Received: May 30, 1996; In Final Form: October 9, 1996<sup>⊗</sup>

The total rate constant for the NH<sub>2</sub> + NO reaction has been measured in the temperature range 305–1037 K using a laser photolysis mass spectrometric technique by probing the rates of H<sub>2</sub>O formation and NO decay. A weighted least-squares analysis of our data gives the following total rate constant expression:  $k_t = 8.29 \times 10^{13} T^{-0.57} \exp(300/T) \text{ cm}^3/(\text{mol s})$ . The branching ratios for the two product channels of the NH<sub>2</sub> + NO reaction, N<sub>2</sub>H + OH ( $\alpha$ ) and N<sub>2</sub> + H<sub>2</sub>O ( $\beta$ ), have also been measured in the temperature range 300–1200 K by detecting CO<sub>2</sub> (formed by the reaction of OH as the added CO) and NO for  $\alpha$  and H<sub>2</sub>O for  $\beta$ . The value of  $\alpha$  was found to increase gradually from 0.1 at 300 K to 0.28 at 1000 K, with a concomitant decrease in  $\beta$  from 0.9 at 300 K to 0.72 at 1000 K. At temperatures between 1000 and 1200 K,  $\alpha$  rapidly increases to 0.47 according to the result of our modeling of observed NO decay rates. The drastic upturn in the value of  $\alpha$  above 1000 K confirms the results of our recent study of the NH<sub>3</sub> + NO reaction by FTIR spectrometry as well as the conclusion reached by modeling of NH<sub>3</sub>–NO flame speeds that  $\alpha \geq 0.5$  above 1500 K. The absolute rate constants of the two branching reactions are recommended for future applications over the temperature range 300–2000 K.

## Introduction

The NH<sub>2</sub> + NO reaction is a key NO removal step in the thermal reduction of NO<sub>x</sub> by NH<sub>3</sub><sup>1–4</sup> and by H<sub>2</sub>NCO.<sup>5–10</sup> The reaction is known to occur by both the radical and molecular product routes:<sup>11–20</sup>

whose branching ratios strongly affect the efficiencies of these reducing agents (i.e., NH<sub>3</sub> and H<sub>2</sub>NCO). This is because reaction 1 effectively produces two key chain carriers, OH and H, on account of the instability of the N<sub>2</sub>H radical at high temperatures.

We have demonstrated that the branching ratio for reaction 1,  $\alpha = k_1/(k_1 + k_2)$ , increases sharply from 0.3 to 0.5 at temperatures between 1000 and 1200 K,<sup>20</sup> bridging the gap between the low-temperature values of  $\alpha \leq 0.3$  and the recently reported large branching ratios ( $\alpha \cong 0.5\text{--}0.9$ ) above 1500 K obtained by NH<sub>3</sub>–NO flame speed modeling.<sup>21,22</sup> In a brief report which appeared most recently in this journal, we showed by a direct product measurement that in the temperature range 300–1000 K  $\alpha$  increases steadily from 0.11 to 0.30 with a concomitant decrease in the value of  $\beta = k_2/(k_1 + k_2)$  from 0.89 to 0.70, illustrating for the first time that  $\alpha + \beta = 1$ .<sup>23</sup>

In this article, we present the results of our new measurements for the total rate constant in the temperature range 305–1037 K and a new set of data for  $\alpha$  covering the critical temperature

Figure 1. Schematic diagram of the experimental apparatus.

range 1000–1200 K, using a pulsed laser photolysis–mass spectrometric technique. The result of this study independently confirms the drastic increase of  $\alpha$  in this critical temperature range which is beneficial to the de-NO<sub>x</sub> process.

## Experimental Section

The total rate constant and branching ratio measurements for the NH<sub>2</sub> + NO reaction were carried out mass spectrometrically using the high-pressure sampling technique developed by Saalfeld and co-workers.<sup>24</sup> The sampling technique has been extensively utilized by Gutman,<sup>25</sup> Matsui, Koshi and their collaborators<sup>26</sup> for kinetic measurements. A schematic diagram of the experimental apparatus is shown in Figure 1. The NH<sub>2</sub>

<sup>⊗</sup> Abstract published in *Advance ACS Abstracts*, December 1, 1996.

radical was generated photolytically with an excimer laser (Lambda Physik EMG 102) in a quartz tubular Saalfeld-type reaction tube which has an i.d. of 10 mm and a length of 150 mm with a conical sampling hole of 120  $\mu\text{m}$  diameter at the center of the reactor. The reactor was mounted perpendicularly to the detection axis of a quadrupole mass spectrometer (QMS, Extrel Model C50). For elevated-temperature experiments, the reaction tube was heated with Nichrome ribbon 0.15 mm thick and 15 mm wide and insulated with ceramic wool. By adjusting the current with a variac through the heater, the reaction tube temperature could be varied from 300 to 1200 K. The temperature was measured using a movable type K thermocouple, located near the center of the reaction tube with an accuracy and uniformity of 2 K.

The detection chamber housing the mass spectrometer was separated from the supersonic expansion chamber which holds the reaction tube by a metal plate with a 1.0 mm orifice skimmer (Beam Dynamics Model 1) mounted at the center and 3.0 mm from the sampling hole in the reaction tube. The expansion chamber was pumped by an Edwards Diffstak Model 160/700 diffusion pump with a pumping speed of 1300 L/s to a chamber base pressure of  $10^{-7}$  Torr. The detection chamber was pumped by a Leybold turbomolecular pump with a speed of 1000 L/s to a chamber base pressure of  $10^{-8}$  Torr. The reaction tube was pumped by an Edward rotary vacuum pump with an oil trap to prevent the back-diffusion of oil vapor. During the experiment, the pressures in the expansion and detection chambers were kept at  $(5-10) \times 10^{-5}$  and  $(5-10) \times 10^{-6}$  Torr, respectively. These conditions produced from the sampling hole a molecular beam which was introduced through the skimmer into the ionization region of the spectrometer.

All experiments were carried out under slow-flow conditions. Mixing of reactants and the helium buffer gas was achieved in a stainless bellows tube prior to the introduction into the reaction tube. The concentration of each individual molecule was obtained by the following formula:  $[\text{R}] = 9.66 \times 10^{16}(\%)PF_{\text{R}}/TF_{\text{T}}$  molecules/cm<sup>3</sup>, where % is the percentage of each molecule in its gas mixture,  $P$  is the total reaction pressure in Torr,  $T$  is the reaction temperature,  $F_{\text{R}}$  is the flow rate of each gas mixture, and  $F_{\text{T}}$  is the total flow rate of all gases. The flow rates were measured by using mass flowmeters (Brooks, Model 5850C and MKS, 0258C), and the gas pressure was measured with an MKS Baratron manometer.

NH<sub>3</sub> (Aldrich), CO (Matheson), CO<sub>2</sub> (Aldrich), and H<sub>2</sub>O (deionized water) were purified by standard trap-to-trap distillation. NO (Matheson) was purified by vacuum distillation through a silica gel trap maintained at 195 K to remove impurities such as NO<sub>2</sub>. The trap was preheated and diffusion pumped for 12 h at 420 K to remove any condensed water. He (99.9995%, Specialty Gases) was used without further purification.

## Results

**A. Total Rate Constant Measurement.** The NH<sub>2</sub> radical was produced by the photolysis of NH<sub>3</sub> at 193 nm at which NH<sub>3</sub> may be photofragmented by the energetically accessible paths

In the photolysis process, the NH<sub>2</sub> product channel in the electronic ground state is the most dominant ( $\Phi = 0.97$ ). A small amount of NH<sub>2</sub> product ( $\Phi = 0.025$ ) in the electronically excited state could be ignored because of its considerably shorter relaxation time than the title reaction.<sup>26</sup> The NH product is also negligible because of its small quantum yield ( $\Phi \leq 0.008$ ).<sup>26-28</sup> The conversion of NH<sub>3</sub> by photodissociation was 1–8% depending on the reaction temperature and photolysis laser energy ( $\sim 30-40$  mJ).

The time-resolved concentration of the H<sub>2</sub>O product or the NO reactant was directly measured in order to determine the total rate constant for the reaction of NH<sub>2</sub> with NO in the temperature range 305–1037 K using various mixtures of NH<sub>3</sub>/NO/He (mainly He diluent). The reaction temperature was limited to 1040 K because of low signal-to-noise ratio caused by high H<sub>2</sub>O background or insensitivity of NO signal to the total rate constant because of secondary reactions above that temperature.

Figure 2 shows the time-resolved transient signals of H<sub>2</sub>O and NO obtained for kinetic measurements at the selected temperatures. At each, the time-resolved signals were taken for 3–4 different reaction conditions. The positive ion signal was obtained by electron impact ionization at 70 eV followed by QMS mass selection. Transient signals were typically averaged over 200–500 laser shots with a repetition rate of 1 Hz. They were recorded on a Nicolet 450 digital waveform acquisition system. As shown in the inset of the figure, the NH<sub>3</sub> signal dropped immediately after laser firing and remained flat for a period of  $\sim 30$  ms until a fresh sample filled the front half of the reaction tube and the NH<sub>3</sub> signal returned to its initial level. During this flat-time period, kinetic and branching ratio measurements were carried out. The repetition rate of 1 Hz allowed enough time between pulses for the NH<sub>3</sub> signal level to return to its initial value.

The experimental conditions for the kinetic measurements were 0.05–0.21 Torr of NH<sub>3</sub> and 0.002–0.062 Torr of NO with  $[\text{NO}]/[\text{NH}_2] = 0.25-50$  and a total pressure of 2.2–9.7 Torr. Under our experimental conditions, we cannot rule out the competing reactions or radical recombination reactions. Thus, time-resolved H<sub>2</sub>O and NO concentration profiles were kinetically modeled with the SENKIN program<sup>29</sup> using a set of reactions to simulate the kinetics of the NH<sub>3</sub>/NO/He system at each experimental temperature. The solid curves presented in Figure 2 represent the modeled results using the mechanism listed in Table 1 without involving CO.

The results of our total rate constant measurement are summarized in Table 2. A weighted least-squares fit of the rate constants obtained between 305 and 1037 K to the Arrhenius equation yielded

$$k_t = 8.29 \times 10^{13} T^{-0.57} \exp(300/T) \text{ cm}^3/(\text{mol s}) \quad (1)$$

**B. Branching Ratio Determination.** Product channel branching ratios for the NH<sub>2</sub> + NO reaction were measured by the mass-selected detection of H<sub>2</sub>O, CO<sub>2</sub>, and NO in the temperature range 300–1200 K. The CO<sub>2</sub> product, which resulted from the rapid reaction of OH with added CO, is a convenient and reliable measure of the OH radical present in the system.<sup>30</sup> In order to kinetically model the values of  $\alpha$  and  $\beta$ , we kept the total rate constant ( $k_t = k_1 + k_2$ ) of the NH<sub>2</sub> + NO reaction unchanged for each temperature using eq 1, and only the relative values of  $k_1$  and  $k_2$  were varied. The actual number densities of each product were calculated by using its

**Figure 2.** Time-resolved transient signals for the total rate constant measurement of the NH<sub>2</sub> + NO reaction. Conditions are given in Table 2.

signal amplitude at the plateau of the product concentration profile and a carefully prepared calibration gas mixture of H<sub>2</sub>O/CO<sub>2</sub>/He.<sup>31</sup>

CO<sub>2</sub> and H<sub>2</sub>O product measurements for the determination of the branching ratios of the NH<sub>2</sub> + NO reaction were limited to 1000 K because of high H<sub>2</sub>O background as mentioned earlier and the possible contamination at *m/z* 44 caused by N<sub>2</sub>O formation from secondary reactions. Thus, NO reactant decay measurement was used for the determination of the branching ratio above 1000 K.

Figure 3 shows the typical transient signals of CO<sub>2</sub> and H<sub>2</sub>O products and the NO reactant for branching ratio measurement obtained in the pulsed photolysis of mixtures of NH<sub>3</sub>/NO/CO/He and NH<sub>3</sub>/NO/He, respectively. The positive ion signals were obtained in the same manner as for kinetic measurement. The slower rise of the signals comparing with those presented in Figure 2 resulted from the use of a higher gain preamplifier in order to get better signal-to-noise ratios in the plateau region.

The typical experimental conditions were 0.05–0.23 Torr of NH<sub>3</sub>, 0.00–0.51 Torr of CO, and 0.15–0.34 Torr of NO with [NO]/[NH<sub>2</sub>] = 0.5–1230 and a total pressure of 2.2–9.7 Torr. In order to account for the radical recombination and other secondary reactions in the calculation of product or reactant number densities, kinetic modeling was carried out with the SENKIN program for each experimental run using the mechanism given in Table 1. Selected experimental conditions for all temperatures studied are summarized in Table 3 with kinetically modeled concentration and branching ratios. The kinetically modeled averaged values of  $\alpha$  and  $\beta$  are presented in Figure 4 for comparison with the results reported by several investigators.<sup>2,16,17,19–21</sup>

In addition to the results obtained from the limiting (plateau) concentrations of H<sub>2</sub>O for the determination of  $\beta$ , we have acquired more data from kinetic modeling of the time-resolved [H<sub>2</sub>O]<sub>t</sub> profiles, whose limiting values are controlled by the magnitude of  $\beta$ .

**C. Sensitivity Analysis.** The key function of the SENKIN program<sup>29</sup> is to compute the value of a sensitivity coefficient ( $S_{ij}$ ) which reflects the degree of influence by a particular

reaction (*j*) on any species (*i*) of interest—reactants, products, or reactive intermediates—as a function of reaction time. The sensitivity coefficient is defined by  $S_{ij} = (\partial C_i / \partial k_j)(k_j / C_i)$ , where  $C_i$  is the concentration of the *i*th species and  $k_j$  is the rate constant of the *j*th reaction included in the mechanism. Effects of key reactions on the removal of NH<sub>2</sub> and NO and the formation of H<sub>2</sub>O and CO<sub>2</sub> will be discussed later on the basis of the calculated sensitivity coefficients.

## Discussion

**A. Total Rate Constant for NH<sub>2</sub> + NO.** Many kinetic measurements have been reported for the rate constant of the NH<sub>2</sub> + NO reaction by probing of NH<sub>2</sub> decay<sup>11–16</sup> or OH product formation<sup>17</sup> using a variety of laser-based methods. These results are summarized in Figure 5 as well as in Table 4, which lists the individual rate constants presented in various forms and the experimental methods and conditions employed.

As indicated in the table and the figure, these experimental data have a spread of  $\pm 35\%$  from the preferred value taken in the middle of the spread by Baulch et al.<sup>18</sup> In view of the scatter in these data, we attempted to measure the rate constant with the rise time of H<sub>2</sub>O production or the decay time of NO using a new, fast amplifier for signal acquisition.

As revealed by the results of sensitivity analyses for NH<sub>2</sub> and H<sub>2</sub>O presented in Figure 6, the rates of NH<sub>2</sub> decay and H<sub>2</sub>O formation depend strongly on the total rate constant,  $k_t = k_1 + k_2$ , in the initial stages of the NH<sub>2</sub> + NO reaction. For NH<sub>2</sub>, reactions 2 and 13 are responsible for its removal, with large negative sensitivity coefficients. On the other hand, for H<sub>2</sub>O, reaction 2 has a positive sensitivity coefficient because it is mainly responsible for its formation. Kinetically, it is understandable why the rise time of H<sub>2</sub>O formation depends strongly on  $k_t$ , whereas the limiting plateau value of [H<sub>2</sub>O]<sub>t</sub> is controlled mainly by the branching ratio,  $\beta = k_2/k_t$ . Accordingly, the absolute values of  $k_t$  and  $\beta$  can be simultaneously and independently determined by modeling a single profile of [H<sub>2</sub>O]<sub>t</sub>, such as those shown in Figure 2.

Our kinetically modeled values of  $k_t$  are also summarized in Figure 5 and Table 4 for comparison with the published results. As indicated in the figure our results, which can be presented by the expression  $k_t = 8.29 \times 10^{13} T^{-0.57} e^{300/T} \text{ cm}^3/(\text{mol s})$ , lie in the middle of the existing scatter and are in close proximity of the preferred values of Baulch et al.<sup>18</sup>

The error limits given in Table 2 for  $k_t$  correspond to 1  $\sigma$ 's of the evaluated values which depend predominantly on NH<sub>2</sub> + NO and weakly on secondary reactions. Since our results lie in the middle of the existing scatter ( $\pm 35\%$ ) of  $k_t$ 's measured by various groups using several techniques throughout the temperature range studied (305–1037 K), they are expected to be reliable within 2  $\sigma$ 's.

**B. Product Branching Ratios:  $\alpha$  and  $\beta$ .** As mentioned in the preceding section,  $\alpha$  and/or  $\beta$  have been determined concurrently or independently. For  $\alpha$  determination, CO was added to the system and the amount of CO<sub>2</sub> formed by the OH + CO reaction was used to model its value. For  $\beta$  determination, H<sub>2</sub>O formed directly in the NH<sub>2</sub> + NO reaction was measured and kinetically modeled for its value. This approach was initially used to determine  $\alpha$  and  $\beta$  in the temperature range 300–1060 K.<sup>23</sup>

In the present study, we extended the measurement to cover the critical temperature range in which the value of  $\alpha$  was noticed to drastically increase in our recent study of the NH<sub>3</sub> + NO reaction by FTIR spectrometry as indicated above.<sup>20</sup> The rates of the disappearance of NH<sub>3</sub> and NO and that of H<sub>2</sub>O

<sup>a</sup> The units of total pressure and all concentrations are in mTorr. <sup>b</sup> Average values from 4–5 experimental runs; the uncertainty represents 1.0σ. <sup>c</sup> Total rate constant was measured with a reactor coated with concentrated H<sub>3</sub>PO<sub>4</sub>.

**Figure 3.** Typical time-resolved transient signals for the branching ratio measurement of the NH<sub>2</sub> + NO reaction.

production determined gravimetrically by Poole and Graven<sup>37</sup> could not be kinetically modeled unless the value of  $\alpha$  was raised from 0.30 at 1060 K<sup>23</sup> to 0.5 near 1200 K, the upper limit of the temperature range covered in these pyrolytic studies.

Our present results summarized in Table 3 and Figure 4 quantitatively confirmed the rapid rise of  $\alpha$  above 1000 K.<sup>20,23</sup> In addition, the value of  $\beta$  determined below 1060 K also quantitatively demonstrates that  $\alpha + \beta = 1$ , suggesting that there is no additional product channel present within the temperature range investigated.<sup>23</sup> It was not possible to reliably determine  $\beta$  above 1060 K because of the high H<sub>2</sub>O background signal resulting from a significant conversion of the thermal de-NO<sub>x</sub> reaction: 4NH<sub>3</sub> + 6NO → 5N<sub>2</sub> + 6H<sub>2</sub>O.

In addition to the new values of  $\alpha$  determined in the 1000–1200 K region, we have obtained new data for  $\beta$  at nine temperatures from time-resolved H<sub>2</sub>O kinetic measurements. These data, denoted by filled circles in the inset of Figure 4, agree closely with the previous results derived from the limiting values of H<sub>2</sub>O yields as illustrated in Figure 3 using an amplifier with a higher gain.<sup>23</sup> Figure 7 summarizes the individual branch rate constants,  $k_1$  and  $k_2$ , calculated with all values of  $\alpha$ ,  $\beta$ , and the total rate constant  $k_t$  given in eq 1.

Figure 8 shows the results of sensitivity analyses for CO<sub>2</sub> and H<sub>2</sub>O products for the system containing NH<sub>3</sub>, NO, CO, and He at 800 K. The high sensitivity of the CO<sub>2</sub> yield to the value of  $k_1$  or  $\alpha$  is also illustrated in Figure 9, where the yield of CO<sub>2</sub> as a function of time is plotted with varying values of  $\alpha$ . At 300 K, a change in  $\alpha$  by  $\pm 0.05$  results in a change of about

50% in [CO<sub>2</sub>] plateau yields. Above 1000 K, the same change in  $\alpha$  from 0.30 leads to about 16% change in NO conversion, which is readily detectable in our experiments. The results of a sensitivity analysis for NO given in Figure 10 shows that NO decay is strongly affected by reaction 1.

On the basis of our total rate constant for NH<sub>2</sub> + NO and the values of  $\alpha$  determined in the present study at 300–1200 K and those reported by Vandooen et al.<sup>21</sup> at 1500–2000 K, the absolute rate constants for reactions 1 and 2 were evaluated by least-squares analysis and are given below (in units of cm<sup>3</sup>/(mol s)) for kinetic modeling:

$$T = 300\text{--}1000 \text{ K}$$

$$k_1 = 8.40 \times 10^9 T^{0.53} e^{+502/T}$$

$$k_2 = 8.28 \times 10^{14} T^{-0.93} e^{+192/T}$$

$$T = 1000\text{--}2000 \text{ K}$$

$$k_1 = 9.19 \times 10^{22} T^{-3.02} e^{-4826/T}$$

$$k_2 = 3.40 \times 10^{14} T^{-0.98} e^{+1311/T}$$

The branching ratios obtained in the present study over the temperature range 300–1200 K were determined at long reaction times by the limiting concentrations of CO<sub>2</sub>, H<sub>2</sub>O, and/or NO, which could be reliably measured with standard calibration mixtures. The results of sensitivity analyses for these species indicate that the key secondary reaction affecting their concentrations is the OH + NH<sub>3</sub> → H<sub>2</sub>O + NH<sub>2</sub> reaction, which has been extensively investigated.

To test the effect of the OH + NH<sub>3</sub> reaction on  $\alpha$ , we varied its rate constant by  $\pm 100\%$  near 1000 K. This led to a concomitant change in the value of  $\alpha = 0.28$  by  $\pm 0.05$  based on CO<sub>2</sub> and by  $\mp 0.03$  based on the NO concentration measured. The changes are expected to be smaller below 1000 K and larger near 1200 K. In view of the critical importance of the N<sub>2</sub>H + OH branching ratio above 1200 K to the de-NO<sub>x</sub> process, a careful shock tube study by OH diagnostics is recommended for the 1000–2000 K range.

**C. NO Reduction.** The magnitude of  $\alpha$  strongly affects the efficiency of NO reduction by NH<sub>3</sub> because the two most reactive chain carriers, H and OH, are produced concurrently by reaction 1. This effect is illustrated by the sensitivity analysis result presented in Figure 10, indicating that the major NO reducing reactions are (1) and (24), H + NH<sub>3</sub>, which generates

more NH<sub>2</sub>. The destruction of NH<sub>2</sub>, on the other hand, is dominated by the removal processes 2 and 13.

The drastic increase of α from 0.3 at 1000 K to 0.9 at 2000 K according to the NH<sub>3</sub>–NO flame speed measurement of Vandooren et al.<sup>21</sup> strongly indicates the efficacy of NH<sub>3</sub> as an NO<sub>x</sub> reducing agent.

**D. Comments on the Effects of Pressure, Reactant Ratio, and Reactor Surface.** In the present experiment, the total pressure was varied from 2 to 10 Torr, limited by the operational range of pressure in the quadrupole mass spectrometer ( $P < 10^{-5}$  Torr). The values of  $k_t$ , α, and β were affected neither by

**Figure 5.** Arrhenius plot for the total rate constant of the NH<sub>2</sub> + NO reaction: A, ref 17; B, ref 18; C, ref 11; D, ref 13; E, ref 14; F, ref 15; G, ref 12; H, ref 16. This work: ○, measured by H<sub>2</sub>O; ●, measured by NO; solid curve, fitted results.

the total pressure nor by the [NO]/[NH<sub>2</sub>] reactant ratio, which was varied over a range of 0.25–1230.

The absence of pressure effect within atmospheric pressure is clearly illustrated by the close agreement among  $k_t$ 's measured over the wide range of pressure employed in various studies as summarized in Table 4 ( $1 \text{ Torr} \leq P \leq 700 \text{ Torr}$ ). Our RRKM calculations carried out earlier<sup>14</sup> on the effects of temperature and pressure on the total rate constant and products branching ratios did not reveal significant dependence of these quantities on pressure either.

To test the possible effect of reactor surface, we have performed an additional measurement with a reactor coated with

**Figure 6.** Sensitivity analyses for NH<sub>2</sub> and H<sub>2</sub>O formed in the NH<sub>3</sub>/NO/He system at 744 K. Conditions are given in Table 3. The method of sensitivity analysis can be found in ref 29.

**Figure 8.** Sensitivity analyses for CO<sub>2</sub> and H<sub>2</sub>O formed in the NH<sub>3</sub>/NO/CO/He system at 800 K. Conditions are given in Table 3.

**Figure 7.** Absolute rate constants for NH<sub>2</sub> + NO → N<sub>2</sub>H + OH (*k*<sub>1</sub>) and NH<sub>2</sub> + NO → N<sub>2</sub> + H<sub>2</sub>O (*k*<sub>2</sub>). Open symbols indicate the results of direct measurements.

concentrated H<sub>3</sub>PO<sub>4</sub>. At the lowest pressure employed in the present study, *P* = 2.18 Torr, the values of both *k*<sub>1</sub> and β measured at 310 K with the coated reactor agree quantitatively with those obtained with uncoated quartz reactors of varying expansion orifices (see Tables 2 for *k*<sub>1</sub> and Table 3 for β).

The insignificance of reactor surface effects on the values of *k*<sub>1</sub> can also be ascertained by the existence of the close agreement among *k*<sub>1</sub>'s measured by a variety of techniques under a wide range of pressure as alluded to above. The remarkable accord in values of α between 950 and 1200 K (see Figure 5) determined by the present laser photolysis/mass spectrometric study at 2–10 Torr pressure and by the kinetic modeling of the data from pyrolytic studies of the NH<sub>3</sub> + NO reaction by FTIR spectrometry at 700 Torr pressure with a static reactor<sup>20</sup> as well as the gravimetric measurement of the H<sub>2</sub>O formed at 800 Torr pressure with two different quartz flow tubes<sup>37</sup> also rules out any significant influence of reactor surfaces.

## Conclusion

The reaction initiated by pulsed photolysis NH<sub>3</sub>–NO mixtures at 193 nm using a high-pressure sampling mass spectrometric technique developed by Saalfeld and co-workers<sup>24</sup> allows us to study the kinetics of NH<sub>2</sub> + NO in detail. From the time-resolved concentration profiles of H<sub>2</sub>O and NO measured between 305 and 1037 K, we obtained the total rate constant for NH<sub>2</sub> + NO: *k*<sub>1</sub> = 8.3 × 10<sup>13</sup>*T*<sup>-0.57</sup>e<sup>300/*T*</sup> cm<sup>3</sup>/(mol s), which is in excellent agreement with the preferred literature value.<sup>18</sup>

**Figure 9.** Sensitivity of CO<sub>2</sub> formation and NO decay to the value of  $\alpha$  (or  $k_1$ ). Conditions are given in Table 3.

**Figure 10.** Sensitivity analyses for NH<sub>2</sub> and NO reflecting the efficiency of NO reduction by NH<sub>3</sub> at 1200 K. Conditions are given in Table 3.

From the accurate measurements of absolute yields of H<sub>2</sub>O and CO<sub>2</sub>, formed by the reaction of OH with added CO, the product channel branching ratios for NH<sub>2</sub> + NO → N<sub>2</sub> + H<sub>2</sub>O ( $\beta$ ) and NH<sub>2</sub> + NO → N<sub>2</sub>H + OH ( $\alpha$ ), respectively, have been obtained in the temperature range 300–1060 K. The value of  $\beta$  was found to decrease from 0.90 at 300 K to 0.70 at 1060 K with a concomitant increase in  $\alpha$  from 0.10 to 0.30. By kinetic modeling of the NO decay profiles measured between 1000 and 1200 K, we have confirmed the results of our recent pyrolytic study of the NH<sub>3</sub> + NO reaction by FTIR spectrometry<sup>20</sup> that the value of  $\alpha$  increases rapidly from 0.3 near 1000 K to 0.47 at 1200 K. The drastic upturn in the value of  $\alpha$  supports the

conclusion reached recently from kinetic modeling of NH<sub>3</sub>–NO flame speeds by Vandooren et al.<sup>21</sup> and by Brown and Smith<sup>22</sup> that  $\alpha \geq 0.5$  above 1500 K. These new results strongly suggest that NH<sub>3</sub> is indeed a highly efficient de-NO<sub>x</sub> agent.

Theoretically, the rapid increase in  $\alpha$  above 1000 K is not clearly understood. The result of a recent variational RRKM calculation by Diau and Smith<sup>39</sup> for the production of N<sub>2</sub>H + OH did not reveal any sigmoidal increase in  $\alpha$ , although its large value above 1200 K ( $\alpha > 0.5$ ) could be accounted for theoretically. Intuitively, one would expect that the sharp upturn in the value of  $\alpha$  above 1000 K might reflect the opening of the new direct, three-body fragmentation process, HNNOH → H + N<sub>2</sub> + OH at higher energies. This direct channel should be included in theoretical modeling also.

**Acknowledgment.** The authors gratefully acknowledge the support of this work by the Office of Naval Research (Contract N00014-89-J-1949) under the direction of Dr. R. S. Miller. We thank the Cherry L. Emerson Center for Scientific Computation for the use of computing facilities and various programs.

**Note Added in Proof:** In Table 4 and Figure 5, we inadvertently left out the recent result of M. Wolf, D. L. Yang, and J. L. Durant which appeared in *J. Photochem. Photobiol.* **1994**, *A80*, 85, for the total rate constant of the NH<sub>2</sub> + NO reaction,  $k_1 = 3.3 \times 10^{24} T^{-4.02} e^{-1034/T}$  cm<sup>3</sup>/(mol s). This is in close agreement with the majority of the published data summarized.

- (31) Four different H<sub>2</sub>O, CO<sub>2</sub>, and He mixtures were used to calibrate the *m/z* 18 and 44 signals for individual runs. The Pyrex bulbs employed for these calibration mixtures were first saturated with several Torr of H<sub>2</sub>O and then evacuated for preparation of samples. The H<sub>2</sub>O concentrations obtained from the *m/z* 18 signals using various calibration mixtures agreed closely.
