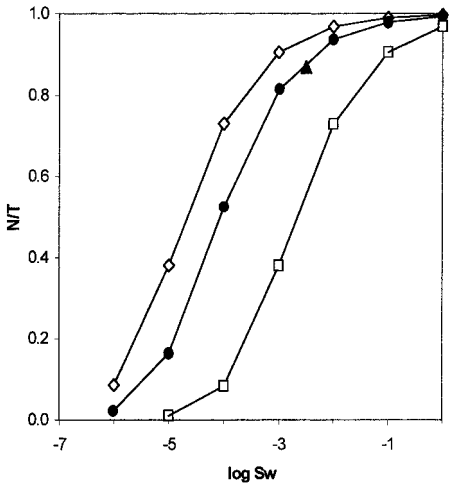

Figure 2—Values of N/T for Bronsted acids as a function of the total solubility, log S_W. Acids pK_a values are 3 (□), 4.37 (●), and 5 (◇), determined value (▲) for *p*-toluic acid.

Thus, the sign and magnitude of the coefficients in eq 10 can be interpreted in terms of known chemical interactions, both between the compound and water, and between molecules of the compound itself. Such interpretation, in turn, leads to information about the physicochemical factors that influence the aqueous solubility of solids and liquids.

We note that in Mobile Order Theory[23−25] the terms in solute volume are interpreted as originating from a balance of entropic effects. The negative dependence of solubility on solute volume arises[24] from the mobile order entropy decrease of the hydrogen-bonded water molecules on introduction of the solute. We have used a cavity theory to interpret volume and other effects because we have used[29] this type of theory (i.e., scaled particle theory[64]) previously to obtain quantitative estimates of cavity terms for solution of gases and vapors in water.

The Solubility of Bronsted Acids and Bases—Grant and Higuchi[65] have noted the effect of pH on the solubility of Bronsted acids and bases and have given equations for the variation of solubility with pH.[65] Most studies on the correlation and prediction of solubility ignore this pH dependency; none of the studies in Tables 1 and 2 mention this problem at all.

If a Bronsted acid, such as a carboxylic acid, is dissolved in water, the pH of the resulting solution will depend both on the acid pK_a and on the total concentration of the acid in solution. For a given acid, the greater the concentration, the lower will be the pH and the larger will be the proportion of the neutral species. Hence, for acids with the same pK_a, the pH of the saturated solution will decrease as the solubility increases. For acids that are quite soluble, the proportion of neutral species will therefore be larger than for acids that are sparingly soluble. Our eq 11 and, indeed, all the other correlation equations in Tables 1 and 2, refer to the solubility of the neutral species, N, so that the predicted (neutral) solubility will be less than the observed solubility, T or S_W, with the difference depending on the acid pK_a value and the actual solubility.

In Figure 2 we give the calculated values of N/T, the fraction of the neutral species, for a series of acids of pK_a 3, 4.37, and 5 as a function of the observed total solubility, log S_W (log T). For an acid with a pK_a of 4.37 or 5, N/T is

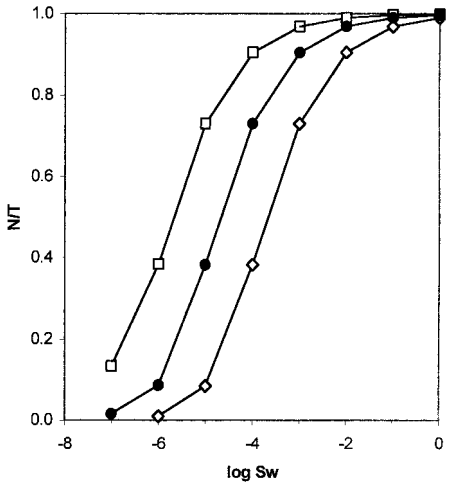

Figure 3—Values of *N*/*T* for Bronsted bases as a function of the total solubility, log S_W; pK_a values are 8 (□), 9 (●), and 10 (◇).

larger than ∼0.5 even down to log S_W values of −4. Now an error of a factor of 0.5 (or 2.0) corresponds to an error of 0.3 log units and is not very important in the context of SD values of 0.5 log units. However, for very insoluble acids, with log S_W of −5 or −6, errors of one or two log units will arise if no consideration is given to ionization of Bronsted acids. For stronger acids with pK_a = 3, large errors will arise at log S_W values less than around −3.5 units.

We have chosen one of our pK_a values as 4.37 because this is the pK_a of *p*-toluic acid, studied in considerable detail by Strong and co-workers.[66] Their determined *N*/*T* value for *p*-toluic acid in the saturated solution at 25 °C is shown in Figure 2, and our calculated value is in excellent agreement.

A similar ionization phenomenon occurs in the solubility of Bronsted bases. Many drug molecules, of course, are strong Bronsted bases, with pK_a values of the conjugate acid ranging from 8 to 10. We give in Figure 3 plots of our calculated *N*/*T* values for three series of bases with pK_a = 8, 9, and 10 as a function of the observed solubility, log S_W. If we consider substantial errors in predicted values to arise when *N*/*T* is less than ∼0.5, these errors will be the case for bases with log S_W < −4 (pK_a 10), < −5 (pK_a 9) and < −6 (pK_a 8).

We can compare observed solubilities with those calculated from eq 10 for the neutral species for Bronsted acids and bases in our data set. In Table 6 are given values for strong Bronsted acids, that is, acids with pK_a values <4. Only in the case of trichloroacetic acid is the value of *N*/*T* <0.5 (0.480) for the saturated solution. The observed solubility would therefore be ∼0.32 log units more than the calculated solubility. For all the other acids in Table 6, the difference will be even less. Inspection of Table 6 shows that for three acids, the observed − calculated log S_W values are −1.2 to −1.5 units, so that other interfering factors are far more important than ionization, at least for the acids in Table 6.

Table 7—Observed and Calculated log S_W Values for Strong Bronsted Bases (pK_a > 10)

base	obs	calc	obs – calc	pK_a
octylamine	–1.460	–2.151	0.691	10.57
hexylamine	–0.250	–1.038	0.788	10.64

pentylamine	0.270	–0.491	0.761	10.64
heptylamine	–0.900	–1.600	0.700	10.66
propylamine	1.520	0.618	0.902	10.69
ethylamine	2.060	1.169	0.891	10.70
triethylamine	–0.140	–0.363	0.223	10.85
diethylamine	1.030	0.395	0.635	11.04
dibutylamine	–1.440	–1.804	0.364	11.25

A similar table can be constructed for the strong bases, those with pK_a > 10 (see Table 7). There is a general trend, with (observed − calculated) log S_W values always positive by ∼0.7 log units, on average. However, this trend cannot be accounted for by ionization; even the value of 0.80 for *N*/*T* for dibutylamine would make a difference of only 0.1 log units.

It seems, therefore, that only for very insoluble strong Bronsted acids and Bronsted bases will ionization lead to significant errors in calculation. However, it is worth pointing out that solubilities calculated with eqs 10 or 11, or by the methods summarized in Tables 1 and 2, refer to the solubility of the neutral species. For Bronsted acids and bases this will be the solubility in solutions of pH near to the compound pK_a (see Figures 2 and 3). The observed solubility is that at the pH of the saturated solution. This observed solubility does not refer to any specific pH, but to a pH that has to be calculated from the observed (total) solubility and the compound pK_a. If the solubility of a Bronsted acid or base is required at a given pH of 7 or 7.4, for example, then Figures 2 and 3 can be used to obtain the correction factor *N*/*T*, at least if the difference in pH between the saturated solution and the given pH is not too large.

Conclusions

An amended solvation equation can satisfactorily correlate and predict log S_W values to 0.56 log units.The descriptors used in the correlation equations are either calculated from structure (R_2 and V_x) or are obtained from experimental data (π_2^H, $\Sigma\alpha_2^H$, $\Sigma\beta_2^H$) as shown by the full lines in Figure 1. Now that the ABSOLVE program for the calculation of π_2^H, $\Sigma\alpha_2^H$, and $\Sigma\beta_2^H$ is in place, the correlation equations set up in this work will enable log S_W values to be predicted from structure in a high throughput manner, as shown by the broken lines in Figure 1. Although the correlation equations are for neutral species, corrections for Bronsted acids and Bronsted bases can be made from the predicted log S_W value and a (predicted) pK_a value.

Solubility of Recombinant Human Tissue Factor Pathway Inhibitor

BAO-LU CHEN,* XIAORONG WU, SUSAN J. BABUKA, AND MANINDER HORA

Contribution from *Department of Formulation Development, Chiron Corporation, 4560 Horton Street, Emeryville, California 94608-2916.*

Received March 4, 1999. Accepted for publication June 8, 1999.

Abstract □ Study of recombinant human tissue factor pathway inhibitor (rhTFPI) solubility shows (1) an inverted bell-shaped pH–solubility profile with a broad solubility minimum between pH 5 and 10 such that the solubility minimum midpoint is 2–3 pH units away from its isoelectric point; (2) a negative temperature–solubility coefficient; (3) a strong dependence of solubility on the valence of electrolytes, with both multivalent cations and anions enhancing this effect; and (4) a significant increase of solubility in the presence of charged polymers. At pH 6–7, rhTFPI solubility–salt profiles display typical salting-in and salting-out biphasic effects. At a slightly lower pH (pH 5), a third phase in addition to the salting-in and salting-out phases was observed at low ionic strength conditions (5 to 50 mM) where rhTFPI solubility increased as salt concentration decreased. The salting-out constant for rhTFPI in NaCl is 1.04 M^{-1} and is independent of the pH of the solution. Resolubilization of rhTFPI precipitates revealed that "insolubility precipitates" (seen during buffer exchanges) resulted from protein solute saturation and could be redissolved by "native" solvent conditions. On the other hand, "instability precipitates" (typically seen after exposure to elevated temperatures or extended storage periods) were caused by insoluble protein aggregate formation and required strongly denaturing conditions to redissolve.

Introduction

Tissue factor pathway inhibitor (TFPI), formerly known as lipoprotein associated coagulation inhibitor (LACI)[1] or extrinsic pathway inhibitor (EPI),[2] is an endogenous inhibitor of tissue factor-mediated blood coagulation. It forms a quaternary complex with tissue factor, factor VIIa, and factor Xa. This complex prevents factor Xa from participating in the formation of prothrombinase complex, thus blocking the generation of thrombin from prothrombin.[3]

Recombinant human tissue factor pathway inhibitor (rhTFPI) expressed from *Escherichia coli* is a pharmaceutically important protein. In animal studies, rhTFPI has been shown to be effective in preventing thrombosis in a rabbit model of vascular trauma.[4] In a baboon sepsis model and a rabbit focus-of-infection model, rhTFPI was associated with a marked improvement in survival rate compared with that of the placebo.[5,6]

The *E. coli*-derived rhTFPI lacks glycosylation and is sparingly soluble in physiological media (approximate solubility in aqueous media under physiological pH conditions is 0.2 mg/mL). Chaotropic agents (e.g., urea) have been employed to maintain its solubility during the purification process.[7] The low solubility of rhTFPI poses a significant challenge during process and formulation development, product manufacturing, and clinical administration of this molecule.

Protein solubility has recently been reviewed in a number of publications.[8−10] Although it is known that pH and salt conditions can have a modulatory effect, strategies for enhancing the solubility of proteins at or near physiological conditions are usually derived through trial and error, and differ considerably from one protein to the other. Low solubility is often thought to result from a combination of electrostatic and hydrophobic interactions between protein−solvent and protein−protein molecules.[11] The solubility of a protein apparently depends on subtle solvent disturbances in the distribution of charged, polar, and hydrophobic residues on the protein surface. However, because the key interactions dictating the mechanisms of insolubility and precipitation are not fully understood, an empirical approach is often taken when attempting to increase the solubility of a protein.

The solubility properties of rhTFPI are unique in being significantly influenced by the distribution of both positively and negatively charged residues in clustered domains on the polypeptide chain. The rhTFPI molecule consists of an acidic amino-terminal region, three Kunitz-type domains in tandem, and a basic carboxyl-terminal region (Figure 1).[7,12] Inter- and intramolecular electrostatic interactions between the two charged termini may confer poor solubility characteristics on the protein under physiological conditions. One goal of the present investigation was to understand the solubility behavior of rhTFPI under various pH, salt, and formulation conditions to aid in developing robust manufacturing processes and an appropriate formulation for this protein.

A second goal of this study was to understand precipitation phenomena in pharmaceutical proteins using rhTFPI as an example. Protein precipitation resulting from changes in protein solubility is a common occurrence during purification and formulation processes. It is often not differentiated from the formation of insoluble protein aggregates caused by protein instability resulting from exposure to stress conditions encountered during production processes or extended storage. For example, a temperature change during processing could either alter protein solubility, resulting in protein precipitation, or affect protein stability, leading to protein aggregation and precipitation. In this article, we have designated a protein precipitate originating from an excess amount in a saturated solution as an "insolubility precipitate". In contrast, a protein precipitate attributable to changes in stability has been labeled as an "instability precipitate". Because the mechanisms of creation of the two precipitates are different, it was hoped that the characterization of these precipitate types would aid in developing approaches to prevent their formation during processing and storage of the protein.

Materials and Methods

Materials—Recombinant human TFPI was expressed in *E. coli* and purified by a series of chromatographic, diafiltration, and associated procedures described previously.[7,12,13] The purified

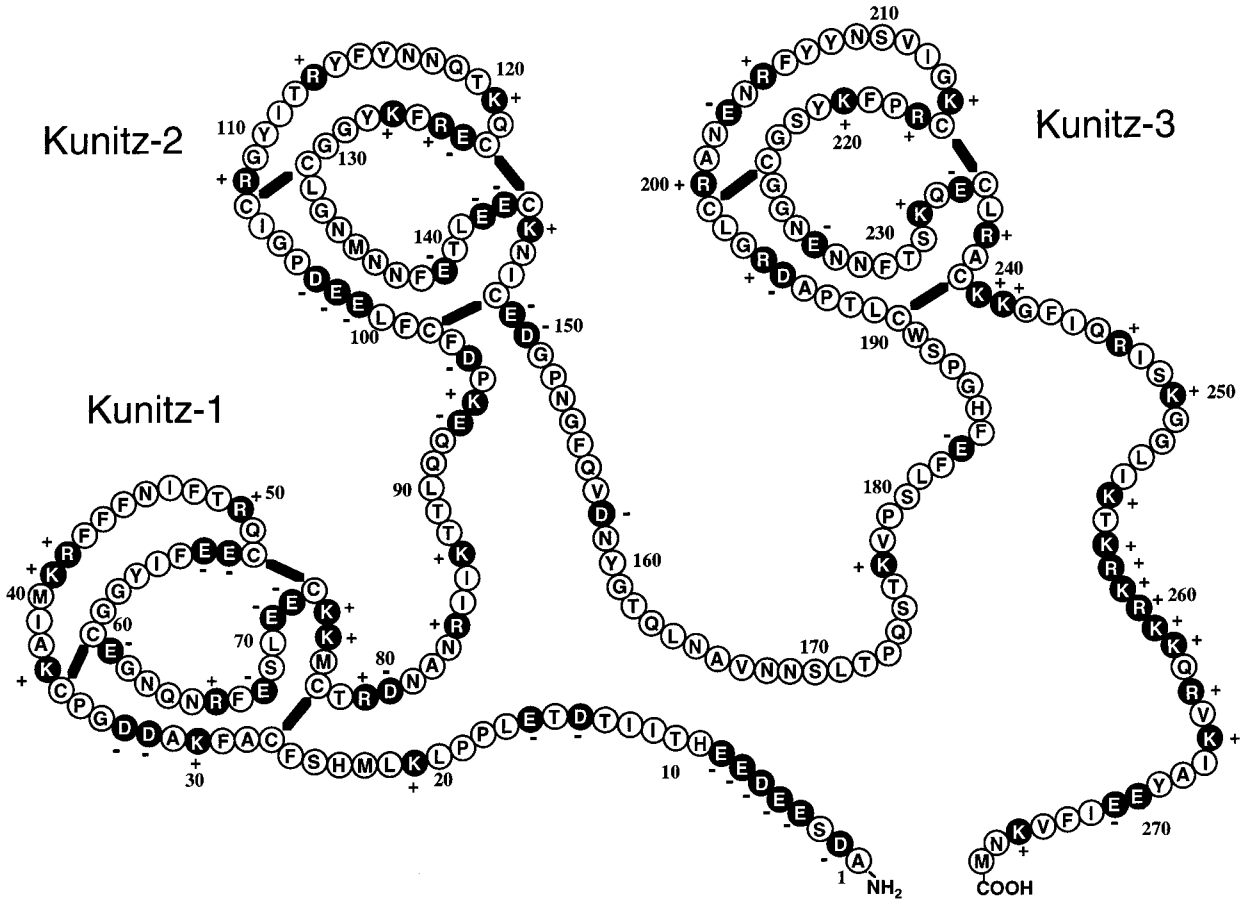

Figure 1—Structure of rhTFPI with the charged amino acid side chains marked. The three Kunitz-type domains are also shown.

protein, 10 mg/mL in a solution containing 150 mM NaCl and 2 M urea buffered with 20 mM sodium phosphate at pH 7, was stored at −70 °C as a frozen bulk. This protein was used as the starting material for all solubility studies. Dextran (MW 10 000), dextran sulfate (MW 10 000), poly-L-arginine hydrochloride (MW 11 800), poly-L-glutamine (MW 10 100), and poly-L-glutamic acid sodium salt (MW 1000) were purchased from Sigma Chemical Co. Poly(acrylic acid) (MW 10 000) was purchased from Polysciences, Inc. All buffer solutions for solubility screening and resolubilization experiments were prepared by Chiron Media Service Groups using reagent grade chemicals.

Solubility Screening—A dialysis method was used for the solubility screening experiments. Approximately 2−3 mL of rhTFPI bulk was loaded into a dialysis tubing (Spectra/Por 7 from Spectrum Inc., MWCO 3500) and dialyzed against 50- to 100-fold excess buffer solution (three exchanges per run) at either 4 °C or ambient temperature for 12 to 24 h. The dialysate was filtered through a 0.2-μm filter (Spin-X centrifuge tube filters from Corning Costar Corp.) to remove visible precipitate, and the resulting clear protein solution was analyzed for concentration of remaining soluble rhTFPI by ultraviolet (UV) absorbance and/or one of two high-performance liquid chromatography (HPLC) methods. Bioactivity, based on the anticoagulation role of TFPI, was assessed by measuring in vitro prothrombin time.

UV Absorbance Measurement—UV absorbance of protein solutions was measured using a Hewlett-Packard Diode Array spectrometer (Model 8452). Absorbance at 278 and 400 nm for protein solutions (P_{278} and P_{400}) and buffer solutions (B_{278} and B_{400}) was recorded using a 1.0-cm path length quartz cuvette. The concentration of rhTFPI in mg/mL was calculated using an extinction coefficient of 0.68 $(mg/mL)^{-1}cm^{-1}$ according to the following expression:

$$[(P_{278} - P_{400}) - (B_{278} - B_{400})]/0.68 \quad (1)$$

High-Performance Liquid Chromatography (HPLC)—Cation-exchange HPLC (CEX-HPLC) was performed on a Pharmacia Mono-S HR 5/5 glass column using a Waters 626 LC system with a 717 heater/cooler autosampler. The column was equilibrated with 80% mobile phase A (70:30 v/v, 20 mM sodium acetate: acetonitrile at pH 5.4) and 20% mobile phase B (70:30 v/v, 20 mM sodium acetate and 1 M ammonium chloride:acetonitrile at pH 5.4). After injection, the protein was eluted by increasing mobile phase B to 85% in 21 min at a flow rate of 0.7 mL/min. The rhTFPI eluted at ~16.5 min as a single peak and was detected by UV absorbance at 280 nm with a Waters 486 absorbance detector. Data acquisition and processing were performed on a Perkin-Elmer Turbochrom system. Protein concentration was estimated by integrating the peak area and comparing it with a standard curve generated from samples of known concentrations.

Reversed-phase HPLC (RP-HPLC) was performed on a Rainin Microsorb-MVC8 column (5 cm × 4.6 mm, 5 μm, 300 Å) using a Waters 626 LC system with a 717 heater/cooler autosampler. The column was equilibrated with 86% mobile phase A (30% acetonitrile/0.45% TFA) and 14% mobile phase B (60% acetonitrile/0.45% TFA). After injection, the protein was eluted by increasing mobile phase B to 20% in 6.5 min, then to 68% in 15.5 min, and finally to 100% in 17 min at a flow rate of 1 mL/min. Eluted protein was detected by UV absorbance at 280 nm with a Waters 486 absorbance detector. Data acquisition and processing were performed on a Perkin-Elmer Turbochrom system.

The Prothrombin Time Bioassay—The in vitro Prothrombin Time bioassay (PT assay) was performed on a Coag-A-Mate RA4 instrument (Organon, Teknika). Samples were first diluted to 150 μg/mL with a urea buffer (2 M urea, 20 mM sodium phosphate, 250 mM NaCl, pH 7.2) and then to 30 μg/mL with a Tris buffer (50 mM Tris, 100 mM NaCl, 1 mg/mL bovine serum albumin, pH 7.5). Finally, standards of known rhTFPI concentrations were diluted to 18, 15, 12 and 9 μg/mL and test samples to ~15 and 12 μg/mL by the Tris buffer. A 10-μL aliquot of diluted sample was first mixed with 90 μL of Verify I (Organon Teknika) in a plastic test tray (Organon Teknika) and the tray was then placed into the Coag-A-Mate instrument. A 200-μL aliquot of Simplastin Excel (Organon Teknika) was added to each well to initiate the clotting process. The clotting times for test samples and standards were recorded. The clotting time for the test sample was converted to

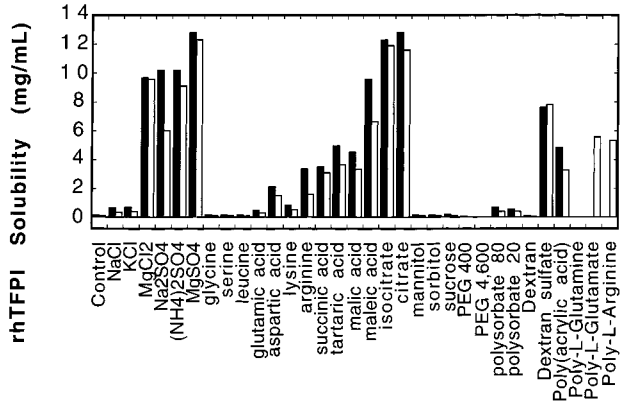

Figure 2—rhTFPI solubility in various solvent systems at 4 °C (shaded) and ambient temperature (open). All solutions were buffered at pH 7 by 10 mM sodium phosphate, which is also shown as the control. Concentrations of tested compounds were 150 mM for salts and amino acids, 5% (w/v) for mannitol and sorbitol, 9% (w/v) for sucrose, 0.1% (w/v) for polysorbates, 0.5% (w/v) for dextran, dextran sulfate, and poly(acrylic acid), 0.75 mM for poly-L-glutamine, and 1 mM for poly-L-glutamic acid and poly-L-arginine. Poly-L-glutamine, poly-L-glutamic acid, and poly-L-arginine show only ambient temperature solubility data.

rhTFPI potency by interpolation on the standard curve, which plotted the natural log of the clotting time versus rhTFPI concentration.

Circular Dichroism (CD) Measurement—Far UV CD spectra of rhTFPI samples were obtained with a JASCO-710 spectropolarimeter (Jasco Inc., Easton, MD) using a 0.2-mm path length cylindrical quartz cell.

Results

Solubility Screening Studies—The solubility of rhTFPI in 10 mM sodium phosphate at pH 7 is <0.5 mg/mL. Known amounts of a number of solubilizing solutes were added to this buffer to enhance the aqueous solubility of rhTFPI, and the data are shown in Figure 2. We have divided the tested solutes into three classes: minor, moderate, or good solubilizing agents. Minor solubilizers were defined as compounds that enhanced rhTFPI solubility by several fold to a concentration not exceeding 1 mg/mL; these include NaCl, KCl, mannitol, sorbitol, sucrose, glycine, leucine, glutamic acid, polysorbate 20, polysorbate 80, dextran, and poly-L-glutamine. Moderate solubilizers were defined as those compounds that increase rhTFPI solubility into the range of 1 to 5 mg/mL; these include lysine, arginine, aspartic acid, succinic acid, malic acid, and tartaric acid. Finally, good solubilizers were those that increased rhTFPI solubility to concentrations >5 mg/mL. These include $MgCl_2$, Na_2SO_4, $(NH_4)_2SO_4$, maleic acid, citric acid, poly-L-glutamic acid, poly-L-arginine, dextran sulfate, and poly(acrylic acid). The classification reveals a clear pattern. Neutral compounds, polymers, and monovalent ions have a marginal effect on rhTFPI solubility, whereas multivalent electrolytes and ionic polymers exhibit a more marked effect.

There was a modest temperature effect on rhTFPI solubility. Solubility of rhTFPI at 4 °C was slightly higher than that measured at ambient temperature. This was independent of the type of solvent tested. Thus, rhTFPI has a negative temperature coefficient for solubility.

Effect of pH on Solubility—The solubility of rhTFPI as a function of pH was investigated in the pH range 3−11 buffered by either 20 mM sodium acetate, sodium glutamate, sodium succinate, sodium phosphate, or glycine. Because the pH profile of a protein may depend on the ionic strength,[14] we included 150 mM NaCl in the buffer systems to minimize the difference in ionic strength for these

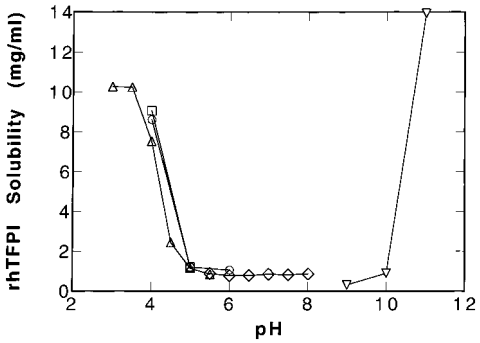

Figure 3—Dependence of rhTFPI solubility on pH in 150 mM NaCl and 20 mM buffer of sodium acetate (triangle), sodium phosphate (diamond), glycine (inverted triangle), sodium L-glutamate (square), and sodium succinate (circle).

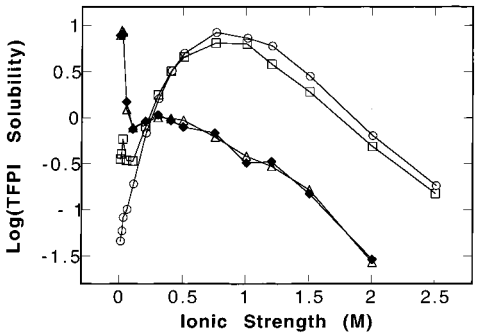

Figure 4—Dependence of logarithm rhTFPI solubility on the ionic strength in sodium chloride solutions buffered with 5 mM sodium acetate at pH 5 (filled diamond) and sodium phosphate at pH 5 (open triangle), pH 6 (open square), and pH 7 (open circle).

buffers. The function appeared as an inverted bell-shaped curve (Figure 3) with a minimum solubility trough between pH 5 and pH 10. The lowest solubility was ~0.5−1 mg/mL centered near pH 7, which is 2−3 pH units away from the isoelectric point of rhTFPI (9.2). Below pH 4.5 and above pH 10.5, rhTFPI solubility rose sharply and eventually exceeded 10 mg/mL.

Effect of Ionic Strength on Solubility—We investigated the dependence of rhTFPI solubility on ionic strength in NaCl solutions buffered by sodium phosphate at pH 5, 6, and 7 and by sodium acetate at pH 5. Figure 4 shows the logarithm of rhTFPI solubility as a function of the ionic strength at the three pH conditions. The ionic strength, I, was defined as

$$I = 1/2 \, \Sigma \, C_i \, Z_i^2 \qquad (2)$$

where C_i is the concentration of the i^{th} ion and Z_i is the charge on the i^{th} ion. At pH 6 and 7, rhTFPI solubility shows typical "salting-in" and "salting-out" biphasic curves. The solubility initially increased with ionic strength to ~1 M and then decreased at subsequent, higher ionic strengths. The entire solubility curve at pH 6 was lower than that at pH 7. At pH 5, buffered by either phosphate or acetate, a triphasic solubility curve was observed. At this pH, the rhTFPI solubility curve in the normal salting-in and salting-out regions was lower than the curve at pH 6. In contrast to the behavior at pH 6 and 7, a large part of the salting-in phase was diminished. Instead, a third phase at low ionic strength conditions was observed in which rhTFPI solubility increased as the ionic strength decreased.

The salting-out part of the solubility curves at pH 5 (0.5−2 M ionic strength), 6, and 7 (1−2.5 M ionic strength) exhibited a linear dependence of the logarithm of the solubility value on ionic strength. This part of the solubility

Table 1—Salting-Out Parameters for rhTFPI in Sodium Chloride Solutions Buffered by Either Acetate or Phosphate to pH 5, 6, and 7[a]

pH (buffer species)	β	K_s (M^{-1})
5 (sodium acetate)	0.51	0.95
5 (sodium phosphate)	0.56	0.99
6 (sodium phosphate)	1.90	1.09
7 (sodium phosphate)	2.07	1.12

[a] The salting-out parameters were calculated by linear fitting salting-out part of the solubility curves from 0.5 to 2 M ionic strength for pH 5 and from 1 to 2.5 M ionic strength for pH 6 and 7.

curve was analyzed by the following empirical equation:[8]

$$\log S = \beta - K_s I \quad (3)$$

where S is protein solubility, β is a constant, K_s is the salting-out constant, and I is the ionic strength. The two salting-out parameters, β and K_s, were calculated (Table 1). Results in Table 1 show the parameter β (solubility extrapolates to zero salt concentration without considering the salting-in effect) depended on pH, whereas the salting-out constant K_s did not and was averaged to be 1.04 M^{-1}. These results are consistent with similar data for other proteins.[15]

Resolubilization of Insolubility Precipitates—Protein precipitates are usually formed from one of two distinct mechanisms. (1) exceeding the solubility limit of the protein in the medium leads to an "insolubility precipitate"; and (2) a partial or complete unfolding of the protein resulting in aggregation that eventually gives rise to an "instability precipitate". The latter is so-called because this type of precipitate is usually seen as a result of prolonged storage of the protein. Experiments were designed to understand these processes by examining the resolubilization behavior of the two types of precipitates in selected media.

A double-dialysis approach was employed for investigation of the insolubility precipitate. In the first step of this experiment, insolubility precipitates were generated within dialysis bags. A bulk solution of rhTFPI was dialyzed against phosphate-buffered saline (PBS) because of its rather limited solubility in this medium. One bag containing the precipitate was removed, and the amount of soluble protein was measured to obtain a control solubility value for each experiment. In a subsequent step, the remaining dialysis bags containing precipitate were transferred into resolubilizing media such as sodium citrate, arginine, or urea, and further dialyzed against those media. After completion of this second dialysis step, the amount of soluble protein in the bag was measured. We compared the amount of rhTFPI resolubilized by a given medium with the control solubility in PBS obtained from the first step to evaluate the effect of the resolubilization condition. We also measured the in vitro bioactivity of the resolubilized rhTFPI to assess its conformational state.

The resolubilization results are shown in Table 2. The control sample (dialyzed against PBS only) showed that 0.69 mg of the initial 10 mg of rhTFPI present per mL in the bag remained soluble after the first dialysis step; that is, >90% of the protein precipitated. In the second dialysis for resolubilization, 0.15 M arginine was able to convert approximately one-fourth to one-third of the precipitated amount into soluble protein, and 0.15 M sodium citrate converted almost the entire precipitate into soluble protein. Urea proved to be another good resolubilization agent, with 2 M urea converting half and 8 M urea converting all of the precipitated rhTFPI into soluble protein. A slightly higher recovery in 8 M urea than the starting concentration was probably caused by concentration due to osmotic pressure produced during dialysis.

Table 2—Resolubilization of rhTFPI Solubility Precipitate[a]

resolubilization buffer	soluble rhTFPI (mg/mL)	specific bioactivity
control (PBS)	0.69	1.10
PBS + 2 M urea	5.52	0.82
PBS + 8 M urea	12.2	1.04
PBS + 2 M urea + 0.1 M DTT	0.01	0.10
PBS + 8 M urea + 0.1 M DTT	11.4	0.11
0.15 M L-arginine	3.01	0.92
0.15 M sodium citrate	9.44	1.01

[a] The concentration of soluble rhTFPI was measured by the RP-HPLC method regardless of peak shift for samples containing DTT. Specific bioactivity was estimated from the PT assay results versus the protein concentration measured by the RP-HPLC.

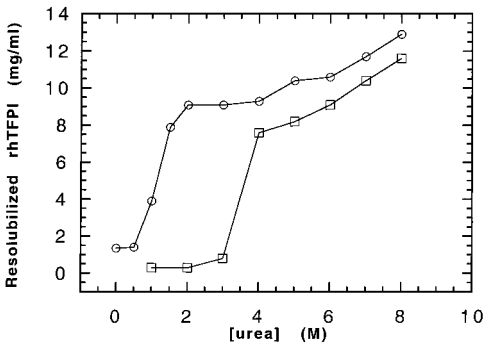

Figure 5—Resolubilization of rhTFPI "insolubility precipitate" in urea solvents in the absence (circle) and presence (square) of 0.1 M DTT.

The addition of 0.1 M dithiothreitol (DTT) to the two different concentrations of urea produced dissimilar effects. In 2 M urea containing 0.1 M DTT, almost no soluble rhTFPI was detected after the second dialysis step, showing that the presence of DTT had an adverse effect on resolubilization in the more dilute urea solution. In contrast, 0.1 M DTT in 8 M urea had little effect on the resolubilization of rhTFPI. Regardless of its effect on resolubilization, DTT evidently produced conformational changes in the rhTFPI molecule. The bioactivity data in Table 2 indicate that resolubilized rhTFPI remained fully active (within the ±20% variation of the assay) except when DTT was present in the resolubilization medium.

To understand the role of DTT in the resolubilization studies more clearly, the urea/DTT resolubilization experiment was repeated using a broader urea concentration range (Figure 5). When the amount of rhTFPI resolubilized in the second dialysis step was plotted as a function of the urea concentration in the dialysis medium, an initial low phase was followed by a transition phase and a high recovery phase regardless of the presence of DTT. However, the transition occurred at a much lower urea concentration (~1.5 M) in the absence of DTT. In 1.5 M urea, rhTFPI was still biologically active, as determined by the PT assay. Measurements by CD or fluorescence showed that the molecule retained its native conformation (data not shown). With DTT present in the resolubilization medium, the transition was shifted to a higher urea concentration (~3.5 M). Because disulfide bonds have been shown to play a critical role in folding and conformational stability of Kunitz-domain-containing proteins,[16] it is thought that reduction of these bonds by DTT may have resulted in the exposure of hydrophobic regions to the aqueous medium, leading subsequently to rhTFPI denaturation. Thus, stronger denaturing conditions were needed to resolubilize the precipitated protein when DTT was present in the medium.

To test this hypothesis further, we analyzed rhTFPI in 8 M urea with and without DTT by CD and a RP-HPLC procedure. As shown in Figure 6, the far UV CD spectrum

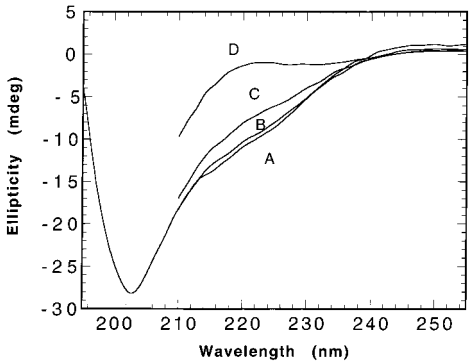

Figure 6—Far UV CD spectra of four rhTFPI samples. These four samples are (A) 0.48 mg/mL rhTFPI in PBS; (B) 0.94 mg/mL rhTFPI in 2 M urea and PBS; (C) 1.24 mg/mL rhTFPI in 8 M urea and PBS; (D) and 1.27 mg/mL rhTFPI in 0.1 M DTT, 8 M urea, and PBS (D). The CD signals were normalized to the 0.48 mg/mL rhTFPI sample for comparison.

Table 3—Percent Remaining Soluble Protein in rhTFPI Samples after Incubation at 40 °C for 0, 3, and 13 Days and after Resolubilization[a]

samples	soluble protein in stability samples with no resolubilization, %	total soluble protein in resolubilized stability samples by the following solvents, %		
		0.1 M citrate	2 M urea	8 M urea
t = 0	100	–	100	–
t = 3 days	73	–	73	110
t = 13 days	44	51	54	96

[a] Resolubilization by 0.1 M sodium citrate (only for $t = 13$ days stability sample), 2 M urea (all three stability samples), and 8 M urea (only for $t = 3$ and 13 days stability samples). All values were normalized to the $t = 0$ stability sample.

of rhTFPI in 8 M urea resembles the spectra in both 2 M urea and PBS, but with a slight loss of conformation, whereas addition of 0.1 M DTT in 8 M urea results in a significant loss of secondary structure. Similarly, RP-HPLC chromatograms showed that the rhTFPI peak eluted at 13 min in both a control sample without urea and an 8 M urea sample. With the addition of 0.1 M DTT in the 8 M urea solution, the rhTFPI peak shifted to 17.5 min, indicating increased hydrophobicity of the protein under this condition. These observations support the conclusion that reduction of disulfide bonds by DTT unfolds the protein, thus exposing hydrophobic regions at the surface.

Resolubilization of Instability Precipitates—Instability precipitates of rhTFPI were generated by incubating a 0.4 mg/mL rhTFPI solution in 10 mM sodium phosphate at pH 7, 150 mM NaCl, and 0.005% polysorbate 80 at 40 °C for various periods of time. Under these conditions, the major degradation pathway of the protein has been determined to be protein aggregation that eventually results in formation of a visible precipitate over time. Stability samples at $t = 0$, 3, and 13 days were withdrawn and were analyzed for remaining soluble protein after removal of the visible precipitate by filtration. Samples containing precipitate (i.e., without filtration) were also dialyzed against 0.1 M sodium citrate, 2 M urea, and 8 M urea in attempts to resolubilize the precipitated protein.

Table 3 displays the remaining soluble protein in stability samples and the total amount of soluble rhTFPI in the stability samples after resolubilization. Upon incubation at 40 °C for 3 and 13 days, the amount of soluble protein decreased to 73 and 44% of the initial value, respectively. When the stability samples containing the soluble and precipitated protein were dialyzed into citrate and urea resolubilizing media, only small fractions of the precipitated protein could be resolubilized using 0.1 M sodium citrate or 2 M urea solutions (7−10% resolubilized from the 13-day stability sample containing 56% rhTFPI as a precipitate). On the other hand, resolubilization by an 8 M urea solution afforded a quantitative recovery of the instability precipitate. These data indicate that the precipitated protein in stability samples was not resolubilized by native or near-native media (such as 0.1 M sodium citrate or 2 M urea) but needed strong denaturing conditions for resolubilization.

Discussion

Adequate solubility of a protein in aqueous media is a critical requirement for development of commercial manufacturing processes and stable formulations for clinical application. Determination of protein solubility often requires preparation of a saturated solution in the given medium. Common techniques include dialysis, ultrafiltration, dissolution of a dried protein powder, or precipitation with poly(ethylene glycol).[10,17,18] We have used a dialysis method to study rhTFPI solubility. The dialysis approach is simple and allows rapid screening of a large number of potential solvents. If the protein concentration in the starting material is sufficiently high and precipitation is observed during dialysis, the soluble fraction of the protein measured within the dialysis membrane represents its saturated solubility in the selected medium. If protein solubility in a particular solvent exceeds the protein concentration in the starting material, further concentration of the dialyzed solution by ultrafiltration may be necessary to obtain the true maximum solubility. In this paper, we used the dialysis approach not only for obtaining the solubility value for a protein but also for performing further studies to elucidate solubility mechanisms.

Attractive Ionic Interaction Limits rhTFPI Solubility—Proteins with poor aqueous solubility are often considered to be "hydrophobic".[9] We have reason to believe that the insolubility of rhTFPI's may originate from attractive electrostatic interaction between the termini of the protein. The rhTFPI molecule consists of a single polypeptide chain of 277 amino acid residues. It has a total of 11 aspartate, 25 glutamate, 17 arginine, and 25 lysine residues. (The histidine residue is not included because the pK_a of its side chain is close to neutral pH, making its protonation state difficult to predict.) These ionizable residues in the protein are randomly distributed within the polypeptide structure, including the three Kunitz domains, except at the two termini where they are present in clusters (Figure 1). The N-terminus contains 3 aspartate and 5 glutamate residues that are located between residues 2 to 16. Similarly, 10 lysine, 4 arginine, and 2 glutamate residues are located between residues 240 to 275 at the C-terminus. At neutral pH, the N-terminus (containing 8 negatively charged residues) behaves as an anionic polymer and the C-terminus (containing 14 positively charged residues) behaves as a cationic polymer. Such uneven charge distribution may result in a large dipole moment on the protein molecule. Thus, electrostatic attractive forces between the two termini and dipole−dipole interaction between two protein molecules may cause both intra- or intermolecular interactions, resulting in reduction of protein solubility.[19]

The hypothesis that insolubility of rhTFPI is attributable to the electrostatic interaction of its two charged termini is supported by the following facts: (1) The rhTFPI pH−solubility curve shows an unusually broad solubility minimum trough around neutral pH (Figure 3). This trough is probably caused by the strong ionic interaction of positively charged lysine and arginine residues with negatively charged aspartate and glutamate residues. In the trough

pH region, these residues are all strongly charged. (2) The C-terminal truncation analogues of rhTFPI exhibit a much greater aqueous solubility than the full-length rhTFPI. For example, an analogue containing the N-terminus and the first two Kunitz domains (analogue 1−160) and missing the positively charged C-terminus, has an aqueous solubility >15 mg/mL (Gustafson, M. E., personal communication). This solubility is almost 2 orders of magnitude higher than the submilligram solubility of the full-length protein. (3) Both cationic (e.g., poly-L-arginine) and anionic polymers (e.g., dextran sulfate, poly-L-glutamate, and poly(acrylic acid)) have remarkable solubilizing effects on rhTFPI. Presumably, ionic polymers can bind to the termini clustered with oppositely charged residues. Such binding shields charges on one terminus, preventing it from interacting with the other terminus. (4) Compounds likely to affect hydrophobic properties of proteins have no effect on rhTFPI solubility. For instance, hydrophobic and neutral amino acids have little effect on rhTFPI solubility (Figure 2). In addition, polysorbate surfactants and poly(ethylene glycol) also did not enhance the protein solubility. Therefore, it is unlikely that hydrophobic interactions play a critical role in rhTFPI insolubility. (5) The solubility of rhTFPI shows a negative temperature coefficient. Because most of the tested conditions are within the salting-in region, where the electrostatic interaction dominates the solubility, the negative temperature effect is probably due to the decreased dielectric constant instead of the increase in the hydrophobic interaction at high temperatures. Decrease in dielectric constant strengthens the electrostatic interaction between the protein termini, thus reducing the solubility. Taken together, these observations strongly suggest that poor aqueous solubility of rhTFPI is a result of ionic interaction of the two charged termini.

Unbalanced Charge Distribution on the Two Termini Shifts the Solubility Minimum Away from the p*I*—Many proteins show an inverted bell-shaped pH−solubility curve with a solubility minimum at or close to the isoelectric point.[20,21] The net zero charge on the protein surface at its p*I* decreases the repulsive forces between protein molecules and makes the protein prone to precipitation. Solubility rises as net charge increases at lower pH due to the protonation of negatively charged residues, and at higher pH, because of deprotonation of positively charged residues. The p*I* of rhTFPI is 9.2 and its solubility minimum is centered around pH 7. The considerable deviation of the solubility minimum from its p*I* may be attributed to the nature of the charge distribution on the polypeptide chain. As already mentioned, the N-terminus contains 8 negatively charged residues and the C-terminus contains 14 positively charged residues. Because the number of positively charged residues on the C-terminus is greater than the number of negatively charged residues on the N-terminus, the interaction between the two termini may not reach a maximum at its p*I* but at neutral pH where all the anionic and cationic residues are fully charged. Therefore, the minimum solubility of rhTFPI is shifted to the neutral pH region.

Salting-In, Salting-Out, and the Third Solubility Phase at Low Ionic Strength—When salt is gradually added to a protein solution, the solubility of the protein usually exhibits two macroscopic processes. First, protein solubility increases, reaching a maximum when the salt concentration produces low to moderate ionic strength conditions. Then, protein solubility decreases as the salt concentration further increases the ionic strength of the solution. These two macroscopic processes are known as "salting-in" and "salting-out" effects. The salting-in effect can be readily explained using the Debye−Hückel screening through nonspecific electrostatic interactions between a charged protein macro-ion and surrounding small ions.[20,22] This theory assumes protein molecules are approximately spherical macro-ions with uniformly distributed charges. Interaction with small counterions stabilizes protein macro-ions and decreases their activity coefficients, resulting in an increase in solubility. At low ionic strengths where the salting-in effect predominates, protein solubility is usually a function of the ionic strength and independent of the ion type.

At higher concentrations of salt, the solute molecules compete with protein molecules for water molecules to attain hydration. An increase in salt concentration promotes hydrophobic interactions between protein molecules, decreasing protein solubility. In contrast to the salting-in effect, protein salting-out depends strongly on the ion type. The effectiveness of a salt for this phenomenon follows the lyotropic or Hofmeister series.[23]

At pH 5, in addition to the expected salting-in and salting-out, a new phase was observed for rhTFPI at low ionic strength conditions (5 to 50 mM). Addition of salt resulted in an effect opposite to the salting-in effect, as protein solubility decreased with increase in salt concentration. The origin of this phase is not clear to the authors at the present time. However, we speculate that increased electrostatic repulsive forces between protein molecules at low ionic strength may increase its solubility. At pH 5, positively charged residues, such as arginine and lysine, are fully charged, whereas negatively charged residues, such as glutamate and aspartate, are only partially charged. Under low ionic strength conditions, an overwhelming population of positively charged residues on rhTFPI may yield a repulsive force strong enough to prevent it from precipitating. The addition of salt to such a solution would increase the dielectric constant of the solution, resulting in a weakening of the electrostatic interactions, thus decreasing solubility.

In addition to the third phase observed at the low ionic strength conditions at pH 5, we also noticed that rhTFPI solubility became somewhat pH independent around an ionic strength of 0.25 M under the tested pH range. Further work is needed to explore this effect.

The salting-in effect explains quite well the solubility effectiveness of the salts we examined in Figure 2. Compared with the relatively poor solubilizing salts NaCl and KCl, the good solubilizing salts $MgCl_2$, Na_2SO_4, $(NH_4)_2SO_4$, and $MgSO_4$ all affect the ionic strength to a much greater extent and are, therefore, believed to be more effective in solubilizing rhTFPI. In contrast, the polyelectrolytes showing good solubilizing effect on rhTFPI act by binding to the basic C-terminus or the acidic N-terminus but not by merely increasing the ionic strength. For example, 0.75 mM poly-L-arginine (MW 11 800 daltons) and 1 mM poly-L-glutamate (MW 1000 daltons) both solubilized rhTFPI to the same extent (Figure 2) despite having widely different effects on the solution ionic strength because of the approximately 10-fold variance in the number of charges they are carrying.

Insolubility Precipitates and Instability Precipitates—As shown in Table 2, rhTFPI insolubility precipitate can be redissolved in media containing sodium citrate, arginine, or low concentrations of urea. These media do not denature the protein and are good solubilizers for native rhTFPI. This result indicates that the interactions responsible for formation of insolubility precipitates are weak and probably nativelike. Therefore, insolubility precipitates are most likely formed from native rhTFPI molecules. The following reaction scheme is indicated:

$$N \leftrightarrow \text{Insolubility Precipitates}$$

In contrast, instability precipitates formed as a result of a thermal treatment or on addition of DTT require media with high concentrations (4 M) of urea for resolubilization (Figure 5). The interactions between precipitated protein molecules are strong in these cases and require denaturing conditions to break them down, suggesting that instability precipitates must be formed from denatured (or partially denatured) protein molecules. The reaction scheme can be described as follows:

$$N \leftrightarrow U \rightarrow \text{Instability Precipitates}$$

Although it is possible that instability precipitates may be converted from insolubility precipitates as shown in the following mechanism, we do not believe this mechanism fits our data on rhTFPI:

$$N \leftrightarrow \text{Insolubility Precipitates} \rightarrow \text{Instability Precipitates}$$

The small temperature coefficient for rhTFPI solubility is unlikely to limit its solubility at 40 °C to create an insolubility precipitate. Further, addition of 2 M urea failed to recover any instability precipitates for the $t = 3$ days stability sample (Table 3), demonstrating an absence of the insolubility precipitates. Finally, the slow kinetics of rhTFPI degradation at 40 °C also ruled out the possibility of a quick conversion from insolubility precipitates to instability precipitates.

The kinetics of formation of insolubility precipitates differ from those for instability precipitates. The amorphous precipitation caused by protein insolubility is often a much faster event than the aggregation and precipitation resulting from protein instability. In rhTFPI, the insolubility precipitate is formed immediately upon buffer exchange, and the turbidity of the solution develops within minutes. On the other hand, rhTFPI instability precipitates are formed over much longer periods of time (weeks to months at high temperatures). For example, loss of soluble rhTFPI (increase of precipitated protein) at 40 °C was estimated to have a half-life of ~12 days, based on the data in Table 3. The kinetics of formation of an insolubility precipitate often contains a lag phase (nucleation) and a rapid growth phase (polymerization),[10] whereas instability precipitate formation may be governed by its unimolecular unfolding as the rate-limiting step that is then followed by a rapid polymerization process.[24]

Conclusions

In conclusion, our studies to determine the solubility of rhTFPI under various solvent conditions showed that rhTFPI solubility is predominantly affected by the charge distribution on the protein molecule itself as well as on the solvent ions present in the surrounding medium. Considering these interactions, the limited solubility of the protein under physiological conditions could be explained and solutes were identified to enhance rhTFPI solubility in aqueous media. Detailed examinations of protein−salt interactions have revealed a third solubilizing phase for rhTFPI at pH 5 under low ionic strength condition that is different from the normal salting-in and salting-out phases of the protein. Finally, by comparing the dissolving power of nondenaturing and denaturing solvent conditions, we have shown that rhTFPI precipitates formed due to the limited protein solubility are different from those resulting from protein instability. Whereas insolubility precipitates can be resolubilized by nondenaturing solvent conditions, such as citrate, arginine, and low concentrations of urea, strong denaturing conditions, such as >4 M concentrations of urea, are required for resolubilization of instability precipitates. These observations are expected to be useful in designing purification processes and formulations needing high aqueous solubility of rhTFPI for further development of the molecule as a therapeutic agent.

Acknowledgments

We appreciate Dr. David Reifsnyder for providing the drawing for Figure 1 and Dr. Heatherbell Fong for excellent text editing of the manuscript.

Abstract □ Inclusion complexes between β-cyclodextrin derivatives and 1,2-dithione-3-thiones were studied in aqueous solution and in the solid state. Phase solubility study was used to evaluate the complexation in solution, at 37 °C, of three cyclodextrins, i.e., β-cyclodextrin (βCD), hydroxypropyl-β-cyclodextrin (HPβCD), sulfobutyl ether-7-β-cyclodextrin (SBE7βCD), and four 1,2-dithiole-3-thiones, i.e., the parent compound dithiolethione (DTT), dimethyldithiolethione (DMDTT), 5-phenyldithiolethione (5PDTT), and anetholetrithione (ATT). Stability constants of the DTT complexes with HPβCD and SBE7βCD were also determined spectrophotometrically using a nonlinear least-squares methodology. Differential scanning calorimetry (DSC) and scanning electronic microscopy (SEM) were used to characterize spray-dried complexes formed between 5PDTT and SBE7βCD, ATT and SBE7βCD. Dissolution studies using the USP paddle method were carried out in water at 37 °C for both ATT and 5PDTT binary systems with HPβCD and SBE7βCD. Solubility enhancements were much greater with the more lipophilic ATT and 5PDTT compared to DTT and DMDTT, whatever the cyclodextrin used, in the rank order SBE7βCD > HPβCD ≫ βCD. Stability constants obtained (between 120 and 12800 mol^{-1}) were also the highest for the more lipophilic drugs and in the same rank order SBE7βCD > HPβCD ≫ βCD. Results obtained by UV spectrophotometry were in good agreement with those obtained by phase-solubility study. DSC thermograms of spray-dried complexes of ATT and 5PDTT with HPβCD and SBE7βCD lacked the endothermal peak of pure drug peak which was found for the physical mixtures (107 °C and 125 °C for ATT and 5PDTT, respectively). Finally, dissolution profiles of spray-dried inclusion complexes studied displayed a faster dissolution rate compared to physical mixtures and pure drugs. The present study showed that complexation of 1,2-dithiole-3-thiones with β-cyclodextrin derivatives resulted in an increase in solubility, allowing intravenous formulation for bioavailability and metabolism studies and an increase in the dissolution rate of the drugs, which shoud be of interest for oral absorption of these lipophilic compounds.

Introduction

1,2-Dithiole-3-thiones are sulfur heterocyclic compounds naturally found in cruciferous vegetables.[1] Among these compounds of pharmaceutical interest, anetholetrithione (ATT) has been marketed since 1947[2] and is prescribed for its choleretic and sialagogue properties. In the last 15 years, it has been shown that these molecules were able to inhibit carcinogenesis by increasing the activity of electrophile detoxification enzymes (phase II enzymes conjugating with carcinogens favoring their elimination)[3] and by increasing intracellular glutathione levels (increasing protection against free radicals, oxidants...). For that reason the pharmaceutical interest of 1,2-dithiole-3-thiones is growing since they may be useful for cancer chemoprevention in humans.[4−6] An oral formulation allowing a chronic administration of these compounds would be highly desirable.

Since 1,2-dithiole-3-thiones are highly lipophilic compounds,[7−8] and since too high a lipophilicity can result in low permeability,[9] there is a need from a biopharmaceutical standpoint to increase the poor aqueous solubility of these nonionizable molecules (around 0.001 mg/mL) in order to circumvent the low and highly variable absorption generally seen with such products.[10] To reach that goal, we used cyclodextrins, since preliminary solubilization studies with cosolvents such as DMSO or PEG resulted in drug precipitation upon dilution. The β-cyclodextrins (βCD) are α-1,4-linked cyclic oligosaccharides composed of seven D-glucopyranose units with a relatively hydrophobic central cavity and an hydrophilic outer surface.[11] These products are able to entrap poorly soluble drug molecules of appropriate size and polarity in their cavities to form reversible noncovalent inclusion complexes. This may improve physical and chemical properties of the incorporated guest molecule allowing, for example, the improvement of stability, solubility,[12] in vivo drug delivery, and bioavailability.[13−14] βCD has been studied extensively despite a very low aqueous solubility but some derivatives such as 2-hydroxypropyl-β-cyclodextrin (HPβCD) and more recently an anionically charged derivative with an average degree of substitution of 7, sulfobutyl ether-7-β-cyclodextrin (SBE7βCD) have attracted growing interest due to their greater intrinsic solubilities allowing improved complexing abilities.[12,15] SBE7βCD and HPβCD appear to be parenterally safer materials, compared to the parent β-cyclodextrin.[16]

The objectives of this work were (i) to examine the potential of βCD, HPβCD, and SBE7βCD as solubilizing agents for four 1,2-dithione-3-thiones, the parent compound dithiolethione (DTT), dimethyldithiolethione (DMDTT), 5-phenyldithiolethione (5PDTT), and anetholetrithione (ATT), using the phase-solubility technique and UV−visible spectrophotometry, (ii) to characterize the complexes formed by differential scanning calorimetry (DSC) and by scanning electronic microscopy (SEM), and (iii) to evaluate the rate of drug dissolution when complexed or not with cyclodextrins according to the USP paddle method.

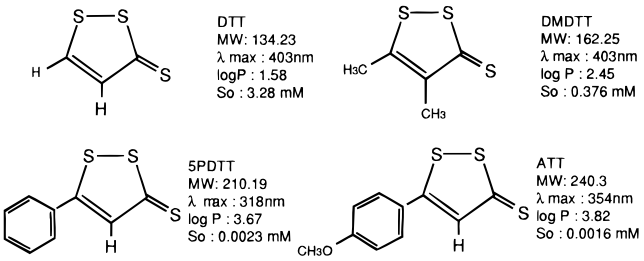

Figure 1—Chemical structures of 1,2-dithiole-3-thiones studied, their molecular weights (MW), λ_{max}, log *P*, and intrinsic water solubility (S_0) values.

Experimental Section

Materials—βCD (KLEPTOSE, MW = 1135 g/mol) and HPβCD (ref 615446, D. S. (degree of substitution) = 5.88; MW = 1476 g/mole) were kindly provided by Roquette (Lestrem, France) and SBE7βCD (CAPTISOL, cat. ref no. 7585−39−9; D. S. = 6.4; MW = 2163 g/mole) by CyDex (Overland Park, KS).

All 1,2-dithiole-3-thiones studied (Figure 1) were synthesized by our team, except that ATT was supplied by Solvay Pharma (Laboratoire de Thérapeutique Moderne, Suresnes, France).

All other reagents and solvents (E. Merck, Darmstadt, Germany) were of analytical grade, and freshly prepared distilled water was used throughout the study.

Phase-Solubility Study—Solubility measurements were determined according to the method of Higuchi and Connors.[17] Excess amounts of 1,2 dithiole-3-thione (10 mg) were weighted into 1 mL screw-cap polypropylene tubes to which were added aqueous solutions containing increasing concentrations of CDs, ranging from 0% to 10% (w/v) for HPβCD and SBE7βCD, 0% to 2% (w/v) for βCD. The suspensions formed were then rotated on a top to bottom shaker, thermostatically controlled at 37 ± 0.1 °C. After one week of agitation (equilibrium and absence of drug degradation were confirmed in preliminary studies), the suspensions were centrifugated (20000*g* for 10 min) and appropriately diluted with the mobile phase, and the total concentration of 1,2-dithiole-3-thione in the filtrate was analyzed by a reversed phase HPLC system according to Lefeuvre et al.[18] It consisted of a Waters Model 6000A pump (Waters Assoc., Milford, MA) equipped with a Waters Model WISP 710 B automatic injector, an LDC Milton Roy Model Spectromonitor 3100 variable-wavelength UV detector (LDC Milton Roy, Riviera Beach, FL), and a Delsi Model Enica 21 integrator (Delsi, Suresnes, France). The analytical chromatography column was a Lichrospher RP−SelectB (Interchim, Montluçon, France) (125 × 3 mm i.d.; particle size 5 μm). The chromatographic conditions were as follows: injection volume, 20 μL; column temperature, 30 °C; mobile phase, mixture of acetonitrile and water (50:50, v/v); flow rate, 0.5 mL/min; detector operated at 318 and 354 nm for 5PDTT and ATT, respectively.

The experiment was carried out in triplicate, and the stability constant of each drug-cyclodextrin system (K_s) was then calculated from the linear portion of the phase solubility diagrams (reporting drug concentration vs cyclodextrin concentration), assuming that a 1:1 stoichiometric ratio complex was formed at the initial step (slope smaller than 1) according to eq 1.[17]

$$K_s = \text{slope}/s_o(1 - \text{slope}) \quad (1)$$

where s_o is the drug solubility in water.

UV−Visible Spectrophotometry—The determination of the stability constants (K_s) of the parent compound DTT with the cyclodextrins HPβCD and SBE7βCD was also realized in solution by UV−visible spectrophotometry ultraviolet (UV) absorption changes of DTT (5×10^{-5} M) in the presence of aqueous solutions of HPβCD or SBE7βCD (various concentrations of 5×10^{-5} M, 10^{-4} M, 2.5×10^{-4} M, 5×10^{-4} M, 10^{-3} M, 2.5×10^{-3} M, 5×10^{-3} M, 10^{-2} M, 2.5×10^{-2} M and 5×10^{-2} M) were recorded from 200 to 500 nm with a Uvikon model 922 UV−visible spectrophotometer (Bio-Tek Kontron instruments, Saint Quentin en Yvelines, France). Absorbance data were treated by a nonlinear least-squares methodology. The stability constants were obtained together with the molar absorptivity coefficient of the DTT−CD complex studied which could not be experimentally determined since the complex could not stand alone in solution owing to the dilution effects. The mathematical model allowing the calculation of absorbances to be compared to the experimental ones according to the nonlinear least-squares methodology, issued from the basic equations:

$$K_s = [\text{DTT−CD}]/[\text{DTT}][\text{CD}] \quad (2)$$

$$[\text{DTT}] + [\text{DTT−CD}] = c_2 \quad (3)$$

$$[\text{CD}] + [\text{DTT−CD}] = c_3 \quad (4)$$

where [DTT], [CD], [DTT−CD] are free equilibrium concentrations of DTT, CD, and complex, respectively; c_2 and c_3 are the analytical concentrations of DTT and cyclodextrin, respectively. The above system of three equations reduced to the second-order equation in [DTT-CD]:

$$K_s[\text{DTT−CD}]^2 - [K_s(c_2 + c_3) + 1][\text{DTT−CD}] + K_s c_2 c_3 = 0 \quad (5)$$

The absorbances were calculated for each of the relative concentrations used according to the Beer−Lambert Law:

$$A^{\text{calc}} = \epsilon_{\text{DTT}}[c_2 - (\text{DTT−CD})] + \epsilon_{\text{DTT−CD}}[\text{DTT−CD}] \quad (6)$$

where ϵ_{DTT} and $\epsilon_{\text{DTT−CD}}$ are the molar extinction coefficients of the pure drug and from the complex, respectively. The minimization of the least-squares function $U = \sum(A^{\text{calc}} - A^{\text{exp}})^2$, calculated over the 10 concentration ratios mentioned above, was achieved by an algorithm developed in our department.[19,20]

Preparation of Solid Complexes—Solid complexes of 1,2-dithiole-3-thiones and cyclodextrins were obtained by spray-drying of stoechiometric amounts of drug (ATT or 5PDTT) and cyclodextrin (HPβCD or SBE7βCD) (1:1 or 1:2 drug−cyclodextrin mole ratio). A solution containing the drug (500 mg in 500 mL 95% ethanol) to which was added 250 mL of an aqueous solution of the cyclodextrin was spray-dried in a Büchi Mini Spray-drier B-191 apparatus (Büchi, Switzerland) under the following conditions: flow rate of the solution, 10 mL/min; drying air flow rate, 600 L/h; air inlet temperature, 100 °C; air outlet temperature, 65 °C; aspirator capacity, 35 m^3/h. The yield of the spray-drying process was about 60% in the receiving vessel.

Physical mixtures of 1,2-dithiole-3-thione−cyclodextrin systems were prepared by gently mixing the drug and the cyclodextrin in a mortar, in the same 1:1 or 1:2 molar ratio.

Particle Size Measurements—Size distribution of pure materials, physical mixtures, and spray-dried products was determined by laser diffractometry using a Mastersizer S (Malvern Instruments, Orsay, France) particle size analyzer. All results were expressed as the median volumetric diameter *d*(v,0.5) which is the diameter that divides the volume distribution curve of the sample analyzed in two equal parts.

Differential Scanning Calorimetry—DSC was used to characterize the interactions between both lipophilic 1,2-dithiole-3-thiones, 5PDTT and ATT, with SBE7βCD. The calorimetric measurements of raw materials as well as 1:1 physical mixtures and 1:1 and 1:2 spray-dried complexes were performed with a Perkin-Elmer DSC-7 differential scanning microcalorimeter (Perkin-Elmer, Norwalk, CT) connected to a DEC 425 calculator. The measurement head was flushed with pure nitrogen gas, and its temperature was stabilized by circulating cold water−ethanol from a thermostatic bath controlled at 7 ± 0.1 °C. Temperatures were calibrated using the melting points of *p*-nitrotoluene (99.99%, mp = 51.5 °C, Carlo Erba, Milan, Italy) and indium (99.99%, mp = 156.6 °C, Perkin-Elmer, Norwalk, CT). Energy was calibrated from the melting enthalpy of indium (28.45 J/g). Samples weighting from 0.1 to 0.2 mg (for pure compounds 5PDTT and ATT allowing precise determination of the fusion point) to 10−20 mg (for physical mixtures and spray-dried complexes with SBE7βCD) were carefully encapsulated in aluminum pans with a crimped cap into which was made a needle hole, allowing water evaporation. Only heat flow measurements were made on all samples at a scanning heating rate of 10 °C/min in the 85−130 °C temperature range.

Scanning Electronic Microscopy—Morphological features of the raw materials were compared with a 1:1 physical mixture and 1:1 and 1:2 spray-dried complexes for the binary system (ATT, SBE7βCD), after examination by SEM (JEOL model JSM-6400, Tokyo, Japan). The samples were fixed on a brass stub using

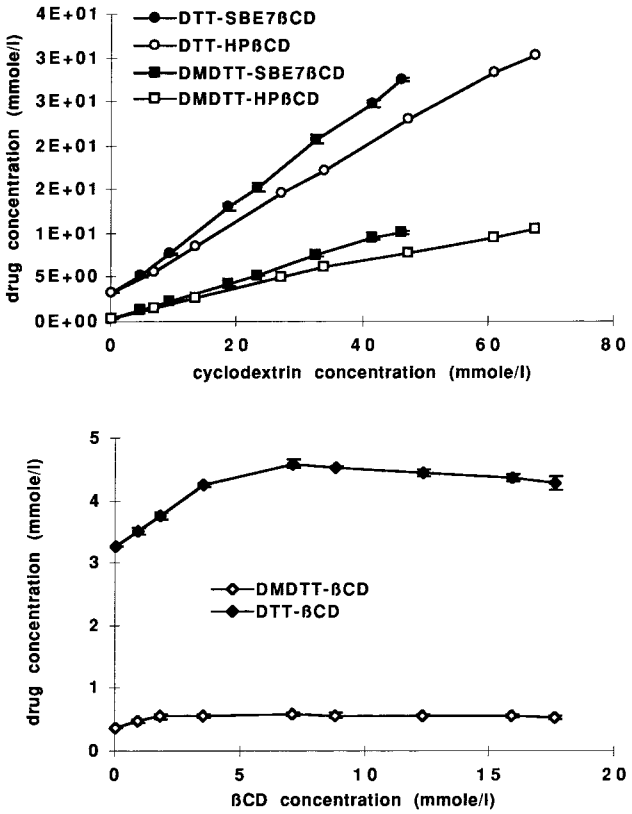

Figure 3—Phase-solubility diagrams of DTT– and DMDTT–cyclodextrin systems. Top: SBE7βCD and HPβCD; bottom: βCD. Each point is the mean (±SD) of three determinations.

double-sided tape and then made electrically conductive by coating in a vacuum with a thin layer of gold/palladium.

Dissolution Study—USP XX Type 2 apparatus (rotating paddle method) was employed to obtain all the dissolution profiles of pure drugs, 1:1 and 1:2 physical mixtures, and spray-dried complexes of ATT and 5PDTT with HPβCD and SBE7βCD. Due to the poor aqueous solubility of these nonionizable compounds, sink conditions (less than 20% of saturation concentration) could not be maintained during the tests. Each powdered sample contained 5 mg of 1,2-dithiole-3-thione. The dissolution medium consisted of 1000 mL of distilled water thermostated at 37 ± 0.1 °C, and the paddle speed was 100 rpm. Concentration of dissolved drug was measured continuously (every 15 min for drugs and physical mixtures, every 30 s for complexes at a wavelength of 318 and 354 nm for 5PDTT and ATT, respectively) using a UV spectrophotometer (Spectronic 1201 Milton, LDC Milton Roy, Riviera Beach, FL). Each experiment was carried out in triplicate.

Results and Discussion

Phase-Solubility Analysis—Phase-solubility diagrams for ATT and 5PDTT, DTT and DMDTT are shown in Figure 2 and Figure 3, respectively. Data obtained from these diagrams are presented in Table 1. Phase solubility diagrams obtained with HPβCD and SBE7βCD showed a linear relationship between the amount of 1,2-dithiole-3-thione solubilized and the concentration of cyclodextrin in solution (*Al* type diagram) for less lipophilic drugs DTT and DMDTT (log P = 1.59 and 2.45, respectively) (Figure 3). According to Higuchi and Connors theory,[17] this may be ascribed to the formation of soluble 1:1 (1,2-dithiole-3-thione–cyclodextrin) inclusion complexes. For more lipophlilic ATT and 5PDTT (log P = 3.82 and 3.67, respectively), the diagrams were of the *Ap* type (Figure 2), the positive curvatures indicating the existence of soluble complexes with an order greater than 1 in cyclodextrin. βCD, however, exhibited *Al* type diagrams according to Higuchi and Connors classification only with the more lipophilic ATT, while *Bs* type diagrams were observed with DTT, DMDTT, and 5PDTT, with an initial rising portion followed by a plateau and/or a very slight decrease in total drug concentration in the filtrate due to solid complex precipitation.

Table 1: Data Obtained from the Phase-Solubility Analysis for Each (1,2-dithiole-3-thione–cyclodextrin) Binary System: Type and Slope of the Diagrams, Apparent Stability Constant (K_s), and Solubility Increase with 2% βCD, 10% HPβCD, and 10% SBE7βCD

1,2-dithiole-3-thione	cyclodextrin	type of curve	slope of curve	stability constant[a] (M^{-1})	solubility increase[a]
ATT	βCD	Al	0.004	2841	41.3

	HPβCD	Al	0.424	225	9.2
	SBE7βCD	Al	0.544	364	8.4

[a] Mean of three determinations.

Solubility enhancements obtained with the three cyclodextrin solutions, i.e. βCD (2% w/v), HPβCD (10% w/v), and SBE7βCD (10% w/v), were much greater with the more lipophilic 1,2-dithiole-3-thiones than with less lipophilic drugs, in the rank order SBE7βCD > HPβCD ≫ βCD (Table 1). The values obtained were near 480 times the intrinsic solubility for 5PDTT (which is 0.0023 mmol/L or 0.48 mg/L) and near 580 times the intrinsic solubility for ATT (0.0016 mmol/L or 0.39 mg/L) while they only reached 9 times the intrinsic solubility for DTT (3.28 mmol/L or 441 mg/L) and 28 times the intrinsic solubility for DMDTT

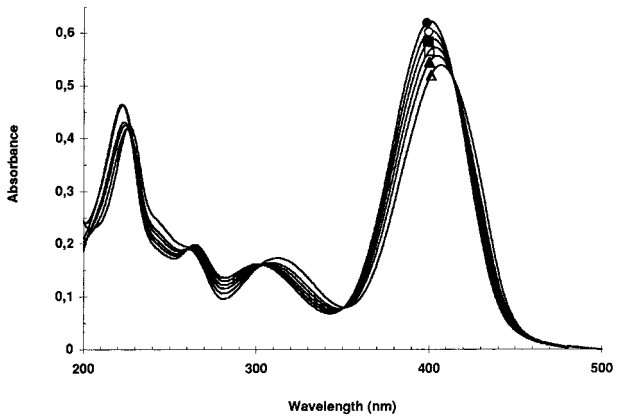

Figure 4—Effect of different concentrations of HPβCD (●: 0 mM; ○: 2.5×10^{-4} mM; ■: 10^{-3} mM; □: 5×10^{-3} mM; ▲: 10^{-2} mM; Δ: 5×10^{-2} mM) on the UV spectrum of DTT (5×10^{-2} mM).

Table 2: Data Obtained from UV Spectroscopy Study of the Complexation between DTT and the Cyclodextrins HPβCD and SBE7βCD: Stability Constants (K_s), Calculated (calcd) and Experimental (exp) Molar Absorptivities of Free (ϵ_{DTT}) and complexed (ϵ_{DTT-CD}) DTT

	K_s (M^{-1})	$(\epsilon_{DTT})^{calc}$ ($cm^{-1}\,M^{-1}$)	$(\epsilon_{DTT})^{exp}$ ($cm^{-1}\,M^{-1}$)	$(\epsilon_{DTT-CD})^{calc}$ ($cm^{-1}\,M^{-1}$)
DTT-HPβCD	178	12441	12458	9982
DTT-SBE7βCD	184	12376	12350	9831

(0.376 mmol/L or 61 mg/L). Apparent 1:1 stability constants (K_s) were obtained from the slopes of the linear portion of each diagram (slopes always lower than 1); the values, ranging from 119 to 12834 mol^{-1}, were also the highest for the more lipophilic drugs (exhibiting *Ap* type diagrams), in the same rank order SBE7βCD > HPβCD ≫ βCD (Table 1). Such results, showing the highest complexing ability of the SBE7βCD compared to HPβCD were also reported by Okimoto et al.[21] for binding constants of several neutral (uncharged) drugs with SBE7βCD and HPβCD, when studing the effect of charge on complexation.

UV−Visible Spectrophotometry—The stability constants (K_s) between the parent compound (DTT) and the cyclodextrins HPβCD and SBE7βCD could also be determined by UV−visible spectrophotometry taking into account the fact that the complex formation gave a bathochromic shift of the maximum located near 403 nm. Figure 4 shows the effect of different concentrations of HPβCD on the UV spectrum of DTT, for example; only 6 of 11 spectra are shown for clarity. The absorption maximum at 403 nm was shifted to higher wavelength with a concomitant decrease in the molar extinction coefficient (Table 2). The complexation of DTT with both cyclodextrins may be related to the high electron density inside the CD cavity on one hand,[22] and to the positive charge of the DTT

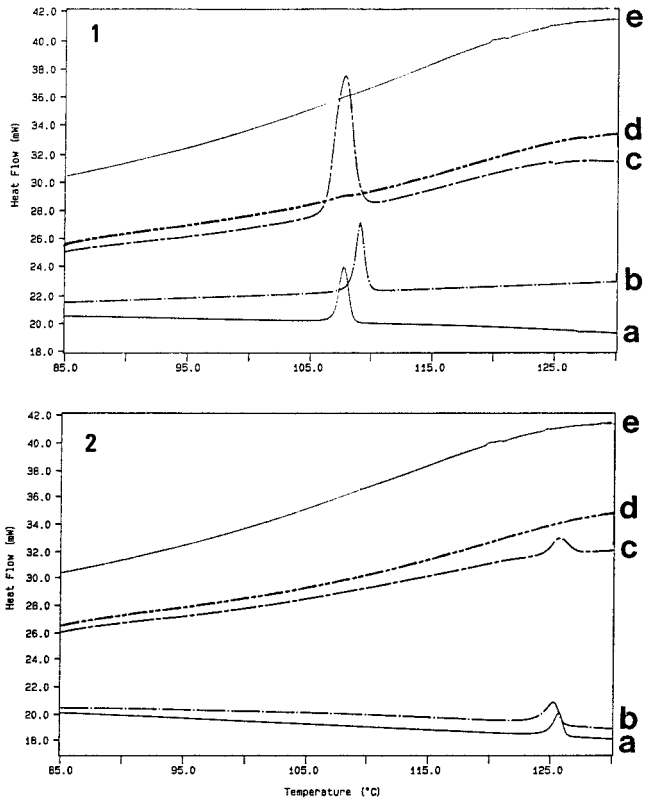

Figure 5—DSC thermograms of (1,2-dithiole-3-thiones, SBE7βCD) binary systems: Figure 5.1 (ATT,SBE7βCD) and Figure 5.2 (5PDTT,SBE7βCD). (a) 1:1 physical mixture (drug + SBE7βCD); (b) drug alone; (c) spray-dried complex obtained with a 1:1 initial mole ratio (drug–SBE7βCD); (d) spray-dried complex obtained with a 1:2 initial molar ratio (drug–SBE7βCD); (e) SBE7βCD alone.

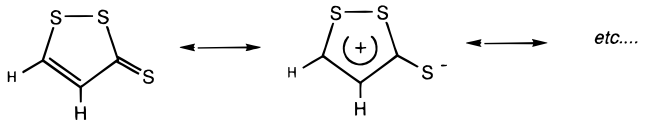
nucleus on the other hand. Indeed, a lot of chemical and physical data indicate that the structure of 1,2-dithiole-3-thiones must be considered to be an hybrid resonance according to the following scheme:[23]



where the two mentioned structures have approximatively the same weight. The partially positive charge brought by the DTT nucleus may explain also on an electrostatic ground, the systematically enhanced stability for the complexes formed with the anionic SBE7βCD compared to those formed with neutral HPβCD, in agreement with Okimoto et al.,[21] i.e., a driving force for complexation being a combination of Coulombic and hydrophobic forces with regard to the binding of charged drugs to

Table 3: Data Obtained from DCS (sample weight, endothermic peak onset, ΔH, complexation efficiency) and Drug Content Determined by HPLC for 1:1 Physical Mixtures (1:1 PM), 1:1 Mole Ratio Spray-Dried Products (1:1 SD), and 1:2 Mole Ratio Spray-Dried Products (1:2 SD) for Each (1,2-dithiole-3-thione, cyclodextrin) Binary System Studied

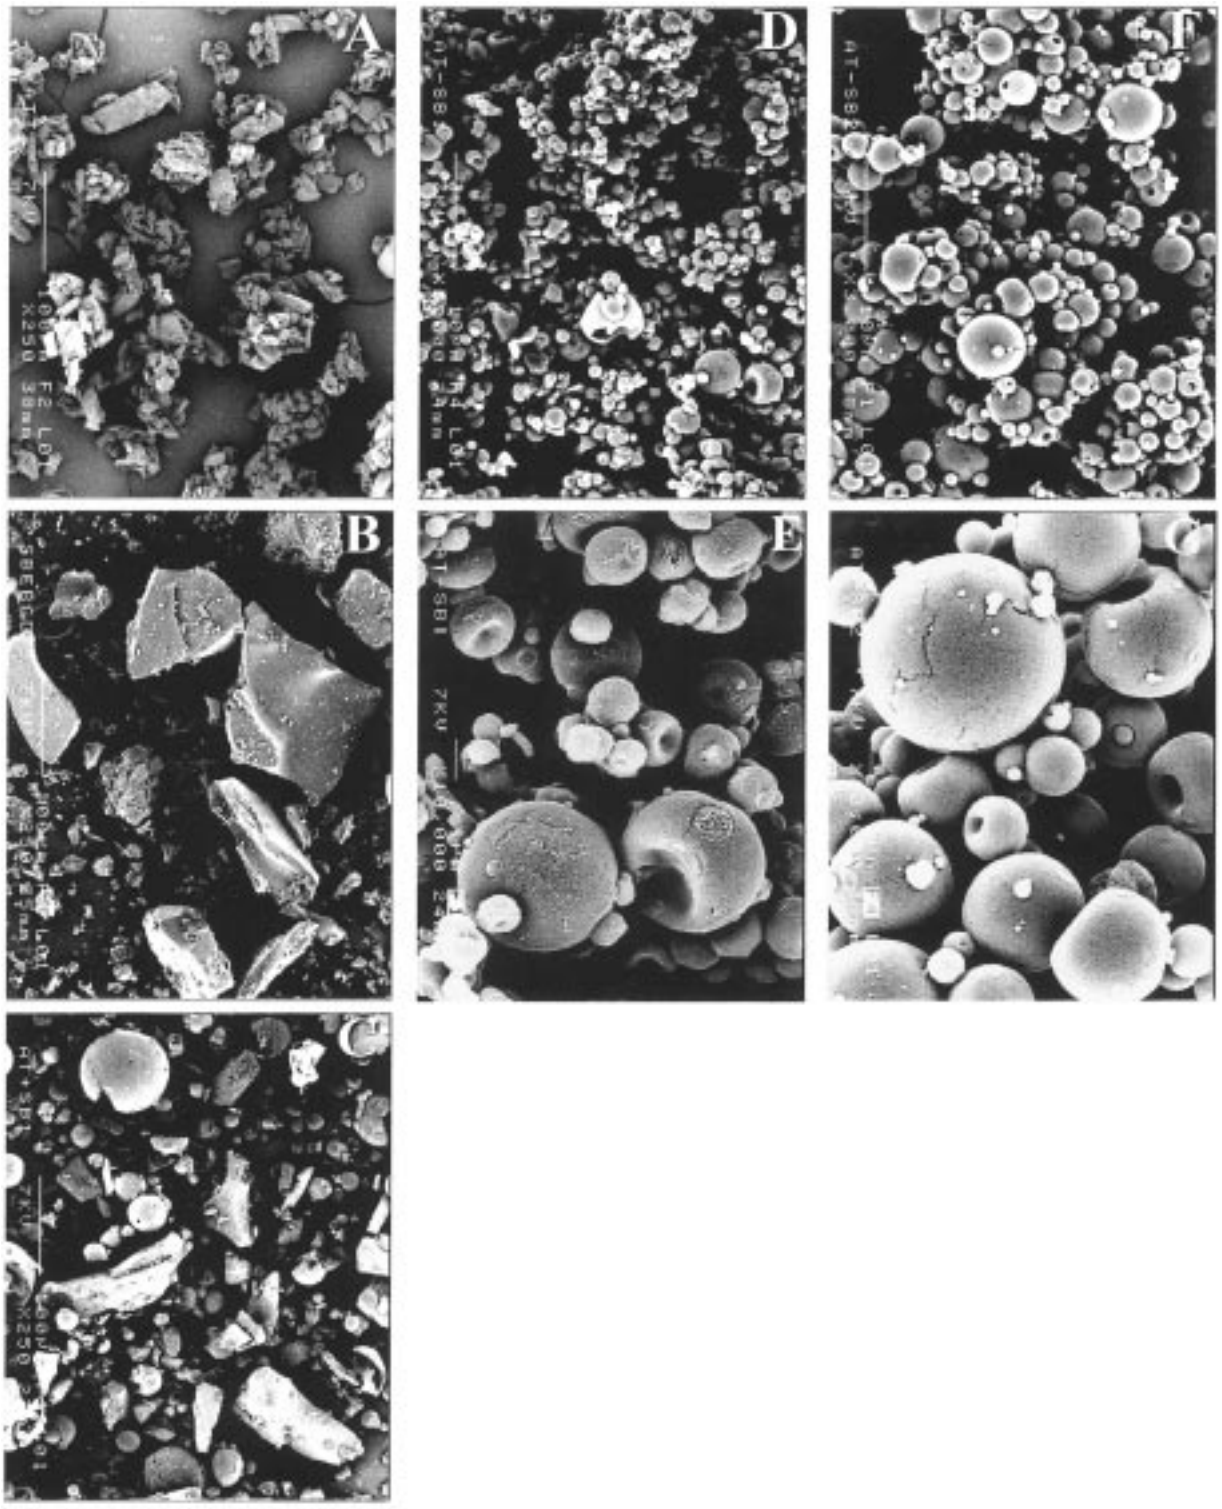

Figure 6—SEM micrographs of of binary system (ATT–SBE7βCD): (A) ATT alone; (B) SBE7βCD alone; (C): 1:1 physical mixture (ATT + SBE7βCD); (D and E) ATT–SBE7βCD spray-dried complex complex obtained with a 1:1 initial molar ratio (ATT–SBE7βCD1), × 3000 and × 10000, respectively; (F and G) ATT–SBE7βCD spray-dried complex complex obtained with a 1:2 initial molar ratio (ATT–SBE7βCD2), × 3000 and × 10000, respectively.

charged cyclodextrins. The occurrence of five isosbestic points at 227, 260, 303, 352, and 414 nm warranted the existence of only one equilibrium between the three species, i.e., the free DTT, the complexed DTT, and the cyclodextrin. This suggests that the model chosen (1:1 complexation) is appropriate and agrees well with the *Al*-type phase-solubility diagrams obtained with both cyclodextrins. Stability constants were extracted from the absorbance data obtained with the different relative concentrations of cyclodextrins and DTT, by a nonlinear least-squares methodology (see Experimental Section). Care was taken to ensure that equilibria were reached before determination of the absorbances. Results, which are given in Table 2, are in satisfactory agreement with those obtained by phase-solubility measurements (Table 1). It is interesting to note that another treatment of the experimental data performed by considering also the molar absorptivity coefficient of the pure DTT as unknown gave the same value for that

grandeur than that determined experimentally (Table 2). This is a strong argument to validate the accuracy of both the chemical model, i.e., the model with one equilibrium, and the experimental data.

Differential Scanning Calorimetry—DSC revealed some information on solid-state interactions between both 1,2-dithiole-3-thiones ATT and 5PDTT and cyclodextrin SBE7βCD. DSC thermograms are presented in Figure 5.1 and 5.2. Table 3 sums up all the data obtained from DSC. The DSC scan of SBE7βCD showed a typical broad endothermic peak between 85 and 150 °C (only the range 85−130 °C is shown) corresponding to its dehydration. DSC thermograms of pure drugs exhibited a sharp endothermic peak corresponding to their melting point, at 109 °C (ΔH = 101.5 J/g) and 124.8 °C (ΔH = 125 J/g) for ATT and 5PDTT, respectively. Both characteristic peaks (due to cyclodextrin water loss and drug melting) were also clearly visible in the physical mixtures of ATT and 5PDTT with SBE7βCD, even if the melting endotherms were slightly shifted to 107 and 123.8 °C for ATT and 5PDTT, respectively. This may be due to an interaction between the two species occurring during their mixing. From the ΔH values obtained (8.1 and 10.25 J/g for ATT and 5PDTT, respectively) it was easy to obtain the percentage of free drug, from the following equation:

$$\% \text{ free drug} = [\Delta H_{DTT,CD} \times 100]/[\Delta H_{DTT} \times (DC)/100)] \quad (7)$$

where ΔH_{DTT} and $\Delta H_{DTT,CD}$ are the enthalpy values of pure drug and of drug from each system with cyclodextrins (physical mixture or spray-dried complex), respectively, and DC is the drug content (%) of each system. From eq 7, we could estimate that the percentage of complexed drug (100 − % free drug) concerned 20 and 7.45% of the drug present in the mixture, for ATT and 5PDTT, respectively. Concerning the spray-dried products obtained with both drugs, increasing the initial concentration of the complexing agent led to a more complete or a total dissappearance of the drug characteristic melting endotherm and also to a higher complexation efficiency (Table 3 and Figure 5). The endothermic peak of pure 1,2-dithiole-3-thione was found for each 1:1 mole ratio spray-dried product with ΔH values of 3.45 and 0.70 J/g, for ATT and 5PDTT, respectively, indicating the presence of 36.3 and 10.3% free drug, respectively. In fact, only DSC thermograms of 1:2 drug−cyclodextrin mole ratio products lacked the melting peak (corresponding to 98.7 and 100% of complexed drug, for ATT and 5PDTT, respectively). As the disappearance of an endothermic peak may be attributed to an amorphous state and/or to an inclusion complexation,[24] these results suggest that only 1:2 spray-dried products can be considered as true and complete inclusion complexes, differing from simple physical mixtures.

Scanning Electronic Microscopy—From SEM (Figure 6) we can see the particle morphology of pure compounds ATT and SBE7βCD (micrographs A and B, respectively), both irregular three-dimensional particles with parallelogram shape. The physical mixture (micrograph C) showed particles of SBE7βCD embedded with ATT particles and a comparable morphology with pure compounds taken separately, revealing no apparent interaction between both species. In contrast, a drastic change in the morphology and shape of particles was observed in 1:1 (micrographs D and E) and 1:2 (micrographs F and G) spray-dried products, revealing an apparent interaction in the solid state. Spherical microparticles obtained also showed a reduction in size due to the spray-drying process, confirmed by laser diffractometry where the median volume diameters d(v,0.5) obtained, i.e., 39.87 μm, 11.54 μm, and 63.53 μm for SBE7βCD, ATT, and their physical mixture, respectively, decreased to 4.13 μm and 3.85 μm for a 1:1 and 1:2 mole ratio of spray-dried products, respectively.

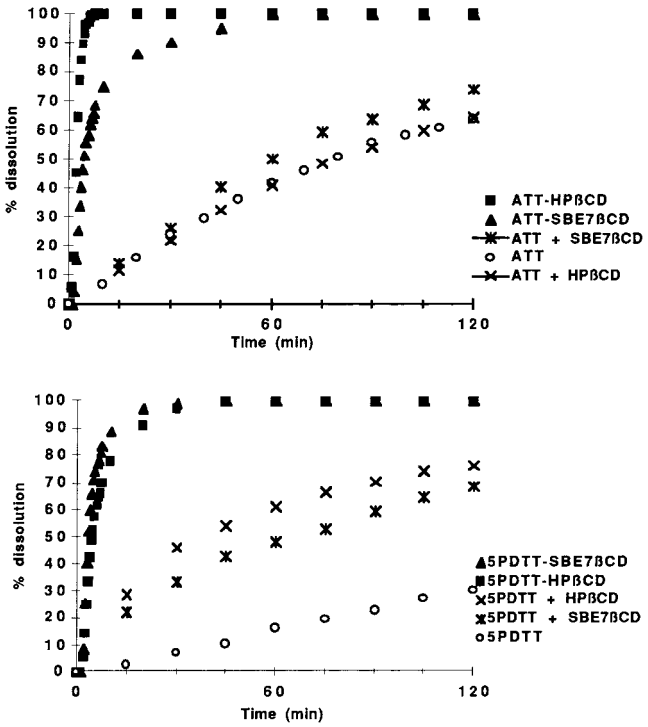

Figure 7—Dissolution rate profiles for ATT (top) and 5PDTT (bottom) systems with SBE7βCD or HPβCD. (○) 1,2-dithiole-3-thione alone; (*) physical mixture with SBE7βCD; (×) physical mixture with HPβCD; (▲) spray-dried complex with SBE7βCD; (■) spray-dried complex with HPβCD.

Dissolution Study—Dissolution profiles of pure ATT and 5PDTT, their 1:1 mole ratio physical mixtures, and spray-dried inclusion complexes with HPβCD and SBE7βCD are presented in Figure 7. From these curves we can see that all binary systems displayed an increase in drug dissolution rate with respect to pure drug. However, the dissolution enhancements of the drugs from the physical mixtures were not as marked, as they were from the spray-dried products (especially for ATT, the more lipophilic drug) and may be explained by mean of greater solubility of the drug in aqueous solution of cyclodextrins because of the hydrophilic environment surrounding the drug in the early stages of dissolution process, resulting in a better wettability of the drug. Concerning the significant enhancement of the dissolution rate that occurred with all spray-dried products, this may be attributed to an increase of solubility upon complexation, to the amorphous state generally occurring during spray-drying (i.e. a decrease in cristallinity), and to the reduction in the particle size resulting in an increase of the surface area of the drug, according to the Noyes−Whitney equation:[25]

$$dC/dt = D/h \times S\,(C_s - C_t) \quad (8)$$

where dC/dt is the dissolution rate, D is the diffusion coefficient of the drug, h is the thickness of the diffusion layer, S is the surface area of the dissolving solid, C_s and C_t are the aqueous solubility and the concentration of the drug in the aqueous medium at time t, respectively.

Conclusion

The present study showed that 1,2-dithiole-3-thiones could form inclusion complexes with β-cyclodextrin deriva-

tives, in solution as well as in the solid state, allowing an increase in solubility, a possible intravenous administration without using cosolvents, and also an increase in the dissolution rate of the drugs. These data shoud be of interest for improving oral absorption of these lipophilic compounds, allowing bioavailability and metabolism studies. An oral formulation allowing a chronic administration of these compounds for cancer chemoprevention is under investigation.

Accepted for publication June 12, 1999.

Abstract □ 1,2-Dioleoyl-*sn*-glycero-3-ethylphosphocholine was prepared in a one-step reaction from phosphatidylcholine by reaction with ethyl trifluoromethanesulfonate. This and related *O*-alkyl phosphatidylcholines constitute the first chemically stable triesters of biological lipid structures and the first cationic derivatives of phospholipids consisting entirely of biological metabolites linked with ester bonds. The complex of cationic phospholipid and plasmid DNA transfected cells with high efficiency. Maximum efficiency of transfection was obtained with complexes in which the positive charge was a few percent in excess over the negative charge. Modest stimulation of transfection of common cell lines was obtained by continuous culture in the presence of 10% serum. Incubation of the phospholipid complex for at least 2 h at 37 °C in nearly pure serum had no deleterious effects on transfection efficiency. The lipid has low toxicity; BHK cells tolerated amounts of 2 mg/2 × 10^6 cells at concentrations of 1 mg/mL. The lipid is biodegradable; it was hydrolyzed by phospholipase A_2 in vitro and was metabolized with a half-life of a few days in cells in culture. The synthetic route to cationic phospholipids is well suited to the preparation of derivatives that are tailor-made to have a wide variety of different properties.

Introduction

Since the demonstration that membrane lipids and other amphipaths of similar structure form closed, membrane-bounded vesicles or liposomes,[1] these structures have been used in many applications.[2] Most recently, dispersions of cationic amphipaths have been used to deliver DNA to cells,[3,4] an application that could become important clinically. Although cationic liposomes were reported to be potential cellular delivery vehicles many years ago,[5−8] it was not until their efficiency in DNA delivery was recognized[9,10] that they have been widely used for that purpose. Cationic lipids are particularly effective in packaging DNA because interactions with the positive surfaces lead to formation of a rather compact particle with a high content of DNA, now frequently termed a "lipoplex".[11] In addition to their uses as DNA delivery agents for gene therapy,[12] cationic lipids may find important applications in the delivery of antisense oligonucleotides.[13] Proteins and small molecules can also be delivered to cells as cationic complexes.[14−17]

The mode of delivery of DNA to the nucleus by cationic lipids remains to be elucidated, although endocytosis is generally accepted as the major route of cellular uptake. For in vitro applications, the cationic lipids are often combined with 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine (DOPE), without which activity is frequently low; however, in vivo[18] or in vitro in the presence of serum,[19] cholesterol is a much more effective helper lipid. The need for DOPE has been rationalized on the basis of the tendency of this lipid to destabilize lamellar phase lipids, and it could be such an activity that facilitates escape from endosomal compartments.[20] However, some form of neutralization, perhaps by cellular lipids[21] or other cellular molecules of the cationic lipid must occur for the DNA to be released from the complex.

The correlation between in vivo and in vitro activity is generally very poor, in part because many barriers are presented to the delivery vehicle by the whole organism that do not exist in the in vitro situation. One set of such factors is due to serum, which contains, among others, proteins that can bind to the surface of the complex, lipids that can mix with or extract the lipid, and nucleases that can degrade the DNA. One test of whether the lipoplex can survive exposure to serum is to measure transfection of cultured cells in the presence of 10% serum. Even at this dilution, serum inactivates many lipoplexes, however, methods have been devised to modify the formulation of some lipoplexes so that their resistance to interference by serum is greatly enhanced.[19,22−25] Recent evidence is beginning to suggest that the complex may remain intact in serum and that the main effect of serum is to reduce cellular uptake.[19,26]

With few exceptions,[27] most cationic "lipids" are synthetic compounds that are physically similar but chemically different from natural polar lipids. The compound described here is an ethyl ester of the common cellular lipid phosphatidycholine, and hence consists of only normal cellular metabolites linked with ester bonds. It exhibits low toxicity and, given its resistance to serum, may be well suited for clinical applications involving gene and drug therapy. A closely related cationic lipid has, in fact, been found to be an efficient gene delivery agent in vivo.[28]

Materials and Methods

Synthetic Methods—1,2-Dioleoyl-*sn*-glycero-3-phosphocholine (DOPC) in $CHCl_3$ was treated at room temperature with 3 (typically) mole equivalents of ethyl triflate (ethyl trifluoromethanesulfonate, Aldrich), and the mixture was allowed to react for several hours under dry argon. In some cases, 0.5−1 mol equivalent of the hindered base, 4-methyl-2,6-di-*tert*-butylpyridine, was included to ensure more complete reaction. The reaction mixture was applied to a silica gel column that was washed with $CHCl_3$, and the product was eluted with $CHCl_3$:MeOH (9:1). Purity and identity of the product were verified by thin-layer chromatography (TLC) and mass spectral (MS) analysis, respectively.

This reaction was also used to convert 1-oleoyl-2-[12-[(7-nitro-2-1,3-benzoxadiazol-4-yl)amino]dodecanoyl]-*sn*-glycero-3-phosphocholine (Avanti), 1,2-dipyrenbutanoyl-*sn*-glycero-3-phosphocholine (DPYPC), and 1-alkyl-2-pyrenebutanoyl-*sn*-glycero-3-phosphocholine to the corresponding fluorescent cationic phospholipids, 1-oleoyl-2-[12-[(7-nitro-2-1,3-benzoxadiazol-4-yl)amino]dodecanoyl]-*sn*-glycero-3-ethylphosphocholine (ENBDPC), 1,2-dipyrenbutanoyl-*sn*-glycero-3-ethylphosphocholine (EDPYPC), and 1-alkyl-2-pyrenebutanoyl-*sn*-glycero-3-ethylphosphocholine, respectively. The latter two compounds were prepared by standard methods. The dipyrene compound was prepared by diacylation of glycerophosphorylcholine[29] and the monopyrene compound was prepared by monoacylation of alkyl lysophosphatidylcholine,[30] both with pyrenebutanoic anhydride that was synthesized from pyrene butanoic acid (Aldrich) according to Selinger and Lapidot.[31]

Lipid Dispersions—Lipids were stored at −20 °C in chloroform. Solvent was removed with a stream of argon followed by high vacuum for at least 30 min. The appropriate aqueous solution was then added, and the tube was vortexed. When used for transfection, normally the aqueous phase was Dulbecco's phosphate-buffered saline (D-PBS; containing calcium and magnesium) and the lipid concentration was 1 mg/mL. The molecular weight of EDOPC triflate is 964 g/mol, so that a 1 mg/mL dispersion is very close to 1 mM.

Enzyme-Catalyzed Hydrolysis—*Activity of Known Phospholipases*—To examine the enzymatic hydrolysis of a cationic phospholipid, ENBDPC, dispersed as liposomes, was incubated with partially purified enzymes,[32] and the reaction was followed by TLC. The enzymes examined were: phospholipase A_2 from *Naja naja* venom, phospholipase C from *Clostridium perfringens*, and phospholipase D from *Streptomyces chromofuscus*, Savoy cabbage, peanuts, and Brussels sprouts. All enzymes were from Sigma except the last, which was prepared according to Christie.[32]

Phospholipase A_2 Activity In Vitro—The procedure used is standard.[33] In brief, 5 mg of lipid in 100 μL of ethyl ether was combined with 10 μL of borate buffer containing 250 μg of calcium acetate and 6 units of phospholipase A_2 from either snake venom (Naja naja) or bee venom (*Apis mellifera*). The mixture was incubated at 37 °C, and samples were removed at desired intervals and analyzed by TLC on silica gel plates developed in chloroform: methanol:water (65:25:4). Reaction products were visualized by iodine staining, fluorescence quenching of fluor incorporated in the plates, or by intrinsic fluorescence of the compound itself.

The rate of hydrolysis of EDPYPC by phospholipase A_2 was quantified with a fluorescence assay,[34] modified to include detergent.[35] The hydrolysis of 0.6 μM EDPYPC in 0.1 M NaCl, 5 mM $CaCl_2$, 5 mM Tris (pH 7) buffer containing 10 mM cholate by phospholipase A_2 from *Apis mellifera* bee venom (Sigma) was measured with a Farrand spectrofluorometer with 5-nm slit widths. Various amounts of enzyme, up to 160 units, were used. At an excitation wavelength of 350 nm, emission spectra were recorded to encompass the monomer (400 nm) and excimer (480 nm) emission peaks, as well as sufficient additional lower wavelength portions of the emission spectrum to allow subtraction of the background from the peak values for the monomer. Enzyme activity was determined from changes in fluorescence intensity using 4-(1-pyrenyl) butyric acid as a standard. Porcine pancreas lipase gave measurable, but lower activity than bee venom. Triton X-100 was also tested as a detergent in this assay and found to be inferior to cholate.

Phospholipase Activity in Cells—To test for degradation of the cationic phospholipid in cultured cells, 50 μg of fluorescent ENBDPC combined with 50 μg of 1,2-dioleoyl-*sn*-glycero-3-ethylphosphocholine (EDOPC) was incubated with BHK cells in 25-cm^2 culture dishes. A second set of experiments was done using lipid complexed 3:1 by weight with DNA (COT-1 DNA from Life Technologies). The lipid or lipid−DNA complexes were incubated with cells for 6 h in the presence of serum-free medium, following which bovine serum was added to 10%. After 1, 3, and 7 days, the cells and the medium (separately) were extracted to isolate total lipids. After removing the medium, the cells were washed with 2.5 mL of D-PBS and then removed from the dish by scraping with a rubber policeman. Then 2.5 mL of chloroform−methanol (2:1) were added to both the medium and cell suspensions. The lower chloroform phase was removed, and the aqueous phase was re-extracted with 3.0 mL of chloroform−methanol−water (2:1:0.8). The chloroform phases were combined, the solvent removed under an argon steam, and the residue dissolved in a known volume of chloroform.[33] The lipids were analyzed by TLC and visualized using long-wave ultraviolet (uv) light. Cells treated and grown under the same conditions were also examined by fluorescence microscopy to determine the distribution of the fluorescent cationic lipid. Similar experiments were done with L-cells.

To verify that the degradation observed was not limited to the NBD derivative, the procedure just described was also carried out with two other fluorescent derivatives of a generic cationic phospholipid (PC+), EDPYPC, and 1-alkyl-2-pyrenebutanoyl-*sn*-glycero-3-ethylphosphocholine.

Transfection Mediated by Cationic Phospholipids—*Standard Procedure*—BHK cells were transfected with plasmid coding for green fluorescent protein (pGreen Lantern-1, Life Technologies) or with plasmid carrying the β-galactosidase gene (pCMV-βgal; Life Technologies). Complete medium was Glasgow minimal Eagle's medium (GMEM) containing 10% fetal bovine serum, 2 mM glutamine, 2% tryptose phosphate, and 50 mg/L of Gentamycin. The cells were seeded at densities to give ∼70% confluence at the time of transfection and incubated at 37 °C under 5% CO_2. Normally, the lipids were suspended in D-PBS at 1 mg/mL and added to the plasmid DNA at 0.1 mg/mL in D-PBS, except as stated otherwise, and incubated at room temperature for 20−30 min. The DNA−lipid complex was added to the cells that were either in medium with 10% fetal bovine serum or in medium lacking serum (total volume bathing cells was 100 μL). In the latter case, 1/10 volume of bovine serum was added to each well after 4−6 h in the incubator. Then, 20−24 h after treatment with the DNA−lipid complex, the cells were assayed for expression of the reporter gene. Expression of green fluorescent protein was monitored by fluorescence microscopy. Measurement of β-galactosidase level in transfected cells was performed by a microplate fluorimetric assay.[36] To date, optimum conditions yield 10−15 milliunits of enzyme activity per well of a 96-well plate. The X-gal (5-bromo-4-chloro-3-indolyl β-galactopyranoside) procedure was used to determine the number of tranfected cells histochemically.[37] Viability of cells after treatment by cationic lipids and lipid−DNA complexes was assessed by staining cells with trypan blue and counting them in a hemacytometer.

For comparison of toxicity and transfection efficiency in the same experiment, replicates of four were used. Twenty hours after transfection, the cells of two replicates were trypsinized for viability determination. The cells from two other replicates were assayed for β-galactosidase activity.

Incubation of Transfection Complexes in Serum—First, 1.2 μL of cationic lipid suspension (10 mg/mL) was added to 4 μL of plasmid solution (1 mg/mL). After 20 min at room temperature, the complex was incubated in 100 μL of fetal bovine serum (not heat inactivated) from 30 min to 2 h at 37 °C. Each cell sample of a 96-well plate was transfected with lipid−DNA complex containing 1.5 μg of cationic lipid and 0.5 μg of plasmid DNA (i.e., 13 μL of the serum−lipid−DNA incubation mixture). The measurement of transfection efficiency was performed as usual.

Assay for Protection of DNA in Transfection Complexes from DNase—A suspension of lipid−DNA complex (3:1, wt/wt) was prepared from EDOPC (10 mg/mL) and plasmid DNA (1 mg/mL) as already described. The EDOPC−DNA complex was then diluted in fetal bovine serum (not heat inactivated) or in D-PBS at a 1:20 ratio and incubated for 2 hs at 37 °C. As a control, plasmid DNA alone was incubated under identical conditions. The incubations were stopped by dilution into gel-loading buffer containing 0.25% bromophenol blue, 0.25% xylene cyanol FF, and 30% glycerol and by addition of sodium dodecyl sulfate to a final concentration of 1%, which also released the DNA from the cationic lipid. Afterward, the samples were electrophoresed through a 1% agarose gel and visualized by ethidium bromide staining.

To test the sensitivity of the complex to restriction endonuclease, plasmid DNA or EDOPC−DNA complex containing the same amount of DNA (4 mg) was treated with 12 units of Eco RI in a total volume of 6 μL of high salt restriction enzyme buffer. The samples were incubated for 2 h at 37 °C and diluted with D-PBS to a final volume of 100 μL. After addition of gel-loading buffer and sodium dodecyl sulfate, they were analyzed by electrophoresis on a 1% agarose gel as already described.

Fluorescence Microscopy of Lipid and DNA Uptake by Cells—BHK cells were grown in 35-mm culture dishes according to conditions already described. To generate fluorescent lipid mixtures, *N*-lissamine-rhodamine-B-phosphatidylethanolamine (RhPE) or ENBDPC was mixed with EDOPC in chloroform,

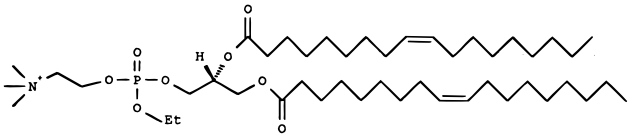

Figure 1—Structure of the cationic phospholipid EDOPC.

usually at 2.5−5 mol % fluorescent lipid. Mouse COT-1 DNA (50−300 bp) was used as is at 1 mg/mL in water or labeled with one of the high-affinity intercalating dyes, YOYO-1 or ethidium homodimer, at a ratio of 2 nanomol of dye per 10 μg of DNA. To verify that the pattern of DNA fluorescence seen in cells was not unique to COT-1 DNA labeled with an intercalating dye, we did additional experiments of this type using the standard plasmid DNA (pCMV-βgal) that was covalently labeled with Alexa maleimide dye with the FastTag Reagent (Vector Laboratories). For these experiments the lipid label was reduced to 0.5 mol % of RhPE to avoid dissimilar intensities of lipid and nucleic acid fluorescence.

Results

***O*-Alkylation of Phospholipids with Alkyl Trifluoromethanesulfonates (Triflates)**—Triflates react with phospholipids (e.g., DOPC) to generate *O*-alkyl derivatives (Figure 1). The reaction was complete in a few hours or less at room temperature, with yields up to 90%. The alkylated product migrates on silica gel plates with a R_f of 0.56 and was well separated from the reactant, which migrates with a R_f of 0.32 in a developing solvent of chloroform−methanol−water, 65:25:4. The structure of the product was verified by proton nuclear magnetic resonance (NMR) and MS analysis. The characteristic new absorption for the *O*-ethyl compound is a double quartet (one quartet for each molecule of the diastereomeric pair) at ~4.2 ppm. It may be mentioned that the reaction with ethyl triflate is not unique, and the reaction of phosphatidylcholines with other alkyl triflates having chain lengths as long as C_{18} (prepared from the corresponding alcohol and triflic anhydride[38]) has also been found to proceed smoothly.[39]

Cationic Phospholipid Stability and Metabolism—Although the experiments reported here were mostly done using material that was synthesized within the previous year, material was on hand from some early syntheses, having been stored in chloroform at −20° for nearly 5 years. Using current conditions for transfection, this material was found to have retained its ability to mediate transfection of DNA. According to TLC results, there was no detectable breakdown over that time period. As an aqueous dispersion, EDOPC can be stored for at least 3 months in the freezer without significant loss in transfection efficiency. This lipid is thus more than adequately stable for a wide variety of applications as a gene transfer agent.

Although stable to hydrolysis in the absence of a catalyst, cationic phospholipids are degraded by some purified phospholipases. ENBDPC was treated with purified phospholipases from various sources by standard procedures. Hydrolysis was established by TLC of the reaction mixture. Reaction in the presence of phospholipase C (Clostridium) was too slow to be detected under our conditions. Phospholipase D (cabbage) produced slow degradation of ENBDPC. The product of this reaction has not been unambiguously identified, but based on its R_f, phosphatidylethanol appears to be the only possibility. Phospholipase A_2 (cobra and bee venom) catalyzed the release of the NBD fatty acid. This reaction was also investigated with EDPYPC, the reaction of which could be monitored in the fluorimeter.

Figure 2 shows the extent of phospholipase A_2-catalyzed hydrolysis of EDPYPC (*O*-ethyl cationic phospholipid with two pyrene butanoic acyl substituents in place of fatty acyl chains) as a function of time. The intact molecule exhibits

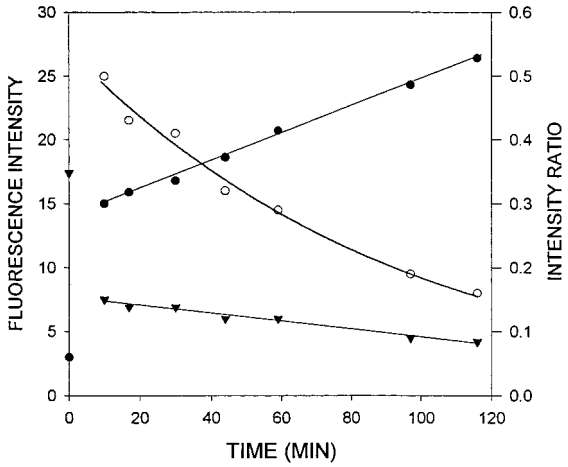

Figure 2—Time course of hydrolysis of dipyrenbutanoyl cationic phospholipid by phospholipase A_2. Hydrolysis of the pyrene-labeled fluorogenic phospholipase substrate is indicated by the increase in monomer emission (solid circles) and decrease in the excimer emission (triangles) as one of the pyrenebutanoic acid moieties is removed from the phospholipid. The substrate was dispersed in Tris buffer containing cholate, calcium ion and phospholipase A_2. The ratio of monomer to excimer emission intensity is given by the open circles.

excimer emission at 480 nm, whereas pyrene moieties that are not in contact with each other emit at 400 nm. Thus, hydrolysis can be quantified according to the rate of decrease in eximer emission and increase in monomer emission. The fluorescence intensity of the monomer (closed circles) increases markedly, but that of the excimer (triangles) falls modestly, as does the ratio of the former to the latter (open circles). This pattern shows that one of the pyrene acyl chains was removed from the molecule, for as hydrolysis occurs, the pyrene butanoic acid becomes diluted into detergent such that its emission as a monomer increases and concomitantly the excimer dissociates, leading to a reduction of its emission. Because there was initially little monomer and much excimer, the fractional change in monomer emission was large and that of the excimer was small.

The generation of product was linear for 2 h, as shown in Figure 2, however, abrupt changes in both monomer and excimer intensities are seen at very early times. This result could be due either to hydrolysis of the first molecules that bind to the enzyme followed by a steady-state rate dictated by a slower dissociation of the product from the enzyme or by a change in the conformation of the substrate—and thus in the probability of excimer formation—as the substrate binds to the enzyme (or perhaps other proteins in the solution). The average hydrolysis rate catalyzed by amounts of enzyme ranging from 40 to 160 units, as measured in experiments such as that of Figure 2, was 66 pmol/h/mg.

Comparison of the rate of hydrolysis of dipyrenebutanoylphosphatidylcholine with that of the cationic compound of Figure 2 showed that the cationic lipid was hydrolyzed at a rate ~40 X slower than that of the zwitterionic compound.

Using TLC, we determined the approximate relative rates of hydrolysis of dioleoylphosphatidylcholine and dipyrenebutanoylphosphatidylcholine. The procedure involved reducing the amount of enzyme used with the former substrate until the amount of product generated in a convenient reaction time (few hours) was approximately the same as that generated from the latter substrate. Based on this experiment, we estimate that pyrene butanoic acid was removed from phosphatidylcholine 1−2 orders of magnitude more slowly than was oleic acid. This result is not surprising, because others who have used the pyrene excimer assay have reported that when the pyrene group

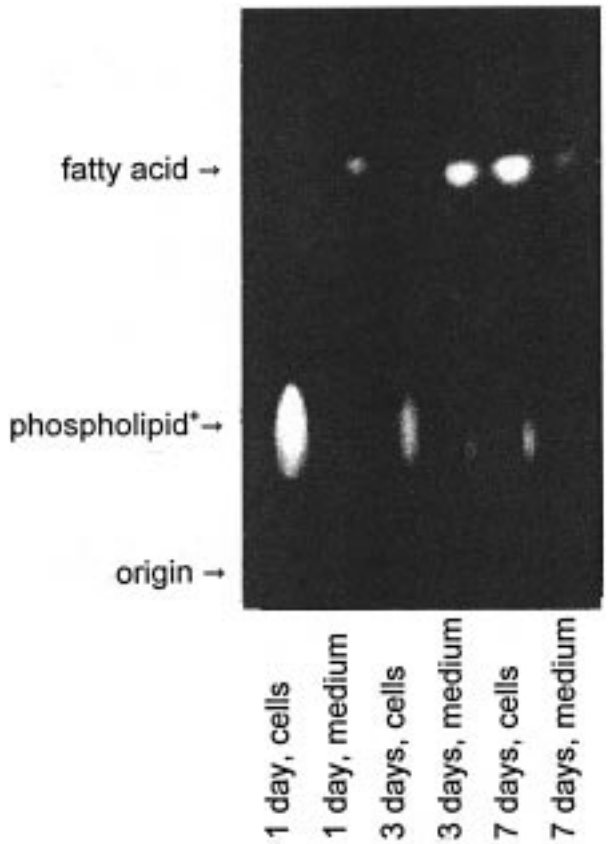

Figure 3—Cationic phospholipid degradation by cells. BHK cells were treated with a DNA–lipid complex in which the lipid was fluorescent (one acyl chain was NBD-dodecanoyl) and incubated with cells. Cells and medium were extracted with chloroform–methanol after 1, 3, and 7 days. The extracts were chromatographed, yielding the thin layer chromatogram shown, which was imaged under fluorescence illumination. Extent of degradation is indicated by growth of the upper spot and diminution of the lower spot.

is close to the ester bond, it reduces reactivity by about one order of magnitude.[40]

In addition to being susceptible to hydrolysis by isolated enzymes, PC+ is degraded by cells, as shown in Figure 3, which is the image of a TLC plate of extracts of ENBDPC that had been combined with DNA (1:1, by charge) and incubated with BHK cells for up to 7 days. Hydrolysis of ENBDPC (lower spot) to NBD−dodecanoic acid (upper spot) and lysoPC+ (not fluorescent) was detectable in the medium after 1 day, in cells after 3 days, and was very extensive in both cells and medium after 7 days. The amount of PC+ in the cells decreased drastically, whereas the fatty acid concentration in the cells rose considerably. In the same way, we also examined the hydrolysis of ENBDPC that had been presented to cells in the absence of DNA. Although there were some perceptible differences in the TLC pattern, essentially the same result was obtained, namely, the cationic phospholipid was largely metabolized within a week under culture conditions. To verify that hydrolysis of the cationic lipid was not limited to the NBD derivative, experiments identical to those of Figure 3 were done with EDPYPC and with 1-alkyl-2-pyrenebutanoyl-*sn*-glycero-3-ethylphosphocholine. These compounds were degraded to essentially the same extent as was the NBD-containing substrate. Furthermore, using the same methods, we found mouse L-cells also hydrolyze ENBDPC.

Transfection of DNA Mediated by EDOPC—To assess transfection efficiency of EDOPC, β-galactosidase and, to a lesser extent, green fluorescent protein were used as reporter genes. Cells used for routine assays were BHK,

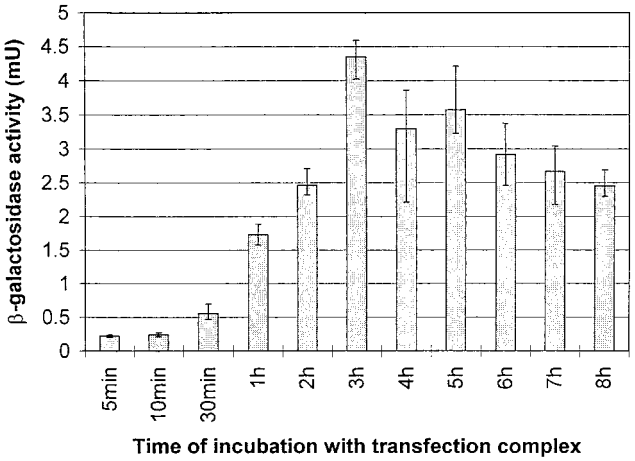

Figure 4—Time course of expression of β-galactosidase following delivery of EDOPC–DNA complex to BHK cells. EDOPC–DNA in amounts of 1.5 μg of EDOPC and 0.5 μg of DNA per well was incubated with BHK cells for various times (5 min to 8 h) as shown in the figure. The total volume of medium in each well was 100 μL. The medium with transfection complex was then aspirated and replaced with medium containing 10% fetal bovine serum. The efficiency of transfection was determined by the standard method. Bars show high and low values of three replicates.

but we also carefully examined the response of CHO cells and did less extensive examination of several other common cell lines. Transfected cells were visualized for expression of green fluorescent protein by fluorescence microscopy. For histochemical detection of β-galactosidase, the X-gal substrate was used. A large proportion of cells—up to 50% of the total—expressed β-galactosidase.

The quantitative assay for β-galactosidase used most frequently was microplate fluorimetry of fluorescein di-β-galactoside as the substrate. As shown in Figure 4, a 3−5 h incubation with EDOPC−β-galDNA complexes was sufficient for maximum expression of β-galactosidase in BHK cells. With both CHO and BHK cells, we found EDOPC gave slightly more transfection than did Lipofectamine at optimal dose and lipid−DNA ratio, although the optimal dose for EDOPC was typically somewhat larger than that for Lipofectamine. Transfection efficiency of EDOPC was rather weakly dependent on the ratio of cationic amphipath to DNA and on the total amount of complex added to cells. For a 3:1 ratio of lipid to DNA (3% excess positive charge), the activity was maximal at 3 and 1.5 μg of lipid per well. With increasing lipid-to-DNA ratio, the transfection efficiency gradually decreased. The underivatized DOPC was devoid of cell transfection activity; β-galactosidase expression in BHK cells treated with DOPC−DNA complexes was the same as background (data not shown).

Figure 5 depicts the relationship between dose of complex and transfection efficiency as well as cell viability, both in the presence and absence of serum. When the cells were cultured in the presence of serum for the entire time (upper panel), expression was higher than when serum was absent for the first 4 h of contact with the transfection complex, except at the lowest doses. This effect seems to be largely due to the better growth of cells in the presence of serum during the entire growth period, as is shown by the cell number data in Figure 5. The points connected by lines in the figure represent the number of live (trypan blue-excluding) BHK cells in wells that were treated with the same amount of transfection complex as those that were assayed for β-galactosidase. As the dose of lipid−DNA complex was increased beyond 1.5−3 μg/well (15−30 μg/mL of lipid or 5−10 μg/mL of DNA), enzyme expression tended to be maintained, even though there was some reduction in cell number, indicating a higher expression per cell.

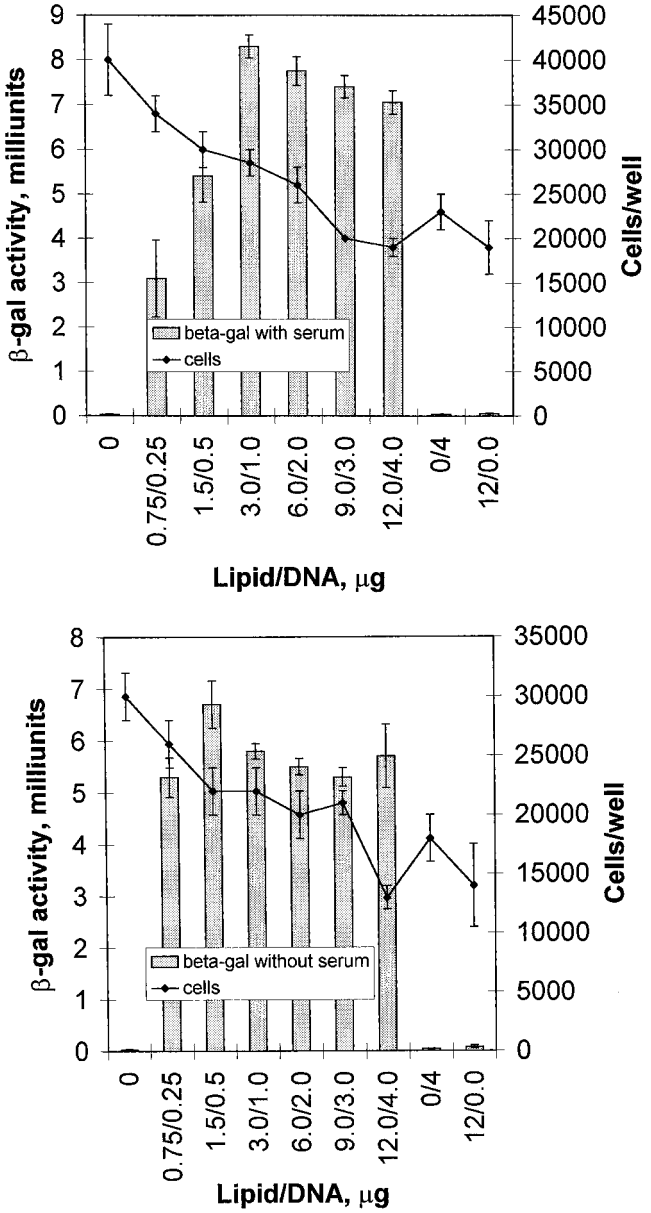

Figure 5—Transfection activity and toxicity of cationic phospholipid as a function of dose, with and without 10% serum. The figures show the level of expression of β-galactosidase (bars) and viable cells (line) for different amounts of lipid–DNA complex (in μg as shown on the horizontal axis) incubated with BHK cells in 96-well plates. The lipid:DNA ratio was 3:1 by weight in all cases, corresponding to a 3% excess of positive charge, except in the case of the control experiments corresponding to the last two bars. Volume per well was 100 μL. Upper panel: Serum present during entire incubation. Lower panel: Serum not present during first 4 h of incubation. Bars show high and low values of three replicates.

The cell number data of Figure 5 indicate that EDOPC has low toxicity because, although the number of viable cells was reduced to about half the initial number at doses of ~10 μg/well, this is a large dose, corresponding to ~2.5 mg of lipid in a 10-cm^2 Petri dish. By this test, EDOPC is ~30 times less toxic than Lipofectamine. The cell number counts in Figure 5 represent a lower limit, because it appears that cationic lipids reduce cell adhesion and some live cells are lost in washing procedures. The effects on cell viability of EDOPC and DNA separately were also examined and found not to differ greatly from that of the complex (two bars on far right of figure).

Addition of DOPE and cholesterol to EDOPC, in amounts >10 mol % at a constant ratio of EDOPC to DNA, reduced transfection. The lack of stimulation by DOPE was surprising given that most cationic amphipaths are nearly inactive in the absence of DOPE, [20,41,42] although at 1:1, DOPE had the smallest inhibitory effect (25−50%) relative to higher or lower amounts.

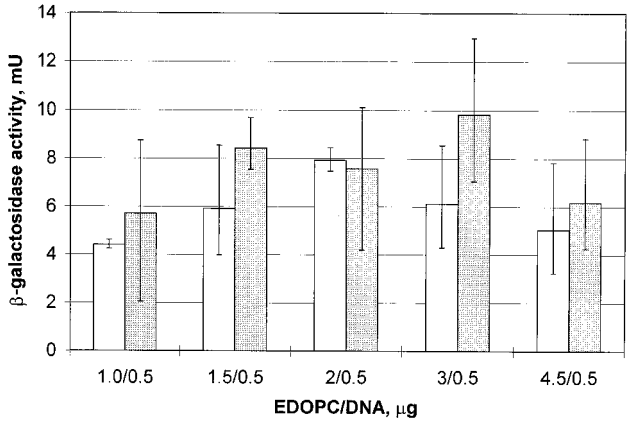

Figure 6—Effect of 10% serum on transfection efficiency as a function of the EDOPC:DNA ratio. EDOPC–DNA complexes were prepared according to the standard protocol using different lipid:DNA ratios. Transfection complexes with 2:1, 3:1, 4:1, 6:1, and 9:1 EDOPC:DNA weight ratios were then applied to BHK cells in medium without supplements (□) and to the cells in medium with 10% fetal bovine serum (■). Volume per well was 100 μL. Bars show high and low values of three replicates.

The EDOPC−DNA complex could be kept in the freezer or at room temperature for at least 3 days without loss of transfection efficiency. The ionic strength of the medium in which the complex was formed could be varied from the lowest value that was easily accessible, namely water, to a physiological value, namely D-PBS; however, this change in conditions had no significant effect on the transfection efficiency of the resultant complex.

Although not described in detail here, the phase state of the lipid appears to be important for transfection. We have examined EDPPC (the *O*-ethyl derivative of dipalmitoylphosphatidylcholine), a derivative that has a chain-melting phase transition temperature of ~40 °C. It was clear from the very low transfection efficiency of EDPPC that the phospholipid must be in the liquid phase to form an effective transfection complex.[43] In addition, extending the alkyl chain to a decyl group, which generates a lipid that resides in the hexagonal lyotropic phase, markedly altered the conditions for formation of transfection complexes with optimal activity.[39]

Another parameter likely to affect transfection efficiency is particle size. Based on dynamic light scattering, the number average particle size of the complex made under standard conditions is ~300 nm. The particle structure, according to both X-ray scattering and electron microscopy, is lamellar, consisting of DNA strands interspersed between lipid bilayers,[43] as are other complexes with low or no proportions of DOPE.[44,45]

To determine if DNA delivery to the nucleus by cationic phospholipid complexes depends on endocytosis and normal vesicle movement in the cell, we performed transfection with compounds that affect intracellular vesicle traffic. Preincubation of cells with chloroquine (60 μM), monensin (3 μM), or nocodazole (20 μM) inhibited transfection activity of EDOPC by >95%. A 2-h exposure to deoxyglucose (50 mM) reduced transfection by ~65%.

Stability of Transfection Complexes in Bovine Serum—Transfection efficiency usually improved in the presence of 10% serum over a wide range of EDOPC−DNA ratios (Figure 6). Given these data, it appeared possible that the EDOPC−DNA complex would survive incubation in a higher concentration of serum. To test for gross structural effects on the complex, which would be reflected

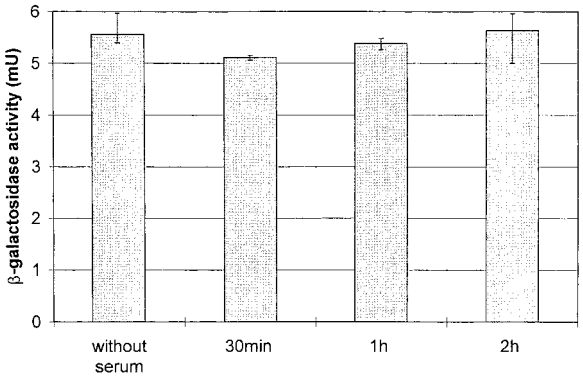

Figure 7—Transfection activity of cationic phospholipid is not affected by incubation with 95% serum. EDOPC–DNA complex was prepared from EDOPC and DNA at concentrations 10 times greater than usual (see *Methods, Standard Transfection Procedure*). The complex was incubated at a ratio of 1:20 with fetal bovine serum for 30 min and 1 and 2 h at 37 °C, and then used for transfection of BHK cells in 96-well plates in amounts corresponding to 1.5 μg of EDOPC and 0.5 μg of DNA in a total volume of 100 μL per well. Bars show high and low values of three replicates.

in the amount of light scattered by the complex, we measured the apparent absorbance of EDOPC−DNA particles at the wavelength of 450 nm (where there is no significant true absorbance) over the course of a 2-h incubation in serum at 37 °C. The compositions of the complexes were 3:1 and 6:1 by weight, prepared by mixing lipid at 1 mg/mL with DNA at 0.1 mg/mL. One volume of serum ($A_{450} = 0.32$) was mixed with one volume of complex dispersion (A_{450} were 0.62 and 0.72 for 3:1 and 6:1 weight ratio EDOPC−DNA complexes, respectively). Immediately after mixing, the absorbance was slightly higher than the sum of the absorbances of the components measured separately. We presume this difference is due to a small amount of aggregation occurring immediately, which amounted to 8% for the EDOPC−DNA complex at a 3:1 weight ratio and ~21% for the complex at a 6:1 weight ratio. Subsequently, there was a slight increase in absorbance with time: 8%/h for the complex with a 3:1 EDOPC−DNA weight ratio and 5.5%/h for the complex with a 6:1 weight ratio.

Given this indication of stability, we therefore examined the effect on transfection of 95% (the highest we could conveniently use) serum. Transfection of BHK cells was performed with lipid−DNA complexes preincubated in fetal bovine serum for 30 min, or 1 or 2 h (Figure 7). For this experiment, EDOPC and DNA were used at concentrations 10 times more than usual, which allowed us to add serum and transfection complex simultaneously to cells. As seen from the figure, the EDOPC−DNA complex retained its transfection efficiency during incubation in serum.

The effect of serum on DNA in the EDOPC−DNA complex was examined using a gel-electrophoresis-based protection assay. Figure 8 shows that after a short incubation of naked DNA in serum, the supercoiled form of plasmid was converted to linear and open circular forms. Although significant conversion to linear form also occurred in the EDOPC−DNA complex, the lipid clearly afforded a considerable amount of protection against nuclease activity. Similar results were obtained after treatment of DNA and EDOPC−DNA complex with the restriction enzyme Eco RI. In that case, the supercoiled plasmid, as well as all of the open circular plasmid present in the preparation, was completely converted to linear form. Again, EDOPC partially protected DNA from the action of restriction enzyme; that is, ~50% of the DNA remained supercoiled over the time course of the experiment.

Uptake by Cultured Cells of Cationic Phospholipids and Their DNA Complexes—Intracellular transport of transfection particles was investigated using separate labels for EDOPC and DNA. Figure 9 shows BHK cells that had been treated with EDOPC doped with RhPE, alone or in combination with DNA. When examined the next day, the pattern of labeling was quite dramatic and differed quite significantly, depending on whether DNA was delivered simultaneously with the lipid. When treated with lipid alone (upper panel), most cells exhibit localized fluorescence in large compartments adjacent to the nuclei. Although not definitively identified, the latter compartments are very similar to those labeled when cells are exposed to FITC−dextran and examined a day later, hence are suspected to be lysosomes.[46] Labeling of cellular membranes outside the perinuclear region was usually relatively weak. When cells were treated with lipid−DNA complexes, the typical lipid fluorescence pattern was significantly different (lower panel). Some fluorescence was seen around the nucleus, but the bulk of it was distributed throughout the cell in a punctate pattern, with extensive labeling of the surface and internal membranes.

When the DNA of the complex contained the tightly bound fluorophore, YOYO-1, the cytoplasm and the nuclei (with the exception of the nucleoli) of some of the cells were also fluorescent with the green fluorescence of intercalated YOYO-1. Our images of cells treated with lipid plus DNA were similar to those of CHO cells obtained by Hui et al.,[47] who introduced this combination of dyes in an earlier study of the transfection agent, 1,2-dioleoyl-3-(trimethylammonio)propane (DOTAP). We obtained the same results when plasmid DNA was covalently labeled with Alexa 488 C_5 maleimide dye as when we used the intercalating dye YOYO-1, indicating that the fluorescence observed was not due to migration of the YOYO-1 from delivered DNA to cellular DNA.

Discussion

We found that it is straightforward to change a zwitterionic phospholipid to a cationic phospholipid that is a highly effective transfection agent. The reaction is one step, involves readily available precursors, and purification is straightforward. The combination of efficacy and low toxicity makes the cationic phospholipids attractive candidates for agents to deliver nucleic acids and other pharmacological and physiological agents[17] to cells. Because the precursors are readily available and inexpensive, these compounds should also be cost-effective options for such applications.

Transfection Activity of Cationic Phospholipids—EDOPC exhibits transfection activity that is similar to that of other available agents, like Lipofectamine. Cationic phospholipids are, however, unaffected by serum, a property that distinguishes them from a number of common cationic amphipaths that are significantly inhibited by even 10% serum. Because it is not completely understood why those compounds are inhibited by serum, we cannot be sure why the cationic phospholipid escapes that fate. Current evidence points to interactions with serum proteins as an important cause for inhibition,[26] and it was found that inhibition could be avoided by changing the ratio of lipid to DNA,[23] the size of the complex,[22] or the concentrations at which it was formed.[25] In the case of EDOPC, because resistance to serum was observed over a wide range of PC+:DNA ratios (Figure 6), it is unlikely that the stability of the complex can be attributed to a particular surface charge density of the particle surface. It therefore would seem to be a property of the complex itself and evidently depends on a characteristic of the cationic phospholipids. The results of protection assays showed that when incubated in serum, supercoiled plasmid DNA complexed with

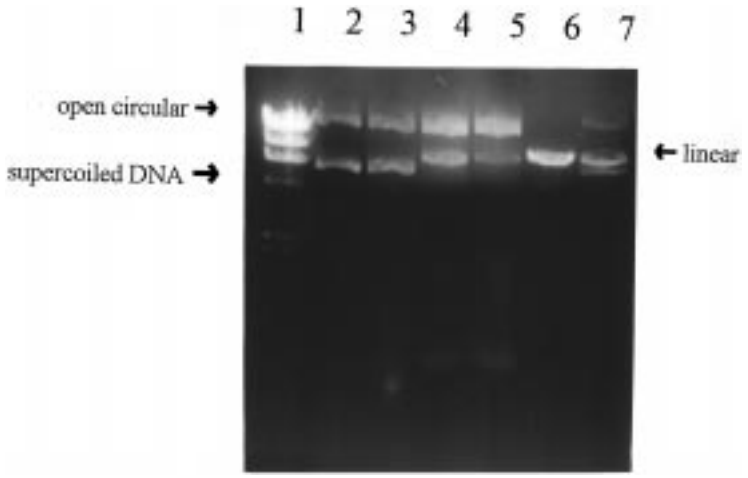

Figure 8—Agarose gel electrophoresis. DNA protection assay. EDOPC–DNA complexes were formed at concentrations 10 times higher than usual and incubated in fetal bovine serum or with the restriction endonuclease EcoRI (see *Methods* for additional details): Lane 1, in λ\HindIII; lane 2, DNA in D-PBS; lane 3, EDOPC–DNA in D-PBS; lane 4, DNA in serum; lane 5, EDOPC–DNA in serum; lane 6, DNA after treatment with EcoRI; lane 7, EDOPC–DNA after treatment with EcoRI.

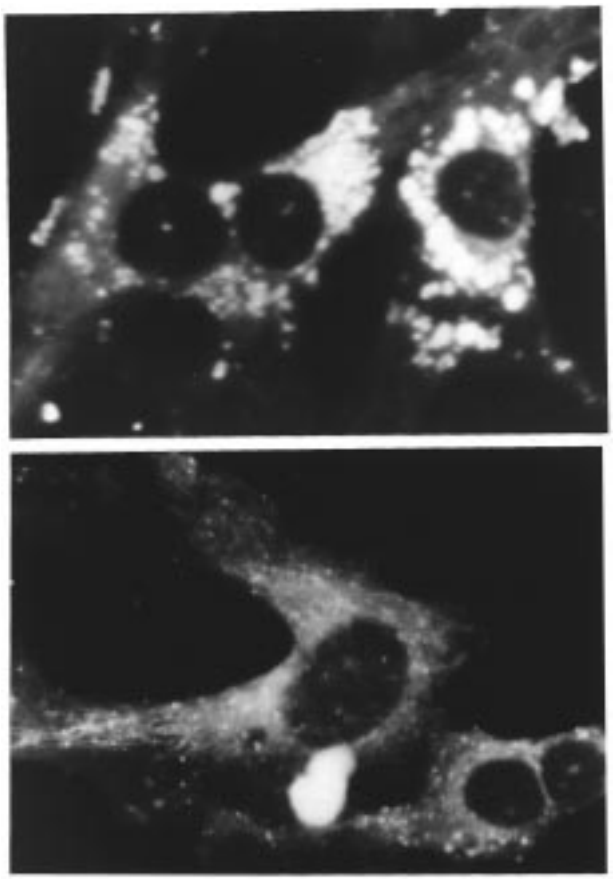

Figure 9—Cell uptake of cationic lipids and DNA–cationic lipid complexes. BHK cell cultures were treated with EDOPC containing 2.5 mol % RhPE either alone (upper panel) or complexed with DNA (lower panel). After incubation for 6 h in serum-free medium and an additional 14–18 h in serum-containing medium, the cells were fixed, mounted, and subsequently photographed. When lipid alone was added to the cells, it accumulated in large cellular vesicles in the region of the nucleus. When cells were treated with lipid–DNA complex, the surface and intracellular membranes often became fluorescent. Punctate fluorescence is also seen in these cells, but is usually distributed throughout the cell in much smaller vesicles than those seen in cells treated with lipid alone. The dark ovals outlined by surrounding fluorescence are the nuclei.

EDOPC was converted mainly to the open circular form instead of the linear form. This protection characteristic of EDOPC could be due to the structure of the polar group region, or to the fact that there is a single type of lipid present (which would exclude the possibility that even small incompatibilities between the two components could lead to some form of disproportionation under the influence of serum). Whether or not this means that cationic phospholipid complexes with DNA bind appreciably less serum protein than other transfection complexes remains to be determined. In any case, the ability to withstand extended contact with serum is an essential characteristic of a transfection complex if it is to be useful in gene therapy, and it is hence a potentially important characteristic of cationic phospholipids.

The cationic phospholipid exhibits relatively low toxicity to cells in culture, for which two possible explanations are apparent. One possibility is simply that the compounds may be sufficiently similar to cellular lipids that they have less disruptive effects on normal membrane function. A second possibility is that the lipids are degraded by cells to species that may either diffuse out of cells or be metabolized further. The rate of degradation was low, with a half time of days for the fluorescent substrates we tested, but if the intracellular phospholipase A_2(s) is similar to the venom enzymes we tested in the test tube, the unlabeled lipid could be degraded an order of magnitude faster. We doubt, however, that this potential advantage is realized under cellular conditions. Rather, we suspect that lipid degradation is limited by accessibility; the very mass of the lipid—both in the lipid by itself and the lipid–DNA complex—is likely to present a significant barrier to access by intracellular lipases. This interpretation is strongly supported by the punctate disposition of fluorescent lipids in the cell; large fluorescent masses appear within cells shortly after administration of lipid or complex and they remain sizable for at least a day.

Unlike many amphipathic cations used as transfection agents, EDOPC does not require DOPE for effectiveness.[41,42] We found that no mixtures of DOPE and EDOPC were as effective as pure EDOPC; however, the 1:1 mixture (the common ratio used with other cationic lipidic transfection agents) was nearly as effective as pure EDOPC. (We do not yet know what phase these mixtures reside in, and we will publish more extensive transfection results on DOPE-containing complexes when their phase structures have been determined.) It has been suggested that DOPE—a hexagonal phase-preferring lipid—may destabilize the endosomal membrane to facilitate escape of the DNA.[21] It may be that this adjunct activity is not required by PC+

because PC+ possesses membrane-destabilizing characteristics on its own; we have observed that cationic phospholipid vesicles fuse with anionic lipid vesicles,[48] EDOPC−DNA particles fuse with the bilayer of phosphatidylglycerol vesicles,[49] and mixtures of EDOPC and dioleoylphosphatidylglycerol form a bicontinuous cubic phase.[50]

Differential Uptake of Lipid and Lipid−DNA Complex by Cells—In the absence of DNA, the lipid fluorophore that was presented to cells accumulated in the perinuclear region. Presented in complex with DNA, the fluorophore was distributed in many small compartments throughout the cell. There are two obvious differences in the physical properties of the lipid and the lipid−DNA complex. One is buffer capacity. The complex could accept protons, because the DNA is present in the complex as a salt. The cationic phospholipid, being a quaternary amine, has no buffer capacity. Endosomal compartments may thus become more slowly acidified if DNA is present along with cationic phospholipid. The lipid is, in fact, delivered to compartments that resemble lysosomes morphologically, as would be expected if there were no significant interference with the normal acidification sequence in cellular vesicle traffic patterns. These results are also consistent with the cell fractionation results reported by Wattiaux et al. for liver cells treated with cationic amphipaths, in which the compounds accumulated in lysosomes.[51] Others have argued that cationic transfection agents function in part by neutralizing endosomal acid, with the result that lysosomal nucleases are inhibited.[52] If this result is true, then perhaps the reason we have noticed a difference between delivery of the lipid and that of the complex is because in our case only the complex would have buffer capacity.

The other obvious difference between the lipid and the complex is in osmolarity. The lipid has an osmolarity that is nearly the same as the concentration of its counteranions. The complex, in contrast, has an osmolarity that is essentially zero, for at the most effective composition for transfection, the charges on both lipid and DNA are almost completely neutralized. But the complex does have a latent high osmolarity, for if the DNA becomes protonated or if hydrophobic cellular anions diffuse into the complex, the complex is no longer a single particle in the osmotic sense. Thus, residence in an endosome could lead to changes in the lipid−DNA complex that could both buffer the endosome and lead to osmotic swelling of the compartment, both of which would delay transit to lysosomes. Generally attention has been focused on the cationic component as instrumental for DNA delivery, but it should not be overlooked that DNA, in complex with a cationic amphipath, acquires new properties that could play a role in its own delivery to the nucleus.

A number of cell lines were transfected by EDOPC, including CHO, mouse 3T3, Niemann-Pick, Rcho-1, L, K562 (erythroleukemia), and quail fibroblasts, although conditions were not optimized except for the first and second of these. Human vascular endothelial cells, primary cells of umbilical cord origin, are also efficiently transfected by EDOPC, however, in this case, not in the presence of serum.[53] In the case of CHO and 3T3 cells, the optimal conditions were not greatly different from those for BHK. Even without optimization, however, it was clear that EDOPC is effective with a wide variety of cells. An important advantage of the relatively low toxicity of EDOPC is that high doses may be used with recalcitrant cell lines. It remains to be determined to what extent cationic amphipaths will acquire clinical importance as gene therapy agents; however, because cationic phospholipids can be synthesized with a considerable variation in structure, there is reason to believe that a variety of these molecules could be constructed as effective delivery agents with minimal toxic effects.

Received December 17, 1998. Accepted for publication June 21, 1999.

Abstract □ The single-step, fast spray-drying process may represent a valuable alternative to the multistep, time-consuming freeze-drying process in the area of formulation and processing of biopharmaceuticals. In this study, we tested the use of sucrose and hydroxypropyl-β-cyclodextrin (HP-β-CD) as stabilizing excipients in the spray-drying of a model protein, β-galactosidase. The solutions were processed using a Büchi 190 cocurrent Mini Spray Dryer at an outlet temperature of 61 ± 2 °C. The powders were redissolved and analyzed for catalytic activity, aggregation, chemical decomposition, and thermal susceptibility as observed by high-resolution calorimetry. Spray-drying significantly inactivated β-galactosidase. Spray-drying β-galactosidase in the presence of sucrose did not prevent inactivation. However, after spray-drying β-galactosidase in the presence of HP-β-CD, or HP-β-CD and sucrose, full catalytic activity was exhibited on reconstitution. Furthermore, the reconstituted product was unchanged in terms of molecular weight, charge, and thermal stability. These findings are consistent with a hypothesis that the change responsible for inactivation of β-galactosidase was mainly a monomolecular, noncovalent change, i.e., the formation of incorrect structures, that arose from surface denaturation. This study clearly demonstrates that cyclodextrins can be useful stabilizing excipients in the preparation of spray-dried protein pharmaceuticals.

With the advent of new drug therapies and the increasing commercial availability of biotechnology-derived proteins, great expectations have arisen from the development of biopharmaceuticals.[1] However, a significant technical challenge lies in the formulation of these drugs. Compounds such as proteins are often physicochemically fragile and readily degrade,[2] the most common degradation pathways being aggregation, fragmentation, deamidation, and oxidation, which influence critical pharmaceutical properties including biological activity, metabolic half-life, and immunogenicity.[3] Freeze-drying has in general been the method of choice for stabilizing labile biopharmaceuticals, while spray-drying has been used for the stabilization of various heat-sensitive biological (enzymes), food (milk and egg products), and pharmaceutical (antibiotics and vaccines) products.[4] Despite the relatively high temperatures involved in the use of a hot airstream as a drying medium, the droplets in a spray-dryer do not attain a high temperature. Additionally, the low water content of the product that leaves the drying chamber allows the labile compound to withstand the effect of heat. Thus, spray-drying has been used under certain conditions to produce fully biologically active proteins.[5,6] The controllable particle size and shape characteristics of spray-dried powders make this process suited to the formulation of pharmaceuticals for inhalation.[7] Thus, the single-step, fast spray-drying process may represent a valuable alternative to the multistep, time-consuming freeze-drying process in the area of formulation and processing of biopharmaceuticals.

Nonetheless, the physical stress of the drying process on proteins may cause degradation,[3,8,9] which necessitates the use of stabilizing excipients when preparing dried biopharmaceuticals. Sugars and other polyols have been used as protein stabilizers because of their preferential interaction behavior in solution.[10] During spray-drying, polyols have been observed to reduce the rate constant of protein inactivation and improve recovered enzyme activity.[11,12] In contrast, cyclic oligosaccharides, or cyclodextrins (CDs), favor protein thermal denaturation in solution.[13] However, cyclodextrins have been reported to stabilize proteins against other protein degradation pathways, such as aggregation[14] and precipitation,[15] and as a result improve protein folding reversibility.[16] Cyclodextrins have also been shown to protect proteins from freeze-drying-induced inactivation[17] and maintain the native structure in elevated temperature stability studies.[3] Cyclodextrins are thought to have an impact on protein behavior through weak interactions between the oligosaccharide hydrophobic core and nonpolar protein groups when these are exposed.

Since polyols and cyclodextrins affect different protein degradation pathways, we wished to probe the influence of a combination of these two types of cosolvents on protein integrity during spray-drying and observe whether the two excipients would have additive, antagonistic, or synergistic effects, to compare these effects to those occurring in solution.[18] In this study, we tested the use of sucrose and hydroxypropyl-β-cyclodextrin (HP-β-CD) as stabilizing agents in the spray-drying of a model enzyme, β-galactosidase derived from *Aspergillus oryzae*. A monomeric glycoprotein, *Aspergillus oryzae* β-galactosidase is a multidomain, 105 kDa, 4.5 pI enzyme.[19,20] In contrast to small, single-domain proteins, β-galactosidase may follow a two-step folding mechanism involving successively fast domain folding and slow domain pairing.[21] Unlike natural cyclodextrins, HP-β-CD is surface active;[22] it was chosen as a model cyclodextrin for its high aqueous solubility and its pharmaceutical relevance as a potential excipient for parenteral and oral routes.[23] Sucrose was chosen because of its good glass-forming abilities and its widespread use as a protein stabilizer. Powder samples were dissolved and analyzed for catalytic activity, aggregation, and chemical change. Further, high-sensitivity differential scanning calorimetry (HSDSC) was used to measure the susceptibility of the reconstituted enzyme to thermal denaturation. This technique measures directly the forces stabilizing the globular structure and has a potential predictive capability of long-term stability of proteins.[24]

Experimental Section

Chemicals—β-Galactosidase (EC 3.2.1.23) derived from *Aspergillus oryzae* (lot 115H1179), *o*-nitrophenyl-β-D-galactoside (ONPG, lot 105H5017), and anhydrous sucrose (lot 70H-018715) were obtained from Sigma-Aldrich Ltd, Poole, UK. Hydroxypropyl-β-cyclodextrin (HP-β-CD, degree of substitution 0.6, batch 07B-271/1) was supplied by Janssen Biotech N. V., Olen, Belgium.

Spray-Drying—Each solution to be processed was prepared by dispersing 4 g of protein in 100 mL of deionized double-distilled water, with or without excipient, and centrifuged for 10 min at 13000 rpm. The concentration level was 1% w/v for each excipient, so that the sucrose:cyclodextrin:protein ratio was 0.25:0.25:1 in terms of mass and 76.8:19.0:1 in molar terms. A silicone tubing of inner diameter 4 mm and a peristaltic pump were used to feed the solutions to the nozzle of a Type B, Büchi 190 co-current Mini Spray Dryer (Büchi Labortechnik AG, Flawil, Switzerland). This dryer has a two-fluid, pneumatic nozzle 0.5 mm in diameter. Cooling water was continuously run through the nozzle to prevent protein degradation in the nozzle. The solution feed rate was 0.36 $\pm$ 0.06 L h^{-1}, the air spray flow consumption 750 $\pm$ 50 L h^{-1}, and the aspirator vacuum level 10 (approximately 30000 L h^{-1}). The inlet and outlet temperatures were set to 190 $\pm$ 2 °C and 61 $\pm$ 2 °C respectively, because these temperatures were expected to cause some inactivation of *Aspergillus oryzae* β-galactosidase.[12]

Catalytic Assay—the samples were reconstituted in 100 mM sodium acetate buffer, pH 4.5, at an approximate protein concentration of 1 mg mL^{-1}, and yielded clear solutions. One hundred microliter aliquots of this solution were added to 3 mL of 4.93 mg.mL^{-1} ONPG substrate solution. The rate of increase in absorbance at λ = 420 nm and 37 °C, caused by the enzyme-catalyzed hydrolysis of ONPG to *o*-nitrophenol, was monitored for 1 to 2 min.[12] The relative standard deviation of this method is 5%. Protein determination was carried out by the Bradford (Coomassie blue) method at λ = 590 nm, as described by Stoscheck.[25]

High-Sensitivity Differential Scanning Calorimetry (HSDSC)—Powders were dissolved in deionized double-distilled water to a protein concentration of 2−3 mg mL^{-1}. The solutions exhibited no turbidity and had a measured pH of 6.5, indicating that none of the excipients used affected the pH significantly. Thermal denaturation profiles for β-galactosidase were generated over the temperature range 20−100 °C using a Micro Calorimetry System high-sensitivity differential scanning calorimeter (MCS DSC, MicroCal Inc., Northampton, MA) controlled by the MicroCal Origin software. The instrument was calibrated for heat capacity using electrical pulses of known power and for temperature using sealed paraffin hydrocarbon standards of known melting points (28.2 °C and 75.9 °C for *n*-octadecane and n-hexatriacontane, respectively). Typically, this instrument has a noise level of 0.3 μW, a reproducibility on refilling the cells of 0.13 mJ K^{-1}, and a relative error in the heat capacity determination of 0.005%.[26]

The accuracy for the temperature measurement was 0.2 °C. All solutions were degassed for 2 min under vacuum before being loaded into the calorimeter, and were held under 2 bar nitrogen excess pressure to avoid bubble formation at higher temperatures. For each sample, a reference profile, obtained from water samples, was subtracted from the protein thermal data, and the excess heat capacity function was normalized for protein concentration. Since several processed samples contained sucrose or/and HP-β-CD, controls made of unprocessed protein and sucrose and/or HP-β-CD (in the same proportions as for processed samples) were prepared and analyzed in the same conditions. Thus, any change occurring both in the processed samples and in the controls would result from an excipient effect during the analysis and not during the spray-drying process.

High-Performance Size-Exclusion Liquid Chromatography (HPSEC)—For the chromatographic and electrophoretical experiments, the water used for reconstitution was deionized and filtered in a Milli-Q system (Millipore), and the samples were reconstituted in 0.1% aqueous acetic acid. Size-exclusion fractionation was performed in 50 mM phosphate buffer saline pH 7 at 40 °C using a TSKgel Super SW3000 column from TosoHaas GmbH (Stuttgart, Germany) made of 4 μm silica particles. This column was setup on a Merck-Hitachi HPLC chromatograph comprising an AS-2000 autosampler, a L-7100 pump, a LiChrograph L-6000 A HPLC pump, a D-6000 A interface, an L-5025 column thermostat, an L-4250 UV−vis detector set to λ = 214 nm, and a water-circulated, temperature-controlled rack at 8 °C for the sample vials. Typically, duplicate samples (5 μL) were analyzed at a concentration of 1 mg/mL and using a flow rate of 0.35 mL/min. The calibration kit from BioRad contained thyroglobulin (670 kDa), bovine γ-globulin (158 kDa), chicken ovalbumin (44 kDa), equine myoglobin (17 kDa), and vitamin B-12 (1.35 kDa). The data were analyzed using the Merck-Hitachi D-7000 HSM Chromatography Data Station Software.

Table 1—Enzymatic Activity of Redissolved Spray-Dried β-Galactosidase Samples Relative to the As-Received, Commercial Protein[a]

	relative activity (%)
no excipient	75.0
sucrose[b]	71.5
HP-β-CD[b]	98.3
HP-β-CD:sucrose[b]	90.0

[a] Reconstituted at a concentration of 1 mg mL^{-1} in 100 mM sodium acetate buffer, pH 4.5. [b] One gram of each excipient was added to the 4% w/v protein solution (100 mL) prior to spray-drying.

Sodium Dodecyl Sulfate Polyacrylamide Gel Electrophoresis (SDS−PAGE) and Isoelectric Focusing (IEF)—All materials were obtained from Amersham Pharmacia Biotech, Uppsala, Sweden, unless specified. Electrophoretical experiments were performed at 10 °C on a Multiphor II unit, with a thermostatic circulating water bath. SDS−PAGE runs were controlled by a BioRad 1000/500 power supply, and IEF ones by an Electrophoresis Power Supply EPS 3500 XL. The samples (run in quadruplicate) were separated according to molecular weight in both reducing and nonreducing conditions on ExcelGel SDS Homogeneous 12.5% containing 120 mM Tris, 120 mM acetate, 1 g L^{-1} SDS, pH 6.4, and using ExcelGel SDS buffer strips at the anode and cathode made of 450 mM Tris-acetate, 4 g L^{-1} SDS, pH 6.6, and 80 mM Tris, 800 mM Tricine, 6 g L^{-1} SDS, pH 7.1, respectively. A high molecular weight calibration kit was used, for the range 36 kDa (beef heart lactate dehydrogenase subunit) up to 330 kDa (hog thyroid thyroglobulin subunit). After fixing, the gels were stained using a Coomassie, PhastGel Blue R solution. IEF experiments were carried out in the pH range 2.5−8.0, with prior rehydration of CleanGel in a mixture of 700 μL of Pharmalyte carrier ampholytes in the pH range 2.5−5.0 and 700 μL Pharmalyte pH 5.0−8.0. The IEF calibration kit covered the pH range 2.80 (pepsinogen) to 6.55 (human carbonic anhydrase B). The gels were stained with a 1 g L^{-1} silver solution. All staining was done with an automated gel stainer (Hoefer Pharmacia Biotech Inc., San Francisco, CA).

Results and Discussion

Catalytic Data—The enzymatic activity data measured for the reconstituted samples are given in Table 1. As expected from the choice of the processing conditions, and in particular the outlet temperature which is the main factor influencing recovered protein activity,[27,28] the reconstituted spray-dried *Aspergillus oryzae* β-galactosidase had a significantly lower catalytic activity (75%) than the as-received, commercial protein. Interestingly, the addition of 1% w/v sucrose in the feed protein solution did not significantly alter the activity of the reconstituted product. Broadhead et al.[12] have found sucrose to stabilize β-galactosidase during spray-drying. A noticeable difference in the conditions, though, was the sucrose:protein mass ratio, which was more than or equal to 1.67 in Broadhead et al.'s study, but as low as 0.25 in our work. In terms of inactivation kinetics, a level as low as 1% w/v sucrose would not slow the spray-drying-induced deterioration of glucose oxidase.[29] However, sucrose concentrations as low as that used here (0.03 M) have been found to stabilize oxyhemoglobin on spray-drying.[6] In contrast, our results show that the use of 1% w/v HP-β-CD fully protected β-galactosidase against inactivation. This is interesting as high concentrations (10 to 20%)[3] of this cyclodextrin are usually needed

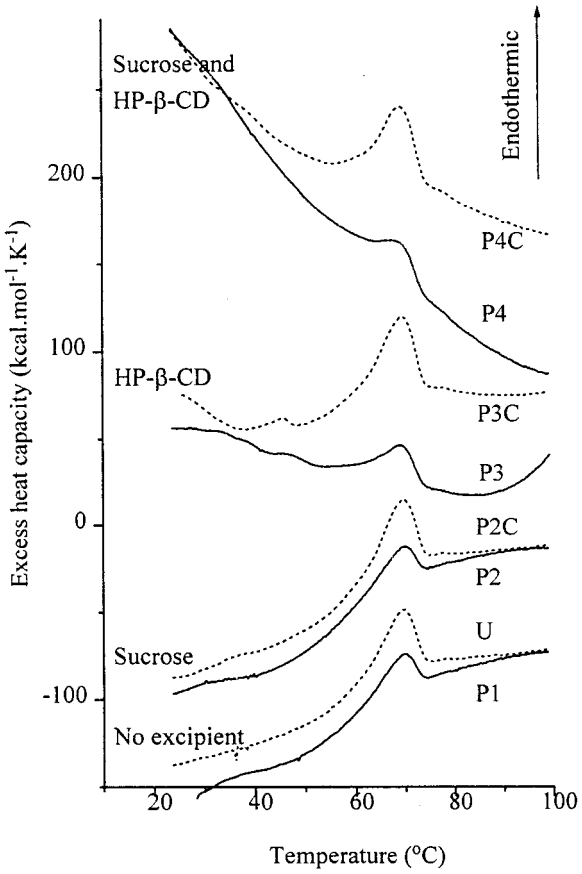

Figure 1—Thermal denaturation profiles for unprocessed (broken lines) and spray-dried (solid lines) β-galactosidase samples reconstituted in water at 2–3 mg mL^{-1} protein concentration, pH 6.5. U: excipient-free, unprocessed; P1: excipient-free, processed; P2: sucrose-containing, processed; P2C: control for P2 (unprocessed enzyme to which sucrose was added); P3: HP-β-CD-containing, processed; P3C: control for P3; P4: sucrose- and HP-β-CD-containing, processed; P4C: control for P4. The excipient composition was matched for each pair of unprocessed/processed samples, as explained in the Experimental Section.

to affect protein stability. The recovered activity (90%) obtained through the use of a combination of both excipients did not differ significantly from that measured for the cyclodextrin-containing sample. Since these carbohydrates at such levels do not interfere with the measurement of enzyme kinetics,[18] it appears that the cyclodextrin used prevented spray-drying-induced inactivation of β-galactosidase, whereas sucrose did not provide any protection. This inactivation process and the excipient effects were further investigated with thermal and biochemical measurements.

Thermal Denaturation Data—The calorimetric profiles and derived thermodynamic parameters are given in Figures 1 and 2 and Tables 2 and 3. The calorimetric profile for commercial β-galactosidase displayed a single endotherm with a transition temperature, T_m, of 69.7 °C. All samples exhibited a similar profile and T_m values were in the range 68.4−70.0 °C. The differences in slope were presumably due to excipient effects, as seen from the control data, and caused the small variations seen in T_m. Differences in transition enthalpies were ascribed to differences in concentrations of the reconstituted samples. All profiles were explained by a similar three-transition, non-two-state model. Differences were found in the relative intensities of the fitted transitions, but no trend appeared. The van't Hoff enthalpy, calculated for each fitted transition under the two-state approximation, yielded calorimetric-to-van't Hoff enthalpy ratios, which can be valuable for

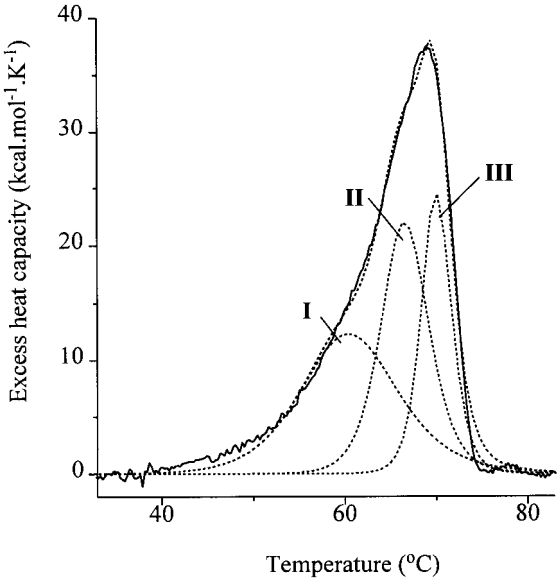

Figure 2—Three-transition, non-two-state model fitted to the calorimetric profile for reconstituted unprocessed β-galactosidase.

Table 2—Observed Denaturation Temperatures (T_m) for Redissolved Unprocessed and Spray-dried β-galactosidase Samples[a]

	denaturation temperatures, T_m (°C)	
	unprocessed	spray-dried
no excipient	69.7	70.0
Sucrose[b]	69.7	69.9
HP-β-CD[b]	69.5	69.1
HP-β-CD:sucrose[b]	69.0	68.4

[a] The excipient:protein mass ratio was 0.25 for each excipient in all preparations. [b] One gram of each excipient was added to the 4% w/v protein solution (100 mL) prior to spray-drying.

estimating the number of cooperative units. Transition I generally exhibited ratios much larger than 1, except for the HP-β-CD sample (P3). Transition II yielded ratios in the interval 0.6−1.1. Transition III showed ratios significantly less than 1, except for the unprocessed sample (U). However, because of the number of factors (e.g., baseline determination, exothermic processes, transition reversibility) that may bias the apparent enthalpies, no conclusions could be drawn from the observed calorimetric-to-van't Hoff enthalpy ratios.

Chromatographic and Electrophoretical Profiles—A representative size-exclusion HPLC trace is shown in Figure 3, with estimated parameters for all samples listed in Table 4. Electrophoretical fractions and estimates, respectively, are given in Figures 4 and 5 and Table 5. Fractionation by HPLC indicated the presence of five separated species, although not fully resolved. They were ascribed to the monomer (143 kDa), two fragments (53 and 42 kDa), a dimer (292 kDa), and a higher-MW aggregate (509 kDa). The peaks at 4.9 and 11.7 min were a high-molecular weight species eluting outside the size limits of the column and the buffer acetate anion, respectively. No effect of the spray-drying process or excipients on the retention times of these fractions was detected, although the relative intensity of the 9.0 min fragment peak was slightly larger for the sucrose sample (P2). Separation with SDS−PAGE of commercial β-galactosidase gave estimates for the main species of 105 kDa in nonreducing conditions and 119 kDa in the presence of mercaptoethanol. This band was attributed to the monomer. Additionally, three main bands appeared with MW estimates of 70, 64, and 40 kDa, which were probably responsible for the 8.7 min and 9.0

[e] Van't Hoff enthalpy change calculated as $\Delta H_{vH} = 4RT_m^2/\Delta T_{1/2}$. [f] 1 cal = 4.184 J.

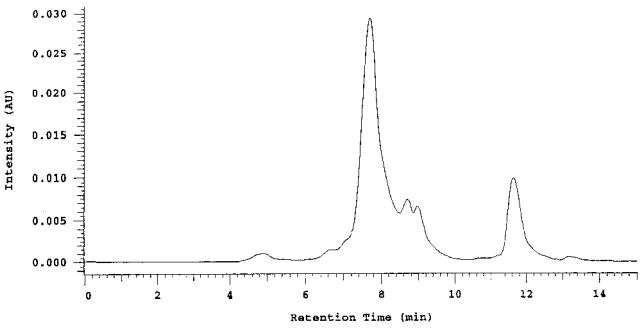

Figure 3—Size-exclusion HPLC profile observed for all unprocessed and spray-dried β-galactosidase samples reconstituted at 1–2 mg mL^{-1} protein concentration in 0.1% aqueous acetic acid.

min HPLC peaks. The use of the surfactant SDS for gel electrophoresis allowed the nature of the aggregates detected with HPLC to be tested. The absence of electrophoretical band above the monomer-size band indicated that the high-molecular weight chromatographic fractions reflected noncovalent aggregates. Faint SDS−PAGE bands appeared in the range 29−35 kDa in reducing conditions, indicative of the presence of multichain species held by disulfides in nonreducing conditions. No spray-drying- or excipient-induced change in the molecular weight or relative amount of protein fractions was found. Isoelectric focusing of unprocessed β-galactosidase revealed a number of bands, of which the two main bands were in the 4.5 and 3.5 pI regions, consistent with the expected value. Neither the process nor the excipients altered the isoelectric profiles.

Nature of the Inactivation Process and Cosolvent Effects—Thus, spray-drying significantly inactivated β-galactosidase as observed by the level of recovered enzyme kinetic activity. The addition of HP-β-CD stabilized the enzyme against inactivation, as did the combination of both

[a] Abbreviations as in Figure 1. Relative areas were calculated without taking into account the 4.9 and 11.7 min peaks, which are a higher-molecular weight species eluting outside the size limits of the column, and the buffer acetate anion, respectively. Peaks 1 and 2 were too poorly resolved for meaningful integration.

HP-β-CD and sucrose, but not sucrose alone. These results demonstrate that cyclodextrins can be useful stabilizers in the preparation of spray-dried protein pharmaceuticals. Further experiments indicated that the spray-dried enzyme was unchanged in terms of thermal stability, size-exclusion HPLC, SDS−PAGE, and IEF patterns. These findings highlight the relevance of functional probes for the detection of certain changes in multidomain proteins that involve interactions between distant sites which remain undetected by physical probes.[21] The reduction in the activity that was observed may reflect either an almost complete loss of activity affecting only a fraction of the population of molecules, or a conformational alteration inducing less activity in most of the molecules.[30] Our data indicate that the structural change causing inactivation was subtle; it is likely that this change was not the formation of covalent or noncovalent aggregates, fragmentation, or deamidation. Since the droplets of a solution atomized in a cocurrent spray-drier usually reach a maximum temperature which is approximately 15 °C below the outlet temperature for 5 to 30 s,[11,31] β-galactosidase was only briefly exposed to temperatures approaching 45 °C, thus undergoing only small and reversible thermal denaturation as inferred from the calorimetric data. Temperatures in this region for a formulation at a pH close to neutral also mean that the inactivation process involved no change in primary structure.[32] Therefore, it is hypothesized that the change responsible for partial inactivation of β-galactosidase was mainly a monomolecular, noncovalent change, i.e., the formation of incorrect structures, and did not affect the thermal susceptibility of the protein but weakened its kinetic properties, i.e., interferred with its active site.

Furthermore, it is known that protein adsorption to surfaces can be a source of destabilization,[33] inducing, for example, inactivation of *Escherichia coli* β-galactosidase.[34] In our study, denaturation at the air−liquid interface was a probable explanation for inactivation because it was consistent with three relevant factors: the consistency between the absence of effect of sucrose and the expected large droplet surface coverage of the protein; indeed, it has been found that for a protein:lactose ratio of 1/99, the protein can dominate the droplet surface due to its higher surface activity than the sugar;[35] the reduction of inactivation in the presence of surface-active cyclodextrin, which may compete with protein molecules at the droplet surface; and the results of atomization studies indicating surface denaturation at the air−liquid interface of droplets in a spray and reduction of this instability by addition of

surfactants.[5] Foaming that has been observed to result from the shear forces occurring during atomization[36] is another phenomenon that could explain the inactivation of β-galactosidase.

Thus, we propose that, in the particular formulation and processing conditions examined, i.e., at low outlet temperatures and low excipient:protein ratios, thermal degradation was small, and the usual thermodynamic stabilization provided by sucrose[29] did not occur to a significant extent; rather, it was primarily surface denaturation that caused inactivation, and HP-β-CD inhibited this instability pathway. It is further proposed that HP-β-CD may impact

protein stability during spray-drying (i) by weak hydrophobic interaction between the oligosaccharide core and the protein nonpolar groups exposed by instability, hence inhibiting undesirable protein−protein and protein-interface interactions and (ii) by changing water properties since HP-β-CD is surface-active. The first of these mechanisms is partly cyclodextrin-specific, and may occur with nonderivatized cyclodextrins of different core dimensions, such as α-cyclodextrin,[13] but is also nonspecific, since any additives masking exposed nonpolar regions should prevent protein−interface interactions.

We believe that, depending on the processing conditions, spray-drying of proteins gives rise to a delicate balance between two instability pathways: thermal degradation and surface denaturation. Thermal degradation occurs in the interior of droplets due to the high water content in this region, but less at the droplet surface where there is less water.[37] It is consistent with the finding that thermal degradation is lower with smaller droplet size.[38] However, for surface denaturation at the droplet−air interface, it may be the opposite: it takes place at the surface and not in the interior, and it increases as droplet size decreases. That is why the ideal spray-dried formulation may necessitate a combination of differents excipients, such as a preferentially excluded stabilizer against thermal denaturation, and a surfactant against interfacial denaturation. Because of the number of effects involved, a multifactorial approach using factorial and/or composite designs[12,18] seems adequate.

In this study, oxidation was initially expected to be another possible degradation pathway.[29] This was not directly tested, e.g., through the use of dithiothreitol. However, the full enzymatic activity found for the cyclodextrin-containing formulation showed that if any oxidation was occurring, it did not affect the activity level of the formulation.

Besides the spray-drying process, the reconstitution step has to be considered explicitly. Aggregation is often observed to take place when dried proteins are reconstituted. It has been found that there may be differences in amount of aggregation based on additives in the initial solution as well as in the reconstitution medium.[39] In our study, the positive cyclodextrin effect might result from the ability of this excipient to prevent aggregation during the redissolution step. Additionally, if refolding occurred on reconstitution, then the presence of cyclodextrin would favor refolding because it would inhibit the off-pathway of aggregation. Overall, cyclodextrins may behave like naturally occurring chaperones that have similar functions in vivo.[40] From this viewpoint, the fast spray-drying process is attractive because, unlike freeze-drying, it occurs at nonequilibrium conditions, thus making less likely the achievement of a thermodynamically stable denatured state.[3] Therefore, on reconstitution, aggregation may not occur before refolding. In any case, our fractionation data suggested no aggregation, hence suggesting that the cyclodextrin effect took place during the process and not on reconstitution.

Conclusions

We used sucrose and hydroxypropyl-β-cyclodextrin (HP-β-CD) as stabilizing agents in the spray-drying of a model enzyme, β-galactosidase. Spray-drying without stabilizing agents significantly inactivated β-galactosidase. The reconstituted samples containing HP-β-CD exhibited full catalytic activity, but not those containing sucrose as the sole stabilizing agent. All samples exhibited similar thermal profiles and transition temperatures. No general effect of the spray-drying process or excipients was detected on the retention times of the protein chromatographic fractions, although the relative intensity of the 9.0 min fragment peak was slightly larger for the sucrose-containing sample. No spray-drying- or excipient-induced change in the molecular weight or relative amount of protein electrophoretical fractions was found. These findings are consistent with a hypothesis that the change responsible for inactivation of β-galactosidase was a subtle monomolecular, noncovalent change, i.e., the formation of incorrect structures, which arose from surface denaturation and weakened the catalytic properties of the protein, i.e., interfered with its active site. The data suggest that the cyclodextrin inhibited protein denaturation by preventing adsorption at the droplet−air interface. This stabilization mechanism occurred mainly during the process rather than on redissolution. Sucrose did not provide any stabilization, presumably because of the nonthermal nature of the stress.

Abstract □ Binary treatment modalities such as photodynamic therapy (PDT) and neutron capture therapy (NCT) combine low-toxicity electromagnetic irradiation with an appropriate radiation sensitizer to enhance selectivity for tumor targets. The porphyrin derivative tetrakiscarborane carboxylate ester of 2,4-(α,β-dihydroxyethyl) deuterioporphyrin IX (BOPP) shows tumor-selective uptake and is active in both treatment modalities. BOPP also chelates paramagnetic ions such as Mn^{2+}, and therefore its tissue accumulation and selectivity can be detected noninvasively by using magnetic resonance imaging. However, local and systemic toxicity appears elevated for the Mn^{2+} chelate (MnBOPP), but is poorly characterized. Here we have developed a liposomal formulation of MnBOPP and compared its toxicity with that of MnBOPP administered to mice in saline. The optimal liposome composition and maximal capacity to accommodate MnBOPP were investigated by differential scanning calorimetry and by encapsulation efficiency. MnBOPP was encapsulated quantitatively at up to 12 mol % (drug:lipid) in liposomes of varying composition, and remained incorporated during extended dialysis. Phase separation of drug- and lipid-rich domains was observed above 12% drug. MnBOPP in buffered saline was lethal to animals at 90 μmol/kg, and caused severe necrosis at the injection site at dose levels of 60 μmol/kg or greater. In contrast, MnBOPP formulated in liposomes was well tolerated at the highest tested dose of 135 μmol/kg, with the elimination of local toxicity.

Introduction

The combination of treatment modalities to achieve greater therapeutic effect and lower side effects is a frequent objective in the development of new cancer therapies. In such approaches as photodynamic therapy (PDT)[1,2] or neutron capture therapy (NCT),[3,4] electromagnetic radiation of comparatively low toxicity interacts with a sensitizer compound of low toxicity, and their combination results in a high cell-kill effect. In both cases, confining the irradiation to the disease field and confining the sensitizer to the tumor cells are essential for maximal selectivity of effect.

In NCT, selective uptake of boronated radiosensitizer compounds into tumor tissues is an important factor that determines the effectiveness of therapy.[3,5] A boronated porphyrin, the tetrakiscarborane carboxylate ester of 2,4-bis-(α,β-dihydroxyethyl) deuterioporphyrin IX (BOPP),[6] has shown selective tumor deposition in mice bearing C-6 murine glioma, and the ratio of BOPP taken up in brain tumor versus normal brain was 400:1.[7] An additional advantage of metalloporphyrins such as BOPP is that the porphyrin nucleus can chelate paramagnetic ions, such as manganese, while retaining their tumor-localizing property, so that the pharmacokinetics and selectivity of uptake can be monitored by noninvasive methods such as magnetic resonance imaging (MRI).[8,9] Therefore, the manganese chelate of BOPP (MnBOPP) is an agent of dual functions: that of a radiation sensitizer in boron NCT and that of a contrast agent for enhancement of tumors in MRI. In this dual-functional agent, boron serves as the key element for therapy and Mn serves as the key element for MRI contrast enhancement. By combining an imaging function with a therapeutic function, therapy could be individualized both to patients and to the disease state, and irradiation could be applied at the time of peak tumor selectivity or effect.

Previously we demonstrated that MnBOPP is selectively localized in intracranial 9L brain tumors in rats,[10] a tumor model that bears many similarities to *Glioblastoma multiforme*, a lethal human brain tumor.[11] In MRIs, the uptake of MnBOPP significantly enhanced the contrast between tumor and normal brain. Preliminary results in our laboratory also suggested that high doses of MnBOPP administered in saline had acute systemic toxicity and delayed chronic toxicity, and that drug encapsulated in liposomes was better tolerated by animals at high doses (≥100 μmol/kg, unpublished data). Moreover, the magnitude of brain tumor contrast enhancement in MRIs suggested that there was comparable tumor-selective uptake of MnBOPP for both the saline and liposomal forms. Peak contrast enhancement was observed at ~24 and 70 h after administration of free and liposomal MnBOPP, respectively.[12] Because liposomes offer the possibility for high-dose administration of MnBOPP with reduced toxicity, we have investigated the optimal conditions for liposomal encapsulation of MnBOPP and compared the in vivo toxic effects of liposomal MnBOPP with that of drug administered in buffered saline.

phatidylethanolamine (DSPE) were purchased from Avanti Polar Lipids (Alabaster, AL). Cholesterol (CHOL) was from Sigma Chemicals (St. Louis, MO) and was recrystallized three times from methanol prior to use. MnBOPP (molecular weight 1485) was synthesized as described previously.[6] Female BALB/C mice (6 weeks, 20−25 g) were purchased from Harlan Sprague Dawley (Indianapolis, IN).

Preparation of Liposomes—Liposomes were prepared by a reversed-phase evaporation (REV) procedure.[13] Typically, 10 μmol of phospholipid in chloroform were mixed at defined ratios with MnBOPP dissolved in methanol (4−5 mM), and the solvents were removed with a rotary evaporator. The dried film of drug and lipid was then resuspended in 0.5−1.0 mL of isopropyl ether, emulsified by brief (15 s) sonication after the addition of 350 μL of saline/HEPES buffer (140 mM NaCl, 20 mM *N*-2-hydroxyethyl-piperazine-*N*′-[2 ethanesulfonic acid], pH 7.4, osmolality 290 mOsm/kg), and converted into a liposome suspension by removal of ether under reduced pressure. Liposome preparations were extruded to a final diameter of ~0.08−0.10 μM by passing three times each under high pressure (~1250 kPa or 185 psi) through double-stacked polycarbonate membranes of decreasing pore size (1, 0.4, 0.2, and 0.08 μm) with a gas extruder (Mico Instrument, Middleton, WI). Extruded liposomes were then dialyzed free of residual drug with a membrane tubing having a molecular weight cutoff of 12 000−14 000 Da (Spectrapor Medical Industries, Los Angeles, CA). Dialysis was performed overnight at 4 °C against three changes of a 400-fold excess of saline/HEPES buffer.

Analytical Methods—The drug concentration in liposome samples before and after processing was determined spectrophotometrically after extraction from liposomes using methanol. The visible absorption spectrum of MnBOPP dissolved in methanol has peaks at 367 and 460 nm. A calibration curve was constructed for optical density at 460 nm as a function of MnBOPP concentration in methanol. Phospholipid concentrations were determined by phosphorus assay.[14] The results were expressed as "encapsulation efficiency", which is defined as the drug:lipid ratio after dialysis divided by the initial drug:lipid ratio (i.e., before extrusion or other processing).

Differential scanning calorimetry (DSC) was performed on a Perkin-Elmer DSC-2C instrument with samples sealed in aluminum pans. Thermograms were acquired and recorded on chart paper using a scan speed of 2.5 K/min, a sensitivity setting of 1 mCal/s, a temperature range of 20−60 °C, and a chart speed of 40 mm/min. After acquisition, the data were input into a computer (Macintosh, Apple Inc., Cupertino, CA) using a digital scanner and DataThief (National Institute for Nuclear Physics and High Energy Physics (NIKHEF), Amsterdam, The Netherlands), a program that extracts scanned data into a digital form. The DSC instrument was calibrated over a wide range of temperatures using various standard samples provided by the manufacturer. Each sample contained 14 μL of liposomes at a phospholipid concentration of 55 mM, and the drug:lipid molar ratios investigated were 0, 3, 7, 11, and 15% (moles of drug per 100 mol phospholipid). Thermograms were also obtained for MnBOPP dissolved in saline/HEPES buffer. All samples were maintained at the initial temperature (295 K) for 15 min to ensure temperature equilibration.

Experiments In Vivo—MnBOPP was administered to mice in saline/HEPES buffer at doses of 45, 60, 75, and 90 μmol drug per kilogram of body weight. The dose range for liposomal drug was 75, 90, 110, and 135 μmol/kg. Six mice per group were treated at each dose level, and the drug was injected via tail vein. The injection volume was <0.3 mL/20 gm body weight. After injection, the mice were observed for mortality and weighed regularly for 6 weeks. The maximum tolerated dose (MTD) is defined as the dose at which animals survived but had ~10% weight loss.

Results

Optimization of the Liposome Formulation—Preliminary experiments raised concern over potential local and systemic toxicity of the Mn^{2+} chelate of BOPP (data not shown), and liposomes were investigated for mitigation of the toxicity. Although MnBOPP is moderately water soluble, it appeared also to be incorporated quantitatively in liposomes, which suggested localization of the drug in the liposome membrane phase (data not shown). Therefore,

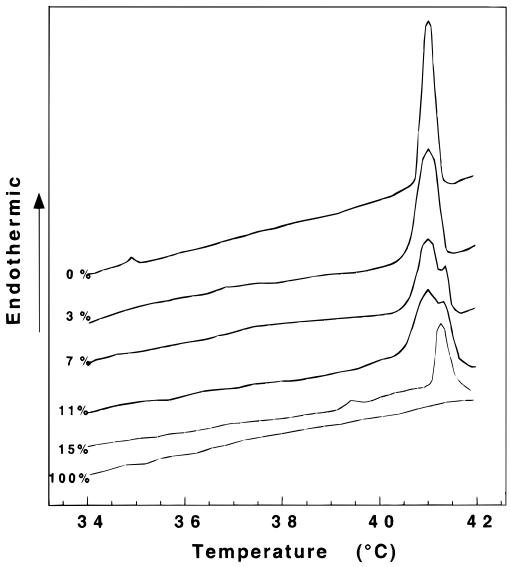

Figure 1—Incorporation of MnBOPP in lipid bilayers. DSC thermograms of DPPC liposomes containing various molar ratios of MnBOPP. Liposomes composed of DPPC and the indicated amount of drug were made, processed, and analyzed by DSC as described in Experimental Procedures. The drug:lipid ratios varied from 0% (no drug) to 100% (no phospholipids). The ratio is calculated as the number of moles of drug per 100 mol of phospholipid; the phospholipid concentration was not adjusted, i.e., the total moles of drug and phospholipid do not sum to 100%.

the interactions between MnBOPP and liposome membrane constituents were investigated in greater detail. The drug:lipid ratio was varied, and the effect on membrane structure was investigated by DSC. DPPC was used as the predominant phospholipid because of its highly cooperative and well-defined phase transition at 41.3 °C. DPPC liposomes without drug showed a large, sharp transition at ~41 °C (Figure 1). MnBOPP alone did not undergo a distinct phase transition, as indicated in Figure 1 by the thermogram for 100% MnBOPP.

Inclusion of 3 mol % MnBOPP in DPPC bilayers (3 mol drug in 100 mol phospholipid) resulted in broadening of the main transition. The transition width at half-height increased from 0.3 to 0.46 °C. At 7 mol % MnBOPP, the main transition peak was further broadened and a shoulder appeared on the high-temperature side, suggesting the formation of a new phase that was possibly enriched in MnBOPP. Because this phase melts at higher temperature, lipid packing in the new phase may be different from, and tighter than, the lipid-rich domain. This new phase became more prominent at 11 mol % MnBOPP, and at 15 mol % MnBOPP, the predominant transition occurred at the temperature characteristic of the new MnBOPP-rich phase. Concomitantly, the transition endotherm characteristic of pure DPPC disappeared. The new phase apparently resulted from interactions between MnBOPP and DPPC; MnBOPP itself does not undergo a thermal transition in this temperature range, and DPPC undergoes a thermal transition at a lower temperature. Based on the DSC results, 10−12 mol % was hypothesized as the maximum capacity for DPPC bilayers to accommodate MnBOPP.

MnBOPP incorporation into DPPC membranes was investigated quantitatively as a function of the initial drug:lipid ratio. Ratios were included that were above and below the optimal suggested by DSC experiments (Figure 1). Following preparation of the liposomes, extrusion through controlled-pore membranes was performed to remove unincorporated drug that had precipitated.[15] Liposomes pass through the membrane pores, and are extruded to a diameter that approximately equals the pore size of the filter.[16] Because extrusion would not remove unencapsu-

Table 1—Encapsulation Efficiency of MnBOPP in DPPC Liposomes[a]

initial drug:lipid ratio, %[b]	drug:lipid ratio after extrusion, %[b]	drug:lipid ratio after dialysis, %[b]	encapsulation efficiency, %[c]
4	3.8 ± 0.46	3.6 ± 0.47	91 ± 11
8	7.6 ± 0.25	7.1 ± 1.5	89 ± 2
12	11.6 ± 0.36	11.0 ± 0.25	91 ± 3
20	11.6 ± 0.46	11.5 ± 0.68	57 ± 5

[a] Data are expressed as mean ± standard deviation from at least 3 experiments. [b] Drug:lipid ratio is the molar ratio between MnBOPP and DPPC phospholipid. [c] Encapsulation efficiency is defined as the ratio between the final (after dialysis) and initial drug/lipid ratio.

lated drug molecules that are in soluble monomer or micellar form, dialysis was performed after extrusion, and the drug:lipid ratio was determined before and after each processing step.

At drug:lipid ratios of ≤10 mol % (MnBOPP:DPPC), incorporation of drug was quantitative (Table 1), which is a characteristic of lipophilic agents located within the membrane bilayer. Neither extrusion nor dialysis reduced the drug:lipid ratio significantly (Table 1), suggesting a lack of substantial precipitated MnBOPP or unincorporated drug in monomer or micellar form. Dialysis was prolonged, and MnBOPP retention in the liposome further suggested stable incorporation of the drug in the bilayer.

For drug:lipid ratios ≥10 mol %, a plateau value of ~12 mol % (MnBOPP:DPPC) incorporation was observed after extrusion. This ratio was determined to be the maximal drug:lipid ratio achievable in DPPC membranes.

The membrane physical state can have major impact on both liposome performance in vivo and on the incorporation of lipophilic molecules. Therefore, encapsulation efficiency was investigated for a selection of liposome compositions that represent a broad range of physical or in vivo performance properties. This selection of compositions (Table 2) included low- and high-transition temperature phospholipids, charged and neutral (zwitterionic) compositions, cholesterol-containing formulations, and polymer-coated liposomes with extended circulation times in vivo.[17] Table 2 shows the effect of lipid composition on the incorporation of MnBOPP. Three phosphatidylcholines (EPC, DPPC, and DSPC) were tested individually, with or without cholesterol, at initial drug:lipid ratios of ~8%. For EPC liposomes, in which the bilayer is in a fluid state, the drug:lipid ratio achieved was ~7% following extrusion, and subsequent dialysis had little effect on the incorporation of MnBOPP. The addition of CHOL had little effect on the encapsulation efficiency in EPC liposomes.

For DPPC liposomes, in which the bilayer exists in the gel phase, encapsulation efficiency was similarly high. The addition of CHOL to DPPC liposomes did not alter MnBOPP incorporation.

In contrast, the drug:lipid ratio achieved for DSPC liposomes prepared with an 8 mol % drug:lipid ratio, the MnBOPP incorporation was ~3.4 mol % after extrusion; overall, only 40% of the initial drug was incorporated. Like DPPC liposomes, DSPC liposomes exist in the gel phase at room temperature. However, the DSPC acyl chain length is greater. The addition of CHOL, which broadens the phase transition and imparts a fluidizing effect, did not increase MnBOPP incorporation markedly.

Liposomes bearing hydrophilic polymer headgroups, such as PEG, and consisting of high-transition temperature phospholipids show greatly extended circulation times in vivo[17,18] as well as intratumor deposition.[18,19] MnBOPP incorporation into PEG-bearing liposomes was investigated for both fluid (EPC) and gel-phase (DPPC) lipids. MnBOPP was incorporated nearly quantitatively in either composition, and the maximal mole ratio achieved was 12% (Table 2).

Comparative Toxicity of MnBOPP Formulations—Free or liposomal MnBOPP was administered to healthy mice at various dose levels to determine the effect of formulation on the maximum tolerated dose (MTD) of the drug. Body weight and vital signs (respiration, heart rate) of the animals were monitored after bolus injection. Preliminary experiments using 2 mice per group showed that 100% (2 of 2) of the animals died following administration of free MnBOPP at a dose of 100 μmol/kg, whereas all survived at 80 μmol/kg (data not shown). A more comprehensive experiment with 6 mice per group showed that 90 μmol/kg free MnBOPP was lethal, resulting in 80% death (5 of 6 animals) within 48 h after injection. For all other doses tested, all animals survived the treatment (data not shown).

Figure 2 shows the percent body weight change following injection of free MnBOPP. MnBOPP at 75 μmol/kg mediated 11% weight loss, which did not recover until 30 days after injection. Local necrosis was observed at the injection site 24 h after injection in animals treated with ≥60 μmol/kg of free drug. Doses of 45 μmol/kg caused ~4% weight loss that recovered within 10 days after injection. Based on body weight changes, the MTD of free MnBOPP appeared to be ~75 μmol/kg.

Two liposome compositions incorporating MnBOPP, PEG−DSPE:EPC:CHOL (1:10:5) and PEG−DSPE:DPPC:CHOL (1:10:5), were tested in preliminary dose-ranging experiments using small numbers of animals. The two liposome formulations appeared to cause similar weight change profiles in mice (data not shown); therefore, only the PEG−DSPE:DPPC:CHOL (1:10:5) liposome formulation was selected for investigation with a larger number of animals. All animals survived injection of MnBOPP at doses up to 135 μmol/kg, and no necrosis was observed at the injection site. Observation of the animals was continued for 3 months. The maximal weight loss (~8%) occurred at the 135 μmol/kg dose level, and the body weight did not recover until day 40 after injection (Figure 3). However,

Table 2—Effect of Lipid Composition on Drug:Lipid Molar Ratios Achieved[a]

lipid composition	initial drug:lipid ratio, %[b]	drug:lipid ratio after extrusion, %[b]	drug:lipid ratio after dialysis, %[b]	encapsulation efficiency, %[c]
EPC	8.0 ± 0.3	7.0 ± 0.4	6.9 ± 0.2	87 ± 5
EPC/CHOL (2:1)	8.0 ± 0.5	6.4 ± 0.9	6.4 ± 1.2	80 ± 15
DPPC	8.0 ± 0.5	7.6 ± 0.5	7.3 ± 0.2	92 ± 4
DPPC/CHOL (2:1)	8.0 ± 0.2	7.4 ± 0.2	7.5 ± 0.5	94 ± 5
DSPC	8.0 ± 1.7	3.4 ± 0.8	3.1 ± 0.1	40 ± 9
DSPC/CHOL (2:1)	8.0 ± 1.0	4.3 ± 0.3	3.9 ± 0.7	50 ± 6
PEG–DSPE/EPC/CHOL (1:10:5)	12.3 ± 0.6	11.8 ± 1.1	11.0 ± 1.8	89 ± 11
PEG–DSPE/DPPC/CHOL (1:10:5)	12.3 ± 0.8	11.9 ± 1.3	10.5 ± 0.9	94 ± 3

[a] Data are expressed as mean ± standard deviation from at least 3 experiments. [b] Drug:lipid ratio is the molar ratio between MnBOPP and DPPC phospholipid. The ratio is calculated as the number of moles of drug per 100 mol of phospholipid. [c] Encapsulation efficiency is defined as the ratio between the final (after dialysis) and initial drug/lipid ratio.

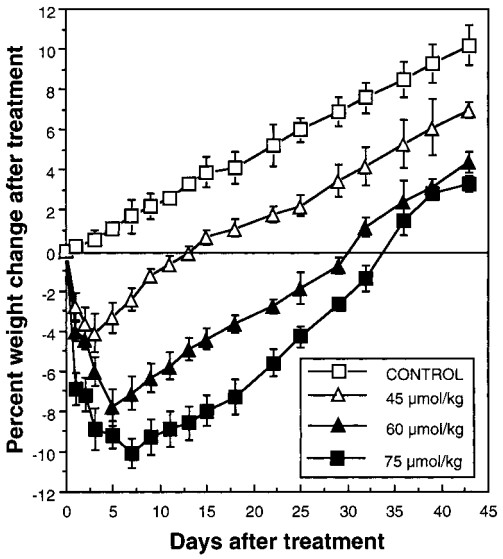

Figure 2—Toxicity of MnBOPP in saline. Body weight changes of mice were recorded after injection of MnBOPP dissolved in buffered saline. The concentration of MnBOPP was 10 mM in saline/HEPES buffer (140 mM, 20 mM, pH 7.4, osmolality 290 mOsm), and the volume of one injection was <0.3 mL/20 gm body weight. The weight change of each animal was normalized to its weight before injection, and each point represents the mean ± standard deviation for each group ($n = 6$).

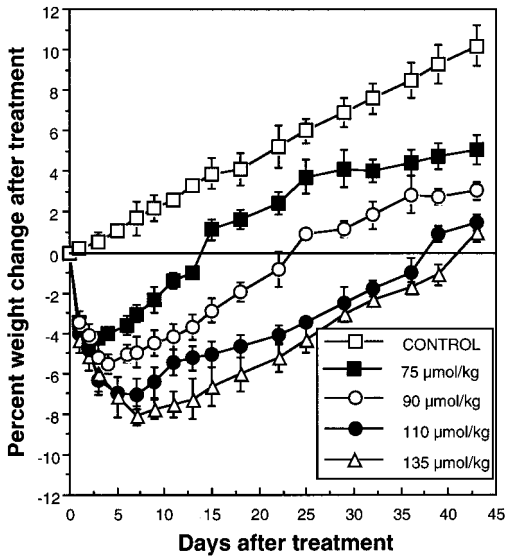

Figure 3—Toxicity of liposomal MnBOPP. Body weight changes of mice were recorded after injection of MnBOPP encapsulated in liposomes. MnBOPP was incorporated at a molar ratio of 12% (with respect to phospholipid) in liposomes composed of PEG–DSPE:DPPC:CHOL (1:10:5). The drug concentration was ~8 mM. If the volume required for a specific dose was >0.3 mL/20 gm body weight, it was split into two injections with an interval of ~10 min. The weight change of each animal was normalized to its weight before injection, and each point represents the mean ± standard deviation for each group ($n = 6$).

the MTD, defined as a 10% loss in body weight, was not observed in the dose range tested for either PEG−DSPE:EPC:CHOL (1:10:5) or PEG−DSPE:DPPC:CHOL (1:10:5) liposomes containing MnBOPP, even though the highest dose tested (135 μmol/kg) was nearly twice the tolerated dose of free drug (75 μmol/kg).

Discussion

Selective delivery of a sufficient quantity of boron (^{10}B) compound to the tumor site via the systemic route is a key requirement for the success of boron NCT as a tumoricidal modality.[3,4] In addition, the selective deposition of MnBOPP in tumor tissues may facilitate its application in diagnosis as an MRI contrast-enhancing agent.[10]

Here we established that the MTD of MnBOPP in saline was ~75 μmol/kg, as judged by body weight loss of animals. However, even at that dose, considerable injection-site toxicity was noted. The MTD determined here for the manganese chelate of BOPP is significantly lower than the MTD of ~200 mg/kg (147 μmol/kg) determined previously for the nonmetalated compound in mice.[7] Thus, free MnBOPP is roughly twice as toxic as BOPP. From the standpoint of dose-limiting systemic toxicity and local injection-site toxicity, mitigation of these effects using liposomes may aid in clinical application of the promising Mn-containing compound.

Liposomes have been shown to reduce the systemic toxicity of encapsulated drugs, and liposomes of small size bearing PEG moieties on the surface have shown enhanced tumor uptake.[17,18,20] Because of the beneficial effects of encapsulation on toxicity and selectivity of deposition, liposomes hold considerable promise for the delivery of boronated compounds in NCT.[21−24] With the reduction in toxicity observed here, dose escalation and possibly increased tumor uptake of MnBOPP may be achievable via liposome encapsulation. However, liposomal formulation of lipophilic compounds involves optimization of the large number of parameters that affect stability;[25−27] these parameters include the preferred membrane physical state, determined by the phase transition temperature (T_m) of the predominant lipid constituent, the lipid acyl chain composition, and the CHOL content, which both modifies T_m and has the effect of stabilizing liposomes in vivo. Additional parameters having impact on drug incorporation include the liposome membrane charge and the presence of surface-localized hydrophilic polymers.

To approach this problem of multiparameter optimization, a prototype liposome formulation was chosen; DPPC, a phospholipid with a defined phase transition, was used as a probe for membrane interaction of the drug. A maximal drug:lipid ratio was determined qualitatively by DSC. In the case of MnBOPP, exceeding the maximal capacity of the bilayer to accommodate the drug was manifested by the appearance of a new, higher-melting drug:lipid phase. This behavior contrasts with other cases,[15,28] in which exceeding the maximum drug:lipid ratio may be marked by an abrupt reappearance of the original T_m of the pure phospholipid component when catastrophic destabilization results in precipitation of drug outside of the membrane environment. An additional advantage of the use of DSC is that the progressive, MnBOPP-dependent changes observed in the T_m confirmed interaction of the drug with the bilayer of the membrane as well as suggested the existence of an unusual, higher-melting drug:lipid complex involving a specific lamellar phase state of the lipid. This unusual phase may be worthy of future study because it suggests the possibility for developing drug-rich particles that may be structurally distinct from liposomes (cf. ref 29).

The qualitative overview of bilayer maximal capacity for drug provided by DSC was investigated in greater detail using simple methodology to quantify the drug:lipid ratio; this investigation involved manipulations to resolve precipitated and weakly associated drug. Extrusion of liposomes through controlled-pore filters[16] not only redefines the mean diameter to a size that circulates more readily in the blood, but also allows the separation of liposomes from precipitated drug.[15] The subsequent dialysis step was performed to eliminate micellar or monomer drug because it would not be removed from liposomes during the extrusion step. Overnight dialysis had little effect on MnBOPP

incorporation, suggesting reasonably stable incorporation of the drug in the membrane.

Once the approximate bilayer capacity for MnBOPP was established using a prototype phospholipid, a small number of liposome compositions were chosen for further investigation, and these represented broad differences in membrane properties and in vivo performance. We observed quantitative incorporation of MnBOPP in most of these formulations, suggesting considerable latitude in selecting liposome constituents. A lack of such latitude could limit the ability to overcome possible future challenges posed as specific in vivo performance objectives are pursued.

The membrane physical state, governed largely by the T_m of the predominant lipid constituent, is a major parameter that affects the performance of liposomes in vivo.[30−32] In this study, liposomes encapsulating MnBOPP were formed from each of three phospatidylcholines (egg PC, DPPC, and DSPC) having increasing T_m. EPC (T_m, −5 to −17 °C) exists in the liquid crystalline state at room temperature, whereas DPPC (T_m, 41.3 °C) and DSPC (T_m, 55.8 °C) exist in the gel state. At room temperature or body temperature, membrane fluidity is decreased in the order EPC > DPPC > DSPC, as indicated by the T_m (EPC < DPPC < DSPC). Both fluid- (EPC) and gel-phase (DPPC) liposomes incorporated MnBOPP quantitatively. Interestingly, the nature of the gel-phase lipid had a major effect on drug incorporation; DSPC, which also forms gel-phase liposomes, had the lowest MnBOPP incorporation capacity (Table 2). This observation may be explained by the highly ordered, cooperative packing of lipid molecules in the gel phase. More fluid membranes, such as DPPC and EPC, may better accommodate bulky, lipid-soluble drugs such as MnBOPP within the bilayers because these lipid bilayers tend to have more disordered hydrocarbon domains.

Cholesterol was tested as a constituent in several formulations. Cholesterol increases the packing density of the phospholipid bilayer by inserting itself between the lipid molecules, resulting in decreased permeability of phospholipid bilayer to small polar molecules and preventing plasma proteins from penetrating.[26,33] Physical stability of liposomes often is enhanced by incorporation of CHOL in the bilayer.[26] Cholesterol also increases the disorder within bilayer, resulting in broadening or elimination of the T_m.[30−32] In this study, the addition of CHOL in EPC- or DPPC-containing liposomes did not change the drug: lipid ratio significantly (Table 2) at a molar ratio of 1:2 (CHOL:phospholipid), suggesting that CHOL did not alter significantly the interaction between EPC or DPPC and MnBOPP molecules. Interestingly, CHOL did not increase the incorporation of MnBOPP in DSPC liposomes, despite the broadening effect of CHOL on the T_m.[31,32]

The PEG headgroup of the PEG−DSPE lipid provides a hydrated coating on the surface of liposome and can hinder the access of plasma proteins to the liposome surface; such "sterically stabilized liposomes" (SSLs)[34] have shown a 5-fold increase in circulation time compared with liposomes without the surface coating.[18] The altered pharmacokinetics may allow increased extravasation of liposomes into tumors, resulting in the enhanced antitumor effect seen in various preclinical and clinical trials.[17] Here, PEG-containing liposomes of both fluid- and gel-phase lipids incorporated MnBOPP as efficiently as the optimal non-PEG formulations.

MnBOPP encapsulated in liposomes was much better tolerated than the free drug. The MTD of free MnBOPP in mice was ~75 μmol/kg, whereas that of the liposomal drug exceeded 135 μmol/kg for the PEG−DSPE-containing formulations that included either EPC or DPPC as the predominant lipid constituent. We observed previously[12] that tumor accumulation of MnBOPP administered in a prototype liposomal form was roughly comparable to that observed for free MnBOPP. The high incorporation of MnBOPP in the diverse liposome compositions defined here provides the opportunity to optimize further the tumor deposition in vivo and shows clearly the potential to increase the dose intensity of MnBOPP, with the aim of further enhancement in tumor delivery.

The amount of phospholipid required to administer the highest dose of MnBOPP (135 μmol/kg) was ~28 μmol lipid per animal. Although this concentration of lipid is high, we have previously administered comparable doses of liposomes to mice[35] up to 9 times in 3 weeks. Although those liposomes contained high concentrations of paclitaxel, a cytotoxic agent, all animals administered a dose of 30 μmol lipid per injection survived the entire 9-course treatment. Caution must be exercised in using these previous experiments to interpret the present results because different lipid compositions were used, and the liposomes contained a potent cytotoxic agent. However, the compositions used here would be cleared less rapidly to the lung, liver, and spleen than those used previously, and thus should have relatively less impact on the overall health of the animal. Thus, liposomal encapsulation appears to provide a means to administer higher doses of MnBOPP with reduced toxicity.

Abstract □ The potential utility of a pulse dose of a deuterium-labeled isotopomer (FLU-D_4) in elucidating the pharmacokinetics of fluphenazine (FLU) at steady state was investigated in dogs. The single-dose oral pharmacokinetics of FLU in dogs were established. After resting the dogs for 3 weeks, the animals were dosed to steady state with oral FLU administered at 12-h intervals. Following 15 doses, one dose of FLU was replaced by a pulse dose of FLU-D_4, after which dosing with FLU was resumed. FLU and FLU-D_4 plasma concentrations were determined by tandem mass spectrometry. Comparable estimates of apparent oral clearance were calculated from (i) a single dose of FLU, (ii) a pulse dose of FLU-D_4, and (iii) over a dosing interval at steady state. Average steady-state plasma concentrations were reliably predictable from a pulse dose of FLU-D_4.

Introduction

A difficult task facing the psychiatrist is the determination of the optimal dose of neuroleptic for an individual patient in the acute phase of a psychosis because therapeutic effects of treatment with classical neuroleptics generally require 2−4 weeks to become optimal. Aggressive dosing in the early stages of treatment, however, may lead to the establishment of unnecessarily high maintenance doses.[1] Dysken and co-workers[2] suggested that a therapeutic window of 0.2 to 2.8 ng/mL trough concentrations of fluphenazine (FLU) in plasma was appropriate for schizophrenic patients. These early studies, however, gave no indication of the extent to which aberrantly high plasma levels are associated with inferior antipsychotic response.[3] A more recent and more sophisticated study by Van Putten and colleagues[4,5] employed logistic regression and survival analysis to examine relationships between plasma concentrations of FLU, estimated probability of improvement, and estimated probability of disabling side effects. Disabling side effects were defined as "side effects that significantly interfered with patients' functioning" or "side effects that outweigh therapeutic effects." The study showed that the probability of improvement increased as plasma FLU concentrations approached 4.0 ng/mL, but so did the probability of disabling side effects. It was found that the maximum probability of improvement without disabling side effects occurred at a plasma FLU concentration of 0.7 ng/mL.[5] Thus, patients who tolerate the drug well may benefit from plasma concentrations >1.0 ng/mL, whereas poorly responding patients with plasma levels of 4.0 ng/mL and above may benefit from a reduction in dosage. These data have provided a more rational basis for the use of plasma concentration data in FLU posology.

The acquisition of pharmacokinetic data from floridly psychotic acute schizophrenics, however, is difficult or impossible because these patients are usually too ill to be able to cooperate by providing samples of body fluids. It is certainly not appropriate to interrupt therapy to obtain single-dose pharmacokinetic data. In this situation, therefore, individualized pharmacokinetic information must be acquired after the clinical condition of the patient has been stabilized by treatment with a neuroleptic drug such as FLU. The use of a pulse dose of a stable isotopomer to assess the pharmacokinetics of a single dose of the drug while at steady state[6] is an appealing technique for two reasons: (i) there is no need to interrupt therapy or to disturb the steady state of active drug; and (ii) stabilized schizophrenic out-patients under maintenance therapy with oral FLU often take their medication at uneven time intervals, which renders uncertain any attempt to estimate pharmacokinetic parameters from plasma concentrations of unlabeled drug at steady state.

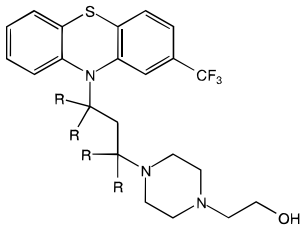

Figure 1—Structures FLU (R = H) and tetradeuterated FLU (R = ^{2}H).

FLU is a lipophilic drug that exhibits after intravenous dosing in humans (Midha et al., unpublished data), a very large apparent volume of distribution (398 ± 202 L), a relatively short half-life (13.1 ± 4.1 h), and a systemic clearance (23.0 ± 12.3 L/h) of ∼25% of liver blood flow. Similar results were obtained after beagle dogs were dosed intravenously with FLU:[7] a large volume of distribution (51.0 ± 17.8 L), a relatively short half-life (6.0 ± 1.5 h), and a systemic clearance (5.8 ± 1.0 L/h) of ∼40% of liver blood flow. These data suggest that FLU undergoes extensive tissue distribution/binding in both humans and dogs. The present exploratory study in dogs was designed to test the hypothesis that exchange of isotopomer with unlabeled drug in tissue compartments would not impede the utility of the technique in practical terms. A tetradeuterated isotopomer (FLU-D_4, Figure 1) to be used in such studies was prepared in these laboratories[8] and was shown to be free of any isotopic metabolic effects in either humans[9] or dogs.[10]

Materials and Methods

Chemicals and Reagents—FLU dihydrochloride was purchased from Sigma-Aldrich Canada, Ltd. (Ontario, Canada). FLU-D_4 was synthesized in our laboratories as described previously.[8] The isotopic purity of FLU-D_4 was >99%. Oral solutions containing FLU dihydrochloride equivalent to 1 mg/mL FLU base in distilled water were prepared daily. Oral solutions of the FLU-D_4 were

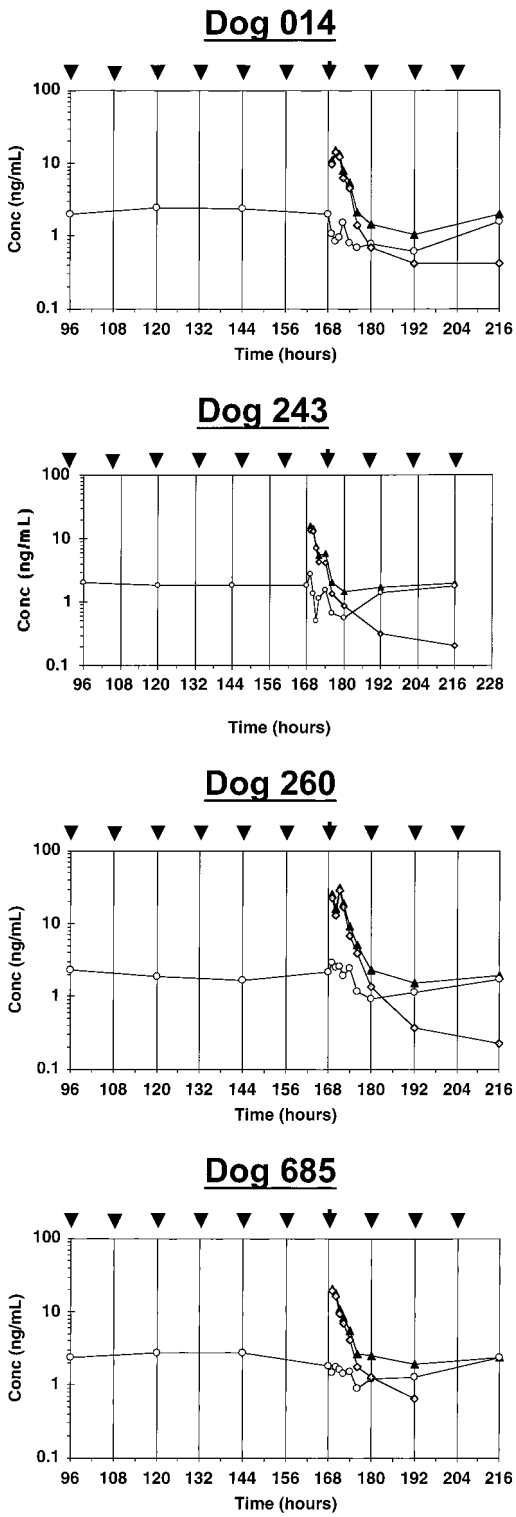

Figure 2—Steady-state trough plasma concentrations over the interval 96–216 h after the initial dose for FLU (circles), FLU-D_4 (diamonds), and total (FLU plus FLU-D_4, triangles) in four dogs. In each panel, black darts represent doses of FLU at 12-h intervals and the gray dart represents the pulse dose of FLU-D_4.

prepared in the same manner. Solvents and other chemicals were of analytical grade and were used without further purification.

Animals and Study Design—The study protocol was approved by the University of Saskatchewan Animal Care Committee. The experiments were carried out according to the Principles of Laboratory Animal Care (NIH Publication #85-23, revised 1985) and under conditions specified by the Canadian Council on Animal Care. Four pure bred female beagle dogs (ID nos. 014, 243, 260, and 685), ranging in weight (initially) from 7.0 to 9.5 kg (mean 8.1 ± 1.1 kg), were used. For each dose, the oral solution (2 mL, containing FLU or FLU-D_4 hydrochloride equivalent to 2 mg of the corresponding base) was trickled from a syringe (3 mL) into the right side of the dog's mouth over a period of 2−3 min. Immediately after administration of the oral solution, the right side of the mouth was slowly irrigated with 5 mL of distilled water. The oral pharmacokinetics of unlabeled FLU were determined from serial blood samples (5 mL) drawn via an indwelling jugular catheter at 0 (predose) and 0.25, 0.5, 1, 2, 4, 6, 8, 12, 24, 36, and 48 h after a single oral dose. The animals were rested for 3 weeks, after which they were dosed to steady state with unlabeled FLU administered at 12-h intervals (09:00 and 21:00 h). After administration of 15 doses of FLU (168 h after the initial dose), the dogs were re-weighed and a pulse dose of FLU-D_4 was given in place of a regular dose of FLU. Blood samples (5 mL) were harvested immediately prior to administration of FLU-D_4 and at 1, 2, 3, 4, 6, 8, 12, 24, 36, and 48 h post FLU-D_4. (Unfortunately the blood samples at 36 h were lost because of a technical error). Administration of unlabeled drug was resumed for a total of three doses post FLU-D_4, as shown in Figure 2. Trough steady-state plasma concentrations were established as the arithmetic mean of minimum concentrations (C_{min}) of FLU plasma concentrations harvested at 72, 96, 120, 144, and 168 h after the initial dose and of total (FLU+FLU-D_4) C_{min} plasma concentrations at 180, 192, and 216 h post initial dose. After collection of each sample, plasma was separated by centrifugation within 0.5 h and frozen (−20 °C) until analysis. Concentrations of FLU and FLU-D_4 in plasma were monitored by means of a validated tandem mass spectrometry technique[11] with a lower limit of detection of 25 pg/mL for both FLU and FLU-D_4, and overall coefficients of variation of 4.82% for FLU and 4.72% for FLU-D_4.

Pharmacokinetic Analysis—The plasma concentrations versus time data for both FLU-D_4 and FLU were analyzed by noncompartmental methods (WinNonlin Version 1.1). Steady-state trough plasma concentrations were estimated as the mean of eight measurements, five taken before administration of the pulse dose of FLU-D_4 and three taken post pulse dose. The accumulation index (R_{ac})[12] was estimated according to eq 1:

$$R_{ac} = \frac{\mathbf{1}}{(\mathbf{1} - e^{-k\tau})} \tag{1}$$

where τ is the dosing interval, and k is an estimated apparent terminal elimination rate constant following a single oral dose. The average plasma concentration of drug at steady state ($Cpss_{av}$) was calculated according to eq 2:

$$Cpss_{av} = \frac{AUC_\tau}{\tau} \tag{2}$$

where AUC_τ was estimated from the total plasma concentration (FLU plus FLU-D_4). Apparent oral clearances (CL_O) were estimated variously as (i) dose/AUC_∞ from a single dose of FLU, (ii) dose/AUC_∞ from a pulse dose of FLU-D_4, and (iii) dose/AUC_τ calculated from the sum of FLU and FLU-D_4 plasma concentrations in dogs at steady state. Apparent volumes of distribution (V_d) were estimated as the quotient of CL_o and k.

A relationship between CL_o and $Cpss_{av}$ was established as follows:[12]

$$Cpss_{av} \propto A$$

$$Cpss_{av} \times V_d = A$$

$$Cpss_{av} \times CL = A \times k = \frac{F \times \text{Dose}}{\tau}$$

$$Cpss_{av} = \frac{F \times \text{Dose}}{CL \times \tau} = \frac{\text{Dose}}{CL_o \times \tau} \tag{3}$$

where A is the amount of drug in the body.

Results and Discussion

FLU and FLU-D_4 (Figure 1) were shown previously to give virtually identical plasma concentration versus time

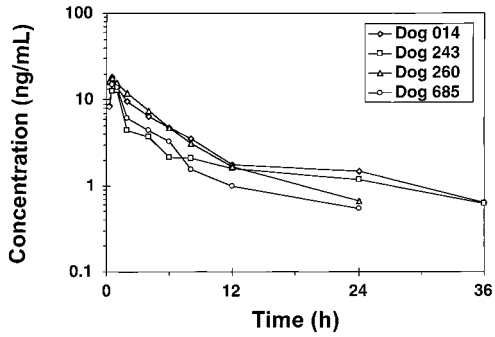

Figure 3—Plasma concentration versus time curves after single oral doses of FLU in four dogs.

profiles in schizophrenic patients[9] and in beagle dogs.[10] It was thereby concluded that the isotopomer was devoid of any isotopic metabolic effects in either humans or dogs.

After a single oral dose, plasma concentrations of FLU were measurable up to 24 h in two dogs and up to 36 h in the remaining two (Figure 3). The very short t_{max} (0.25 h in 1/4 dogs and 0.5 h in 3/4 dogs) may have been attributable to rapid absorption through the buccal mucosae. This method of administration was chosen for two reasons. Earlier (unpublished) experiments had shown that oral administration of the drug in gelatin capsules to dogs led to erratic absorption characteristics. Administration of an oral solution was clearly desirable but it was not practicable to inflict gastric intubation on the animals twice a day for 1.5 weeks. Thus, the irrigated oral solution was the best compromise to give minimal variability. The apparent elimination half-life of FLU after the single oral dose was 12.75 ± 3.25 h, which is comparable to that obtained[13] after a single oral dose in humans, but at variance with an earlier study from our laboratories[7] in which the reported half-life was 6.0 ± 1.5 h after intravenous administration of FLU in four different beagle dogs (ID nos. 236, 244, 341, 960).

Once dosing to steady state with a lipophilic drug has commenced, drug from each successive dose undergoes exchange with drug from earlier doses sequestered in deep compartments. In the present study, dosing at 12-h intervals with unlabeled drug was continued until the dogs had received 15 doses, which in clinical terms would be a minimum number of doses after which rational dosage adjustments might be attempted. Moreover, it is possible that the deep compartments were fully loaded at this point. Individual plasma concentration versus time plots rather than averaged data are shown in Figure 2 to give an impression of (i) the steady state, (ii) the profile of the pulse dose of FLU-D_4, and (iii) the behavior of unlabeled FLU after the administration of the pulse dose of isotopomer.

Figure 2 shows a segment from 96 through 216 h of the steady state achieved by regular 12-h doses of 2 mg of FLU. At 168 h, one dose of FLU was replaced by a pulse dose of FLU-D_4 after which the mass spectrometer discriminated between FLU-D_4 (diamonds) and FLU (circles). Arithmetic mean trough steady-state plasma concentrations (mean ng/mL ± SD) were as follows: dog 014, 2.06 ± 0.29; dog 243, 1.77 ± 0.23; dog 260, 1.98 ± 0.29; and dog 685, 2.24 ± 0.47. In each case, the geometric mean steady-state concentration was close to the corresponding arithmetic mean (ng/mL): dog 014, 2.04; dog 243, 1.75; dog 260, 1.96; and dog 685, 2.19. The accumulation index (eq 1) was relatively low (mean ± SD = 2.089 ± 0.377).

It was possible to monitor FLU-D_4 for 48 h post pulse dose in 3 of the 4 dogs. Each animal showed undulations in the plasma concentrations of FLU after the pulse dose of FLU-D_4, suggesting that FLU arising from earlier doses of unlabeled drug appeared to rebound. Observation of this phenomenon indicates the presence of saturable distribution and/or tissue binding because rebound would not be expected to occur if distribution and/or tissue binding processes were linear. Saturable tissue binding has no effect on CL_o but does affect V_d and therefore the apparent elimination rate constant. As anticipated, therefore, estimates of apparent volume of distribution after a pulse dose of FLU-D_4 at steady state tended to be smaller than those estimated from the single dose (Table 1) because the latter was beginning the process of loading deep compartments. Maximum change in apparent volume of distribution should occur when the deep compartments are fully loaded. Failure to reach statistical significance (ANOVA) was probably due to low statistical power in this pilot study. The effects of saturable tissue binding, however, might explain why the terminal portions of the plasma concentration versus time curves of FLU-D_4 do not appear to be log linear (Figure 2). Consequently the data points at 48 h post FLU-D_4 were not used in estimates of apparent elimination rate constants. The weight-corrected apparent oral clearances estimated from the pulse dose were very similar to those estimated by dose/AUC_τ or from the single oral dose in each dog (Table 1).

Table 1— Comparison of Apparent Oral Clearance and Volume of Distribution after a Single Oral Dose of Fluphenazine or a Pulse Dose of Isotopomer in Dogs at Steady State on Fluphenazine

[a] Dose/AUC∞. [b] Dose/AUCτ (where AUCτ estimated from total FLU + FLU-D4 over a dosing interval). [c] CL_o/k (where CL_o estimated as dose/AUC∞).

Table 2— Comparison of Observed $Cpss_{av}$ (ng/mL) at Steady State with Values Calculated from Single Dose Data and from a Pulse Dose of Isotopomer

		predicted steady state	
dog	observed steady state[a]	single dose[b]	pulse dose[b]
014	6.0	10.0	6.1
243	5.7	6.9	6.5
260	11.8	8.5	11.0
685	7.4	5.6	7.9
mean ± SD	8.9 ± 2.2	7.7 ± 1.9	8.4 ± 2.4

[a] AUCτ/τ (where AUCτ estimated from total FLU + FLU-D4 over a dosing interval). [b] Dose/CL_o*τ (where CL_o estimated as dose/AUC∞).

$Cpss_{av}$, however, is not affected by saturable tissue binding. One would therefore expect predictions of $Cpss_{av}$ from a single dose of FLU calculated by eq 3 to be similar to those estimated from a pulse dose of FLU-D_4 at steady state (eq 2). Table 2 shows good within-dog agreement between $Cpss_{av}$ values estimated from the pulse dose and those observed in the steady state. Pharmacokinetic parameters calculated from the steady state, however, may not be of value for patients in whom the dosing interval may vary, whereas a pharmacokinetic parameters calculated from a pulse dose of the isotopomer should be applicable in such patients.

Conclusions

The results from this study suggest that the oral pharmacokinetics estimated from a pulse dose of FLU-D_4 would

be a viable method applicable to patients at steady state on oral FLU. The technique is potentially useful in schizophrenic patients who respond to treatment with potent neuroleptics but are sensitive to side effects and therefore require doses at the low end of the therapeutic range.

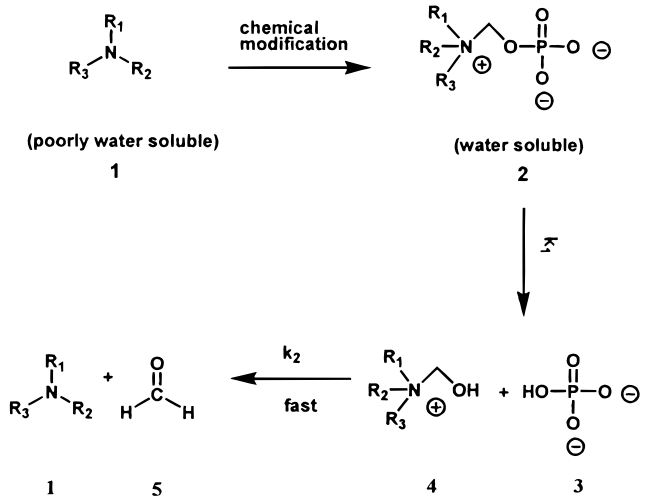
Accepted for publication May 26, 1999.

Abstract □ Quaternary amine prodrugs resulting from *N*-phosphonooxymethyl derivatization of the tertiary amine functionality of drugs represents a novel approach for improving their water solubility. Separate reports have demonstrated the synthetic feasibility and rapid and quantitative prodrug to parent drug conversion in rats and dogs. This work is a preliminary evaluation of the physicochemical and in vitro enzymatic reversion properties of selected prodrugs. The loxapine prodrug had over a 15 000-fold increase in aqueous solubility relative to loxapine free base at pH 7.4. The loxapine prodrug was also shown to be quite stable at neutral pH values. The time for degradation product (parent drug) precipitation from an aqueous prodrug formulation would be expected to dictate the shelf life. Using this assumption, together with solubility and elevated temperature chemical stability studies, the shelf life of a parenteral formulation of the loxapine prodrug was projected to be close to 2 years at pH 7.4 and 25 °C. In addition, the prodrugs of cinnarizine and loxapine have been shown to be substrates for alkaline phosphatase, an enzyme found throughout the human body, and revert to the parent compound in its presence. The results from these evaluations demonstrate that the derivatives examined have many of the ideal properties required for potential clinical application.

Introduction

In separate reports, the synthesis and biological evaluation of a novel prodrug approach for improving the water solubility of tertiary amine containing drugs was described.[1,2] A representation of the prodrug strategy is shown in Scheme 1. The parent tertiary amine containing drug **1** is chemically modified to produce the quaternary, water-soluble, prodrug **2**. The prodrug releases the parent tertiary amine in vivo through a two-step bioreversion process. The first step (k_1, rate determining step) in this bioreversion involves a dephosphorylation (phosphatase-catalyzed) to give the resultant hydroxymethyl quaternary ammonium intermediate **4** and inorganic phosphate (**3**). This intermediate **4** is highly unstable at neutral pH and spontaneously breaks down (k_2) to give the parent tertiary amine **1** plus formaldehyde (**5**).

Drugs are most often identified by their ability to interact with target receptors, and their physicochemical properties are initially of secondary concern. With a drug exhibiting poor aqueous solubility, the safe and efficient delivery to the site of action may be an obstacle.[3,4] The solubility behavior of weakly basic drugs such as tertiary amine



Scheme 1—Illustration of the Novel Prodrug Strategy.

containing drugs is dependent upon individual molecular properties and the environment in which the drug finds itself. Generally, an ionized molecule is more water-soluble than an un-ionized form, and aqueous formulations are sometimes designed at low pH to utilize the greater solubility of the ionized species.[5] With weakly basic amines (low pK_a), the pH necessary for acceptable solubility may be too acidic to be of practical use. In addition, the intrinsic solubility of the amine salt may be low. This being the case, other means for improving the solubility are often used, such as the addition of cosolvents[6] or complexing agents.[7] Whether using pH extremes and/or organic solvents to improve the solubility, the risk of drug precipitation at the injection site is high for parenterally administered drug.[8,9] This is due to pH changes and/or dilution of cosolvent.

Producing quaternary ammonium prodrugs (of tertiary amine containing drugs) to improve the solubility has been attempted.[10−13] The toxic nature of many quaternary amines[14−16] along with the superior chemical stability of derivatives resulting from simple *N*-alkylation may be responsible for the lack of favorable results.

The shelf life of fosphenytoin (**9-P**), a water soluble prodrug of phenytoin, has been shown to be dictated by the time it takes for phenytoin to precipitate from the aqueous formulation at neutral pH.[17] Likewise, the stability-limiting factor for a formulation containing *N*-phosphonooxymethyl prodrugs would be expected to be the same and not simply be the time for some percentage (i.e., 10%) loss of prodrug.

This report also serves to confirm the in vitro enzymatic lability of selected prodrugs in the presence of alkaline

phosphatase. Alkaline phosphatase is found throughout the body and is mainly associated with membranes of the intestine, placenta, bone, liver, and kidney in high concentration.[18,19] As mentioned, these prodrugs are designed to be substrates for phosphatases in vivo, which would trigger a rapid chemical breakdown releasing the parent tertiary amine.

Structures of the compounds examined in this work are depicted in Figure 1.

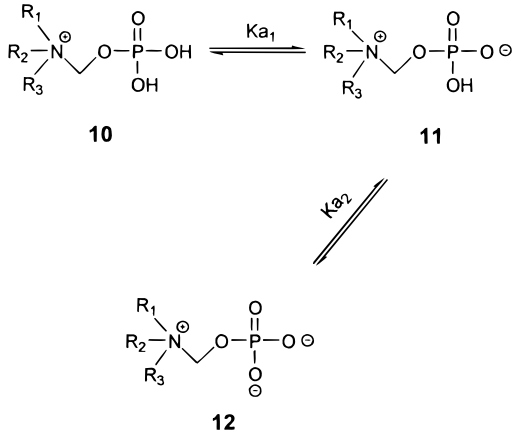
Experimental Section

Materials—**6-P**, **7-P**, and **8-P** were synthesized from a previously described synthetic procedure.[1] Loxapine succinate was obtained from Research Biochemicals Incorporated (Natick, MA). **9-P** was obtained from Parke-Davis Pharmaceuticals (Ann Arbor, MI). Human placental alkaline phosphatase, Type XVII (4.4 units/mg) was obtained from Sigma Chemical Company (St. Louis, MO). All other chemicals were obtained from conventional sources and were used without further purification.

pK_a Determination (Potentiometric)—A 0.01 M quinuclidine prodrug aqueous solution (dihydrogen phosphate form) was titrated using a buret containing a 0.1 N sodium hydroxide volumetric standard solution. The pH was recorded with a calibrated Corning pH/ion analyzer (Corning Incorporated, Corning, NY) after each 0.25 mL addition of NaOH. This experiment was conducted at 25 °C, and all solutions were purged with dry nitrogen gas. The pK_a was calculated from the titration data according to the method of Albert and Seargent.[20]

pK_a Determination (^{31}P NMR)—A 0.25 mmol quantity of the prodrug was dissolved in a 10% v/v D_2O in H_2O solution to prepare a stock solution of 10 mL total volume. Samples spanning the expected pK_a were made by adding minute volumes of a 0.1 N NaOH aqueous solution and recording the pH. Aliquots (0.5 mL) were withdrawn from the stock solution after each pH measurement, transferred to NMR tubes, capped, and frozen at −20 °C until analysis at 25 °C. Spectra were recorded from a Bruker AM 500 MHz NMR spectrophotometer that was tuned to the ^{31}P nucleus. The change in chemical shift was recorded as a function of pH. An insert tube, containing 30% H_3PO_4, was inserted into each NMR tube prior to analysis to serve as an internal reference for the ^{31}P chemical shift of the prodrugs.

The equilibrium for the second ionization of the prodrugs' phosphate monoester (K_{a2}) is represented in Scheme 2. Ignoring the first ionization (K_{a1}), the fraction of prodrug in the zwitterionic form (f_Z) and the fraction in the net anionic form (f_A) are expressed



Scheme 2—Possible Ionic Species of the *N*-phosphonooxymethyl Prodrugs.

in eqs 1 and 2, respectively, where $[H^+]$ represents hydronium ion

$$f_Z = \frac{[H^+]}{[H^+] + K_{a2}} \quad (1)$$

$$f_A = \frac{K_{a_2}}{[H^+] + K_{a2}} \quad (2)$$

molar concentration. The observed chemical shift (δ_{obs}) of the ^{31}P signal is expressed in eq 3, where δ_Z and δ_A represent the chemical

$$\delta_{obs} = f_Z\delta_Z + f_A\delta_A \quad (3)$$

shift for the zwitterionic and net anionic prodrug, respectively. Substituting eqs 1 and 2 into eq 3 gives eq 4. The experimental

$$\delta_{obs} = \frac{[H^+]\delta_Z + K_a\delta_A}{[H^+] + K_a} \quad (4)$$

data was fit to eq 4 using SigmaPlot graphics software (SPSS Inc., Chicago, IL) to estimate values for K_{a2}.

Solubility Determinations—Loxapine succinate was converted to the free base before conducting experiments. All experimental solutions contained 0.05 M buffer and were adjusted to

an ionic strength of 0.2 with NaCl. The pH values with each buffer composition are listed: pH 3.24, HCl/CH_3COONa; pH 3.96 and 4.96, CH_3COOH/CH_3COONa; pH 5.82−7.94, NaH_2PO_4/Na_2HPO_4; pH 8.95 and 9.98, H_3BO_3/NaOH. To glass containers were added 0.2 mL of buffer for the **6-P** samples and 2 mL for the samples of **6**. Each buffered solution was saturated with **6** or **6-P**. The vials were then capped, sonicated, and vortexed prior to submersion in a constant temperature shaking water bath at 25 °C. The samples were shaken at a rate of 100 shakes/min for 24 h. The samples were then centrifuged, and the clear supernatants were diluted and analyzed by HPLC for **6**/**6-P**.

Chemical Stability Evaluations—All experimental solutions contained 0.05 M buffer and were adjusted to an ionic strength of 0.2 with NaCl. The pH values along with their buffer composition are listed: pH 2.05, HCl; pH 3.27, HCl/CH_3COONa; pH 3.94 and 4.95, CH_3COOH/CH_3COONa; pH 5.82−7.94, 8.36, NaH_2PO_4/Na_2HPO_4. Stock solutions for each pH were prepared by dissolving approximately 0.2 mg of **6-P** in 10 mL of buffer. The solution was then assayed for initial prodrug concentration. One-milliliter aliquots were taken and separated into nine glass ampules and sealed. The samples were then submerged in a constant temperature water bath at 65, 75, or 85 °C until analysis. At predetermined times the ampules was opened and mixed with 0.5 mL of acetonitrile to dissolve any precipitate. Each solution was then assayed for prodrug content by HPLC. Individual estimations of k_{obs} were obtained in triplicate by curve-fitting the experimental data to eq 5 (SigmaPlot, SPSS Inc., Chicago, IL), where A is the

$$A = A_0\, e^{-k_{obs}t} \tag{5}$$

prodrug concentration, A_0 is the initial prodrug concentration, k_{obs} is the first-order rate constant for loss of prodrug, and t is time. The loss of prodrug was followed for at least one half-life for all determinations.

In Vitro Enzymatic Lability Evaluations—All experiments involving alkaline phosphatase were performed in a pH 10.4 glycine buffer at 37 °C. The buffer solution contained 1 mM $ZnCl_2$, 1 mM $MgCl_2$, and 0.1 M glycine. The final pH of the buffer was adjusted to pH 10.4 with additions of 2 N NaOH.

For the Michaelis−Menten kinetic evaluation, an alkaline phosphatase stock solution was prepared at a concentration of 149.1 μg/mL (656.0 units/L) in glycine buffer. Four stock solutions of **6-P** (815.3, 163.0, 81.5, and 16.3 μM) were prepared in glycine buffer. To 200 μL of each **6-P** stock solution in a shaking water bath maintained at 37 °C was added 120 μL of the alkaline phosphatase stock solution (at 37 °C). The final concentration of alkaline phosphatase was 245.9 units/L, and the final concentrations of **6-P** were 509.5, 101.9, 51.0, and 10.2 μM. Each reaction was quenched and diluted with addition of 192 μL of a 0.2 N acetic acid solution, 250 μL of acetonitrile, and 232 μL of HPLC mobile phase at predetermined time points (t = 0, 5, 15, and 20 min). Each solution was then vortexed for 30 s, injected into the HPLC, and assayed for **6**.

The initial linear appearance of loxapine was plotted as a function of time for each initial loxapine prodrug concentration following alkaline phosphatase addition. The slope of each was recorded as the initial rate of the reaction. The calculation of Michaelis−Menten parameters was done through plotting the data according to the Lineweaver−Burke equation (eq 6), where V is

$$\frac{1}{V} = \frac{K_m}{V_{max}}\frac{1}{S} + \frac{1}{V_{max}} \tag{6}$$

the initial rate of the reaction, S is the initial concentration of the prodrug, K_m is the Michaelis−Menten constant, and V_{max} is the maximum velocity of the reaction. The slope of this linear plot is equivalent to K_m/V_{max}, and the y-intercept is equal to $1/V_{max}$. From these two relationships the K_m and V_{max} were calculated.

For the enzymatic lability comparisons, stock solutions of alkaline phosphatase (588.7 units/ml), **7-P** (815.9 μM), **6-P** (815.3 μM), and **9-P** (803.6 μM) were prepared in glycine buffer. To 200 μL of prodrug stock solution in a shaking water bath maintained at 37 °C was added 120 μL of the alkaline phosphatase stock solution (at 37 °C). The final concentration of alkaline phosphatase was 220.1 units/L and the final **7-P**, **6-P** and **9-P** concentrations were 509.9, 509.5, and 502.3 μM, respectively. The reaction was quenched and diluted with 100 μL of a 0.4 N acetic acid solution and 200 μL of acetonitrile at predetermined time points (t = 0, 10, 20, 30, 40, and 60 min.). After quenching, each solution was vortexed for 30 s, injected into the HPLC, and assayed for prodrug.

HPLC Conditions—The HPLC system hardware used for all compounds consisted of a Shimadzu LC-6A pump (Kyoto, Japan), a Shimadzu RF-535 fluorescence detector, a Shimadzu SPD-6A UV spectrophotometer, a Shimadzu CR-601 integrator, and Rheodyne 7125 injector (Cotati, CA).

For the analysis of **6**/**6-P**, the mobile phase consisted of acetonitrile (32% v/v) and a 25 mM ammonium phosphate monobasic buffer solution adjusted to pH 3.8 with phosphoric acid (68% v/v). This was pumped at a flow rate of 0.9 mL/min. The injection volume was 20 μL, and the detection was performed by absorbance at 254 nm. The column used for analysis was a Waters Symmetry C-18 150 mm × 4.6 mm with 5 μm particle size (Milford, MA). The retention times were 3.5 and 4.5 min for **6-P** and **6**, respectively.

For the analysis of **7-P**, the mobile phase consisted of acetonitrile (40% v/v) and a 25 mM potassium phosphate monobasic buffer solution adjusted to pH 3.8 with phosphoric acid (60% v/v). The entire mobile phase contained 0.5 mM tetrabutylammonium dihydrogen phosphate (0.5 mM). This was pumped at a flow rate of 1 mL/min. The injection volume was 20 μL, and the detection was by absorbance at 254 nm. The column used for analysis was a Chemco Nucleosil C-18 150 mm × 4.6 mm with 5 μm particle size (Osaka, Japan). The retention time of **7-P** was 4 min.

For the analysis of **9-P**, the mobile phase consisted of acetonitrile (35% v/v) and a 25 mM potassium phosphate monobasic buffer solution adjusted to pH 3.8 with phosphoric acid (65% v/v). This was pumped at a flow rate of 1.1 mL/min. The injection volume was 50 μL, and detection was by fluorescence using an excitation wavelength of 260 nm and an emission wavelength of 315 nm. The column used for analysis was a C18 ODS Hypersil 15 cm × 4.6 mm with 5 μM particle size. The retention time of **9-P** was 4 min.

Results and Discussion

Solubility Evaluation—For the *N*-phosphonooxymethyl prodrugs to be useful for parenteral delivery, they must have sufficient water solubility at the desired formulation pH, preferably in the physiologically acceptable pH range. Limited quantities of prodrug materials prevented us from fully elucidating the pH solubility behavior of the prodrugs. Some limited estimates and predictions were made, however.

The prodrugs have a quaternary center that bears a cationic charge at all pH values, and the phosphate monoester has an ionization scheme depicted in Scheme 2. The phosphate ester exists in equilibrium between the diacidic **10**, monobasic **11**, and the dibasic species **12**, and the fraction of each species present in solution is a function of the pK_a values and the pH of the solution. The overall net charge of the prodrug will be zero when the phosphate ester is predominantly monobasic **11**. Accordingly, at this pH, the water-solubility of this prodrug species would be expected to be the least. Lowering or raising the pH several units from this pH should increase the solubility of the prodrug, as the net charge of the prodrug will become plus one and minus one, respectively.

The pK_{a_2} of the phosphate ester is important considering its potential influence on the solubility, chemical stability, and effectiveness as an enzymatic substrate in the physiological pH range. The pK_{a1} is expected to be less than one and of little physiological importance, except that it is quite acidic. The pK_{a2} was determined by ^{31}P NMR and was found to be 4.7 and 4.9 for **6-P** and **8-P**, respectively. A plot of the ^{31}P NMR chemical shift as a function of pH for **8-P** is shown in Figure 2. The pK_{a2} for **8-P** was 5.0 by potentiometric titration, which was in close agreement with the value determined by ^{31}P NMR.

The measured solubility of **6-P** at pH 3 was 290.5 ± 2.9 mg/mL, which is expected to be a reasonable estimate of

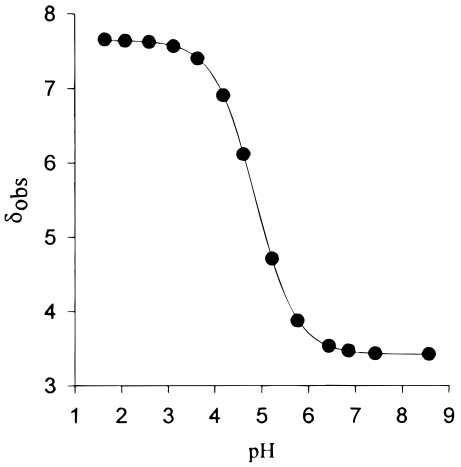


Figure 2—Plot of the observed chemical shift of the ^{31}P NMR signal from **8-P** as a function of pH. The solid line is the curve fit to the experimental data.

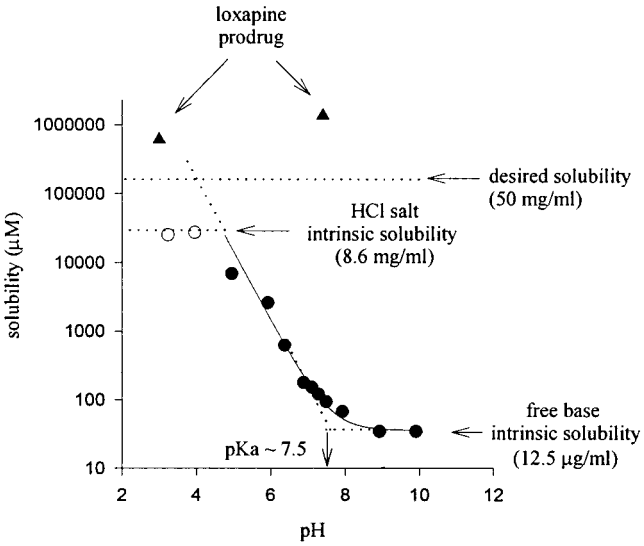

Figure 3—Plot of the water solubility of **6** (●, ○) and **6-P** (▲) as a function of pH.

the solubility of **6-P** in the least soluble zwitterionic form. When the pH was raised to 7.4, the solubility of the prodrug more than doubled (648.2 ± 0.6 mg/mL). Figure 3 compares the solubility behavior of **6-P** relative to **6** as a function of pH. The solid points represent the experimentally determined solubilities for **6** as a function of pH. The line through these points is a theoretical plot of the solubility profile obtained through curve fitting the experimental data to eq 7, where S_t is the total measured solubility of **6**,

$$\log S_t = \log\left(\frac{[H^+]}{K_a} + 1\right) + \log S_o \qquad (7)$$

$[H^+]$ is the hydrogen ion molar concentration, K_a is the acid dissociation constant for the protonated amine, and S_o is the intrinsic solubility of the free base. Estimates of S_o and pK_a were obtained through curve fitting and were found to be 12.6 μg/mL and 7.5, respectively.

Lowering the pH is a common method used for improving the solubility of weakly basic drugs through ionization. Even at pH 3.2, however, the solubility of **6** only reaches 8.2 mg/mL, which is still distant from the desired formulation concentration of 50 mg/mL. **6-P** offers over a 15 000-fold increase in solubility compared to the free base at pH 7.4. This translates to prodrug solubilities that are over

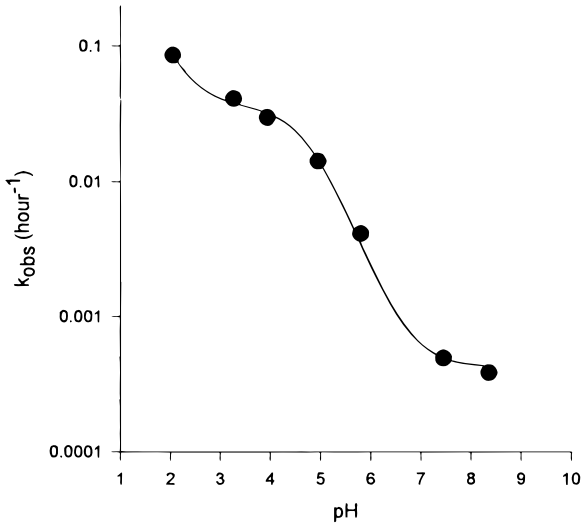

Figure 4—Plot of the observed rate constant (k_{obs}) for loss of **6-P** as a function of pH at 65 °C. The solid line is the curve fit to the experimental data.

nine times higher than those used in the im formulation without the need for cosolvents.

Chemical Stability Evaluation—The prodrugs must have adequate chemical stability in any formulation, especially in ready-to-use parenteral dosage forms. The pH rate profile for **6-P** at 65 °C is shown in Figure 4. The pH of maximum stability occurs in the neutral pH range, which is ideal for formulation from a physiological viewpoint.

The prodrug can exist in three distinct ionic species (see Scheme 2). Because each of these is potentially reactive, several mechanistic pathways for the degradation are possible. A theoretical profile, in reasonable agreement with the observed profile, was constructed according to eq 8, where k_{obs} is the observed rate constant for loss of

$$k_{obs} = \frac{k_o[H^+]^2 + k'_oK_{a1}[H^+] + k''_oK_{a1}K_{a2}}{[H^+]^2 + [H^+]K_{a1} + K_{a1}K_{a2}} \qquad (8)$$

prodrug while K_{a1} and K_{a2} are the first and second acid dissociation constants for the phosphate ester. The k_o, k'_o, and k''_o variables represent the rate constants for water-catalyzed or spontaneous hydrolysis of the diacidic **10**, monobasic **11**, and dibasic **12** phosphate species of the prodrug, respectively. Values for k_o, k'_o, k''_o, and K_{a2} were estimated through curve fitting while the value for K_{a1} was fixed at 0.4 (estimated value). The parameters used to generate the theoretical profile in Figure 4 were as follows: $k_o = 2.32 \pm 0.21$ h^{-1}; $k'_o = (3.62 \pm 0.24) \times 10^{-2}$ h^{-1}; $k''_o = (4.24 \pm 1.95) \times 10^{-4}$ h^{-1}; $K_{a1} = 0.4$; $K_{a2} = (1.73 \pm 0.36) \times 10^{-5}$. The kinetically determined pK_{a2} value of 4.76 ± 0.08 at 65 °C was in good agreement with the value of 4.7 ± 0.01 determined by ^{31}P NMR at 25 °C, especially considering the temperature differences.

The shape of this profile is consistent with other phosphate monoesters for which the increased rate of hydrolysis at low pH is consistent with the higher reactivity of the monobasic phosphate species.[21−26]

A concentrated parenteral formulation of a water-soluble prodrug (of a sparingly soluble drug) might produce sparingly soluble products following degradation. The stability-limiting factor, therefore, may be parent drug precipitation. The precipitation is expected to occur far in advance to the time for 10% loss of prodrug ($t_{90\%}$) often used as an indicator of shelf life of pharmaceuticals. Figure 5 shows Arrhenius plots for the loss of **6-P** at pH values 5.8, 7.45, and 8.36 at temperatures of 65, 75, and 85 °C. From the slope of these plots, Arrhenius activation energies were calculated to be

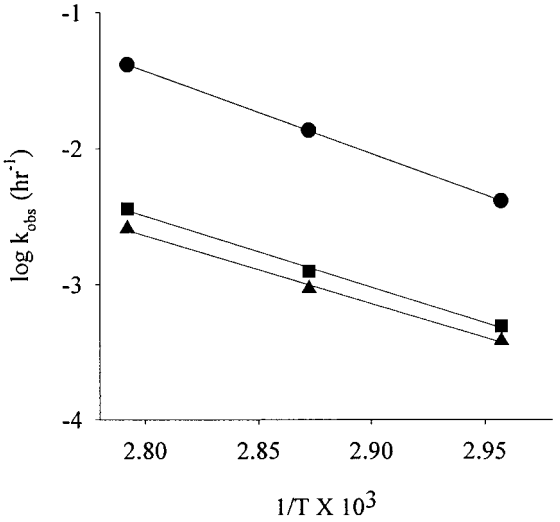

Figure 5—Arrhenius plots for **6-P** degradation at pH values 5.8 (●), 7.4 (▲), and 8.36 (■). The temperatures studied were 65, 75, and 85 °C. Error bars are hidden by the symbols.

Table 1—Arrhenius Plot Extrapolations of the Mean (±SD) k_{obs}, Half-Life, and $t_{90\%}$ for *N*-Phosphonooxymethyl Loxapine Degradation at 25 °C at Several pH Values

pH	k_{obs} (hr^{-1} 10^6)	$t_{1/2}$ (years)	$t_{90\%}$ (years)
5.36	16.2 ± 0.1	4.8 ± 0.1	0.7 ± 0.1
7.45	3.7 ± 0.7	21.1 ± 5.3	3.2 ± 0.8
8.36	3.6 ± 0.7	21.7 ± 5.6	3.3 ± 0.8

27.7 ± 0.2, 23.9 ± 0.8, and 22.9 ± 0.7 kcal/mol at pH values 5.8, 7.4, and 8.3, respectively. These values were then used to predict the $t_{90\%}$, half-life ($t_{1/2}$), and k_{obs} for **6-P** degradation at 25 °C listed in Table 1.

To estimate the shelf life based upon precipitation of **6**, the following example is used. An im formulation of **6-P** at a concentration of 72 mg/mL (equivalent to 50 mg/mL of **6**) at pH 7.4 could only tolerate 0.06% degradation before the solubility of **6** (30 μg/mL) is exceeded. Using the k_{obs} from Table 1 at pH 7.4 to calculate the time for 0.06% degradation ($t_{99.94\%}$) gives a value of 6.7 days, which is drastically shorter than the 3.2 year $t_{90\%}$ estimate from Table 1. This calculation assumes that upon degradation **6-P** is quantitatively converted to **6** and that the solution of **6-P** does not alter the solubility of **6**. Fortunately, a solution of **6-P** at a concentration of 72 mg/mL does in fact improve the solubility of **6**. The intrinsic solubility of **6** at pH 11.8 in a solution containing 72 mg/mL of **6-P** ($n = 1$, as a result of lack of prodrug material) was found to be 2.7 mg/mL. Taking this solubility change into account, a possible shelf life ($t_{94.6\%}$) for **6-P** at pH 7.4 would be about 1.7 years. The solubility of **6** would be expected to be higher than 2.7 mg/mL at pH 7.4 compared to pH 11.8. Therefore, the shelf life of 1.7 years is probably an underestimate.

In Vitro Evaluation—For the derivatives to behave as prodrugs, they must undergo a rapid and quantitative enzymatic bioreversion. The prodrugs are designed to undergo a two-step bioreversion process to give the parent amine, formaldehyde, and inorganic phosphate (Scheme 1). The first step in bioreversion is a rate-determining, enzyme-catalyzed dephosphorylation step ($\mathbf{k_1}$) followed by a fast chemical breakdown ($\mathbf{k_2}$) of the hydroxymethyl derivative (**4**).

In an earlier report, **6-P** and **7-P** were shown to be substrates for alkaline phosphatase. Further evaluation of this enzymatic process can provide information on the kinetics of hydrolysis. The hydrolysis kinetics of **6-P** were

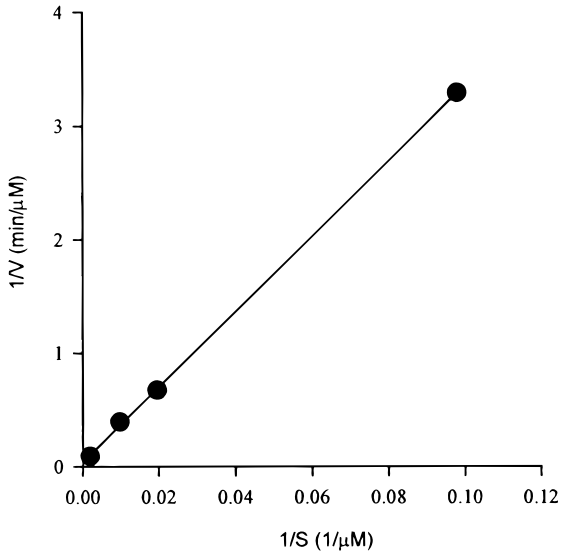

Figure 6—Lineweaver–Burke plot for the enzymatically catalyzed dephosphorylation of **6-P** with alkaline phosphatase at pH 10.4 and 37 °C.

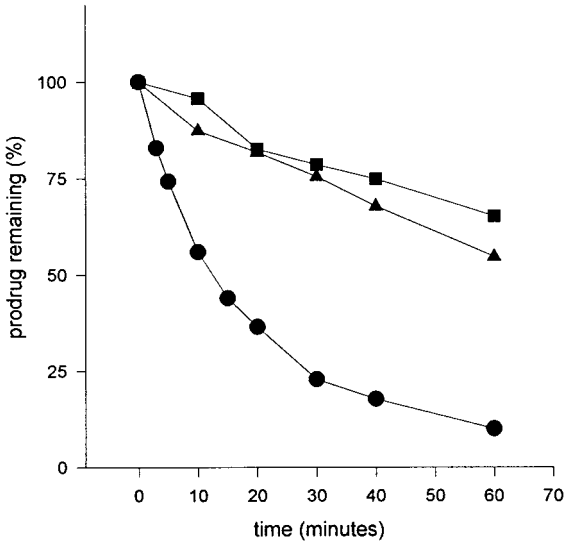

Figure 7—Plot of percent prodrug remaining as a function of time for **9-P** (●), **6-P** (▲), and **7-P** (■) in the presence of alkaline phosphatase.

found to be consistent with a Michaelis–Menten kinetic model similar to other phosphate monoesters reported in the literature.[27,28]

The values for K_m and V_{max} were 872 μM and 26 μM/min obtained from a Lineweaver–Burke plot shown in Figure 6. The value for k_{cat} (0.9 s^{-1}) was obtained by dividing V_{max} by the molar enzyme concentration. The value for k_{cat}/K_m (the second-order rate constant for catalysis) was 1063 M^{-1} s^{-1}. This value is similar to[27] and significantly lower[29] than values others have reported, but comparing these k_{cat}/K_m values may be somewhat meaningless because the enzyme source and experimental conditions of temperature and pH were different.

Fosphenytoin (Cerebyx, **9-P**) is a commercially available phosphate prodrug of phenytoin that requires an in vivo enzyme-catalyzed dephosphorylation step to release phenytoin.[30] Fosphenytoin is rapidly converted to phenytoin in humans with a half-life of approximately 8 min.[31] A comparison of the in vitro labilities of the prodrugs in the presence of isolated alkaline phosphatase would provide some insight as to how the cinnarizine and loxapine prodrugs might behave in vivo. Figure 7 is a plot of % prodrug remaining versus time for **6-P** and **7-P** compared

to fosphenytoin with isolated alkaline phosphatase. Each of the prodrugs was found to be chemically stable under the experimental conditions when the solution was devoid of enzyme. From this plot it appears that enzyme-catalyzed breakdown of **7-P** and **6-P** are similar, and **9-P** appears to be catalyzed at a significantly faster rate. The rapid in vivo conversion of the *N*-phosphonooxymethyl prodrugs in rats and dogs would not have predicted this trend; however, the inability of in vitro trends to predict in vivo results is not uncommon. It also cannot be ruled out that alkaline phosphatase may not exclusively be responsible for the catalytic dephosphorylation; catalytic promiscuity displayed by other enzymes (i.e., esterases) may be responsible for a significant fraction of the in vivo enzymatic reversion.

Conclusion

The *N*-phosphonooxymethyl prodrug approach has been described as a novel method for improving the water solubility of tertiary amine containing drugs. Separate reports have demonstrated the synthetic feasibility and rapid and quantitative prodrug to parent drug conversion in rats and dogs, which are essential characteristics for a clinically useful prodrug. This work has confirmed the prodrugs to have dramatically improved water solubility behavior and very good chemical stability at physiological pH values. The prodrugs have also been shown to be substrates for alkaline phosphatase, which triggered the release of the parent molecule. These results suggest that this approach for improving the water solubility of tertiary amine containing drugs is very promising and deserves further evaluation.

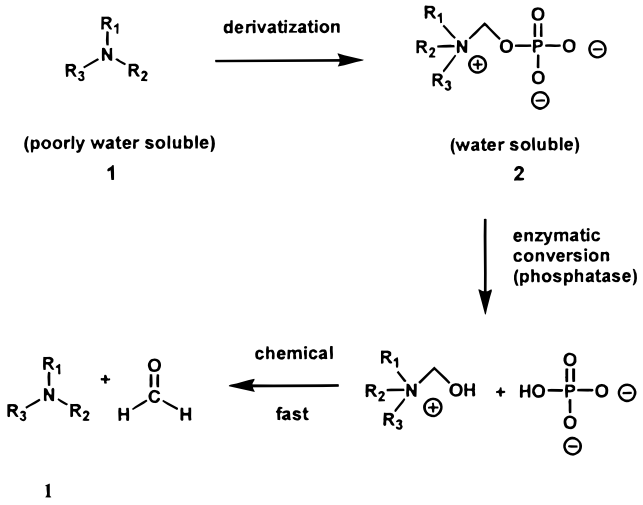
Abstract □ *N*-Phosphonooxymethyl derivatives of tertiary amine containing drugs have been identified as a novel prodrug approach for improving aqueous solubility. The in vivo reversion of two prodrugs to the corresponding parent compounds following iv and im administration to rats and dogs was investigated. Equimolar doses of parent drugs (loxapine or cinnarizine) and the corresponding prodrugs were each administered via a rapid iv infusion to rats and dogs. Equimolar doses of loxapine and its prodrug were each administered im to rats only. Blood samples were collected over 12 h, and plasma was assayed for both parent drug and intact prodrug by HPLC. Comparison of the plasma AUC for the parent drugs following administration of the parent drugs and prodrugs allowed estimation of the apparent bioavailability of parent drug from prodrug dosing. Plasma levels of the prodrugs fell below the limit of detection 5 min after iv infusion with an approximate half-life of 1 min. The mean AUCs following iv and im dosing of parent drugs were not statistically different from the parent drug AUCs obtained after prodrug dosing. The results are consistent with rapid and quantitative prodrug to parent drug reversion following administration of the phosphonooxymethyl prodrugs to the rats and dogs. This information, together with previous studies on the synthesis and physicochemical evaluation of the prodrugs, suggests that this novel prodrug strategy is a very promising approach for overcoming solubility limitations seen with many tertiary amine containing drugs at physiological pH values.

Introduction

The synthesis and the physicochemical and in vitro enzymatic evaluation of a novel prodrug approach for improving the water solubility of tertiary amine containing drugs has been described.[1,2] A schematic of this prodrug strategy is shown in Scheme 1. The tertiary amine drug **1** is chemically derivatized to produce the quaternary water-soluble derivative **2**. This derivative was designed to behave as a prodrug and release parent tertiary amine following in vivo administration. This bioreversion process is thought to occur through two steps, the first step being a rate-determining (enzyme-catalyzed) dephosphorylation.

The *N*-phosphonooxymethyl prodrugs of two drugs, cinnarizine[3−7] and loxapine,[8] were selected for the in vivo evaluation of this prodrug strategy. Both drugs are sparingly water soluble. Cinnarizine is not formulated as an injectable, whereas loxapine (formulated for im use) requires a potentially toxic cocktail of propylene glycol and polysorbate 80.[9] Each of the prodrugs can be formulated in pure water at physiological pH, which might eliminate the vehicle-related toxicities encountered with poorly soluble drugs.



Scheme 1—Illustration of the *N*-Phosphonooxymethyl Prodrug Strategy.

The objective of the work described in this paper was to show that the *N*-phosphonooxymethyl derivatives of loxapine and cinnarizine quickly and quantitatively revert to parent compounds after administration to rats and dogs. To realize quantitative parent drug delivery, the rate of prodrug reversion must be optimal. Assuming that the prodrug does not extensively distribute into tissues, the prodrug can be removed by elimination (k_e) and conversion (k_r) to parent drug. If k_e is fast or even comparable to k_r, then quantitative recovery of parent drug would not occur. If k_r was large relative to k_e, quantitative delivery of parent drug would be realized and the pharmacokinetic profiles would be identical to those resulting from direct delivery of parent compound. Theoretically, a conversion that is too rapid may lead to some complications; however, in most cases a fast k_r is desirable both for quantitatively delivering parent drug and for reducing the risk of a pharmacological effect by the prodrug, if the prodrug is not completely inert.

Materials and Methods

Chemicals—Cinnarizine was obtained from Sigma Chemical Co. (St. Louis, MO). Loxapine succinate was obtained from Research Biochemicals Incorporated (Natick, MA). *N*-Phosphonooxymethyl derivatives of cinnarizine (**7-P**) and loxapine (**6-P**) (Figure 1) were synthesized as previously described.[1] $(SBE)_{7M}$-β-cyclodextrin (Captisol) was obtained from Cydex, Inc. (Overland Park, KS). Methyl *tert*-butyl ether was obtained from EM Science (Gibbstown, NJ). Isoflurane (Forthane) was obtained from Abbott

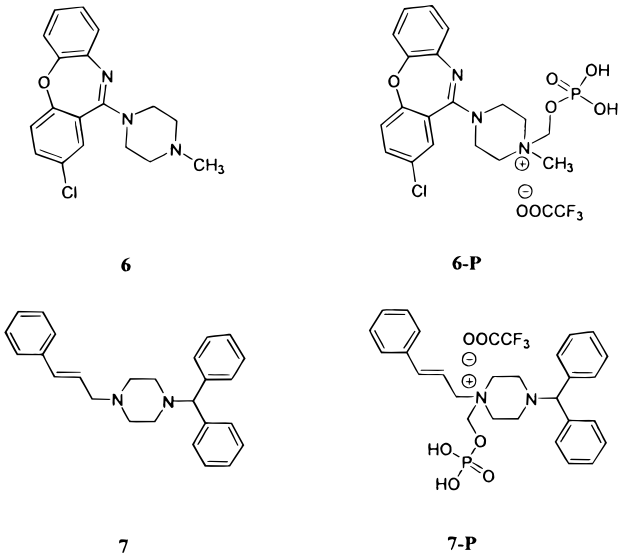

Figure 1—Structures of loxapine (**6**), *N*-phosphonooxymethyl loxapinium trifluoroacetate (**6-P**), cinnarizine (**7**), and *N*-phosphonooxymethyl cinnarizinium trifluoroacetate (**7-P**).

Australasia (Kurnell, Australia). All other chemicals were obtained from conventional sources.

Experimental Procedure, Rat Study—Male Sprague-Dawley rats (weight range 250−300 g) were fasted for 24 h prior to experimentation. The rats were anesthetized with a continuous 2% dose of isoflurane given by inhalation with a 95% O_2, 5% CO_2 carrier gas flowing at 1 L/minute. The rats were implanted with in-dwelling polyethylene cannulae (i.d. 0.58 mm, o.d. 0.965 mm) inserted into the jugular vein and the carotid artery for drug administration and blood sampling, respectively. The cannulae were sutured into position and then exteriorized through a subcutaneous tunnel made from the frontal neck incision to the back of the neck. The rats were then connected to a harness that secured the cannula while allowing the rat free mobility and access to water. The rats awoke 10 min after the cessation of anesthesia and were allowed to recover from the surgical procedure for at least 12 h before dosing. Intravenous doses were administered over 3 min into the jugular cannula, after which the cannula was flushed with 1 mL of normal saline containing 20 units/mL of heparin sodium. Intramuscular doses were administered into the hind leg using a 25 gauge needle. Blood samples (200 μL) for parent drug and prodrug analysis were taken from the carotid cannula before dosing and at predetermined time points following drug/prodrug administration. The sampling times for **6**/**6-P** were 0, 5, 15, and 30 min and 1, 2, 3, and 4 h postinfusion and 1, 5, 15, 30, and 45 min and 1, 2, 4, 6, and 8 h after the im injection. The sampling times for **7**/**7-P** were 0, 5, 10, 20, and 40 min and 1, 2, and 4 h postinfusion. After each blood sample, 200 μL of heparinized saline (20 units/mL) was infused through the carotid cannula. All blood samples were collected in microcentrifuge tubes containing 100 units of heparin sodium (20 μL of a 5000 units/mL solution) and were immediately centrifuged at 3000 rpm for 10 min with a Beckman SG-6R series centrifuge (Fullerton, CA). One hundred microliters of plasma was then separated and stored at −20 °C until analysis.

Experimental Procedure, Dog Study—The study was conducted as a 3 × 3 randomized crossover study in male beagle dogs (weight range 11.8−17.8 kg). The dogs were fasted for 1 day prior to drug/prodrug administration and were given a 1 week washout period between doses. In-dwelling venous catheters were placed in each front leg, one for dosing and the other for sampling. Blood samples (3 mL) for **6** and **6-P** analysis were taken before dosing and at 0, 5, 15, and 30 min and 1, 2, 4, and 6 h postinfusion. All catheters were flushed with 3 mL of heparinized saline (1 unit/mL) after dosing and after each blood sample. Blood samples were collected into 5 mL collection tubes containing EDTA and were immediately centrifuged at 10 000 rpm for 4 min, and 1.5 mL of plasma was separated and stored at −20 °C until extraction.

iv and im Formulations—A solution of **6** for iv infusion was prepared in a cosolvent formulation consisting of 10% (v/v) ethanol, 1.5% (v/v) benzyl alcohol, and 40% (v/v) propylene glycol. This is the commercially used vehicle for iv diazepam[10] and was employed because **6** is not available for iv delivery. A solution of **6** for im delivery was prepared in a cosolvent consisting of 70% (v/v) propylene glycol and 5% (v/v) polysorbate 80 in sterile water for injection, which is the commercially available im injection formulation for loxapine.[11]

A method of formulating **7** for iv infusion was adapted from Järvinen et al.[12] **7** was prepared in a 10 mM sodium phosphate buffer solution containing 37.5 mM of Captisol as a solubilizing excipient. The pH of the solution was lowered to pH 3.5 with addition of 1 M HCl solution. The solution was allowed to stir overnight at room temperature, and the final pH was adjusted to 5.5 with addition of 1 M NaOH.

All prodrugs for all routes of administration were formulated in phosphate buffered saline at pH 6.5 except for **6-P** for im delivery, which was formulated in normal saline. All solutions were passed through a 0.22 μM nylon filter and assayed for drug/prodrug content just prior to administration.

Plasma Extractions of 6, 6-P, 7, and 7-P—One milliliter or 100 μL plasma samples were obtained from the dog or rat blood, respectively, at specified time points. To the plasma following administration of **6**/**6-P** was added 20 μL of H_2O and 20% plasma volume of saturated $ZnSO_4$ (in 0.5 N NaOH). To the plasma following administration of **7**/**7-P** was added 20 μL of acetonitrile−H_2O (50:50) and 20 μL of 10% (w/v) trichloroacetic acid aqueous solution. To the protein-precipitated plasma was added 2 mL of methyl *tert*-butyl ether. Each sample was subsequently vortexed for one minute and centrifuged at 3000 rpm for 10 min. To assay for **6** or **7**, an aliquot of the organic layer (1.7 mL) was taken and evaporated to dryness with a stream of nitrogen gas. The residue was redissolved in 200 μL of HPLC mobile phase, vortexed briefly, and injected onto the HPLC. The efficiencies of the extraction procedure were 88% and 83% for **6** and **7**, respectively. To assay for **6-P** or **7-P**, the remaining aqueous phase from the ether extraction was evaporated to dryness under a stream of nitrogen gas (for rat plasma samples) or lyophilized (for dog plasma samples). To the dried residue was added 2 mL of methanol and 40 or 400 μL of 10% (w/v) trichloroacetic acid aqueous solution for the rat and dog samples, respectively. The mixture was vortexed for 5 min and centrifuged at 3000 rpm for 10 min. An aliquot of the organic layer (1.7 mL) was taken and reduced to dryness under a stream of nitrogen gas. The resulting residue was redissolved in 200 μL of water and vortexed briefly, after which the solution was filtered through a 0.2 μM microcentrifuge filter unit and injected into the HPLC. The efficiencies of the extraction procedure were 47% and 70% for **6-P** and **7-P**, respectively.

Stability of all drugs and prodrugs under the previously described conditions was assessed. Drugs **6** and **7** had complete stability for at least 2 h in whole blood. Prodrugs **6-P** and **7-P**, however, had detectable conversion to **6** and **7** in whole blood that was very temperature-dependent. The extent of this conversion was determined by spiking freshly drawn blood with a known concentration of prodrug and assaying for parent drug and prodrug with the described method. The extent of prodrug to drug conversion was less than 10% for both prodrugs within a 2 h period at room temperature, whereas approximately 50% of **6-P** was converted to **6** at 37 °C in the same amount of time. As a result, all blood samples were chilled on ice and processed as quickly as possible to limit ex vivo conversion.

To evaluate intraday and interday precision of the extraction methods, each procedure was repeated five times in 1 day and on 3 separate days with low, medium, and high plasma drug/prodrug concentrations. The percent standard deviations using either peak height or peak area values were generally less than 10% for both intraday and interday evaluations. Linear standard curves (r^2 > 0.990) resulted by spiking known amounts of drug/prodrug in blank plasma to achieve plasma concentrations in the range of interest for each compound.

HPLC Analysis—The HPLC system for all compounds consisted of a Waters model 510 pump, a Waters 717 autosampler (Milford, MA), a Perkin-Elmer LC240 fluorescence detector (Beaconsfield, Buckinghamshire, England), an LDC Analytical Spectromonitor 3100 variable wavelength detector, a Waters C18 Symmetry column (3.9 × 150 mm, Milford, MA), a Shimadzu CR6A intergrator (Kyoto, Japan), and a column heater (Timberline Instruments Inc., Boulder, CO).

For the analysis of **6**, the mobile phase consisted of acetonitrile (50% v/v) and a 10 mM ammonium dihydrogen phosphate buffer adjusted to pH 7 with ammonium hydroxide (50% v/v). This was pumped at a flow rate of 0.9 mL/min. The injection volume was 150 μL with detection at 251 nm. Under these conditions, the retention time was 11.4 min.

For the analysis of **6-P**, the mobile phase consisted of acetonitrile (25% v/v) and a 10 mM ammonium dihydrogen phosphate buffer adjusted to pH 3 with phosphoric acid (75% v/v). The solvent was pumped at a flow rate of 0.9 mL/min. The injection volume was 150 μL with detection at 251 nm. Under these conditions, the retention time was 12 min.

For the analysis of **7**, the mobile phase consisted of acetonitrile (50% v/v) and a 10 mM ammonium dihydrogen phosphate buffer (50% v/v). This was pumped at a flow rate of 0.9 mL/min. The injection volume was 50 μL with fluorescence detection using an excitation wavelength of 249 nm and an emission wavelength of 311 nm. Under these conditions, the retention time was 7.7 min.

For the analysis of **7-P**, the mobile phase consisted of acetonitrile (30% v/v) and a 10 mM ammonium dihydrogen phosphate buffer (70% v/v). Solvent was pumped at a flow rate of 0.9 mL/min, and the injection volume was 150 μL. Detection was conducted at 253 nm with an observed retention time of 9 min.

AUC and Bioavailability Calculations—After intravenous administration, all concentration versus time profiles were fit to eq 1 using SigmaPlot graphics software (SPSS Inc, Chicago, IL)

$$C = A\,e^{-\alpha t} + B\,e^{-\beta t} \quad (1)$$

with reciprocal concentration weighting. Equation 1 describes the plasma drug concentration as a function of time for a drug that exhibits biexponential pharmacokinetics. The parameters A, α, B, and β generated from the curve fit were used to calculate the AUC_0^∞ values.

After intramuscular administration the AUC_0^t, where t was the last time point, was estimated using the trapezoidal method,[13] and the area under the last point to infinity was estimated by dividing the last point by the apparent elimination rate constant obtained from the curve fit to the iv data. The area under the tail was combined with AUC_0^t to give estimates of AUC_0^∞.

The apparent bioavailability of the parent drug following administration of the prodrug (F_{app}) was calculated by dividing the parent drug AUC following prodrug dosing by that from parent drug dosing as is shown in eq 2. The absolute bioavailability (F_{abs})

$$F_{app} = \frac{\text{Parent Drug AUC (after prodrug dosing)}}{\text{Parent Drug AUC (after parent drug dosing)}} \quad (2)$$

of parent drug following parent and prodrug intramuscular dosing were calculated using eq 3. A one-way ANOVA test was used to

$$F_{abs} = \frac{AUC_0^\infty(\text{im})}{AUC_0^\infty(\text{iv})} \times \frac{\text{Dose(iv)}}{\text{Dose(im)}} \quad (3)$$

compare mean AUCs following drug and prodrug dosing.

Results and Discussion

In all studies, equimolar doses of drug and prodrug were administered and plasma concentrations of both parent drug and prodrug were recorded as a function of time. Doses between different routes of administration did differ. The area under the concentration versus time profile for parent drug following prodrug administration was compared to that following parent drug administration to quantitatively assess the bioreversion. Table 1 summarizes the mean AUCs from each dosing along with the calculated availability, where relevant. Results are discussed in more detail below.

Evaluation of 6-P—Plasma concentration versus time profiles for **6** following equimolar (4.6 μmol/kg) intravenous infusions of **6** and **6-P** to dogs are shown in Figure 2. Plasma concentrations of **6-P** at 0 and 5 min postinfusion

Table 1—Summary of AUC Values and Bioavailabilities of 6 and 7 Resulting from Administration of Parent Drugs (6 and 7) and *N*-Phosphonooxymethyl Prodrugs (6-P and 7-P) to Rats and Dogs

compd	dose (μmol/kg)	route	animal (n)	AUC[a] (ng·hr/mL ± SE)	F_{app}	F_{abs}
6	4.6	iv	dog (3)	663 ± 115		
6-P	4.6	iv	dog (3)	564 ± 75	0.86

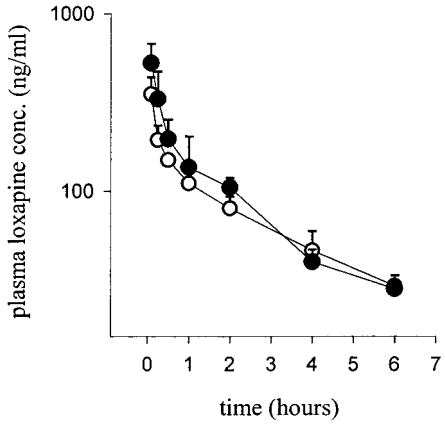

Figure 2—Semilog plot of mean (±SD) plasma concentration versus time profiles of **6** following equimolar (4.6 μmol/kg) 3 min iv infusions of **6** (●) or **6-P** (○) to beagle dogs in a 3 × 3 randomized crossover study.

Table 2—Summary of Plasma Prodrug Levels following Prodrug Administration to Dogs and Rats[a]

compd	dose (μmol/kg)	route	animal (n)	plasma prodrug concn (ng/mL ± SE) 0 min	5 min
6-P	4.6	iv	dog (3)	11,902 ± 983	414 ± 218
6-P	21.3	iv	rat (3)	1605 ± 737	386 ± 145
6-P	30.5	im	rat (3)	0[b]	0[b]
7-P	6.2	iv	rat (3)	1388 ± 615	96 ± 9

[a] After 5 min, prodrug levels were below the limit of detection for all samples collected. [b] Levels were below the limit of detection.

are shown in Table 2. Levels of **6-P** were below the limit of detection (48 ng/mL) following the 5 min sample. The mean AUC values of **6** resulting from dosing of **6-P** and **6** were not significantly different ($\alpha = 0.05$), and the apparent bioavailability of **6** following **6-P** administration was found to be 0.86. Similar results are shown in Figure 3 following equimolar (21.3 μmol/kg) iv infusions of **6** and **6-P** to rats. Again, the prodrug was rapidly cleared from the plasma, and the mean AUCs of **6** resulting from **6** and **6-P** dosing were not statistically different ($\alpha = 0.05$) and gave a calculated bioavailability of **6** following **6-P** administration of 1.13. Rapid disappearance of the prodrug from the plasma along with the virtual superimposability of plasma parent drug profiles following equimolar iv infusions of parent drug and prodrug are consistent with rapid and quantitative reversion, which was evident for all animals tested.

As **6** is currently formulated for intramuscular injection at a concentration of 50 mg/mL in a predominantly nonaqueous cosolvent (70% v/v propylene glycol and 5% v/v

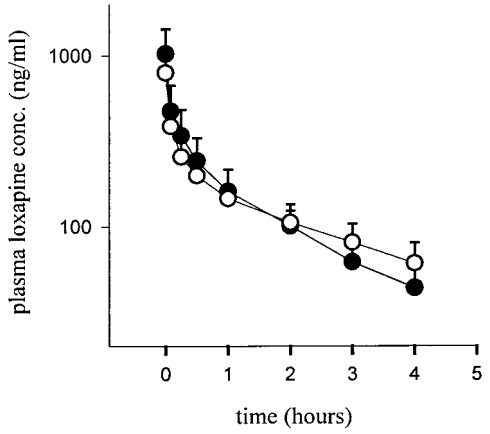

Figure 3—Semilog plot of mean (±SD) plasma concentration versus time profiles of **6** following equimolar (21.3 μmol/kg) 3 min iv infusions of **6** (●) or **6-P** (○) to conscious rats ($n = 3$).

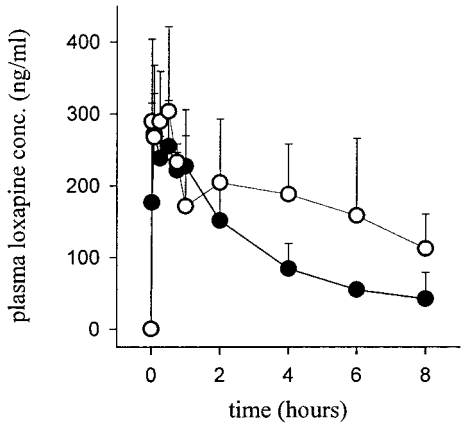

Figure 4—Plot of mean (±SD) plasma concentration versus time profiles of **6** following equimolar (30.5 μmol/kg) im injections of **6** (●) or **6-P** (○) to conscious rats ($n = 3$).

polysorbate 80), the ability of **6-P** to deliver **6** following intramuscular injection in an aqueous vehicle was investigated. Figure 4 illustrates the plasma concentration versus time profile following equimolar (30.5 μmol/kg) intramuscular injections of **6** and **6-P**. The mean AUCs of **6** after dosing with **6** and **6-P** were not significantly different ($\alpha = 0.05$) and the apparent bioavailability of **6** following **6-P** administration was found to be 1.27. Plasma levels of **6-P** were below the limit of detection (80 ng/mL) for all blood samples collected. Following intramuscular injection of **6-P**, a large fraction of the dose was immediately converted to **6**, which led to high plasma levels of **6** within 5 min of dosing. The **6-P** injections also resulted in some apparent elevations in **6** plasma levels 2−6 h postdosing; however, these apparent elevations are not statistically significant. The advantage of intramuscular administration of **6-P** in a purely aqueous formulation relative to **6** in its cosolvent system would be the potential avoidance of the tissue damage that is often associated when injecting organic cosolvents intramuscularly.[9,14]

Evaluation of 7-P—Figure 5 illustrates the plasma level versus time profiles of **7** following equimolar (6.2 μmol/kg) intravenous infusions of **7** and **7-P** to rats. There was no significant difference ($\alpha = 0.05$) between mean AUCs of **7** resulting from dosing with **7** and **7-P**. The apparent bioavailability of **7** following **7-P** administration was found to be 0.91.

To examine the potential for enzyme saturation, a **7-P** iv dose of 18.6 μmol/kg ($n = 3$) was given to the rats and compared to a 6.2 μmol/kg dose. This comparison is shown

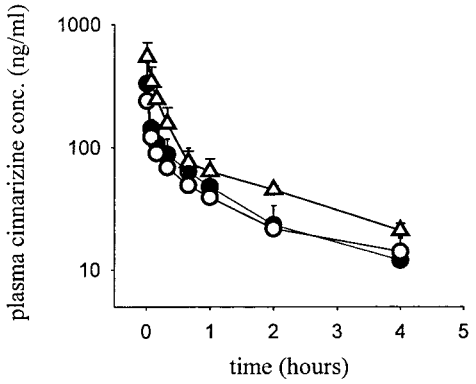

Figure 5—Semilog plot of mean (±SD) plasma concentration versus time profiles of **7** following equimolar (6.2 μmol/kg) 3 min iv infusions of **7** (●) or **7-P** (○) or 18.6 μmol/kg of **7-P** (△) to conscious rats ($n = 3$).

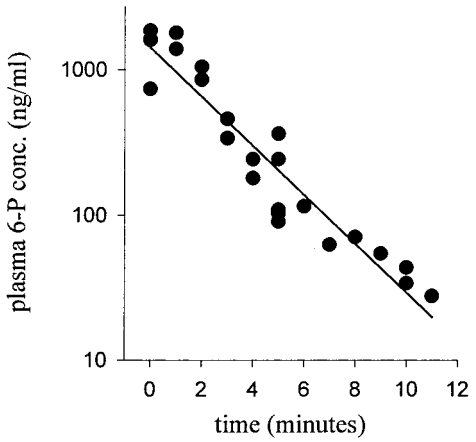

Figure 6—Semilog plot of plasma concentration of **7-P** as a function of time following a 3 min iv infusions of 6.2 μmol/kg of **7-P** (●) to conscious rats ($n = 4$).

in Figure 5. The mean AUC from the 18.6 μmol/kg dose (Table 1) was not statistically different from that for the 6.2 μmol/kg dose after dose correction. Any saturation that may have occurred through tripling of the dose of **7-P** could not be detected through AUC comparisons. As a result of limited quantities of prodrug, this experiment was not repeated with **6-P**.

The concentration versus time profile of **7-P** in plasma is shown in Figure 6. This plot contains data from a rat dosed with 6.2 μmol/kg of **7-P** for which blood samples were taken continuously for the first 10 min postinfusion to obtain a more complete profile. The disappearance of **7-P** from plasma was extremely rapid, and the half-life was estimated to be 2 min.

Conclusion

N-Phosphonooxymethyl derivatives have been evaluated as prodrugs for increasing the aqueous solubility of drugs containing a tertiary amine functional group. Previous reports have demonstrated the synthetic feasibility, improved water solubility, good chemical stability, and ability to revert to parent drug in vitro in the presence of alkaline phosphatase.[1,2] To prepare injectable solutions of cinnarizine and loxapine required additions of complexing agent and cosolvents, respectively. Each of the prodrugs, however, was easily formulated in water near physiological pH. Following iv administration to rats and dogs, the prodrugs were rapidly and quantitatively reverted to parent drug. In addition, the loxapine prodrug was able to deliver parent drug by the im route.

Saturation of the enzyme systems responsible for prodrug to drug reversion was not evident following iv dosing of cinnarizine prodrug to rats when the prodrug dose was tripled from 6.2 to 18.6 μmol/kg. Evaluations of the linearity at higher doses was not possible because of limited prodrug quantities.

The in vivo hydrolysis of the prodrugs was remarkably fast considering the relatively slow in vitro hydrolysis in the prescence of alkaline phosphatase and in blood (see Experimental Section). One could speculate that enzymes contained in blood alone (at their respective concentrations) are not sufficient to explain the rapid hydrolysis found when the prodrugs were administered in vivo. It could be that a significant fraction of the enzymes responsible are membrane-associated and/or organ-specific. Additionally, contribution of enzymes other than alkaline phosphatase may significantly contribute to the in vivo hydrolysis.

As is shown in Scheme 1, prodrug reversion generates a mole equiv of formaldehyde and inorganic phosphate. Although formaldehyde has some known toxicity that may preclude long term, repetitive dosing with these prodrugs, the small amount of formaldehyde released should not present any significant problems. In fact, most drugs that undergo N- or O-demethylation will release formaldehyde as a metabolic product, and many of these drugs are clinically approved and minimally toxic.

In conclusion, the described prodrug approach appears to be a promising technique for safely overcoming the solubility limitations observed with tertiary amine containing drugs.

Abstract ☐ The goal of oral insulin delivery devices is to protect the sensitive drug from proteolytic degradation in the stomach and upper portion of the small intestine. In this work, we investigate the use of pH-responsive, poly(methacrylic-*g*-ethylene glycol) hydrogels as oral delivery vehicles for insulin. Insulin was loaded into polymeric microspheres and administered orally to healthy and diabetic Wistar rats. In the acidic environment of the stomach, the gels were unswollen due to the formation of intermolecular polymer complexes. The insulin remained in the gel and was protected from proteolytic degradation. In the basic and neutral environments of the intestine, the complexes dissociated which resulted in rapid gel swelling and insulin release. Within 2 h of administration of the insulin-containing polymers, strong dose-dependent hypoglycemic effects were observed in both healthy and diabetic rats. These effects lasted for up to 8 h following administration.

Introduction

Diabetes mellitus affects 20 million people in the U.S. alone.[1] Approximately, 10% of these diabetics are treated using insulin therapy. The most common form of this therapy is twice-daily subcutaneous injections of insulin. This type of treatment is painful and as a result encourages noncompliance by up to half of the diabetics.[2] One way to significantly improve patient compliance would be by developing oral delivery systems for insulin.[3] Oral delivery is the most popular method for drug delivery. However, two problems exist in developing oral delivery systems for insulin. The major problem is the inactivation of insulin by digestive enzymes in the gastrointestinal (GI) system, mainly in the stomach and the proximal regions of the small intestine.[3−10] This can be overcome by designing carriers which can protect the insulin from the harsh environments of the stomach before releasing the drug into more favorable regions of the GI tract, specifically the colon.[4−13] Additionally, researchers have attempted to incorporate protease inhibitors into oral insulin formulations which serve to prevent insulin degradation by the proteolytic enzymes.[4,7−10,12,14]

The other major barrier is the slow transport of insulin across the lining of the colon into the blood stream. Researchers have attempted to bypass this hurdle with the addition of compounds known as absorption enhancers which can facilitate the transport of macromolecules across the lining of the GI tract.[4,7−10]

Several research groups have attempted to use polymeric carriers as oral delivery systems for insulin. Touitou and Rubinstein[11] designed a system consisting of insulin encapsulated by polyacrylates. The coating was designed to dissolve only in the colon. In this work, weak hypoglycemic effects were observed only with very high insulin doses and the addition of absorption enhancers. Saffran[4] developed a system of insulin dispersed in a terpolymer of styrene and hydroxyethyl methacrylate cross-linked with a difunctional azo-containing compound. The azo bond was cleaved by microflora present in the colon, and the polymer degraded allowing for release of insulin into the colon. In this work, a hypoglycemic effect was obtained only with addition of absorption enhancers and protease inhibitors. However, the hypoglycemic effect obtained was not affected by the initial dosing.

Morishita et al.[12] administered insulin contained within Eudragit 100 gels. We observed strong hypoglycemic effects in healthy and diabetic rats after the addition of absorption enhancers. Platé et al.[7] developed a hydrogel system containing immobilized insulin and protease inhibitors that was effective in lowering the blood glucose levels in rabbits. More recently, Mathiowitz et al.[13] have developed insulin containing poly(anhydride) microspheres. These materials adhered to the walls of the small intestine and released insulin based on degradation of the polymeric carrier. They observed a 30−50% decrease in the blood glucose levels of healthy rats.

In this work, we have used a pH-responsive carrier designed to protect the insulin in the harsh, acidic environment of the stomach before releasing the bioactive agent in the small intestine. The delivery system consists of insulin-containing microparticles of cross-linked copolymers of poly(methacrylic acid) which are grafted by ethylene. These new systems glycol (henceforth designated P(MAA-*g*-EG)) function because the structure of the copolymers exhibits pH sensitive swelling behavior due to the reversible formation of interpolymer complexes stabilized by hydrogen bonding between the carboxylic acid protons and the etheric groups on the grafted chains.[15] The complex formation in the insoluble copolymers is sensitive to the nature and pH of the surrounding fluid as well as the copolymer composition and graft chain length.[15]

In the acidic environment of the stomach, the gels are in the complexed state. Under these conditions insulin cannot readily diffuse through the membrane because of the small mesh size, ζ, and is protected from the harsh environment of the stomach.[16] As the particles pass the stomach into the intestine, the environmental pH increases above the transition pH of the gel. The complexes immediately dissociate and the network pore size rapidly increases leading to the release of insulin.[16] Because of their nature, these materials may be ideal for the delivery of drugs at rates specified by the pH of the environmental fluid.[16,17]

Experimental Section

Hydrogel Synthesis—Microparticles of P(MAA-*g*-EG) were prepared[18] by a free-radical bulk, suspension polymerization of methacrylic acid (MAA, Sigma Chemical Co., St. Louis, MO) and

poly(ethylene glycol) (PEG) monomethacrylate (PEGMA, Polysciences Inc., Warrington, PA) with PEG of molecular weight 1000. The MAA was vacuum-distilled prior to use to remove the inhibitor. The PEGMA was used as received.

For the polymerization reaction, the suspending phase, 250 mL of silicon oil, Dow 200 fluid (Dow Chemical Co., Midland, MI) was added to a three-necked flask and heated to 70 °C while being agitated at 250 rpm using an overhead stirrer. A reflux condenser was attached to the flask. The flask was sealed and purged with nitrogen to ensure an inert atmosphere for the reaction vessel.

The monomers were mixed in appropriate molar ratios to yield a 1:1 ratio of MAA:EG units in the gel. Tetraethylene glycol dimethacrylate (TEGDMA, Polysciences Inc., Warrington, PA) was added as a cross-linking agent in the amount of $X = 0.075$ mol of TEGDMA per mole MAA. Following complete dissolution of the monomers, nitrogen was bubbled through the well-mixed solution for 30 min to remove dissolved oxygen, a free radical scavenger, which would act as an inhibitor. 2,2′-Azobis(isobutyronitrile) (AIBN) was added in the amount of 0.5% of the total monomers as the thermal reaction initiator. Poly(dimethyl siloxane-*b*-ethylene oxide) (P(DMS-*b*-EO), Polysciences Inc., Warrington, PA) containing 25% DMS was added in the amount of 1% of total monomers as a surfactant to prevent microparticle aggregation during and after the reaction.

The monomer mixture was added to the oil phase, agitated at 350 rpm, and allowed to react for 3 h at 70 °C. After 3 h, the temperature was increased to 90 °C and allowed to react for an additional 2 h. Following the higher temperature reaction period, the solution was cooled to 37 °C, and the agitation rate was decreased to 250 rpm. Once the temperature reached 37 °C, 20 mL of deionized water was added to the reaction vessel, and the polymer suspension was mixed for an additional 2 h.

The suspension was allowed to settle and the oil was decanted. The reaction flask was filled with deionized water, and the swollen particles were stirred for 24 h at 100 rpm. After 24 h, the particles were filtered and rinsed with fresh deionized water. This process was continued until all of the silicon oil had been removed (approximately one week). Following the washing, the particles were stored in deionized water with the pH adjusted to 8 by the addition of NaOH.

Drug Loading—Drug loading was accomplished by equilibrium partitioning of insulin into the P(MAA-*g*-EG) microparticles. Crystalline porcine insulin (10 mg, 26.9 IU/mg, Shimizu Pharmaceutical Co., Ltd., Shizuoka, Japan) was dissolved in 100 μL of 0.1 N HCl. The insulin solution was diluted with 19.8 mL of phosphate buffer solution (pH = 7.4) and normalized with 100 μL of 0.1 N NaOH. The final pH of the loading solution was 7.4. Loading was accomplished by soaking 140 mg of dried P(MAA-*g*-EG) microparticles for 24 h in the insulin solution. The concentration of insulin in the solution was monitored over time using HPLC.

The particles were then filtered using filter paper with 1 μm pores and washed with 100 mL of 0.1 N HCl solution to collapse the microparticles and exude the remaining buffer solution. The insulin-loaded microspheres were dried under vacuum and stored at 4 °C. The degree of loading was determined from HPLC analysis of the insulin concentrations of the initial solutions and the filtrate from the washings. Using this loading technique, 94 ± 9% of the insulin in the initial solution was entrapped within the polymer.[19] The activity of the insulin loaded in the gels was verified using an Insulin EIA kit (Abbot Laboratories, Chicago, IL).

In Vivo Studies—For these studies, male Wistar rats (200 g) were used. Diabetes was induced[12] in the rats by intraperitoneal injection of streptozotocin (40 mg/kg body weight once daily for three consecutive days) dissolved in citrate buffer at pH = 4.5. The rats were considered diabetic when the fasted glucose levels exceeded 250 mg/dL at 2 weeks following the streptozotocin treatment. The average blood glucose levels of the healthy animals used in the studies was 80 mg/dL while the diabetic animals had average glucose levels of 345 mg/dL.

Prior to administration of the insulin-loaded polymer, the animals were fasted for 48 h. The rats were restrained in the supine position. The insulin-loaded P(MAA-*g*-EG) microparticles and the control solutions were administered via the mouth using a gelatin capsule. The gelatin capsules dissolved readily in the stomach. During the experiment, a 0.2 mL aliquot of blood was collected from the jugular vein at 0.25, 0.5, 1, 2, 4, 6, and 8 h following dosing. The blood serum was separated by centrifugation at 3000 rpm for 3 min and stored in a freezer until analysis. The serum insulin levels were determined by an enzyme immunoassay using an Insulin EIA kit (Abbot Laboratories, Chicago, IL). Serum glucose levels were determined by the glucose oxidase method using a glucose B-test kit.

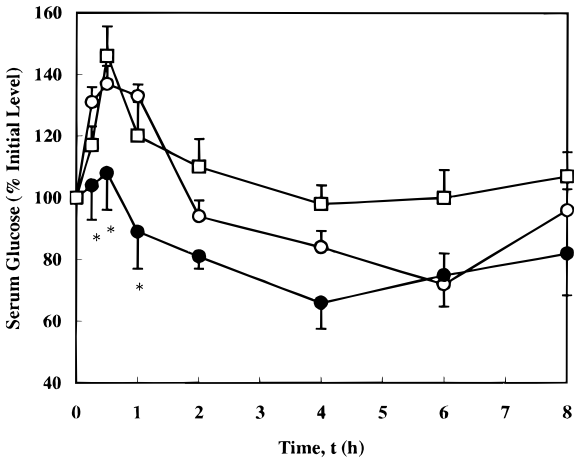

Figure 1—Blood glucose response in healthy male Wistar rats following the oral administration of P(MAA-*g*-EG) microspheres containing insulin doses of (○) 25 IU/kg body weight ($n = 7$) and (●) 50 IU/kg body weight ($n = 5$) and (□) insulin solutions (50 IU/kg body weight, $n = 4$). Comparison calculated between the doses at each point *$p < 0.05$.

To determine the relative efficacy of each formulation, healthy and diabetic rats received sc injections, and the blood glucose levels were monitored over time. Healthy rats received injections of 0.5, 1, and 3 IU/kg, while diabetic rats received injections of 0.25, 0.5, and 1.0 IU/kg. The cumulative area under the curve (AUC) was determined from each dosage, and the following dose dependent AUC relationships were developed for subcutaneous injections:

$$\text{healthy Rats } (n = 4): \ \text{AUC} = 219.29 \log(\text{sc dose}) + 145.96 \quad (1a)$$

$$\text{diabetic Rats } (n = 4): \ \text{AUC} = 512.64 \log(\text{sc dose}) + 319.76 \quad (1b)$$

Results and Discussion

In designing a device for oral delivery of sensitive peptide drugs such as insulin, it was important to protect the drug in the harsh environment of the stomach and upper GI tract and release the drug into the distal portions of the intestine. Therefore, in an effective carrier the release rates must be significantly greater in neutral or basic conditions than acidic conditions. One significant parameter in evaluating the viability of a particular hydrogel for oral delivery of proteins and peptides was the ratio of the diffusion coefficients of the drug in the carrier in the stomach (acid environment) and the intestine (neutral environment). In the P(MAA-*g*-EG) gels, the release rates in neutral or basic conditions were more than 1 order of magnitude greater than the release rates in acidic solutions.[16]

In Vivo Response to Oral Administration of P(MAA-*g*-EG) Microspheres—The blood glucose response of rats following oral administration of insulin doses contained in P(MAA-*g*-EG) microparticles is shown in Figure 1. The rats received insulin doses of 25 IU/kg and 50 IU/kg contained in the polymer microparticles and a control solution (50 IU/kg). Initially, the blood glucose levels rose due to the physical stress on the animals during administration and blood sampling. The initial rise was followed by a decrease back to normal levels due to absorption into the muscle. Because of the nature of these gels, little if any of the insulin was released in the stomach, as the gels were in the collapsed state due to the formation of polymer

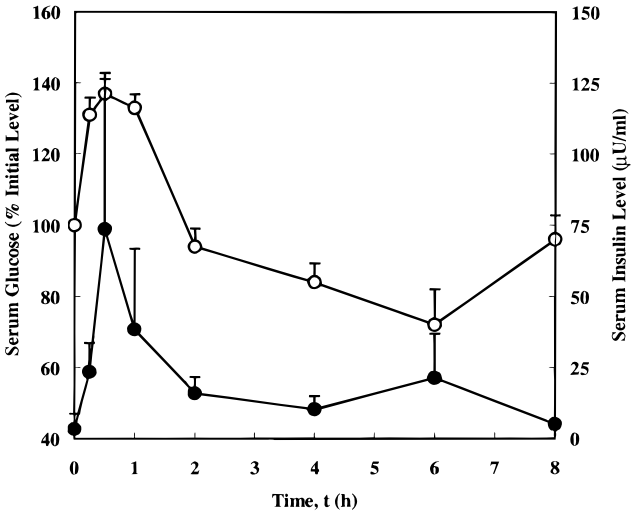

Figure 2—Serum (○) glucose and (●) insulin levels in healthy male Wistar rats following oral administration of insulin-containing P(MAA-g-EG) microspheres (25 IU/kg body weight doses) ($n = 7$).

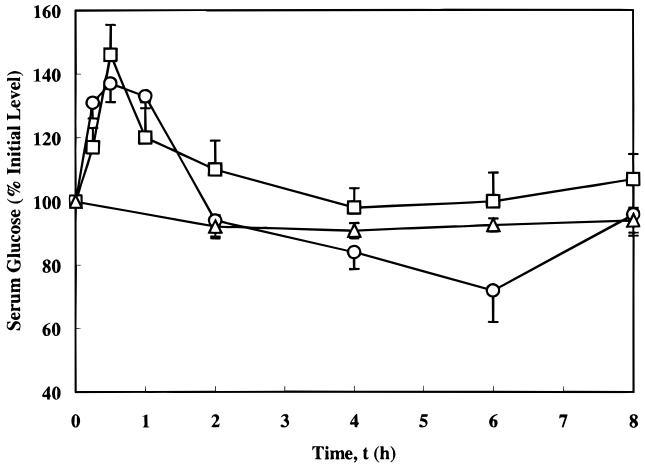

Figure 3—Blood glucose response in healthy male Wistar rats following the oral administration of 25 IU/kg body weight insulin doses contained (○) P(MAA-*g*-EG) microparticles ($n = 5$) and (△) Eudragit microspheres ($n = 10$) and (□) insulin solutions ($n = 4$).

complexes in the acidic environment of the stomach. The insulin was protected inside of the gel from the proteolytic enzymes that were unable to penetrate the gel.

Within 2 h of receiving the polymeric dosage form, a strong hypoglycemic effect or lowering of the blood glucose level was observed in the animals that had received the polymeric dosage forms. This was clear evidence that the insulin was delivered effectively in the biologically active form to the small intestine. Insulin delivery in the small intestine was due to the rapid dissociation of the polymer complexes in the basic environment of the intestine. As the complexes dissociated, the pore size of the gels increased dramatically, and insulin was rapidly released into the intestine. Additionally, the reduction of the blood glucose levels depended strongly on the insulin dose. The reduction in blood sugar was greater in the animals receiving the higher doses of insulin (50 IU/kg). The hypoglycemic effects were present for up to 8 h in these animals.

The serum insulin levels of the rats following oral administration of the dosage forms are shown in Figure 2. Within 1 h of administration, the insulin levels in the rats receiving the insulin containing rose to greater than 20 times their initial levels. The serum insulin levels remained at elevated levels for up to 6 h following administration as the polymer delivered the insulin to the proximal small intestine. As a result, the blood glucose levels were decreased for the period.

One major reason for the effectiveness of this device is the pH-sensitive swelling behavior of the gels. However, such strong effects could not be obtained with the use of another pH-responsive carrier that had been used as oral delivery vehicle for insulin, Eudragit L100. In our previous work,[12] we prepared insulin-containing microspheres of Eudragit L100 to serve as oral insulin delivery systems. A comparison of the hypoglycemic effects following oral administration of 25 IU/kg doses of insulin contained in P(MAA-*g*-EG) and Eudragit L100 microparticles is shown in Figure 3. Clearly, the hypoglycemic effects observed following administration of the complexation gels are much greater than those obtained using the Eudragit carrier.

The P(MAA-*g*-EG) gels are significantly more effective in delivering biologically active insulin than traditional enteric coating-type carriers because of the presence of the PEG-grafts. Such strong hypoglycemic effects were not observed using other oral delivery carriers without the addition of additives such as protease inhibitors or absorption enhancers.[4,7,12,13] The addition of PEG to the gels is critical because the PEG chains participate in the macromolecular complexes, function as a peptide stabilizer, and enhance the mucoadhesive characteristics of the gels. In these gels, the PEG will form interpolymer complexes with the PMAA in acidic media. Not only do the complexes contribute strongly to the pH-dependent changes in the network structure,[15–18] they also serve to stabilize the insulin.[16,20] Additionally, the presence of the PEG grafts helps maintain the biological activity of the insulin by stabilizing the drug and preventing binding to ionizable backbone chain.[16,17,21]

Another important characteristic of these gels is their ability to adhere more strongly to the mucosa of the small intestine than the mucosa of the stomach. This is significant because the major impetus for controlled drug release is to maintain a steady flux of an active agent over an extended period of time. One such means of increasing the residence time would be through the use of a mucoadhesive carrier. The primary goal of such devices is to localize the delivery vehicle within the desired location to enhance the drug absorption process in a site-specific manner.[22–24] Hydrogels of P(MAA-*g*-EG) exhibit excellent mucoadhesive characteristics for delivery of drugs to the small intestine due to the presence of the graft PEG chains which serve as adhesion promoters.[16,17] Adhesion promoters, such as polymer grafts or even linear polymers, function by penetrating the gel/mucosa or gel/gel interface and forming temporary anchors.[25,26]

The mucoadhesive characteristics of P(MAA-*g*-EG) hydrogels are strongly dependent on the pH of the environmental fluid. These gels adhere to the mucosa of the intestine to a much greater extent than the stomach.[16] Therefore, the residence of insulin carriers would be much greater in regions where the insulin could be absorbed, such as the distal regions of the small instestine.

The reduction of blood glucose in healthy animals following oral administration of the insulin-loaded polymers was significant in that it showed the efficacy of P(MAA-*g*-EG) carriers. However, it is more significant if these results can be obtained in diabetic animals. The blood glucose response of diabetic rats following oral administration of insulin containing P(MAA-*g*-EG) microparticles (25 IU/kg doses) is shown in Figure 4. The blood glucose levels of the diabetic rats were lowered by up to 40% for greater than 8 h. The degree to which the glucose levels were suppressed was in fact greater for the diabetic animals

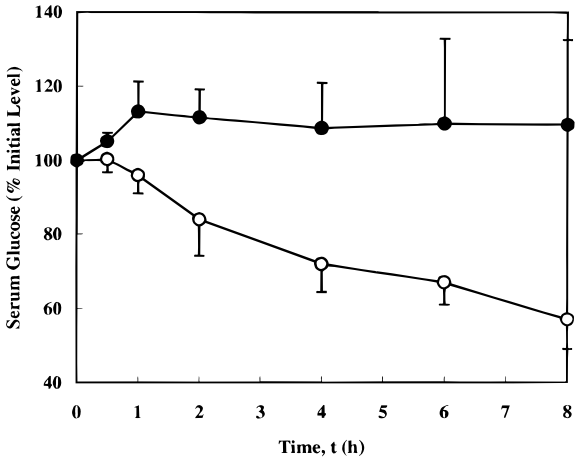

Figure 4—Blood glucose in diabetic, male Wistar rats following oral administration of 25 IU/kg body weight doses contained in (○) P(MAA-*g*-EG) microspheres and (●) insulin solutions ($n = 5$).

Table 1—Efficacy of Oral Administration of Insulin Using Complexation Polymers Relative to iv Injection

dosage form	insulin dose (IU/kg)	bioavailability	
		healthy rats	diabetic rats
P(MAA-g-EG)	25	3.40 ± 1.53	2.44 ± 0.41
	50	4.22 ± 2.09	ND[a]
solution	25	ND	0.88 ± 0.34
	50	0.55 ± 0.08	ND
Eudragit L100[12]	25	0.9 ± 0.3	1.1 ± 0.2

[a] ND: no data collected.

than the healthy animals. Additionally, the strong hypoglycemic effects were observed to last longer in the diabetic animals.

Relative Efficacy of P(MAA-*g*-EG) Carriers to S. C. Injection—The overall efficacy of each of the formulations was determined in comparison to the efficacy of an iv injection. For each dosage form, the AUC was determined. The overall efficacy was determined as the ratio of the AUC for the oral dosage divided by the AUC for a sc injection of the same dose. These data appear in Table 1. When the insulin was administered orally using solutions, the efficacy of the formulation in comparison to sc injection was less than 1%. However, when the insulin was delivered using polymer microparticles, the efficacy was increased significantly. Of all of the samples tested, the greatest efficacy or bioavailibility (4.22%) was observed for the P(MAA-*g*-EG) gels containing 50 IU/kg doses delivered to healthy rats. Significant bioavailibilities were also observed for polymers containing 25 IU/kg doses in both healthy and diabetic animals. All of the P(MAA-*g*-EG) devices were found to be significantly more effective than Eudragit L100 as oral delivery devices for insulin.

Conclusions

Oral insulin delivery systems must be able to protect the sensitive macromolecular drug from the harsh environment of the stomach and deliver biologically active insulin for an extended period of time to more favorable regions for absorption along the GI tract. Because of their nature, complexing P(MAA-*g*-EG) hydrogels are ideal for such an application. P(MAA-*g*-EG) hydrogels were able to effectively deliver biological active insulin via the oral route. Microparticles prepared from these gels were prepared and loaded with insulin. Following administration of insulin-loaded microparticles to healthy and diabetic rats, the blood glucose levels in these animals were decreased significantly for at least 8 h due to the absorption of insulin in the GI tract. The strong hypoglycemic effects were observed without the addition of additives such as absorption enhancers or protease inhibitors and were found to be strongly dependent on the administered dose.

Accepted for publication June 21, 1999.

Abstract □ Peptide metabolic pathways in blood or other tissues are often complex because multiple enzyme systems are involved in the degradation of parent drug and its metabolites. Michaelis–Menten-type studies with isolated enzymes have been frequently employed for evaluating the metabolism of peptides. Alternatively, studies with selective enzyme inhibitors or the evaluation of the area under the drug– or metabolite–time profiles have been employed. We tested in this study the usefulness of a multicompartmental pharmacokinetic approach for the assessment of the apparent first-order metabolism of dynorphin A1–13 up to the fourth metabolite generation in human plasma. This multicompartmental kinetic analysis proved instrumental in clarifying ambiguous degradation pathways not easily detectable by the other methods of assessment (enzyme inhibition studies and noncompartmental analysis) because of the lack of specific enzyme inhibitors or specificity problems of the analytical technique employed. The proposed multicompartmental fitting approach was also highly suitable to verify the overall metabolic pathways suggested by the other methods up to the fourth metabolite by testing whether the rate constants obtained by these methods are suitable to describe the overall degradation profile after Dyn A1–13 degradation. Local sensitivity analysis for the degradation of DYNA 1–13 revealed that the model was, however, not able to adequately identify on its own all of the parameters involved in the degradation of dynorphin A1–13. Thus, the method proved beneficial in evaluating and testing the correctness of the overall degradation pathways suggested by other methods.

Introduction

Biologically active peptides often exert their effects via active metabolites. With the use of peptides as therapeutic agents, a detailed understanding of their metabolism is therefore important. The model peptide Dyn A1−13 used in this study is extensively metabolized in plasma.[1] N-terminally intact metabolic fragments of Dyn A1−13 (Dyn A1−12 through Dyn A1−5) retain opioid receptor affinity,[2] while N-terminally truncated dynorphin derivatives such as Dyn A2−13 modulate morphine tolerance via nonopioid pathways, possibly the NMDA-receptor[3,4] and/or melanocortin receptor.[5]

The in-vitro metabolic pathway of Dyn A1−13 in human plasma is complex, as previously assessed up to the fourth metabolic generation by enzyme inhibition studies and a noncompartmental analysis of the metabolic pathway.[1] Enzyme inhibition studies can only assess the contribution of one enzymatic system to the overall metabolic fate of the parent drug or identified metabolites; and they depend on the specificity of the enzyme inhibitors involved. A noncompartmental (AUC-based) approach introduced in these studies[1] compared the area under the concentration−time profiles of a given metabolite during degradation of the parent drug (e.g., Dyn A1−13) with the area observed after direct degradation of the synthesized metabolite. This approach allows simultaneously monitoring of several metabolites and does not depend on the availability of selective enzyme inhibitors but on the high selectivity of the chromatographic system for the determination of parent drug and metabolites. Because of the limitations found for both methods, this study focuses on the applicability of a structured multicompartmental kinetic analysis (nonlinear curve fitting procedures for apparent first-order kinetic processes) for the analysis of complex metabolic events. The results presented here suggest that this mode of analysis has certain advantages over the above methods and that it should be applied in conjunction with the other methods to assess complex metabolic degradation pathways of peptide drugs.

Materials and Methods

Data—Concentration−time profiles of parent compound (generally Dyn A1−13 or shorter fragments such Dyn A1−12 or Dyn A2−12, Dyn A 3−12, Dyn A 4−12, Dyn A 1−10, Dyn A 2−13) and resulting metabolites obtained after incubation of peptides at 37 °C in neat plasma in the presence or absence of specific enzyme inhibitors (GEMSA, bestatin, captopril, leucinetiol) have been previously described.[1] These data were reanalyzed in this study.

Data Analysis—Differential equations describing sequential and parallel pathways of dynorphin metabolism (see Figures 1 and 2, for the metabolic pathways of Dyn A1−13 investigated, see Figure 1 for final pathway) were established.[6] These equations incorporated the overall rate of degradation of a given peptide (degradation rate constant of DynA1−13: k_1; degradation rate of metabolites: $k_2 - k_7$) and the rate of generation of metabolites (k_{12}, k_{16}, k_{23}, k_{63}, k_{27}...). See Figure 1 for explanation of the abbreviations of rate constants used. The Laplace transform of the concentration of a given dynorphin fragment (as,c) was calculated as the product of the input (ins; here the initial amount of peptide spiked into the incubation solution) and the following modified disposition function ($d_{s,c}$).[7]

$$d_{s,c} = \frac{\prod_{i=2}^{N}(s + k_i)}{\prod_{i=1}^{N}(s + k_i) - \sum_{j=2}^{N}[k_{1_j}\prod_{\substack{m=2 \\ m\neq j}}^{N}(s + k_m)]}$$

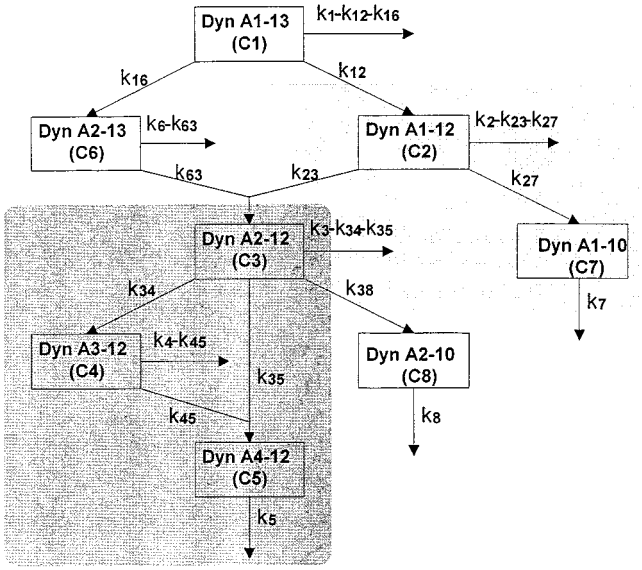

Figure 1—Kinetic model describing the arrangement of metabolite pools in the plasma metabolism of Dyn A 1–13. This model was the basis for compartmental kinetic analysis of Dyn A1–13. Single digit abbreviations (e.g., k_1) are used for degradation rate constants that describe the total outflow of a certain compartment (in this example C1). Rate constants that describe the specific flow from one compartment to another have double digit denominations (e.g., k_{12}) and represent the generation rate constants. The difference between the overall degradation rate constant (e.g., k_1) and relevant generation rate constants (e.g., k_{16} and k_{12}) reflect unknown metabolic events not incorporated into the model. The area in dark gray highlights the metabolic events of Dyn A2–12 under captopril inhibition, the added area in the medium gray shade shows the extension of the model in the metabolic events of Dyn A1–12. The dashed lines signify compartments for which direct data (from HPLC) was not available.

where $d_{s,c}$ is the disposition function for compartment 1 (it is a function of s, the Laplace operator); $\prod$ is the continued product where any term is defined as equal to 1 when the index takes a forbidden value (that is, $i = 1$ in the numerator or $m = j$ in the denominator); $\sum$ is the continued sum where any term is defined as equal to zero when the index takes a forbidden value; k_{1j} is the first-order generation of a metabolite, estimated from relevant generation rate constant; k_i, k_m is the overall degradation rate of a dynorphin fragment, estimated from relevant degradation rate constants; N is the number of the compartments.

The Anti-Laplace of $a_{s,c}$ was obtained by the method of partial fractions.[7] The resulting equations for the final model of Dyn A1−13 (C1) with its metabolites Dyn A1−12 (C2), Dyn A2−12 (C3), Dyn A3−12 (C4), Dyn A2−13 (C6), and Dyn A4−12 (C5) coeluting with Dyn A1−10 (C7) are listed in Appendix 1. The nonlinear curve fitting program Scientist (Micromath, Salt Lake City, Utah) was used to fit the experimental data to the derived equations.

The initial estimates of the degradation rate constants for the parent compound and metabolites (but not generation rate constants) were taken from the estimates obtained from direct incubations of this fragment.[1] Fitting parameters were not allowed to differ from these initial estimates by more than 30% (the maximum variability generally excepted), if not otherwise stated. Initial estimates for the generation rate constant were based on the initial estimates of the degradation rate constants under enzyme inhibition (Table 1). Since some enzyme inhibitors lacked selectivity, these generation rate constants were generally allowed to vary in the curve fitting procedure between 10% and 130% from the initial estimate of the overall rate constant of the relevant metabolic step.

Goodness of fits were evaluated by r^2 and the Model Selection Criterion (MSC), a value based on the Akaike Information Criterion.[8] A local sensitivity analysis was carried out for each of the Dyn derivatives along with some summary measures.[9] The normalized sensitivity coefficient (SC) detailed by Bieniasz and Speiser was calculated for each Dyn derivative (see Appendix 2).[10]

Results and Discussion

Peptides are of importance as therapeutic agents. For a detailed assessment of their therapeutic and clinical properties a detailed knowledge of the metabolic fate of a given peptide is necessary. Approaches employing Michaelis−Menten-type kinetics would depend on the detailed assessment of enzyme kinetics[11] of parent compound and metabolites, as well as the identification and measurement of all relevant (iso-) enzyme concentrations in the investigated biological media. Using Dyn A1−13 as a model compound, we have previously shown that the size of metabolic pools of peptides can be efficiently evaluated over several metabolic generations by noncompartmental analysis (area under the concentration time profiles) and enzyme inhibition studies with parent drug and synthesized metabolites.[1] Within this study, it was also shown that the degradation of Dyn A1−13 and all its metabolites followed apparent first-order kinetics, similar to results for other peptide drugs.[12] It was therefore of interest to test whether a structured compartmental curve fitting approach is helpful for the assessment of complex metabolic events using Dyn A1−13 degradation as an example. Plasma was chosen since it often represents a major metabolic site for peptide drugs given intravenously.[12] In the following, the advantages and disadvantages of such a multicompartmental kinetic analysis are presented in three examples.

Example 1: Identification of the Metabolic Pathways of Peptide Degradation—The following section demonstrates some of the advantages of the multicompartmental modeling approach for the identification of metabolic pathways. As shown in Figure 1, the metabolic fate of Dyn A2−12, one of the main metabolites of Dyn A1−13, produces Dyn A3−12 and Dyn A4−12. To investigate this N-terminal metabolism in more detail, captopril was added to the incubation solution to suppress the C-terminal metabolism of Dyn A2−12 which is dominated by the angiotensin converting enzyme[1] and restricted the metabolic events on the N-terminus. Initial enzyme inhibition studies[1] with the established aminopeptidase inhibitor bestatin were able to fully block the amino-terminal degradation pathway of Dyn A2−12, suggesting a unidirectional degradation from Dyn A2−12 to Dyn A3−12 and subsequently to Dyn A4−12. A comparison of the AUC estimates of Dyn A3−12 obtained from metabolism of Dyn A2−12 under captopril inhibtion with those obtained after direct incubation of Dyn A3−12 contradicted this hypothesis, as the AUC of Dyn A3−12 was smaller than expected for a unidirectional degradation.[1] Quite in agreement, a simulation with the multicompartmental model using rate constants determined from direct degradation of the involved fragments (degradation rate constant under captopril inhibition for Dyn A2−12, Dyn A3−12, Dyn A4−12 using a sequential metabolism from Dyn A2−12 to Dyn A3−12 to Dyn A4−12) failed to describe the data adequately (Figure 2A). Therefore the metabolic pathways differed somewhat from the simple sequential metabolism suggested by bestatin data.

AUC data would support this unidirectional model of metabolic pathways only, if the rate constant of Dyn A3−12 degradation (under captopril: $k_{45} = k_4$) was increased by 10-fold from its initial estimate (obtained from direct degradation of Dyn A3−12). Such an increase in the metabolic rate of Dyn A3−12 could not be fully excluded if the cleavage of Gly2-Gly3 of Dyn A2−12 would facilitate the subsequent cleavage of Gly3-Phe4 of Dyn A3−12 by the same enzyme (the generated Dyn A3−12 would not have to enter the enzymatic pocket for further cleavage). Such cases of "rate enhancement" have been reported in the literature for other peptides.[13] The reference AUC of

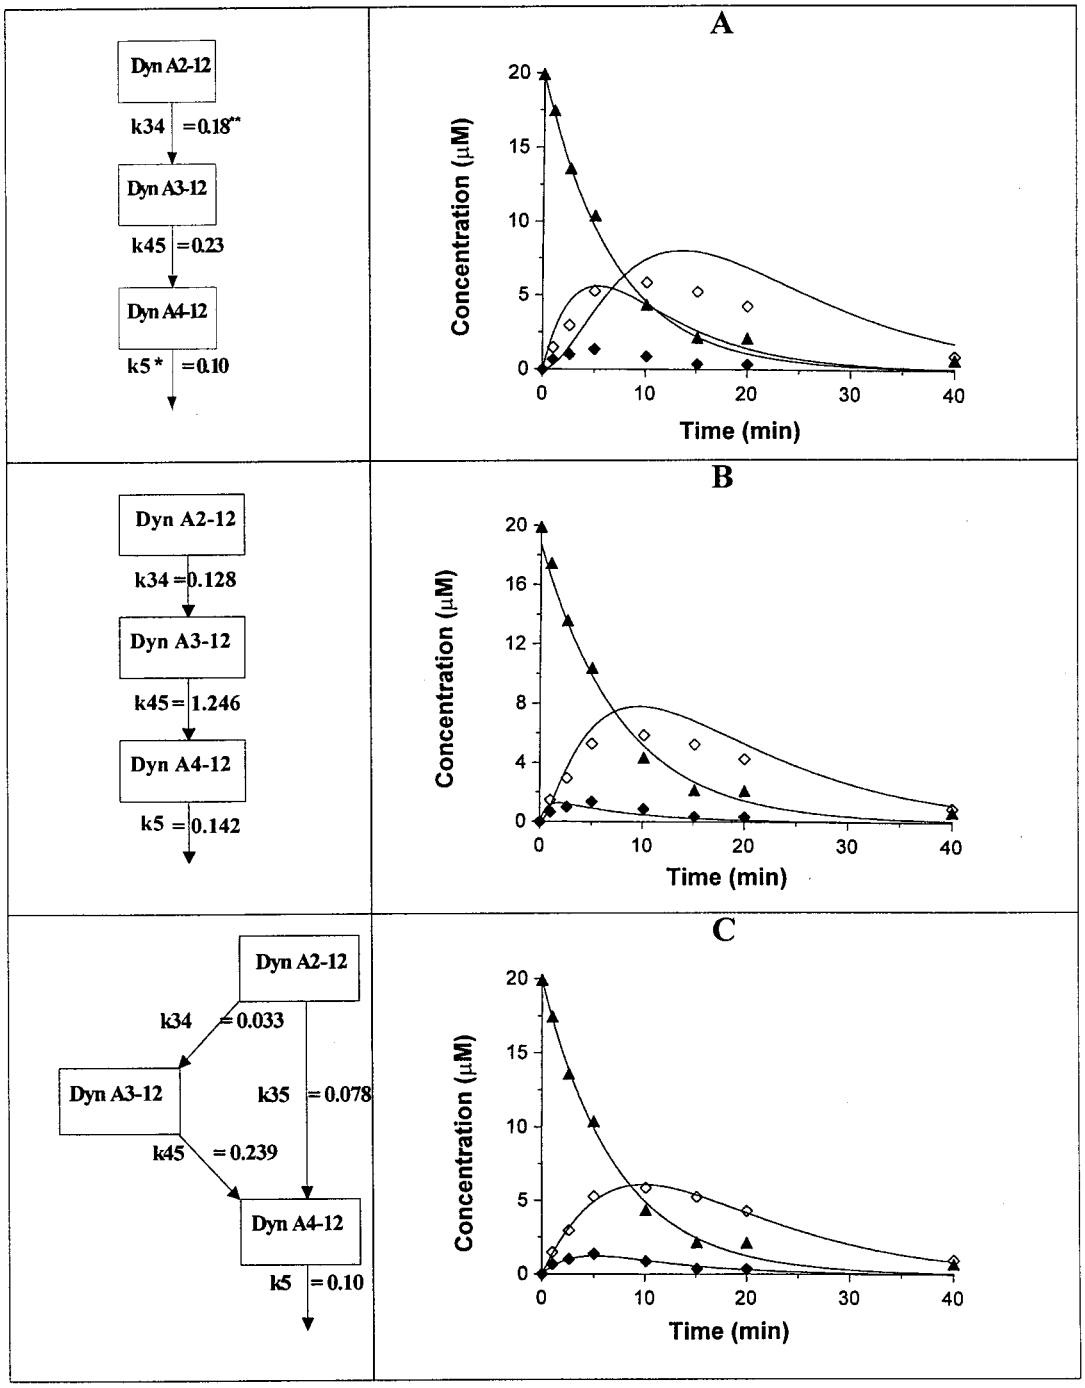

Figure 2—(A) Simulation of concentration–time profiles of Dyn A2–12 (▲) and major metabolites (Dyn A3–12 ◆ and Dyn A4–12 ◇, $r^2 = 0.216$, MSC = –2.781) in human plasma at 37 °C under captopril inhibition using the model of sequential metabolism of Dyn A2–12 into Dyn A3–12 and Dyn A3–12 into Dyn A4–12 with previously obtained rate constants (rate constants under captopril inhibition taken from from Table 1. *k_5 in the presence of captopril was calculated as k_5 (0.17 min^{-1}) minus rate constant associated with captopril sensitive pathway (0.07 min^{-1}): 0.17–0.07 = 0.10 min^{-1} (see Table 1), **k_{34} was based on bestatin enzyme inhibition data ($k_{34} + k_{35}$, see Table 1). (B) Least-squares fit of concentration–time profiles of Dyn A2–12 (▲) and major metabolites (Dyn A3–12 (◆) and Dyn A4–12 (◇), $r^2 = 0.989$, MSC = 3.491) in human plasma at 37 °C under captopril inhibition using model of sequential metabolism of Dyn A2–12 into Dyn A3–12 and increased rate constant k_{45}. k_{34} and k_5 were allowed to float freely (limits for deviation from initial estimates did not apply, see Materials and Methods). (C) Least-squares fit of concentration–time profiles of Dyn A2–12 (▲) and major metabolites (Dyn A3–12 (◆) and Dyn A4–12 (◇), $r^2 = 0.988$, MSC = 5.244) in human plasma at 37 °C under captopril inhibition using the model of simultaneous metabolism of Dyn A2–12 via aminopeptidase and dipeptidylaminopeptidase.

Dyn A3−12 for total conversion from Dyn A2−12 would then be smaller than the AUC observed after direct incubation of Dyn A3−12. For testing this hypothesis with the compartmental model, the rate constant for converting Dyn A3−12 into Dyn A4−12 by the relevant aminopeptidase was assumed to be larger in a series of metabolic events than its estimate obtained from direct degradation of Dyn A3−12. In our data set obtained under captopril inhibition (no C-terminal enzymatic attack), all Dyn A2−12 was then assumed to be converted into Dyn A3−12, and in turn all Dyn A3−12 into Dyn A4−12. However, discrepancies between fitted and observed estimates of Dyn A3−12 or Dyn A4−12 concentration−time profiles were observed in the relevant compartmental model (Figure 2B).

Table 1—Rate Constants of Dynorphin Fragments in Plasma. Listed Is the Overall Rate Constant and the Contribution of Various Enzymatic Systems to the Overall Rate Constant[a]

peptide	*n*	overall rate constant (min^{-1})	rate constant associated with blocked enzyme pathway (min^{-1})			
			GEMSA	bestatin	leucinethiol	captopril
Dyn A1–13	3	0.78 (k_1)	0.61 (k_{12})	0.22 (k_{16})	–	N.T.
Dyn A1–12	3	0.38 (k_2)	N.T.	0.30 (k_{23})	0.28 (k_{23})	0.067 (k_{27})
Dyn A2–13	1	0.99 (k_6)	N.T.	N.T.	N.T.	N.T.
Dyn A2–12	4	0.22 (k_3)	–	0.18 ($k_{34} + k_{35}$)	0.08 (k_{34})	0.07 (k_{38})
Dyn A3–12	2	0.28 (k_4)	N.T.	0.23 (k_{45})	–	0.043
Dyn A4–12	3	0.17 (k_5)	N.T.	0.13	0.09	0.07
Dyn A1–10	1	0.50 (k_7)				

[a] Calculated from ref 1 by transforming half-lives of Table 2 listed in ref 1 into the rate constants associated with the blocked enzyme (associated rate constants of Figure 1 are given in parentheses). NT = not tested; –: no effect.

Table 2—The Formation of Metabolites from Their Parent Compound As Calculated from Multicompartmental Fitting, Enzyme Inhibition Experiments, and Noncompartmental (AUC-based) Analysis[c]

peptide incubated	metabolite formation in % of starting material as calculated by					
	fit	inhibitor	AUC	fit	inhibitor	AUC
Dyn A1–13	79	Dyn A1–12 82	78	10	Dyn A2–13 0 (30[a]	15
Dyn A1–12	78	Dyn A2–12 83 (85)[a]	78	20	Dyn A1–10 19	*b*
Dyn A2–12	15	Dyn A3–12 37 (80)[a]	17	39	Dyn A4–12 28	42

[a] Based on leucinethiol data, bestatin data in brackets. [b] Coeluting with Dyn A4–12. [c] Enzyme inhibition and noncompartmental data taken from ref 1.

These deviations between experimental and modeled concentration−time profile, detected by multicompartmental kinetic analysis, showed the invalidity of the "rate enhanced" unidirectional model.

Finally, a model employing parallel pathways, consequently contradicting the high selectivity of bestatin for aminopeptidase, was investigated using simultaneous least-squares fitting of Dyn A2−12 degradation under ACE inhibition. Rate constants for parallel metabolic pathways were allowed to vary within the limits outlined in the data analysis section. This model adequately described the experimental data (Figure 2C). Thus, the use of the compartmental analysis, suggested the nonspecificity of bestatin, a widely used aminopeptidase inhibitor, very much in agreement with findings by Otero.[14] The consequent use of the more specific inhibitor leucinethiol in the original publication[1] triggered by the results of this fitting procedure supported a smaller involvement of aminopeptidase in the N-terminal metabolism of Dyn A 2−12 (see Table 2). In addition, the analysis suggested a direct degradation of Dyn A2−12 into Dyn A4−12, a pathway which was not revealed by enzyme inhibition studies alone, but in agreement with results of the noncompartmental analysis. These results already argue for one strength of the compartmental approach, namely to incorporate information on the concentration−time relationships in the analysis of complex metabolic events.

Example 2: Detection of Assay Selectivity Problems—Another advantage of simultaneous curve fitting was revealed in the analysis of Dyn A1−12 data. The degradation of Dyn A1−12 under ACE inhibition with captopril using a similar, yet extended, metabolic model described accurately the experimental data (data not shown). Contrary to these results, the concentration−time profile of Dyn A1−12 in naive plasma (no enzyme inhibition) showed a persistent underfit in the profile of Dyn A4−12 in both visual assessment and the correlation statistics on the data set of Dyn A4−12 (Figure 3A).

The hypothesis was that the poor fit might be attributed to the small amounts of generated Dyn A1−10 which was present in the Dyn A1−12 but not in the Dyn A2−12 incubations. Dyn A1−10 and Dyn A4−12 were known to have very similar chromatographic retention profiles in the applied chromatographic system[1] and therefore probably coelute. To investigate the possibility of this peak impurity causing the observed underfit, the concentration−time profile of Dyn A4−12, Dyn A1−10, and their cumulative profile were simulated using the rate constant estimates of k_{27}, k_7, k_2, k_{35}, k_{45}, k_5 from Table 1 (for explanation of abbreviations, see Figure 1) obtained by separate degradation of the relevant dynorphin fragments with or without enzyme inhibitors. The cumulative profile closely resembled the observed data points (Figures 3B and 3C). A fit of Dyn A1−12 degradation in naive plasma taking the impurity into account resulted in a good description of the observed data points (Figure 3C). Although the contributions of Dyn A1−10 to the overall AUC was minor (see relevant degradation rate constants), it illustrates the dependency of noncompartmental kinetic data on chromatographic resolution. Unfortunately, the likelihood of chromatographic impurity increases with the number analytes to be separated; as this was the case for the degradation of Dyn A1−13 for which a total of 17 metabolites were identified. Since all metabolic processes followed apparent first-order kinetics, the multicompartmental modeling approach was instrumental in detecting coelution of chromatographic peaks which none of the other methods would have been able to detect.

Example 3: Application of the Model to Data Sets Describing Entire Degradation Pathways—The above sections showed several advantages of the simultaneous curve fitting procedures in evaluating isolated events in the analysis of complex metabolic systems. In the following the ability to describe and analyze entire degradation pathways is assessed. The applied method, presented so far, incorporated degradation constants based on enzyme inhibition studies into the compartmental analysis to ensure valid initial estimates for the rate constants during the curve fitting procedure. This ensured that the fitting procedure stayed within limits imposed by direct degradation or valid enzyme inhibition experiments of parent drug and metabolites. The same procedure applied to the entire degradation pathway resulted in fits shown in Figure 4 and rate constants observed under rigid limits in Table 3. The agreement between experimentally found and predicted values (Figure 4) strongly supports the validity of the identified metabolic pathway (Figure 1). Table 2 compares the results of the multicompartmental approach, noncompartmental method, and results of the enzyme inhibition studies. Here, the rate constants of degradation or generation obtained from above fitting procedures of Dyn A2−

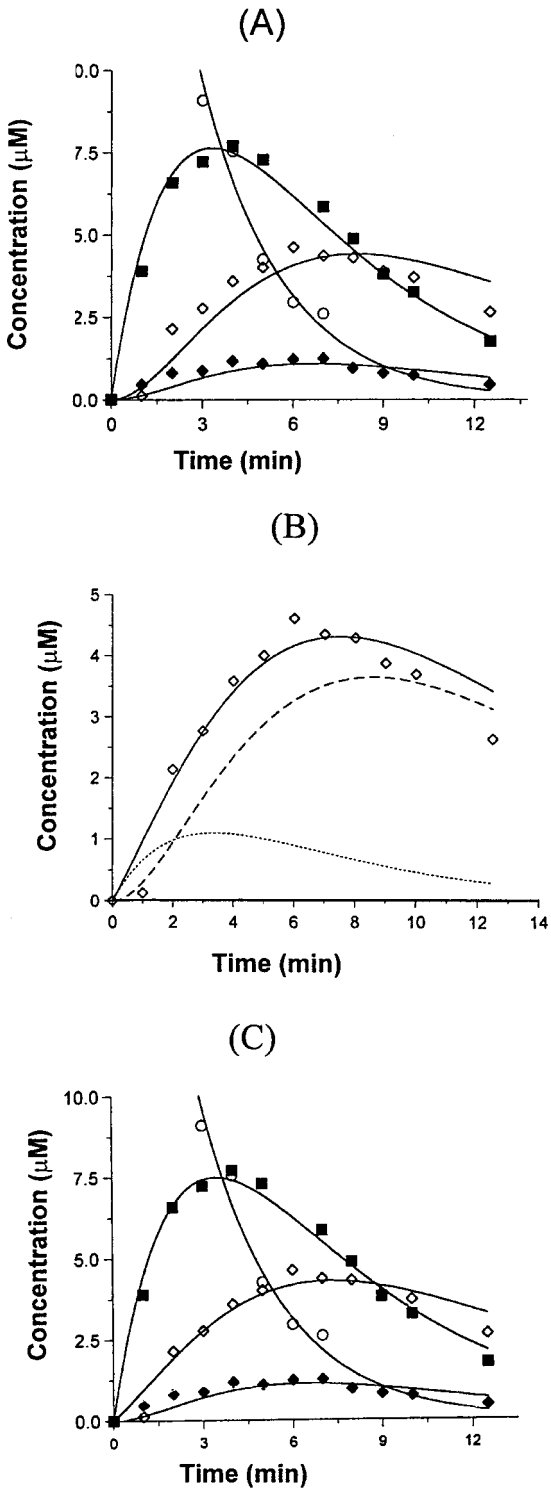

Figure 3—(A) Least-squares fit of concentration–time profiles of Dyn A1–12 (○) and major metabolites (Dyn A2–12 ■, Dyn A3–12 ◆, and assumed Dyn A4–12 (see Figure 3B for more information on "mixed peak") ◇, $r^2 = 0.996$, MSC = 4.81) in human plasma at 37 °C based on the model of Figure 1. (B) Simulation of concentration–time profiles of Dyn A4–12 (- - -) and Dyn A1–10 (•••) after incubation of Dyn A1–12 with overlay of mixed peak (◇). Concentration–time profiles were simulated using unfitted initial estimates of the relevant rate constants (Table 1) or estimates obtained in Figure 2C: $k_7 = 0.5$ min^{-1}, $k_{27} = 0.067$ min^{-1}, $k_{23} = 0.30$ min^{-1}, $k_{34} = 0.008$ min^{-1}, $k_4 = 0.28$ min^{-1}, $k_{45} = 0.239$ min^{-1}, $k_{35} = 0.078$ ($r^2 = 0.987$, MSC = 0.861). (C) Least-squares fit of concentration–time profiles of Dyn A1–12 (○) and major metabolites (Dyn A2–12 ■, Dyn A3–12 ◆, and mixed Dyn A4–12 and Dyn A1–10 ◇, $r^2 = 0.998$, MSC = 5.213) in human plasma at 37 °C based on the model of Figure 1, accounting for coelution of Dyn A4–12 and Dyn A1–10.

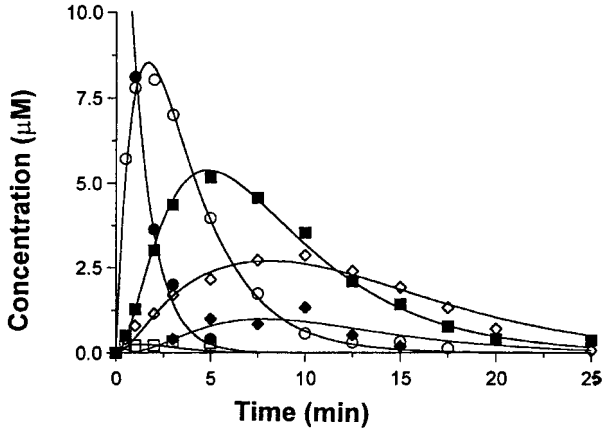

Figure 4—Least-squares fit of concentration–time profiles of Dyn A1–13 (●) and major metabolites (Dyn A1–12 ○, Dyn A2–13 □, Dyn A2–12 ■, Dyn A3–12 ■, and coeluting Dyn A4–12 and Dyn A1–10 ◇, $r^2 = 0.995$, MSC = 4.485) in human plasma at 37 oC accounting for coelution of Dyn A4–12 and Dyn A1–10.

Table 3—Initial Concentration and Rate Constants (min^{-1}) of Dyn A1–13 and Metabolic Fragments in Plasma Fitted to the Model Depicted in Figure 1[a]

parameter	rigid limits*	free-floating parameters**
degradation of A1–13 (k_1)	0.901 ± 0.013	0.892

[a] Parameters were kept in rigid limits as outlined in the data analysis section or allowed to vary freely ("float") between zero and infinity. *$n = 6$, **$n = 1$.

12, Dyn A1−12, and Dyn A1−13 (Table 3) were used to calculate the % of Dyn A 1−13, Dyn A 1−12, or Dyn A2−12 entering a specific metabolite pool. A good agreement between the compartmental curve fitting approach and the other two methods[1] suggests that one strength of the structured multicompartmental approach is the ability to test the correctness of metabolic pathways suggested by other methods.

Removing the limits of the curve fitting procedure, while retaining the initial estimates for the rate constants, probed how well the compartmental model could stand on its own. After least-squares optimization, the majority of rate constants compared to the rate constants obtained with imposed limits (Table 3). However, minor metabolites, rate constants of metabolites for which no direct data were available and/or fast degradation processes (Dyn A2−13 and Dyn A1−10, Table 3) deviated markedly. This suggests that the unrestricted use of parameter estimates carries the danger of "overfitting" the data (e.g., of minor metabolites) to suit a certain model and the loss of identifiability. Although the resulting fit is good, the predicted rate constants are irrelevant, since they do not possess any practical significance (Table 3) when compared with rate constants obtained from enzyme inhibition studies. Another attempt was made to perform the fitting procedure without

good initial estimates for the rate constants (setting all to 0.5 or 1) and without limits. Under these circumstances the data for Dyn A1−13 and its metabolites could not be fitted to the model outlined in Figure 1 (data not shown). More detailed evaluation of the fits described in Figure 4 by local sensitivity analysis identified k_{12} (linked to k_1), k_{63}, and k_{23} as the most sensitive rate constants, while k_{16}, k_{27}, k_{34}, k_{35} represent overall the least sensitive (see Appendix 2 for a more detailed description of the method and Table 4 for a representation of the results of the analysis). Thus, the sensitivity analysis confirmed the presence of general identifiability problems, similar to those indicated by comparing results of rigid and free-floating parameter estimations. The sensitivity analysis reemphasized that the isolated use of such complex models is not feasible. However, the use of experimentally derived estimates of rate constants (e.g., obtained from incubations of synthesized metabolites in the presence or absence of enzyme inhibitors, see Materials and Methods for more detail) in the model is very helpful in probing for the acceptability of a metabolic scheme proposed by the other methods. Thus, structured multicompartmental modeling approaches will be useful in the evaluation of complex peptide degradation pathways when used hand in hand with alternative forms of analysis, such as enzyme inhibition studies and noncompartmental analytical approaches.

In conclusion, the presented apparent first-order multicompartmental approach has several advantages. It is relatively rapid and focuses only on the metabolically relevant processes. The presented model can be extended to include Michaelis−Menten kinetics when necessary. However, such an extension would add several parameters which have to based on further experiments and should only be applied when necessary (i.e., the half-life changes in the experimental concentration range). The application of the compartmental approach in the evaluation of the metabolic fate of Dyn A1−13 and related fragments helped to identify a lack of chromatographic resolution and a low selectivity of one of the enzyme inhibitors employed in the study. It further was able to support the correctness of the proposed metabolic pathways.

Peptide metabolism has been generally evaluated by biochemists with the help of enzyme inhibition studies. The application of pharmacokinetic tools such as noncompartmental approaches have been recently incorporated into such investigations.[1] The results presented in this study suggest distinct advantages of the compartmental analysis for evaluating complex metabolic events. Because of the inherent possible pitfalls of all three methods, the combined use of all approaches might be best suited to assess complex metabolic degradation patterns of peptides in a detailed fashion.

For Dyn A2−12: $C3 = k_{12}k_{23}C0/((k_2 - k_3)(k_1 - k_3))\exp((-k_3)t) + k_{12}k_{23}C0/((k_3 - k_2)(k_1 - k_2))\exp((-k_2)t) + k_{12}k_{23}C0/((k_3 - k_1)(k_2 - k_1))\exp((-k_1)t) + k_{16}k_{63}C0/((k_6 - k_3)(k_1 - k_3))\exp((-k_3)t) + k_{16}k_{63}C0/((k_3 - k_6)(k_1 - k_6))\exp((-k_6)t) + k_{16}k_{63}C0/((k_3 - k_1)(k_6 - k_1))\exp((-k_1)t)$

For Dyn A3−12: $C4 = k_{12}k_{23}k_{34}C0/((k_3 - k_4)(k_2 - k_4)(k_1 - k_4))\exp((-k_4)t) + k_{12}k_{23}k_{34}C0/((k_4 - k_3)(k_2 - k_3)(k_1 - k_3))\exp((-k_3)t) + k_{12}k_{23}k_{34}C0/((k_4 - k_2)(k_3 - k_2)(k_1 - k_2))\exp((-k_2)t) + k_{12}k_{23}k_{34}C0/((k_4 - k_1)(k_3 - k_1)(k_2 - k_1))\exp((-k_1)t) + k_{16}k_{63}k_{34}C0/((k_3 - k_4)(k_6 - k_4)(k_1 - k_4))\exp((-k_4)t) + k_{16}k_{63}k_{34}C0/((k_4 - k_3)(k_6 - k_3)(k_1 - k_3))\exp((-k_3)t) + k_{16}k_{63}k_{34}C0/((k_4 - k_6)(k_3 - k_6)(k_1 - k_6))\exp((-k_6)t) + k_{16}k_{63}k_{34}C0/((k_4 - k_1)(k_3 - k_1)(k_6 - k_1))\exp((-k_1)t)$

For Coeluting Dyn A4−12 (C5) and Dyn A1−10 (C7): $C5 = k_{12}k_{23}k_{35}C0/((k_3 - k_5)(k_2 - k_5)(k_1 - k_5))\exp((-k_5)t) + k_{12}k_{23}k_{35}C0/((k_5 - k_3)(k_2 - k_3)(k_1 - k_3))\exp((-k_3)t) + k_{12}k_{23}k_{35}C0/((k_5 - k_2)(k_3 - k_2)(k_1 - k_2))\exp((-k_2)t) + k_{12}k_{23}k_{35}C0/((k_5 - k_1)(k_3 - k_1)(k_2 - k_1))\exp((-k_1)t) + k_{16}k_{63}k_{35}C0/((k_3 - k_5)(k_6 - k_5)(k_1 - k_5))\exp((-k_5)t) + k_{16}k_{63}k_{35}C0/((k_5 - k_3)(k_6 - k_3)(k_1 - k_3))\exp((-k_3)t) + k_{16}k_{63}k_{35}C0/((k_5 - k_6)(k_3 - k_6)(k_1 - k_6))\exp((-k_6)t) + k_{16}k_{63}k_{35}C0/((k_5 - k_1)(k_3 - k_1)(k_6 - k_1))\exp((-k_1)t) + k_{12}k_{23}k_{34}k_{45}C0/((k_4 - k_5)(k_3 - k_5)(k_2 - k_5)(k_1 - k_5))\exp((-k_5)t) + k_{12}k_{23}k_{34}k_{45}C0/((k_5 - k_4)(k_3 - k_4)(k_2 - k_4)(k_1 - k_4))\exp((-k_4)t) + k_{12}k_{23}k_{34}k_{45}C0/((k_5 - k_3)(k_4 - k_3)(k_2 - k_3)(k_1 - k_3))\exp((-k_3)t) + k_{12}k_{23}k_{34}k_{45}C0/((k_5 - k_2)(k_4 - k_2)(k_3 - k_2)(k_1 - k_2))\exp((-k_2)t) + k_{12}k_{23}k_{34}k_{45}C0/((k_5 - k_1)(k_4 - k_1)(k_3 - k_1)(k_2 - k_1))\exp((-k_1)t) + k_{16}k_{63}k_{34}k_{45}C0/((k_4 - k_5)(k_3 - k_5)(k_6 - k_5)(k_1 - k_5))\exp((-k_5)t) + k_{16}k_{63}k_{34}k_{45}C0/((k_5 - k_4)(k_3 - k_4)(k_6 - k_4)(k_1 - k_4))\exp((-k_4)t) + k_{16}k_{63}k_{34}k_{45}C0/((k_5 - k_3)(k_4 - k_3)(k_6 - k_3)(k_1 - k_3))\exp((-k_3)t) + k_{16}k_{63}k_{34}k_{45}C0/((k_5 - k_6)(k_4 - k_6)(k_3 - k_6)(k_1 - k_6))\exp((-k_6)t) + k_{16}k_{63}k_{34}k_{45}C0/((k_5 - k_1)(k_4 - k_1)(k_3 - k_1)(k_6 - k_1))\exp((-k_1)t)$

$C7 = k_{12}k_{27}C0/((k_2 - k_7)(k_1 - k_7))\exp((-k_7)t) + k_{12}k_{27}C0/((k_7 - k_2)(k_1 - k_2))\exp((-k_2)t) + k_{12}k_{27}C0/((k_7 - k_1)(k_2 - k_1))\exp((-k_1)t)$

Appendix 2

Calculation of Sensitivity Coefficients—A local sensitivity analysis was carried out for each Dyn along with some summary measures, e.g., see Rabitz for a detailed description.[9] The normalized sensitivity coefficient (SC) detailed in Bieniasz and Speiser was calculated for each Dyn i as[10]

$$SC_{ij}(t) = \frac{\partial \ln C_i(t)}{\partial \ln k_j}\Big|_{k_j = k'_j} \qquad (1.1)$$

where i, $i = 1, 2, 7$, the rate constant j corresponds to the set $j = \{12, 16, 23, 27, 34, 35, 45, 5, 63, 7\}$, and the equations for the C_i's are given in Appendix 1. The values for the k_j are given in Table 3. Furthermore, the SC for C5 and C7 was calculated jointly, since C5 and C7 were considered additive, i.e., the joint SC was given by $SC_{5,j} + SC_{7,j}$. The rate constants k_1, k_2, k_3, k_4, k_6 were linked to the other rate constants through the equations $k_1 = k_{16} + k_{12} + k_{1u}$ or $k_2 = k_{23} + k_{27} + k_{2u}$ or $k_3 = k_{34} + k_{35} + k_{3u}$ or $k_4 = k_{45} + k_{4u}$ or $k_6 = k_{63} + k_{6u}$, where k_{1u}, k_{2u}, k_{3u}, k_{4u}, k_{6u} represents degradation of specific metabolites not included in known metabolic pathways. The absolute magnitude of the SC's were summarized across time as

$$ASC_{i,j} = \sum_{k=1}^{7} |SC_{i,j}(t_k)|, \quad (1.2)$$

where $t_1 = 1$, $t_2 = 2$, $t_3 = 5$, $t_4 = 10$, $t_5 = 20$, $t_6 = 30$, and $t_7 = 40$. The results are given in the body of Table 4. The values were then averaged for each rate constant in order to provide a global measure of sensitivity across time. To calculate the overall mean sensitivity, we did not average in the values of $ASC_{i,j} = 0$.

Solubilization of Flavopiridol by pH Control Combined with Cosolvents, Surfactants, or Complexants

PING LI,† S. ESMAIL TABIBI,‡ AND SAMUEL H. YALKOWSKY*,†

Contribution from *Department of Pharmaceutical Sciences, College of Pharmacy, University of Arizona, Tucson, Arizona 85721, and Pharmaceutical Resources Branch, National Cancer Institute, NIH, Bethesda, Maryland 20892.*

Received March 30, 1999. Accepted for publication June 11, 1999.

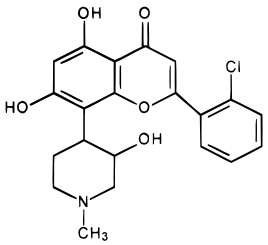
Abstract □ This study investigates the roles of both ionized and un-ionized species of flavopiridol in solubilization by complexation, micellization, and cosolvency. Control of pH was used in combination with surfactants (polysorbate 20 and polysorbate 80), cosolvents (ethanol and propylene glycol), as well as uncharged and anionic complexing agents [hydroxypropyl β-cyclodextrin (HPβCD) and sulfobutyl ether β-cyclodextrin (SBEβCD)] to solubilize flavopiridol. These combined techniques increase not only the solubility of the un-ionized flavopiridol but also the solubility of the ionized drug. This study confirms that previously developed equations effectively characterize the roles of pH, pK_a, and either complexation constant, micelle partition coefficient, or cosolvent solubilizing power in determining drug total aqueous solubility.

Introduction

Flavopiridol is a synthetic derivative of rohitukine that is currently undergoing clinical trails by the National Cancer Institute as an antineoplastic agent. This compound is a potent cyclin-dependent enzymes (CDK) inhibitor and promotes apoptosis when combined with other chemotherapeutic agents.[1] It has a water solubility of 0.025 mg/mL, which is 400 times lower than the desired concentration for intravenous (iv) infusion. Although this compound has an apparent pK_a value of 5.86, solubilization by pH control could not produce a stable 10 mg/mL solution that does not precipitate upon injection.[2] Furthermore, other solubilization techniques, such as cosolvency, micellization, and complexation, were ineffective in providing adequate solubilization within a physiologically acceptable vehicle.[2]

In a previous study, we investigated the combined effect of pH control and complexation on drug solubilization.[3] It was shown that the solubility of the complex is proportional to the product of the complexation constant and the solute solubility for both the un-ionized and ionized solutes. Though the ionized solute has a smaller complexation constant, it has greater water solubility compared with that of the un-ionized solute. A change in pH favoring solute ionization will not simply increase the solubility of the solute in water, but it will increase the solubility of the complex because the latter is proportional to solute concentration. Further studies also suggest that under certain circumstances the solubilization of the ionized solute by either cosolvent or surfactant is more important than the solubilization of the un-ionized solute in determining the total solubility.[4] It is of note that the current iv flavopiridol dosage form used for clinical trails is formulated in a 10 mg/mL solution by using pH control in combination with complexation. This formulation does not precipitate upon dilution by isotonic Sorensen's phosphate buffer.[2,5]

This paper compares the role of the ionized flavopiridol species with the role of the un-ionized species in drug solubilization by complexation, micellization, and cosolvency. Control of pH is used in combination with surfactants (polysorbate 20 and polysorbate 80), cosolvents (ethanol and propylene glycol (PG)) as well as the uncharged and anionic complexing ligands [hydroxypropyl β-cyclodextrin (HPβCD) and sulfobutyl ether β-cyclodextrin (SBEβCD)], respectively.



Flavopiridol

Materials

Flavopiridol was provided by the National Cancer Institute and used as received. Hydroxypropyl β-cyclodextrin (HPβCD), with an average molecular weight of 1390 and an average degree of substitution of 4.4, was obtained from Cyclodextrin Technologies Development Inc. (Gainesville, FL). Sulfobutyl ether β-cyclodextrin (SBEβCD), with an average molecular weight of 2162 and an average degree of substitution of 7, was a gift from CyDex, L. C. (Overland Park, KS). All other chemicals were of reagent grade, purchased from Sigma (St. Louis, MO) or Aldrich (St. Louis, MO), and used without further purification. Citrate-phosphate buffers were prepared according to Scientific Tables.[6]

Methods

Solubility Determination. An excess of flavopiridol was added to duplicate vials containing 0.5 mL of the following solutions: HPβCD, SBEβCD, polysorbate 20, polysorbate 80, ethanol, and propylene glycol with concentrations of 0, 2.5, 5, 10, and 20% in citric-phosphate buffers at pH 4.3 and 8.4. The sample vials were then rotated using

an end-over-end mechanical rotator at 20 rpm (Glas-Col Laboratory Rotator, Terre Haute, IN) at 25 °C for 6 days (preliminary data indicate that flavopiridol is stable for 2 months under these conditions). Samples with drug crystals present were considered to have reached their equilibrium solubility and were removed from the rotator. The samples were filtered through a 0.45-μm filter and the pH at equilibrium was measured before performing the high-performance liquid chromatography (HPLC) analysis.

HPLC Analysis. The HPLC assay was modified from a previous report.[6] Briefly, a Pinnacle octylamine column (150 cm × 4.6 mm, Restek, Bellefonte, PA) was used with a mobile phase composed of 0.1% triethylamine in 50 mM phosphate buffer at pH 2.5 (adjusted by H_3PO_4) and acetonitrile in a ratio of 35: 65. The flow rate was controlled at 1 mL/min (125 Solvent Module, Beckman, Fullerton, CA), and the effluent was detected at 263 nm (168 detector, Beckman, Fullerton, CA). Neither the buffer nor any of the solubilizing agents interfere with the assay.

Results and Discussions

Solubilization by pH Control and Complexation. Figure 1 shows the effect of the complexation agents, HPβCD and SBEβCD, on the solubility of flavopiridol at pH 4.3 and 8.4. The drug solubility in the absence of either HPβCD or SBEβCD is ~0.055 mM at pH 8.4 and ~1.37 mM at pH 4.3. The solubility increases linearly as a function of the concentration of both cyclodextrins at both pH conditions. However, the solubility increase is far more significant at the low pH where the drug is cationic. For example, in the presence of 10% HPβCD, its solubility is 6-fold greater at pH 4.3 than that at pH 8.4. Similarly, when SBEβCD is used, the solubility difference between the two solution pHs is 12-fold.

Li et al.[3] showed that eq 1 describes the dependency of total solubility of a drug on the concentration of complexation ligand at any pH.

$$[D^{tot}] = [D_u] + [D_u]10^{(pK_a - pH)} + K_u[D_u][L] + K_i[D_u]10^{(pK_a - pH)}[L] \quad (1)$$

where $[D_u]$ is the solubility of free un-ionized drug, $[L]$ is the ligand concentration, and K_u and K_i are the complexation constants of the un-ionized and of the ionized species, respectively. The equation describes the total solubility as the sum of four species: free un-ionized drug $[D_u]$, free ionized drug $[D_u]10^{(pK_a - pH)}$, un-ionized drug−ligand complex $K_u[D_u][L]$, and ionized drug−ligand complex $K_i[D_u]10^{(pK_a - pH)}[L]$. The solubility data from Figure 1 were used to calculate the complexation constants of neutral and cationic flavopiridol species with a neutral ligand, HPβCD, or with an anionic ligand, SBEβCD, via eq 1. The values obtained are $K_u = 485\ M^{-1}$ and $K_i = 149\ M^{-1}$ for HPβCD, and $K_u = 991\ M^{-1}$ and $K_i = 421\ M^{-1}$ for SBEβCD.

Although the complexation constant is greater for the uncharged form than for the cation, the latter is often more efficiently solubilized. The solubility of a weak base increases exponentially with a decrease in solution pH below the pK_a. As a result, the ratio of the solubility of the ionized to un-ionized drug often exceeds the ratio of the complexation constant of the un-ionized to ionized drug, that is, $10^{(pK_a - pH)} > K_u/K_i$ (or $[H]/K_a > K_u/K_i$). Accordingly the cationic drug−ligand complex can have a greater solubility than the un-ionized drug−ligand complex. This result is consistent with the results of other studies.[7−9]

Solubilization by pH Control and Micellization. Figure 2 shows the solubility of flavopiridol as a function of both surfactant concentration and pH of the solution. An increase in the concentration of surfactants, either polysorbate 20 or polysorbate 80, produces a linear increase in drug solubility. Again, the solubility increase is much greater at pH 4.3 than that at pH 8.4. This phenomenon can be described by eq 2.[4]

$$[D^{tot}] = [D_u] + [D_u]10^{(pK_a - pH)} + \kappa_u[D_u][C_m] + \kappa_i[D_u]10^{(pK_a - pH)}[C_m] \quad (2)$$

where κ_u and κ_i are micellar partition coefficients for the un-ionized species and the ionized species of drugs, respectively, and $[C_m]$ is micellar concentration. The value of $[C_m]$ is approximately equal to the total surfactant concentration when the critical micellar concentration is small. Note that eq 2 is analogous to eq 1, which characterizes solubilization by combined pH control and complexation.

The solubility data from Figure 2 are incorporated into eq 2 and the micellar partition coefficients are calculated to be $\kappa_u = 375\ M^{-1}$ and $\kappa_i = 194\ M^{-1}$ with polysorbate 20, and $\kappa_u = 551\ M^{-1}$ and $\kappa_i = 214\ M^{-1}$ with polysorbate 80. The lower micellar partition coefficients for the cation is obviously due to its greater affinity to water. According to eq 2, the solubility of drug in micelles is determined by the product of the micellar partition coefficient and drug water solubility, that is, $\kappa_u[D_u]$ for the un-ionized drug and $\kappa_i[D_i]$ for the ionized drug. As in the case of complexation, the solubility of the drug in micelles will be greater for the ionized species than for the un-ionized species if $10^{(pK_a - pH)} > \kappa_u/\kappa_i$. Again, the greater solubility of ionized drug in micelles at pH 4.3 results from its greater solubility in water. The slightly higher solubilization capacity of polysor-

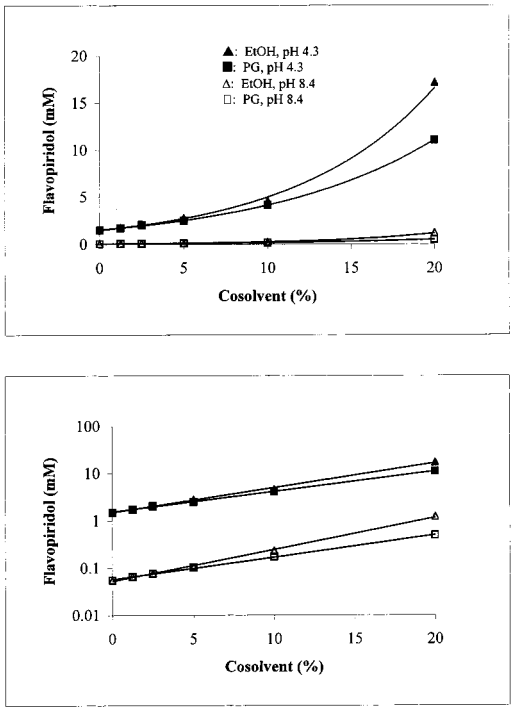

Figure 3—(a) Total experimental aqueous flavopiridol solubilities (symbols) in cosolvent solutions at different pHs. (b) Schematic semilogarithmical plot of the total aqueous solubility of flavopiridol against cosolvent volume fraction.

bate 80 in comparison with polysorbate 20 is because of the larger hydrophobic core produced by its longer alkyl chains.

Solubilization by pH Control and Cosolvency. Figure 3a shows the effects of ethanol and propylene glycol on the total solubility of flavopiridol as a function of pH. Unlike the effects of complexant or surfactant, an increase in the concentration of cosolvents produces an exponential increase in drug solubility. Once more, the drug solubility at pH 4.3 is much higher than that at pH 8.4. In a previous study,[4] the pH related solubilization produced by a cosolvent was described by

$$[D^{tot}] = [D_u]10^{\sigma_u f} + [D_u]10^{(pK_a - pH)}10^{\sigma_i f} \qquad (3)$$

where f is the volume fraction of cosolvents and σ_u and σ_i are the solubilizing powers of the cosolvent for the un-ionized and the ionized species, respectively. Note that because the values of σ_u and σ_i are dependent on the polarity of the solute, σ_u will be greater than σ_i for both cosolvents. If the difference between the drug pK_a and the solution pH is greater than the difference between the cosolvent solubilizing powers for the un-ionized species and for the ionized species (i.e., $pK_a - pH > \sigma_u - \sigma_i$), then the solubilization of the charged species can exceed that of the neutral species.

Figure 3a can be re-plotted semilogarithmically as is seen in Figure 3b, where linear relationships between log-[D^{tot}] and cosolvent volume fraction f are evident at both pHs in both cosolvents. The slopes at pH 4.3 and pH 8.4 show that σ_u and σ_i are only slightly different, with respective values of 0.06 and 0.05 for ethanol, and 0.05 and 0.04 for propylene glycol. Although the un-ionized drug solubility increases by a slightly higher factor than that of the ionized drug (i.e., $\sigma_u > \sigma_i$ for both cosolvents), the amount of drug solubilized is much greater at the lower pH where the drug ionizes because the concentration of cation far exceeds the concentration of the uncharged drug in the solution at pH 4.3. It was also observed that both σ_u and σ_i in ethanol are slightly larger than in propylene glycol. This larger increase in drug solubility results from the fact that ethanol is less polar than propylene glycol.

Conclusions

As described by eqs 1, 2, and 3, pH control can be used in combination with complexation, micellization, or cosolvency, respectively, to improve the ionized drug solubility as well as the un-ionized drug solubility. These equations characterize the effects of un-ionized and particularly ionized species with respect to the pH, pK_a, and either the complexation constant K, micelle partition coefficient κ, or solubilizing power σ. They provide a theoretical background for understanding the dynamics of these combined techniques. The knowledge gained in this study may help in producing physically stable formulations for weakly ionizable drugs.

Blood–Brain Barrier Properties of Human Immunodeficiency Virus Antiretrovirals

MEHRAN YAZDANIAN

Contribution from *Department of Pharmaceutics, Boehringer Ingelheim Pharmaceuticals Inc., 900 Ridgebury Road, P.O. Box 368, Ridgefield, Connecticut 06877.*

Received June 7, 1999. Final revised manuscript received July 14, 1999.
Accepted for publication July 21, 1999.

Introduction

Human immunodeficiency virus (HIV) enters the central nervous system (CNS) early in infection and forms a reservoir in the brain as evidenced by the presence of large quantities of unintegrated viral DNA in the brains of HIV infected individuals.[1,2] The mechanism by which HIV enters the brain is not well understood, however, the resulting infection leads to a number of CNS disorders such as autoimmune deficiency syndrome (AIDS) dementia complex, HIV encephalitis, and peripheral neuropathy.[3,4] Current HIV therapies are focused on reducing the viral load in serum, however, the presence of HIV in sequestered compartments such as the brain significantly limits their efficacy. Hence, the ability of antiretrovirals to enter the brain in therapeutic amounts to treat HIV infection is an essential part of effective HIV therapy. The main barrier for transport of antiretroviral agents to the brain is the blood−brain barrier (BBB). To combat infection and inhibit the replication of HIV in the brain, antiretroviral agents must cross the BBB. Remarkably, there are very few studies that have addressed this issue. This review presents the current understanding of the BBB transport properties of the Food and Drug Administration (FDA)-approved HIV antiretrovirals. Future directions for a better understanding of the BBB permeability of current and upcoming HIV antiretrovirals to treat the devastating neurological and cognitive disorders seen in AIDS patients are also discussed.

Blood–Brain Barrier

The brain is protected by a unique regulatory barrier composed of brain microvessel endothelial cells (BMEC), astroglia, pericytes, perivascular macrophages, and basal lamina, which is collectively known as the BBB. The BMECs provide the functional and morphological basis of the BBB, which acts as a regulatory interface and limits the permeability of the brain to drugs. The selective permeability of the BBB is due to BMECs distinct morphological and enzymatic properties that enable them to form continuous and unfenestrated tight junctions with minimal endocytotic and pinocytotic activity. The presence of tight junctions limits the entry of many blood-borne elements, including small molecules and macromolecules as well as circulating leukocytes, to the brain.[5] The presence of efflux pumps such as P-glycoproteins, which are associated with multidrug resistance (MDR) in BMECs, also limits the transport of drugs across the BBB.

The Effect of HIV on the BBB

HIV infection of the brain is believed to occur through direct and indirect effects on BMECs of the BBB. For example, in vitro studies have shown that HIV readily infects human BMECs to allow its direct entry into the brain.[6] The indirect passage of HIV-infected monocytes or lymphocytes across the BBB via adhesion molecules of BMECs and astrocytes has also been reported.[6] Moreover, HIV entry to the brain may be facilitated by alterations in the BBB permeability due to elevated levels of circulating cytokines, such as TNFα and IL2, in infected patients.[7]

Only indirect methods have been used for determining changes in the integrity of the BBB. These methods include immunostaining for fibrinogen and immunoglobulin G, which are markers of vascular permeability, in postmortem brains, monitoring changes in the magnetic resonance imaging of the brain, and measuring cerebrospinal fluid (CSF) serum protein levels of the HIV-infected individuals. The results of immunostaining for immunoglobulin G and fibrinogen deposition in postmortem brains of AIDS and control patients to detect excess leakage across the BBB due to HIV infection have been inconclusive.[8] Histological, immunocytochemical, and ultrastructural analysis of brain tissues have not shown significant abnormalities either.[7] However, marked accumulations of serum proteins have been seen in the brains of patients with AIDS dementia.[7] Given the limited data and shortcoming of the methods used, the functional integrity of the BBB is thought to remain intact after HIV infection.[9]

HIV Antiretroviral Agents

Currently there are three classes of compounds available for treatment of HIV infection; these are nucleoside reverse transcriptase inhibitors (NRTI), nonnucleoside reverse transcriptase inhibitors (NNRTI), and protease inhibitors. NRTI inhibit HIV replication by blocking reverse transcription of the viral RNA and preventing the formation of DNA as a template for future viral replication. NNRTI inhibit HIV replication by binding through hydrophobic interactions to the reverse transcriptase catalytic sites. Protease inhibitors stop viral replication by inhibiting HIV encoded protease and result in the release of noninfectious immature viral particles. The generic name, brand/common

[a] Solubility in water at room temperature and protein binding as reported in the *Physician's Desk Reference*.[25] [b] Log D_{oct} = logarithm of octanol/phosphate buffered saline (pH 7.4) distribution coefficient.[11]

names, molecular weight, octanol/water distribution coefficients, and plasma protein binding of the approved HIV antiretroviral drugs are listed in Table 1.

The physicochemical properties of the currently marketed HIV antiretrovirals are vastly different. NRTIs are low molecular weight, highly water soluble, and (with the exception of the most recently approved NRTI, abacavir) very hydrophilic drugs. The extent of protein binding of NRTIs ranges from negligible for stavudine to ~50% for abacavir. Among the NNRTIs, nevirapine has significantly higher solubility and lower protein binding than either delavirdine or efavirenz. The latter two are almost completely protein bound. Protease inhibitors have higher molecular weights and are highly lipophilic compared with NRTIs and NNRTIs. Except for indinavir, protease inhibitors are highly protein bound.

Measuring BBB Penetration

In Vitro Studies—Isolation and culture of BMECs from the brain has led to the development of in vitro models for studying a variety of CNS drug delivery issues ranging from passive diffusion, carrier-mediated transport, and metabolism to specific factors affecting the BBB permeability.[10] In these models, BMECs can be grown as monolayers and retain the characteristics of brain endothelial cells in vivo, including the morphology, specific BBB enzyme markers, and tight intercellular junctions. The in vitro bovine BMEC monolayer permeability coefficients, P_{BMEC}, of different classes of HIV antiretroviral agents have recently been reported.[11,12] These agents included four NRTIs (didanosine, stavudine, zalcitabine, and zidovudine), two NNRTIs (nevirapine and delaviridine), and three protease inhibitors (amprenavir, indinavir, and saquinavir). Figure 1 shows P_{BMEC} values for these HIV antiretrovirals as well as for abacavir compared with those of progesterone, a highly permeable transcellular marker, and sucrose, a paracellular marker.[11,12]

The P_{BMEC} value for nevirapine is significantly higher than all the other HIV antireterovirals tested. The P_{BMEC} value for saquinavir is >2 orders of magnitude lower than nevirapine. The values for indinavir, amprenavir, and all

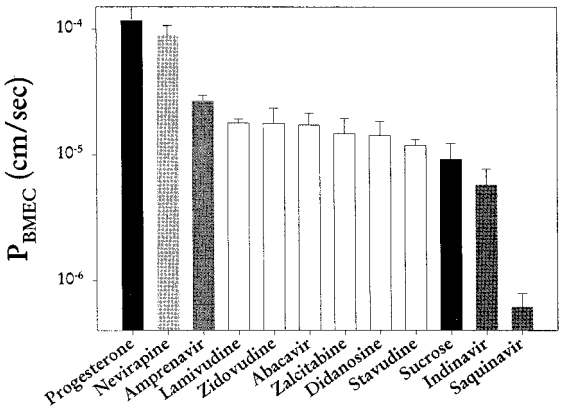

Figure 1—In vitro permeability of HIV antiretrovirals across the BMEC monolayers.[11,12]

NRTIs are also significantly lower than that of nevirapine. Moreover, the P_{BMEC} values for all NRTIs are not significantly different from each other because they have similar molecular weights and, with the exception of abacavir, very similar partitioning values. The low permeability of the protease inhibitors was attributed to their high lipophilicity and large molecular weights as well as higher potential for hydrogen bonding. The order of in vitro BBB permeability is: nevirapine ≫ amprenavir > abacavir, didanosine, stavudine, zalcitabine, and zidovudine > indinavir > saquinavir.[11,12]

In Vivo Studies—The concentration of antiretrovirals necessary to suppress HIV replication in the human brain is not known and naturally cannot be obtained in vivo. Hence, in vivo measurements of the extent of HIV antiretroviral penetration across the BBB in humans are limited to obtaining CSF concentrations from lumbar punctures. Clinical studies show that the presence of HIV antiretrovirals, such as stavudine and zidovudine, in CSF correlates well with improvement of HIV dementia.[13,14] HIV antiretroviral CSF concentrations have been most commonly used in conjunction with plasma concentrations to obtain the so-called CSF-to-plasma concentration ratios as a surrogate marker for the extent of the BBB permeability. These values have been reported with more frequency for the newly approved HIV antiretroviral inhibitors as a measure of their effectiveness in treating the CNS component of HIV infection (Table 2).

The major shortcomings of CSF-to-plasma concentration ratios as potential markers for drug penetration into the brain are the manner in which they are determined and interpreted. Direct comparisons cannot be made because of the varied experimental conditions (e.g., steady state versus non-steady state) under which these values have been obtained. Nor have these values been corrected for possible metabolism or protein binding in the brain. For example, the values for CSF-to-plasma concentration ratios reported for zidovudine are in the range of 0.15 to 1.35 and depend on the route of administration and dose given and hence do not conclusively determine how readily zidovudine crosses the BBB. Moreover, it has been shown that the CSF peak lags behind the plasma peak in concentration curves for zidovudine in plasma and CSF.[15] Hence, CSF-to-plasma concentration ratios are strongly time dependent and one time point measurements of CSF-to-plasma concentration ratios are not reliable. Furthermore, the absence of protein in CSF necessitates comparing CSF concentrations of HIV antiretrovirals to unbound plasma concentrations. Such comparisons are rarely done when CSF-to-plasma concentration ratios are reported.

The use of CSF levels may also be misleading because of differences in permeability of blood–CSF barrier (BCB)

Table 2—Cerebrospinal Fluid-to-Plasma and Brain-to-Plasma Concentration Ratios in Humans and Rat for Various HIV Antiretrovirals

antiretroviral	[CSF]/[plasma] in humans	[brain]/[plasma] in rat
	nucleoside-inhibitors	
abacavir	—	—
didanosine	0.16–0.19[52] not detected in CSF[55]	0.05, 0.007[41 a]
lamivudine	0.06–0.31[24]	—
stavudine	0.16–0.97[54]	0.33[55]
zalcitabine	0.09–0.37[24]	not measurable[56]
zidovudine	0.15–1.35[57]	0.19,[28] 0.23 ± 0.02[58]

[a] Corrected for blood contribution to total brain concentration. [b] Mean CSF-to-plasma concentration ratios.

and the BBB.[9] The BBB is a more restrictive barrier than the BCB and because of its 5000-fold greater surface area, it is the main route of entry for drugs from blood to the brain.[9] Moreover, CSF and brain interstitial fluid are not in equilibrium and therefore the drug concentration in CSF does not necessarily reflect the extent of BBB transport of that drug because it may also include transport through the choroid plexus via the BCB. It then appears that CSF and CSF-to-plasma concentration ratios can only be used as qualitative measures of the ability of HIV antiretrovirals to cross the BBB and cannot be used to rank and order compounds in terms of their BBB permeability.

Due to inherent difficulty and indirect nature of the methods used in obtaining human data, a number of investigators have used laboratory animals to determine brain-to-plasma concentration ratios of HIV antiretrovirals. This parameter is the simplest and most direct measure of the BBB penetration of a given drug. The extent of brain drug uptake can also be presented by brain uptake index (BUI) or blood-to-brain transfer constant values.[16] The BUI is the extraction ratio of a drug relative to highly permeable compounds such as water or butanol. The major shortcomings of all of these values are that they are time dependent, require sacrificing of the animals, and must be corrected for the amount of drug retained in vascular space of the brain.[17] Furthermore, the relevance of these values in predicting the extent of penetration of the BBB in humans by HIV antiretroviral has not yet been established.

The reported in vivo studies of BBB properties of different classes of HIV antiretroviral agents are summarized next.

NRTI—There is no clear correlation between the BBB properties of NRTIs determined from animal studies and measurements of CSF values in humans. Available data on surrogate markers for BBB permeability, such as CSF-to-plasma concentration ratios in humans and brain-to-plasma concentration ratios in rats, suggest that the extent of BBB penetration for NRTIs is low and, in the case of stavudine and zidovudine, highly variable (Table 2). Moreover, clinical studies have shown that the BBB permeability of NRTIs could also be significantly different in humans. For example, in a small study of 16 patients, CSF HIV-1 RNA levels were reduced following zidovudine and not didanosine treatment.[18] Similarly, there were no clinical benefits associated with didanosine treatment suggesting that the extent of its BBB penetration in humans was also low.[19] The BBB permeability of zidovudine in humans is further supported by data suggesting reduction in the risk of developing AIDS dementia as well as improvement in cognitive impairment of AIDS patients after systemic treatment with zidovudine.[20,21] Lamivudine and stavudine also appear to penetrate the BBB in humans as indicated by a recent study where the levels of CSF HIV-1 RNA in 22 patients were reduced following treatment with these NRTIs.[22]

NNRTI—Nevirapine was the first NNRTI approved for treatment of HIV, and its BBB properties have been extensively studied.[11,12,23] The plasma-to-brain concentration ratios of nevirapine in rats and monkeys were shown to be close to 1.[23] In humans, nevirapine has a CSF-to-plasma concentration ratio of 0.45, which is approximately equal to the fraction not bound to plasma protein.[24] Taken together, these data support the contention that nevirapine readily crosses the BBB and enters the brain. In contrast, the penetration of delavirdine into the CNS appears to be low, as evidenced by its low CSF-to-plasma concentration ratio of 0.004.[25] Similarly, the BBB penetration of efavirenz is reported to be low, with a CSF-to-plasma concentration ratio of 0.01.[26]

Protease Inhibitors—In general, the extent of the BBB penetration of protease inhibitors has been reported as being low.[27–31] For example, CSF-to-plasma concentration ratios for indinavir are in the range of 0.06 to 0.16, and only negligible concentrations of ritonavir and saquinavir were present in CSF after oral administration.[27–31] Moreover, nelfinavir was not detected at all in CSF of patients following a variety of oral dosing regimens.[32] Limited BBB permeability of indinavir has also been observed in rats where a brain-to-plasma concentration ratio of 0.18 at steady state was reported.[33]

Combination Therapy—Currently, the recommended approach to HIV treatment is combination therapy with at least one protease inhibitor. Although protease inhibitors do not appear to cross the BBB to the extent of showing significant therapeutic efficacy, combinations of protease inhibitors (indinavir, ritonavir, or saquinavir) with zidovudine have been reported to prevent or reverse the progression of AIDS dementia, as suggested by brain magnetic resonance imaging studies.[34] Similarly, ritonavir and saquinavir, when taken in combination suppressed CSF HIV-1 RNA levels in 9 of 10 nucleoside-experienced patients, suggesting potential increases in the extent of their BBB penetration.[35] The addition of stavudine to this regimen increased the number of patients with undetectable HIV viral loads in serum and CSF to 80%.[36]

The effect of combination therapy on BBB permeability has only been reported in one in vitro study where there were no significant effects on the P_{BMEC} value for nevirapine in combination with amprenavir, delavirdine, didanosine, indinavir, saquinavir, stavudine, zalcitabine, or zidovudine.[11]

The Effect of Partitioning

It is generally accepted that the degree of lipophilicity of compounds is a determinant factor for their BBB permeability. For example, in vitro BBB permeability has been shown to correlate well with octanol/water partitioning and molecular weight for a variety of solutes.[37] The relationship between in vitro P_{BMEC} values and distribution coefficients (D) in pH 7.4 octanol/phosphate buffered solution for a variety of HIV antiretrovirals has been described as being roughly bell shaped.[11,12] Nevirapine appeared to have the optimum distribution coefficient ($\log D_{oct} = 1.81$) to allow for the highest permeability among the HIV

antiretrovirals studied. The permeability of hydrophilic NRTIs and very lipophilic protease inhibitors was significantly less than nevirapine. This relationship was descriptive only for the limited number of antiretroviral agents used in that study and was not meant to establish a general relationship between P_{BMEC} and D for all HIV antiretrovirals.[11]

The Effect of Efflux Pumps

P-Glycoprotein efflux pumps are present ubiquitously in both the BBB and the gastrointestinal tract.[38] A number of recent studies have shown that protease inhibitors, in general, are substrates for P-glycoprotein efflux pumps.[11,12,39,40] For example, it has been shown that indinavir, ritonavir, and saquinavir are substrates for these efflux pumps in BMECs and Caco-2 cells.[11,12,39] It has also been shown that the transports of indinavir, nelfinavir, and saquinavir in P-glycoprotein expressing cell lines L-MDR1 and Caco2 are affected by P-glycoprotein efflux pumps.[12,40] Similarly, the concentration of these protease inhibitors in the brain was shown to increase 7.4-, 10.6-, and 36.3-fold, respectively, in mice in which the MDR1a gene had been disrupted compared with the wild type.[40] This study clearly demonstrates the potetial effect of P-glycoprotein efflux pumps in reducing the BBB permeability of HIV protease inhibitors.

The effect of BBB efflux pumps on the limited distribution of NRTIs in the CNS after systemic administration is not clearly understood.[41−44] For example, microdialysis techniques in rabbits have shown that zidovudine is actively transported across the BBB and the BCB from brain to blood resulting in lower levels of zidovudine in brain and CSF than in plasma after systemic administration.[44] Similarly, it was shown that both zidovudine and didanosine were transported from the brain to the circulating blood across the BBB via saturable, probenicid sensitive efflux transporters.[45,46] However, in vitro transport studies using bovine BMECs could not identify selective efflux transport systems for NRTIs such as zidovudine.[11,12,43]

Future Directions

Understanding the mechanism of transport of HIV antiretrovirals across the BBB is essential for design and implementation of novel strategies for drug delivery to the brain to inhibit viral replication. The effect of HIV infection and the stage of the disease on the BBB properties and CNS uptake of drugs have not been fully understood. Further development of therapeutic strategies with the use of prodrugs, efflux inhibitors, and both in vitro and whole animals to evaluate intrinsic BMEC cellular permeability is needed. Although an HIV antiretroviral that is a substrate for BMEC efflux pumps may be taken alone with no adverse affects, the addition of other drugs that are competitive substrates for these pumps may affect the BBB permeability and efficacy of the first drug. Hence, the role of cellular efflux pumps on permeability of HIV antiretrovirals should be further studied to allow for rational drug delivery approaches for optimum BBB penetration.

This field of research is active and is likely to expand based on the paucity of information on the BBB permeability of currently used HIV antiretrovirals. Moreover, the BBB properties of novel classes of HIV antiretrovirals, such as HIV fusion and integrase inhibitors, need to be evaluated to determine their overall effectiveness in HIV therapy.

Transdermal Penetration Enhancers: Applications, Limitations, and Potential

BARRIE C. FINNIN* AND TIMOTHY M. MORGAN

Contribution from *Department of Pharmaceutics, Victorian College of Pharmacy, Monash University, 381 Royal Parade, Parkville, Victoria 3052, Australia.*

Received May 13, 1999. Final revised manuscript received July 19, 1999.
Accepted for publication July 21, 1999.

Introduction

Delivery of drugs via the skin has many attractions, including increased patient acceptability (noninvasiveness) and avoidance of gastrointestinal disturbances[1] and first-pass metabolism of the drug.[2] The fact that this route is not more widely used is because of the inherent barrier properties of the skin.[3] It is generally difficult to get drugs to cross the skin at a sufficient rate to deliver a therapeutic dose even when the drug is potent. Many different approaches have been taken to overcome the barrier presented by the skin, including mechanical disruption,[4,5] electrical disruption,[6,7] and chemical modification[8,9] of the barrier function. This review will focus on the use of chemicals to alter the penetration rate of drugs across the skin.

Agents capable of modifying the barrier to penetration presented by the skin have been called "penetration enhancers". There is usually a distinction drawn between chemicals that have their effect merely by occlusion of the skin leading to hydration of the skin, which in turn leads to increased permeability and those that interact with either the formulation applied or the skin itself. The former are generally not classified as "penetration enhancers".[10] Much research has been performed to identify penetration enhancers with the aid of in vitro screens,[11,12] and literally hundreds of different chemicals with a wide divergence of chemical structure that are able to modify the penetration characteristics of different drugs and marker compounds into the skin have been identified.[13,14] However, only a small number of these agents have been shown to produce useful enhancement in vivo, only a few have actually been incorporated into products and successfully tested in humans, and, other than previously used ingredients of topical preparations, none has yet been successful in the market place. This review is intended to examine why, despite all this work, we seem to have had very little success to date.

Historical and Current Perspectives

The idea of delivering drugs through the skin is old, as far back as the 16th century B.C., the Ebers Papyrus recommended that the husk of the castor oil plant be crushed in water and placed on an aching head and "the head will be cured at once, as though it had never ached." [15] Today transdermal drug delivery (TDD) is a well-accepted means of delivering many drugs to the systemic circulation, and currently transdermal patch devices are used to treat motion sickness, hypertension, angina, female menopause, severe pain states, nicotine dependence, and male hypogonadism.[16] The advantages of TDD are summarized in Table 1.

Despite all these advantages, a timely warning to formulators was issued by Hadgraft and Guy in 1987,[18] "TDD is not a subject which can be approached simplistically without a thorough understanding of the physicochemical and biological parameters of percutaneous absorption. Researchers who attempt TDD without appreciating this fact do so at their peril."

Our knowledge of these processes has been well reviewed in relation to percutaneous penetration by Barry.[19] Some specific issues that are worth singling out are the variability of the skin both within and between individuals,[20] the importance of metabolism in the viable epidermis as a metabolic barrier,[21] and the role of the immune system in limiting the use of some agents on the skin.[22,23]

The factors influencing the suitability of a drug for TDD are as follows:

⇒ potency of the drug − the daily systemic dose should be ≤20 mg
⇒ molecular size − the drug should have a MW of <500 Daltons
⇒ lipophilicity − the log P should be in the range 1−3
⇒ melting point − should be <200 °C
⇒ hydrogen bonding groups—should be ≤2
⇒ irritation − the drug should not be directly irritant to the skin
⇒ immunogenicity − the drug should not stimulate an immune reaction in the skin

A predictive rule of thumb is that the maximum flux of drug through the skin should decrease by a factor of 5 for an increase of 100 Da in MW, and decrease by a factor of 10 for an increase of 100 °C in melting point.[24]

Enhancement of Delivery

In addition to the potential for enhanced TDD to improve transdermal delivery rate control, the main reason that drug delivery across the skin needs to be enhanced is because of the low permeability of most transdermal candidates across the skin.[25] Traditionally, enhanced TDD has been achieved with patch devices that occlude the skin. Occlusion traps the natural transepidermal moisture of the skin, which increases the water content of the horny layer and swells the membrane, thus compromising its barrier function.[10] Prolonged occlusion of this nature can cause a 10−100-fold increase in drug permeability.[26] However, the tradeoff with these occlusive delivery systems is their propensity to cause local skin irritation.[27]

Physical Enhancement

Although many different physical approaches to enhancing percutaneous absorption have been attempted, the most

Table 1—Advantages of TDD

- provides constant blood levels in the plasma for drugs with a narrow therapeutic window, thus minimizing the risk of toxic side effects or lack of efficacy
- avoids first-pass metabolism in the gastrointestinal tract and liver, which allows drugs with poor oral bioavailability and/or short biological half-lives to be administered at most, once a day, and which can result in improved patient compliance[17]
- the problems of the gastrointestinal environment, such as chemical degradation of the drug and gastric irritation, are avoided
- removing the transdermal drug reservoir from the stratum corneum can easily terminate drug input
- provides a noninvasive alternative to parenteral, subcutaneous, and intramuscular injections
- suitable for patients who are unconscious or vomiting

notable approaches are iontophoresis,[6] ultrasound (sonophoresis),[4] and electroporation.[7] None of these enhancement methods is passive in that they require the input of energy to achieve their effects. To date, these methods show most promise for TDD systems that incorporate a large drug reservoir on the surface of the skin, and that need to deliver very large molecular weight compounds in the kiloDalton range.[16]

Supersaturation

The thermodynamic activity of a drug can be increased by employing supersaturated systems that give rise to unusually high thermodynamic potentials; this effect was first shown in a volatile:nonvolatile vehicle by Coldman et al.[28] However, topical vehicles relying on supersaturation have the major limitation of formulation instability, both prior to and during application to the skin, unless the formulation can be stabilized with antinucleant and anti-crystal-growth agents.[29]

For example, Kondo et al.[30] used supersaturation to enhance the transdermal delivery of nifedipine in rats. The bulk vehicle was stabilized with polymers and this formulation formed an appreciable mass on the surface of the skin. The vehicle remained on the surface of the skin for a prolonged period (many hours). Therefore, although Kondo et al.[30] advocated the use of a metered spray to deliver these formulations, in reality it would be impossible to obtain a nonocclusive TDD system with a short application time and cosmetic acceptability and still maintain a clinically useful transdermal penetration enhancement.

Metabolic or Biochemical Enhancers

Chemicals that provoke biochemical and metabolic events within the skin can potentially be used to alter skin permeability. For example, these types of enhancers can reduce the barrier properties of the skin by either inhibiting enzymes responsible for the synthesis of specific stratum corneum lipids during stratum corneum repair[31] or by promoting the metabolism of existing skin lipids that are responsible for skin barrier function.[32] Although promising, both of these approaches need to undergo further investigation in vivo of their enhancement effects and their potential to produce skin irritation. It should be noted that chemical penetration enhancers may also provoke unwanted reactionary biochemical and metabolic events within the skin that could alter skin permeability,[16,33] however this is not their aim.

Chemical Penetration Enhancers

Ideally, the goal of dermal penetration enhancement is for the accelerant to reversibly reduce the barrier resistance of the stratum corneum without damaging viable cells.[10,34] The properties proposed for an ideal penetration enhancer are shown in Table 2.

Over the last 15 years, a tremendous amount of work has been directed toward the search for specific chemicals, or combinations of chemicals, that can act as penetration enhancers.[9,35] The bulk of this work has been carried out by pharmaceutical companies that regard the results of their work as proprietary. Consequently, much of the cited literature is found in patents[13] as well as the usual pharmaceutical science literature.[14]

Table 2—Properties of an Ideal Penetration Enhancer[10]

- pharmacologically inert
- nontoxic, nonirritating, and nonallergenic
- rapid onset of action; predictable and suitable duration of action for the drug used
- following removal of the enhancer, the stratum corneum should immediately and fully recover its normal barrier property
- the barrier function of the skin should decrease in one direction only, and efflux of endogenous materials should not occur
- chemically and physically compatible with the delivery system
- readily incorporated into the delivery system
- inexpensive and cosmetically acceptable

Despite the large amount of work performed and the large number of different chemical entities identified, few have made it to the market place because of the following reasons.

1. The Applicability of the Method used to Demonstrate Enhancement—Most of the investigations involve in vitro penetration studies using a variety of membranes.[12,36] The follies of these methods have recently been pointed out by Barry.[37] Although attempts are currently being made to develop a generally accepted standardized methodology for in vitro testing,[11] there is still a large extrapolation to be made from performance in vitro to use in a clinical setting.

2. Incorporation of the Enhancer into a Doseform that is Acceptable to the User While Retaining the Activity of the Enhancer—When developing topical preparations for optimum bioavailability it is necessary to formulate them to ensure that the drug has the maximum tendency to leave the vehicle and partition into the skin. The driving force behind diffusive transport is a gradient in the chemical potential,[38] which is the continuous function (not the concentration) across interfaces. The presence of enhancers, which often will have good solvent properties, can decrease the chemical potential. The formulator needs to balance the solubility, and therefore the ability to use high concentrations of drug in a formulation, with the need to increase the chemical potential. These difficulties were realized early in the evaluation of laurocapram (Azone) where it was shown that incorporation of laurocapram into a commercially available cream containing fluocinolone acetonide did not increase vasoconstrictor activity, whereas simply incorporation of the steroid with 2% laurocapram in ethanol resulted in strong outperformance of the cream.[39]

3. The Need for Delivery of the Enhancer to the Skin and the Maintenance of Skin Concentrations of Enhancer for the Required Time Intervals—Although ethanol can act as a penetration enhancer, and various mechanisms of action have been postulated,[40] in practice its use as a penetration enhancer has relied on the application of a bulk aqueous ethanol vehicle to the skin whereupon the increase in the flux of the drug across the skin is mainly due to a solvent drag effect shown previously.[41] The mechanism of effect relies on the rapid

penetration of the solvent itself and the subsequent drag of the penetrant with it. A necessary corollary of this rapid flux is that the concentrations cannot be prolonged unless there is a reservoir present, thus limiting the applications of this type of enhancer to reservoir-based systems.

Clinical Usefulness

Of all of the potential enhancers identified those that have undergone significant clinical testing are discussed next.

In 1964, Stoughton and Fritsch reported that dimethyl sulfoxide (DMSO) enhanced the percutaneous penetration of various agents.[8] This characteristic was exploited clinically in many different circumstances but it did not lead to significant commercial products partly because of the high concentration needed for an effect and partly because DMSO is unpleasant to use.[42,43] It is interesting to note that after being virtually discarded, DMSO has recently been revived, and topical products containing DMSO with diclofenac are currently undergoing clinical trials.[44]

Laurocapram (Azone) is probably the most widely known chemical enhancer, and it is often used by transdermal research groups because of its good overall enhancing abilities,[45,46] which also makes it a useful basis of comparison for new chemical enhancers. However, because of its potential to irritate the skin,[47−50] laurocapram has failed to gain general clinical acceptance.

Fatty acids and fatty acid esters have been known for some time to enhance penetration. The major attraction of these compounds is that many of these materials are classified as Generally Recognized As Safe (GRAS). For example, Theratech Inc. uses a combination of glyceryl monooleate and lauryl lactate to enhance the diffusion of testosterone across nonscrotal skin in hypogonadal males in the Androderm patch.[51] A major concern is the irritation caused by these agents.[52] In clinical practice, one of the marketers of this product (SmithKline Beecham Pharmaceuticals) suggests the prior application of triamcinolone acetonide to overcome this irritation problem.[53]

There are also attempts to gain regulatory approval for newly synthesized enhancers, such as Macrochem's SEPA enhancer, 2-*n*-nonyl-1,3-dioxolane,[54] and NexMed's NexACT enhancers, alkyl *N*,*N*-dialkyl-substituted amino acetates.[55] Both of these types of agents have already shown good enhancing abilities that are comparable to those of laurocapram.[49, 56−58] Topical gel formulations containing SEPA with ibuprofen or alprostadil are currently in phase II clinical trials in the USA.[59] The NexACT enhancers are undergoing pre-Phase II toxicology studies in the USA, and a Phase III clinical trial in China has been completed for a topical gel formulation of alprostadil.[59] The success of these formulations will probably depend as much on the irritation observed in these trials as on the actual clinical effect.[60]

We have identified some novel GRAS chemical enhancers[61] that are currently used as topical sunscreening agents.[62] The main chemical enhancers in this group are padimate O, octyl salicylate, and octyl methoxycinnamate. As sunscreens, these agents have maximum approved topical concentrations of 8.0, 5.0, and 7.5%, respectively, in the USA, Europe, Japan, and Australia.[62] Over their many years of use as topical sunscreens, these agents have shown a low incidence of local skin reactions.[63]

These compounds have been shown to increase the penetration rate of a range of different drugs across skin from a number of different animal species in vitro.[64−66] We have also shown the enhancing effect of these compounds in vivo using microdialysis in conscious rats to measure the penetration of ibuprofen from topically applied gels.[67] The enhancers in these studies were incorporated into gel formulations suitable for clinical use. The effect of these enhancers in circumstances relevant to clinical use has also been demonstrated in vivo with the hormones estradiol and testosterone applied in the form of a spray to weanling pigs.[68] Significantly higher plasma levels of both of these compounds were found when the enhancer was incorporated into the spray formulations. These enhancers were also used in a small clinical trial in postmenopausal women designed to demonstrate the feasibility of delivery of estradiol via a transdermal spray.[69] The dose form was shown to deliver clinically relevant amounts of estradiol without signs of irritation.

The future will tell whether the enhancers currently under investigation can be formulated into acceptable and nonirritant products. Regardless, the search for new enhancers with ideal properties (Table 2) will continue.

Abstract □ The measurement and analysis of frequency-domain photon migration (FDPM) measurements of powder absorbance in pharmaceutical powders is described in the context of other optical techniques. FDPM consists of launching intensity-modulated light into a powder and detecting the phase delay and amplitude modulation of the re-emitted light as a function of the modulation frequency. From analysis of the data using the diffusion approximation to the radiative transport equation, the absorption coefficient can be obtained. Absorption coefficient measurements of riboflavin in lactose mixtures are presented at concentrations of 0.1 to 1% (w/w) at near-infrared wavelengths where solution absorption cross sections are difficult to accurately measure using traditional transmission measurements in nonscattering solutions. FDPM measurements in powders enabled determinations of absorption coefficients that increase linearly with concentration (w/w) according to Beer–Lambert relationship. The extension of FDPM for monitoring absorbance of low-dose and ultralow-dose powder blending operations is presented.

1. Introduction

The blending of powders of differing particle size, density, shape, and surface characteristics can result in demixing and segregation phenomenon that can have a critical impact on pharmaceutical powder blending and tableting processes. Indeed, the complexity of the blending process and the uncertainty in assessment of spatial homogeneity of the active agent in the powder bed within the blender are especially crucial in low dose (<1% w/w) or ultralow-dose (<0.1% w/w) formulations involving high potency pharmaceutical compounds. While much progress has been made toward a better physical understanding of the complexities involved in powder blending, measurements which validate the end point of a mixing process and provide assurance of the blend homogeneity remain as missing tools required to better address the quality assurance issues facing the pharmaceutical industry. In 1993, the "Barr decision" highlighted the litigious nature of incomplete knowledge of powder blending and sampling operations that could impact the uniformity of pharmaceutical tablets. Furthermore, the decision underscored the necessity for a measurement technique that (i) provides assessment of blend homogeneity, (ii) minimizes the error associated with powder sampling, (iii) provides sampling size measurements reflective of no more than three unit dosages and, (iv) enables real time measurements of blend homogeneity during the mixing operation. Currently, the "gold-standard" measurement of blend homogeneity rests with "thief sampling" combined with HPLC or other wet chemistry analysis. The typical sampling "thief" consists of an inner cylinder with sampling compartments along its axis and an outer, rotating, hollow cylinder stamped with apertures that permit flow into the inner sampling chambers when both cylinders are properly aligned. The difficulties associated with thief sampling are (i) the induced variance error associated with uneven flow of differing sized particles into sampling chambers, (ii) the disturbance of powder bed by the insertion of the thief, and (iii) the inability to make in situ, real time variance measurements, σ_m^2, related to actual variance in drug concentrations, σ_d^2, during the blending operation. It should be emphasized that the measured variance, σ_m^2, reflects a contribution from sampling, σ_s^2, analysis, σ_a^2, and drug concentration, σ_d^2, variances, i.e., $\sigma_m^2 = \sigma_s^2 + \sigma_a^2 + \sigma_d^2$. The Barr decision stipulates the largest sample volume for analysis must be less than three times that of a single tablet.

Numerous investigators have sought to develop techniques to assess the blend homogeneity without the need to remove a sample from the powder bed, thereby eliminating the influence of sampling error or variance, σ_s^2. In a system to model blend homogeneity, Muzzio and coworkers[1] have developed a technique to investigate the blending phenomenon that involves solidification of the contents of a mixing vessel and slicing cross sections of the solid mixture for image analysis. The blend homogeneity is then studied by using statistical methods to assess the mixing of differently colored glass beads in the size range of tens of microns. Their technique to assess mixing in a model system is static, and restricted to a specific model system of glass beads, yet provides a means for assessing measured variances independent of σ_s^2, and aids in building process models for validation of powder mixing.

Other investigators have sought optical means to assess blend homogeneity. Diffuse-reflectance fiber optic probes are being investigated extensively for evaluating powder characteristics.[2,3] Using near infrared (NIR) fiber optics reflectance from powders, Cho et al. (1997)[4] measured

derivative spectra from backscattered light in the wavelength range between 1100 and 2500 nm to measure blend homogeneity of a lactose, microcrystalline cellulose, and sodium benzoate mixture based on its variance as a function of mixing time. Since the spectra can be measured in situ, the sampling variance arises only from the volume of powders probed in the diffuse backscattered light and is not impacted by the powder flow problems associated with a sampling thief. Their results suggest that backscatter techniques using fiber optics can interrogate 0.154 to 0.858 g of powder with a standard deviation of 0.16 g. Arguing that single doses range from 0.1 to 1.0 g, these investigators contend that the backscatter technique fits the regulatory requirements for probing 0.3 to 3.0 g of total tablet mass. Analysis of diffuse reflectance and backscatter measurements often assumes wavelength-independent scattering so that variance of the derivative spectra is assumed to be a measure of the variance of light-absorbing constituents in the blend. Unfortunately, the assumption of wavelength-independent scattering is not always correct, and monitoring spectral derivatives for blend homogeneity studies may not always be a prudent approach for minimizing artifact.

In this contribution, we introduce the techniques of frequency-domain photon migration for assessment of blend homogeneity and demonstrate its applicability for determination of powder absorbance for pharmaceutical process monitoring. In contrast to diffuse reflectance and backscatter measurement and analysis currently pursued for such applications, FDPM is based upon the *time-dependent diffusive* scattering of light. Owing to the measurement approach, the variance of analysis and measurement are minimized when compared to thief sampling and time-invariant diffuse reflectance or backscatter techniques, respectively. In the following, we briefly review the theory describing light transport in powders and describe the inherent difficulties associated with time-invariant measurement of diffuse reflectance. We describe the physics of FDPM measurements as well as the instrumentation and analysis of measurements and present FDPM absorbance values of riboflavin in lactose powders to demonstrate the feasibility of the technology. Finally, we comment upon the diagnostic ability of FDPM for pharmaceutical monitoring of intermediate and final powder-based products.

2. Light Transport in Powders

Optical techniques for monitoring the absorbance associated with active ingredients in a powder bed are typically based upon diffuse reflectance or backscatter techniques that employ a constant intensity source of broadbeam illumination or a point source illumination via fiber optic coupling. Analysis of backscatter or diffuse reflectance are typically employed using empirically based chemometric analyses or physically based radiative transfer equations and associated assumptions. Since chemometrics is beyond the scope of this contribution, we refer the reader to a treatise on the subject by Muhammad and Kowalski[5] and Adams.[6] Instead, in this contribution we are concerned with extraction of the absorption coefficient, $\mu_a(\lambda)$, at wavelength λ, within the powder bed. Assuming that the absorption coefficient is the sum of different light absorbing species, i.e., $\mu_a(\lambda) = \Sigma_i \epsilon_{\lambda,i}[C_i]$, measurements made at multiple wavelengths enable determination of concentration of the light absorbing components from the simultaneous solution of a series of linear equations. However, as briefly described below, it is difficult and in some approaches impossible to determine absorption coefficients independently from first-principles data analyses of time-invariant, reflected light.

Radiative Transfer of Light in Scattering Media—Light propagation is ubiquitously described by the radiative transfer equation (RTE), that can be solved with proper boundary conditions to predict the radiance, L, [Watts/(m^2 sr)] associated with light traveling in direction of unit vector $\hat{s}$ per unit solid angle.

$$\frac{1}{c}\frac{\partial L(\bar{r},\hat{s},t)}{\partial t} + \bar{\nabla} L(\bar{r},\hat{s},t)\hat{s} = -(\mu_s + \mu_a)L(\bar{r},\hat{s},t) + \mu_s \int_{4\pi} L(\bar{r},\hat{s}',t) f(\hat{s},\hat{s}') d\Omega' + Q(\bar{r},\hat{s},t) \quad (1)$$

Briefly, the first and second terms on the left hand side of eq 1 describe the accumulation of radiance (where c is the speed of light in the medium), and the net rate of increase of radiance associated with light traveling in direction $\hat{s}$, respectively. The first term on the right hand side denotes the loss mechanisms whereby light traveling in direction $\hat{s}$ is lost through absorption and scattering out of direction $\hat{s}$. Here, μ_s and μ_a [1/(length)] are the linear scattering and absorption coefficients, respectively. The second term describes a "gain term" by which light traveling all directions $\hat{s}'$ (or solid angle $\hat{\Omega}'$) is scattered into the preferred direction $\hat{s}$. To properly account for this "inscattering," into direction $\hat{s}$, the phase function, $f(\hat{s}',\hat{s})$ must be known. $f(\hat{s}',\hat{s})$ describes the probability of photons traveling in direction $\hat{s}'$ being scattered into direction $\hat{s}$ and must satisfy the relation:

$$\int_{4\pi} f(\hat{s},\hat{s}') d\Omega' = 1 \quad (2)$$

$Q(\bar{r},\hat{s},t)$ represents the source term for the photons traveling in direction $\hat{s}$.[7−10]

Diffusion Approximation to RTE—The typical powder bed of micron-sized particles scatters light multiple times in all directions. Integration of eq 1 over all possible solid angles, Ω, leads to the equation of continuity shown below.

$$\frac{1}{c}\frac{\partial \phi(\bar{r},t)}{\partial t} + \bar{\nabla}\bar{j}(\bar{r},t) = -\mu_a \phi(\bar{r},t) + S(\bar{r},t) \quad (3)$$

where

$$S(\bar{r},t) \equiv \int_{4\pi} Q(\bar{r},\hat{s},t) d\Omega,$$

$$\phi(\bar{r},t) \equiv \int_{4\pi} L(\bar{r},\hat{s},t) d\Omega$$

and

$$\bar{j}(\bar{r},t) \equiv \int_{4\pi} L(\bar{r},\hat{s},t)\hat{s}\, d\Omega$$

$S(\bar{r},t)$ is an isotropic source term, $\phi(\bar{r},t)$ is the angle-independent fluence rate, and $\bar{j}(\bar{r},t)$ is the photon flux.

The *diffusion approximation*, which assumes weak angular dependence of radiance, $L(\bar{r},\hat{s},t)$, and predominant scattering such that $\mu_a \ll (1 - g)\mu_s$, is typically valid in powders. Specifically, in the standard diffusion approximation, the angular radiance, $L(\bar{r},\hat{s},t)$, is expressed as a sum of the angle independent fluence rate, $\phi(\bar{r},t)/(4\pi)$, and a small directional flux, $3/(4\pi)\hat{s}\cdot\bar{j}(\bar{r},t)$. Details regarding the diffusion approximation as well as higher order approximations to the RTE are available in literature[11,12] and not described here for brevity. Nonetheless, the optical diffusion equation derived from RTE describing the angle-independent fluence of light $\phi(\bar{r},t)$(W/m^2) is written as:

$$D\nabla^2\phi(\bar{r},t) - \mu_a\,\phi(\bar{r},t) = \frac{1}{c}\frac{\partial\phi(\bar{r},t)}{\partial t} - S(\bar{r},t) \qquad (4)$$

where

$$D \equiv \frac{1}{3[(1-g)\mu_s + \mu_a]} \equiv \frac{l_{tr}}{3}.$$

D is the optical diffusion coefficient (cm), g is the average cosine of the scattering angle and the term $(1-g)\mu_s$ is the isotropic scattering coefficient. l_{tr} is the transport mean free path of the diffusing photon. Equation 4 can be solved for different boundary conditions (see section 3). However, the diffusion theory has limitations. The diffusion theory assumes that the radiance is nearly isotropic in its angular dependence and the sources are isotropic. These conditions are satisfied in strongly scattering situations, i.e., $\mu_a \ll (1-g)\mu_s$, and far from the boundaries and sources. The minimum distance from the source and boundaries at which light is detected must be at least greater than $10l_{tr}$ without having to resort to higher order approximations. As described in the section below, the diffusion equation can be solved for incident intensity-modulated light to enable determination of absorption independently of scattering properties and without the need to know scattering phase functions.

3. Frequency Domain Photon Migration

The technique of frequency-domain photon migration depends upon launching intensity modulated, monochromatic light at modulation frequencies ranging from 100's of kHz to 100's of MHz. As the resulting "photon-density wave" propagates through the scattering media, its amplitude is attenuated and it is phase-delayed relative to the incident light. The transport of photons via FDPM in the media can be treated as a diffusive process. The light detected in reflectance or transmittance mode is modulated at the same frequency as that of the incident light. This light is found to be phase-shifted, θ', and its amplitude attenuated by a factor M relative to the incident light. Measurements of θ' and M are acquired at different modulation frequencies, $\omega/2\pi$, of the source. The solution of the diffusion equation (section 2) is used to relate the phase-shift, θ', and amplitude modulation attenuation, M, to the two separate optical properties of the powder, the absorption coefficient, μ_a, and the isotropic scattering coefficient, μ'_s. The advantages of FDPM are twofold: first, these measurements do not require an external calibration, and second, the absorption and isotropic scattering coefficients are obtained as separate parameters rather than as a single product (as determined in continuous wave measurements analyzed with multiflux approximations to the radiative equation).

3.1. Theory of FDPM—The measurements described herein were conducted with the frequency-domain photon migration apparatus illustrated in Figure 1. The light source was a 670 nm laser diode (150 mW) which was sinusoidally modulated at the frequency of interest by modulation of the current input. The light from the laser sources was split so that approximately 10% of the light was collected by a reference photomultiplier tube (Hamamatsu R928, Hamamatsu, Japan) via a 1000 μm optical fiber. The remaining transmitted light was launched into the lactose–riboflavin powder mixture using a 1000 μm source optical fiber positioned flush with the wall of the sample container. The scattered light from the powder was detected by another 1000 μm optical fiber that was mounted at known distances away from the source fiber, also flush

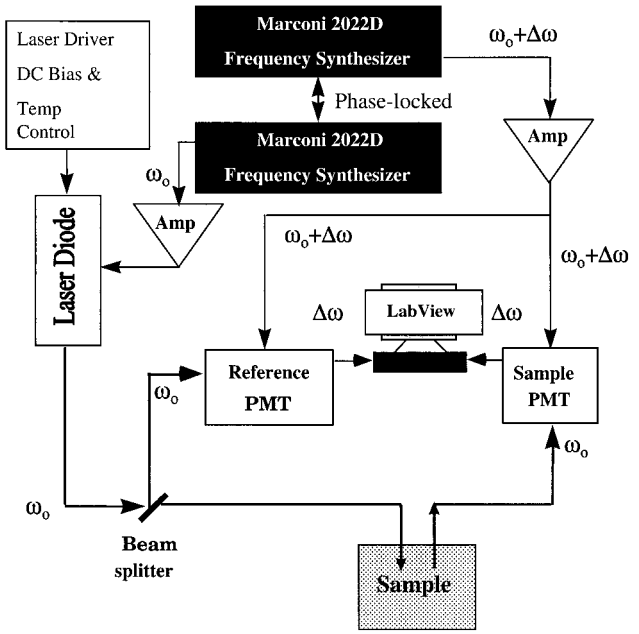

Figure 1—A schematic of an experimental setup of the frequency domain photon migration (FDPM). The light source is a laser diode, but can be substituted with a Ti:sapphire laser.

with the wall of the container. The other end of this detecting optical fiber was directed to a second photomultiplier tube. The source and detector fibers were maintained in a coplanar geometry. Estimates of the isotropic scattering and absorption coefficients using the phase-difference and amplitude modulation data were obtained by regression from analytical solutions to the optical diffusion equation described below. The relative separations between the source and detector fibers were chosen such that the distances between them were at least 10 isotropic scattering mean free paths l^* (or $1/\mu'_s$) to ensure multiple light scattering. The photomultiplier tubes (PMT's) were gain modulated at a modulation frequency, $\omega/2\pi$, of the laser diode plus an offset frequency ($\Delta\omega/2\pi$) of 100 Hz. This standard heterodyne technique yielded a 100 Hz signal at the photomultiplier output from which the phase shift, θ', and modulation, M, could be extracted. A data acquisition software (Labview 4.01, National Instruments) was customized to acquire and process the experimental data.

A pulsed light source was also employed for the frequency-domain studies enabling us to interrogate the samples with a Ti:sapphire system at other wavelengths. The source was a tunable 2 ps pulsed optical train output of a Tsunami picosecond-pulsed titanium–sapphire (Ti:sapphire) laser (Model 3950B, Tsunami, Spectra Physics, CA) pumped by a 10 W argon-ion laser (Beamlok 2060, Spectra Physics). Near infrared wavelengths of 750 and 820 nm were generated using this Ti:sapphire laser. The Ti:sapphire laser pulse train was delivered at a repetition rate of 4 MHz with an average output power level of 20 mW. The light was delivered to the powder mixtures in the same manner as that for the 670 nm laser diode. For the Ti:sapphire light source, PMT gain modulation was achieved at a harmonic of the pulsed laser repetition rate plus the 100 Hz offset frequency. Details of the instrumentation have been discussed elsewhere.[13]

The experimentally measured quantities were the phase lag, θ', at the detector relative to a reference signal as a function of modulation frequency, ω. To nullify instrument responses (i.e., phase delays induced by instrumentation), measurements at multiple detector positions were used to determine relative phase shifts ($\Delta\theta'_{rel}$).

3.2. Prediction of FDPM Measurements—For photon diffusion in an infinite medium, the optical diffusion equation (section 2) has been solved to obtain analytical expressions for different boundary conditions.[11,14] The following solutions for infinite and zero boundary conditions have been obtained by Haskell et al.

Zero Boundary Condition—The zero boundary condition sets the fluence rate, ϕ, to zero at the physical boundary. This condition was found suitable for our experimental setup. The solution for the diffusion equation with this boundary condition leads to the following expression for $\Delta\theta'_{rel}$.

$$\Delta\theta'_{rel}(\lambda) = |d_1 - d_2|k_{imag} - \arctan\left(\frac{k_{imag}}{k_{real} + \frac{1}{|d_1 - d_2|}}\right) \quad (5)$$

where

$$k_{imag} = \sqrt{\frac{3}{2}\mu_a\mu'_s\left(\left(1 + \left(\frac{\omega}{\mu_a c}\right)^2\right)^{1/2} - 1\right)}$$

and

$$k_{real} = \sqrt{\frac{3}{2}\mu_a\mu'_s\left(\left(1 + \left(\frac{\omega}{\mu_a c}\right)^2\right)^{1/2} + 1\right)}$$

$$k = k_{real} + ik_{imag}$$

where d_1 and d_2 are the two source-detector positions, λ is the wavelength of light in vacuum, and c is the speed of light in the continuous medium. k is the wavenumber which has a real component, k_{real}, and an imaginary component, k_{imag}. The experimental data of phase-shift versus modulation frequency was then fit to eq 5 using a Marquardt–Levenberg nonlinear regression algorithm to yield independent parameter estimates of the absorption coefficient, μ_a, and the isotropic scattering coefficient, μ'_s. The measured variance in θ' at different frequencies was less than 1%.

The volume sampled by diffusing light depends upon the absorption and scattering properties of the powder. The average distance traveled by photons into the powder bed from the light source can be calculated from the approach developed by Sevick et al.[15] The fluence of the photons is determined at various points in the powder bed, and the amount of photons detected at various source-detector separations is calculated. The average distance of travel of photons into the powder increases with separation, and then drops off. For example, in these set of measurements at source-detector separations of 0.55 and 1.22 cm, and for a scattering coefficient of 120.0 cm^{-1}, and an absorption coefficient of 0.02 cm^{-1}, the average distance that the photons traveled into the powder bed are 0.44 and 0.50 cm respectively. Assuming a spherical profile of the photons propagating in the powder bed, the volume sampled does not exceed more than 0.5 cm^3. We can see that the volume probed by this technique is not very large, and is well within the sampling volume limit.

4. Experimental Section

Materials—In order to demonstrate the ability to detect small changes in absorbance, we chose to employ riboflavin/lactose powder mixtures as a model system. Lactose monohydrate USP was supplied by Sheffield, Inc. (Norwich, NY), and riboflavin USP was provided by Hoffmann LaRoche Laboratories Inc. (Nutley, NY). Both materials were used as received. In the following, we describe measurements of riboflavin and lactose absorption cross section using conventional attenuation measurements in dilute nonscattering solutions, as well as by FDPM techniques.

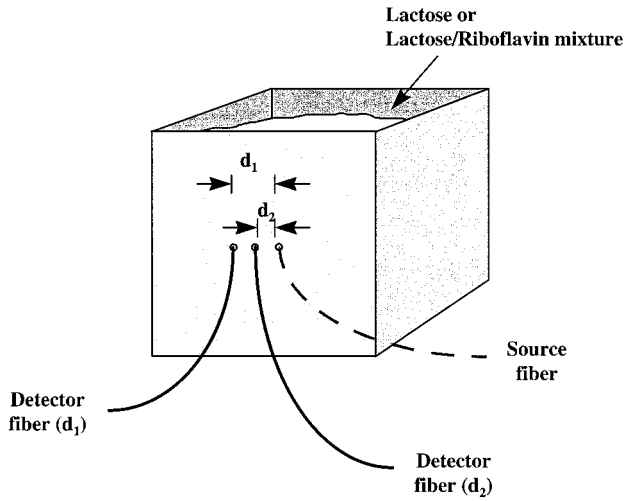

Figure 2—An illustration of the sample box used for making FDPM measurements on lactose–riboflavin mixtures.

4.1. Absorption Coefficient of Riboflavin Solution—The extinction coefficient for riboflavin (molecular weight = 376.4) was measured using a Perkin-Elmer UV-vis spectrophotometer. Riboflavin is sparingly soluble in water; hence, in order to facilitate the dissolution of riboflavin, sodium hydroxide solution was added dropwise until a clear solution was obtained. The solution was centrifuged to remove debris. A stock solution was prepared with riboflavin concentration of 0.014 g/L. The samples were prepared 1 h prior to experiments, because riboflavin is unstable in solution and the instability increased with increasing sodium hydroxide concentrations. The measurements were accomplished on the stock solution and dilutions of the stock solution of 1:2 and 1:5 by deionized water. The absorption spectra was obtained at wavelengths ranging from 200 to 900 nm scanned at a rate of 240 nm/minute. The extinction coefficient of a light-absorbing species in a mixture is determined from the Beer–Lambert's law, $(1/l)\log_{10}(I_o/I) = \mu_a(\lambda) \equiv \epsilon(\lambda)[C]$, where μ_a is the absorption coefficient of the solution, I_o is the incident light, I is the detected light passing through a sample of thickness l. C denotes the concentration of the absorbing species, i.e., riboflavin, in the solution. $\epsilon(\lambda)$ is the extinction coefficient of the species and can be obtained for a particular wavelength by measuring the absorption coefficient (μ_a) at various concentrations. The slope of the straight line fit to the data provides the extinction coefficient.

4.2. Extinction Coefficient of Lactose-Riboflavin Mixtures—The extinction coefficients for various lactose–riboflavin mixtures were obtained for wavelengths ranging from 350 to 470 nm. Riboflavin content in the lactose varied from 0 to 1.0 wt %. The powder samples were dissolved in deionized water, and their absorption coefficient was obtained at different riboflavin concentrations. The slope of the straight line fit gave the extinction coefficient of the total lactose–riboflavin mixture.

4.3. Absorption Coefficients and Extinction Coefficients of Lactose–Riboflavin Powder Mixtures by FDPM—In order to measure the isotropic scattering and absorption coefficient of the powder mixtures, the samples were placed in a rectangular box. Three optical fibers were inserted into one side of the box and the tip of the fibers were flush with the interior side of the box as shown in Figure 2. Such an arrangement prevented movement of the

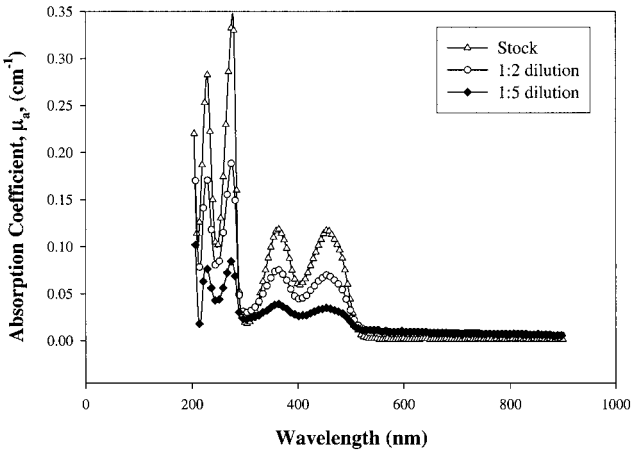

Figure 3—Absorption spectra obtained at three dilutions of a riboflavin stock solution of 0.0372 mM in deionized water. The dilutions were effected in the ratios of (i) 1:1 (0.0186 mM), (ii) 1:2 (0.0124 mM), and (iii) 1:5 (0.0062 mM) with deionized water. The wavelengths scanned were from 200 to 900 nm.

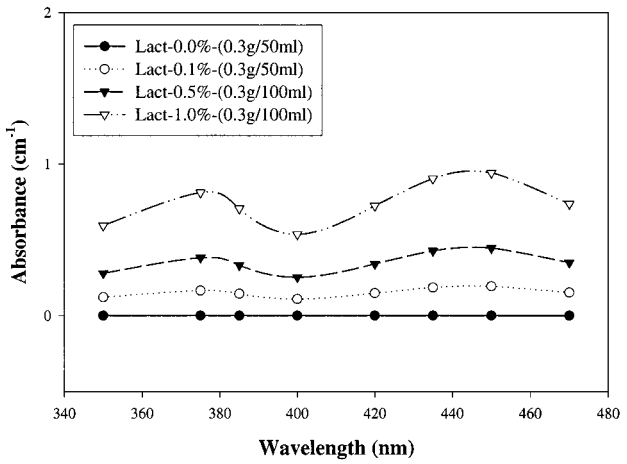

Figure 4—Absorption spectra of four dissolved lactose–riboflavin mixtures. Measurements were accomplished from 350 to 475 nm. Riboflavin concentrations ranged from 0 to 1 wt % for the four powders. The symbols denote the concentrations of the four powder mixtures dissolved in deionized water. Lines are spline fits to the data.

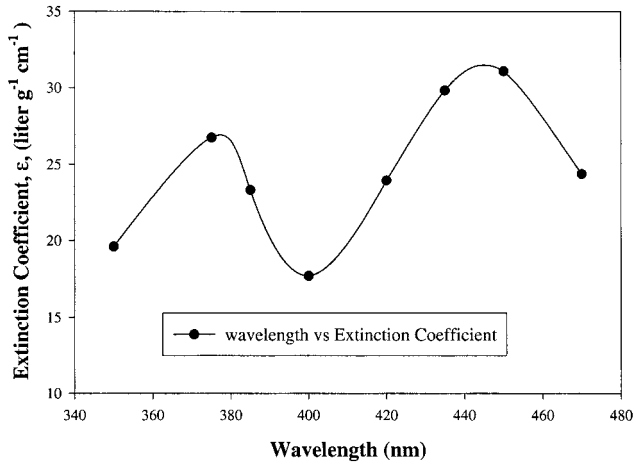

Figure 5—Plot of the extinction coefficients of riboflavin calculated from the experimentally measured absorption coefficients at wavelengths from 350 to 475 nm, using a UV-spectrophotometer. The UV extinction coefficients for lactose were negligible and hence neglected. The symbols represent the calculated extinction coefficients, and the lines are spline fits to the data.

powder arising due to insertion of fibers or probes. One fiber delivers monochromatic light from the laser source, and the scattered light is collected by the other two fibers. All the fibers were of the same length, and the fiber separations were 0.55 and 1.22 cm. In order to eliminate instrumentation errors, the relative phase shifts between the two detector positions were measured by taking the difference of the measured phase shifts for each position d_1 and d_2. The fibers could be used in any combinations as source and detectors. The powder mixtures were poured into the box (5.7 × 7.2 × 7.6cm), and measurements were carried out without any compaction of the powders. The powders were mixed in a V-blender, in batches of 250 g.

FDPM measurements were accomplished on four different powder mixtures. The four mixtures were lactose with 0, 0.1, 0.5, and 1 wt % riboflavin mixed uniformly in a blender. Riboflavin absorbs strongly at 470 nm. Extensive trial runs were carried out to determine the scattering and absorption coefficients of the powder mixtures at different wavelengths. Initially, modulated light at wavelengths of 488 and 515 nm was used. At these wavelengths, a good signal could be detected for the pure lactose powder. However, the lactose powder containing riboflavin tended to absorb a substantial amount of light, causing a significant attenuation of the amplitude and preventing an accurate measurement of the phase-delay, θ'. As a result, FDPM measurements were conducted at wavelengths of 670 nm and higher, away from the absorbance maximum of riboflavin. At these wavelengths and smaller absorption cross sections, absorption by the riboflavin does not predominate and FDPM provided accurate signals for determination of powder optical properties. The two other wavelengths of light used were 750 and 820 nm.

It is noteworthy that the FDPM technique is capable of measuring small changes in the absorbance of the powders, due to the absorption by riboflavin.

5. Results and Discussion

5.1. Absorption Coefficient of Riboflavin Solution—Figure 3 shows a plot of the absorption spectrum of riboflavin in alkaline solution. As can be seen from the figure, there is significant absorption in the UV range from 300 to 500 nm. Two peaks are observed in the spectra at around 360 and 480 nm. The absorption drops to negligible values beyond 500 nm, thus providing only a small window for measuring riboflavin concentrations. Owing to the small absorption cross section of the riboflavin at wavelengths greater than 500 nm, it is not possible to accurately detect solution riboflavin concentrations outside the UV range.

5.2. Extinction Coefficient of Lactose−Riboflavin Mixtures—On the basis of these results, further measurements were made on lactose−riboflavin mixtures in the UV range 350 to 470 nm. The mixtures were dissolved in deionized water in concentrations ranging from 3 to 6 g/L. Lactose dissolves very easily in water and does not show any detectable absorption in the UV range that was studied. Results are presented in Figure 4. It can be seen that as the riboflavin content in the lactose is increased from 0 to 1% (by weight) at constant lactose concentration, the absorption spectra shows two peaks originating at the same wavelength ranges (360 and 480 nm) as those for pure riboflavin (Figure 3). The results from Figure 4 were then utilized to calculate the extinction coefficient of riboflavin in the powder mixtures at different wavelengths. The slope of a straight-line plot of the absorbance for the solutions of the mixtures at different riboflavin concentration gave the extinction coefficient of riboflavin. The extinction coefficients thus determined for riboflavin in the powder mixtures at different wavelengths are plotted in Figure 5.

5.3. Absorption Coefficients and Extinction Coef-

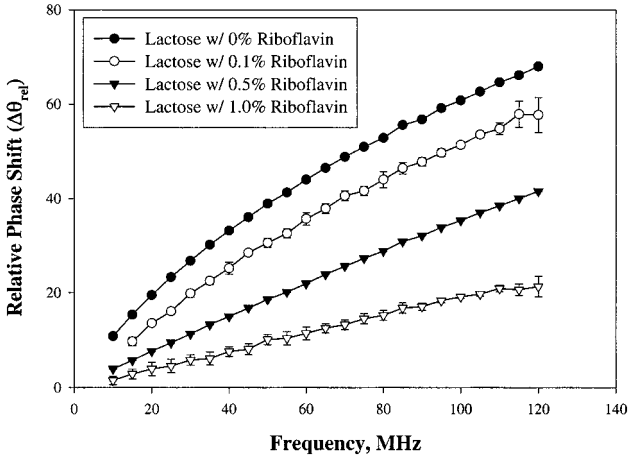

Figure 6—The relative phase shifts of four different lactose–riboflavin powder mixtures plotted at different modulation frequencies. The lactose–riboflavin mixtures are in the same ratios as given in Figure 4 represented by symbols. Measurements were accomplished at 670 nm using a laser diode. Error bars are a result of 10 measurements at each frequency.

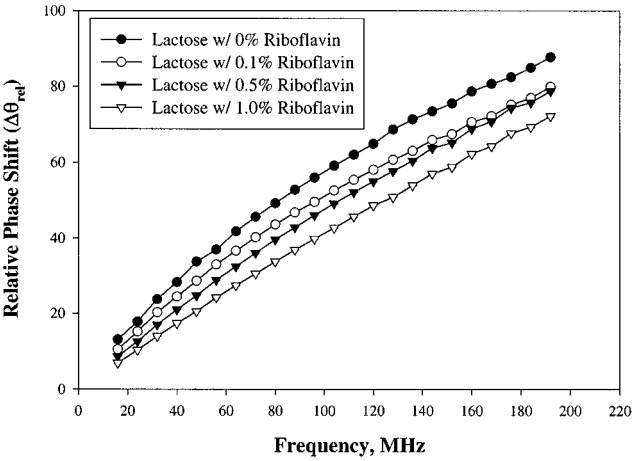

Figure 7—The relative phase shifts of four different lactose–riboflavin powder mixtures plotted at different modulation frequencies. The lactose–riboflavin mixtures are in the same ratios as given in Figure 4 represented by symbols. Measurements were accomplished at 750 nm using a Ti:sapphire laser. Error bars are a result of 10 measurements at each frequency.

ficients of Lactose−Riboflavin Powder Mixtures by FDPM—Again, owing to the sensitivity of FDPM measurements to absorption, measurements at 488 and 515 nm were not possible in the presence of 0.1−1.0% riboflavin. For this reason, we conducted FDPM measurements at a wavelength where riboflavin absorption was small. At these wavelengths, the absorption cross section spectra cannot be accurately measured using conventional attenuation measurements due to low extinction coefficients of the powder mixtures.

Shown in Figure 6 are the relative phase shifts, $\Delta\theta'_{rel}$, for the four different powders at different modulation frequencies measured at 670 nm. Each data point is an average of at least 10 continuous measurements, with the respective error bars as shown in the Figure 6. A steady decrease in the $\Delta\theta'_{rel}$ values is observed at a given modulation frequency with increase in the riboflavin content in lactose. This is expected due to an increase in absorption coefficient by riboflavin. Similar results were obtained for $\Delta\theta'_{rel}$ measurements carried out at 750 and 820 nm as shown in Figures 7 and 8, respectively. A noticeable difference in each of these plots is the magnitude of the change in $\Delta\theta'_{rel}$ as a function of riboflavin content. At higher wavelengths, the change is smaller, indicating lower absorption coefficients of the powder, which can be attributed to lower extinction coefficients for riboflavin. $\Delta\theta'_{rel}$ values at the various frequencies for each wavelength and powder composition were regressed using eqs 5 (reflectance mode) to give the isotropic scattering and absorption coefficients. The absorption coefficients at 670, 750, and 820 nm obtained by regression using eqs 5 are plotted in Figure 9. At 670 nm, the FDPM data for powder mixtures containing 1% riboflavin could not be fit to the solution of the diffusion equation. This may have been due to high absorption levels at this wavelength, which (i) causes significant dampening of the light signal before it can reach the PMT's and (ii) invalidates the diffusion approximation. Nonetheless, for a given wavelength, an increase in the absorption coefficient is observed with increasing riboflavin content in the powder mixtures. Furthermore, the change in absorbance with increasing riboflavin content is greatest at 670 nm, consistent with the largest extinction coefficient value. At longer wavelengths of 750 and 820 nm, the sensitivity drops further, indicating evidence of a reduction of riboflavin extinction coefficients.

If the absorbance due to the lactose constituent is taken to be the *Y*-intercept of the absorbance versus riboflavin content plots, and then its contribution can be subtracted to provide the absorbance owing to riboflavin only. The results plotted in Figure 10 show a linear relationship between the riboflavin absorption coefficient with its concentration in the powder, from which an extinction coefficient can be determined. It is noteworthy that there

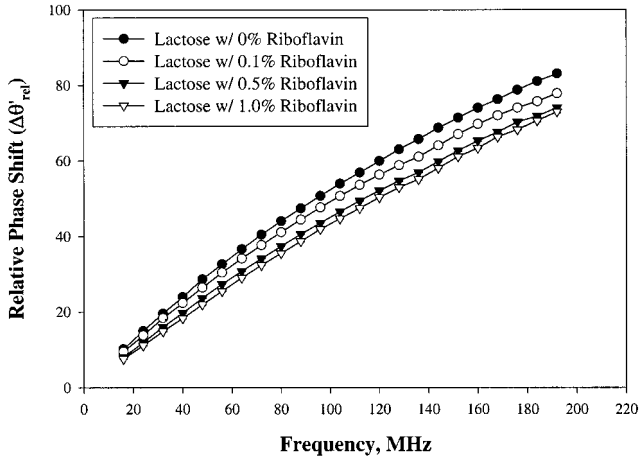

Figure 8—The relative phase shifts of four different lactose–riboflavin powder mixtures plotted at different modulation frequencies. The lactose–riboflavin mixtures are in the same ratios as given in Figure 4 represented by symbols. Measurements were accomplished at 820 nm using a Ti:sapphire laser. Error bars are a result of 10 measurements at each frequency.

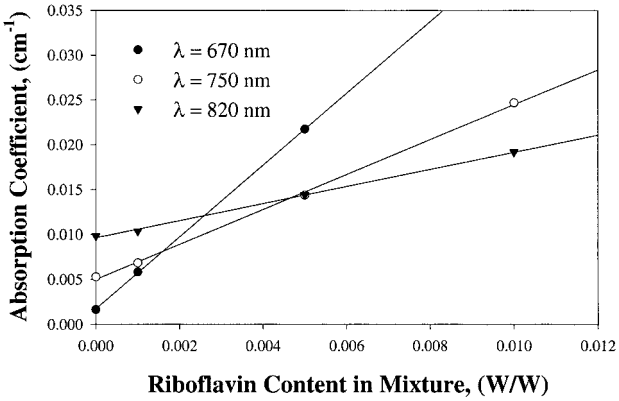

Figure 9—The absorption coefficients for four lactose–riboflavin powder mixtures at three wavelengths, 670, 750, and 820 nm, represented by the three symbols. The absorption coefficients were obtained by regressing the measured relative phase shifts at various frequencies to eq 5.

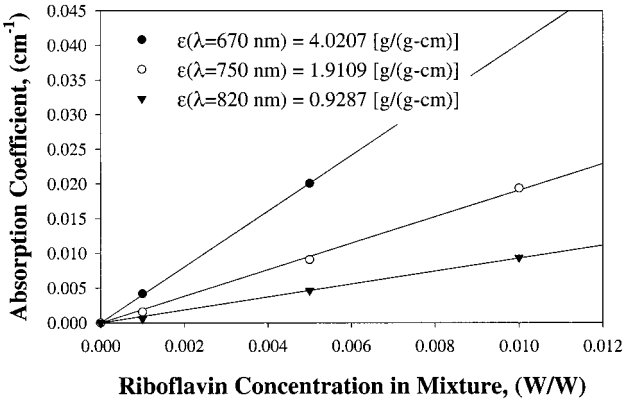

Figure 10—The symbols represent the net absorption coefficients for riboflavin in the four powder mixtures obtained by subtracting the absorption coefficient of pure lactose at each wavelength. The extinction coefficients of riboflavin, shown in the plot, at each wavelength were obtained by regressing the absorption data at the known concentrations using Beer–Lambert's law.

is no significant difference between the extinction coefficients obtained from infinite and reflectance modes of regression of the raw $\Delta\theta'_{rel}$ data. In addition, the riboflavin extinction coefficients are observed to decrease with increasing wavelengths as expected from the UV-spectrophotometer results.

The analysis of the experimental data of the four powder mixtures also yielded the isotropic scattering cross section of the particles. The isotropic scattering coefficients vary from 87 to 123 cm^{-1} for all the four samples at the three wavelengths used, i.e., 670, 750, and 820 nm. The wide range in the measured values may be attributed to the significant polydispersity of the powder mixtures.

6. Conclusions

We have presented FDPM measurements for a simple, two-component powder mixture of riboflavin and lactose. Owing to the sensitivity of FDPM to powder absorbance, we were forced to conduct measurements at wavelengths where riboflavin absorbance did not entirely attenuate the light signal in the powder bed. That is, the measurements were conducted at wavelengths away from the absorbance peaks for the powder mixtures, and the modulated light signal could be detected. At these photon migration wavelengths, the absorbance of riboflavin could not be assessed using conventional attenuation measurements in dilute nonscattering solutions. The results illustrate that for a two-component powder system, the FDPM absorbance increases linearly with riboflavin concentration. The extension to multicomponent mixtures requires additional wavelength sources, but does not require illumination at absorption maxima for maximum sensitivity. Indeed, the ability to detect small absorption cross sections promises applications in low-dose blending operations. Owing to our first principles approach that does not require differential spectroscopy, the variance associated with our analysis should be minimized. Since there is no sampling of powder involved (measurements are made within the powder bed as described herein), there are no sampling variances that need to be assessed. Consequently, the measured variances should be predominantly due to variances associated with the constituents within the powder bed. Finally, since FDPM does not involve *relative* intensity measurements, but rather *absolute* "time-of-flight" phase-delay measurements, there are no measurement errors associated with calibration on an external standard. At the NSF I/UCRC Center in Pharmaceutical Processing at Purdue University we are currently adapting FDPM technology as an in-situ sensor of blend homogeneity.

Nomenclature

Symbols:

c	speed of light in medium (cm/s)
d_1, d_2	source-detector distances (cm)
D	optical diffusion coefficient (cm)
g	average cosine of scattering angles
$\bar{j}(\bar{r},t)$	photon flux (W/m^3)
k	wavenumber (cm^{-1})
k_{real}	real part of k
k_{imag}	imaginary part of k
l^*	isotropic scattering mean free path (cm)
l	thickness of sample (cm)
l_{tr}	transport mean free path of photon (cm)
L	radiance ($W/(m^2\ sr)$)
n	refractive index of the medium
$Q(\bar{r},\hat{s},t)$	photon source term
$\bar{r}$	position vector (cm)
r	radial distance (cm)
$\hat{s},\hat{s}'$	unit vectors in the direction of flux of the photons
$S(\bar{r},t)$	source term

Greek:

$\phi(\bar{r},t)$	isotropic fluence rate (W/m^2)
λ	wavelength of light in media (cm)
μ_a	absorption coefficient (cm^{-1})
μ'_s	isotropic scattering coefficient (cm^{-1})
$\omega/2\pi$	modulation frequency (MHz)
θ'	phase shift angle (radians)
$\Delta\theta'_{rel}$	relative phase-shift (radians)
Ω,Ω'	solid angles of orientation about direction, $\hat{s}$ and $\hat{s}'$ (radians), respectively

Solubilization of Fluasterone

LUWEI ZHAO, PING LI, AND SAMUEL H. YALKOWSKY*

Contribution from *Department of Pharmaceutical Sciences, College of Pharmacy, The University of Arizona, Tucson, Arizona 85721.*

Received April 30, 1999. Accepted for publication July 30, 1999.

Abstract □ Solubilization of nonpolar drugs constitutes one of the most important tasks in parenteral formulations design. This study investigates and assesses the solubility enhancement of Fluasterone by various techniques including cosolvency, micellization, and complexation. Of the solubilizing agents used, the modified β-cyclodextrins were found to be the most effective. The solubility of Fluasterone is 1.55×10^{-4} mM, 3.13 mM, and 4.04 mM in water, 20% sulfobutyl ether-β-cyclodextrin (SBEβCD), and 20% hydroxypropyl-β-cyclodextrin (HPβCD), respectively.

Introduction

A structural analogue of dehydroepiandrosterone, Fluasterone (16α-fluoro-5-androsten-17-one, see Figure 1) has recently been developed for cancer treatment. The aqueous solubility of Fluasterone is 0.045 μg/mL (1.55×10^{-4} mM) and the desired dose is 1000 μg/mL (3.44 mM). This study evaluates Fluasterone solubilization by various techniques that are commonly encountered in parenteral formulation design.

The major approaches for increasing drug solubility are alteration of the solute or alteration of the solvent. Solvent modification is the most effective means of producing a thermodynamically stable increase in solubility.[1] The four most commonly used types of solubilizing agents are cosolvents, surfactants, complexation ligands, and pH control by buffers. With each technique, there is a maximum in the solubility that can be obtained. The choice of a solubilization technique also depends on many other factors: the physicochemical property of the drug molecule, the desired concentration, the effectiveness of the method, the safety and cost of solubilizing agents, and possible precipitation upon injection.

With Fluasterone of such low aqueous solubility, it is interesting to explore the effect on drug solubilization enhancement by using cosolvents, surfactants, and complexation ligands (cyclodextrins). The control of pH is not covered here since the drug has no ionizable group. The results obtained may provide guidance to the solubility improvement of other highly nonpolar drugs and steroidal compounds in particular.

Experimental Section

Materials—Fluasterone was used as provided by Aeson Therapeutics Inc., Tucson, AZ. Hydroxypropyl-β-cyclodextrin (HPβCD), with an average molecular weight of 1390 and an average degree of substitution of 4.4, was obtained from Cyclodextrin Technologies Development Inc. (Gainesville, FL). Sulfobutyl ether-β-cyclodextrin (SBEβCD), with an average molecular weight of 2162 and an average degree of substitution of 7, was a gift from CyDex, L.C. (Overland Park, KS). All other chemicals were of analytical or HPLC grade, purchased from Sigma and Aldrich.

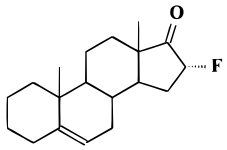

Figure 1—Structure of Fluasterone (MW: 290.42).

Solubility Measurement—The Fluasterone powder was added to vials containing various percentages of a variety of cosolvents, surfactants, or complexation ligands. The duplicate sample vials were prepared for each particular solubilizing agent at its particular concentration and were placed on an end-over-end mechanical rotator at 20 rpm at 25 °C for 6 days. Samples with drug crystals present were considered to have reached equilibrium and were removed from the rotator. The samples were then filtered through a 0.45-μm filter and diluted before injection into HPLC system.

The cosolvents used were ethanol (EtOH), propylene glycol (PG), and poly(ethylene glycol) 400 (PEG400) and glycerin. The surfactants were polyethylene sorbitan monolaurate (Tween 20), polyethylene sorbitan monooleate (Tween 80), and bile salts—sodium cholate, sodium deoxycholate, and sodium taurocholate. The complexation ligands were α-cylcodextrin (αCD), hydroxypropyl-β-cyclodextrin (HPβCD), sulfobutyl ether-β-cyclodextrin (SBEβCD), and hydroxypropyl-γ-cyclodextrin (HPγCD). The concentration ranges were given in Table 1.

HPLC Assay—A Beckman Gold HPLC system equipped with a model no. 168 detector at 220 nm was used for all assays. A Pinnacle octylamine column (150 cm × 4.6 mm, Restek, Bellefonte, PA) was used with a mobile phase composed of 75% acetonitrile in water. The flow rate was controlled at 1.1 mL/min. The retention time of Fluasterone was 6.2 min. The injection volume was 100 μL. The evaluation of the assay was conducted by using Fluasterone standard solutions at concentrations ranging from 0.001 to 0.1 mg/mL, intraday and interday, at the presence of different solubilization agents. The relative standard deviation was 1.05%. None of the solubilization agents interfere with the assay.

Results and Discussion

Cosolvency—Figure 2 shows the exponential increase in Fluasterone solubility with the increasing concentration of cosolvents EtOH, PG, PEG400. The semilogarithmic relationship between total drug solubility (D_{tot}) and cosolvent concentration (C) can be described by eq 1[2,3]

$$\log D_{tot} = \log D_u + \sigma C \qquad (1)$$

where D_u is drug solubility in water and σ is cosolvent solubilization power. The value of σ depends inversely on polarities of both the solute and the cosolvent. Similar solubilization curves were reported for hundreds of nonpolar compounds.[1]

For a single nonpolar solute, the value of σ depends only on cosolvent polarity. Table 1 indicates that Fluasterone solubility enhancement follows the cosolvent order as: EtOH (σ: 5.8) > PEG400 (σ: 4.9) > PG (σ: 4.1) (see Table

Table 1—Solubilization Parameters for Fluasterone

excipent	concentration range, %	dependence of D_{tot} on D_u ([C]: excipient concentration[c])
EtOH	0–80 (v/v)	$10^{5.8\,[C]}$
PG	0–80 (v/v)	$10^{4.1\,[C]}$
PEG400	0–80 (v/v)	$10^{4.9\,[C]}$
glycerin	0–20 (v/v)[a]	$10^{1.1\,[C]}$
Tween 20	0–20 (v/v)	32 258 [C]
Tween 80	0–20 (v/v)	43 226 [C]
sodium cholate	0–20 (w/v)	43 871 [C]
sodium deoxycholate	0–20 (w/v)	55 484 [C]
sodium taurocholate	0–10 (w/v)[b]	24 516 [C]
HPβCD	0–20 (w/v)	180 000 [C]
SBEβCD	0–20 (w/v)	216 129 [C]
αCD	0–14 (w/v)[b]	645 [C]
HPγCD	0–20 (w/v)	19 355 [C]

[a] Maximum concentration prepared due to the increased viscosity of cosolvent solution. [b] Maximum concentrations prepared due to the limited solubility of the excipients. [c] The units for *C* are % for cosolvents and mM for surfactants and cyclodextrins.

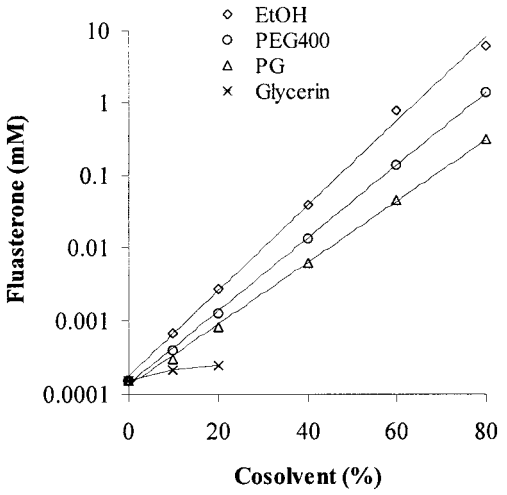

Figure 2—Effects of cosolvents on Fluasterone solubility.

1). Note that the unit for σ is $\%^{-1}$. Glycerin (σ: 1.1), up till 20%, only produces a negligible drug solubility increase, which can be explained by the fact that the glycerin is quite polar. The less polar the cosolvent, the more effective it is at disrupting hydrogen bonding interactions in water molecules. This in turn reduces the ability of the newly formed solvent (aqueous−cosolvent mixture) to squeeze out nonpolar solutes. As a result, nonpolar drugs such as Fluasterone can be solubilized most efficiently by EtOH, the least polar cosolvent.

Micellization—Figure 3 shows the effect of several representative surfactants on Fluasterone solubility. The relationship between the drug solubility and the surfactant micellar concentration is described by eq 2

$$D_{tot} = D_u + \kappa D_u S \qquad (2)$$

where S is the concentration of micellar surfactant (i.e., the total surfactant concentration minus the critical micellar concentration), and κ is the micellar partition coefficient. The product of κ and D_u reflects the number of surfactant molecules required to solubilize a solute molecule. Note that when the critical micellar concentration (CMC) is small, S can be approximated to the total surfactant concentration.

Figure 3 indicates that Fluasterone solubility enhancement is relatively small by Tween 20 or Tween 80 if less than 10% are used. The slightly higher κ value of Tween

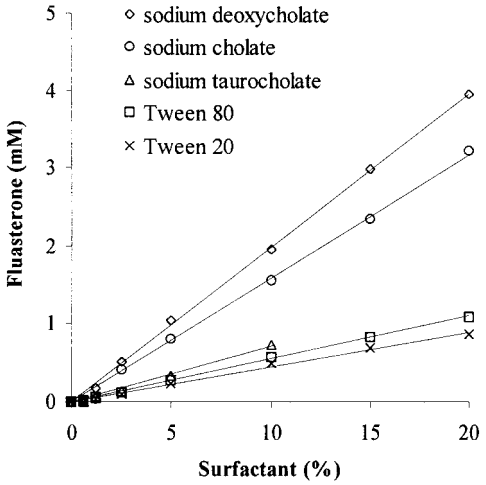

Figure 3—Effects of surfactants on Fluasterone solubility.

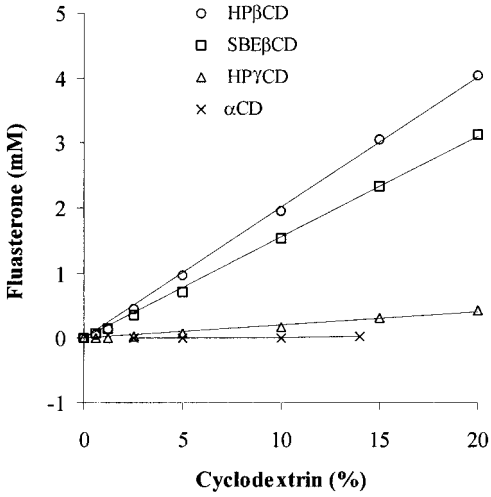

Figure 4—Effects of cyclodextrins on Fluasterone solubility.

80 is likely a result of its longer chains. Interestingly, two bile salts, both sodium cholate and sodium deoxycholate have solubilization capacities that are comparable to those of the polysorbates. These molecules are so arranged that all of the polar moieties are on one side and form a single diffused polar region.[1] As surface-active agents, the bile salts are known for their ability to form aggregates or small micelles in aqueous solutions.[4] Because it has a similar hydrocarbon backbone structure, Fluasterone is likely to fit efficiently into the bile salt micelles, and may even facilitate the formation of these micelles. The reason for the relatively low κ value for sodium taurodeoxycholate (24 516 M^{-1}) is not clear.

Complexation—Figure 4 shows that the effects of various cyclodextrins on Fluasterone solubility can be described by eq 3

$$D_{tot} = D_u + K D_u L \qquad (3)$$

where L is the total ligand concentration, and K is the complexation constant of the drug−ligand complex. As an equilibrium constant, K depends on the polarity and geometry of the solute and the compatibility between the solute and the cyclodextrin cavity. The linear rise in Fluasterone solubility as a function of the ligand concentration indicates that the drug−ligand complex has a one-to-one stoichiometry. This is commonly observed when the ligand concentration is low. Note that higher order complexes may form at relatively high ligand concentrations.

The modified β-cyclodextrins have been widely used and reportedly have higher solubilization capacity than natural βCD for most drugs.[5,6] Figure 4 shows that HPβCD and SBEβCD are better complexation ligands than both αCD and HPγCD, indicating that the 7 Å interior diameter of βCDs' cavity has greater ability to accommodate the Fluasterone molecule, most likely the ring A. The rationale is that the ring A with a 6.5 Å cross-sectional length is more nonpolar than ring D to which both a ketone group and a fluorine group are attached. In fact studies on most steroidal compounds such as testosterone have indicated that the ring A is indeed the part to be complexed into the βCD's cavity due to the matched sizes. Both αCD and HPγCD have the interior cavities that are either too tight (5 Å for αCD) or too loose (9 Å for HPγCD) for efficient incorporation of Fluasterone, which explains the small drug solubility increase by HPγCD and the negligible effect by αCD. It was also found that the solubilization capacity K by SBEβCD (216 129 M^{-1}) is slightly greater than that by HPβCD (180 000 M^{-1}), which is consistent with other reports.[7]

Choice of Technique—Cosolvents are employed in approximately 10% of FDA approved parenteral products.[8] The 10% ethanol−40% propylene glycol cosolvent system is commonly used in iv preparations such as digoxin, diazapam, and phenytoin. In this study the great impact of cosolvents on Fluasterone solubility is clearly shown in Figure 2. For example, the drug solubility is 2.8×10^{-3} mM, 3.96×10^{-2} mM, and 0.77 mM at EtOH concentration 20%, 40%, and 60%, respectively. However, cosolvent use has its clinical limitations: high concentrations often lead to high tonicity, high toxicity, and the precipitation of solubilized drugs upon injection or infusion which are associated with phlebitis.[9,10] Also, EtOH in concentration of greater than 10% may produce significant pain.[1]

Safety is the major concern in using surfactants: though numerous long-chain anionic, cationic, and nonionic surfactants are available as solubilizing agents, only Tween 80 have been used to significant extent in parenteral formulation (0.01−10%; e.g.: 10% in Amiodarone injection), while Tween 20 is much less (0.01−1.7%; e.g; 1.7% in multivitamin injection).[11] This is because surfactants are known to be toxic to blood, which restricts their use in parenteral preparations. With 10% of Tween 80, the drug solubility can be improved to 0.58 mM, but still far below the desired dose, while with 10% sodium cholate and 10% sodium deoxycholate, the drug solubility can be increased to 1.56 and 1.95 mM, respectively. It is of note, though, that the surfactants are very useful for low-dose parenteral preparations.

On the other hand, the complexation ligands HPβCD and SBEβCD provide an effective method for drug solubilization. Fluasterone concentrations of over 3 mM can be obtained with 20% HPβCD or 20% SBEβCD (4.04 mM and 3.13 mM, respectively). This is substantially higher than 60% of any cosolvents or 10% of any surfactants investigated. Clinically, the complexation offers an important benefit: it does not produce precipitation upon injection or upon dilution. Though not employed in any FDA-approved parenteral preparations,[8] cyclodextrins and the modified βCDs in particular have drawn enormous research interest over the past decade. The parent cyclodextrins have their drawbacks: in addition to the limited solubility, they are also found to have toxic effects on the kidney, which is the main organ for the removal of CDs in the proximal convoluted tubule after glomerular filtration. The chemically modified βCDs such as HPβCD and SBEβCD, however, have offered a much increased intrinsic solubility and much reduced renal toxicity.[12] It has been reported that SBEβCD is safe on acute dosing without the nephrotoxicity and membrane-destabilizing properties of parent βCD.[12−14] Currently SBEβCD is undergoing extensive chronic safety assessment.[15]

Conclusion

This study discussed and compared Fluasterone solubility enhancement by cosolvency, micellization, and complexation. It was found that solutions containing 20% of either SBEβCD or HPβCD enable the formulation of 3 mM Fluasterone that will not precipitate upon dilution.

Abstract □ Acetyl groups were introduced to the hydroxyl groups of heptakis(2,6-di-*O*-methyl)-β-cyclodextrin (DM-β-CyD), and the resulting heptakis(2,6-di-*O*-methyl-3-*O*-acetyl)-β-CyD (DMA-β-CyD) was evaluated for the inclusion property and hemolytic activity. It was confirmed by means of NMR and mass spectroscopies that in the DMA-β-CyD molecule, all seven hydroxyl groups at the 3-position were substituted by acetyl groups. Thus, it has the degree of substitution (DS) of 7, whereas DMA4-β-CyD with the lower substitution (DS 3.8) was a mixture of components with different DS. The aqueous solubility of DMA-β-CyD was higher than those of β-CyD, DM-β-CyD, and heptakis(2,3,6-tri-*O*-methyl)-β-CyD (TM-β-CyD). The hydrophobicity of the whole molecule, assessed from measurements of surface tension, increased in the order of DM-β-CyD < DMA-β-CyD < TM-β-CyD. The half-life of DMA-β-CyD for hydrolysis in pH 9.5 and 60 °C was about 19 h, and there was only slight liberation of acetic acid in rabbit plasma and carboxylesterase (EC 3.1.1.1) at 37 °C. DMA-β-CyD had an inclusion ability similar to that of TM-β-CyD for *p*-hydroxybenzoic acid esters with different alkyl chain lengths and an antiinflammatory drug, flurbiprofen, although it was inferior to that of DM-β-CyD. The hemolytic activity and rabbit muscular irritation of DMA-β-CyDs were much weaker than those of DM-β-CyD: no hemolysis was observed even in the presence of 0.1 M DMA-β-CyD with DS 7. The results suggest that the water-soluble CyD derivative with superior bioadaptability and inclusion ability can be prepared by properly designing substituents at the 3-position and by optimally controlling their degree of substitution.

Introduction

Cyclodextrins (CyDs) are cyclic oligosaccharides usually consisting of six to eight glucose units and are used successfully as drug carriers with improved levels of solubility, stability, and bioavailability, etc.[1−3] Recently, various kinds of CyD have been prepared in order to improve physicochemical properties and inclusion capacities of parent CyDs.[4−6] For example, hydrophilic CyD derivatives such as methylated, hydroxyalkylated, and branched CyDs are useful for the improvement of low solubility, dissolution rate, and bioavailability of poorly water-soluble drugs.[7,8] On the other hand, hydrophobic CyDs such as ethylated and acylated derivatives have potential as sustained release carriers for water-soluble drugs.[9,10] Among these derivatives, heptakis(2,6-di-*O*-methyl)-β-CyD (DM-β-CyD) is of interest because of its powerful solubilizing ability for the majority of lipophilic drugs such as steroid hormones,[11] vitamins A, E, and K,[12,13] cyclosporin A,[14] and long chain fatty acids.[15] However, one of the drawbacks of DM-β-CyD is its membrane toxicity, causing tissue irritation and hemolysis in a concentration-dependent manner.[16] For example, the concentration of DM-β-CyD to induce 50% hemolysis of human erythrocytes is lower than that of the so-called bioadaptable CyD derivatives such as 2-hydroxypropyl-β-CyD, sulfobutyl ether of β-CyD, and maltosyl-β-CyD.[17−23] The hemolytic activity of CyDs is associated with the extraction of membrane components, mainly through inclusion complexation with cholesterol. In this study, we have attempted to reduce the membrane toxicity of DM-β-CyD, through a chemical modification of hydroxyl groups at the 3-position of glucose units of DM-β-CyD. As a first step of the modification, acetyl groups were introduced to the hydroxyl groups, and the resulting heptakis(2,6-di-*O*-methyl-3-*O*-acetyl)-β-CyD (DMA-β-CyD) was evaluated for the inclusion property, the hemolytic activity, and muscular tissue irritation.

Experimental Section

Materials—β-CyD, DM-β-CyD, and heptakis(2,3,6-tri-*O*-methyl)-β-CyD (TM-β-CyD) were supplied by Japan Maize Co. (Tokyo, Japan). Flurbiprofen, 2-(2-fluoro-4-biphenylyl)propionic acid, was donated by Mitsubishi Kasei Co. (Tokyo, Japan), and *p*-hydroxybenzoic acid esters with different alkyl groups were purchased from Tokyo Kasei Co. (Tokyo, Japan). All other chemicals and solvents were of analytical reagent grade, and deionized double-distilled water was used throughout the study.

Apparatus—Nuclear magnetic resonance (NMR) spectra were taken on a JEOL JNM-α 500 instrument (Tokyo, Japan) operating at 500.16 MHz for protons at 25 °C. The concentration of DMA-β-CyDs was 1.0×10^{-2} M in deuterated chloroform ($CDCl_3$), and the chemical shifts were given as parts par million (ppm) downfield from that of tetramethylsilane. Fast atom bombardment mass (FAB-MS) spectra were measured in a negative mode at 25 °C by a JEOL JMS-DX 303 mass spectrometer (Tokyo, Japan) using the matrix (methanol/glycerol/*m*-nitrobenzyl alcohol). Ultraviolet (UV), fluorescence, and circular dichroism (CD) spectra were measured at 25 °C using Hitachi U-2000 UV and F-4010 fluorescence spectrometers (Tokyo, Japan) and a Jasco J-720 polarimeter (Tokyo, Japan), respectively. Surface tension was measured at 25 °C by a Shimadzu duNouy surface tensionmeter (Kyoto, Japan).

Preparation of DMA-β-CyD—Dried DM-β-CyD (10 g, 7.5 mmol) was dissolved in dried pyridine (50 mL), acetic anhydride (10.7 g, 105 mmol) was added dropwise for 2−3 h, and the mixture was stirred at 80 °C for about 24 h. The reaction was terminated by addition of ice−water, and the resulting oil was extracted with chloroform. The organic phase was washed with 2 mM sodium carbonate and in turn with water, dried with anhydrous sodium sulfate, and evaporated under reduced pressure. The residue was subjected to silica gel chromatography (Kieselgel 60, 0.063−0.2 mm, 70−200 mesh) with an eluent of methanol/chloroform increasing the methanol concentration from 0 to 12% v/v. DMA-β-CyD (DS 7) was recrystallized from water and obtained as white crystals (yield 60%). Mp 126 °C; TLC $R_f = 0.3$ (silica gel 60 F_{254}, methanol/chloroform 2:15 v/v); FAB MS (negative mode) *m*/*z* 1777 [M + *m*-nitrobenzyl alcohol (matrix) − H)$^-$; ^{1}H NMR ($CDCl_3$) δ 5.16 (t, 1H, CyD H-3), 5.00 (d, 1H, CyD H-1), 3.91−3.87 (m, 2H, CyD H-5 and H-6b), 3.79 (t, 1H, CyD H-4), 3.54 (d, 1H, CyD H-6a), 3.37 (s, 3H, 6-CH_3), 3.33 (s, 3H, 2-CH_3), 3.21 (dd, 1H, CyD H-2), 2.04 (s, 3H, 3-CH_3). DMA4-β-CyD with a low degree of substitution

(DS) was prepared by using small amounts of the acid anhydride (4.6 g, 45 mmol) versus DM-β-CyD (10 g, 7.5 mmol). The other condition of preparation was identical to that described above, except for the recrystallization due to the fact that it was a mixture of components with different DS. The residue after the extraction and evaporation was subjected to the silica gel chromatography described above, and the factions containing acetylated DM-β-CyDs (TLC $R_f = 0.4-0.5$, silica gel 60 F_{254}, methanol/chloroform 2:15 v/v) were collected and evaporated under reduced pressure. DMA4-β-CyD was obtained as white powder (yield 80%). It was confirmed that DMA4-β-CyD contains neither DM-β-CyD (R_f = 0.7) nor DMA-β-CyD (DS 7, $R_f = 0.3$) by TLC analysis and no solvents such as methanol and chloroform by ^{1}H-MMR spectroscopy. The DS value was determined by a peak ratio of the CyD anomeric or skeleton protons and the methyl proton of acetyl groups in ^{1}H NMR spectra (see Supporting Information), and was 3.8. This value coincided with that (DS = 3.9 ± 0.1) determined by the amount of acetic acid released after alkaline hydrolysis in 2.0 N NaOH solution. Unfortunately, the mass spectroscopic determination of DS was difficult because of the partial degradation of DMA4-β-CyD to DM-β-CyD during the ionization.

Solubility Measurements—The solubility method was carried out according to the method of Higuchi and Connors.[24] The screw-capped vials containing drugs in excess amounts in aqueous CyD solutions at various concentrations ($1.0-5.0 \times 10^{-2}$ M) were shaken at 25 °C. After equilibrium was attained (about 5 days), the solution was centrifuged at 800*g* force for about 5 min, and the supernatant was filtered through a membrane filter (Advantec DISMIC-3CP (TOYO−Roshi), Tokyo, Japan) and analyzed for drugs by high-performance liquid chromatography (HPLC) under the following condition: a Hitachi L-6000 pump and an L-4000 UV detector (Tokyo, Japan) at 256 nm, a YMC AM-312 column (6.0 × 150 mm), flow rate of 1.0 mL/min. The mobile phases for the analysis of flurbiprofen and *p*-hydroxybenzoic acid esters were methanol/0.1 M acetic acid (7:3 v/v) and methanol/water (7:3 v/v), respectively. The stability constants ($K_{1:1}$) of 1:1 complexes were calculated from the slope and intercept of straight line of the phase solubility diagram according to the equation of Higuchi and Connors.[24] In the case of phase solubility diagrams with positive curvature, the diagrams were analyzed according to the method of Kristiansen[25] to obtain the 1:1 and 1:2 ($K_{1:2}$, guest:host) stability constants.

Hydrolysis Studies—Alkaline hydrolysis of DMA-β-CyD (1.0×10^{-2} M) was conducted in 0.1 M phosphate buffers (pH 8.5−11.5) at 60 °C. At timed intervals, the reaction solution (20.0 μL) was sampled and analyzed for the resulting acetic acid by HPLC under the following condition: a YMC AP-303 column (4.6 × 250 mm), a mobile phase of 0.1% phosphoric acid, a flow rate of 1.0 mL/min, a detection of 210 nm. The hydrolysis was monitored by measuring acetic acid at an early stage of the reaction (240 min, 150, 120, and 30 min at pH 8.5, 9.5, 10.5, and 11.5, respectively), because the pH of the solution changed due to the liberation of acetic acid. The rate constant (k) was calculated according to the following equation: $\ln(7C_0 - C) = -kt + \ln 7C_0$, where C_0 and C are the initial concentration of DMA-β-CyD and the concentration of the liberated acetic acid at time t, respectively. The total concentration of acetic acid at infinite time is supposed to be $7C_0$.

Carboxylesterase-catalyzed hydrolysis of DMA-β-CyD was conducted in 0.1 M *N*-(2-hydroxyethyl)piperazine-*N*′-ethanesulfonic acid (HEPES)/NaOH buffer solution (pH 7.4) at 37 °C. The concentrations of DMA-β-CyD and the enzyme (EC 3.1.1.1 obtained from porcine liver, purchased from Sigma Aldrich Japan, Tokyo) were 5.0×10^{-3} M and 0.25 or 25 units/mL, respectively. At timed intervals, an aliquot (20.0 μL) was sampled and analyzed for acetic acid by HPLC under the aforementioned condition.

Hydrolysis of DMA-β-CyD was conducted in 50% and 80% rabbit plasma at 37 °C. Rabbit blood was taken by heparinized injection syringe and centrifuged at 12000*g* for 5 min at 4 °C. DMA-β-CyD solution (1.0 mL, 2.0×10^{-2} M in pH7.4 isotonic phosphate buffer) was added to the plasma (1.0 mL). At appropriate times, an aliquot (0.3 mL) of the reaction solution was ultrafiltered using a membrane filter (Amicon Kit (Tokyo, Japan), a centrifugation of 2000*g* for 15 min at 4 °C), and the filtrate was analyzed for acetic acid by HPLC under the aforementioned condition.

Hemolysis Studies—Erythrocytes were separated by centrifugation of freshly drawn citrated rabbit blood at 1000*g* for 5 min, washed three times with phosphate buffer (0.154 M sodium chloride and 0.01 M phosphate, pH 7.4), and resuspended in the buffer solution to give a hematocrit of 5%. The cell suspension (0.1 mL) was added to the buffer solution (2.0 mL) containing β-CyDs at various concentrations. Each mixture was incubated for 30 min at 37 °C and centrifuged at 1000*g* for 5 min. The release of hemoglobin from the cells was measured spectrophotometrically at 543 nm. Results were expressed as percentages of the total efflux of hemoglobin which was obtained when water was used instead of the buffer solution. The morphological observation of erythrocytes was carried out as follows: the cell suspension (5%, 0.1 mL) was incubated with the buffer solution (2.0 mL) containing β-CyDs at 37 °C for 60 min, and fixed with 2% glutaraldehyde solution (5.0 mL). After standing for 1 h at room temperature, the fixed cells were washed three times with water, dried under reduced pressure for 16 h, coated with gold, and observed by scanning electron microscope (Akashi, MSM4C, Tokyo, Japan).

Determination of cholesterol: the cell suspension (5%, 0.2 mL) was incubated with the buffer solution (4.0 mL, pH 7.4) containing β-CyDs at 37 °C for 30 min. After centrifugation (1000*g*, 5 min), cholesterol in the supernatant (3.0 mL) was extracted with chloroform (5.0 mL), the organic phase was evaporated under reduced pressure, and cholesterol in the residue was determined by the cholesterol oxidase method with using a Cholesterol E-test kit (Wako, Osaka, Japan). Results were expressed as percentages of the total amount of cholesterol which was released when water was used instead of the buffer solution.

Intramuscular Irritation Studies—The intramuscular irritation study was carried out by the method of Shintani et al.[26] β-CyD solutions (100 mg/1.0 mL of normal sterile saline) were injected into *M. vastus lateralis* of three rabbits (2.5−3.0 kg) using a 23-gauge 0.5 in. needle. The rabbits were killed 2 days after the injection, the muscle was exposed and cut longitudinally, and the lesion were scored according to the method of Shintani et al.,[26] that is, score 0, no discernible gross reaction; score 1, slight hyperemia and discoloration; score 2, moderate hyperemia and discoloration; score 3, distinct discoloration in comparison with the color of surrounding area; score 4, brown degeneration with small necrosis; score 5, widespread necrosis.

Results and Discussion

Some Physicochemical Properties of DMA-β-CyD—It was confirmed by means of NMR and mass spectroscopies that in DMA-β-CyD molecule, all seven hydroxyl groups at the 3-position were substituted by acetyl groups, thus having DS 7. DMA4-β-CyD with the lower substitution (DS 3.8) was a mixture of components with different DS. In the following evaluation of physicochemical and inclusion properties, DMA-β-CyD with DS 7 was employed, and the lower DS form was used only for comparative studies of hemolysis and muscular irritation.

The melting point decreased in the order, DM-β-CyD (295−300 °C), the parent β-CyD (280 °C), TM-β-CyD (157 °C), and DMA-β-CyD (126 °C). The aqueous solubility of DMA-β-CyD (>60 g/dL at 25 °C) was much higher than those of the parent β-CyD (1.85 g/dL), DM-β-CyD (57 g/dL), and TM-β-CyD (31 g/dL); however, DMA-β-CyD ≥ 70%w/v gave a viscous solution. DMA-β-CyD exhibited an exothermic dissolution in water in the similar manner as DM- and TM-β-CyDs[27] and thus precipitated at higher temperature. The hydrophobicity of DMA-β-CyD was assessed by measurements of the surface tension, because the oil/water partition method is affected by the inclusion of organic solvents in the CyD cavity. As shown in Figure 1, the surface tension of DMA-, DM-, and TM-β-CyDs decreased as the concentration increased, and the hydrophobicity of the whole molecule increases in the order of DM-β-CyD < DMA-β-CyD < TM-β-CyD. This order was in accordance with that of the π value of the substituents introduced at the hydroxyl groups, that is, −0.67 (OH of DM-β-CyD) < −0.64 (OCOCH$_3$ of DMA-β-CyD) < −0.02 (OCH$_3$ of TM-β-CyD).[28] The hydrolysis of DMA-β-CyD in alkaline solution was studied by monitoring the resulting acetic acid, because it was difficult to determine partially hydrolyzed

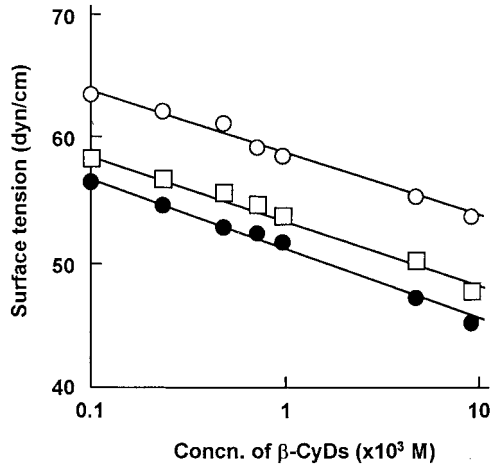

Figure 1—Surface tension of DMA-β-CyD (□), DM-β-CyD (○), and TM-β-CyD (●) in water at 25 °C.

DMA-β-CyDs having various regioisomers by means of HPLC. The hydrolysis was followed at an early stage of the reaction, because pH of the solution changed owing to the liberation of acetic acid. The appearance rates of acetic acid from DMA-β-CyD were 9.0 ($\pm$1.5) $\times$ 10^{-5} min^{-1} (mean ($\pm$SE), n = 3, pH 8.5), 6.2 ($\pm$0.2) $\times$ 10^{-4} min^{-1} (pH 9.5), 2.1 ($\pm$0.1) $\times$ 10^{-3} min^{-1} (pH 10.5), and 1.9 ($\pm$0.1) $\times$ 10^{-2} min^{-1} (pH 11.5) at 60 °C, giving the linear rate−pH profile (correlation coefficient = 0.990) with a slope of 0.75. The carboxylesterase-catalyzed hydrolysis of DMA-β-CyD was conducted at concentrations of 5.0 $\times$ 10^{-3} M of DMA-β-CyD and 0.25 or 25 units/mL of the esterase in HEPES buffer (pH 7.4) at 37 °C. No liberation of acetic acid (less than the detection limit of 3%) in the 0.25 units/mL enzyme solution was observed for 10 h, and the releases even in the 25 units/mL enzyme solution were less than 5% and 15% of the total amounts of acetic acid for 5 and 10 h, respectively. Furthermore, no liberation of acetic acid (less than 3%) was observed in 50% and 80% plasma of rabbits for 12 h, suggesting that DMA-β-CyD is chemically stable in biological fluids such as plasma.

Inclusion Property of DMA-β-CyD—The inclusion property of DMA-β-CyD was compared with those of the parent β-CyD and DM- and TM-β-CyDs. Table 1 shows the results of phase solubility diagrams of β-CyDs with *p*-hydroxybenzoic acid esters with different alkyl chains. The guest molecules with short alkyl chains showed A_L type phase solubility diagrams where the solubility of the guests increased linearly as a function of CyD concentrations (0−0.02 M), indicating the 1:1 complexation.[24] On the other hand, the ester with longer alkyl chains showed A_P type diagrams where the solubility curve deviated positively from a straight line, indicating the 1:2 (guest:host) complexation.[25] The stability constant of the 1:1 complexes increased as the alkyl chain lengthens up to the propyl ester, whereas the butyl ester formed the 1:2 complex with DMA-β-CyD and the hexyl eater formed the 1:2 complex with the three CyDs. The stability constants were generally in the order of DM-β-CyD ≫ TM-β-CyD ≈ DMA-β-CyD.

Table 1—Stability Constants ($K_{1:1}$ and $K_{1:2}$, M^{-1})[a] and Types of Phase Solubility Diagrams for Inclusion Complexes of *p*-Hydroxybenzoic Acid Esters with β-CyDs in Water at 25 °C

Spectroscopic studies on the interaction of flurbiprofen with DMA-β-CyD was carried out, because the complexation of the drug with DM- and TM-β-CyDs had been investigated in detail.[29] Figure 2 shows the UV, CD, and fluorescence spectra of flurbiprofen in the absence and presence of DM-, TM-, and DMA-β-CyDs in pH 7.0 phosphate buffer. Flurbiprofen gave a UV absorption maximum (λ_{max}) at 246 nm, and by the addition of β-CyDs the intensity decreased with concomitant shifts to longer wavelength. This bathochromic shift was largest with DMA-β-CyD (λ_{max} 251 nm) compared with those of DM-β-CyD (249 nm), TM-β-CyD (249 nm), and β-CyD (247 nm),

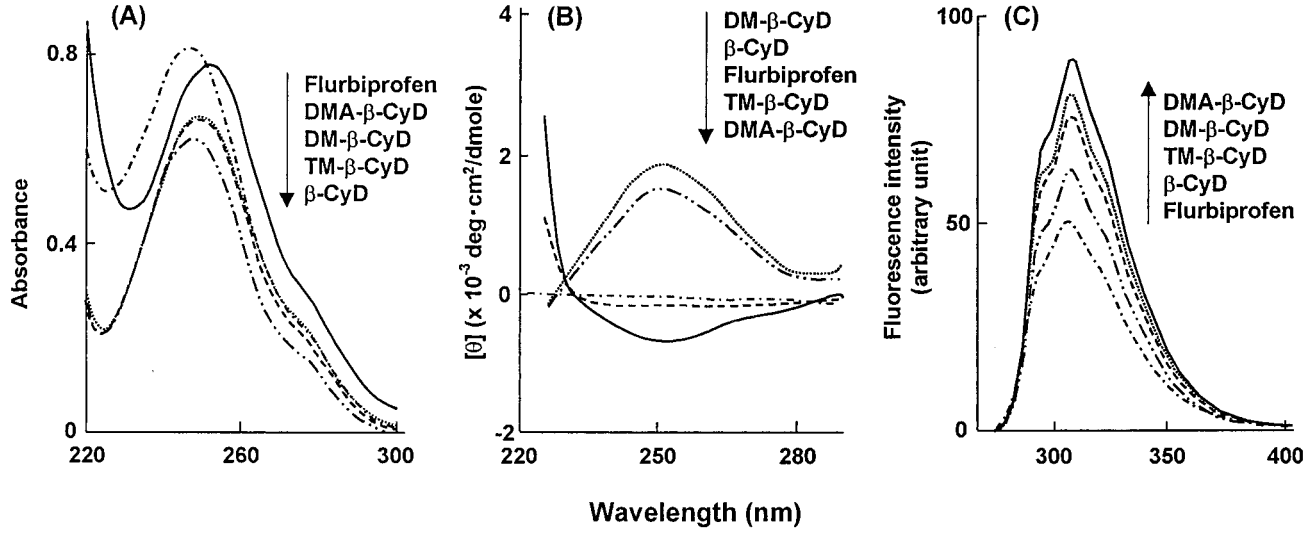

Figure 2—UV (A), CD (B), and fluorescence (C) spectra of flurbiprofen in the absence (–·–) and presence of DMA-β-CyD (—), β-CyD (–··–), DM-β-CyD (····) and TM-β-CyD (---) in 0.1 M phosphate buffer (pH 7.4, I = 0.2) at 25 °C. The concentrations of flurbiprofen and β-CyDs in UV and CD spectroscopic studies were 4.0 $\times$ 10^{-5} M and 4.0 $\times$ 10^{-3} M, respectively, and those in fluorescence spectroscopic studies were 1.0 $\times$ 10^{-6} M and 1.0 $\times$ 10^{-3} M, respectively. The excitation wavelength was 256 nm.

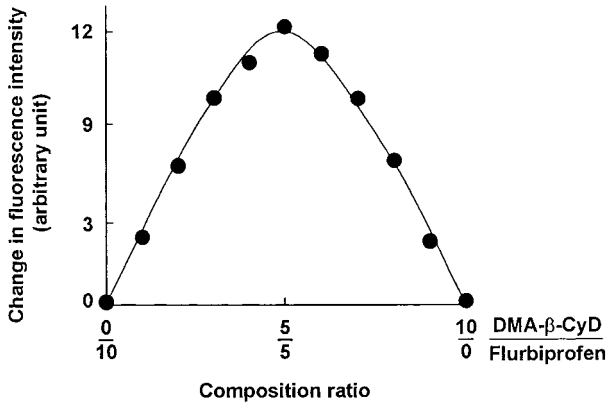

Figure 3—Continuous variation plot for flurbiprofen/DMA-β-CyD system (total concentration of the host and guest molecules = 5.0×10^{-6} M) in 0.1 M phosphate buffer (pH 7.4, $I = 0.2$) at 25 °C.

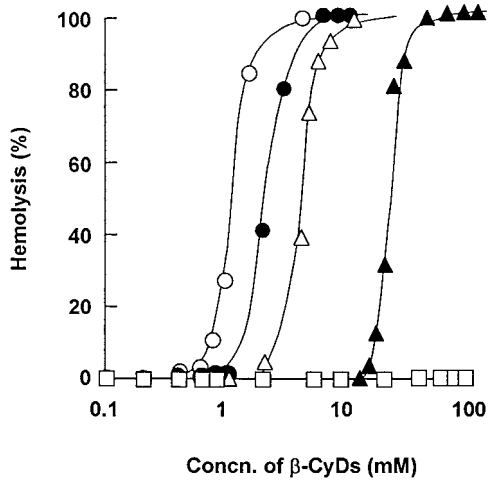

Figure 4—Hemolytic effects of β-CyDs on rabbit erythrocytes in isotonic phosphate buffer (pH 7.4) at 37 °C. Key: (□) DMA-β-CyD; (▲) DMA4-β-CyD; (△) β-CyD; (○) DM-β-CyD; (●) TM-β-CyD.

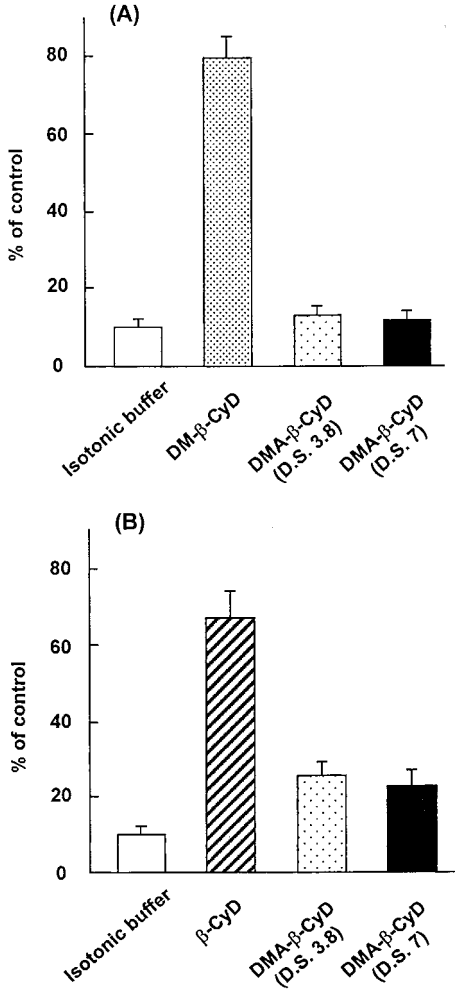

Figure 5—Cholesterol release from intact erythrocytes of rabbits treated with β-CyDs (A, 0.5 mM; B, 3.0 mM) in isotonic phosphate buffer (pH 7.4) at 37 °C. Each value represents the mean ± SE of three experiments.

although the intensity change was small with DMA-β-CyD. In the CD spectra, the optical activity of flurbiprofen was induced positively by the addition of DM-β-CyD and β-CyD, whereas it was induced negatively by DMA-β-CyD and TM-β-CyD where the effect of DMA-β-CyD was larger than that of TM-β-CyD. The sign of CyD-induced CD bands depends on a spatial relationship between the asymmetric center of CyD cavity and the perturbed chromophore of guest molecules. For example, the electronic transition of an included guest with a transition dipole moment, parallel to the z-axis of the CyD cavity, gives a positive CD, and that with a transition dipole moment perpendicular to the z-axis gives a negative CD.[30] Our crystallographic studies indicated that flurbiprofen is included in such a manner that the long molecular axis of the drug is parallel to the z-axis of the β-CyD cavity, that is, an axial inclusion, whereas the long axis of the drug is inclined in the TM-β-CyD cavity.[31,32] These dispositions of flurbiprofen in CyD cavities were reflected in the sign of induced CD bands, giving a positive CD with β-CyD and a small negative CD with TM-β-CyD. DMA-β-CyD gave a larger negative CD band than TM-β-CyD, suggesting that the drug is more inclined in the former cavity than in the latter cavity. The fluorescence intensity of flurbiprofen at 315 nm was markedly increased in the order of β-CyD < TM-β-CyD < DM-β-CyD < DMA-β-CyD. Since the fluorescence of the drug is known to be increased significantly in organic solvents such as ethanol, the CyD-induced fluorescence change suggested that the drug is included within the hydrophobic CyD cavity. The largest enhancement of the fluorescence by DMA-β-CyD may be attributable to the increase in hydrophobicity of the cavity, although the hydrophobicity of the whole molecule of DMA-β-CyD was lower than that of TM-β-CyD as is apparent from the surface tension. The methyl moieties of acetyl groups in the DMA-β-CyD molecule seem to be directed inside the cavity, while the carbonyl moieties are directed outside the cavity, providing a more hydrophobic environment of the cavity. On the other hand, TM-β-CyD is known to have the distorted macrocyclic ring in which the secondary rim is wider whereas the primary rim is narrower,[33] thus allowing water molecules easily to access the inside of the cavity. This may be a reason the fluorescence enhancement of TM-β-CyD was smaller than DMA-β-CyD, despite the higher hydrophobicity of TM-β-CyD as a whole molecule. Figure 3 shows a continuous variation plot of the fluorescence intensity at 310 nm of the flurbiprofen/DMA-β-CyD system. The plot gave a maximum at 0.5, indicating the 1:1 stoichiometry which was the same as that of β-CyD, DM-β-CyD, and TM-β-CyD complexes.[29] Therefore, the fluorescence change as a function of concentrations of the four β-CyDs was analyzed quantitatively by the Scott equation[34] to obtain the stability constant ($K_{1:1}$) of the 1:1 complexes. The $K_{1:1}$ values in pH 7.0 phosphate buffer at 25 °C were 3610 (±120) M^{-1} (mean (± SE), $n = 3$), 8060 (±600) M^{-1}, 1660 (±80) M^{-1}, and 1410 (±80) M^{-1} for the complexes with β-CyD, DM-β-CyD, TM-β-CyD, and DMA-β-CyD, respectively. Furthermore, the phase solubility diagram of flur-

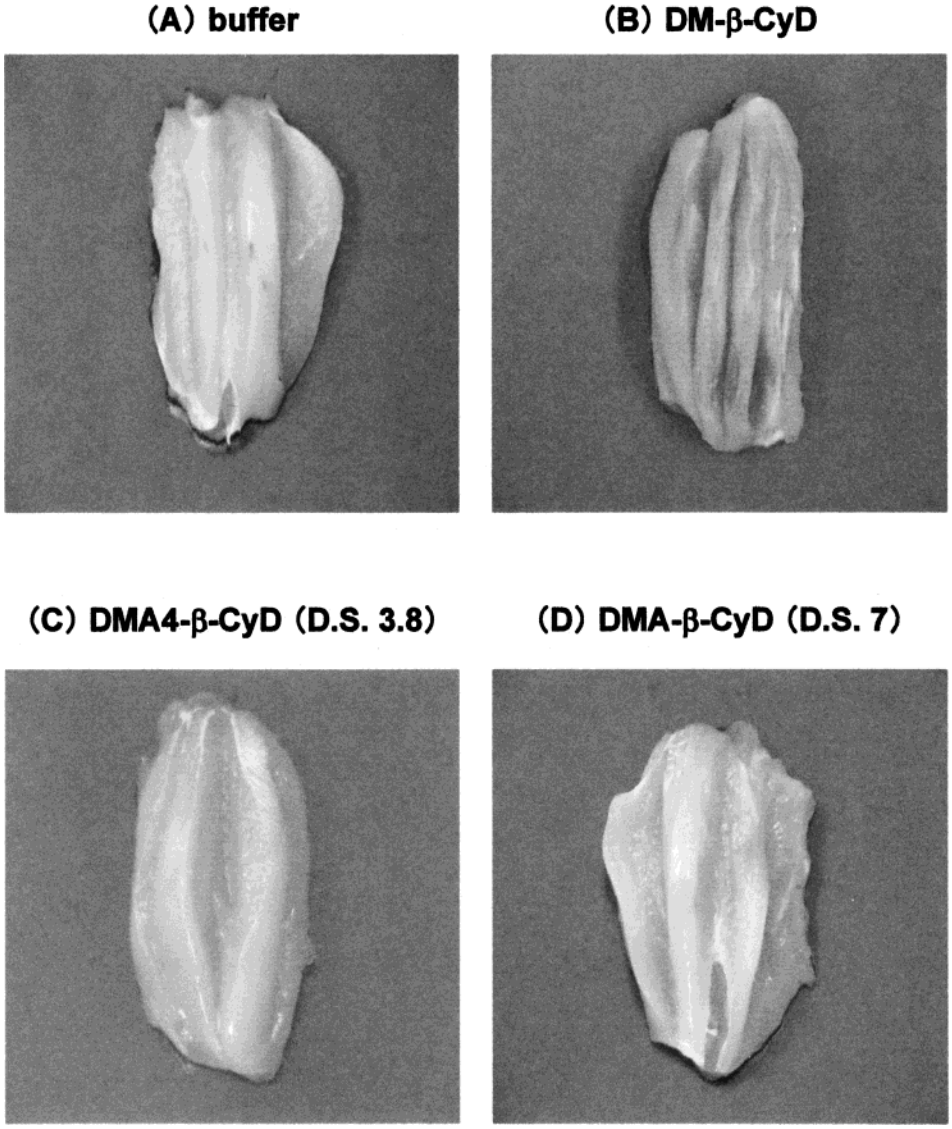

Figure 6—Macrographs of *M. vastus lateralis* after intramuscular injections of β-CyDs (100 mg/site, 1.0 mL) to rabbits. (A) Isotonic buffer; (B) DM-β-CyD; (C) DMA4-β-CyD; (D) DMA-β-CyD.

biprofen with DMA-β-CyD ($0.0-5.0 \times 10^{-2}$ M) in water at 25 °C showed the A_L type and gave the stability constant of 2020 ($\pm$90) M^{-1}. This value was the same as that (2200 ($\pm$110) M^{-1}) of the TM-β-CyD complex, but was smaller than that (14700 ($\pm$900) M^{-1}) of the DM-β-CyD complexes determined under the same conditions. The stability constants determined by the fluorescence method in pH 7.0 phosphate buffer were smaller than those determined by the solubility method in water, which may be due to the acid-ionization of flurbiprofen (pK_a 3.8). These results suggested that DMA-β-CyD has the same inclusion ability as TM-β-CyD, although it is inferior to that of DM-β-CyD, and the hydrophobicity of the DMA-β-CyD cavity is higher than that of TM-β-CyD.

Hemolysis and Muscular Irritation of DMA-β-CyD—Hemolytic activity of DMA-β-CyDs was compared with that of other CyD derivatives in order to estimate its local irritation. Figure 4 shows hemolysis profiles of β-CyD, DM-β-CyD, TM-β-CyD, and DMA-β-CyDs with different DS (7 and 3.8), measured under the same conditions. It is apparent that the hemolytic activity of DMA-β-CyDs was weaker than those of β-CyD, DM-β-CyD, and TM-β-CyD. For example, the hemolysis began at about 2 mM, 0.5 mM, and 1 mM, and the concentrations to induce 50% hemolysis were about 4 mM, 1 mM, and 2 mM for β-CyD, DM-β-CyD, and TM-β-CyD, respectively. On the other hand, the hemolysis of DMA4-β-CyD with DS 3.8 began at about 12 mM, and its 50% hemolysis concentration was about 22 mM. In the case of DMA-β-CyD with DS 7, no hemolysis was observed up to 100 mM. Scanning electron micrographic studies indicated no change in the shape of erythrocytes even at a concentration of 100 mM DMA-β-CyD, that is, they maintained the discocyte shape same as that in the buffer control (Supporting Information). One of the causes of CyD-induced hemolysis is known to be extractions of cholesterol and phospholipids from erythrocytes through the inclusion complex formation.[16] Therefore, the cholesterol release behavior from rabbit erythrocytes by the addition of DMA-β-CyDs was investigated and compared with those of β-CyD and DM-β-CyD. Figure 5 shows the released amounts of cholesterol from the intact erythrocytes of rabbits treated with β-CyDs in 0.1 M phosphate buffer (pH 7.4) at 37 °C. DM-β-CyD induced about 80% release of cholesterol at a concentration of 0.5 mM at which the hemolysis only slightly occurred (see Figure 4). On the other hand, DMA-β-CyDs induced only 10% release of cholesterol at the same concentration, and this release was the same as that of the control experiment conducted in isotonic buffer. Similarly, the 3 mM parent β-CyD solution induced 65% release of cholesterol, whereas

DMA-β-CyDs induced only about 20−25% release of cholesterol. These results indicated that the hemolytic activity of DMA-β-CyDs, particularly the DS 7 derivative, is much weaker than those of the parent β-CyD and the methylated β-CyDs.

Figure 6 shows macrographs of *M. vastus lateralis* of rabbit dissected 2 days after the single injection of DM-β-CyD and DMA-β-CyDs with DS 7 and 3.8 at a dose of 100 mg/site. In the case of DM-β-CyD, a discoloration of the muscle with hemorrhage was observed, and the irritation score according to Shintani et al.[26] was 4.0 ± 1.0. On the other hand, both DMA- and DMA4-β-CyD gave negligible damage to the muscle, giving the irritation score of 0.3 ± 0.7 which was the same as that of the saline injection.

In conclusion, the hemolytic activity and the muscular tissue irritation of DM-β-CyD were significantly reduced by acetylating hydroxyl groups at the 3-position of the glucose units, and the inclusion ability of DMA-β-CyD was comparable to that of TM-β-CyD. These results suggest that water-soluble CyD derivatives with superior bioadaptability and inclusion ability can be prepared by pertinently designing substituents at the 3-position and by optimally controlling their degree of substitution.

Accepted for publication July 14, 1999.

Abstract □ Changes in membrane fluidity have been shown to alter the sodium-dependent renal transport of glucose and phosphate; however, this has not been examined for sodium/sulfate cotransport in the renal proximal tubule. Sodium/sulfate cotransport regulates the homeostasis of sulfate in mammals. The objective of this study was to investigate the influence of alterations of membrane fluidity on sodium-coupled sulfate transport in the Madin–Darby canine kidney cells, which have been stably transfected with sodium/sulfate cotransporter (NaSi-1) cDNA (MDCK-Si). Preincubation of cells with 0.2 mM cholesterol significantly decreased the V_{max} for sodium/sulfate cotransport (13.69 ± 1.11 vs 10.15 ± 1.17 nmol/mg protein/5 min, mean ± SD, $n = 4$, $p < 0.01$) with no significant alteration in K_m. The addition of benzyl alcohol (20 mM) to cells increased the V_{max} of sulfate uptake by 20% (11.97 ± 0.91 vs 14.35 ± 0.56 nmol/mg protein/5 min, mean ± SD, $n = 3$, $p < 0.05$) with no significant change in K_m. Membrane fluidity, as measured by the fluorescence polarization of 1,6-diphenyl 1,3,5-hexatriene (DPH), was significantly increased in MDCK-Si cells treated with 20 mM benzyl alcohol and decreased in the cells preincubated with 0.2 mM cholesterol, compared with control cells. Our results suggest that alterations in membrane fluidity that may occur as a result of disease states, aging, and pregnancy may play an important role in the modulation of renal sodium/sulfate cotransport.

Introduction

Membrane fluidity (membrane motional order or lipid packing order) affects the activity and kinetics of membrane-bound enzymes and transport carriers, accessibility of membrane receptors, and passive permeability properties of membranes.[1] Membrane fluidity can be determined by two factors: environmental factors, such as temperature, and intrinsic factors, such as membrane composition. Alterations in fluidity have been reported in a variety of physiological/pathological conditions such as aging, organ maturation, ischemia, low phosphate diet, vitamin D-induced hypercalcemia, succinylacetone-induced Fanconi syndrome, streptozotocin-induced diabetes mellitus, and liver disease produced by biliary obstruction.[2−4] Drug treatment including treatment with estrogens, gentamicin, anesthetic alcohols (pentanol, hexanol and heptanol), and salicylic acid can also alter membrane fluidity.[2,5,6]

Cholesterol is an essential constituent of the membranes of mammalian cells and is involved in normal cell growth and function. It is mainly located in the cell plasma membrane and acts as the main lipid rigidifier in natural membranes under physiological conditions.[7] The increase in brush border membrane (BBM) cholesterol content and decrease in BBM fluidity in aged rats are associated with a decrease in the V_{max} of sodium-dependent transport of phosphate in renal BBM.[8] Furthermore, Levi et al.[9] have reported that cholesterol directly modulates renal BBM Na^+/phosphate cotransport activity without affecting Na^+/glucose and Na^+/proline cotransport.

Numerous investigations have used the local anesthetic, benzyl alcohol, to alter the physical properties of membranes by increasing their motional order or fluidity. The increase in renal BBM fluidity produced by benzyl alcohol treatment reduced sodium-dependent glucose transport and stimulated Na^+/phosphate cotranport with no change in the affinities of glucose and phosphate for their transport proteins.[2] Friedlander et al.[10] have also confirmed that the increase in apical membrane fluidity achieved by benzyl alcohol produces an increase in phosphate uptake and a decrease of glucose uptake in renal epithelial cells.

Inorganic sulfate, a physiological anion involved in conjugation reactions involving both endogenous and exogenous substrates, is predominantly reabsorbed in the proximal tubule of the mammalian kidney by a sodium-dependent mechanism at the BBM.[11,12] The sodium/sulfate cotransporter is distinct from sodium-dependent phosphate, amino acid, and glucose transport proteins,[13] and the NaSi-1 cDNA identified by Markovich et al.[14] is involved in renal sodium-dependent sulfate transport at the BBM. Unlike other renal sodium-coupled solute transport systems, the effect of membrane fluidity on sodium/sulfate cotransport has not been studied. The objective of the present investigation was, therefore, to examine whether the alterations in membrane fluidity produced by preincubation with cholesterol or by benzyl alcohol treatment affect the activity of the apically located sodium-dependent sulfate transport protein in Madin−Darby canine kidney cells (MDCK) which have been stably transfected by NaSi-1 cDNA (MDCK-Si).[15]

Materials and Methods

Materials—$^{35}SO_4^{2-}$ (as Na_2SO_4, 1050−1600 Ci/mmol) was obtained from New England Nuclear Research Products (DuPont Company, Boston, MA). Biodegradable counting scintillant was purchased from Amersham Co. (Arlington Heights, IL). Commassie blue dye reagent concentrate and bovine plasma γ-globulin protein standard were supplied from Bio-Rad (Richmond, CA). Dulbecco's modified Eagle's medium, fetal bovine serum, and trypsin were obtained from Gibco BRL (Buffalo, NY). All other chemicals were obtained from Sigma Chemical Co. (St. Louis, MO) or J. T. Baker (Phillipsberg, NJ).

Cell Culture Conditions—MDCK cells which had been stably transfected with NaSi-1 cDNA (MDCK-Si)[15] were maintained in Dulbecco's modified Eagle's medium, which contained 22 mM $NaHCO_3$, 2 mM L-glutamine, 50 IU/mL penicillin, 50 μg/mL

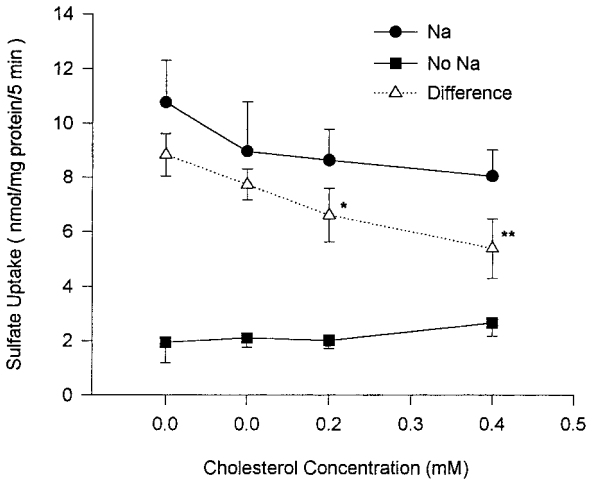

Figure 1—Concentration-dependent effect of cholesterol on sulfate uptake in MDCK-Si cells. Uptake rates were determined at 5 min in the presence of NaCl or of *N*-methyl-D-glucamine. Each data point is the mean ± SD of three separate experiments in which triplicate determinations were obtained. * $p <$ 0.01 compared with control (0 mM cholesterol), ** $p < 0.001$ compared with control.

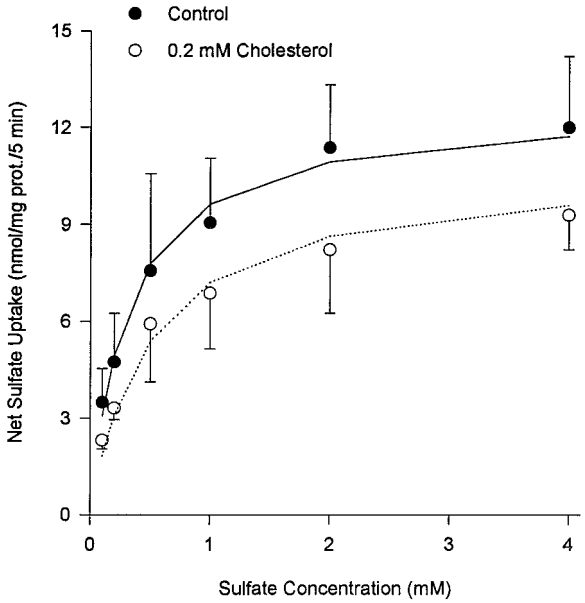

Figure 2—Concentration-dependent sulfate uptake in 0.2 mM cholesterol-preincubated MDCK-Si cells. Sodium-dependent sulfate uptake was calculated as the difference between sulfate uptake rates determined with and without sodium. Each data point is the mean ± SD from four separate preparations, with triplicate determinations of uptake in each preparation. The data were fitted to the Michaelis–Menten equation using nonlinear regression analysis, and the lines represent the fitted lines for the mean data.

streptomycin, 1% nonessential amino acids, and 10% fetal bovine serum, under an atmosphere of 95% air/5% CO_2 at 37 °C. MDCK-Si cells were used up to 15 passages and induced by an incubation with 10^{-6} M dexamethasone for 16 h before sulfate uptake studies.[15]

Sulfate Uptake Studies—The uptake of inorganic sulfate was determined in MDCK-Si cells grown to confluency on culture dishes (35 mm), as described by Hansch et al.[16] Uptake studies were performed at room temperature in a buffered solution which consisted of 137 mM NaCl, 5.4 mM KCl, 2.8 mM $CaCl_2$, 1.2 mM $MgCl_2$, 10 mM HEPES/Tris (pH 7.4) containing K_2SO_4 and tracer amounts of radiolabeled sulfate (2 μCi/mL). At the end of incubation, the uptake was stopped by washing the cells three times with ice-cold stop solution (137 mM NaCl, 10 mM Tris/HCl, pH 7.4). Cells were then solubilized with 1% Triton X-100, and radioactivity and protein concentrations of aliquots were determined by liquid scintillation counting and the Coomassie blue binding method[17] using bovine plasma γ-globulin as the protein standard, respectively.

For estimation of transport kinetic parameters, V_{max} and K_m, for sulfate BBM transport, sulfate uptake into MDCK-Si cells was determined at 5 min at various concentrations of sulfate (0.1−6 mM) in the presence and absence of NaCl. For studies done in the absence of sodium, NaCl was replaced by an equimolar amount of *N*-methyl-D-glucamine/HCl. The difference between the uptake rates at the same sulfate concentrations with and without sodium represents the sodium-dependent transport process. Preliminary studies have demonstrated that the 5 min uptake value provides an estimate of the linear uptake of sulfate in MDCK-Si cells. Cells were preincubated with cholesterol at 37 °C for 2 h for the experiments with cholesterol, whereas benzyl alcohol was added to the uptake solution in studies examining the effect of benzyl alcohol on sulfate uptake.

Membrane Fluidity Measurements—The membrane fluidity of intact MDCK-Si cells which were treated with 20 mM benzyl alcohol or preincubated with 0.2 mM cholesterol was examined by measuring the fluorescence polarization of 1,6-diphenyl-1,3,5-hexatriene (DPH). MDCK-Si cells were diluted with 2 mL of phosphate-buffered saline solution (PBS, pH 7.4), and 5 μL of 1 mg/mL DPH in tetrahydrofuran was added. One potential problem of measuring fluorescence polarization using the DPH probe in intact cells is the larger particle size of the intact cells which causes depolarization. This problem was partly alleviated by diluting the cells with 2 mL of PBS. Further, the depolarization due to light scattering was corrected by conducting appropriate control experiments as described previously.[18] The binding of the probe to cell components and restricting motions of the probe were evaluated by using various probe-to-cell ratios, produced by serial dilution of the cell suspension.

Fluorescence polarization measurements were performed using a SLM Aminco (SLM Aminco, Urbana, IL) 8000 spectrofluorometer with film polarizers (FP110) at temperatures of 25 °C and 37 °C with the excitation wavelength of 355 nm and the emission wavelength of 430 nm.[6] The temperature equilibration was established by maintaining the chamber at appropriate temperatures for 15 min prior to the measurements using a Neslab (RTE 110) water bath.

Data Analysis—The Michaelis−Menten equation was used to fit the data representing linear sulfate uptake (5 min determinations) over a wide range of concentrations using nonlinear regression analysis (PCNONLIN, Statistical Consultants Inc., Lexington, KY) with a weighting factor, 1/variance, to obtain estimates of the V_{max} and K_m values for sodium/sulfate cotransport.[19] The uptake values were determined in triplicate in any one experiment, and the data from each experiment were fitted to the Michaelis−Menten equation. Three or four experiments were performed, and the mean ± SD for these parameter estimates are reported.

The measured polarization and anisotropy values were used to calculate the lipid order parameter S, using the formula $S^2 = [(4r/3) - 0.1]/r_0$ where r_0 is the maximal fluorescence anisotropy value in the absence of any rotational motion (0.40), and r is the steady state anisotropy value. The lipid order parameter was used to estimate the membrane fluidity, as they are inversely related. The static and dynamic components of S were analyzed as described by Pottel et al.[20]

Statistical Analysis—All results were reported as the mean ± SD, unless stated otherwise. The data were compared by unpaired Student's *t*-test between two groups and by ANOVA followed by a Tukey's test among more than two groups. The differences were considered to be statistically significant when $p < 0.05$.

Results

Time Course of Sulfate Uptake—Sodium-dependent sulfate uptake into MDCK-Si cells was examined at various times and increased linearly with time, up to 20 min of incubation. The uptake of sulfate in cells reached a plateau after 60 min, indicating equilibrium (data not shown).

Effect of Cholesterol on Sulfate Uptake—In all studies, sulfate uptake in MDCK-Si cells was significantly increased in the presence of sodium compared with that in the absence of sodium, indicating the sodium dependence

Table 1—Transport Parameter Estimates for Sodium-Dependent Sulfate Uptake into Cholesterol-Preincubated MDCK-Si Cells[a]

	V_{max} (nmol/mg prot/5 min)	K_m (μM)
control	13.69 ± 1.11	435.5 ± 142.8
0.2 mM cholesterol	10.15 ± 1.17[b]	416.7 ± 153.9

[a] Values are presented as mean ± SD of four separate experiments. The estimate for V_{max} was significantly different in control and cholesterol-preincubated cells ($p < 0.01$) with no significant change in the K_m value. [b] $p < 0.01$.

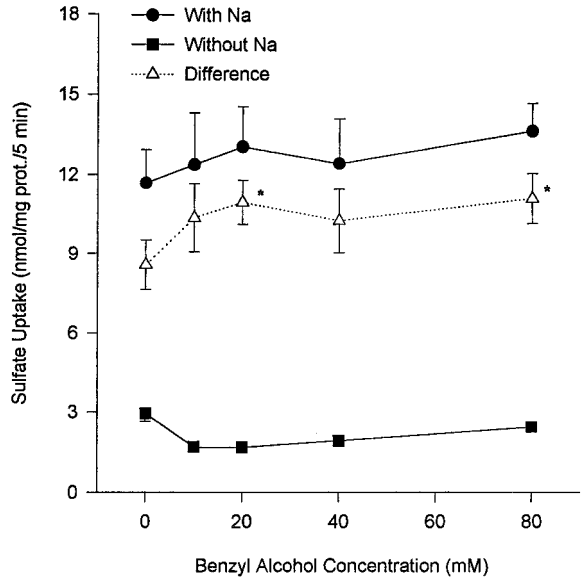

Figure 3—Concentration-dependent effect of benzyl alcohol on sulfate uptake in MDCK-Si cells. Sulfate uptake rates at 5 min were examined in the presence and absence of sodium. Each data point is the mean ± SD of four separate preparations in which triplicate determinations were obtained. * $p < 0.05$ compared with control (0 mM benzyl alcohol).

Table 2—Transport Parameter Estimates for Sodium-Dependent Sulfate Uptake into Benzyl Alcohol-Treated MDCK-Si Cells[a]

	V_{max} (nmol/mg prot./5 min)	K_m (μM)
control	11.97 ± 0.91	464.1 ± 55.9
20 mM benzyl alcohol	14.35 ± 0.56[b]	406.9 ± 174.7

[a] Values are reported as mean ± SD of three separate experiments. The V_{max} value was statistically different in control and benzyl alcohol-treated cells ($p < 0.05$) with no significant difference in the K_m estimate. [b] $p < 0.05$.

of the transport process (Figure 1). Increasing concentrations of cholesterol reduced sulfate uptake in a dose-dependent manner with no significant influence on the sodium-independent component of sulfate transport (Figure 1). The concentration-dependent sulfate uptake in MDCK-Si cells preincubated with 0.2 mM cholesterol is presented in Figure 2. Over a wide range of sulfate concentrations, sodium-dependent sulfate uptake in cholesterol-preincubated cells was decreased compared with the control group. The V_{max} estimate for sodium/sulfate cotransport in cholesterol-enriched cells was significantly lower than that in control cells, while the K_m value was not significantly altered (Table 1).

Effect of Benzyl Alcohol on Sulfate Uptake—Benzyl alcohol increased sodium/sulfate cotransport activity in MDCK-Si cells (Figure 3). As shown in Table 2, the increase of sodium-dependent sulfate uptake in the presence of 20 mM benzyl alcohol (Figure 4) resulted from a increase in the V_{max} estimate of this transport process with no significant change in the K_m value.

Membrane Fluidity—The steady-state fluorescence polarization of DPH represents membrane motional order

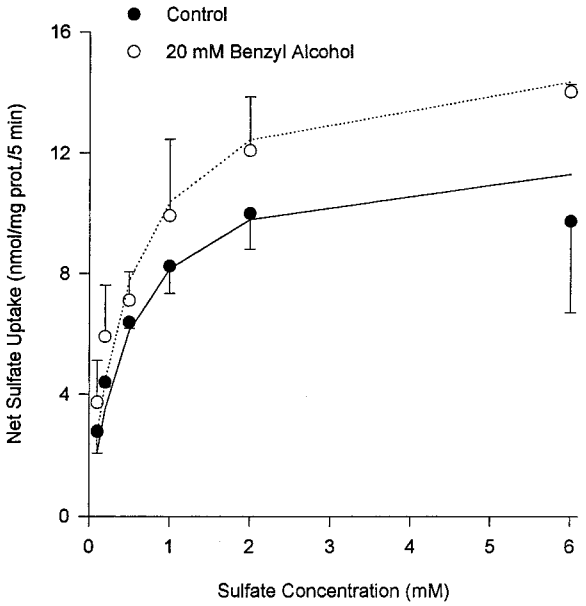

Figure 4—Concentration-dependent sulfate uptake in 20 mM benzyl alcohol-treated MDCK-Si cells. Sodium-dependent sulfate uptake was determined from the difference between uptake rates at 5 min measured in the presence of NaCl or of *N*-methyl-D-glucamine. Each data point is the mean ± SD from three separate experiments, with triplicate determinations of uptake in each preparation. The data were fitted to the Michaelis–Menten equation using nonlinear regression analysis, and the lines represent the fitted lines for the mean data.

Table 3—Lipid Order Parameter and Fluorescence Polarization of DPH in MDCK-Si Cells[a]

temperature	sample	polarization	anisotropy	lipid order parameter (*S*)
25 °C	control	0.396 ± 0.008	0.3041	0.8738
	benzyl alcohol	0.351 ± 0.002[b]	0.2650	0.7958
	cholesterol	0.419 ± 0.009[b]	0.3246	0.9121
37 °C	control	0.292 ± 0.014	0.2156	0.6845
	benzyl alcohol	0.212 ± 0.010[b]	0.1520	0.5066
	cholesterol	0.365 ± 0.011[b]	0.2770	0.8205

[a] Values for fluorescence polarization are expressed as mean ± SD from five measurements. The fluorescence polarization of DPH as a function of temperature was determined in MDCK-Si cells treated with 20 mM benzyl alcohol and preincubated with 0.2 mM cholesterol as well as in control cells. Benzyl alcohol treatment significantly decreases and cholesterol treatment significantly increases the fluorescence polarization of DPH in intact MDCK-Si cells at both temperatures, compared with the value in control cells. The data were compared by ANOVA followed by a Tukey's test among three groups at same temperature. [b] $p < 0.001$.

in the hydrophobic core of the membrane lipid bilayer and is inversely related to membrane fluidity.[6] The calculated lipid order parameter *S* is a measure of lipid packing of the bilayer and can be defined as fluidity. The observed changes in *S* indicate that benzyl alcohol treatment resulted in the fluidization of the membrane, and cholesterol treatment produced a more rigid membrane. The membrane fluidity of MDCK-Si cells treated with 20 mM benzyl alcohol was significantly higher than that of control cells at 25 °C and 37 °C. Cholesterol, at a concentration of 0.2 mM, significantly reduced the membrane fluidity of the cells at both temperatures, compared with controls (Table 3).

Discussion

Changes in membrane fluidity and/or membrane composition have been reported in various physiological and

pathological conditions. Devi et al.[21] have reported an age-dependent increase in membrane cholesterol content and a gradual decrease in membrane fluidity during the prenatal period of liver development in humans. Schwarz et al.[22] have also shown that there are age-dependent increases in total cholesterol and the cholesterol/phospholipid molar ratio, as well as a significant reduction in fluidity in basolateral membranes from rabbit proximal colon throughout postnatal maturation. In rat liver plasma membrane, the cholesterol content increases and the extent of unsaturated fatty acids as well as membrane fluidity decrease during aging.[23] In diabetic rats, the fluidity of renal BBM and BLM is reduced due to changes in the composition of fatty acids esterified in membrane phospholipids.[3] Reversible ischemia increases renal BBM fluidity while a decrease in renal BBM fluidity has been observed in hypercalcemia[25] and liver disease.[4]

Previously, we reported that sodium-dependent sulfate transport in renal BBM was increased in young and pregnant guinea pigs.[24] We also observed that the fluorescence polarization of DPH was decreased in BBM isolated from the kidney cortex of young and pregnant animals, indicating an increased fluidity in the hydrophobic core of the membrane. These results suggested that the increase in BBM fluidity may represent one possible mechanism for the observed changes in sodium/sulfate cotransport during development and pregnancy. The purpose of this study was to investigate whether the modulations of apical membrane fluidity affect sodium/sulfate cotransport in MDCK-Si cells. The present investigation represents the first examination of the effects of membrane fluidity on sodium-dependent sulfate transport.

Preincubation of MDCK-Si cells with 0.2 mM cholesterol significantly decreased the membrane fluidity of the cells. This is consistent with the decreased membrane fluidity in the presence of an increased membrane cholesterol content reported in a number of cell lines including akata cells (lymphoid cell line), human umbilical vein endothelial cells, rat aortic smooth cells, guinea pig keratinocytes, human renal carcinoma cells, and rat prostatic epithelial cells.[7,25–30] In the present studies, the increase in cholesterol concentration produced a reduction of sodium-dependent sulfate uptake in cells in a concentration-dependent manner due to a reduction in the V_{max} of sodium/sulfate cotransport in MDCK cells transfected with NaSi-1. Levi et al.[8] also reported a decreased V_{max} for sodium/phosphate cotransport with no change in K_m in the BBM isolated from aged rats which exhibit a decrease in BBM fluidity and an increase in BBM cholesterol content. In addition, the adaptive increases in the V_{max} of BBM sodium-dependent phosphate transport and BBM fluidity as a result of a low phosphate diet were completely reversed by the increase of cholesterol content in BBM.[9] In vitro enrichment of renal BBM with cholesterol decreases sodium/phosphate transport but has no effect on Na^+/H^+ exchange, sodium/glucose, or sodium/proline cotransport activities which suggests the presence of different lipidic environments (microdomains) for different transport carriers and the absence of an effect on the sodium gradient.[2,9]

Addition of 20 mM benzyl alcohol to the uptake buffer significantly increased the membrane fluidity of the MDCK-Si cells at 25 °C and 37 °C in the present investigation. Friedlander et al.[31] have reported that treatment of MDCK cells with increasing concentrations of benzyl alcohol decreases the steady-state anisotropy of propionyl-diphenylhexatriene and trimethylammonium-diphenylhexatriene, which are located in the hydrophilic surface of the lipid bilayer, suggesting an increased cell plasma membrane fluidity. Our results demonstrated a significantly increased sodium-dependent sulfate uptake in MDCK-Si cells in the presence of 20 mM and 80 mM concentrations of benzyl alcohol. The treatment of cells with 20 mM benzyl alcohol produced an increase in the V_{max} of sodium/sulfate cotransport activity with no change in K_m value. We have also found that benzyl alcohol, at 5 mM and 20 mM concentrations, significantly stimulates the sodium-dependent sulfate uptake at 10 s (linear uptake) in BBM vesicles isolated from the kidney cortex of rats (M. E. Morris, unpublished data). These results are consistent with our previous finding that the increase in sodium/sulfate BBM cotransport was associated with an increased BBM fluidity in young and pregnant guinea pigs.[24] Unlike the effect of benzyl alcohol on sodium/sulfate cotransport, the increase in membrane fluidity by benzyl alcohol altered sodium-dependent phosphate uptake in renal epithelial cells in a bimodal manner: a moderate increase in fluidity (benzyl alcohol concentration less than 20 mM) enhanced phosphate uptake while larger increases reduced it markedly. This biphasic phenomenon for modulation in membrane fluidity by local anesthetics or aliphatic alcohols was also shown for the activity of Na^+,K^+-ATPase,[32,33] whereas fluidization of isolated renal BBM[34] and intact LLC-PK_1 cells[10] decreased the V_{max} of sodium/glucose cotransport in a concentration-dependent manner. Benzyl alcohol concentrations greater than 30 mM also resulted in an increased affinity for glucose for the transporter in kidney BBM vesicles.[34] Therefore, membrane fluidity may influence not only the V_{max} but also the K_m of the substrate for a transporter. The different alterations in the activities of the apically located transporters involved in the sodium-dependent uptake of phosphate, glucose, and sulfate, following the same modification of membrane fluidity, suggest that the lipidic domain around each carrier may be different and the sodium-dependent sulfate transport protein is distinct from sodium/phosphate and sodium/glucose cotransporters.[2,13] Additionally, the different alterations observed for these sodium-dependent transport processes suggest that a change in the driving force (sodium gradient) is not responsible for changes in the observed transport.[2]

Based on the fluidity measurements, we speculate that membrane fluidity changes alter the sulfate transport through altered domain dynamics (altered lipid mobility within a domain). Even though DPH may not be a suitable probe to investigate the lamellar domain properties, due to their fluorescence lifetime alterations (thus polarization), DPH can provide qualitative information regarding the dynamics of lamellar domains. In studies carried out using DPH-labeled artificial membranes, the probe showed higher fluorescence polarization values for the gel phase and reduced polarization values as the fraction of liquid crystalline phase increased.[6,35] This is due to the changes in the fluorescence lifetime of the probe as a result of altered molecular motions. The fluorescence lifetime values decrease from 10.5 to 7.5 ns, as the bilayer transfers from a solid gel phase to a more fluid liquid crystalline phase.[35] Thus, polarization values provide qualitative information regarding the domain formation. In the present study we observed that benzyl alcohol-treated cell membranes are more fluid (decrease in polarization values) as a result of an increase in the fraction of liquid crystalline domains. This alteration in the domain size and dynamics may alter the lipid mobility in the lamellar plane in which the protein is embedded. A secondary effect of this change in lipid dynamics is that the percolation of lipids at the protein–lipid interface and in lipid–protein domains may be altered.

In conclusion, the decrease in fluidity of apical membranes of MDCK-Si cells produced by preincubation with cholesterol resulted in a reduction of sodium/sulfate cotrans-

port whereas the increase in apical membrane fluidity of the cells treated with benzyl alcohol produced an increase in sodium-dependent sulfate uptake. These results suggest that membrane fluidity may play an important role in the regulation of sulfate renal reabsorption in physiological/pathological conditions, including aging and pregnancy.

Abstract □ S-nitrosocaptopril (CapNO) has been proposed as a compound possessing capacities of both a nitric oxide (NO) donor and an inhibitor of angiotensin converting enzyme (ACE). In the present study, we characterized the physicochemical, pharmacokinetic, and pharmacological properties of the crystalline CapNO. The novel stable crystals are in a red flake form. Spectroscopic analyses of CapNO revealed its UV/visible λ_{max} and the corresponding extinction coefficients, and characteristic infrared frequencies for the N═O and S–N stretch. The NMR signals corresponding to the protons attached to the carbon (C–S) and the carbon itself were remarkably shifted downfield upon S-nitrosylation. Mass and HPLC analyses, solubility, and melting point of CapNO were determined. Simultaneous on-line analyses of pharmacodynamic and pharmacokinetic profiles of CapNO in catheterized awake rats of spontaneous hypertension (SHR) showed acute decreases in mean arterial pressure (MAP), concomitant with the corresponding increases in plasma levels of CapNO after po or iv administration. The pharmacokinetic parameters for CapNO, i.e., $t_{1/2}$, T_{max}, C_{max}, V_d, AUC, and oral bioavailability were analyzed to understand the dose-dependent potency and effective period of CapNO. The highest concentrations of oral CapNO distributed in tissues were found in kidney, liver, lung, and small intestine. CapNO was excreted predominantly via urine, and second via feces in the detectable forms of thiols and nitrogen oxide although a small portion of CapNO was found in bile. The results provide the evidence of in vivo cleavage of the S–N bond and biotransformation of CapNO.

Introduction

The endothelium-derived relaxing factor, known as EDRF,[1] is generally considered to be a labile NO-containing precursor. Evidence has accumulated implicating that reduced generation of NO has been involved in several diseases.[2,14] Thus, there is a great demand for exogenous, potent NO donors to treat NO-deficient diseases. However, it is difficult to reliably introduce NO into most biological systems for therapeutic purposes without premature decomposition. Due to a growing appreciation for NO-related responses that are not mediated directly by NO itself, there is an increasing interest in compounds which generate NO, mimic its biological function, and might have pharmacological effects in a controlled manner.

Water-soluble RSNOs, where R can be any one of a large range of chemical entities, might meet these major requirements as possible storage and transport forms for the otherwise highly reactive NO molecule.[3−5] Many efforts have been made to prepare a solid powder of RSNOs; however, most RSNOs are reported to be too unstable to isolate as pure solids. It has long been known that RSNOs decompose to yield NO and the corresponding disulfide RSSR;[7−9] the latter could then be reduced by either an intracellular spontaneous recovery mechanism[10] or a general protein disulfide reductase.[11] Therefore, an RSNO composed of an NO group and another pharmacological active component RSH would have considerable theoretical and practical significance. CapNO may be the best candidate due to its dual role as an ACE inhibitor and an NO carrier.[3,6,12,13]

We have recently developed a facile synthesis of CapNO in a good yield. The first synthesized red crystals, after being dried, could be stored in the dark at about 25 °C for at least two months and 4 °C for at least one year without a significant decay. The stability of the red crystals provides us with an opportunity to characterize the authentic physicochemical properties of the novel crystalline CapNO in the present report. Although numerous reports concerning the cardiovascular pharmacology of RSNOs have been published,[3−6,11−13] none of them has addressed the pharmacokinetic profiles and oral bioavailability of RSNOs. The exemplary CapNO, that nonenzymetically releases NO in a manner similar to most of RSNOs,[8,15] is certainly a very useful tool for exploring pilot information regarding in vivo biotransformation and functional significance of RSNOs. Therefore, we investigated the overall pharmacokinetical profiles and antihypertensive effects of CapNO simultaneously and evaluated the drug's tissue distribution and elimination.

Experimental Section

Spectral Analyses—The preparation of crystalline CapNO was accomplished via a S-nitrosylation reaction of captopril (Cap) as described in detail.[12] The resulting red crystals were dissolved in distilled water at a final concentration of 1 mM. Five different spectrometers (Perkin-Elmer Lambda 2S, Hewlett-Packard 8452 A, Beckman DU-7, Shimadzu UV 2101PC, Shimadza UV 160) were calibrated with 0.5 mM of $K_2Cr_2O_7$ (Aldrich, Milwaukee, WI) before experiments. These spectrometers were then used to determine the peak wavelengths and the corresponding extinction coefficients of CapNO. Infrared spectra were analyzed using Nicolet Impact 400 Fourier Transform IR spectrometer (Nicolet Instruments, Inc., WI). The polyethylene film (KBr) was used to calibrate the full scale and features of the spectrometer. The purified CapNO in an NMR tube was dissolved in $CDCl_3$ for ^1H NMR analysis with a Varian 300 MHz NMR system (Oxford Instruments, Osney Mead, Oxford), or dissolved in D_2O for ^{13}C NMR analysis with a Unity 500 MHz system, respectively. Chemical shifts were recorded as parts per million relative to tetramethylsilane (TMS) as the internal standard (for ^1H NMR) and to $CDCl_3$ as the external

standard (for ^{13}C NMR). Mass spectral analysis was carried out with VG 70-SE analyzer (VG Analytical, Manchester, England) equipped with an electron-impact ionization source and a data-processing system.

Chromatographic Analyses—Thin-layer chromatography (TLC) was performed on Analtech silica gel F_{254} plates (0.25 mm thick). A 5-μL of CapNO (1 mM in H_2O) was spotted on the origin of the plates, which were developed a distance of 6 cm in a solvent-developing system consisting of isopropyl alcohol−acetic acid−water (4:1:1, by volume). CapNO, its parent compound Cap, and the corresponding disulfide were analyzed using a reversed phase HPLC system (Shimadzu, Kyoto, Japan) consisting of a LC-10A liquid delivery module, a SPD-10A ultraviolet detector, a CTO-10A column oven, and a Shim-pack CLC-ODS column (150 mm × 6.0 mm i.d., 5 μm particle size). The system was controlled with an SCL-10A system controller under the following conditions: flow rate, 1.0 mL/min; column temperature, 25 °C; UV detection wavelength, 220 nm. A 5-μL aliquot of CapNO, Cap, or its corresponding disulfide was injected into the injection loop, respectively, and chromatographed using the C_{18} (octadecylsilane) column eluted isocratically with a mobile phase of 50% methanol and 50% phosphoric acid (0.1%). The area under each peak was calibrated with a Shimadzu data processor. The detection limits were 1 μg/ mL on the basis of peak:noise ratio at 3:1. All samples were diluted with 0.1 N HCl immediately before injection.

Simultaneous Measurement of CapNO Plasma Level and Effect Relationship in Awake SHR—Male SHR rats, weighing 365 ± 32 g, were anesthetized with sodium thiopentone (50 mg/kg, ip) and underwent cannulation of the left femoral artery (PE 50), which was used for periodic blood sampling and monitoring of the MAP with a transducer. After recovery from general anesthesia, the catheterized SHR rats were placed in individual restraining cages with free access to food and drinking water. For intravenous administration, the femoral vein was used for the drug injection. For oral administration, the rats were fasted for 4 h before CapNO was given by gavage. CapNO solutions (50 mg/mL) were prepared using saline (for iv) or water (for po) immediately before administration. Serial blood samples (0.2 mL) were collected each time with heparinized 1 mL syringes and replaced with 0.2 mL of normal saline at 0, 1, 5, 30, 60, 120, and 240 min after each iv injection, or 0, 10, 20, 30, 60, 120, 240, and 480 min after the oral dosing. Between samplings, the arterial cannula was connected to a pressure transducer for measurement of MAP. Blood samples were immediately centrifuged at 10000*g* for 5 min. The plasma was prepared and diluted with ice-cold Milli Q water in order to observe the appropriate area of signals. The diluted plasma was collected in airtight syringes and introduced via a HPLC pump (Shimadzu, Kyoto, Japan) into a photolysis−chemiluminescence system at a fixed flow rate of 1 mL/min, where the homolytic cleavage of NO from CapNO was completed. The CapNO concentration is directly proportional to detected signal area, which could be converted to the plasma level of CapNO by using the peak−concentration standardization curve of CapNO. The pharmacokinetic study was performed in each individual rat with the PharmK kinetic software.[16] Pharmacokinetic parameters for individual plasma concentration−time data were determined by a nonlinear least-squares regression program of the PharmK, using a one-compartment open model for single oral dosing, and a two-compartment model for single bolus iv dosing (Table 1). The goodness of fit was assessed from the distribution of residuals. The bioavailability was calculated using the values of area under the concentration−time curve (po versus iv).

Six calibration standard concentrations ranging from 2.5 to 500 ng/mL of CapNO were prepared by spiking blank plasma with CapNO working standards. To determine sensitivity and specificity of the assay prior to the initiation of the study, CapNO and its major contaminants, $NaNO_2$, the starting compound Cap, and the corresponding disulfide, were detected in Milli Q water or rat blank plasma. The diluted rat blank plasma itself gave no signal peaks, indicating no interfering materials present. The detection limit for CapNO was approximately 2.5 ng/mL, which was sensitive enough to measure the predicted plasma levels of CapNO for at least three $t_{1/2}$ periods after single oral dose (5 mg/kg). However, the detection limit for $NaNO_2$ was 2.5 μg/mL with the retention time remarkably shifted, and the system did not respond to the parent Cap and its disulfide, indicating the assay specificity for plasma CapNO. To assess accuracy, precision, and reproducibility, five sets of quality control samples were analyzed together with the diluted plasma and urine samples, or kidney homogenates. The mean predicted quality control concentrations were within 3.6% of the nominal values. The within-day and between-day coefficients of variation were determined for triplicate spiked samples of CapNO at 12.5, 25, and 250 ng/mL and resulted in values of 4.1−8.4%. The recovery of CapNO spiked to rat plasma, urine, bile, and various tissue homogenates was >89%. The relationship between peak areas and CapNO concentrations (2.5, 12.5, 25, 62.5,125, and 500 ng/mL) in rat plasma, urine, bile, and tissue homogenates was linear with correlation coefficients > 0.99.

Table 1—Pharmacokinetic Data for CapNO after Dosing to SHR

route	parameter	dose 5 mg/kg	dose 10 mg/kg	dose 50 mg/kg
iv	$t_{1/2(\alpha)}$ (min)	1.9 ± 0.5	1.9 ± 0.3	5.3 ± 0.4
	$t_{1/2(\beta)}$ (min)	24.6 ± 3.5	19.7 ± 5.9	26.2 ± 5.9
	K_{12} (min^{-1})	0.17 ± 0.03	0.12 ± 0.03	0.05 ± 0.01
	K_{21} (min^{-1})	0.24 ± 0.03	0.28 ± 0.05	0.31 ± 0.03
	K_{10} (min^{-1})	0.07 ± 0.02	0.06 ± 0.01	0.04 ± 0.01
	V_d (L/kg)	0.09 ± 0.01	0.11 ± 0.01	0.21 ± 0.02
	$CL_{(T)}$ (mL/min/kg)	16.0 ± 0.7	22.4 ± 3.2	25.0 ± 1.7
	AUC (μg/mL·min)	247 ± 13	408 ± 25	1122 ± 165
po	K (min^{-1} 10^{-3})	12.3 ± 2.1	13.3 ± 1.0	8.9 ± 0.5
	$K\alpha$ (min^{-1} 10^{-3})	54.9 ± 10.9	62.5 ± 12.1	67.7 ± 18.4
	$t_{1/2}$ (min)	64.4 ± 12.3	70.6 ± 10.0	78.8 ± 5.0
	$CL_{(T)}$ (mL/min/kg)	15.8 ± 0.7	16.4 ± 0.7	23.6 ± 1.8
	V_d/F (mL/kg)	52.7 ± 2.1	56.4 ± 2.2	106.5 ± 8.5
	T_{max} (min)	45.3 ± 2.6	41.8 ± 5.2	37.7 ± 4.4
	C_{max} (μg/ mL)	393 ± 81	606 ± 40	1199 ± 105
	AUC (μg/mL·min)	60 ± 5	89 ± 24	277 ± 29
	bioavailability (%)	24.3	21.8	24.7

For iv route, $t_{1/2(\alpha)}$ and $t_{1/2(\beta)}$ were the half-life of distribution and elimination, respectively. K_{12} was the rate constant for the movement of drug from central to tissue compartment; K_{21}, rate constant for the movement of drug from tissue to central compartment; K_{10}, elimination rate constant. For po route, K was elimination rate constant, and $K\alpha$, absorption rate constants. $t_{1/2}$ was elimination half-life. $CL_{(T)}$, systemic clearance; V_d, apparent volume of distribution; F, bioavailability; T_{max}, time to attain maximum plasma concentration; C_{max}, maximum plasma concentration. AUC, the total area under plasma concentration-time curve from 0 to 4 h.

Tissue Preparation for CapNO Distribution Studies—CD-1 mice, 25 ± 6 g, eight males and seven females were used. Mice were fasted overnight with water available ad libitum. Tissues were excised following ether anesthesia at 0.5, 1, and 5 h after oral administration of CapNO. The intestine was cut opened and rinsed with cold saline to remove the contents. Tissues were washed three times with cold saline, weighed, and minced with scissors. Homogenization of each tissue (0.2 g) was performed in five volumes by tissue weight of ice-cold 10 mM potassium phosphate buffer (pH 7.4) for 5 min. The homogenates were then centrifuged at 14000*g* for 15 min (0−4 °C). The supernatants were removed and diluted with 10-fold excess of Milli Q water. An aliquot of 100-μL diluted supernatants was assayed for CapNO by the photolysis−chemiluminescence method described above. CapNO concentrations in the various tissue samples were determined with standardization curves ranging from 2.5 to 500 ng/mL prepared in the corresponding tissue samples.

Urine, Feces, and Bile Collection—SD rats individually resided in stainless steel metabolism cages, where urine and feces were separated by a cone-shaped device. Pooled urine and feces were collected overnight prior to drug administration and then at 5, 10, 24, and 48 h after a single oral dose. Feces were homogenized in a mortar in two volumes by fecal weight of cold water. Both fecal homogenates and urine were centrifuged at 14000*g* at 0 °C for 15 min. The supernatants of urine and feces were diluted with 10^3−10^4 fold excess of Milli Q water, and the diluted supernatants were analyzed by Ellman test[17] for SH groups, and by Griess assay[18] for nitrite determination. Rats were anesthetized with sodium thiopentone (50 mg/kg, ip), and the peritoneal cavity was opened by an incision along the bloodless midabdominal line. The common bile duct was cannulated with tubing PE50 toward the liver. The abdominal wall was then closed by suturing to prevent hypothermia and dehydration. The open end of the tubing was kept in a sample tube for bile collection before and at 20, 30, 60, 120, 240, and 360 min after oral administration of CapNO (50 mg/

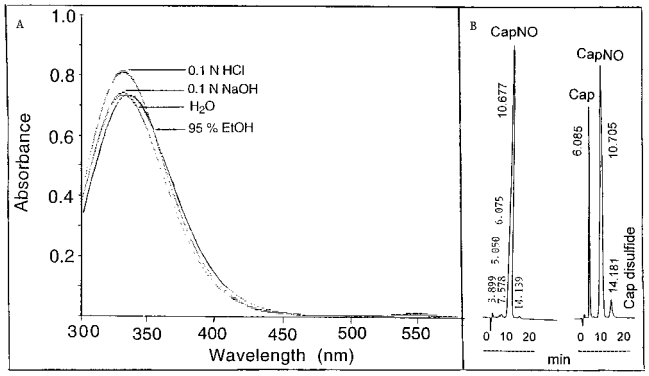

Figure 1—UV-visible spectroscopic and chromatographic characterization of CapNO. A. UV–visible absorption spectra revealed the presence of two maxima at 332 and 546 nm when CapNO was prepared in Milli Q water. HCl caused a hyperchromic shift, and ethanol resulted in a bathochromic shift, whereas NaOH did not have significant effects on the absorption maxima. B. Representative HPLC analysis using UV detection at 220 nm revealed that CapNO solution (50 mM) prepared with its flake crystals in 0.1 N HCl showed only one peak at t_R = 10.6 min without the corresponding monosulfide and disulfide (left tracing), whereas a mixture solution consisting of CapNO, its monosulfide, and its disulfide exhibited three peaks at different retention times (right tracing).

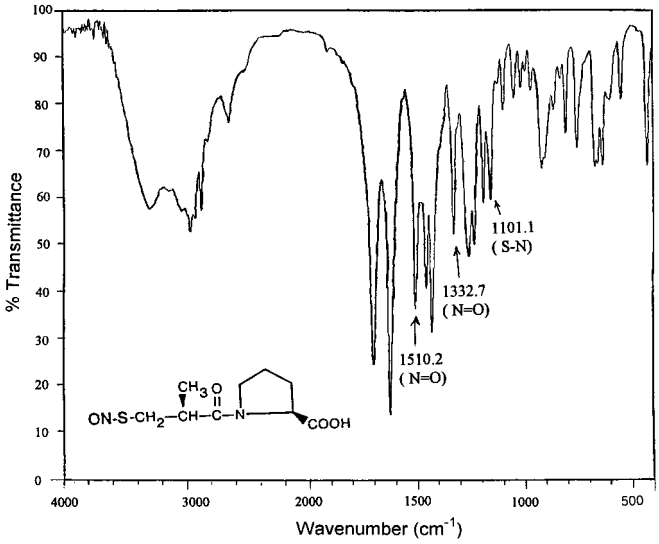

Figure 2—Infrared spectra observed in CapNO molecules showed the most important frequencies at 1332 and 1510 cm^{-1} corresponding to the functional group N═O; 1101 cm^{-1} was assigned to the S–N stretch.

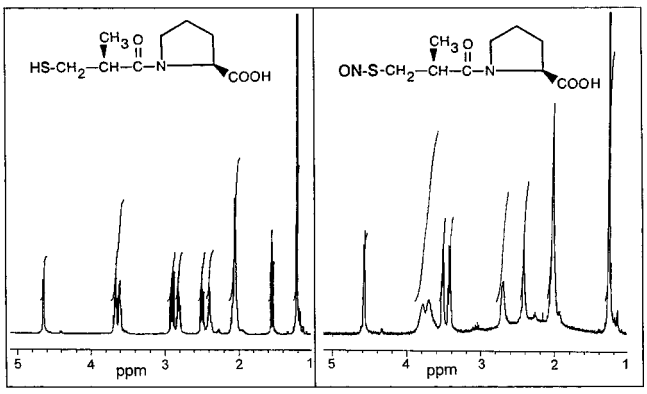

Figure 3—Representative ^1H NMR spectra of CapNO crystals (right) and its starting compound Cap (left). The substitution of SH group with SNO was confirmed by an electron-withdrawing effect of the SNO group, which shifted the signals of the methylenic protons (SCH_2) from δ 2.8–2.9 (in Cap) to δ 3.4–3.5 (in CapNO). In addition, the peak at about 1.5 ppm corresponding to the HS proton disappeared.

kg). CapNO levels in rat bile were determined by the photolysis–chemiluminescence method using the corresponding standardization curve.

Statistical Analyses—Unless otherwise noted, all results are presented as mean ± SE. In some figures, only one SE is shown either above or below the mean to improve clarity. Differences were analyzed by Student's *t* test, a $p < 0.05$ was accepted as significant.

Results

Physicochemical Properties of CapNO—The red flake crystals of CapNO were not hygroscopic, and the stability of the crystals was significantly improved after purification. The red flake crystals were freely soluble in ethanol, chloroform, acetone, and ether and soluble in H_2O, NaOH (0.1 N), and HCl (0.1 N). The melting point of CapNO was found in the range of 49–52 °C, which was determined in open capillary tubes with a melting point apparatus. After being heated over the melting point, the red crystals instantaneously decomposed to an off-white color, which was demonstrated to be captopril disulfide according to the disulfide's retention time of HPLC. The off-white material exhibited a beehive-like appearance when the temperature passed through 104 °C.

Spectral Analyses of CapNO—Scanning by the five UV–visible spectrometers at every ±0.5 nm around the two maxima revealed the peak wavelengths for CapNO at 332 and 546 nm with a molar extinction coefficient (mol^{-1} m^2) of 874.8 ± 12.1 and 15.5 ± 0.2, respectively. Solvent effects on the absorption maxima of CapNO were compared (Figure 1A). TLC spots were detected with UV light (254 nm) or visualized with iodine vapors. TLC showed Cap and CapNO with R_f values of 0.90 and 0.72, respectively (not shown). From the HPLC study (Figure 1B), in each case a single major peak was observed, indicating that the crystalline CapNO has a purity of >99% without detectable monosulfide and disulfide Cap residues. Retention time ranged from 10.6 min for CapNO to 6.1 min for the starting compound Cap to 14.1 min for the major metabolite Cap disulfide. The HPLC analysis revealed that the peak area generated was linear over a range of 1.64 μg/mL to 1.64 mg/mL ($r = 0.99$).

The presence of a S–NO group in CapNO can be readily determined from the strong IR band at 1332 and 1510 cm^{-1}, which corresponds to the stretching vibration of the N═O bond. An absorption band at 1101 cm^{-1} is characteristic of the vibration of the S–N bond. The other absorption bands were identical by IR (KBr) to the bands found in the starting compound Cap although the frequency associated with a particular group varies slightly owing to the influence of the molecular environment. These bands appeared at 1626 cm^{-1} for the amide C–N, 2962, 2930, 2883, and 1460 cm^{-1} for the stretching vibration of the C–H bond, and 3400, 1703, 1433, and 922 cm^{-1} corresponding to the COOH group (Figure 2).

The ^1H NMR spectrum of CapNO is shown in Figure 3. Upon completion of S-nitrosylation of Cap, the signals corresponding to the methylenic protons (SCH_2) of the side chain of Cap were shifted downfield from δ 2.8–2.9 to δ 3.4–3.5. This shift is expected because a thiol is transformed into a more electron-withdrawing nitrosothiol group. The disappearance of the triplet signals of the sulfur proton of Cap at δ 1.53 is indicative of the conversion of Cap to CapNO as well. Reported below are the ^1H NMR data for the CapNO: δ 1.25 (3H,d, CH_3), 2.01(3H, m, 3,4-CH_2CH in proline), 2.42 (1H, q, 4-CH in proline), 2.70 (1H, m, CH), 3.50 (2H, m, SCH_2 in side chain), 3.75 (2H, t, CH_2 in side chain), 4.58 (1H, t, 5-CH in proline). The replacement of SH with S–NO induced the ^{13}C NMR signals of

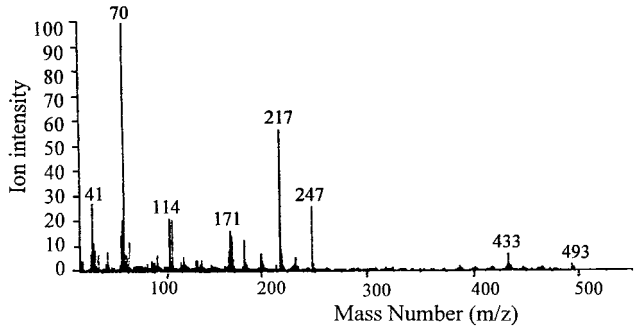

Figure 4—Mass analysis of CapNO crystals using fast atom bombardment mass spectrum analysis of CapNO. The analysis revealed *m/z* 247 and 493, which corresponds to CapNO and a dimer of Cap, respectively. The ion intensity is expressed in an arbitrary unit by taking the height of the base peak at *m/z* 70 as 100.

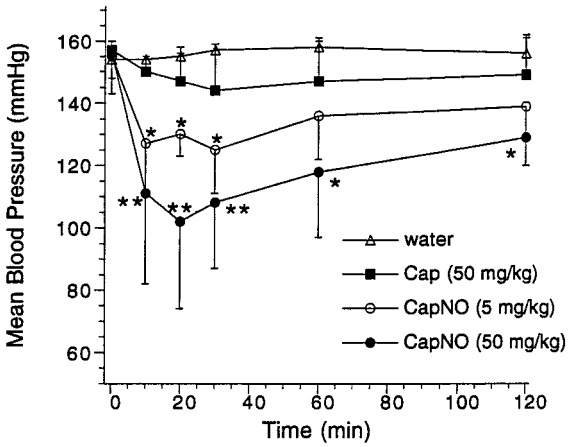

Figure 5—Time course of mean arterial pressure after oral administration of water, Cap, and CapNO to SHR rats. Points and vertical bars represent the mean ± SD (n = 4–6). *p < 0.05, **p < 0.01, compared with water group.

the methylenic carbon (S−CH_2) to shift from δ 42.437 to δ 37.801 (data not shown).

Mass analysis indicated an apparent molecular ion of *m/z* 217 and *m/z* 247, both of which provided valuable diagnostic evidence for the proposed structure of CapNO. First, the base peak of molecular ion at *m/z* 30 (NO) and the largest *m/z* 217 (Cap) strongly suggested the homolysis of the S−NO bond in the CapNO after electron-impact ionization. Second, analysis of the molecular weight of CapNO by fast atom bombardment mass spectrometry (Figure 4) yielded values of *m/z* 247 and 493 $[M + H]^+$, which correspond to CapNO and a dimer of Captopril, respectively. Third, high-resolution mass spectrum analysis of CapNO using glycerol as the reference indicated that the ion at *m/z* 247 (calculated 247.07525) represented a $C_9H_{15}O_4N_2S$ formula for the tested compound.

Pharmacodynamics and Pharmacokinetics of CapNO—After collection of blank blood samples, CapNO was administered (po or iv) to the conscious SHR (n = 6, each group). CapNO (iv) immediately resulted in hypotensive responses in awake SHR. MAP fell to the nadir within 2 min. At doses of 5 and 50 mg/kg, CapNO decreased MAP from 160 ± 7 to 102 ± 8 mmHg (p < 0.01), and 154 ± 5 to 82 ± 9 mmHg (p < 0.001), respectively. The hypotensive effects lasted for more than 4 h. The plasma concentrations of CapNO at 1 min after injections reached the peak of 35.9 ± 1.3 μg/mL (5 mg/kg), 64.4 ± 1.4 μg/mL (10 mg/kg), 219.6 ± 18.8 μg/mL (50 mg/kg); thereafter, the drug concentrations declined with time (Figure 6). Oral administration of CapNO to catheterized awake SHR produced reduction in MAP from 153 ± 10 to 126 ± 18 mmHg (p < 0.05, 5 mg/kg), from 151 ± 5 to 130 ± 5 mmHg (p < 0.05,

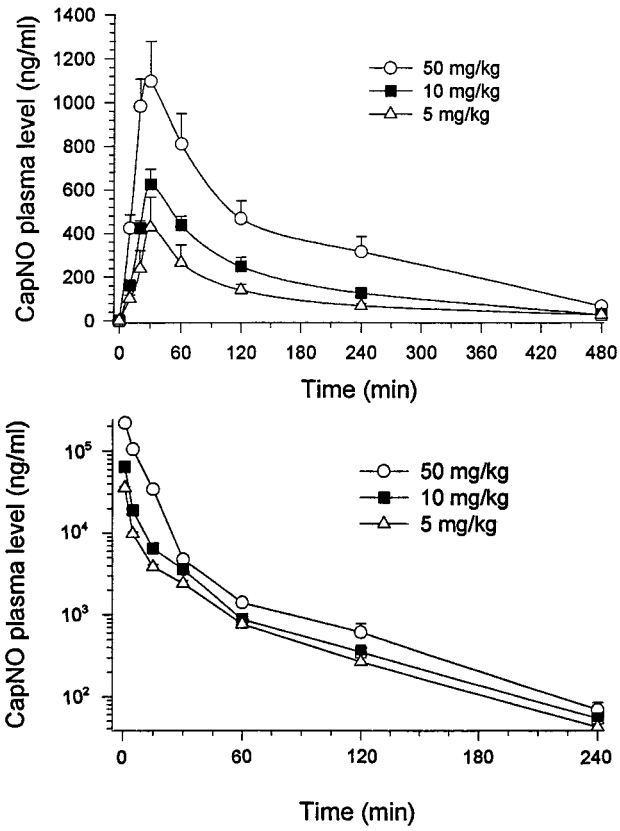

Figure 6—Plasma concentration–time course of CapNO after oral (upper) or intravenous (lower) administration to awake SHR rats (n = 6).

10 mg/kg). As shown in Figure 5, CapNO 50 mg/kg (po) produced a marked and sustained hypotension. In contrast, both vehicle (H_2O) and Cap (50 mg/kg) did not produce significant hypotensive effects in SHR rats (Figure 5).

The plasma concentration−time curves for CapNO after po and iv administration are shown in Figure 6. Concomitant with this decrease in blood pressure, CapNO level in plasma reached 425 ± 62 ng/mL at 10 min and 1092 ± 183 ng/mL at 30 min after oral administration. The time course of decreases in blood pressure and increases in CapNO plasma levels paced almost simultaneously. Peak effect and peak plasma level were noted synchronously by 30 min intervals (Figures 5 and 6). The relationship between single oral CapNO doses (5, 10, and 50 mg/kg) and the area under the plasma concentration−time curves was linear. The pharmacokinetic parameters of CapNO after po and iv dosing are listed in Table 1. The bioavailability of oral CapNO, as determined by the ratio of oral AUC to intravenous AUC, ranged from 22 to 25% (Table 1). The results suggest that CapNO is subject to either incomplete absorption or hepatic first-pass metabolism when administered orally.

CapNO Tissue Distribution and Excretion—Tissue levels of CapNO were shown in Table 2. The kidney, liver, lungs, and small intestine were found to contain the highest levels of CapNO, while brain and fat tissues contained almost no CapNO. The urinary levels of CapNO were not detectable 5 h after dosing with 50 (data not shown) and 500 mg/kg of CapNO by using either the photolysis−chemiluminescence or Saville assay[4] to quantify the *S*-nitroso content of CapNO. This result reflected the in vivo biotransformation of CapNO caused by the cleavage of the S−NO bond. However, the major CapNO metabolites such as NO_2^- and thiols, were detected in the pooled urine and feces by the Griess and Ellman assays (Table 3). The data indicate that CapNO was subjected to extensive

Table 2—Tissue Distribution of CapNO (50 mg/kg) after Oral Administration to Mice

metabolism. CapNO excretion via the rat bile within 6 h after a single dose was shown in Table 4.

Discussion

This is the first report systematically characterizing physicochemistry of the novel crystalline CapNO by spectral UV−visible, IR, MS, and NMR. The two absorption maxima at 332 nm (UV, assigned to B band) and 546 nm (visible) are indicative of S-nitrosylation. The λ_{max} of CapNO solution at 546 nm indicates that the solution absorbs a green light, and thus the solution color looks like pink, which is complementary to the color of green. The formation of CapNO could be conveniently monitored by the visible pink and quantified at 332 and 546 nm. Neither such maxima nor the pink color could be observed when the S-nitrosylation reactions were carried out using equimolar concentrations of $NaNO_2$ and disulfides (either Cap disulfide or glutathione disulfide dimer) under the same conditions of reaction. This indicates a specific replacement of SH with SNO.

Infrared and NMR spectra of crystalline CapNO are excellent probes for the nitrosation of thiols in structural determinations. Chemical shifts of CapNO are significantly different from those of the parent Cap. The greater electronegativity of the *S*-nitroso group has a deshielding effect, which is readily identified by downfield shifts of resonance of the α-protons and α-carbon atom attached to the SNO group. The characteristic infrared frequencies assigned to the stretching vibration of the N=O bond are indicative of the presence of S-nitrosylation (Figure 2).

Single oral doses of CapNO are capable of reducing blood pressure in the awake SHR and causing the quick onset of hypotension (approximately 32% reduction in MAP), whereas Cap possesses no such quick activity. It is likely that the variation in the extent of hypotension between the two compounds arises from the NO moiety since only the crystalline CapNO produces immediate vasodilation in vitro[12] and an acute antihypertensive effect in vivo. Very importantly, the concomitant measurement of CapNO plasma concentration and efficacy in the awake SHR has been incorporated to establish the relationships between pharmacokinetics and pharmacodynamics for CapNO in the present studies. The potency and duration of action of CapNO were clearly dose-dependent and were paralleled to the plasma levels of CapNO (Figures 5 and 6). The mean time courses for decreases in blood pressure and increases in CapNO plasma concentration were parallel and concurrent (Figures 5 and 6). Also the oral plasma T_{max} of CapNO (Figure 6, Table 1) was close to the peak time of efficacy (Figure 5). The pharmacokinetic analyses for single doses showed that CapNO displayed a linear pharmacokinetic relationship between doses and dose-normalized AUC values (data not shown). The oral bioavailability of CapNO in the SHR was assessed 22−25% on the basis of the ratio of oral AUC to intravenous AUC. Consistent with these results was the comparison of antihypertensive effects produced by oral and intravenous administration of CapNO (both 5 mg/ kg). The oral effect was about 30% as potent as the intravenous effect calculated by dividing the area under the oral effect-time tracings by the intravenous ones. The differences in bioavailability determined by plasma data and pharmacological effects may be attributed to the additive effects caused by CapNO metabolites, which might not be detectable in plasma by the photolysis−chemiluminescence.

Distribution of CapNO in awake animals reached a peak at 30 min in tissues, where blood flow is relatively rapid. CapNO was eliminated 5 h after oral administration. The results indicate a rapid equilibrium of CapNO between the central and peripheral compartments. The negligible amounts of CapNO found in brain and fat tissues reflects the compound's poor penetration into brain and fat tissues owing most likely to the hydrophilic properties of CapNO. After oral administration, CapNO is excreted as its metabolites, i.e., reduced thiol and NO_2, predominantly in the urine and to a lesser extent in the feces (Table 3). The cumulative urinary recovery of CapNO within 48 h accounted for about 40% of the dose in the form of nitrogen dioxide, and to a minor portion in the form of thiols (Table 3). The relatively less elimination of thiols might be explained by the formation of disulfide dimers after dosing. Failure to detect the vulnerable S−NO bond of CapNO in the pooled urine and feces indicates the extensive metabolism due to the cleavage of S−NO bond when CapNO was eliminated out of the body. It is unlikely that the bile is a major excretion route for CapNO. We only recovered 8×10^{-5} of total CapNO from rat bile (Table 4) within 6 h although the CapNO bile excretion rate was fairly high within 1 h after oral dosing. The hepatic metabolism of RSNOs is worthy to be further investigated.

The mechanism by which CapNO reduced blood pressure in SHR may have involved the ability of CapNO to deliver NO to the blood vessels within a short period, and inhibit ACE[6,19] in vivo for a longer period. A more likely explanation of the antihypertensive action of CapNO can be divided into two phases: an early phase and a late phase. The early

phase involves a direct action of CapNO as an exogenous NO donor to restore the impaired intrinsic NO-mediated vasodilation and directly counteract the vasoconstrictive influences of angiotensin II and other vasoconstrictors that ACE inhibitors may not directly antagonize. The early phase represents a potent hypotensive effect of exogenous NO donors. The time course of this phase is described in Figure 6. The late phase displays a moderate antihypertensive effect produced by a number of bioactive metabolites of CapNO after homolytic cleavage of the S−N bond in CapNO. The metabolites may include Cap disulfides, Cap-cysteine, and Cap-glutathione disulfides.[20] Indirect evidence from the early studies of Cap suggests that these disulfides may play a role in the maintenance of the antihypertensive action of Cap.[21] Compounds containing S−NO group usually have a biotransnitrosylation effect, which involves conjugation with endogenous thiol-containing amino acids to form mixed S-nitrosothiol-thiols.[22] Hence, these potential effects produced by S-nitrosothiol-cysteine, -glutathione, and -serum albumin cannot be excluded from antihypertensive action of CapNO.

It has been known that the photolysis−chemiluminescence method is superior to others in accuracy, reproducibility, and convenience for determining NO and RSNOs.[4] Photolysis homolytically releases NO, and cold traps remove all nonvolatile parent compounds or derivatives. Therefore, the plasma, urine, and other biological samples do not need to be pre-prepared before measurement. This ensures our obtaining more accurate data without facing the problems such as sample processing and thermal and chemical decomposition of the target compound. The NO group exchange between a biochemical active thiol and a RSNO has been reported.[22−24] Because S-nitrosothiol-thiol exchange may produce a detectable signal in the photolysis−chemiluminescence, we cannot be absolutely certain of the nature of the derivative, especially when samples were obtained hours after CapNO was administered. Although it cannot unequivocally distinguish among different RSNOs, this methodology is valuable for studies of CapNO pharmacokinetics when coupled with pharmacodynamic studies.

Unlike glyceryl trinitrate, CapNO is not subject to tolerance,[25] and has no cross-tolerance with glyceryl trinitrate in vivo in dogs.[26] Our preliminary data proved that chronic oral administration of CapNO showed a potent effect in the SHR and SS/Jr hypertensive models (unpublished observation). CapNO is among the most advantageous of the known NO donor drugs from the therapeutic and toxicological point of view. The studies described herein is valuable in predicting effects of the related RSNOs in animals and planning clinical studies of CapNO.

Accepted for publication July 30, 1999.

Abstract □ Indirect Response Models account for the pharmacodynamics of numerous drugs which inhibit or stimulate the production (k_{in}) or loss (k_{out}) of the response variable (R). The dose and pharmacokinetics, capacity (S_{max}, I_{max}), and potency (SC_{50}, IC_{50}) factors of the Hill function incorporated in these models are the primary determinants of overall responsiveness. However, the initial or baseline value for the response ($R_0 = k_{in}/k_{out}$) should also be considered as an important factor for the net response. Using Indirect Response Model III (stimulation of input) as an example, the net area under the effect curve ($AUEC_{NET}$) can be proportional to the R_0 values. Such a feature is demonstrated in this report by computer simulations, by examination of the integral of the simulated response vs time profiles, and with examples from the literature. Also shown is an adjustment of R_0 when the therapeutic agent is an endogenous substance. These analyses show that the role of R_0 and k_{in} should not be overlooked as determinants of indirect responses and source of variation among subjects or patient groups.

Introduction

The role of the initial or baseline value of a pharmacological response is often overlooked in considering factors which control pharmacodynamics. For indirect responses where drugs alter the production or loss of the response, the initial or baseline value (R_0) is a dependent variable which is usually described as the ratio of k_{in} (zero-order formation rate constant) ÷ k_{out} (first-order elimination rate constant).[1] The k_{in} is under the direct control of many drugs and subject to physiological and pathophysiologic alterations. Many biotech products produce their pharmacodynamic effects in a similar fashion: Interleukin-10 (IL-10) increases the blood monocyte and neutrophil counts,[2] growth hormone (GH) stimulates the formation for insulin-like growth factor I (IGF-I),[3] interferon α-2a (INF α-2a) induces the production of MX protein,[4] and erythropoeitin stimulates reticulocyte/red blood cell production,[5] and soluble transferrin receptor.[6] Drugs with actions according to Indirect Response Models,[1] especially Model III which accounts for stimulation of k_{in} when k_{out} remains unchanged, can exhibit variable responses in patients when there are marked interindividual differences in R_0 and k_{in} values.[4,6] This report provides simulations to demonstrate how differences in R_0 and k_{in} among patients or different groups will affect net responses to pharmacological agents and points out how this is of particular concern for the drugs which are intended to stimulate natural physiologic processes.

Experimental Section

Methods—Computer simulations were performed using the ADAPT II program.[7] The pharmacokinetic/pharmacodynamic (PK/PD) relationships for a hypothetical drug concentration (C) and the induction of the response (R) were simulated.

Pharmacokinetics—The pharmacokinetics were described by the Bateman Function with a baseline value (C_{BL}):

$$C_p = C_{BL} + \frac{k_a \text{dose}}{V(k_a - k_{el})}(e^{-k_{el}t} - e^{-k_a t}) \quad (1)$$

The assigned PK parameter values were as follows: dose = 250, 500, 1000, and 2000 μg; absorption rate constant $k_a = 0.693\ h^{-1}$; elimination rate constant $k_{el} = 4\ h^{-1}$; CL = 10 L/h; volume V = 2.5 L. Simulations were performed with both $C_{BL} = 0$ and 1 ng/mL.

Pharmacodynamics—Assuming that the drug stimulates the formation rate of R, Indirect Response Model III (1) was applied:

$$\frac{dR}{dt} = k_{in}(1 + S(t)) - k_{out}R \quad (2a)$$

where

$$S(t) = \frac{S_{max}C_p}{SC_{50} + C_p} \quad (2b)$$

and

$$k_{in} = k_{out}R_0 \quad (3a)$$

where S_{max} is the maximum effect and SC_{50} is the drug concentration which can produce 50% of the maximum stimulation of the formation rate.

When the therapeutic agent is an endogenous substance, the basal response occurs when $C_p = C_{BL}$. As a result, the relationships between k_{in}, k_{out}, and R_0 should be defined as follows:[3]

$$k_{in} = \frac{k_{out}R_0}{(1 + S(BL))} \quad (3b)$$

where

$$S(BL) = \frac{S_{max}C_{BL}}{SC_{50} + C_{BL}} \quad (3c)$$

The assigned PD parameter values for the simulations were $R_0 = 25$, 50, 100, or 200 ng/mL; $k_{out} = 0.4\ h^{-1}$; $S_{max} = 5$; $SC_{50} = 4$ ng/mL.

If the baseline level (C_{BL}) = 0, then $k_{in} = k_{out}R_0 = 10$, 20, 40, or 80 ng/mL/h.

If $C_{BL} = 1$ ng/mL, then

$$k_{in} = \frac{k_{out}R_0}{(1 + S(BL))} = \frac{k_{out}R_0}{2} = 5, 10, 20, \text{or } 40 \text{ ng/mL/h}$$

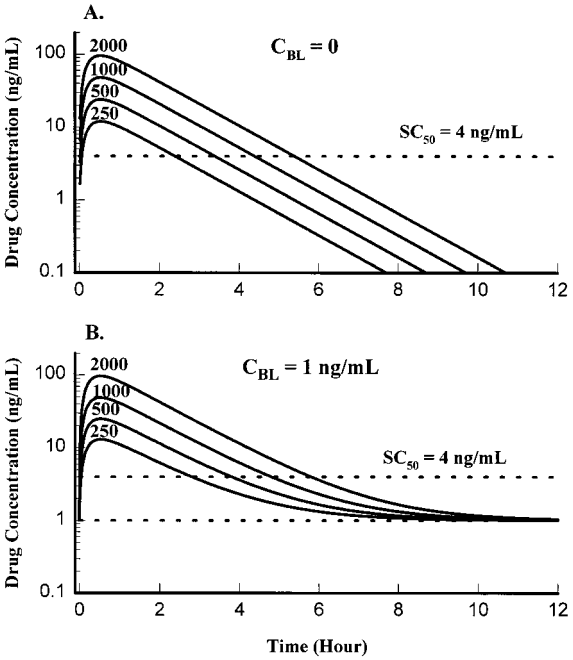

Figure 1—Simulated values for the pharmacokinetic profile of a hypothetical drug at doses of 250, 500, 1000, and 2000 μg. Top (Figure 1A): $C_{BL} = 0$ when the baseline value is negligible. Bottom (Figure 1B): $C_{BL} = 1.0$ ng/mL when the drug is an endogenous substance with a constant baseline value.

Area Analysis—The total areas under the response curves ($AUEC_{total}$) from time 0 to 20 h after drug dosing were obtained by integrating eq 2 in the ADAPT II program.[7] The net AUEC values ($AUEC_{NET}$) = $AUEC_{total} - AUEC_{base}$, where $AUEC_{base} = R_0(20\ h)$.

Results

Pharmacokinetics—Simulations for drug concentration vs time profiles after four different doses are shown in Figures 1a ($C_{BL} = 0$) and 1B ($C_{BL} = 1$ ng/mL). The curves show an expected up-curve, a C_{max} proportional to dose, a t_{max} at 0.5 h, and monoexponential decline. The presence of the baseline adds curvature to the lower profiles.

Pharmacodynamics—*No Baseline*—Simulations for the response vs time profiles are shown in Figure 2. When R_0 (or k_{in}) is a constant, the maximum response as well as the time to reach the maximum response increases when the dose increases. These are the basic characteristics of Indirect Response Model III.[8] As shown in Figure 2, R_0 (or k_{in}) has a profound effect on the magnitude of the overall response. When the dose is constant, the maximum response is proportional to R_0 (or k_{in}).

Presence of Baseline—Simulations for the response vs time profile are shown in Figure 3. Since R_0 is now regulated by the endogenous drug concentration (C_{BL}), the k_{in} value is a fraction of $k_{out}R_0$ as defined in eq 3b. In this particular case, $(1 + S(BL)) = 2$. These response profiles are similar to the results shown in Figure 2. However, the magnitudes of the responses are approximately one-half of those with $C_{BL} = 0$ owing to the lower k_{in} values.

Area Analysis—$AUEC_{NET}$ vs log dose profiles are shown in Figures 4a ($C_{BL} = 0$) and 4b ($C_{BL} = 1$ ng/mL). Within the dose range of 250 to 2000 μg, all curves show linear relationships ($r^2 = 0.9991-0.9997$). The slopes obtained by linear regression are listed in the figure legend.

As shown in Figure 4, the slope coefficients are proportional to R_0 (or k_{in}) values. Krzyzanski and Jusko[9] provided an exact solution for the $AUEC_{NET}$ based on Indirect Response Model III:

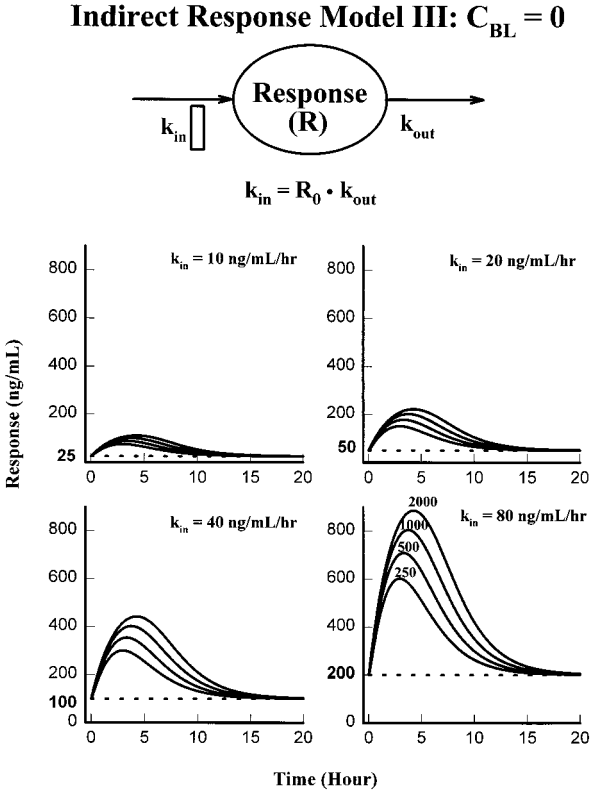

Figure 2—Simulations for drug effects on the production of responses based on the principles of Indirect Response Model III. Four dose levels were simulated: 250, 500, 1000, and 2000 μg. Assuming the baseline is negligible ($C_{BL} = 0$), four different R_0 values were utilized in the simulation: 25 (top, left), 50 (top, right), 100 (bottom, left), and 200 ng/mL (bottom, right). Based on the relationship described by eq 3a, the k_{in} values are 10, 20, 40, and 80 ng/mL/h, respectively.

$$AUEC_{NET} = R_0 \frac{S_{max}}{k_{el}} \ln\left(1 + \frac{dose/V}{SC_{50}}\right) \quad (4)$$

where k_{el} is the elimination rate constant for the function $C(t) = dose(e^{-k_{el}t})/V$. When doses are large, then

$$AUEC_{NET} \sim R_0 \frac{S_{max}}{k_{el}} \ln(Dose) \sim 2.3 R_0 \frac{S_{max}}{k_{el}} \log(Dose) \quad (5)$$

Therefore, the slope coefficient is approximately equal to $(2.3R_0S_{max}/k_{el})$. The k_{el} should be replaced by k_a when flip-flop kinetics occurs in eq 1. The estimates of slopes based on eq 5 for $R_0 = 25$, 50, 100, and 200 ng/mL are 415, 831, 1661, and 3323. These values are close to the results from linear regression for AUEC analysis, although they are slightly overestimated owing to the approximation and use of the Bateman Function.

The $AUEC_{NET}$ vs log dose profiles and the results for linear regression when $C_{BL} = 1.0$ ng/mL are shown in Figure 4B. The slope coefficients are also proportional to R_0 values. When the same R_0 values are compared, the slope coefficients are less than 50% of the estimates for which $C_{BL} = 0$. This disproportionality is due to the alteration of the definition for k_{in} (between eq 3a and 3b), and the different ratios of the stimulation factor, $S(t)$.

Application—The stimulating effects of a single sc dose of Interleukin-10 (IL-10) on monocytes in blood were characterized in normal volunteers[2] using Indirect Response Model III. Figure 5 shows the mean plasma concentrations of IL-10 and the time-course of monocyte numbers. The SC_{50} of IL-10 averaged 0.66 ± 0.70 ng/mL while the S_{max} was predetermined to be 1.5. The relation-

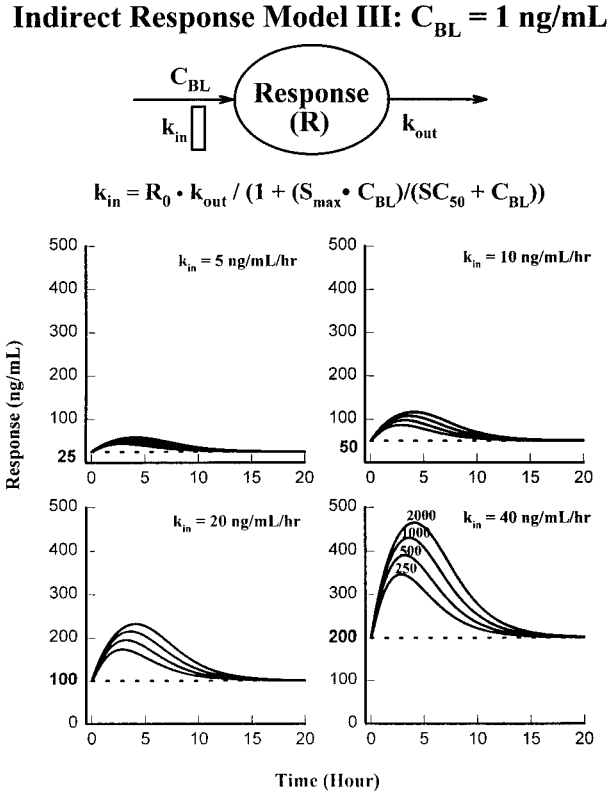

Figure 3—Simulations for drug effects on the production of responses based on the principles of Indirect Response Model III and eq 3b assuming that the drug is an endogenous substance with a constant baseline (C_{BL} = 1.0 ng/mL). Other conditions and simulations are the same as in Figure 2.

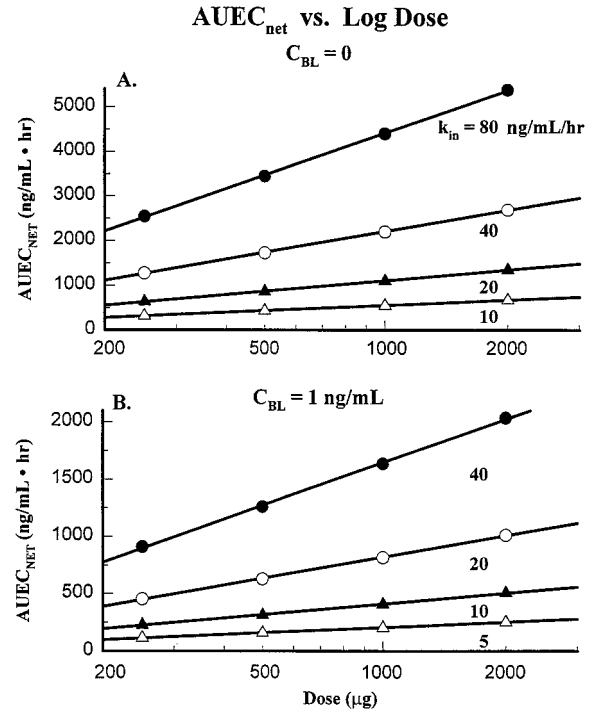

Figure 4—$AUEC_{NET}$ vs log dose for the response profiles in Figures 2 and 3. Top (Figure 4A): baseline is negligible (C_{BL} = 0). Slopes are 394, 787, 1574, and 3148. Bottom (Figure 4B): the drug is an endogenous substance with a constant baseline value (C_{BL} = 1 ng/mL). Slopes are 155, 310, 620, and 1248.

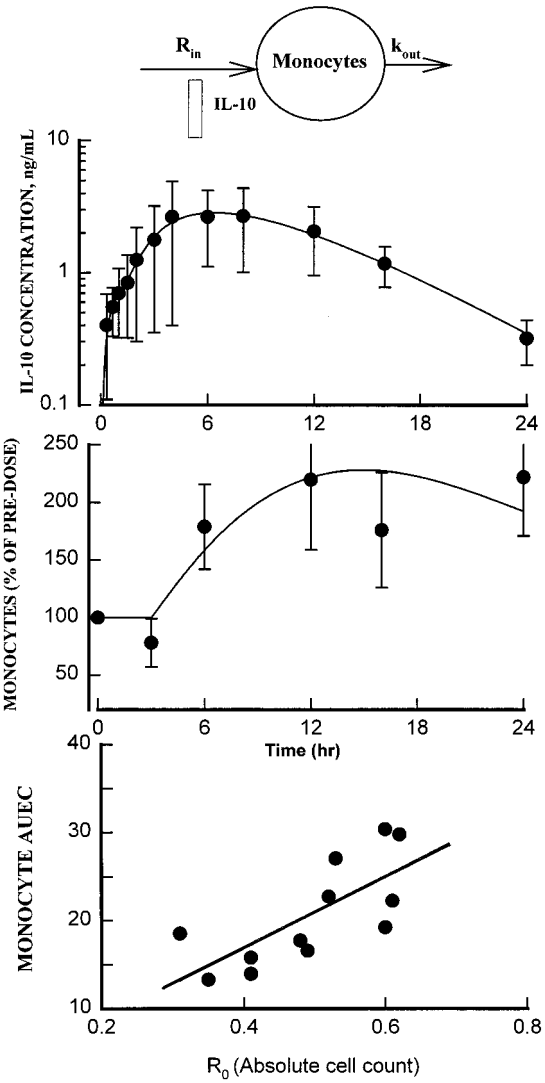

Figure 5—Pharmacokinetics of Interleukin-10 (IL-10) in normal volunteers (top), time course of stimulation of monocytes in blood (middle), and relationship of AUEC of monocytes to initial cell number in blood (R_0) (bottom). Adapted from ref 2.

ship between AUEC and R_0 was found to correlate strongly and indicated that R_0 was a major determinant of the net response.

Discussion

Our simulations show that the baseline value of the pharmacodynamic response (R_0) may play an important role in affecting the extent of the response if its PK/PD relationship can be described by Indirect Response Model III. When other factors remain unchanged (such as S_{max}, SC_{50}, k_{out}), the R_0 which intrinsically reflects the k_{in}/k_{out} ratio dictates the overall magnitude of the response. The same principles apply for drugs which inhibit k_{in} (Indirect Response Model I). The extent of the observed response is also jointly determined by k_{in} and the Hill Function,[1,8,9] and an equation analogous to eq 4 exists.[9] The net response ($AUEC_{NET}$) is also proportional to R_0 in a more complex fashion for drugs which inhibit or stimulate k_{out}.[9] However, such equations also indicate that the present simulations are generally applicable to all drugs with indirect mechanisms of action.

Many protein therapeutic agents stimulate natural physiological processes. For example, IL-10 increases the

blood monocyte and neutrophil counts.[2] GH stimulates the formation of IGF-I, which is a mediator for the growth effect and is often used as a surrogate measurement.[3] IFN α-2a induces the production of MX protein which exerts various antiviral activities.[4] EPO stimulates soluble transferrin receptor.[6] The PK/PD relationships for these biotech products were characterized by Indirect Response Model III.[2−4,6] The relationship between k_{in}, k_{out}, and R_0 can be adjusted accordingly using eq 3B when the pharmacodynamic effect is produced by an endogenous substance which is present at the time of dosing.[3]

Disease states, physiological conditions, medication history (treated vs naive patients, drug interactions, etc.), and other factors may affect the R_0 values of the response. Even for well-controlled studies, interindividual variation in R_0 values is often noticeable. For example, about a 2-fold difference of MX protein baseline values were observed among healthy subjects in a study where IFN α-2a effects were measured.[4] As a result, marked interindividual variation for MX protein production was found. For the effect of EPO on the increase of soluble transferrin receptors (sTfr) in athletes, interindividual variation in sTfr baseline values may be one reason there were large differences in responses observed among the subjects.[6]

These simulations show that the $AUEC_{NET}$ values are well correlated with log(dose) and R_0. The relationship is linear-log and predictable especially when $C_{BL} = 0$, and doses are relatively large.[6] Further investigations of the role of noticeable C_{BL} values on the response profiles are needed. These results suggest that dosages may have to be adjusted according to individual R_0 values. For example, a patient with a lower R_0 value may require higher doses compared to another patient with a higher R_0 value in order to produce similar overall responses. If pathophysiologic alterations of R_0 occur, dosage regimens designed for patients should not solely depend on the response profile obtained from healthy subjects. Finally, when indirect response models are applied to agents which are endogenous substances, the equations for the models will require utilization of eq 3b in order to account for the role of the naturally present active substance. In conclusion, for those therapeutic agents stimulating (or inhibiting) the production rate (or k_{out}) of the response, the R_0 and k_{in} are important determinants of the extent of the response and adjustment of model equations for baseline effects may be needed.

Accepted for publication July 23, 1999.

Abstract □ The structure of the hormone glucagon is identical among humans and several species of other mammals. Equivalence of recombinant glucagon (rG) to animal-source glucagon (aG) was assessed in this two-part, open-label, randomized study. Part I was a four-way crossover intravenous dose-ranging study of rG (pH 2.8) involving 12 subjects. Part II was a six-way crossover study of 29 subjects comparing rG (diluent pH 2.0 and 2.8) with aG administered subcutaneously (sc) and intramuscularly (im). Maximum glucagon plasma concentrations (C_{max}) and area under the glucagon concentration curve (AUC) were calculated. Additionally, maximum blood glucose concentrations (BG_{max}), maximum absolute BG excursion (MAE), and area under the glucose concentration curve from time of dosing to return to baseline (AUC_{rtb}) were calculated. The primary focus was equivalence of the formulation intended for marketing (rG pH 2.0) to aG. Administration of rG pH 2.0 through the im route demonstrated equivalence to aG for all pharmacokinetic and glucodynamic comparisons. Subcutaneous administration of rG pH 2.0 demonstrated standard bioequivalence for AUC (5.87 versus 6.63 ng·h/mL; NS) and near equivalence for C_{max} (7.94 versus 9.12 ng/mL; $p < 0.05$). rG pH 2.0 showed glucodynamic equivalence to aG (BG_{max}, 136 versus 133 mg/dL; MAE, 50.0 versus 47.4 mg/dL, respectively) and statistically greater AUC_{rtb} values (151 versus 126 mg·h/dL, $p < 0.05$). rG and aG were equally safe and well tolerated. In conclusion, rG provides equivalent safety and efficacy to aG.

Introduction

Glucagon is a naturally occurring protein hormone secreted from the α cells of the pancreas. The primary sequence of glucagon is highly conserved in mammals and is identical in man, cattle, pigs, dogs, and rats. The principal function of glucagon is to maintain glucose production, through both glycogenolysis and gluconeogenesis, at a rate sufficient to meet glucose requirements. In man, approximately 75% of net glucose production is mediated through glucagon.[1]

Glucagon is used therapeutically to treat severe hypoglycemia, particularly in patients with diabetes when intravenous glucose is unavailable.[2,3] Glucagon is also used intravenously to relax the intestinal tract to facilitate radiographic examination of the upper and lower gastrointestinal tract.[3,4] Although glucagon is used to treat diabetic hypoglycemia, it may induce hyperglycemia in patients with diabetes when used for radiologic purposes if the patients are in good metabolic control. However, glucagon can induce gut immobilization at lower doses than 1 mg. Lower doses of glucagon may provide necessary gut immobilization while inducing lesser amounts of hyperglycemia and therefore achieving greater safety in patients with diabetes.

Historically in the United States, commercial glucagon has been produced through an extraction process of beef and pork pancreas glands, followed by a high degree of purification. With a trend away from the manufacturing of beef and pork insulins, the availability of quality animal pancreas glands has diminished. Recent advances in recombinant deoxyribonucleic acid (DNA) technology have provided a reliable and efficient source of purified glucagon, recombinant glucagon (rG), with an amino acid sequence identical to that of animal glucagon. The purpose of this study was to compare the pharmacokinetic and pharmacodynamic parameters of rG and animal-source glucagon (aG).

Methods

Patient Population—Forty-one healthy volunteers (24 males, 18 females) between the ages of 23 and 60 years and who were within 15% of normal body weight for their height and frame size (Metropolitan Life Insurance standards) were enrolled in Part I ($n = 12$) or in Part II ($n = 29$) of this study. Subjects participated in only one part of the study. Each subject had a complete medical history, physical examination, complete blood count, urinalysis, a fasting chemistry panel, and chest X-ray prior to enrollment.

For this study, the primary study drug was rG, and the comparator study drug was aG. Each was supplied by Eli Lilly and Company (Indianapolis, IN). The study drug was supplied as a lyophilized powder and reconstituted at the time of injection to a concentration of 1 mg/mL. The diluting solutions were pH 2.0 and 2.8 for rG and pH 2.8 for aG. The Institutional Review Board of the participating institution approved the study, and each subject gave written informed consent for the study.

Study Design—Part I was a randomized, open-label, four-way crossover study that assessed the pharmacokinetics, glucodynamics, dose proportionality, and safety of rG after intravenous (iv) administration. Each healthy volunteer received four doses (0.25, 0.5, 1.0, and 2.0 mg) of rG pH 2.8 as an iv bolus injection with a 7−10 day interval between each dose.

Part II was a randomized, open-label, six-way crossover study that assessed the bioequivalence of rG pH 2.0 and pH 2.8 with aG pH 2.8 after intramuscular (im) and subcutaneous (sc) administration. Two separate pH values were used, since the pH used currently (2.8, for aG) occasionally results in a gel formation. Reduction of the pH to 2.0 reduces the occurrence of this phenomenon. Each subject was scheduled to receive all six possible dose combinations: (1) aG sc, (2) rG pH 2.8 sc, (3) rG pH 2.0 sc, (4) aG im, (5) rG pH 2.8 im, and (6) rG pH 2.0 im. Each dose (sc or im, aG or rG) was 1 mg and was separated by a 7−10 day interval. Administrations were given sc in the lower abdomen and im in the upper deltoid muscle.

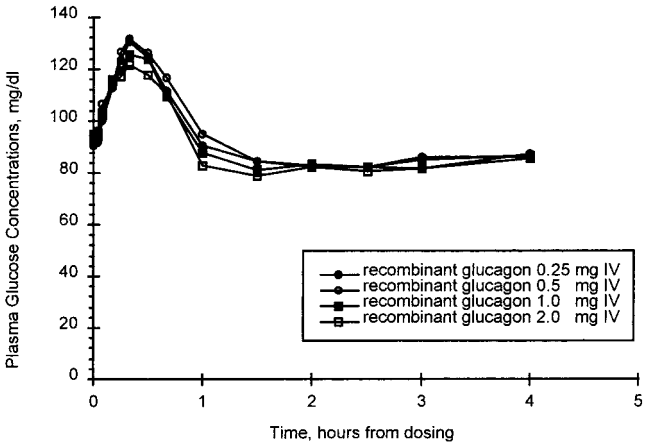

Figure 1—Mean blood glucose concentration versus time curves, all intravenous treatments (part I). $n = 10$. ● = 0.25 mg, ○ = 0.5 mg, ■ = 1.0 mg, □ = 2.0 mg.

For Part I and II, patients received doses of glucagon after an overnight fast, and they remained fasting during the test. Serum samples were collected over a 4-h period after each injection for measurement of glucose and glucagon concentrations. For Part I, samples were collected at 0, 2, 5, 10, 15, 20, 30, 40, 60, 90, 120, 150, 180, and 240 min after administration. For Part II, samples were collected at 0, 5, 10, 15, 20, 25, 40, 60, 90, 120, 150, 180, and 240 min after administration. Serum glucagon concentrations were measured at a central laboratory (Pharmaco International, Richmond, VA) using radioimmunoassay (RIA) techniques. A modified commercial glucacon RIA kit (LINCO, St. Louis, MO) was used for measurement of rG. The modification consisted of replacing the kit calibration standards with standards prepared with rG in the kit's ligand-free matrix. Test samples, standards, and QC samples were analyzed after extracting all samples with four volumes of methanol, evaporation of the extracts, and reconstitution in assay buffer. Although the primary sequence of aG is highly conserved in mammals (the 29-amino acid sequence is identical for man, cattle, pigs, dogs, and rats), aG was cross-validated within this assay, showing equivalent potency, parallel dilution, and nearly identical recovery. The lowest quantifiable concentration for the assay was 40 pg/mL.

Additionally, blood glucose concentrations were determined using a glucose hexokinase method (Clinical Laboratory of MDS Harris, Lincoln, NE).

Pharmacokinetic Measurements—Pharmacokinetic parameters were estimated by noncompartmental pharmacokinetic methods. Maximum glucagon concentration (C_{max}), the time at which C_{max} was observed relative to drug administration (t_{max}), area under the glucagon concentration versus time curve from time 0 to infinity ($AUC_{(0-inf)}$), and apparent terminal elimination phase half-life ($t_{1/2}$) for glucagon plasma concentrations derived from Parts I and II were calculated. Additional parameters, including total systemic clearance (CL), the volume of distribution at steady-state (V_{ss}), and the extrapolated volume of distribution (V_{ext}) were calculated from the iv bolus data (Part I).

Glucodynamic Measurements—Several glucodynamic measurements were derived from the blood glucose concentrations, including the following: maximum blood glucose concentration (BG_{max}), time to BG_{max} (TBG_{max}), area under the glucose versus time curve from time 0 to the time of return to baseline ($AUC_{(0-rtb)}$), area under the glucose excursion versus time curve from 0 to return to baseline (AUC_{ex}), maximum absolute BG excursion (MAE), and earliest recorded time of the MAE (TBG_{ex}). "Baseline" is defined as the blood glucose concentration reported just prior to injection. "Return to baseline" is the achievement of that baseline concentration after blood glucose peaked. If necessary, $AUC_{(0-rtb)}$ and AUC_{ex} values were interpolated. The excursion values (AUC_{ex}, MAE, TBG_{ex}) reflect a subtraction of the baseline value from all measured concentrations and calculations in a fashion similar to the nonadjusted values. All AUC measurements were calculated using the trapezoidal rule.

Statistical Methods—For Part I, a parametric (normal theory) general linear model was applied to the pharmacokinetic and glucodynamic parameters using the SAS GLM procedure. The analysis of variance (ANOVA) model included sequence, period, and treatment as fixed effects and subject within sequence as a random effect. Differences between the treatments with respect to any given parameter were further assessed using pairwise multiple *t*-tests (Bonferroni method). Dose linearity was assessed by linear regression of the dose-normalized parameters with respect to dose. Dose linearity with respect to a parameter was concluded if the slope was not significantly different from 0 ($\alpha = 0.05$). For Part II, a similar ANOVA was performed comparing the pharmacokinetic and glucodynamic parameters and the log-transformed values of C_{max}, $AUC_{(0-t)}$, $AUC_{(0-inf)}$, BG_{max}, $AUC_{(0-rtb)}$, AUC_{ex}, and MAE. The two one-sided hypotheses (Schuirmann two one-sided tests procedure) were tested at the 5% level for the parameters by constructing 90% confidence intervals for the ratio of the test and reference means. The 90% confidence intervals were obtained from the antilogs of the lower and upper bounds of the 90% confidence intervals for the difference in the means of the log-transformed data. Bioequivalence was concluded if the 90% confidence intervals for the variables C_{max}, $AUC_{(0-t)}$, $AUC_{(0-inf)}$, BG_{max}, $AUC_{(0-rtb)}$, AUC_{ex}, and MAE were contained within the range of 80% to 125%.

Results

Part I—For Part I, 10 out of the 12 subjects successfully completed the study. Two subjects withdrew from the study for reasons unrelated to the study. All adverse events in Part I occurred within 24 h following dosing and were mild in severity. The most common adverse events were dizziness and nausea.

Pharmacokinetics—The pharmacokinetic parameters are shown in Table 1. rG pH 2.8 exhibited dose proportionality for C_{max} ($p = 0.186$ for the test of 0 slope), $AUC_{(0-t)}$ ($p = 0.099$), and $AUC_{(0-inf)}$ ($p = 0.104$) when administered intravenously over the 0.25 to 2.0 mg dose range. Mean maximal plasma glucagon concentrations ranging from 37 to 368 ng/mL occurred within 0.05 h following the iv bolus dose. Glucagon was rapidly eliminated, with mean half-lives ranging from 0.13 to 0.30 h. Half-life appeared to increase with increasing dose. This could be an effect of the appearance of a second compartment that only becomes apparent with higher glucagon doses. The mean clearance was similar between the treatments (≈59 L/h). The volume of distribution (V_{ext}), which is affected by changes in the rate of elimination, increased with increasing doses.

Glucodynamics—Glucodynamic parameters are shown in Table 1. Mean maximal blood glucose concentrations were similar for each treatment (129 to 136 mg/dL) and occurred within 0.36 h after the iv bolus dose of glucagon. This finding indicates that even at the lowest glucagon dose, a

maximum glucodynamic effect was present. Blood glucose returned to baseline value by 1 h in most subjects (Figure 1). There were no statistically significant differences among the four glucagon doses with respect to any glucodynamic parameters.

Part II—For Part II, 25 out of the 29 subjects successfully completed the study. Three subjects withdrew from the study for reasons unrelated to the study, and one patient withdrew due to difficult venipuncture. One subject was removed from the study due to nausea, dizziness, and pallor after a 1 mg dose of aG. rG and aG appeared to be equally safe and well tolerated. The most common adverse events reported were nausea, dizziness, and headache, occurring throughout treatment with both aG and rG.

Pharmacokinetics—Visual inspection of the mean glucagon concentration−time plots suggests that the profiles have similar absorption and elimination when comparing the glucagon formulations (aG, rG pH 2.8, and rG pH 2.0) for either route of administration (Figure 2). Slight differences in glucagon concentrations were noted between the injection routes with higher plasma concentrations occurring after sc administration. The absorption was rapid by either route, with maximum concentrations attained approximately 0.21 to 0.35 h after dosing.

A summary of the pharmacokinetic parameters is given in Table 2 and Table 3 for the sc and im routes of administration, respectively. rG pH 2.0 and pH 2.8 administered sc met the standard criteria for bioequivalence to aG with respect to $AUC_{(0-t)}$ and $AUC_{(0-inf)}$ and was nearly equivalent with respect to C_{max} comparisons. Following im administration, both rG formulations met standard bioequiv-

alence criteria to aG with respect to all pharmacokinetic parameters.

The mean absolute bioavailability for the subcutaneous administrations of aG, rG pH 2.0, and rG pH 2.8 were 0.39, 0.35, and 0.38, respectively, using mean $AUC_{(0-inf)}$ measurements from the intravenous administrations as an index. Similar absolute bioavailability calculations for im administrations showed values of 0.25, 0.23, and 0.27 for of aG, rG pH 2.0, and rG pH 2.8, respectively.

Glucodynamics—All glucagon formulations produced nearly identical glucose response curves after sc or im administration (Figure 3). A summary of the glucodynamic parameters is given in Table 4 and Table 5 for the sc and im administrations, respectively. Comparison of glucodynamic response following sc administration showed that both rG formulations had equivalent BG_{max} and MAE values when compared to aG. Furthermore, aG and rG pH 2.8 were equivalent with respect to $AUC_{(0-rtb)}$ and glucose excursion AUC_{ex}. Compared with aG, rG pH 2.0 had a statistically greater $AUC_{(0-rtb)}$ and AUC_{ex}. All im administrations had statistically equivalent $AUC_{(0-rtb)}$ values. The rG pH 2.8 formulation showed greater BG_{max} and MAE values. However, since maximum activity appears to be achieved with low intravenous doses, this "greater" activity is likely a type I statistical error. Additionally, the AUC_{ex} of rG pH 2.0 was glucodynamically equivalent to that of aG.

Discussion

Historically, commercial glucagon has been produced through an extraction of beef and pork glands. However, recombinant DNA technology has led to an efficient process for producing pure glucagon. Moreover, the Food and Drug Administration has recently approved for marketing glucagon manufactured by that technology. The present study was designed to compare the pharmacokinetic and pharmacodynamic parameters of recombinant glucagon and animal-source glucagon. Since the sequence of animal-source glucagon is identical to that of recombinant glucagon, no difference in biological effect was expected when comparing the two formulations.

Part I of the study provided a dose-ranging assessment of rG given intravenously. Our analysis showed that rG exhibits linear disposition, with AUC and C_{max} increasing in a dose-proportional fashion. The half-life was short, with relatively high clearance (approximately 1 L/h) and small volume of distribution. The small volume of distribution is typical with proteins with their large molecular weight and polarity.

No dose−response was found with rG between the various intravenous doses. A maximum response was achieved by even the lowest dose tested, suggesting that the use of even small doses may induce hyperglycemia in patients with diabetes who use rG for radiologic procedures.

Part II of the present study demonstrated that both rG formulations administered sc were glucodynamically equivalent with respect to BG_{max} and MAE values when compared to aG. Furthermore, rG pH 2.8 was equivalent with respect to $AUC_{(0-rtb)}$ and glucose excursion AUC_{ex} when compared to aG. However, rG pH 2.0 induced higher glucose-related areas than aG following sc administration. When calculating $AUC_{(0-rtb)}$ and AUC_{ex}, it is necessary to assume that baseline glucose concentrations are stable within subject. In reality, fluctuations can occur in a subject's baseline, which can cause high intersubject variability in $AUC_{(0-rtb)}$ (41% to 53%) and AUC_{ex} (29% to 89%) and broad confidence intervals. For these reasons, the glucose-related areas may not be the most robust pharmacoynamic parameters for comparing the glucagon formulation.

TBG_{max} was observed to be greater than t_{max} after administration of glucagon by any route, although the discrepancy is smallest for sc and largest for iv. The size of this hysteresis and relative delay appears to be inversely related to the rate of appearance in the bloodstream (rate of absorption for sc and im routes) and is typical for a compound which exerts an effect in a tissue distant to where it is being measured. Nonetheless, the onset can still be considered rapid with the peak effects from the slowest absorption (sc) averaging approximately 30 min after dosing.

A review of the literature yielded a single study that investigated the pharmacokinetics and glucodynamics of a recombinant glucagon. Urae and colleagues[5] measured the pharmacokinetics and glucodynamics of a 1 mg dose of recombinant glucagon administered iv and sc (upper arm). Unlike the present study, recombinant glucagon was not compared to animal-source glucagon to determine bioequivalence. Minor differences in pharmacokinetic and glucodynamic parameters for rG pH 2.0 were noted compared to those determined by Urae et al. The glucodynamic parameter of $AUC_{(0-rtb)}$ for both iv and sc administrations was lower than those reported by Urae et al.[5] One possible explanation for this difference is the duration of blood sampling. In the Urae study, blood samples were collected over 720 min,[5] while in the present study blood samples were collected for only 240 min. Although we cannot verify the calculations of the Urae study, it appears that calculations were performed to the end of collection rather than the return to baseline. Both studies show rapid absorption of glucagon following sc administration (TBG_{max}, 0.34 ± 0.083 h and 0.52 ± 0.54 h, respectively). However, the mean BG_{max} was slightly lower in the present study when compared to the values determined by Urae et al.[5] (136 ± 19.8 mg/dL versus 160.4 ± 26.5 mg/dL, respectively). In general, mean values of pharmacokinetic parameters in the current study tended to be higher than those determined by Urae et al.[5] The minor discrepancies that were noted may be related to differences in assays, injection sites, and methods of injection.

In conclusion, we have demonstrated that glucagon produced through recombinant DNA technology demonstrates equivalent activity to the currently marketed animal-source glucagon following im and sc administration. Additionally, we have provided evidence of the pharmacokinetic equivalence between rG and aG when given by the im and sc routes. We have also shown the pharmacokinetic dose-proportionality of glucagon and that the glucose response appears to be saturated with even low doses of glucagon. Nonetheless, it is best to ensure the achievement of a maximum glucose response in emergency situations, with a clinical dose of 1 mg recommended.

Received March 4, 1999. Accepted for publication July 19, 1999.

Abstract □ Two poly(ethylene glycol) (PEG)-peptides were synthesized and tested for their ability to bind to plasmid DNA and form soluble DNA condensates with reduced spontaneous gene expression. PEG-vinyl sulfone or PEG-orthopyridyl disulfide were reacted with the sulfhydryl of Cys-Trp-Lys$_{18}$ (CWK$_{18}$) resulting in the formation of nonreducible (PEG-VS-CWK$_{18}$) and reducible (PEG-SS-CWK$_{18}$) PEG-peptides. Both PEG-peptides were prepared on a micromole scale, purified by RP-HPLC in >80% yield, and characterized by ^{1}H NMR and MALDI-TOF. PEG-peptides bound to plasmid DNA with an apparent affinity that was equivalent to alkylated (Alk)CWK$_{18}$, resulting in DNA condensates with a mean diameter of 80–90 nm and ζ (zeta) potential of +10 mV. The particle size of PEG-peptide DNA condensates was constant throughout the DNA concentration range of 0.05–2 mg/mL, indicating these to be approximately 20-fold more soluble than AlkCWK$_{18}$ DNA condensates. The spontaneous gene transfer to HepG2 cells mediated by PEG-VS-CWK$_{18}$ DNA condensates was over two orders of magnitude lower than PEG-SS-CWK$_{18}$ DNA condensates and three orders of magnitude lower than AlkCWK$_{18}$ DNA condensates. PEG-VS-CWK$_{18}$ efficiently blocked in vitro gene transfer by reducing cell uptake. The results indicate that a high loading density of PEG on DNA is necessary to achieve highly soluble DNA condensates that reduce spontaneous in vitro gene transfer by blocking nonspecific uptake by HepG2 cells. These two properties are important for developing targeted gene delivery systems to be used in vivo.

Introduction

A variety of macromolecules including cationic lipids,[1] polylysine,[2] polyethylenimine,[3] and dendrimers[4] have been used as carriers to bind to negatively charged plasmid DNA and facilitate spontaneous gene transfer in cell culture as a result of charge interaction between the DNA carrier complex and the cell surface. Unfortunately, the performance of these nonviral gene delivery carriers are far less efficient in vivo due in part to the rapid pharmacokinetics and clearance of DNA complexes.[5,6] This relates to both the particle size and surface charge of the delivery system.[7] For example, cationic lipids form large DNA complexes that are trapped in the capillary beds of the lung[5] whereas smaller (<100 nm) peptide DNA condensates are scavenged by mononuclear phagocytic system (MPS) cells of the liver,[6] limiting the development of DNA delivery systems that target peripheral tissues.

The intravenous dosing of most colloids leads to opsonization and MPS cell uptake in the lung, liver, and spleen.[8] In the case of liposomes, this limitation has been largely overcome by simultaneously reducing the particle size to <100 nm and modifying the surface with PEG[9] since this polymer possesses the ideal hydration and flexibility to create a steric layer that allows liposomes to avoid opsonization and detection by MPS cells.[10]

Several studies have described the synthesis of PEG-containing polymers designed to create a steric layer on the surface of DNA condensates,[7,11−17] with the aim of improving their solubility and in vivo performance. An early study by Wolfert et al. described the synthesis of grafted copolymers of PEG (5 or 12 kDa) and polylysine$_{100}$ prepared by carbodiimide coupling 5−10 mol % of succinylated-PEG onto the side chains of polylysine.[11,12] The resulting PEG-peptides were less toxic to cells in culture compared to polylysine$_{100}$, formed DNA condensates possessing a reduced effective surface charge, and had slightly improved solubility over control polylysine DNA condensates but surprisingly were unable to reduce spontaneous gene transfer in HepG2 cells[12] in vitro, suggesting that they would not be able to block nonspecific interactions with cells in vivo.

Subsequently, Choi et al. derivatized the side chains of polylysine$_{120}$ with 5−25 mol % low molecular weight PEG of 550 Da.[13] The resulting PEG-peptide DNA condensates were also less toxic to cells than polylysine$_{120}$ DNA condensates but were similar to Wolfert's PEG-peptides in their inability to reduce spontaneous gene transfer in HepG2 cells, indicating that low molecular weight PEG was no more effective than high molecular weight PEG. Using a similar approach, PEG polylysine dendrimer copolymers were recently reported by the same group and used to form DNA condensates that were more nuclease resistant than polylysine DNA condensates but which were not examined for gene transfer.[14]

In addition, Katayose et al. synthesized PEG-polylysine block copolymers to incorporate 5 kDa PEG into polylysine by random polymerization of *N*-carboxyanhydride ϵ-(benzyloxycarbonyl)-lysine with amino-PEG, resulting in a polymer with a lysine to PEG ratio of approximately 18:1[15,16] representing approximately 5 mol % PEG. These PEG-polylysine DNA condensates were also reportedly much more resistant to endonuclease than uncondensed DNA but were not examined for solubility or gene transfer.[16,17]

To date, there are no reports of a PEG-peptide DNA condensing agents that significantly increase the solubility of the DNA condensates and/or reduce spontaneous gene transfer to HepG2 cells. These are both significant problems since the poor solubility of peptide DNA condensates of approximately 50−100 μg/mL limits the dosing volume and precludes dose escalation during in vivo gene transfer. Likewise, reducing the level of spontaneous gene transfer in vitro is a first step toward developing DNA formulations that avoid nonspecific gene transfer to cells in vivo and may allow the development of DNA formulations that target to peripheral sites. Here we describe the synthesis and formulation properties of two PEG-peptides, both of which

significantly improve DNA condensate solubility and one of which dramatically reduces spontaneous gene transfer of DNA condensates in vitro. The results suggest that these two properties are closely linked to the loading level of PEG on peptide DNA condensates.

Materials and Methods

PEG-orthopyridyl disulfide (PEG-OPSS, 5 kDa) and PEG-vinyl sulfone (PEG-VS, 5 kDa) were purchased from Shearwater Inc. (Huntsville, AL) and Fluka (Ronkonkoma, NY), respectively. Fetal calf serum and LipofectAce were obtained from Gibco BRL (Gaithersburg, MD). Minimum essential media (MEM) and CM Sephadex C50 were purchased from Sigma (St. Louis, MO). TCEP (tris(2-carboxyethyl)phosphine hydrochloride) was purchased from Aldrich, (Milwaukee, WI). D-Luciferin and luciferase from *Photinus pyralis* were from Boehringer Mannheim (Indianapolis, IN). The 5.6 kb plasmid (pCMVL) encoding the reporter gene luciferase under the control of the cytomegalovirus promoter was a gift from Dr. M. A. Hickman at the University of California, Davis.[18] pCMVL was produced in *E. coli* and purified using a Qiagen Ultrapure-100 kit (Santa Clarita, CA). Bradford reagent was purchased from Bio-Rad (Hercules, CA). Preparative and analytical C18 reverse phase HPLC columns were purchased from Vydac (Hesperia, CA). HPLC was performed using a computer-interfaced HPLC and fraction collector from ISCO (Lincoln, NE).

Synthesis of PEG-VS-CWK$_{18}$ and PEG-SS-CWK$_{18}$—CWK$_{18}$ (Cys-Trp-Lys$_{18}$) and dimeric-CWK$_{18}$ were synthesized and characterized as described previously.[19] The Cys residue on CWK$_{18}$ was alkylated with iodoacetic acid resulting in AlkCWK$_{18}$ as reported.[19] The synthesis of PEG-VS-CWK$_{18}$ utilized dimeric-CWK$_{18}$ (0.5 μmol) which was reduced to form 1 μmol of CWK$_{18}$ by reaction with 25 μmol of TCEP[20] in 0.5 mL of 0.1 M sodium phosphate pH 7 for 4 h at room temperature. PEG-VS-CWK$_{18}$ was formed by reacting 1 μmol of reduced CWK$_{18}$ with 30 μmol of PEG-VS in a total volume of 1.2 mL of 0.1 M sodium phosphate pH 7 at room temperature for 12 h. The progress of the reaction was monitored by analytical RP-HPLC eluted at 1 mL/min with 0.1% TFA and a gradient of acetonitrile (5−65% over 30 min) while detecting by A_{280nm}. The reaction mixture was applied to a CM Sephadex C50 cation-exchange column (0.7 × 15 cm) eluted with 60 mL of water to remove free PEG-VS as the unbound fraction and then with 15 mL of 1.5 M sodium chloride while collecting 5 mL fractions. PEG-VS-CWK$_{18}$ and CWK$_{18}$ were detected by A_{280nm} and were pooled and desalted by 5 h dialysis against 4 L of water in 1000 MWCO tubing and then freeze-dried. PEG-VS-CWK$_{18}$ was resolved from CWK$_{18}$ by injecting 0.5 μmol onto a semipreparative C18 RP-HPLC column (2 × 25 cm) eluted at 10 mL/min with 0.1% TFA and a gradient of acetonitrile (5 to 65% over 30 min) while detecting by A_{280nm}. The peak eluting at 25 min yielded 0.8 μmol of PEG-VS-CWK$_{18}$ (80%) based on tryptophan absorbance (ϵ_{280nm} = 5600 M^{-1} cm^{-1}).

A disulfide bond exchange reaction was used to prepare PEG-SS-CWK$_{18}$. Prior to conjugation of PEG-OPSS, dimeric-CWK$_{18}$ was reduced and then purified by RP-HPLC eluted as described above. Reduced CWK$_{18}$ (1 μmol) was reacted with 4 μmols of PEG-OPSS in 1 mL of 0.1 M sodium phosphate pH 7 at room temperature for 30 min. The reaction was monitored by analytical RP-HPLC which detected a single new product peak eluting at 25 min. PEG-SS-CWK$_{18}$ was purified by injecting 0.5 μmol portions onto semi-preparative RP-HPLC eluted as described above resulting in an isolated yield of 95%.

PEG-VS-CWK$_{18}$ and PEG-SS-CWK$_{18}$ (1 μmol) were prepared for ^{1}H NMR by D_2O exchange followed by dissolving the sample in 0.5 mL of D_2O (99.96%) containing acetone as an internal standard. ^{1}H NMR spectra were generated on a Bruker 500 MHz spectrometer operated at 23 °C. PEG-peptides were prepared for MALDI-TOF by dissolving 5 nmol in 20 μL of water. These (0.5 μL) were combined with 0.5 μL of saturated α-cyano-4-hydroxycinnamic acid in 50 v/v % acetonitrile and 0.3% trifluoroacetic acid and then analyzed on a Vestec LaserTec MS (PerSeptive Biosystems, Framingham, MA) operated in the linear mode at 20 kV.

Formulation of Peptide DNA Condensates—Peptide DNA condensates were formed by adding 75 μg of DNA (pCMVL in 750 μL of 5 mM Hepes pH 7.4) to varying amounts of peptide (7.5 to 90 nmol in 750 μL of Hepes) while vortexing, followed by equilibration at room temperature for 1 h. Peptide binding to DNA was monitored by a fluorescent dye displacement assay.[19] A 1 μg aliquot of the peptide DNA condensate was diluted to 1 mL in Hepes containing 0.1 μM thiazole orange. The fluorescence of the intercalated dye was measured on an LS50B fluorometer (Perkin-Elmer, UK) in a microcuvette by exciting at 500 nm while monitoring emission at 530 nm.

The particle size of peptide DNA condensates were analyzed at a DNA concentration of 50 μg/mL in Hepes by quasielastic light scattering (QELS). The particle surface charge was determined by ζ (zeta) potential analysis using a Brookhaven ZetaPlus (Brookhaven Instruments). The solubility of peptide DNA condensates were determined by measuring particle size as a function of DNA concentration (50 μg/mL to 2 mg/mL) at a constant peptide: DNA stoichiometry of 0.4 nmol of peptide per μg of DNA corresponding to a charge ratio (NH_4^+:PO_4^-) of 2.3:1.

DNA cocondensates were prepared by add-mixing AlkCWK$_{18}$ and PEG-VS-CWK$_{18}$ in ratios ranging from 0 to 100 mol % and condensing DNA at a charge ratio of 2.3:1 as described above. To establish the mol ratio of peptides bound to DNA, condensates were dialyzed in a fixed volume (0.5 mL) dialyzer for 75 h against water using a 100 000 MWCO membrane. Peptide DNA condensates in the retentate (0.5 mL) were dissociated by adding 50 μL of 5 M sodium chloride in 0.1% TFA. AlkCWK$_{18}$ and PEG-VS-CWK$_{18}$ were quantified by injecting 1 nmol of peptide (100 μL) onto analytical RP-HPLC eluted with 0.1% TFA and a gradient of acetonitrile (5 to 65% over 30 min) while detecting tryptophan by fluorescence ($\lambda_{ex280nm}$, $\lambda_{em350nm}$). The peak integration areas were used to quantify AlkCWK$_{18}$ and PEG-VS-CWK$_{18}$ with reference to standard curves developed for each peptide.

In Vitro Gene Expression and Cell Binding—HepG2 cells were plated at 1.5 × 10^5 cells per 35 mm well and grown to 40−70% confluence in MEM supplemented with 10% fetal calf serum (FCS). Peptide DNA condensates (10 μg of DNA) were added dropwise to triplicate sets of cells in 2% FCS containing 80 μM chloroquine. After 5 h incubation at 37 °C, the media was replaced with MEM supplemented with 10% FCS, and luciferase expression was determined at 24 h. Cells were washed twice with ice-cold phosphate-buffered saline (calcium and magnesium free) and then treated with 0.5 mL of ice-cold lysis buffer (25 mM Tris hydrochloride pH 7.8, 1 mM EDTA, 8 mM magnesium chloride, 1% Triton X-100, 1 mM DTT) for 10 min. The cell lysate was scraped, transferred to 1.5 mL microcentrifuge tubes, and centrifuged for 7 min at 13 000g at 4 °C to pellet debris. Lysis buffer (300 μL), sodium-ATP (4 μL of a 180 mM solution, pH 7, 4 °C), and cell lysate (100 μL, 4 °C) were combined in a test tube, briefly mixed, and immediately placed in the luminometer. Luciferase relative light units (RLU) were recorded on a Lumat LB 9501 (Berthold Systems, Germany) with 10 s integration after automatic injection of 100 μL of 0.5 mM D-luciferin (prepared fresh in lysis buffer without DTT). The expression level of luciferase was normalized for protein using the Bradford assay,[21] and the relative light units were converted to fmol of luciferase/mg of protein using a standard curve developed by adding luciferase to cell supernatant. Each experimental result represents the mean and standard deviation derived from a triplicate set of transfections.

LipofectAce (Gibco BRL, 1:2.5 w/w dimethyl dioctadecylammonium bromide and dioleoylphosphatidylethanolamine) was optimized for use to mediate gene transfection in HepG2 cells according to the manufacturer's instructions. DNA/LipofectAce complexes were prepared by combining 10 μg of DNA in 100 μL of serum free media (SFM) with 60 μL of LipofectAce prepared in 150 μL of SFM. The LipofectAce DNA complex was then diluted with 1.7 mL of SFM and used to transfect HepG2 cells for 5 h followed by replacement of the transfecting media with MEM supplemented with 10% FBS. The cells were incubated for a total of 24 h, harvested, and then analyzed for luciferase as described above.

Iodinated plasmid DNA was prepared with specific activity of 300 nCi per μg of DNA as described previously.[22] Prior to forming DNA condensates, the specific activity of the ^{125}I DNA was adjusted to 4.5 nCi per μg of DNA by combining with unlabeled plasmid. DNA condensates were prepared using AlkCWK$_{18}$, PEG-SS-CWK$_{18}$, or PEG-VS-CWK$_{18}$ as described above. Peptide ^{125}I-DNA condensates (10 μg) were used to transfect HepG2 cells for 5 h according to the procedure described above. The radioactive media was removed, cells were washed with phosphate-buffered saline, harvested with lysis buffer, and the cell-associated radioactivity was quantified by gamma counting.

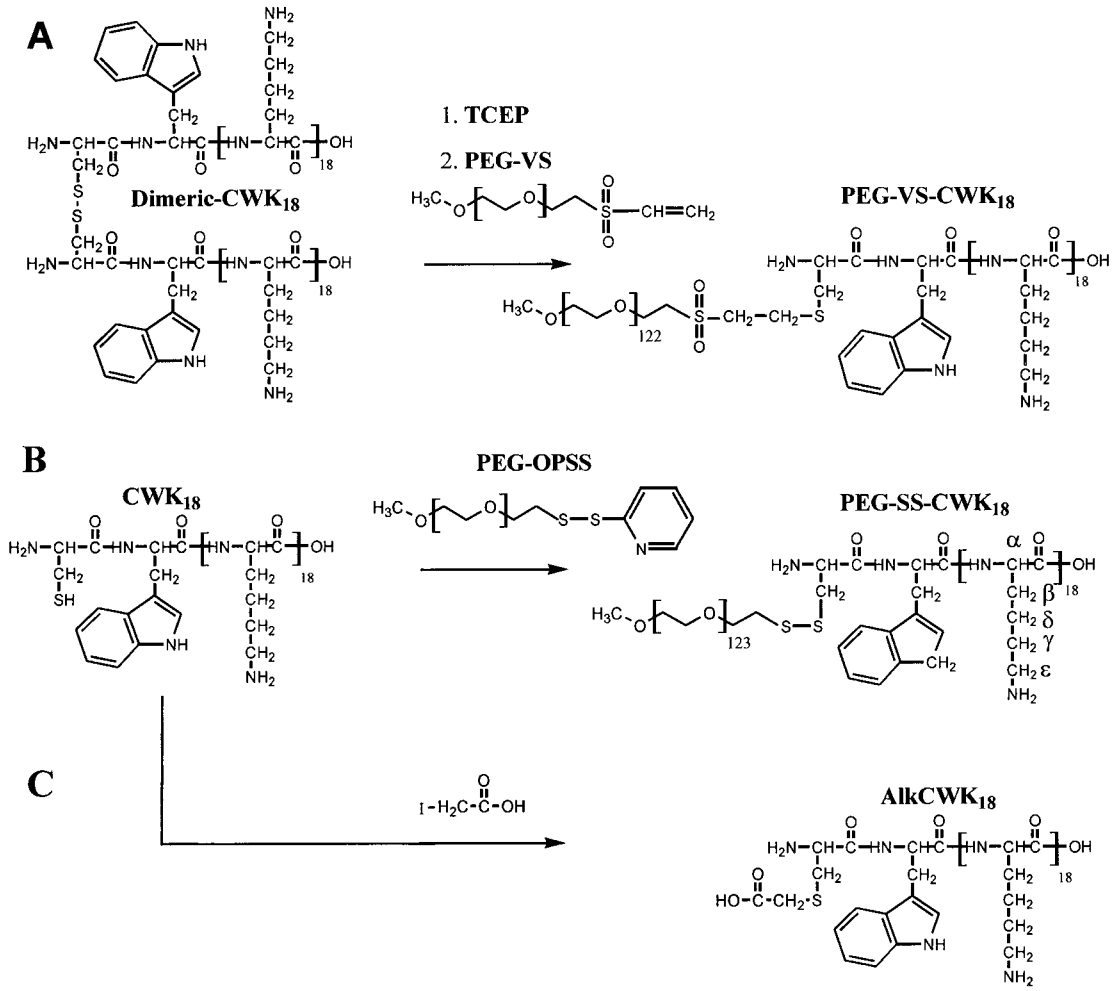

Figure 1—Reaction schemes for the synthesis of PEG-CWK_{18} conjugates. (A) TCEP was used to reduce dimeric-CWK_{18} to generate CWK_{18}. This was reacted in situ with PEG-VS to form PEG-VS-CWK_{18}. (B) Alternatively, the reaction of CWK_{18} with PEG-OPSS formed PEG-SS-CWK_{18}. (C) AlkCWK_{18} was produced by reacting CWK_{18} with iodoacetic acid. The α, β, γ, δ, and ϵ protons of Lys of PEG-SS-CWK_{18} illustrate the nomenclature used for assigning PEG-peptides in Figure 3.

Results

PEG-Peptide Synthesis—PEG was covalently attached to the Cys residue of a 20 amino acid synthetic peptide (CWK_{18}) to prepare two PEG-peptides possessing either a reversible (PEG-SS-CWK_{18}) or irreversible (PEG-VS-CWK_{18}) covalent linkage (Figure 1). Each reaction was optimized by systematically changing the pH and the stoichiometry of peptide to PEG while monitoring the product formation by analytical RP-HPLC. Since the reaction of CWK_{18} with PEG-VS at pH 7 was slow (12 h), TCEP was added to reduce dimeric-CWK_{18} and also inhibit its re-formation during conjugation with PEG-VS. At pH 7, a mol ratio of PEG-VS:CWK_{18} of 30:1 resulted in optimal conjugation to form PEG-VS-CWK_{18}. At suboptimal stoichiometries or lower pH the reaction was incomplete whereas at a higher pH, dimeric-CWK_{18} re-formed as the major product.

In contrast to the synthesis of PEG-VS-CWK_{18}, the optimal reaction conditions to prepare PEG-SS-CWK_{18} only required a 4 mol excess of PEG-OPSS over CWK_{18} at pH 7. In this case, attempts to block the formation of dimeric-CWK_{18} with TCEP led to the reduction of PEG-OPSS, completely inhibiting the desired reaction. Instead, reduced CWK_{18} was prepared and found to react rapidly (30 min) with PEG-OPSS with minimal formation of dimeric-CWK_{18}.

RP-HPLC analysis of the crude reaction product of PEG-VS-CWK_{18} demonstrated a nearly complete disappearance of CWK_{18} with the formation of a new peak eluting at 25 min (Figure 2B). Despite the apparent complete resolution of the desired product, careful examination revealed that PEG-VS coeluted with PEG-VS-CWK_{18}. This was evident from NMR analysis which determined a 10-fold excess of PEG relative to CWK_{18} in the HPLC purified product (data not shown). Consequently, PEG-VS-CWK_{18} was purified using cation exchange to remove excess PEG-VS and then by RP-HPLC to remove unreacted CWK_{18} resulting in a product that rechromatographed as a single peak on RP-HPLC (Figure 2D). Proton NMR analysis identified resonances assigned to the α, β, γ, δ, and ϵ protons of the Lys residues as well as the Trp aromatic resonances (Figure 3A). Integration of protons at 3.67 ppm (PEG) relative to the signal at 2.97 ppm (Lys ϵ) produced a peak area ratio of 13.5:1 corresponding to a 1:1 conjugate of PEG_{122} and CWK_{18}.

RP-HPLC analysis of the crude reaction product of PEG-OPSS and CWK_{18} identified a product peak eluting at 25 min, a PEG-OPSS reagent peak at 28 min, a thiol pyridine (TP) byproduct peak at 5 min, and a trace of dimeric-CWK_{18} eluting at 15 min (Figure 2C). PEG-SS-CWK_{18} was isolated in a single step by semipreparative RP-HPLC, rechromatographed as a single peak on analytical HPLC (Figure 2E), and produced an NMR spectrum with an integration ratio of PEG:Lys also establishing a 1:1 conjugate of PEG_{123} and CWK_{18} (Figure 3B).

MALDI-TOF analysis of PEG-VS-CWK_{18} and PEG-SS-CWK_{18} produced a broad peak centered at 8433 and 8297

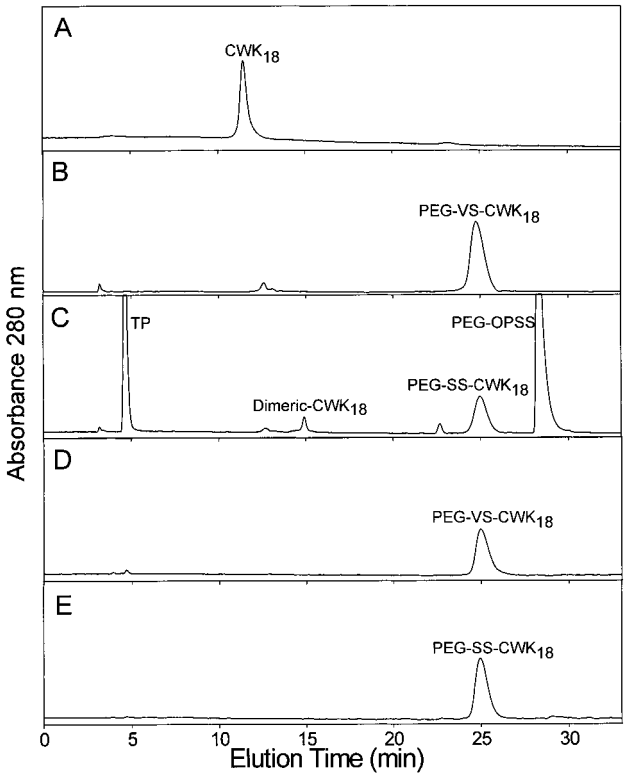

Figure 2—Analytical RP-HPLC analysis of PEG-CWK_{18} conjugates. The reaction of dimeric-CWK_{18} with TCEP and PEG-VS formed a single major product as shown in panel B. Alternatively, reduced CWK_{18} (panel A) reacted with PEG-OPSS to produce PEG-SS-CWK_{18}, dimeric-CWK_{18}, thiol-pyridine (TP), and unreacted PEG-OPSS as shown in panel C. Purified PEG-VS-CWK_{18} and PEG-SS-CWK_{18} both eluted as a single peak as shown in panels D and E, respectively.

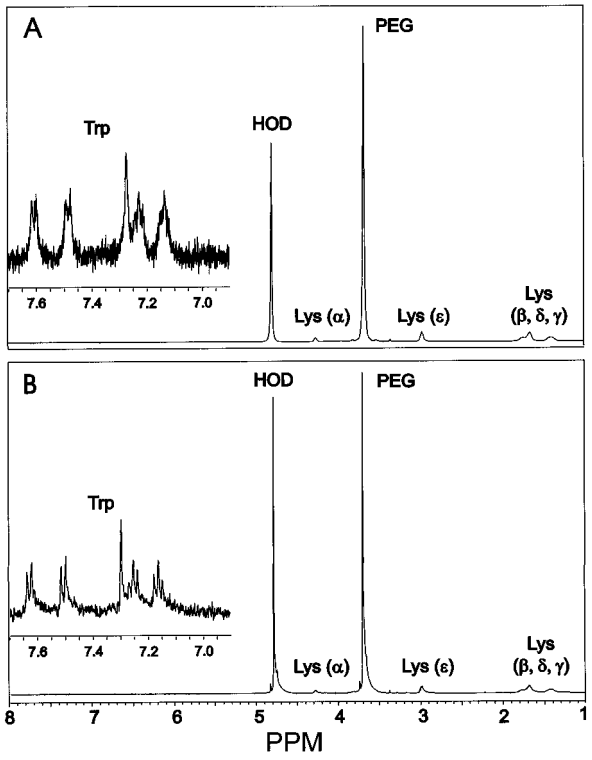

Figure 3—^{1}H NMR analysis of PEG-CWK_{18} conjugates. The 500 MHz ^{1}H NMR spectrum of PEG-VS-CWK_{18} (panel A) and PEG-SS-CWK_{18} (panel B) are illustrated with the key signals of the Lys, Trp and PEG identified according to Figure 1. The integration of the ϵ protons of Lys relative to the PEG protons established a degree of polymerization of 122 for PEG-VS-CWK_{18} and 123 for PEG-SS-CWK_{18}.

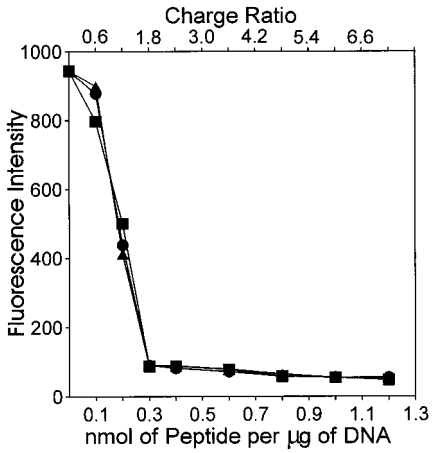

Figure 4—Relative binding affinity of PEG-CWK_{18} conjugates to DNA. The fluorescence intensity resulting from the titration of AlkCWK_{18} (●), PEG-SS-CWK_{18} (■), and PEG-VS-CWK_{18} (▲) to compete for intercalator dye binding to DNA is shown. An asymptote at 0.3 nmol of each peptide per μg of DNA established that each peptide binds to DNA with equivalent affinity.

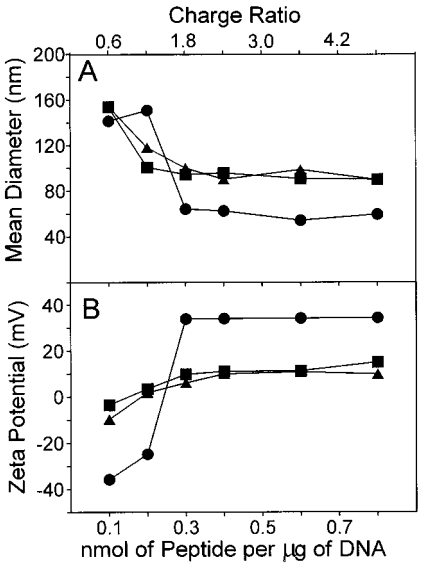

Figure 5—QELS particle size and ζ potential analysis of PEG-CWK_{18} DNA condensates. The mean particle size of AlkCWK_{18} (●), PEG-SS-CWK_{18} (■), and PEG-VS-CWK_{18} (▲) DNA condensates is plotted as a function of peptide:DNA stoichiometry in panel A. The mean ζ potential for each DNA condensate is plotted in panel B. An indistinguishable particle size and ζ potential was determined for each PEG-CWK_{18} conjugate. However, a significant decrease in the ζ potential for PEG-CWK_{18} DNA condensates (+10 mV) versus AlkCWK_{18} DNA condensates (+35 mV) provided evidence of the formation of a steric barrier.

m/z, respectively. These results were consistent with the formation of conjugates of CWK_{18} (2648 amu) and polydisperse PEG of approximately 5800 Da.

PEG-Peptide DNA Condensate Formulation—The DNA binding affinity of AlkCWK_{18}, PEG-VS-CWK_{18}, and PEG-SS-CWK_{18} were compared using a fluorescent dye displacement assay. A coincident titration curve for each peptide with an asymptote at 0.3 nmol per μg of DNA corresponding to a charge ratio of 1.8:1 suggested that both PEG-peptides bind to DNA with equivalent affinity as AlkCWK_{18} (Figure 4).

The particle size and ζ potential of DNA condensates prepared with AlkCWK_{18}, PEG-VS-CWK_{18}, and PEG-SS-CWK_{18} were examined as a function of peptide:DNA stoichiometry (Figure 5). The mean diameter for both PEG-peptide DNA condensates was 90 nm at a charge ratio of 1.8:1 or higher whereas the mean diameter for AlkCWK_{18}

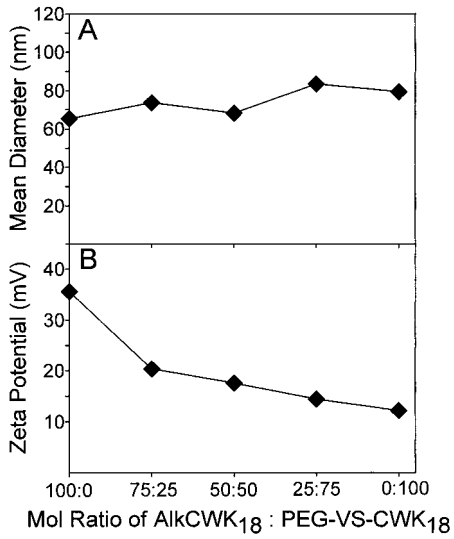

Figure 6—QELS particle size and ζ potential analysis of peptide DNA cocondensates. Particle size analysis was used to characterize peptide DNA cocondensates prepared at 50 μg/mL of DNA and varying mol % of $AlkCWK_{18}$ and PEG-VS-CWK_{18} as shown in panel A. The ζ potential of DNA cocondensates is shown in panel B. The mean particle size changes from 65 to 80 nm whereas the ζ potential of DNA cocondensates decreases from +35 to +10 mV with increasing mol % of PEG-VS-CWK_{18}.

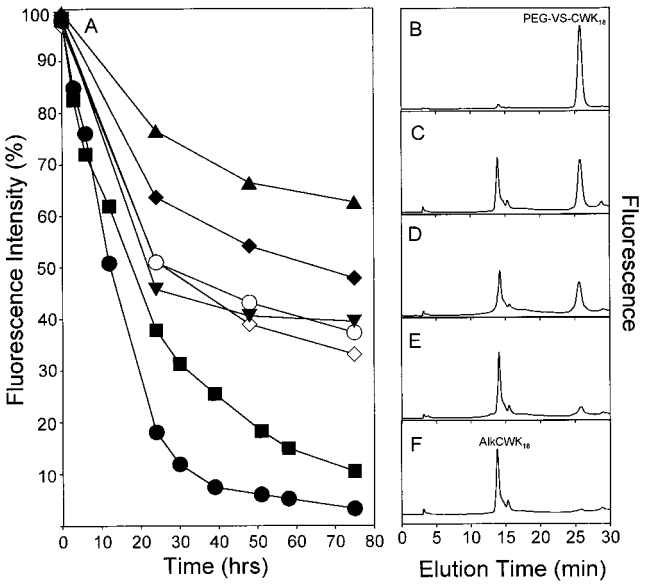

Figure 7—RP-HPLC analysis of peptide DNA cocondensates. The time course of dialysis of free $AlkCWK_{18}$ (●), free PEG-VS-CWK_{18} (■), $AlkCWK_{18}$ DNA condensates (▼), PEG-VS-CWK_{18} DNA (▲), and cocondensates of 25:75 (◆), 50:50 (○), 75:25 (◇) mol % of $AlkCWK_{18}$:PEG-VS-CWK_{18} bound to DNA was determined by tryptophan fluorescence of the retentate (panel A). After 75 h of dialysis, peptide DNA condensates in the retentate were dissociated with sodium chloride and directly chromatographed on RP-HPLC. Panels B–F illustrate chromatograms resulting from 100 mol % PEG-VS-CWK_{18} DNA condensates (panel B), DNA cocondensates prepared with 75:25 (panel C), 50:50 (panel D), 25:75 (panel E) PEG-VS-CWK_{18}:$AlkCWK_{18}$, and 100 mol % $AlkCWK_{18}$ DNA condensates (panel F).

DNA condensates was 60 nm (Figure 5A). In contrast, a large decrease in ζ potential of +25 mV was identified for PEG-peptide DNA condensates at a charge ratio of 1.8:1 compared to $AlkCWK_{18}$ DNA condensates (Figure 5B).

Since PEG-VS-CWK_{18} and $AlkCWK_{18}$ possess equivalent DNA binding affinity, add-mixtures of the two peptides were used to prepare DNA cocondensates. The average particle size increased from 65 to 80 nm using add-mixtures of $AlkCWK_{18}$ and PEG-VS-CWK_{18} varying from 0 to 100 mol % while keeping the charge ratio constant at 2.3:1

Table 1—Quantitative Analysis of DNA Cocondensates

input add-mixture (mol % $AlkCWK_{18}$: mol % PEG-VS-CWK_{18})	recovery ratio[a] (mol % $AlkCWK_{18}$: mol % PEG-VS-CWK_{18})
0:100	0:100
25:75	41:59
50:50	59:41
75:25	82:18
100:0	100:0

[a] Based on HPLC standard curves developed for $AlkCWK_{18}$ and PEG-VS-CWK_{18}.

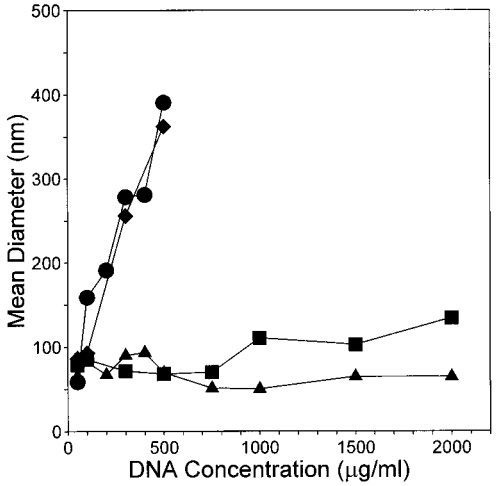

Figure 8—Solubility of peptide DNA condensates. Particle size analysis was performed as a function of DNA concentration using 100 mol % $AlkCWK_{18}$ (●) and 100 mol % PEG-VS-CWK_{18} (▲) DNA condensates and using $AlkCWK_{18}$:PEG-VS-CWK_{18} DNA cocondensates prepared with 50 (◆) and 90 (■) mol % PEG-VS-CWK_{18}. The particle size increased to >400 nm above 500 μg/mL for $AlkCWK_{18}$ DNA condensates but remained at <100 nm for PEG-VS-CWK_{18} DNA condensates throughout concentrations up to 2 mg/mL.

(Figure 6A). Likewise, the ζ potential decreased from +35 mV to +10 mV as the stoichiometry of PEG-VS-CWK_{18} increased (Figure 6B), suggesting the formation of DNA cocondensates with intermediate PEG loading.

To further confirm the formation of DNA cocondensates, unbound peptides were removed by microdialysis and the ratio of peptides bound to DNA was determined by HPLC. Control experiments established the nearly complete removal (>90%) of free $AlkCWK_{18}$ or PEG-VS-CWK_{18} from the retentate after 75 h of dialysis (Figure 7A). However, the dialysis of DNA cocondensates prepared at charge ratios of 2.3:1 resulted in the removal of unbound peptide and retention of >35% of the tryptophan fluorescence. Dissociation and RP-HPLC analysis of the retained peptide (Figure 7B–F) allowed recovery of $AlkCWK_{18}$ and PEG-VS-CWK_{18} at ratios that agreed to within 16% of the input ratio for each DNA cocondensate (Table 1) in which the loss of PEG-VS-CWK_{18} was greater than that of $AlkCWK_{18}$.

DNA condensate solubility was evaluated by examining the particle size of concentrated solutions. $AlkCWK_{18}$ DNA condensates increased in particle size from 60 to 400 nm when increasing DNA concentration from 50 to 500 μg/mL and then formed visible flocculates at higher concentrations. Alternatively, PEG-VS-CWK_{18} DNA condensates maintained a mean diameter of <100 nm throughout concentrations ranging from 0.05 to 2 mg/mL and showed no sign of increasing in size (Figure 8). Likewise, substitution of PEG-SS-CWK_{18} for PEG-VS-CWK_{18} resulted in the formation of DNA condensates with 88 nm mean diameter at 2 mg/mL.

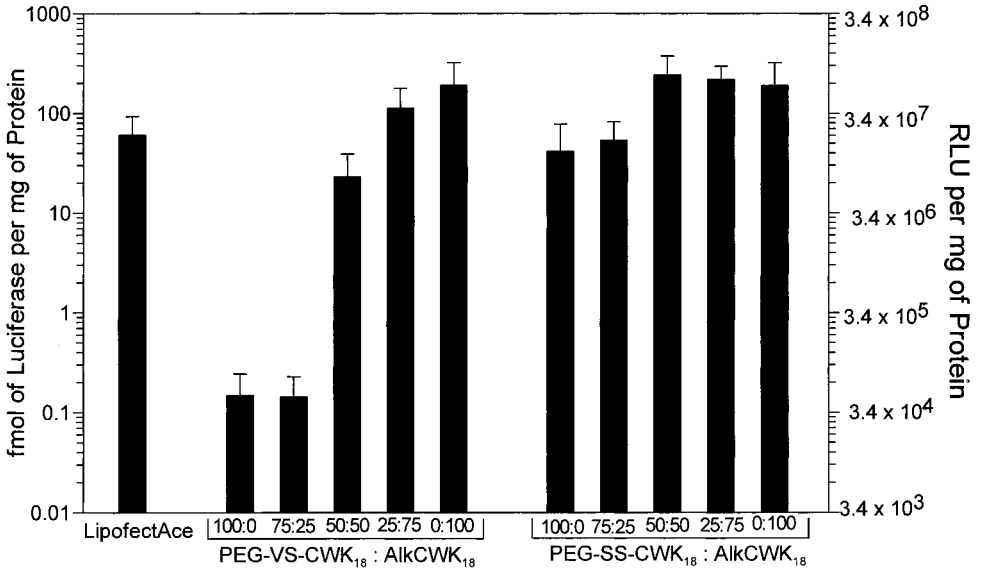

Figure 9—In vitro gene transfer efficiency of PEG-CWK_{18} DNA condensates. The in vitro expression of luciferase in HepG2 cells is compared for PEG-VS-CWK_{18} and PEG-SS-CWK_{18} as well as cocondensates prepared with $AlkCWK_{18}$ at the ratios indicated. LipofectAce is included as a control gene transfer agent.

DNA cocondensates containing 50 mol % PEG-VS-CWK_{18} and $AlkCWK_{18}$ possessed similar poor solubility properties to that of 100 mol % $AlkCWK_{18}$ DNA condensates. However, DNA cocondensates composed of 90 mol % PEG-VS-CWK_{18} and 10 mol % $AlkCWK_{18}$ also maintained a particle size of <100 nm up to 750 μg/mL and then formed larger particles (>100 nm) at DNA concentrations of 1 mg/mL or higher (Figure 8).

DNA condensates prepared with PEG-VS-CWK_{18}, PEG-SS-CWK_{18}, $AlkCWK_{18}$, and add-mixtures of $AlkCWK_{18}$ and PEG-peptides were compared by measuring luciferase expression in HepG2 cells 24 h post-transfection (Figure 9). PEG-VS-CWK_{18} DNA condensates reduced spontaneous gene transfer by three orders of magnitude compared to $AlkCWK_{18}$ DNA condensates. The reduction was only 10-fold when transfecting with DNA cocondensates prepared with 50 mol % PEG-VS-CWK_{18} and only 2-fold using cocondensates composed of 25 mol % PEG-VS-CWK_{18} (Figure 9).

The gene transfer properties of PEG-SS-CWK_{18} DNA condensates were significantly different than PEG-VS-CWK_{18} DNA condensates. DNA condensates prepared with 100 or 75 mol % PEG-SS-CWK_{18} reduced spontaneous gene transfer by 5-fold relative to $AlkCWK_{18}$ DNA condensates while DNA cocondensates prepared with 50 or 25 mol % of PEG-SS-CWK_{18} were equivalent to $AlkCWK_{18}$ DNA condensates (Figure 9).

The cell binding of ^{125}I-DNA was compared for $AlkCWK_{18}$, PEG-VS-CWK_{18}, and PEG-SS-CWK_{18} DNA condensates during a 5 h transfection. Approximately 14% of the radioactivity was cell-associated for $AlkCWK_{18}$ DNA condensates whereas only 6.8% and 0.2% were cell-associated when using PEG-SS-CWK_{18} and PEG-VS-CWK_{18} as DNA condensing agents, respectively (Figure 10). These results correlated well with the observed gene transfer efficiency for each peptide DNA condensate, suggesting differences in the uptake of these condensates was the main cause of their difference in gene expression.

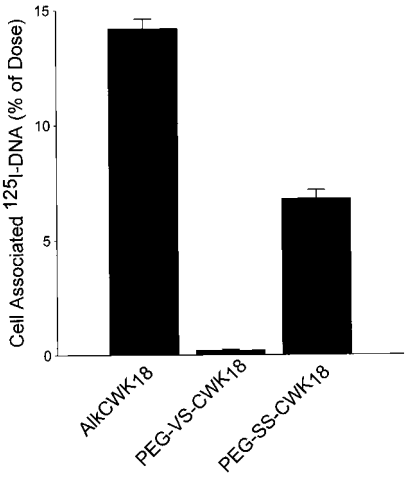

Figure 10—HepG2 cell binding of peptide DNA condensates. HepG2 cells were transfected for 5 h with 45 nCi (10 μg) of ^{125}I-DNA condensates prepared with either $AlkCWK_{18}$, PEG-VS-CWK_{18}, or PEG-SS-CWK_{18}. The cell associated DNA recovered is expressed as the percent of ^{125}I-DNA dosed onto cells. The results represent the mean ± SD for three determinations.

Discussion

The targeting of DNA to specific cells in vivo for the purpose of mediating therapeutically relevant levels of gene expression will require systematic optimization of the drug delivery system.[23] The design of such delivery systems must attempt to minimize the carrier's toxicity and antigenicity, increase the DNA's metabolic stability, control the particle size and charge, and increase the DNA condensate solubility as well as provide a means to target DNA to the nucleus of the cell. Thus far, PEG-peptides have been reported to decrease toxicity,[11–13] increase DNA stability,[14,17] and improve DNA solubility.[12] In the present study we report the synthesis of two PEG-peptides that simultaneously create very soluble DNA condensates and significantly inhibit spontaneous gene transfer of peptide DNA condensates in vitro. A major finding is that both of these properties are influenced to different degrees by the load level of PEG on DNA condensates.

The directed synthesis of the low molecular weight PEG-peptides reported here is a major distinction of this work compared to others. The conjugation of PEG (5000 Da) to a single cysteine of CWK_{18} afforded highly purified PEG-peptides that controlled the PEG attachment site and allowed comparison of reducible and nonreducible linkages. Notably, the apparent binding affinity of both PEG-peptides for DNA were equivalent to $AlkCWK_{18}$ as determined by the intercalator exclusion assay (Figure 4),

indicating that conjugates of CWK_{18} retain their ability to bind and condense DNA. Due to the homogeneity of the peptide portion of PEG-VS-CWK_{18} and PEG-SS-CWK_{18}, DNA condensates formed at charge ratios of 1.8:1 or higher achieved a constant particle size and ζ potential, establishing both the absence of interfering peptides and that excess PEG-peptide does not bind to fully condensed DNA.

ζ potential measurements revealed evidence that PEG-peptides altered the surface properties of DNA condensate. The ζ potential of PEG-VS-CWK_{18} and PEG-SS-CWK_{18} DNA condensates were indistinguishable and reached a minimum of +10 mV at a calculated charge ratio of 1.8:1 (Figure 5B). The decrease in ζ potential resulted from the covalent attachment of PEG since the addition of equivalent amounts of free PEG to AlkCWK_{18} DNA condensates did not influence its ζ potential (data not shown). Likewise, analysis of DNA cocondensates established a correlation between the ζ potential and the mol % of PEG-VS-CWK_{18} incorporated into the cocondensate (Figure 6B). The recovery of the approximate input ratio of AlkCWK_{18} and PEG-VS-CWK_{18} following prolonged dialysis confirmed the formation of DNA cocondensates. This allowed add-mixing of two condensing peptides (AlkCWK_{18} and PEG-VS-CWK_{18}) to systematically alter both physical and biological properties of peptide DNA condensates.

The formation of a steric layer is highly dependent on the amount PEG loaded onto DNA condensates.[10,12] This is most evident with DNA cocondensates possessing between 0 and 25 mol % PEG-peptide where the ζ potential decreased sharply to +20 mV and then only declined gradually to reach +10 mV at 25−100 mol % PEG-peptide. Even though the ζ potential only changed by +10 mV when titrating between 25 and 100 mol % of PEG-peptide (Figure 6B), these DNA condensates were most altered in solubility and gene transfer efficiency.

The solubility achieved for 100 mol % PEG-peptide DNA condensates (2 mg/mL) is far greater than the solubility reported (60 μg/mL) for other PEG-peptides DNA condensates.[12] This physical property appears to be very dependent on the loading density of PEG since cocondensates prepared with 50 mol % PEG-VS-CWK_{18} were not improved in solubility relative to AlkCWK_{18} DNA condensates. Even cocondensates formed with as much as 90 mol % PEG-VS-CWK_{18} demonstrated an increase in particle size at concentrations greater than 750 μg/mL, indicating that even slightly less PEG on the DNA condensate will result in lower solubility.

Earlier studies demonstrated that the in vitro gene transfer efficiency for peptide DNA condensates was dependent on the charge ratio.[19,24] The expression reached a maximum when AlkCWK_{18} DNA condensates were formed at charge ratio of 1.8:1 or higher, suggesting that the positive charge on DNA condensates contributes to their spontaneous transfection in cell culture. In support of this hypothesis, fully condensed PEG-VS-CWK_{18} DNA condensates prepared at a charge ratio of 2.3:1 possess a lower ζ potential of +10 mV and reduced spontaneous gene transfer by 1000-fold compared to AlkCWK_{18} DNA condensates. Likewise, DNA cocondensates possessing intermediate ζ potential partially reduced gene transfer, further demonstrating a correlation between DNA condensate charge and the level of spontaneous gene transfer. However, these data also established that the PEG load level needed to block spontaneous gene transfer in vitro is much lower than that required to create soluble PEG-peptide DNA condensates.

Even though PEG-VS-CWK_{18} and PEG-SS-CWK_{18} DNA condensates were equivalent in their physical properties, they proved to be unequivalent in their ability to reduce spontaneous gene transfer (Figure 9). Since the two peptides only differ in their linkage between PEG and peptide, a possible explanation was the reduction of PEG-SS-CWK_{18} either outside or inside the cell to form CWK_{18} DNA condensates during the time of transfection. To test this hypothesis, radioiodinated DNA condensates were used to determine the percent cell associated after a 5 h transfection (Figure 10). PEG-VS-CWK_{18} DNA condensates did not significantly bind to cells, with only 0.2% of the dose being cell associated. In contrast, 14% of AlkCWK_{18} DNA condensates and 6.8% of PEG-SS-CWK_{18} DNA condensates dose were cell-associated following 5 h transfection, supporting the hypothesis that differences in cell uptake are responsible for the 2 orders of magnitude difference in gene expression mediated by PEG-SS-CWK_{18} and PEG-VS-CWK_{18} DNA condensates. To determine if PEG-SS-CWK_{18} underwent reduction during gene transfer, its stability was analyzed while incubating in cell culture media containing 2% FCS. This led to its partial reduction over time (data not shown), suggesting that the removal of PEG by disulfide bond scission results in the formation of CWK_{18} DNA condensates in situ and is a likely explanation of the difference between PEG-SS-CWK_{18} and PEG-VS-CWK_{18} DNA condensates.

Therefore, the utility of PEG-SS-CWK_{18} may be in generating soluble DNA condensates that can be formulated within a gene-activated matrix intended for implantation in which targeting is not necessary and spontaneous transfection of infiltrating cells is desired.[25] Alternatively, the greater stability of PEG-VS-CWK_{18} may result in its utility in modifying the surface of DNA condensates used during intravenous gene delivery.

Future studies will demonstrate the utility of PEG-peptides in gene activated matrixes and in altering the biodistribution of DNA condensates in vivo. The ability to form DNA cocondensates that incorporate both PEG and targeting ligands attached to CWK_{18} may provide a unique approach to systematically optimize gene delivery formulations for maximum efficacy in vivo.

Abstract □ To make rapidly disintegrating tablets with sufficient mechanical integrity, tablets were prepared by compressing wet granules under low compression force and then drying the resulting wet mass in a circulating-air oven (wet compression method). Lactose with various particle sizes was used as the excipient, and water was used as a wetting agent. The effect of drying time, compression force, size of lactose particles, and moisture content of wet granules on tablet properties indicated that the formation and disintegration time of tablets were related to the effect of the formation of solid bridges between lactose particles. By optimizing compression force, size of lactose particles, and moisture content of the granules, tablets meeting tensile strength greater than 0.5 MPa and disintegration time shorter than 15 s were obtained by the wet compression method.

Introduction

Due to a decline in swallowing ability with age, a great many elderly patients complain that it is difficult for them to take some currently used dosage forms such as tablets, capsules, or powders.[1] For this reason, tablets which can rapidly dissolve or disintegrate in the oral cavity have attracted a great deal of attention. Rapidly dissolving or disintegrating tablets are not only indicated for people who have swallowing difficulties, but also are ideal for active people.

Commercially available rapidly dissolving or disintegrating tablets are obtained by various methods.[2−4] Fast disintegrating tablets were developed using wet powders containing drugs. Such tablets were produced by two methods, compression[4] and molding.[5] The preparation processes are usually as follows: after blending the excipient with the drug, the powder mixture is moistened with solvent. The resultant wet powder will then be molded or compressed under low compression force, and after drying in ambient air or an oven, the desired tablets will be obtained. The most commonly used solvent is aqueous alcohol, although other volatile solvents such as acetone and hydrocarbons have also been used. To increase the hardness and reduce erosion of the edges of the tablets during handling, binding agents such as glucose, sucrose, acacia, or povidone are usually added to the solvent mixture.

As volatile solvents are often used, it is difficult to protect the wet mass from solvent evaporation. Therefore, the moisture content of the wet mass is prone to become uneven, which will result in poor uniformity of the tablets. The binding agent must also be added with care, since if used in excessive amounts such agents can markedly decrease the rate of disintegration of the tablets.

particle density (g/cm^3)	1.52	1.52	1.52

[a] Heywood diameter (n = 500). [b] Shape factor (SF) represents sphericity of particles (when particle is spherical, SF = 1). ML: maximum length of particle, A: projection area of particle (n = 500).

Previously, we developed rapidly disintegrating tablets by a direct compression method.[6−8] In the present study, we prepared rapidly disintegrating tablets by the wet compression method using lactose as the excipient. The objective of the study was to delineate the mechanism of formation and rapid disintegration of the tablets prepared by the wet compression method.

Experimental Section

Excipient and Its Physical Properties—α-Lactose monohydrate with various particle sizes (Pharmatose 80M, 200M, and 450M, DMV Co., Holland) was used as the excipient. Its particle density was measured with a helium−air pycnometer (Model 1302, Micromeritics Instrument Co., Norcross, GA). Heywood diameter and shape factor, SF, were determined with an image analyzer (Luzex 500, Nireco Co., Japan). Data are listed in Table 1.

Preparation of Tablets—Kneading was performed in a multipurpose powder handling mill (MECHANOMiLL, Okada Seiko, Co., Ltd., Japan) with the rotation speed of the paddles fixed at 2000 rpm. Distilled water was added to 50 g of lactose powder in milliliter increments, and then the powder was agitated for 60 s. To ensure moisture homogeneity of the mixture, water addition and agitation processes were conducted alternately until the moisture content of the powder mass reached a predetermined value.

The wet powder mass was then extruded through a sieve with a pore size of 710 μm into a container which was then covered with a wet paper towel. The wall of the container was high enough to prevent the wet granules coming into direct contact with wet paper towel. Wet granules were then compressed into flat-faced tablets 10 mm in diameter using a hydraulic press (O. J. Shop, press model 10, Osaka Jack MFG. Co., Japan). The necessary weight of wet granules was calculated from the true density of dry powder and the moisture content of the wet mass to make tablets with a dry weight of 300 mg. The wet tablets were dried in a circulating-air oven at 60 °C. After drying, the tablets were kept in a desiccator for 12 h at room temperature before testing of tablet properties.

Moisture Evaporation of Wet Granules—Wet lactose (450M) granules with a moisture content of 10% were placed in desiccators at 25 °C, each containing a different saturated solution of inorganic salt.[9] The samples were weighed every 10 min, and the moisture loss at each relative humidity (RH) was calculated. The moisture loss of wet granules kept in a container covered with a wet paper towel (our manufacturing humidity conditions) was measured by the same method.

Differential Scanning Calorimetry (DSC)—Samples (10 mg) were analyzed in crimped vented aluminum pans using a MAC Science 3100 type differential scanning calorimeter. Thermographs were recorded over a temperature range of 30−200 °C, with a scanning rate of 10 °C min^{-1}.

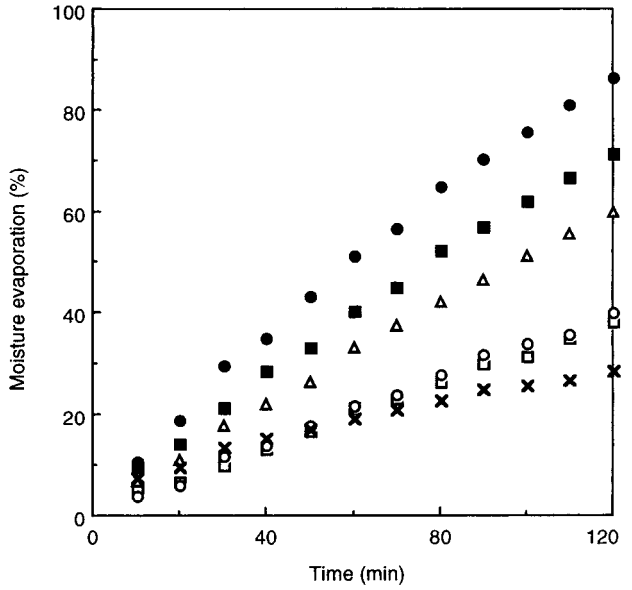

Figure 1—Water evaporation curves of lactose wet granules under various humidity conditions. Relative humidity: □ 100%, ○ 93%, △ 84%, ■ 75%, ● 61.8%, × water evaporation under our manufacturing humidity conditions.

Measurement of Tablet Tensile Strength—The tablet crushing load, which is the force required to break a tablet into halves by compression in the diametral direction, was measured using a tablet hardness tester (TS-50N, Okada Seiko Co., Ltd., Japan). The plunger was driven down at a speed of 20 mm/min. Tensile strength for crushing (T) was calculated using the following equation:

$$T = 2F/(\pi d h) \quad (1)$$

where F is the crushing load, and d and h denote the diameter and thickness of the tablet, respectively.

Measurement of Tablet Porosity—Tablet porosity ϵ was calculated as follows:

$$\epsilon = 1 - m/(\rho_t V) \quad (2)$$

where ρ_t is the true density and m and V are the weight and volume of the tablet, respectively.

Measurement of Disintegration Time—The disintegration test was performed using a JP 13 disintegration apparatus, using distilled water at 37 ± 1 °C.

All tablet property values are shown as averages of five determinations.

Results

Moisture Evaporation of Wet Lactose Granules under Various Humidity Conditions—The moisture content of wet granules markedly affected the properties of the resultant tablets (discussed later). Thus, it is necessary to regulate the ambient humidity to protect the wet granules from moisture evaporation during the tableting process. In our experiments, a wet paper towel covering on the container of wet granules was used for this purpose. Figure 1 shows the evaporation curves of wet granules under various humidity conditions.

The evaporation data of wet granules under our manufacturing humidity conditions are shown as crosses. Moisture evaporation percentage under such conditions was a little larger than that at 93% RH within 40 min, but after 50 min the moisture loss showed values even smaller than that at 100% RH. In our experiments, the tableting process finished within 20 min, during which time less than 10% of the moisture would be lost. In contrast, the moisture loss of wet granules at 61.8% RH was twice as fast as that under our manufacturing humidity conditions. The tablet

Tablets used were the same as those described in Figure 2.

properties determined in our experiments showed small relative standard deviation (RSD) values, which confirmed that although a very simple procedure, covering the container with a wet paper towel is an effective method to slow the moisture evaporation rate.

Effects of Drying Time on the Properties of Tablets—The effects of drying time on porosity, tensile strength, and disintegration time of tablets were evaluated, and the results are shown in Figure 2. No obvious changes in tablet properties were found with increases in drying time.

DSC curves of α-lactose monohydrate raw powder and tablets dried for 1, 3, 10, and 24 h are shown in Figure 3. All samples showed an endothermic peak at about 152 °C, corresponding to the dehydration (elimination of crystal water) of α-lactose monohydrate crystals. Lactose raw

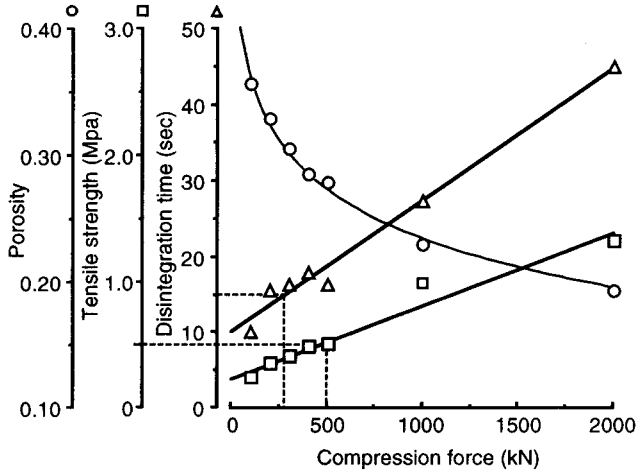

Figure 4—Effects of compression force in tablet porosity. Lactose: 450M; moisture content of wet granules: 8.56%. Dotted lines showed the compression forces corresponding to the tensile strength of 0.5 MPa and disintegration time of 15 s.

powder and tablets with a drying time of 1 h showed a shoulder peak before the endothermic peak of crystal water, suggesting that the two samples contained absorbed water. The DSC results were in agreement with the report of Lerk.[10] According to this report, an unstable anhydrous product was formed when α-lactose monohydrate crystals were heated at temperatures of 100−130 °C. When heated at temperatures below 100 °C, α-lactose monohydrate crystals do not undergo any change. The drying temperature (60 °C) was far lower than 100 °C, and hence drying time had almost no effect on the crystal water of α-lactose monohydrate. Although absorbed water was present in 1 h dried tablets, its amount was too little to affect the properties of the tablets (Figure 2).

The changes in tablet weight with drying time were also measured. After drying for 3 h, tablet weight became constant. Hence, in the following experiments, all tablets were dried at 60 °C for 3 h.

Effects of Compression Force in Tablet Properties—Properties of tablets compressed at 100−2000 kN were investigated. With the increase in compression force, a decrease in porosity and increases in tensile strength and disintegration time were observed (Figure 4). Furthermore, both tensile strength and disintegration time showed linear relationships with the logarithm of tablet porosity (Figure 5).

Compression forces corresponding to our requirements for rapidly disintegrating tablets, i.e., tensile strength greater than 0.5 MPa and disintegration time shorter than 15 s, were found (Figure 4). The results were >500 kN and <280 kN, respectively; i.e., no conditions meeting the requirements were found. Although compression force is a very important factor regulating tablet properties, it is not the only such factor. To obtain tablets with desirable properties, the effects of other factors on tablet properties were investigated. Here, because tablets prepared under 500 kN had a disintegration time of shorter than 20 s, which is close to the requirement, in the following section tablets were prepared under 500 kN.

Effects of Moisture Content and Particle Size on the Properties of Tablets and Optimization of the Two Factors—Besides compression force, many factors affect properties of wet compressed tablets. Among these, particle size and shape of raw materials and moisture content of wet granules are supposed to be the most important. Consequently, lactoses with various particle sizes were used. Wet granules with various moisture contents were made into 14 kinds of tablets to evaluate the effects of factors other than compression force on tablet properties. The shapes of the lactose particles with various sizes were almost the same (see Table 1). Therefore, particle size of lactose and moisture content of wet granules were selected as controlling factors, tablet tensile strength and disintegration time were selected as response variables, and a polynomial regression algorithm was used to relate the controlling factors to the response variables.

The values of 14 groups of controlling factors and response variables are listed in Table 2, and the resultant multiple regression equations are as follows:

$$T_s = -0.1426x + 0.1540y - 0.0312xy + 0.5736 \quad (3)$$

$$N = 14 \quad R^2 = 0.968 \quad T < 0.05 \quad F(3,10) = 10.4842$$

$$\mathrm{Dis} = -10.328x + 15.625y + 18.683 \quad (4)$$

$$N = 14 \quad R^2 = 0.563 \quad T < 0.05 \quad F(2,11) = 7.093$$

Where T_s is tablet tensile strength (MPa), Dis is the disintegration time (s). x and y stand for the transformed

particle size and moisture content, respectively, and the transformation was processed using the method described in our previous report.[7] N is the number of samples, and R is the multiple correlation coefficient. T denotes the P value determined by Student's t-test, and F, that obtained by F-test. Student's t-test showed that coefficients for all the components on the right side of eqs 3 and 4 were highly significant ($P < 0.05$).

In the multiple regression equation of disintegration time, the multiple correlation coefficient R was not very large. Therefore, an artificial neural network (ANN) was also constructed by Takayama's method to relate the controlling factors to the response variables.[11–13] Three-dimensional surface plots based on multiple regression and ANN are shown in Figures 6 and 7, respectively. The surface plots of tensile strength obtained by multiple regression analysis and ANN were almost the same. In detail, tensile strength increased with increases in moisture content. When moisture content was constant, tablets made of small lactose particles showed higher tensile strength. Disintegration time increased with increases in moisture content and decreases in particle size, which is analogous to the tendency of tensile strength. Although the tendencies of disintegration plots obtained by the two methods were similar, the disintegration plot obtained by ANN method more accurately reflected the experimental data.

Disintegration time showed a similar tendency to tensile strength with the changes in particle size and moisture content. However, the requirements of tensile strength and disintegration time of rapidly disintegrating tablets are the converse of this tendency. A rapidly disintegrating tablet should disintegrate rapidly in the mouth, while having sufficient structural integrity to withstand handling without substantial breakage. To find suitable tableting conditions under which desired tablets could be obtained, contour plots response to surface plots in Figure 7a,b were also constructed and are shown in Figure 8a,b. With 0.5 MPa as the minimum expected tensile strength, and 15 s as the maximum expected disintegration time, we superimposed the contour plots and obtained the optimum particle size and moisture content combination (the region marked with horizontal lines in Figure 8c). More desirable particle size and moisture content combination could be obtained by changing the target tablet property values. For example, tablets with tensile strength greater than 0.75 MPa and disintegration time shorter than 15 s can be found in the region marked with both horizontal and vertical lines in Figure 8c.

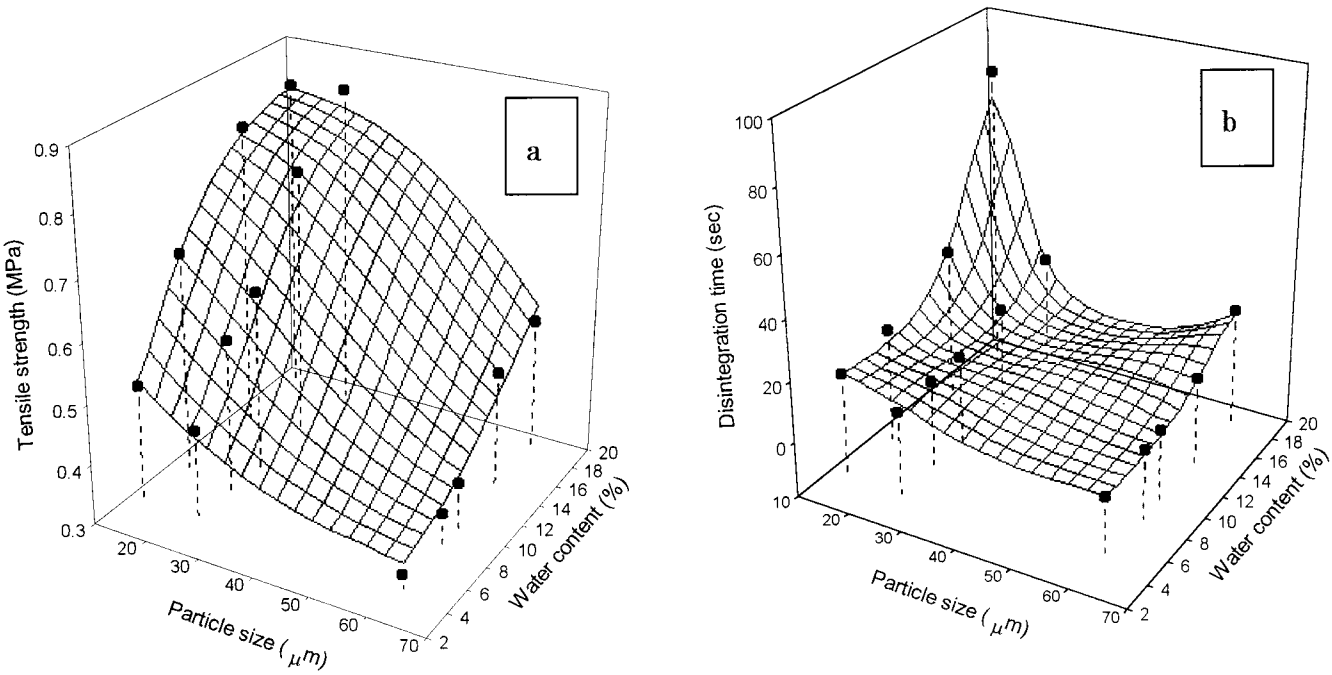

Figure 7—Response surfaces of tablet tensile strength and disintegration time obtained by ANN using particle size and moisture content as input factors. (a) Tensile strength, (b) disintegration time. Parameters of ANN: input layer unit: 2, output layer unit: 2, hidden layer unit: 3, reconstruction: 0, sigmoid curve: 2, training times: 1000, mean error: <0.03, neuron weight: 12. Figure 8—Contour plots of tablet tensile strength and disintegration time obtained by ANN using particle size and moisture content as input factors. (a) Tensile strength, (b) disintegration time, (c) superimposition of plots a and b. The values marked vertically within plots refer to tensile strength (MPa), while values marked horizontally refer to disintegration time (s).

Discussion

Preliminary experiments indicated that for lactose tablets with the same porosity (0.31), the tensile strength of tablets made by the wet compression method (0.4 MPa) is 10-fold greater than that of tablets prepared by the common compression methods (0.035 MPa). Such results suggested that the mechanisms of formation of the two tablets are different.

Discussion of tablet formation must necessarily start with a consideration of the particle–particle bonding mechanism involving adhesion and cohesion of particles. Several forces that can act between small neighboring particles have been identified. Among these, although van der Waals forces are not very large (1kal/mol), they can act over distances up to 1000 Å and must be considered capable of forming interparticle bonds. This intermolecular force plays the most important role in the formation of common compressed tablets. Lactose has many hydroxyl groups, and therefore hydrogen bonding is also an important interparticle force that cannot be neglected. The formation of lactose tablets prepared by the common compression method was thought to be mainly due to the above two forces. In contrast, for tablets prepared by the wet compression method, the solvent (water in this study) plays a key role in the tableting process. The postulated mechanism of formation of wet compressed tablets is shown in Figure 9. After mixing with water, the surface of lactose particles will be wetted and dissolve in water, and the particles will be coated with a layer of lactose solution. During the drying process, interparticle bonds, the so-called solid bridges, will result from recrystallization of lactose. It is these solid bridges which endow wet compression tablets with greater tensile strength, while maintaining relatively high porosity. This mechanism of formation of wet compressed tablets is similar to that of powder metallurgy, which is quite different from that of common compressed tablets.

For common compressed tablets, the number of contact points between particles is another factor which plays an

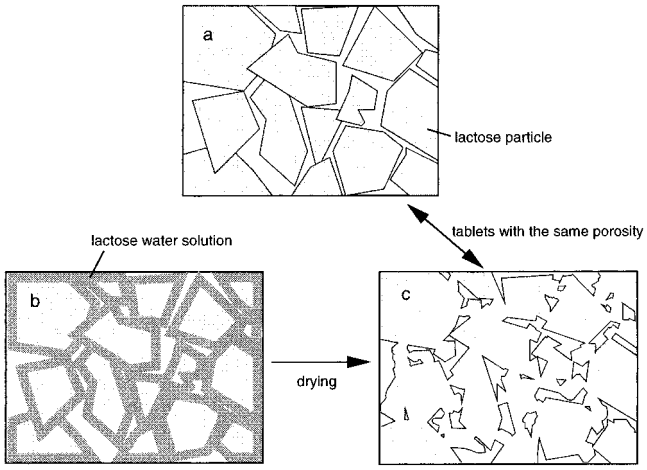

Figure 9—Hypothesized mechanism of formation of wet compressed tablets. (a) Tablets prepared by common compression method. (b) Wet compressed tablets before drying. (c) Wet compressed tablets after drying.

important role in tablet tensile strength.[14] With decreases in tablet porosity, the number of contact points increases, and tensile strength of the tablets shows a higher value. For wet compressed tablets, with increase in compression force, tablet porosity decreases, and the distances between particles become small. Thus, more solid bridges can be formed between particles. As a result, the tensile strength of wet compressed tablets increases linearly with the logarithm of porosity (Figure 5a).

Disintegration time showed a similar tendency to tensile strength with changes in tablet porosity (Figure 5b). Our previous studies indicated that porosity, hydrophilicity (solubility if the tablet constituents are water-soluble), swelling ability of the particles, and interparticle force are important factors for tablet disintegration.[6] Lactose is not a swellable material, and thus for lactose tablets the most important factors for disintegration are tablet porosity and interparticle force. With increases in compression force, tablet porosity decreases. Consequently, water penetration into the tablets would slow with decreases in porosity.[15] This is one reason disintegration time was prolonged with decreases in tablet porosity. When porosity decreases, more solid bridges are formed, which would make the annihilation of interparticle force more difficult. For such reasons, the effect of tablet porosity on disintegration time is similar to that on tensile strength.

Tensile strength and disintegration time of wet compressed tablets were markedly affected by tablet porosity, which can be easily controlled by compression force. In this study, size of lactose particles and moisture content of wet granules showed little effect on tablet porosity (see Table 2, porosity values of all tablets were around 0.3). However, they were shown to be the other two factors which are very important for determining tensile strength and disintegration time of wet compressed tablets (Figures 6 and 7).

As mentioned above, the number of contact points is one of the key factors regulating the integrity of tablets. When tablet porosity and the shape of the constituent particles of tablets are the same, the number of contact points per unit cross-sectional area of the fracture plane of a tablet is mainly dominated by particle size of tablet constituents. Smaller particle size is accompanied by a large number of contact points, as confirmed by SEM (Figure 10a–c). With

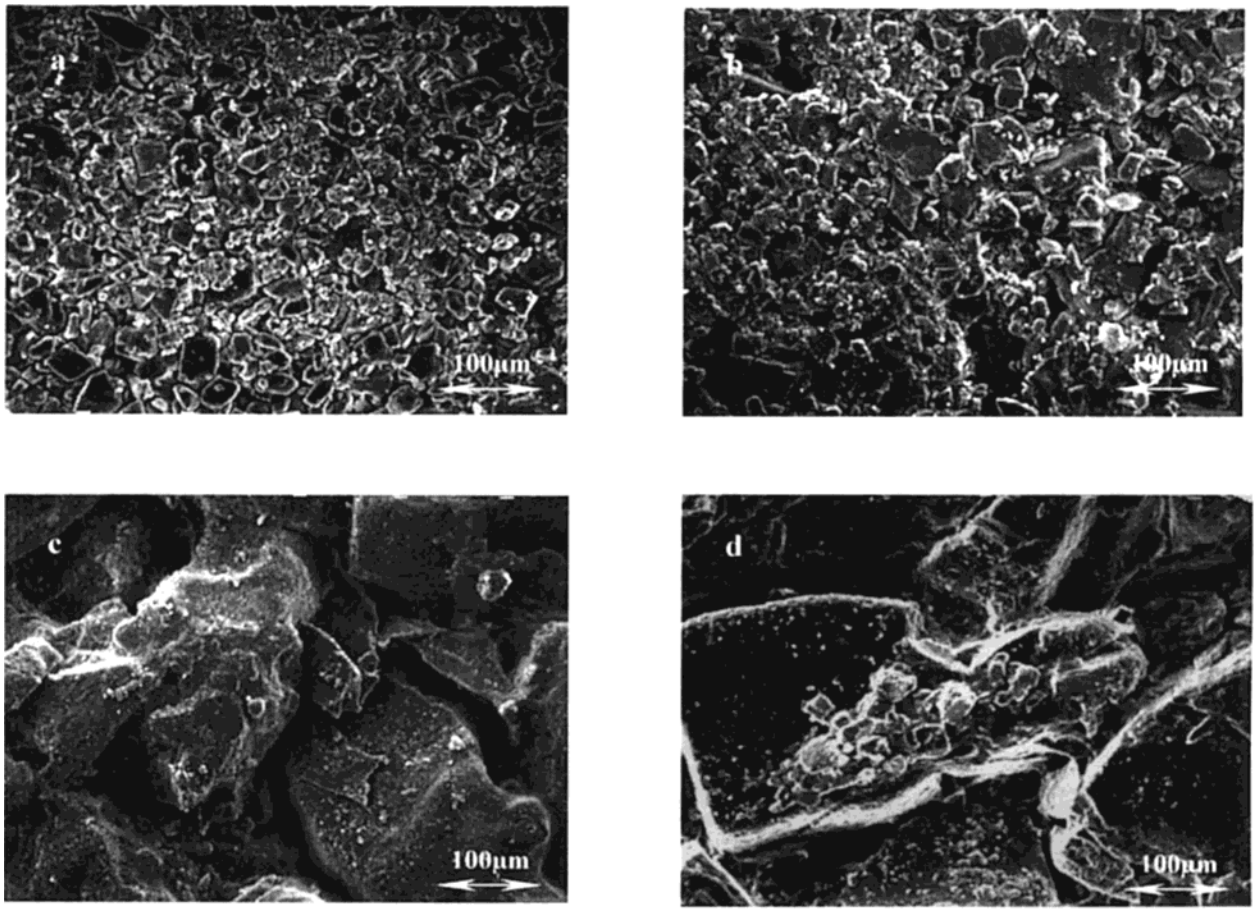

Figure 10—Scanning electron microscopic analysis of wet compressed lactose tablets. (a) Lactose: 450M; moisture content of wet granules: 8.56%. (b) Lactose: 200M; moisture content of wet granules: 8.56%. (c) Lactose: 80M; moisture content of wet granules: 8.56%. (d) Lactose: 80M; moisture content of wet granules: 18.80%.

increases in lactose particle size, the cracks and pores between particles became larger and the number of contact points decreased. This may explain why tensile strength increased with decreases in lactose particle size.

The effect of moisture content on tablet tensile strength can also be readily explained by the hypothesized mechanism of formation mentioned above. When more water is added in the kneading process, more lactose will dissolve in water, and then more small lactose crystals will recrystallize between the existing lactose particles, and stronger tablets will be formed. When moisture content of wet granules was 8.56%, the cracks between particles could be distinguished clearly, while when moisture content was increased to 18.8%, so many small lactose crystals recrystallized that the large cracks almost disappeared (Figure 10c,d).

Disintegration time showed the same tendency as tensile strength for the reasons mentioned above (Figures 6b and 7b). As the porosity values of these tablets were almost the same, disintegration time was only affected by interparticle force.

All our experimental results can be explained by the hypothesized mechanism of formation of wet compressed tablets.

Conclusions

In this study, we proposed a mechanism of formation of wet compressed tablets which was then confirmed by experimental results.

Tensile strength and disintegration of wet compressed tablets are closely related to the formation and annihilation of the solid bridges formed between lactose particles. The intensity and number of the solid bridges are influenced by compression force, moisture content, and size of lactose particles.

With increases in compression force and moisture content, and the decreases in particle size, the distances between constituent particles will become shorter, more lactose will dissolve and recrystallize, and the number of contact points between particles will increase. Consequently, the resulting tablets will become harder and disintegrate less readily.

By optimization of compression force, moisture content of wet granules, and particle size, rapidly disintegrating lactose tablets meeting our design specifications were obtained by the wet compression method.

Accepted for publication June 25, 1999.

Abstract □ A number of medium-chain saturated and long-chain unsaturated fatty acids and their monoglycerides were tested against herpes simplex virus (HSV-1) to determine which lipids were most active during a short incubation time. The aim was to find which lipid would be preferable as the active ingredient in a virucidal hydrogel formulation for the purpose of preventing transmission of pathogens to mucosal membranes, particularly sexually transmitted viruses, such as herpes simplex virus and human immunodeficiency virus (HIV), and bacteria, such as *Chlamydia trachomatis* and *Neisseria gonorrheae.* The main strategy was that the formulations would be fast-acting, killing large numbers of virus or bacteria on contact in a short time, preferably causing at least a 10000-fold reduction in virus/bacteria titer in 1–5 min. Monocaprin, the 1-monoglyceride of capric acid, and lauric acid were found to be most active of all the lipids tested, causing a greater than 100000-fold reduction in virus titer in 1 min at a concentration of 20 mM. When tested at a concentration of 10 mM for 1 min, monocaprin was still fully active whereas lauric acid had no or neglible activity. It was concluded that monocaprin was most suitable as the active ingredient in a fast-acting virucidal gel formulation, and several hydrogel formulations containing monocaprin were tested. Formulations where the monoglyceride was dissolved in glycofurol were found to be active against HSV-1. The hydrogel formulations containing 20 mM monocaprin were highly virucidal in vitro and caused a greater than 100000-fold (HSV-1) inactivation of virus in human semen in 1 min. Formulations in dilution 1:10 were cytotoxic in monolayers of CV-1 cells, but they were 10–100 fold less cytotoxic than a commercial product which contains 2% nonoxynol-9.

Introduction

There are several published reports on antiviral and antibacterial activities of lipids.[1−5] Research has shown that enveloped viruses, such as herpes simplex virus type 1 (HSV-1), vesicular stomatitis virus (VSV), and visna virus are inactivated by long-chain unsaturated and medium-chain saturated fatty acids, whereas long-chain saturated and short-chain fatty acids have no or only a minor virucidal effect at the highest concentrations tested. Electron microscopy studies of VSV suggest that fatty acids disrupt the lipid envelope of the virus, but the mechanism is not known.[4]

It has been proposed that fatty acids and monoglycerides may be used as intravaginal microbicides for protection against sexually transmitted diseases.[6] To prevent infection by a sexually transmitted pathogen it is important that the micobicide is fast acting and kills the infectious agent before it has time to infect cells of the genital mucosa. It is also important that the microbicide be solubilized in a pharmaceutical formulation which can be easily and effectively applied to mucosa or skin areas which can serve as entry sites for infectious agents. The objective of the work was the development of hydrogels which could be used as vehicles for microbicidal lipids for the purpose of preventing transmission of pathogens to mucosal membranes, particularly sexually transmitted viruses, such as HSV and HIV, and bacteria, such as *Chlamydia trachomatis* and *Neisseria gonorrheae.* The main strategy was to design fast-acting formulations which kill large numbers of virus or bacteria on contact in a short time, preferably causing at least a 10000-fold reduction in virus/bacteria titer in 1−5 min. The effectiveness of the hydrogel formulations was tested against HSV-1 as a model.

Materials and Methods

Materials—Fatty acids and monoglycerides as well as sodium carboxymethylcellulose (NaCMC) and poly(vinylpyrrolidone) (PVP) were purchased from Sigma Chemical Co., St. Louis, MO. Carbomer (Carbopol 934) was obtained from Nomeco, Copenhagen, Denmark, and hydroxypropylmethylcellulose (HPMC) was from Aldrich Chemical Co. Inc., Milwaukee, WI. All other chemicals were of reagent grade.

Hydrogel Formulations—Hydrogels containing either 10 or 20 mM monocaprin were formulated using as gel-forming agents either NaCMC and PVP (series 1A−M) or carbomer and HPMC (series 2A−D). The concentration of gel-forming agents was such that the viscosity of the gels was comparable. One of the following compounds was used to bring the monoglyceride into solution: glycofurol 75, Tween 80, Chremophor PH40, Chremophor EL, 2-hydroxypropyl-β-cyclodextrin.

Formulations based on 2% w/v NaCMC and 1% w/v PVP were produced by adding 1.0 g of NaCMC and 0.5 g of PVP to a solution of monocaprin. The pH of gel formulation 1A is 7 but for formulations 1B−M the pH is adjusted to 5.0 by the dropwise addition of a lactic acid solution. Finally, purified water is added, bringing the solution to a final weight of 50 g. Immediately after the addition of water, the solution is stirred continuously until a hydrogel is produced. The hydrogel is centrifuged at high speed (>8000 rpm) for 60 min in order to remove air bubbles.

Hydrogels based on 0.5% w/v carbomer and 1% w/v HPMC are produced by dispersing 0.5 g of HPMC in 10 mL of hot (80−90 °C) purified water in a glass beaker. The solution is allowed to cool to about 30−35 °C under continuous stirring at room temperature and then chilled in a refrigerator at about 4 °C for at least 1 h. A 0.25 g amount of carbomer is suspended in 5 mL of purified water at room temperature under vigorous stirring to prevent lumping. The carbomer solution is mixed with the HPMC solution, and then a solution of monocaprin is added. Gelling of the carbomer polymer is induced by raising the pH to approximately 5.5 with the dropwise addition of a 2 w/v % sodium hydroxide solution. The hydrogel is brought to its final weight (50 g) with purified water. Finally, the hydrogel is centrifuged at high speed (>8000 rpm) for 60 min to remove air bubbles.

Cell Cultures and Media—CV-1 cells (African green monkey kidney cell line) were grown in Dulbecco's Modified Eagle Medium

(D-MEM) with 2 mM L-glutamine, 20 μg/mL of gentamicin, and 10% heat-inactivated fetal bovine serum (FBS). The maintenance medium (MM) for CV-1 cell monolayers was D-MEM with 2% FBS. All media were obtained from GIBCO, Paisley, Scotland.

Virus and Virus Titration—HSV-1 strain MacIntyre was obtained from the American Type Culture Collection, Rockville, MD, and grown in CV-1 cells. Virus stocks with an infectivity titer of $10^{6.5}$–$10^{7.5}$ $CCID_{50}$ (50% cell culture infective dose) per 100 μL were used in the experiments. Virus was titrated by inoculation of 10-fold dilutions in MM into monolayers of CV-1 cells in 96-well microtiter tissue culture plates (Nunc, Roskilde, Denmark). One hundred microliters of each virus dilution were inoculated into quadruplicate wells. The plates were incubated at 37° C in a humidified incubator with 5% CO_2 in air and examined for cytopathic effect daily for 5 days. All virus titers were calculated by the method of Reed and Muench.[7]

Assay of Virucidal Activity of Fatty Acids and 1-Monoglycerides in Medium—The stock lipid solutions were diluted to the desired concentration in MM by vortexing at the highest speed for 10 min. The lipids were thoroughly mixed with equal volumes (200 μL) of HSV-1 in 12 × 75 mm polystyrene round-bottom tubes (Falcon) and incubated for 1 min at room temperature. The action of the lipid was then stopped by immediately diluting the mixture 100-fold in medium. Virus mixed with MM alone and with 2% ethanol in MM served as controls. The virus titers of the mixtures were determined by inoculation of 10-fold dilutions into cell cultures as previously described. The lowest inoculated dilution was 10^{-2} because of toxic effect of the lipids on cells. In such lipid–virus mixtures where no cytopathic effect was detectable in the 10^{-2} dilution the titer was assumed to be $\leq 10^{1.5}$ $CCID_{50}$ per 100 μL. The titer (log_{10}) of a lipid–virus mixture was subtracted from the titer (log_{10}) of the control mixture and the difference, i.e., the reduction in viral infectivity, was used as a measure of the virucidal activity of the lipid.

Assay of Virucidal Activity of Hydrogel Formulations—A hydrogel (200 μL) was placed in a 35 mm tissue culture dish (Nunc), and equal volume of HSV-1 in medium was added. The hydrogel was thoroughly mixed with the virus at room temperature for 1, 5, or 10 min. The mixtures were then immediately diluted 100-fold in medium and titrated in 10-fold dilutions. Virus mixed with medium instead of hydrogel was used as a control. The activity of the hydrogels was calculated as in the experiments with lipid solutions. Virucidal activity against HSV-1 in semen was tested in the same way except that the virus was first concentrated 10-fold by centrifugation in a Sorvall ultracentrifuge at 100000*g* for 90 min and then diluted 1:10 in fresh (<2 h) liquefied human semen. Virus-spiked semen mixed with medium was used as a control.

Evaluation of Toxic Effects of Gel Preparations in Monolayers of CV-1 Cells—Tenfold dilutions of hydrogel formulas were added to monolayers of CV-1 cells, 4 wells per dilution, and the cell layers were examined for lysis or other toxic effects after 1 and 24 h.

HPLC Assay of Monocaprin—The monoglyceride content was determined using a high-performance liquid chromatography (HPLC) component system consisting of a Thermo Separations Products Spectra Series P200 HPLC solvent delivery system, a μBondapak C18 125A 10μm (3.9 × 300 mm) column, a Waters Intelligent Sample Processor (WISP) Model 710B, a Thermo Separations Products SP4400 Integrator, and a Thermo Separations Products Spectra Series UV150 detector. The wavelength was 218 nm, and the mobile phase consisted of acetonitrile, water, and tetrahydrofuran (57:42:1) with the retention time being 2.1 min at 1.25 mL/min flow rate.

Drug Release from Hydrogels—Release of monoglyceride was investigated using a membraneless diffusion cell at 37 °C. Phosphate buffer (pH = 4.5) containing 0.1% 2-hydroxypropyl-β-cyclodextrin was used as the receiver phase. Samples were taken from the receiver phase at regular intervals and filtered through a 0.22 μm membrane filter. After each sampling, the volume was replaced. The amount of monoglyceride released was determined by HPLC using a calibration curve of the monoglyceride in the receiver phase. Each experiment was carried out in triplicate.

Results

Anti-HSV-1 Activity of Fatty Acids and 1-Monoglycerides in MM—In a previous study[4] medium-chain saturated and long-chain unsaturated fatty acids were found to inactivate HSV-1 in 30 min at 37 °C, and 1-monoglycerides were found to be more active than the corresponding fatty acids. In the present study caprylic acid (8:0), capric acid (10:0), lauric acid (12:0), myristic acid (14:0), palmitoleic acid (16:1), and oleic acid (18:1) and their 1-monoglycerides were tested against HSV-1 for 1 min at room temperature. In addition, undecylenic acid (11:0) was tested. The purpose of this experiment was to determine which of these compounds would be preferable as the active ingredients in a fast-acting virucidal gel formulation, i.e., would inactivate an enveloped virus such as HSV-1 within 1 min. In the first experiment all of the lipids were tested at a concentration of 20 mM. The results are shown in Figure 1. Of the fatty acids only lauric acid (12:0) and palmitoleic acid (16:1) caused a 100000-fold reduction of virus titer in 1 min. All the other fatty acids had no or a very small effect. Of the monoglycerides, monocaprin (10:0) was the most active, but monolaurin also had considerable activity and caused a 100000-fold reduction in virus titer. The most active compounds were tested further in concentrations of 2.5 mM, 5 mM and 10 mM. The results are shown in Tables 1 and 2. Both lauric and palmitoleic acid lost most of their activity at 10 mM or lower concentrations, whereas the activity of monolaurin was unchanged. Monocaprin had by far the highest activity and caused a greater than 700000-fold reduction of virus titer in 1 min at a concentration of 5 mM (Table 2). The virucidal activities of less active compounds were additive if two or more were mixed together (results not shown).

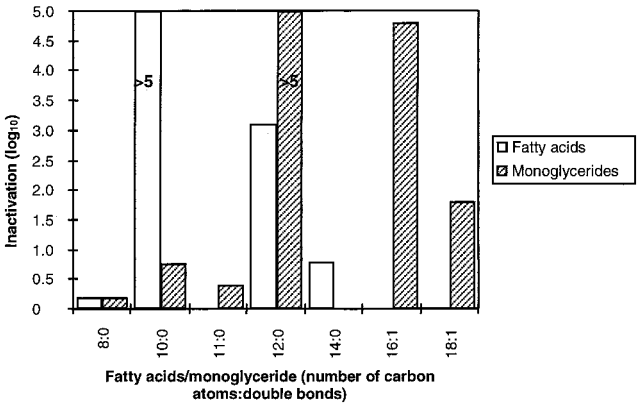

Figure 1—Inactivation of HSV-1 by incubation with an equal volume of 20 mM fatty acid or monoglyceride at room temperature for 1 min. Fatty acids and monoglycerides are indicated by the number of carbon atoms and double bonds. Inactivation is expressed as log reduction of virus titer. The data are the means of at least three experiments.

NaCMC (series 1A−M), both compounds that have good bioadhesive properties and have been used for the formulation of vaginal dosage forms.[8,9] As monocaprin is not soluble in water the hydrogels were formulated in such a way that the monoglyceride was solubilized in the dosage form. It was attempted to use a surface active agent (Tween 80, Cremophor RH40, Cremophor EL) to solubilize the compound, and complex formation with a cyclodextrin (2-hydroxypropy-β-cyclodextrin) was also attempted. Solvents were used to dissolve the monoglyceride (propylene glycol, glycofurol 75) as well as a combination of solvents and surfactants. Table 3 shows the inactivation of HSV-1 by incubation at room temperature for 1 min with hydrogels, with or without monocaprin. The results indicate that both propylene glycol and glycofurol 75 are suitable solvents for monocaprin in hydrogels with either Carbopol or NaCMC as carrier. Addition of surfactants or complex-forming compounds such as 2-HPβCD inhibits the activity of monocaprin in the hydrogels. As propylene glycol can cause irritation of mucosal membranes it was decided to continue the work using hydrogels formulated with glycofurol 75.

Hydrogel formulations 1A, 1B, and 2A were further tested for activity against HSV-1. The hydrogels were mixed with equal volumes of HSV-1, incubated at room temperature for 1 or 10 min, and then titrated as described in Materials and Methods. The results are shown in Table 4. Control hydrogels without monocaprin had an insignificant effect on the virus except hydrogel 2A after incubation for 10 min. In all the hydrogels, monocaprin at 5 mM or higher concentration inactivated the virus more than 100000-fold (>5 log) in 1 min. Monocaprin concentration of 2.5 mM was less active.

The virucidal activity of the hydrogels was further tested against HSV-1 suspended in semen rather than in maintenance medium. The results are shown in Table 5. The virucidal activity was considerably less in semen with only the 20 mM concentration causing greater than 100000-fold inactivation in 1 min.

In Vitro Study of Drug Release—The drug release profiles from the different hydrogels are shown in Figure 2. Drug release profile from the 1B hydrogels, containing

	10	10^{-1}	10^{-1}
	20	10^{-1}	10^{-1}
Gynol-plus[c]		10^{-2}	10^{-3}

[a] In parentheses: round cells, not lysed. [b] Without parentheses: complete lysis of cells. [c] A commercial (Cilag AG, Schaffhausen,Switzerland) spermicidal gel containing 2% nonoxynol-9 in Povidone K30 and propylene glycol.

NaCMC and PVP as the gelling agents, show a burst effect phenomenon during the first 30 min. Comparison of the release from the two hydrogel bases reveals that the monoglyceride release rate is appreciably higher from the hydrogel 2A containing carbomer and HPMC. This could be due to a less dense gel structure or a different release mechanism in the two hydrogel structures. These results indicate that the release of monocaprin is suitable for prolonged spermicidal and virucidal activity.

Cytotoxic Effect of Hydrogel Formulations in Monolayers of CV-1 cells—Hydrogels containing 10 or 20 mM of monocaprin were found to be cytotoxic in dilution 10^{-1} in virus titrations. Hydrogels 1A and 2A without monocaprin and with 10 or 20 mM monocaprin were inoculated in dilution 10^{-1} onto cell monolayers. The cells were then examined microscopically for cytotoxic effect after 1 and 24 h. Gynol-plus, a commercial contraceptive containing nonoxynol-9, was tested in the same way for comparison. The results are shown in Table 6. Both hydrogel formulations without monocaprin showed some toxic effect after 1 h and complete lysis after 24 h. Hydrogels with monocaprin were more cytotoxic and lysed all the cells in 1 h. No visible toxic effect was seen in 10^{-2} or higher dilutions even after incubation for 4 days (results not shown). A vaginal gel (Gynol-plus) which contains 2% nonoxynol-9, caused a complete cell lysis in 1 h in dilution 10^{-2} and in 24 h in dilution 10^{-3}. It was therefore 10- to 100-fold more toxic to the cell layers than formulations 1A and 2A containing 20 mM (0.5%) monocaprin.

Discussion

In this paper we report novel pharmaceutical formulations in the form of hydrogels of various compositions, which contain a simple lipid, i.e., monocaprin, as the microbicidal ingredient. Monocaprin was selected after a comparison of the virucidal activity of several fatty acids and monoglycerides. In addition to monocaprin, some of these lipids showed considerable activity when suspended in maintenance medium, particularly lauric and palmitoleic acid (Figure 1). However their activities in hydrogel formulations have not yet been studied.

Hydrogels containing monocaprin in concentrations of 5−20 mM are highly active against HSV-1, which was used as a test virus, and cause greater than 100000-fold inactivation of the virus in 1 min. Since some viruses are transmitted by semen, we tested the activity of the hydrogels against HSV-1 suspended in semen and found that a monocaprin concentration of 20 mM was needed for maximum efficacy of the gels. A lower activity of monocaprin in a biological fluid like semen could be expected because previous studies have shown that as much as 10-fold higher lipid concentrations are required for inactivation of virus in human blood than in culture medium.[6] Several enveloped viruses, such as HSV-1, VSV, measles virus, respiratory syncytal virus, cytomegalovirus, visna virus, and HIV-1 have been found to be equally susceptible to lipids.[1,10−12] It was therefore considered appropriate to use HSV-1 as a model in the present experiments to study the rapid microbicidal effect of various lipids. Recent studies on the effect of fatty acids and monoglycerides on *Chlamydia trachomatis*[13] have shown that monocaprin is also the most active in killing this bacterium in a short time and that hydrogel formulations 1A, 1B, and 2A containing 10 mM monocaprin kill *Chlamydis trachomatis* and *Neisseria gonorrheae* at high titers in 5 and 1 min, respectively.[14]

The hydrogel formulations in 10^{-1} dilution were found to be toxic to monolayers of CV-1 cells, but they were 10- to 100-fold less cytotoxic than a commercial spermicidal product containing 2% nonoxynol-9. However, such a comparison must also be carried out in vivo. A preliminary experiment with hydrogel fomulation 1A in mice showed no adverse effect on their vaginal mucosa.[14] Testing of the hydrogel formulations 1A and 2A by the standard rabbit vaginal irritation test showed no irritation of the vaginal mucosa after daily application for 10 days.[14] A comparison of the toxicity of the hydrogels and a vaginal contraceptive gel which contains 4% nonoxynol-9 is now in preparation.

Conclusions

The hydrogel formulations containing 20 mM monocaprin are highly virucidal in vitro and cause a greater than 100000-fold inactivation of virus (HSV-1) in 1 min, even in the presence of semen which considerably reduces the activity at a concentration of 10 mM. Formulations in dilution 1:10 are cytotoxic in monolayers of CV-1 cells, but they are 10- to 100-fold less cytotoxic than a commercial product which contains 2% nonoxynol-9.

Accepted for publication July 26, 1999.

Abstract ☐ The biopharmaceutics and pharmacokinetics of 5-phenyl-1,2-dithiole-3-thione (5PDTT) were investigated in rabbits, after administration as a complex with sulfobutyl-ether-7-β-cyclodextrin (SBE7-β-CD) by intravenous and oral routes and as a micronized powder by oral route. 5PDTT had a rapid and large red blood cell partitioning that was not dependent on drug concentration either in vitro or ex vivo. The blood clearance was very high (354 ± 131 mL/min) suggesting extrahepatic metabolism and/or nonrenal elimination and a significant volume of distribution (67 ± 76 L). The renal clearance was 0.17% of total clearance. 5-phenyl-1,2-dithiol-3-one (5PDTO) was identified as a metabolite in blood and urine. The bioavailability of 5PDTT following administration of 5PDTT/SBE7-β-CD complex was estimated to 41% while it was close to zero when 5PDTT was given as a micronized powder.

Introduction

Some chemical agents can inhibit carcinogenesis at different stages and could be used in cancer chemoprevention. Epidemiological studies suggest that consumption of cruciferous vegetables such as brussel sprouts, broccoli, or cabbage, which are probably sources of 1,2-dithiole-3-thiones,[1] results in decreased cancer risk in humans in various localizations.[2,3] In vitro and animal studies suggest that the cruciferous vegetables and 1,2-dithiole-3-thiones protect against carcinogens by an increase in the activities of electrophile detoxification Phase II enzymes, in conjunction with an increase of intracellular glutathione level.[4] The Phase II enzymes, such as glutathione-S-transferase and quinone reductase can conjugate potential carcinogens with glutathione favoring their elimination. Glutathione is a cellular thiol, which is very important for the cellular integrity by protection against free radicals, oxidants, and electrophilic intermediates of various compounds. Animals studies have shown an inhibition of experimental carcinogenesis in liver, bladder, breast colon, lung, and skin cancer after administration of dithiolethiones such as anetholtrithione and oltipraz.[5−7] On the basis of these data, dithiolethiones appear to be promising chemopreventive agents. 5PDTT was chosen among 1,2-dithiole-3-thiones because derivatives substituted on the carbon-5 by an aryl moiety have exhibited the most interesting antioxidant properties.[8,9] Furthermore, oltipraz and anetholtrithion, which are known for their cancer chemoprevention properties, are also substituted on the carbon-5 by such a moiety.

Biopharmaceutic and pharmacokinetic studies have only been conducted with two dithiolethiones: anetholtrithione used for its scialogogue and choleretic properties, and oltipraz which has been developed for its antischistosomal activity.[10] These studies have been conducted only after oral administration in animals[11] and in humans.[5,12−14]

The goal of the current work was to study the pharmacokinetics and biopharmaceutics of 5-phenyl-1,2-dithiole-3-thione (5PDTT) after administration by intravenous and oral routes in rabbits. To study this un-ionized and highly lipophilic compound (log $P = 3.67$, intrinsic solubility 0.48 mg/L),[15] we used sulfobutyl-ether-7-β-cyclodextrin (SBE7-β-CD) that has been shown to significantly increase 5PDTT aqueous solubility[16] (480 times the intrinsic solubility at a 10% SBE7-β-CD concentration).

Materials and Methods

Materials—5-Phenyl-1,2-dithiole-3-thione and 5-phenyl-1,2-dithiol-3-one were synthesized according to A. Thuillier and J. Vialle.[17] Their chemical structure is presented in Figure 1.

The sulfobutyl-ether-7-β-cyclodextrin was supplied by Cydex L. C. (Overland Park, KS). Heptane and acetonitrile (Merck, Darmstadt, FR, Germany), ethyl acetate (Carlo Erba Reagenti, Milano, Italy), and diethylene glycol monoethyl ether (Sigma Chemical, St Louis, MO) were of analytical grade.

Analytical Method—Analysis of 5PDTT and 5PDTO was carried out by a one-step extraction procedure. 5PDTT was quantified in plasma, blood, red blood cells, and urine samples, and 5PDTO was quantified in blood and urine.

One milliliter of biological sample (plasma, red blood cells, or blood) was extracted with 2 mL of a 80:20 (v/v) mixture of heptane and ethyl acetate. Extraction was performed by mixing for 5 min (horizontal shaker, model Agitelec SL 200). Then, the vials were centrifuged at 2000*g* for 5 min. The supernatant (≈1.5 mL) was poured into a polypropylene tube, containing 50 μL of a solution of diethylene glycol monoethyl ether (5 μL) and heptane-ethyl acetate (80:20, v/v, 45 μL). Diethylene glycol monoethyl ether (bp = 194 °C) was necessary to avoid the adsorption of 5PDTT and 5PDTO onto the polypropylene tubes. Then, the volatile organic phase was evaporated at room temperature under a nitrogen stream. The residue was diluted in acetonitrile (50 μL) and then stored at 4 °C until analysis.

For urine sample extraction, the volume of the samples was 5 mL, the extraction was performed by mixing for 15 min (rotary shaker Bioblock), and the vials were centrifuged at 4500*g* for 15 min.

The samples were analyzed using a HPLC system, consisting of a Waters Model 6000 A pump (Waters Assoc., Millford, MA) equipped with a Waters 717 Autosampler (Waters Assoc., Millford, MA), and a Delsi integrator, model Enica 21 (Delsi, Suresnes, France). Chromatography was performed using a Lichrospher RP-

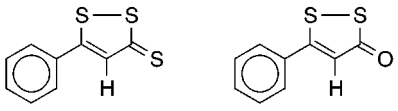

Figure 1—Chemical structure of 5-phenyl-1,2-dithiole-3-thione (left) and of 5-phenyl-1,2-dithiol-3-one (right).

SelectB column maintained at 30 °C (5 μm, 125 × 3 mm; Interchim, Montluçon, France) with a water−acetonitrile (50:50, v/v) mobile phase at a flow-rate of 0.5 mL/min.

The detection was set at 318 nm (λ_{max} of 5PDTT: 318 nm and λ_{max} of 5PDTO: 288 nm) using a Milton Roy model Spectromonitor 3100 (LDC Milton Roy, Riviera Beach, FL).

The yields of extraction of 5PDTT from whole blood and urine were 88.5 ± 2.6% and 91.0 ± 5.5%, respectively. The yields of extraction of 5PDTO from whole blood and urine were 95.5 ± 1.5% and 94.6 ± 8.3%, respectively. The selectivity factor (α) for the separation of 5PDTT and 5PDTO was 1.6. The linearity was established for concentrations up to 1000 ng/mL. The limits of quantification of 5PDTT and 5PDTO in blood were 1.3 ng/mL and 2.4 ng/mL, respectively. The limits of quantification of 5PDTT and 5PDTO in urine were 0.3 ng/mL and 0.5 ng/mL, respectively. The within-day reproducibilities, checked at a blood concentration of 200 ng/mL, were 7.8% and 4.5% for 5PDTT and 5PDTO, respectively. The within-day reproducibilities, checked at a urine concentration of 20 ng/mL, were 5.6% and 6.6% for 5PDTT and 5PDTO, respectively.

Red Blood Cell Partitioning—Red blood cell (RBC) partitioning of 5PDTT was evaluated in vitro and ex vivo in rabbits. In the in vitro experiment, the kinetics of partitioning (incubation time of 1, 5, 15, and 30 min at a blood concentration of 500 ng/mL, n = 3) and the influence of the 5PDTT concentration (blood concentration of 200, 500, and 1000 ng/mL at the incubation time of 30 min, n = 2) were investigated at 37 °C. A 30 mL blood sample maintained under gentle agitation was spiked with 20 μL of a solution of 5PDTT/SBE7-β-CD complex.

In the ex vivo experiment, the influence of 5PDTT concentration on the RBCs partitioning was checked in blood samples drawn at 1, 5, 15, and 30 min following an iv administration of a solution of 5PDTT/SBE7-β-CD complex (2 mg in 10 mL).

Blood samples (2 mL) were immediately centrifuged (9800 g for 1 min), and RBCs were lysed by freezing at −20 °C. 5PDTT concentrations in RBCs and plasma were determined as described above.

The extent of RBCs partitioning ($K_{e/p}$) was determined according to Hinderling[18] as follows:

$$K_{e/p} = C_e/C_p$$

where C_e and C_p are the concentration in the RBCs and plasma, respectively.

The whole blood-to-plasma concentration ratio ($K_{b/p}$) represents an additional drug distribution parameter of interest depending on the hematocrit (H_c). $K_{b/p}$ was determined according to Hinderling[18] as follows:

$$K_{b/p} = K_{e/p} \cdot H_c + (1 - H_c)$$

Study Formulations—*Pure Drug*—5PDTT was micronized using a rotomill SRM 100 apparatus (Beckman, Nyon, Switzerland). The mean diameter, expressed by D[4,3] (Mastersizer, Malvern, Orsay, France), was 29 μm. 5PDTT was administered as a capsule containing 20 mg of the drug.

Inclusion Complex—An ethanolic solution of 5PDTT (20 mg in 10 mL) was diluted in an aqueous solution of SBE7-β-CD (11.88 g in 80 mL) to obtain a 1/10 molar ratio and a final ethanol concentration of 25%. The resulting solution was concentrated under vacuum at 60 °C using a rotavapor apparatus until elimination of ethanol. The solution was then diluted with water to obtain a 5PDTT concentration of 1 mg/mL and 0.2 mg/mL for oral and iv dosing, respectively. The solutions were checked for 5PDTT concentration by HPLC and stored protected from light at ambient temperature.

Experimental Protocol—New Zealand adult males rabbits (n = 15, mean weight 3.2 kg) were housed individually in standard cages, and were provided free access to food and water. They were fasted 12 h before each experiment. The study was approved by the Local Committee of Laboratory Animal Care in accordance with the rules and guidelines concerning the care and use of laboratory animals.

Six rabbits received 5PDTT as a complex at a dose of 2 mg (10 mL) as an iv bolus injection via the marginal ear vein. Blood samples (1.5 mL) were collected from the controlateral marginal ear vein before drug administration and at 0.5, 1, 2, 5,10,15, 20, 30, 60, 90, 120, 180, 240, 300, 360, 420, and 480 min. The samples were immediately frozen at −20 °C.

Six rabbits received 5PDTT as a complex at a dose of 20 mg (20 mL) by oral route with a gastric catheter which was subsequently flushed with water (10 mL). Three rabbits received 5PDTT as a capsule of pure drug (20 mg) and then received water (30 mL) with a syringe. Blood samples were collected before drug administration and at 15, 25, 30, 40, 45, 60, 90, 120, 180, 240, 300, 360, 420, and 480 min. The samples were immediately frozen at −20 °C.

To obtain a regular urine flow throughout the experiments, the rabbits were hydrated by a sc infusion of normal saline (250 mL over 30 min) the day before and within the hour preceding the drug administration. During the study, the animals received iterative iv infusions 20% mannitol (20 mL/h for the first hour and then for 30 min every 2 h) and normal saline (60 mL/h between the administration of mannitol). Urine was collected by miction. Samples (5 mL) were kept frozen until analysis.

Pharmacokinetic Analysis—After iv dosing, a model with two-exponential or three-exponential functions and first-order elimination from the central compartment was fitted to the individual 5PDTT blood concentrations, using weighted nonlinear least-squares regression analysis with the reciprocal of squared concentration as a weighting factor (WinNonlin version 1.5, Scientific Consulting Inc., Apex, NC). The choice between the models was judged by the distribution of residuals and comparison of the sum of squared deviations.[19] Standard methods were used to calculate the following parameters: total body clearance (CL), renal clearance (CL_r), apparent volume of distribution of the central compartment (V_c), apparent volume of distribution at steady-state (V_{ss}), distribution rate constants (K_{12}, K_{13}, K_{21}, and K_{31}), elimination rate constant (K_{10}), and apparent distribution and elimination half-lives ($t_{1/2}\,\alpha$, $t_{1/2}\,\beta$, and $t_{1/2}\,\gamma$). The extrapolated area was calculated as the ratio of the last measured whole blood concentration (C_{last}) and the slope of the terminal phase.

After oral dosing, individual 5PDTT and 5PDTO blood concentration data were analyzed using noncompartmental analysis assuming a first-order elimination from the central compartment with the software package WinNonlin. Peak plasma concentration (C_{max}) and corresponding time to peak concentration (T_{max}) were derived from raw data. The area under the whole blood curve from zero to the last sampling point (AUC_{0-last}) and from zero to infinity (AU_{0-inf}) were calculated by linear trapezoidal method from experimental data. The extrapolated area was calculated as the ratio of the last measured whole blood concentration (C_{last}) and the slope of the terminal phase. Standard methods were used to calculate the following parameters for 5PDTT: total body clearance (CL/F), renal clearance (CL_r/F), apparent volume of distribution at pseudodistribution equilibrium (V_z/F), and apparent elimination half-lives ($t_{1/2}\,\lambda z$). Pharmacokinetic parameters were corrected by the average bioavailability (F).

Q_u is the cumulative amount of 5PDTT or 5PDTO recovered in urine during 480 min.

The average absolute bioavailability of 5PDTT (F) was determined according to: F = (mean $AUC_{0-inf(oral)}$/oral dose)/(mean $AUC_{0-inf(iv)}$/iv dose).

Statistical Analysis—All data are presented as the mean ±SD Student's t-test was used to compare individual means. A p value less than 0.05 was considered as statistically significant.

Results and Discussion

Red Blood Cell Partitioning—Most pharmacokinetic studies are derived from drug concentrations measured in plasma or in serum. To investigate 5PDTT pharmacokinetics, quantitation in whole blood has to be considered owing to the high lipophilicity of the drug.[15] Among the cellular constituents of blood, RBCs represent the largest population and drugs may bind to their membrane, to

hemoglobin, and to proteins in the cytosol. The determination of concentrations in whole blood or erythrocytes rather than in plasma should be more suitable for studying the drug disposition of lipophilic drugs that usually have a high hepatic extraction (flow-rate-limited clearance). Moreover, in case of a significant RBC distribution, measuring blood concentrations increases the sensitivity of an analytical method allowing a follow-up of the drug elimination for at least one additional half-life.[18]

The results of the in vitro and ex vivo experiments are presented in Table 1. The extent of RBC partitioning of 5PDTT, estimated by $K_{e/p}$ and $K_{b/p}$, was significant (around 50% of the drug in the RBCs). The RBC partitioning was not dependent on the concentration ex vivo in a blood concentration range from 92 to 1136 ng/mL and in vitro in a blood concentration range from 200 to 1000 ng/mL. The distribution equilibrium was obtained rapidly, 95% of the maximum RBC concentration being reached in 1 min in the in vitro experiment. The high lipophilicity of 5PDTT may account for this rapid distribution in RBCs. On the basis of these data, we choose to study the blood pharmacokinetics of this lipophilic compound.

Although RBCs contain drug-metabolizing enzymes,[20] 5PDTT was not apparently metabolized in vitro in RBCs since the recovery of the drug in RBCs and in plasma aliquots were close to the initial blood loading. Moreover, 5-phenyl-1,2-dithiol-3-one (5PDTO), which is a metabolite of 5PDTT measured in plasma and urine, was not detected in the in vitro experiments.

Biopharmaceutics and Pharmacokinetics—The mean concentration−time profiles of blood 5PDTT and 5PDTO in rabbits following iv and oral dosing of 5PDTT are presented in Figure 2. The pharmacokinetic parameters of 5PDTT after iv and oral dosing are listed in Tables 2 and 3, respectively.

The 5PDTT blood concentration−time curves following iv administration were best described using a tricompartmental model. The extrapolated area averaged 7.2 ± 5.4% indicating that the sampling schedule was suitable.

Due to its high lipophilicity and significant RBC partitioning, 5PDTT was expected to have a high tissue distribution. The volume of distribution (V_{ss}(iv)) was high, suggesting a large distribution. However, the volume of distribution was highly variable compared to other pharmacokinetic parameters. Considering the respective values of the distribution rate constants (K_{12} plus K_{13}) compared to the elimination rate constant (K_{10}), 5PDTT has, from a statistical point of view, more chance to be distributed in tissues than to be eliminated, even though the systemic clearance of 5PDTT was high. The tissue affinity of 5PDTT

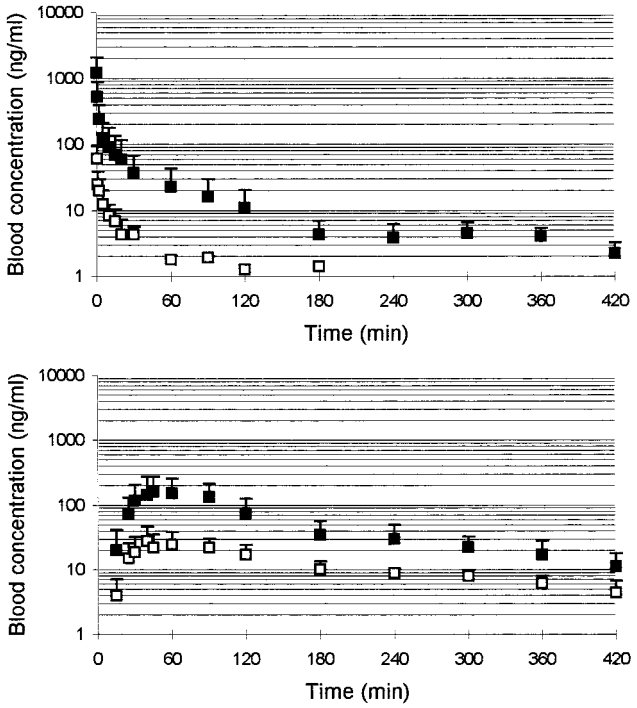

Figure 2—Mean (±SD) whole blood concentrations of 5PDTT and 5PDTO after administration of 5PDTT as a complex with SBE7-β-CD at a dose of 2 mg by intravenous route (top) and at a dose of 20 mg by oral route (bottom) in rabbits. 5PDTT (filled square); 5PDTO (empty square).

can be illustrated by the rapid distribution half-lives. Moreover, the values of the redistribution rate constants (K_{21} and K_{31}) were on average five to six times lower than the corresponding distribution rate constants (K_{12} and K_{13}), also suggesting the affinity of 5PDTT for tissue components. It should be noticed that a very slow redistribution back into the central compartment cannot be ruled out. However, the LOQ of our assay precluded such investigation.

The total blood clearance was three times higher than the hepatic blood flow described in rabbits (around 120 mL/min),[21] suggesting a significant extrahepatic metabolism and/or extrarenal excretion. However, the omission of a very slow redistribution might have led to an underestimation the AUC, leading to an overestimation of the clearance. Considering this assumption, a terminal half-life of around 35 h will lead to a clearance close to the liver blood flow.

The contribution of the renal clearance to the overall clearance was very low, 0.2% of the administered dose

being excreted in urine. The high RBC partitioning may account for such a low contribution. A low renal excretion (less than 1% of the dose) has also been shown for oltipraz after oral administration in mouse, rat, monkey, and humans.[11,14]

The use of cyclodextrins to solubilize drug administered by the iv route raises the problem of a potential alteration of the drug pharmacokinetics by an incomplete or a delayed release of the drug from the cyclodextrin.[22] This problem should be considered for 5PDTT given the magnitude of the stability constant obtained with SBE7-β-CD (10 705 M^{-1}).[16] The answer to this problem would be given by a comparative pharmacokinetic study of the drug with a control formulation providing that the excipient(s) used (e.g., organic solvent, surfactant in case of lipophilic drugs) are themselves devoid of any effect on drug kinetics. The influence of complexation on 5PDTT pharmacokinetics cannot be ruled out in the current study since we did not compare the drug disposition to that obtained with a control formulation. However, 5PDTT can be expected to be quickly released from its complex as a result of (i) the dilution of the study formulation in the blood circulation, (ii) the rapid and significant distribution of 5PDTT in RBCs, and (iii) the extensive distribution of 5PDTT that further dilutes the complex. Furthermore, competitive displacement of the drug from its complex by lipophilic plasma components may also favor the drug release. Moreover, in an in vitro study comparing the RBC partitioning from a solution of SBE7-β-CD complex to that of obtained from an ethanol−DMSO solution of 5PDTT, it appeared that the RBC partitioning were similar. The RBC and plasma concentrations of 5PDTT (687 ± 11 ng/mL and 374 ± 31 ng/mL, respectively) were close to those obtained with the SBE7-β-CD complex (Table 1), suggesting that the complexation between 5PDTT and SBE7-β-CD was not a limiting factor for 5PDTT partitioning and should not be a limiting factor for 5PDTT disposition.

5PDTO was identified as a metabolite of 5PDTT. The urinary excretion of this metabolite represented around 0.025% of the dose of 5PDTT administered. A metabolic investigation is in progress to identify other metabolites, the structures of which are not so far determined. Following iv administration of 5PDTT, it was not possible to delineate the metabolite kinetics since 5PDTO blood concentrations were below the LOQ in five of the six animals after 90 min postdosing. However, following oral administration, 5PDTO blood concentrations were measured until 420 min with a C_{max} (209 ± 110 ng/mL) and a T_{max} (64 ± 22 min) being close to those of the parent drug. The apparent terminal elimination half-life of 5PDTO ($T_{1/2}$ λ-z = 190 ± 89 min) was close to that of 5PDTT, suggesting a formation rate-limited metabolite kinetics.

Given that dithiolethiones have a chemopreventive potential against solid tumors,[7] a more precise investigation of the distribution of 5PDTT should be performed to specify if the drug has a selective distribution in particular organs and tissues. In this respect, the evaluation of the distribution in the colon, breast, skin, bladder, and lung should be investigated. In an autoradiographic study in mice, ^{14}C-anetholtrithione given orally displayed high concentrations in intestine, liver, gall-bladder, kidney, and urinary bladder.[23] The study of the organ and tissue distribution of ^{14}C-oltipraz orally administered in mice showed that, during the 6 h postdosing, the highest levels were found, in a decreasing order, in stomach and intestine contents, in gall-bladder, in bladder, and at a lower level in brown fat, liver, and kidney.[11]

Individual concentration−time profiles of complex 5PDTT-SBE7-β-CD following oral dosing displayed a distribution-nose, indicating the multicompartmental pharmacokinetic pattern of 5PDTT. However, concentration−time profiles could not be suitably fitted according to a pharmacokinetic model so that a noncompartmental analysis was performed. With the exception of one animal, whose concentration−time profile was rather unusual and displayed some scattering, the extrapolated area averages 10.3 ± 3.0%, indicating that the sampling schedule was suitable. T_{max} was much smaller and less variable that described for oltipraz in humans[13] (mean 2.8 h, range: 0.5 to 8 h). Following oral administration, the volume of distribution (V_z/F) also indicated a large distribution but the difference was less pronounced than after bolus regimen. The apparent elimination half-life of 5PDTT was slightly higher than that observed following iv dosing ($p = 0.54$) and lower than

that described for oltipraz in humans (4.2 to 11.1 h with increase in dose). The contribution of the renal clearance to the overall clearance of oral 5PDTT was very low, 0.16% of the administered dose being recovered in urine.

In two of three rabbits receiving 5PDTT as a micronized powder, 5PDTT was not detectable during the study period (until 8 h). In the third animal, 5PDTT was detected only at 7 h (100 ng/mL). These data suggest that the absorption of 5PDTT given as a powder did not occur, highlighting the need of a particular oral formulation for such lipophilic drugs. The optimization of the formulation of the complex between 5PDTT and SBE7-β-CD is currently in progress in order to reduce the amount of cyclodextrin (11.88 g of cyclodextrin by 20 mg of 5PDTT in the formulation studied) and to obtain a solid-state complex.[16]

Biopharmaceutic data on dithiolethiones are scarce and have only be obtained for oltipraz following oral dosing in animals[11] and humans.[5,12−14] These studies have shown that the pharmacokinetics of oltipraz was dose-dependent, suggesting a increased oral bioavailability with increasing doses that may result from a saturable first-pass effect.[5,10,11] Since 5PDTT was not administered by iv and oral routes in the same animals, the oral bioavailability could not be determined individually. The average absolute oral bioavailability of 5PDTT complexed with SBE7-β-CD was estimated to 41% while its was close to zero when administered as a micronized powder.

The current study has shown that 5PDTT had a rapid and significant red blood cell partitioning. After administration by intravenous and oral routes in rabbits, 5PDTT had a very high clearance, suggesting extrahepatic metabolism and/or nonrenal elimination, and a large volume of distribution. 5PDTO was identified as a metabolite of 5PDTT in plasma and urine. The bioavailability of 5PDTT after administration as complex 5PDTT/SBE7-β-CD was estimated to 41% while it was close to zero when it was given as a micronized powder.

Abstract □ Eprosartan mesylate (SKF 108566-J; EM) is an antihypertensive agent approved for marketing in the USA. EM dihydrate was prepared by three methods, one of which included suspending the anhydrous drug in an aqueous solution of 1.0 M methanesulfonic acid to form a slurry, followed by filtration. The dehydration kinetics of EM dihydrate were derived by analyzing the fit of the isothermal thermogravimetric analytical (TGA) data to numerous kinetic models. EM dihydrate undergoes dehydration in two distinct steps, each involving the loss of 1 mol of water at 25–70 °C and 70–120 °C, respectively. Recrystallization of EM occurs at ~120–140 °C after dehydration to the anhydrous phase. This explanation is supported by variable temperature powder X-ray diffractometry. The mechanism of the dehydration reaction is complex, the dependence of the reaction rate on temperature varying as a function of the particles size. For the dihydrate of sieve fraction <125 μm, the kinetics of the first and second dehydration steps are consistent with the Avrami–Erofeev equation (A3, $n = 1/3$) over the temperature range studied, corresponding to three-dimensional growth of nuclei. In contrast, for the 125–180-μm and 180–250-μm sieve fractions, the kinetics are best described by the two-dimensional phase boundary reaction (R2) at a lower dehydration temperature (i.e., 28.3 °C), and by the Avrami–Erofeev equation (A3, $n = 1/3$) at a higher dehydration temperature (i.e., 93.7 °C). The activation energies (15–40 kcal/mol) and frequency factors of the dehydration of EM dihydrate were determined both by Arrhenius plots of the isothermal rates determined by TGA and by Kissinger plots of the nonisothermal differential scanning calorimetric data. Hot stage microscopy of single crystals of EM dihydrate showed random nucleation at the surface and dehydration with the growth of microcrystals along the needle *a* axis. Cerius^{2TM} molecular modeling software showed the existence of water channels along the *a* axis and enabled the observed dehydration behavior of EM dihydrate crystals to be explained in terms of the bonding environment of water molecules in the crystal structure.

Introduction

The presence of water of hydration is common in molecular crystals of both organic and inorganic compounds. Numerous pharmaceuticals exist in both hydrated and anhydrous forms.[1,2] More than 90 hydrates are listed in the *United States Pharmacopoeia*,[3] and at least one-third of the solid crystalline substances of the *European Pharmacopoeia*[4] are reported to form hydrates. The stability and behavior of hydrates can vary widely,[5−7] and hydrate formation and dehydration may occur during processing or storage of pharmaceuticals. Knowledge of the hydration and dehydration behavior of drug substances is essential in the development of stable formulations because the physicochemical, mechanical, processing, and biological properties of hydrates can differ significantly from those of the corresponding anhydrate; these differences are ascribed to differences in crystal structure[7−14] brought about by the presence of lattice water. In general, water molecules in hydrates are almost always involved in hydrogen bonds that usually contribute to the coherence of the crystal structure. Shefter and Higuchi[13] found that the apparent dissolution rate and solubility of the anhydrous form of several drugs are greater than those of the hydrate, which crystallizes from water at the same temperature as in the dissolution experiments (e.g., theophylline, caffeine, and glutethimide). Poole et al.[14] showed that the enhanced bioavailability of ampicillin correlated positively with the greater aqueous solubility and dissolution rate of anhydrous ampicillin compared with that of the trihydrate form. Lerk et al. reported that the binding capacity and flowability of α-lactose monohydrate[15] and of α-D-glucose[16] increased after dehydration because of a difference in pore size distribution. Because the phase transition on hydration or dehydration is accompanied by a change in the physicochemical properties, it is important to understand the mechanisms of these transitions, the experimental and environmental conditions under which they take place, and their rates under various conditions.

Classic dehydration kinetics is treated as a solid-state reaction, as shown in eq 1.[7,17]

$$A{\cdot}H_2O\ (s) \rightarrow A\ (s) + H_2O\ (g) \qquad (1)$$

Usually, reactions involving solids start from the surface and proceed inward as the reactant−product boundary layer contracts.[18] The initial generation of small product crystallites at the reactant−product interface is termed nucleation.[19] Such nucleation is most likely to occur at surfaces, where the molecules are usually more energetic than in the bulk of the crystal.[20] For a reaction such as desolvation, which involves a single solid, nucleation may occur rapidly over all surfaces or at the points of initial contact between the constituents of a mixture of solids. Two general points should be taken into consideration for solid-state reactions. First, the reactivity of a solid substance is often dependent on the total concentrations of highly deformed, or defective, regions of the lattice. Damaged external surfaces, superficial lattice imperfections, and scratches are often chemically more reactive than more perfect crystal faces. Second, the kinetics of a solid-state reaction may be controlled by the surface area, which is related to the mean particle size and to the particle size

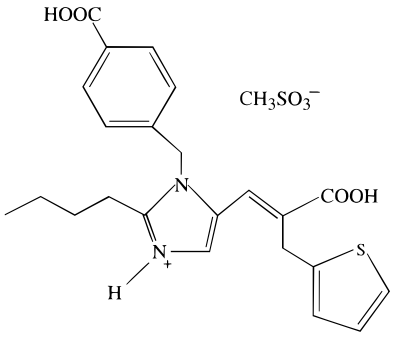

Scheme 1—The Molecular Structure of Eprosartan Mesylate (EM)

distribution. Because of the intrinsic heterogeneity of solid phases, the dehydration reaction is also sensitive to the environmental and reactant conditions, such as temperature, water vapor pressure, sample pre-history, sample weight,[21,22] and the geometry of the solid particles.[23]

Growth of nuclei in three dimensions has been observed during the decomposition of several compounds, but is not general because experimental observations for other substances have shown that the growth of nuclei under other conditions may be confined to particular lattice planes (i.e., along one or two dimensions).[19] Numerous methods have been used to study the dehydration process, including thermomicroscopy (hot stage microscopy, HSM), differential scanning calorimetry (DSC), thermogravimetric analysis (TGA), X-ray crystallography (powder X-ray diffractometry, PXRD), and analysis of the evolved gases.[7] The experimental dehydrated fraction, x, at different times, t, is plotted against t according to the kinetic models of the reaction mechanisms that are capable of operating in the solid-state decomposition.[18,24,25] The goodness of the fit to each kinetic equation was derived by examining the scatter of the residuals, s_e, about the mean, the standard deviation of the regression, S, and the determination coefficient, R^2, with less emphasis on the latter. Davis and Pryor[26] and Brown and Galwey[27] have criticized the use of R^2 alone as the sole determinant of the kinetic equation of best fit, especially when it has similar values for closely related equations. Random s_e without a trend and relatively small values of S of the regression are required for demonstrating a good fit to any reasonable kinetic model.[21,26] However, a good fit to a particular equation does not necessarily imply that the corresponding mechanism is correct.

Eprosartan mesylate (EM, Scheme 1) is used in the treatment of hypertension and exists as a dihydrate and anhydrate.[28,29] EM dihydrate can be prepared under a variety of conditions, for examples, by exposing the anhydrous drug substance to 98% RH for >15 days, by suspending the drug in an aqueous solution of 1.0 M methanesulfonic acid to form a slurry, and by granulating the drug in the presence of 3% corn starch. Little work has been done to study the dehydration behavior and kinetics of EM dihydrate, which is the basic information required for predicting the stability and other physicochemical properties of EM tablets. The purpose of this paper is to elucidate the dehydration kinetics of EM dihydrate, especially the effects of the particle size and temperature. Variable temperature PXRD and HSM should help to justify a mechanistic interpretation of the data. Cerius^{2TM} molecular modeling was used to visualize the crystal packing and to provide insight into the dehydration process at the molecular level. Preliminary reports of this work have been presented at the 1997 Annual Meeting of the American Association of Pharmaceutical Scientists.[30,31]

Experimental Section

Materials—Eprosartan mesylate (EM) anhydrate was supplied by SmithKline Beecham Pharmaceuticals, King of Prussia, PA. Methanesulfonic acid used for the preparation of EM dihydrate was supplied by Aldrich Chemical Company, Milwaukee, WI.

Preparation of EM Dihydrate—EM dihydrate was prepared by suspending 1.6 g of the anhydrous drug in 40 mL of 1.0 M aqueous methanesulfonic acid (to prevent the formation of eprosartan free base and to reduce the solubility of the salt, EM dihydrate, by the common ion effect) at 22.5 °C (room temperature). The suspension was sonicated for 2 min at 22.5 °C, and was then stirred for 2 h. The solid phase was collected by filtration, thoroughly washed with distilled water at 0 °C, and dried for 48 h at 22.5 °C in a 58% RH chamber. EM dihydrate was also prepared by exposing the anhydrous drug to 98% RH at 45 °C for 15 days or longer and by granulating the anhydrous drug in the presence of 3% (w/w) corn starch and 10% (w/w) distilled water. The experimental techniques for solid-state characterization, described later, show that the materials prepared by each of the three methods (slurry process, exposure to 98% RH, or granulation with 3% (w/w) corn starch) are indeed the same phase of EM dihydrate. The crystals, prepared by each method, were fractionated using USP standard sieves into the following three particle size ranges: <125 μm, 125−180 μm, and 180−250 μm.

Differential Scanning Calorimetry (DSC)—A DuPont differential scanning calorimeter (model 910, TA Instruments, New Castle, DE) equipped with a data station (Thermal Analyst 2000, TA Instruments) was used for the nonisothermal DSC studies. The temperature axis and cell constant of the DSC cell were calibrated with indium. The sample (2.05 ± 0.02 mg) was heated in open pans at heating rates of 5, 10, 15, 20, 25, 30, and 35 °C/min under 300−400 mL/min nitrogen purge. The activation energy of each dehydration step was determined by Kissinger's method[32] in which the heating rate, ϕ in °C/min, and the temperature at peak maximum, T_m in degrees Kelvin, are plotted according to the eq 2. This equation is derived with the assumption that the rate of reaction is maximal at the temperature at which the endothermic peak reaches a maximum. The activation energy was calculated from the slopes of the plots of $\ln(\phi/T_m^2)$ versus $1/T_m$.

$$\mathrm{d}\ln(\phi/T_m^2)/\mathrm{d}(1/T_m) = -E_a/R \qquad (2)$$

Thermogravimetric Analysis (TGA)—A DuPont thermogravimetric analyzer (model 951, TA Instruments, New Castle, DE) linked to a data station (Thermal Analyst 2000, TA Instruments) was used for the isothermal dehydration studies. The weight loss, expressed as fraction dehydrated, x, at time t, was fitted to the known solid-state kinetic equations.[7,18,25] The activation energy and the frequency factor for the dehydration of EM dihydrate were calculated from the slope and the intercept, respectively, of the Arrhenius plots of the logarithm of the rate constants versus reciprocal absolute temperature. For the first dehydration step, corresponding to the formation of the monohydrate, isothermal scans of x versus t were obtained at fixed temperatures covering the range of 28 to 35 °C. The fraction dehydrated was calculated as the ratio, weight of water lost/maximum possible weight loss of water, in dehydrating EM dihydrate to the monohydrate. Therefore, 100% fraction dehydrated ($x = 1$) corresponds to the loss of 1 mol of water of hydration. For the second dehydration step, corresponding to the formation of the anhydrate from the monohydrate, the samples were heated in advance to 40 °C to allow completion of the first dehydration step. Analogous isothermal x versus t plots were obtained at fixed temperatures from 75 to 95 °C. Therefore, 100% fraction dehydrated ($x = 1$) corresponds the loss of 1 mol of water from EM monohydrate leading to the anhydrate. Prior to each isothermal scan, the sample (10.00 ± 0.02 mg) was rapidly heated to the set temperature at a rate of 150 °C/min and maintained at that temperature until the each dehydration step was completed. Nitrogen purge at a constant rate (300−400 mL/min) was maintained during each run.

Variable Temperature Powder X-ray Diffraction (PXRD)—Variable temperature PXRD of EM dihydrate was carried out at ambient temperature and atmosphere using a diffractometer (Scintag 2000, Sunnyvale, CA) with a hot stage attachment, with Cu Kα radiation (40 mA, 45 kV). Samples were packed in a copper

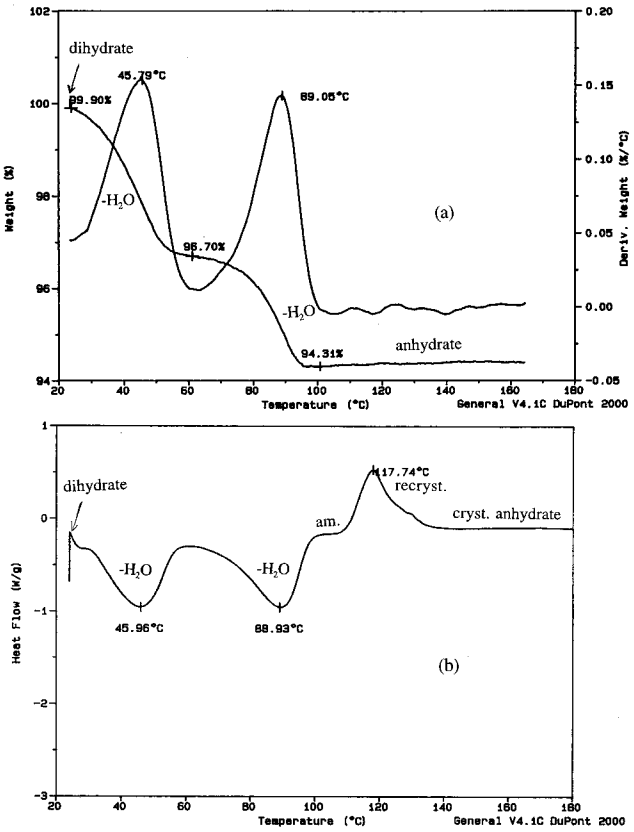

Figure 1—Typical curves for (a) thermogravimetric analysis (TGA), derivative thermogravimetric analysis (dTGA), and (b) differential scanning calorimetry (DSC) of eprosartan mesylate (EM) dihydrate.

holder and heated at the rate of 10 °C/min to the set temperature. The diffraction angle, 2θ, was scanned from 5° to 15° and increased at a rate of 3°/min with a counting time of 1 s.

Polarized Light Microscopy—EM dihydrate and the solid phase remaining after dehydration were observed under an optical microscope equipped with polarized light accessories (M3J, Wild Heerbrugg, Heerbrugg, Switzerland).

Hot Stage Microscopy (HSM)—The thermal events were observed on a hot stage (FP80, Mettler Instrument Corp., Highstown, NJ) under a microscope (M3J, Wild Heerbrugg, Heerbrugg, Switzerland). The EM dihydrate crystals were heated at a constant rate of 5 °C/min up to the melting point of anhydrous EM at ~250 °C.

Molecular Modeling—All molecular modeling calculations were performed using Cerius^{2TM} software, program version 3.5 (Molecular Simulations, San Diego, CA), running on the commercial workstations (Silicon Graphics, Personal Iris 4D/20, Power Series 2×R3000 and Indigo R4000).

Results and Discussions

Identification of Dehydration Steps—EM dihydrate exhibits two successive dehydration steps at 25−70 °C and 70−120 °C in open-pan TGA (Figure 1a), each corresponding to the loss of 1 mol of water. When EM dihydrate samples were subjected to DSC in an open pan under experimental conditions similar to those for TGA, the peak maximum temperatures in the DSC curve (46 °C and 89 °C in Figure 1b) agreed well with those in derivative TGA (dTGA) (46 °C and 89 °C in Figure 1a) for both dehydration steps. In addition, the DSC curve showed an exotherm with a peak maximum at 118 °C, suggesting recrystallization of EM anhydrate from the amorphous phase that was presumably formed immediately after the second dehydration step. These results were confirmed by variable temperature PXRD (Figure 2), despite the low signal-to-noise

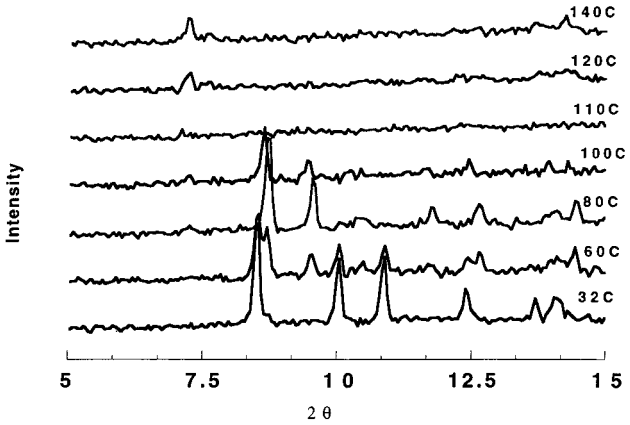

Figure 2—Variable temperature powder X-ray diffraction patterns for eprosartan mesylate (EM) dihydrate.

ratio, which is attributed to the small sample size and to the narrow range of scan angles. At 32 °C, EM dihydrate remains as its original form, as indicated by the PXRD pattern, which is similar to that of EM dihydrate (Figure 3a). As the temperature increases from 32 to 100 °C, the EM dihydrate gradually loses 1 mol of water to yield a mixture of the original dihydrate and a new phase, presumably the monohydrate, at 60 and 80 °C, and the monohydrate alone at 100 °C. Above 100 °C, the EM monohydrate gradually loses the final 1 mol of water and to form an amorphous phase, presumably that of EM anhydrate at 110 °C. At 150 °C, the PXRD pattern shows a new solid phase with low intensity peaks corresponding to a phase of low crystallinity, presumably the EM anhydrate that crystallized at ~118 °C in DSC (Figure 1b). Unlike the amorphous anhydrate, the partially crystalline anhydrate appeared birefringent under polarized light microscopy (Figure 4f). The phase changes of EM dihydrate on heating are summarized as follows:

first step dehydration:

$$EM{\cdot}2H_2O\ (crystal) \xrightarrow{25-70\ ^\circ C} EM{\cdot}H_2O\ (crystal) + H_2O\ (g)$$

second step dehydration:

$$EM{\cdot}H_2O\ (crystal) \xrightarrow{70-120\ ^\circ C} EM\ (amorphous) + H_2O\ (g)$$

recrystallization:

$$EM\ (amorphous) \xrightarrow{120-140\ ^\circ C} EM\ (crystal)$$

melting:

$$EM\ (crystal) \xrightarrow{\sim 250\ ^\circ C} EM\ (liquid)$$

The single-crystal structure of EM dihydrate[33] has four water molecules per asymmetric unit, with the following two types of intermolecular hydrogen bond interactions, as shown in Table 1: (a) each oxygen atom in each water molecule forms a hydrogen bond with the hydrogen atom on the carboxyl group of the same asymmetric unit; and (b) each hydrogen atom in each water molecule forms a hydrogen bond with the oxygen atom on the mesylate anion either within the same or in the neighboring unit cell. Each of the four different water molecules forms two or three hydrogen bonds. The hydrogen bond lengths and angles for each water molecule were calculated using Cerius^{2TM} molecular modeling software and are summarized in Table 1. The $H_2O(3)$ molecule is probably more loosely bound than the other water molecules because it forms only two hydrogen bonds, whereas the other three water molecules

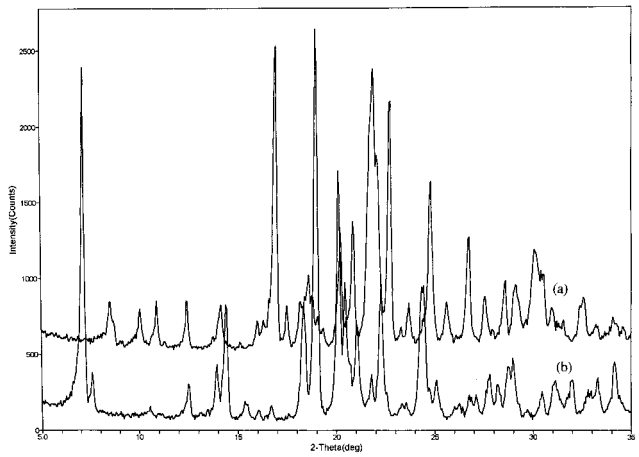

Figure 3—Typical powder X-ray diffraction patterns for eprosartan mesylate (EM): (a) dihydrate and (b) anhydrate.

form three hydrogen bonds. The $H_2O(4)$ molecule may also be more loosely bound than the $H_2O(1)$ and $H_2O(2)$ molecules because of its slightly greater hydrogen bond lengths and smaller hydrogen bond angles. Therefore, $H_2O(3)$ or $H_2O(4)$ may be included in the 1 mol of water that escapes during the first dehydration step at 25−70 °C in open-pan TGA (Figure 1a), whereas $H_2O(1)$ and $H_2O(2)$ may correspond to the second mole of water released during the second dehydration step at 70−120 °C.

Isothermal Dehydration Studies—Typical isothermal dehydration curves are shown in Figure 5 for the <125-μm sieve fraction of EM dihydrate; Figure 5a depicts the first step dehydration and Figure 5b depicts the second step dehydration. The isothermal dehydration curves for the other sieve fractions show similar features; namely, sigmoidal profiles and dehydration rates that increase with increasing temperature. The sigmoidal curves are characterized by an induction period at low x values, a growth period with an inflection at intermediate values of x, and a deceleratory period at high x values. The sigmoid-shaped curves usually result from reactions that occur at a reactant−product interface. The interface is initially established as a limited number of points on the surface of the reactant crystal by the formation of microcrystals (nuclei) of the product. Reaction thereafter proceeds within the strained contact area at the reactant−product interface. At the start of the reaction, the area of such an interface is small and limited to a number of surface sites so that the reaction is slow. At a later stage of the reaction, some nuclei have grown to a significant size and other nuclei are being formed. The reaction rate is greater than that during the initial formation of nuclei because of the increase of the reactant−product interfacial area. On continued growth of such nuclei, a point is reached at which the reactant−product interfaces from different nuclei begin to overlap so that the rate of expansion of the interface and the rate of reaction decrease.[19]

For the <125-μm fraction and for both the first and second dehydration steps, Table 2 shows that the Avrami−Erofeev equation (A3, $n = 1/3$) gave the smallest S, whereas the s_e values were randomly distributed without a trend and R^2 was largest. Thus, the successive dehydrations of the <125-μm fraction of EM dihydrate best fit the Avrami−Erofeev equation ($n = 1/3$) for which Figures 6a and 6b are the representative plots.

For the 125−180-μm and 180−250-μm fractions of EM dihydrate, the statistical parameters (S and R^2) and the dehydration equations of best fit are summarized in Tables 3 and 4, respectively. These isothermal dehydration studies were carried out between 28.3 and 93.7 °C. Up to 90.8 °C, for the first and second dehydration steps of the 125−180-μm fraction, the dehydration kinetics are best represented by the equations for a phase boundary reaction, in particular R2, the two-dimensional cylindrical symmetry reaction. At 91.2 °C, corresponding to the second dehydration step, the equation of best fit is the three-dimensional nucleation-controlled equation, A3, suggesting the dominance of nucleation and growth processes at this higher temperature. Similar dehydration kinetics were observed for the 180−250-μm fraction. At temperatures <90.7 °C for the first and second dehydration steps of the 180−250-μm fraction, the dehydration kinetics are best described by R2, the two-dimensional cylindrical phase boundary reaction. At 90.7 and 93.7 °C for the second step dehydration of the 180−250-μm sieve fraction, the equation of best fit is A3. The best fitting kinetic equations for dehydration of various sieve fractions of EM dihydrate, and the s_e values (i.e., the experimental x − the predicted x), are shown in Table 5.

The previous paragraph (Table 5) shows that the dehydration kinetics of the relatively large particles (125−180-μm and 180−250-μm fractions) up to 90.7 °C most closely follows the two-dimensional phase boundary equation (R2). Indeed, visual observation of the larger crystals under HSM (Figure 4) supports this mechanism. Direct microscopic observations of single crystals of EM dihydrate showed that tiny ruptures first appeared at a few random positions on the crystal surface, indicating initial formation of the reactant−product interface. The appearance and growth of the microcrystals proceeded along the needle axis of the crystals. The growth rate of these centers perpendicular to the needle-axis was slower than that along the needle-axis, indicating that the water molecules escape along this long axis during dehydration. The needle shape of the crystals was retained even after completion of the dehydration at the higher temperatures. This observation suggests that the dehydration reaction is confined to two-dimensions rather than to three-dimensions, which was indicated by fragmentation of the larger crystals upon dehydration.

Molecular modeling simulation (Cerius^{2TM} software) was used to visualize the crystal packing and to interpret the dehydration behavior of EM dihydrate under HSM, and revealed the existence of a water channel at the molecular level. Figures 7a and 7b show the crystal packing pattern of EM dihydrate. In general, the structure of EM dihydrate, when viewed in the direction of the a axis, is composed of alternate layers of hydrophobic regions, containing aromatic rings and hydrocarbon chains, and hydrophilic regions, containing polar functional groups and water molecules that form the hydrogen-bonded networks. A discrete hydrogen-bonding tunnel lies parallel to the a crystallographic axis as presented in Figures 7a and 7b, indicating that the water channel is also parallel to the a axis. The water molecules can leave the EM dihydrate crystal along these water channels with the smallest resistance. Dehydration along other crystallographic directions (i.e., along the b and c axes) would require the water molecules to penetrate the somewhat closely packed layers of nonpolar groups along these directions, which is unlikely. Suzuki et al.[34] and Gerdil et al.[35] applied microscopic observations and crystallographic data to the dehydration of caffeine 4/5-hydrate. Scanning electron micrographs showed that the needle-shaped crystals of the anhydrous dehydrated phase of caffeine are oriented parallel to the long axis forming channel-like cavities. This arrangement is consistent with crystallographic studies that show the chains of water molecules arranged along this axis. Byrn[7] reported that the tunnels of water molecules in thymine hydrate are oriented along the c crystallographic axis, and that rapid dehydration is consistent with the preferential exit of water molecules through these tunnels. We note that

[a] and [b] represent two different hydrogen bonds within one water molecule. [c] Distance is >4.0 Å, suggesting insignificant hydrogen bonding. [d] Bond angle is <90.0°, suggesting insignificant hydrogen bonding.

many of these hydrates crystallize with the long crystal axis parallel to the water tunnels and nearly perpendicular to the aromatic rings.

The kinetic equations of best fit for the first and second isothermal dehydration steps of three sieve fractions of EM dihydrate differ somewhat at different temperatures (Table 5). For the <125-μm fraction, the A3 equation (three-dimensional growth of nuclei) may arise from the greater total surface area or from the greater surface-to-volume ratio of these smaller crystals because nucleation is fre-

quently initiated at the crystal surfaces. The A3 equation may also arise from the greater fraction of the more reactive zones of the smaller particles (i.e., the crystal faces, edges, corners, and cracks). The smaller crystals usually have more lattice imperfections on their surfaces, which are believed to be more reactive chemically than the more perfect crystalline faces of the larger crystals. The initial generation of the small product nuclei may be a difficult process that can occur only at a limited number of the reactive sites on the crystal surface. Reaction may thereafter proceed with greater facility at the reactant−product interface. Griesser and Burger[36] reported that the dehydration of caffeine 4/5-hydrate is controlled by nucleation and growth for the smaller crystals but by diffusion for the larger crystals. In the dehydration of the larger EM dihydrate crystals (125−180 μm and 180−250 μm) at lower temperatures, the escape of water molecules from the crystal lattice follows the R2 equation (two-dimensional

phase boundary reaction). The explanation offered is that the escape of the loosely bound water molecules in the crystal lattice produces a vacancy on the surface of the EM dihydrate crystals. This intermediate structure is unstable, so recrystallization to the anhydrous phase occurs. In this way, a phase boundary is formed that is preferentially oriented along the a axis inside the crystal. At higher temperatures, the large EM dihydrate particles can presumably break up to produce smaller crystals. A large number of reactive crystal defects, which are the initial sites for the nucleation, are presumably produced by the fragmentation of the larger particles into smaller ones.

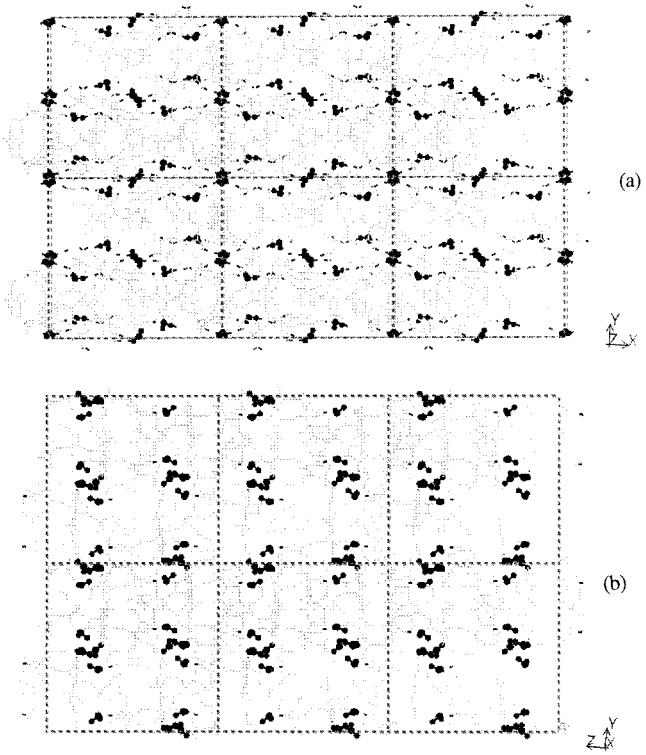

Figure 7—Packing diagrams of eprosartan mesylate (EM) dihydrate, where the dotted lines between the atoms indicate the hydrogen bonds along (a) the *a* axis and (b) the *c* axis.

Hence, for the larger crystals, the dominant dehydration process (two-dimensional phase boundary, R2, cylindrical symmetry) at low temperatures is replaced by three-dimensional nucleation-controlled (A3) dehydration at high temperatures because of the creation of increased surface area and crystal defects at high temperatures, which are the reactive sites for the formation of nuclei.

For the first and second dehydration steps of EM dihydrate, the activation energies, E_a, obtained from Arrhenius plots (Figure 8) and the frequency factors according to the best-fitting mechanism are presented in Table 6. In all cases, E_a for the second dehydration step (~32 kcal/mol) is higher than that for the first step (~19 kcal/mol), which indicates that the second mole of escaping water molecules is more tightly bound. This conclusion agrees

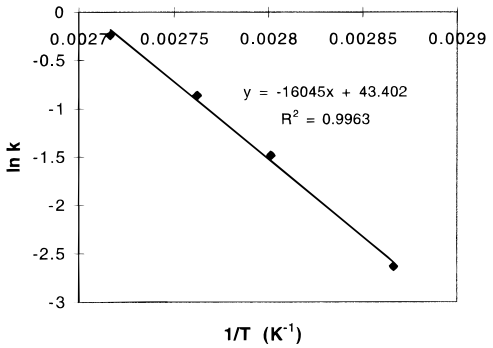

Figure 8—Arrhenius plot from the best-fitting dehydration mechanism for the second dehydration step of eprosartan mesylate (EM) dihydrate samples (<125-μm sieve fraction).

with that from the study of the bonding environment of water molecules in EM dihydrate, already discussed. Neither the activation energy nor the frequency factor depend significantly on the particle size. However, Agbada and York[21] and Van Dooren[37] reported the tendency toward lower activation energy with decreasing particle size for the dehydration of theophylline monohydrate and sodium citrate.

Nonisothermal Dehydration Studies—For the EM dihydrate samples prepared by different methods, the activation energies and the frequency factors of the first and second dehydration steps were calculated from the Kissinger plots of DSC data and are listed in Table 7. The activation energies for dehydration of the EM dihydrate samples depend on the method of preparation and increase in the following order: slurry process < 98% RH < in the presence of 3% corn starch. The dependence of the activation energy of dehydration on the manufacturing process suggests the influence of variables, such as crystals defects, sample geometry, and surface characteristics, on the properties of the crystals. Similarly, Agbada and York[21] noted that the sample history plays a critical role in the dehydration reactions of theophylline monohydrate.

Conclusions

The two consecutive dehydration reactions of EM dihydrate are complex and represent different kinetic processes that are greatly dependent on the particle size and tem-

perature. Both three-dimensional growth of nuclei and two-dimensional phase boundary equations are postulated to represent the predominant processes in the dehydration kinetics of EM dihydrate. Such information is essential for understanding and improving the stability of EM dihydrate, which may be compromised during the processes of manufacture and storage. In addition, the activation energies for the two consecutive dehydration processes of EM dihydrate depend on the sample preparation history. HSM and variable temperature PXRD are valuable complementary tools for the interpretation of dehydration behavior, whereas molecular modeling provides structural insight into the dehydration mechanisms.

Acknowledgments

We thank the following: Dr. Victor G. Young, Jr., for solving the crystal structure of eprosartan mesylate dihydrate (ref 33) on which Figure 7 and associated discussion is based; Geoff G. Z. Zhang and Linna R. Chen for helpful discussions; SmithKline Beecham Pharmaceuticals, King of Prussia, PA, for financial support and for supplying eprosartan mesylate; and the Supercomputing Institute of the University of Minnesota for financially supporting our use of the Medicinal Chemistry/Supercomputing Institute Visualization−Workstation Laboratory.

Accepted for publication August 2, 1999.

Abstract □ The effects of transdermal iontophoresis (IP) codelivery of hydrocortisone (HC) on metoclopramide hydrochloride (MCP) pharmacokinetics and on skin-induced reactions were evaluated in a randomized, crossover clinical study. MCP, an antiemetic, low molecular weight, cationic drug intended for systemic delivery, was delivered from the anode of IP systems at a constant current of 100 μA/cm^2. HC, a neutral endogenous antiinflammatory agent, was codelivered from the same electrode, primarily by electroosmotic processes. Each subject ($n = 7$) wore two identical IP systems (MCP alone or MCP plus HC), each supplying 500 μA, one on each upper arm for 4 h. One week later, each subject repeated the procedure with the alternate type of MCP system. HC did not change the pharmacokinetics of MCP: There were no statistically significant differences in MCP plasma concentrations, half-life, area under the curve (AUC), or rate of absorption between the two treatment groups. However, HC significantly decreased erythema and edema scores produced by the IP of MCP. In both groups, a steady-state MCP flux of about 100 μg/(cm^2 × h) was achieved after only 1 h of transport, and input rate dropped dramatically immediately after removal of the system. In vitro, HC flux through human epidermis from an MCP plus HC formulation was 2.8 ± 1.1 μg/(cm^2 × h) after 4 h transport at 100 μA/cm^2, suggesting negligible systemic exposure to hydrocortisone. These data indicate that MCP input rate and its clearance from the skin are unaltered by HC and that the codelivery of HC by IP is an effective strategy for inhibition of local reactions resulting from the transdermal delivery of drugs.

Introduction

Transdermal drug delivery was introduced as a means to deliver drugs intended for systemic therapy more than 20 years ago. Typically, transdermal systems deliver a drug in a zero-order fashion over several days.[1] This mode of delivery is particularly desirable for drugs with a low therapeutic index.[2] For these agents, zero-order delivery may result in reduction of systemic side effects. Unfortunately, local delivery results in high drug concentrations in the delivery site that can result in irritation and sensitization to the drug being delivered.[3] Several clinically available transdermal systems have been reported to produce local irritation or sensitization.[4−6] In addition, reports indicate that many potential candidates for transdermal delivery may be too irritating or sensitizing for development.[7,8] Various strategies have been developed to minimize these local side effects.[9−14] One of the most promising strategies consists of pretreating the skin with a glucocorticoid (GC) or codelivering it with the drug.[15] This pretreatment strategy has been applied to several transdermal systems already on the market.[4,16] To date, there are no commercialized combination products. One of the potential problems associated with the use of the topical delivery of GCs results from their local vasoconstrictive effect.[17] This pharmacological effect is directly dependent on the potency and the flux of the GC[18] and may possibly affect the pharmacokinetics of the drug being delivered.

Surprisingly, there are only a few reports of the effect of GCs on the pharmacokinetics of a drug being delivered transcutaneously. Ito and O′Connor reported that pretreatment with a 0.5% HC cream did not affect the pharmacokinetics of clonidine delivered from Catapres-TTS applied to the same skin site.[16] Unfortunately, this study did not address HC delivery through the skin—in particular if HC was codelivered efficiently during the 7-day patch application. Finally, the effectiveness of HC in reducing the clonidine-induced skin reaction could not be accurately evaluated because the subjects were not previously sensitized to clonidine.

IP offers a means to deliver drugs through the skin with a minimum lag time and an optimal control of drug flux.[19] IP delivery of MCP, an antiemetic drug intended for systemic delivery, was previously found to result in moderate skin irritation at the site of delivery (unpublished data). We decided to use the IP technology to demonstrate that hydrocortisone can be used in transdermal delivery to minimize skin reactions caused by the transdermal delivery of drugs without significant alteration of drug flux and drug clearance from the skin.

Materials and Methods

In Vitro Studies—For in vitro studies, human skin from cadavers was used. The epidermis was separated from the dermis after incubating the skin for about 1 min in water heated to 60 °C. The separated epidermis was mounted in custom-made IP cells (two compartment cells) with the stratum corneum facing the donor compartment. IP cells were assembled with a silver foil anode in the drug donor compartment and a silver/silver chloride cathode in the receptor compartment. The donors were filled with 2 mL of saturated HC (USP clinical grade, Diosynth, Chicago, IL) aqueous solution in Dulbecco's phosphate-buffered saline or 10% (w/w) MCP (USP clinical grade, Lee Lab, Arlington, VA) aqueous solution saturated with HC. The receptors were filled with 1.8 mL of Dulbecco's phosphate-buffered saline. The permeation cells were thermostated at 32 °C. Experiments were run without current or under constant current set at 0.1 mA/cm^2 for 18 h with samples taken every 4 h. Both HC and MCP were assayed by high-performance liquid chromatographic (HPLC) methods.[20,21]

Clinical Study—Electrically assisted delivery of MCP was accomplished with custom-built IP systems. The IP systems had

a silver anode (donor) and an anodic reservoir gel containing a 10% (w/w) aqueous solution of MCP with or without a 0.5% (w/w) saturated aqueous solution of HC and 3% (w/w) hydroxy ethyl cellulose (HEC, Aqualon, Wilmington, DE) to form a gel. The IP systems also had a silver chloride cathode (counter electrode) and a cathodic reservoir containing a buffered saline gel. The reservoir gels (i.e., both the anodic and cathodic gels) each had a volume of approximately 600 μL and a skin-contacting surface area of about 5 cm^2. The electrodes were connected to a DC power source that supplied a constant level of electric current of 500 μA or 100 μA/cm^2. The study was undertaken in volunteers after approval by the Medical Review Board at ALZA, which, at the time the study was performed, met FDA criteria, and in accordance with the principles of the Declaration of Helsinki. Each study volunteer met all of the following inclusion criteria: male, 18−50 years old; medical history, physical examination demonstrating no clinically relevant abnormalities, SMA 17 blood profile tests (glucose, blood-urea-nitrogen, uric acid, calcium, phosphorus, total protein, albumin, cholesterol, total bilirubin, alkaline phosphatase, aspartate aminotransferase, alanine aminotransferase, lactate dehydrogenase, sodium, potassium, creatinine, bicarbonate, and chloride), complete blood count, urinalysis, and electrocardiogram; normotensive. Exclusion criteria included dermatological disorders, application sites presenting scar tissue or moles, known hypersensitivity to any component of the IP system, use of antiinflammatory drugs such as steroids, nonsteroidal antiinflammatory drugs, and abnormal clinical laboratory tests. Informed, written consent was obtained from each subject. The IP systems were applied to and removed from the upper arms of subjects by the study investigators. The application site was wiped with 70% isopropyl alcohol pads prior to system application. Each week, each subject wore two identical IP systems simultaneously, one per arm, for 4 h. On the first week, four subjects wore two systems containing MCP and four subjects wore two systems containing MCP plus HC. One week later, each subject repeated the procedure with the alternate type of MCP system. Seven subjects completed this study.

Voltage and current were measured at 0.5, 1, 2, 3, and 4 h after system application. To perform voltage measurements at each individual electrode, an adjacent skin site was lightly abraded using electrocardiogram-grade abrasive tape (One-Step Skin Prep, 3M Canada Inc, London, Ontario). An electrocardiogram electrode (TenderTrace, NDM, Dayton, OH) was immediately applied to this skin site. Voltage was measured between this reference electrode and the anode or cathode of the IP system at each time point. Electrode resistance was extrapolated from current and voltage measurements. Blood samples (10 mL) were drawn at hours 0, 0.5, 1, 2, 3, 4, 4.5, 5, 6, 8, and 20 (systems were removed at hour 4). Blood samples were centrifuged immediately after collection. The plasma was divided into duplicate aliquots and frozen at −20 °C until analysis. MCP analysis was performed by Harris Labs (Lincoln, NE) with a validated HPLC method.[21] The MCP assay quantification limit was 3.0 ng/mL.

Individual plasma concentrations were used for all pharmacokinetic calculations and were summarized by nominal sampling times. Plasma MCP concentrations below the assay quantification limit of 3.0 ng/mL were assigned a value of 0. The maximum observed plasma MCP concentration (C_{max}) and corresponding sampling time (T_{max}), expressed in hours following initial dosing, were determined for each treatment. The plasma MCP apparent elimination rate constant (k) was estimated by linear regression of the log-transformed (natural log) plasma MCP concentrations during the log-linear phase of the data after system removal. Apparent half-life values were calculated as 0.693 divided by k. MCP area under the plasma concentration versus time values (AUC) were determined by the linear trapezoidal method from study hours 0 to 20, and from hour 0 to the last detectable concentration at time t, AUC_t. The AUC value extrapolated to infinity, AUC_{inf}, was determined as the sum of AUC_t plus the area extrapolated to infinity, as calculated by the concentration at time t (C_t) divided by k. The average MCP concentration, C_{avg}, was calculated as $AUC_{(0-20)}$ divided by 20 h. The cumulative amount of metoclopramide absorbed and the rate of MCP absorption was calculated according to the Wagner and Nelson method.[22]

Visual skin inspection following system removal was done to evaluate the presence and extent of erythema, edema, papules, and pustules. Edema, extent of erythema, papules, and pustules were scored using a 0−2 visual scale and rated as follows: 0 = none, 1 = <50% of occluded area, 2 = >50% of occluded area. Scores for erythema: 0 = none, 1 = barely perceptible redness, 2 = definite redness, 3 = beet redness. Subjects were also asked to report any itching. Visual skin site evaluations were conducted by a trained nurse under the supervision of a medical doctor at 0 (within 10 min after system removal), 1, 4, 24, and 48 h following system removal and were continued until skin sites were clear. Skin sites were also evaluated by skin color reflectance using a Chroma meter CR 210 (Minolta, Ramsey, NJ) at 1, 4, 24, and 48 h following system removal.[23] Reflectance measurements were made by taking the mean a^* value of three readings at adjacent untreated sites and subtracting that value from the mean of three readings taken at the treated site.

Table 1—In Vitro Transdermal Flux of HC and MCP 4 Hours after Initiation of Transport. Transdermal Flux Was Evaluated at 32 °C. HC solubility was determined at 25 °C

formulation	current (μA/cm^2)	HC solubility (mg/mL)	flux (μg/(cm^2 h)	
			HC	MCP
HC	0	0.26	0.02 ± 0.00	NA
HC	100	0.26	0.32 ± 0.11	NA
HC + MCP	100	4.0	2.84 ± 1.12	131 ± 27

Table 2—Subject Demographics of the Seven Caucasian Healthy Men Completing the Study

	mean	SEM	range
age (years)	32.3	1.9	25–39
height (cm)	183	3.0	173–198
weight (kg)	76.6	3.7	68–91

Statistical Analysis—All results are presented as the mean with its associated standard error of the mean (SEM). Statistical analysis was performed using the Student's t test. A probability value of $p < 0.05$ was considered statistically significant.

Results

In Vitro Studies—HC flux through human epidermis was found to be 2.8 ± 1.1 μg/(cm^2×h) after 4 h transport at 0.1 mA/cm^2 from a 10% MCP solution saturated with HC. The flux of MCP from the same formulation was 131 ± 27 μg/(cm^2 × h) (Table 1). HC flux from this formulation was almost 1 order of magnitude greater than that from the formulation containing no MCP. A 0.1 mA/cm^2 current increased the passive flux of HC by more than 1 order of magnitude. Under IP conditions, steady-state flux was achieved for both drugs at or before the 4-h time point (data not shown). Solubility of hydrocortisone at 25 °C was increased from 0.26 mg/mL in the solution without MCP to 4 mg/mL in the presence of 10% MCP.

Demographics—Laboratory exams conducted before the study showed that all subjects were healthy. Eight Caucasian men entered the study and seven completed it. One subject dropped out due to an unrelated illness. Subject demographics are summarized in Table 2.

System Functionality—All IP systems reached the desired current setting within 30 min after application. With MCP alone, average current at this time was 470 ± 6 μA, and was not significantly different from 484 ± 3 μA for MCP plus HC. Current remained constant for the remaining application time. At 4 h, current was 478 ± 3 μA for MCP versus 486 ± 5 μA for MCP plus HC. Anode resistance values at the MCP anode 30 min and 4 h after application were 24 ± 3 kΩ × cm^2 and 18 ± 2 kΩ × cm^2, respectively. In the presence of HC, anode resistance values were 21 ± 2 and 14 ± 1 kΩ × cm^2 at the same time points. At 4 h, cathode resistance was 2.0 ± 0.4 kΩ × cm^2 for MCP versus 3.1 ± 1.3 kΩ × cm^2 for MCP plus HC. Resistance

Table 3—Pharmacokinetics Parameters of MCP Delivered by IP from an MCP System or an MCP Plus HC System

	MCP		MCP + HC	
parameter	mean	SEM	mean	SEM
C_{max} (ng/mL)	16.1	2.3	17.3	1.6
T_{max} (h)	4.07	0.07	4.14	0.09
$t_{1/2}$ (h)	4.76	0.38	4.86	0.49
elimination rate constant	0.153	0.015	0.151	0.013
AUC_t (ng × h/mL)	80.1	12.4	86.9	10.6
AUC_{inf} (ng × h/mL)	143	25	163	29
C_{avg} (ng/mL)	4.01	0.62	4.35	0.53

values were not significantly different when MCP alone was compared with MCP with HC.

Plasma MCP Pharmacokinetics—Measurable MCP plasma concentrations were detected in most subjects 1 h after system application. The mean plasma MCP concentrations, with and without HC, are displayed in Figure 1. C_{max} averaged 16 ng/mL for MCP alone, and was not significantly different from the 17 ng/mL C_{max} value for MCP plus HC. T_{max} coincided with the time of system removal in both groups (Table 3). Mean plasma concentrations of MCP, with or without HC, started to drop 0.5 h after system removal (Figure 1). Sixteen hours after system removal, mean plasma drug concentrations were all below the limits of detection. The mean half-life and AUC values of MCP, with and without HC, were equivalent (Table 3). The mean rate of MCP absorption (Figure 2) was not significantly different for the two groups. Steady-state input for MCP of about 100 μg/(cm^2 × h) was achieved by 1 h. Half an hour after removal of the systems, the input rate had dropped by about a factor of 4 to less than 25 μg/(cm^2 × h). The cumulative amount of MCP absorbed per subject is shown in Figure 3. After 4 h IP, about 4 mg MCP had been absorbed, irrespective of the treatment (3.8 ± 0.6 mg for MCP alone versus 4.1 ± 0.7 mg for MCP plus HC). Little absorption was observed following removal of the IP systems.

Topical Effects—all subjects presented some erythema at the anode following system removal. The erythema was homogeneously distributed and limited to the skin-contacting area of the gel (1 h after removal of the system, erythema extent at the anode was 2.0 ± 0.0 versus 1.9 ± 0.1 for MCP and MCP with HC, respectively). Erythema had resolved in all subjects by 72 h. HC significantly decreased erythema scores as assessed visually at all time points except 1 h (Figure 4). Similar results were obtained

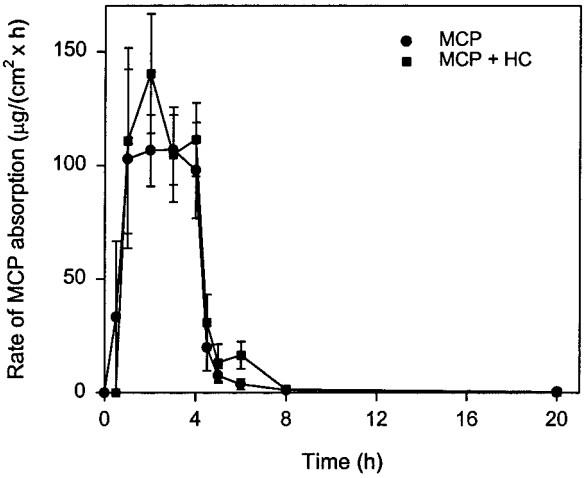

Figure 2—Mean rate of MCP absorption in subjects receiving IP of MCP or IP of MCP plus HC. Systems were removed at the 4-h time point.

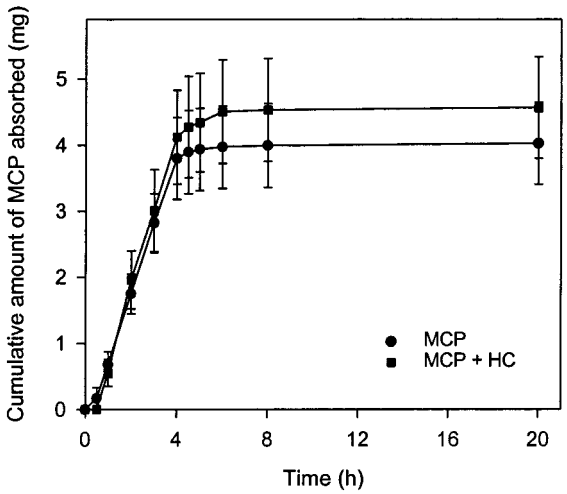

Figure 3—Mean cumulative amount of MCP absorption in subjects receiving IP of MCP or IP of MCP plus HC. Systems were removed at the 4-h time point.

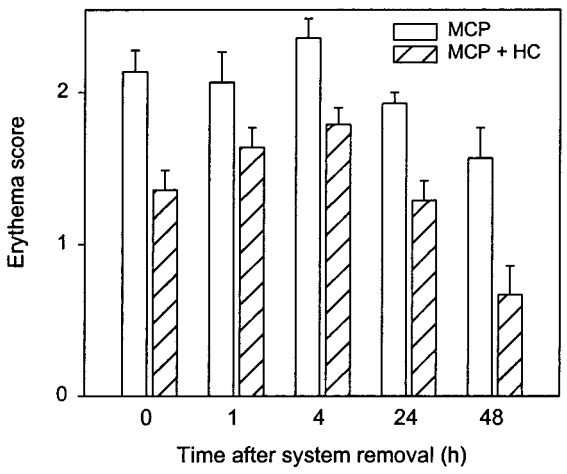

Figure 4—Mean erythema scores at the anode after 4 h IP of MCP or MCP plus HC.

with skin color reflectance measurements: One hour after removal of the system, reflectance values were 2.1 ± 0.3 and 0.8 ± 0.3 for MCP and MCP with HC, respectively. Four hours after removal of the system, reflectance values were 2.7 ± 0.2 and 0.7 ± 0.3 for MCP and MCP with HC, respectively. At 24 and 48 h after removal of the system,

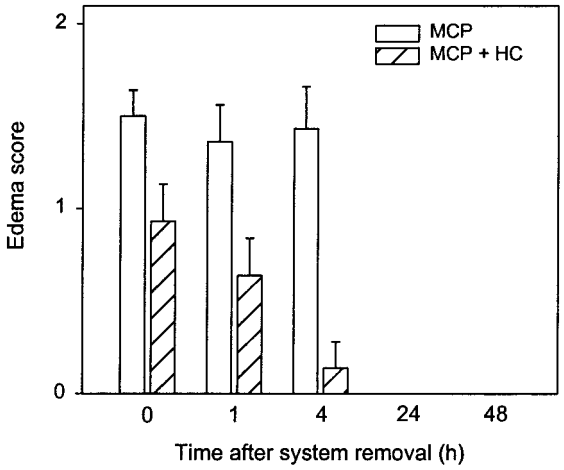

Figure 5—Mean edema scores at the anode after 4 h IP of MCP or MCP plus HC.

reflectance values were below 1 in both groups and were not statistically significant between the two groups.

Edema at the site of system application was observed in most subjects. HC significantly decreased edema score at 0, 1, and 4 h. Four hours after system removal, the mean edema score at the anode delivering MCP was 1.4. HC almost completely inhibited edema at this time point. Edema was resolved in all subjects by 24 h following system removal (Figure 5). There were no papules or pustules observed in any of the subjects and no subjects reported itching.

Discussion

MCP is an antiemetic prescription drug used in the treatment of gastroesophageal reflux and in the prevention of nausea and vomiting. This drug is intended for systemic delivery (iv or oral), and clinical MCP doses range between 10 and 60 mg/d.[24] Subjects in this study wore two 5-cm^2 IP transdermal systems, and input rate was about 1 mg/h at steady state. The cumulative amount of MCP absorbed systemically was about 4 mg after 4 h IP. Steady-state MCP flux of about 100 μg/($cm^2 \times$ h) was achieved after only 1 h of transport, indicating a brief lag time, and input rate dropped dramatically immediately after removal of the systems. The brief lag time observed and the rapid drop in calculated input rate is consistent with a negligible MCP depot or accumulation in the skin. In addition, the calculated MCP half-life is similar to values reported in the literature following iv administration,[24] an outcome also consistent with an absence of skin depot. Collectively, these results indicate that usable MCP therapy could be achieved with an electrode size of about 5 to 30 cm^2.
