#### Abstract

To clarify the origin of nonplanarity in eight $\pi$-electron heterocyclic conjugated systems, an energy component analysis was carried out for the ground states by using ab initio MCSCF method with $6-31++G(d, p)$ basis set. Inspection of the energy components comprised in the total energy reveals that the type of pseudo-JT stabilization is classified into two groups, one in which the stability of nonplanar structure arises from a lowering of the interelectronic and internuclear repulsion energies and the other in which the stability results from a lowering of the electron-nuclear attraction energy. This sharp distinction in energy changes is accounted for in terms of an expansion or contraction of the molecular skeleton and a proximity among the nuclei and the electron clouds owing to a folding of the six-membered ring. Besides, it is shown that the theoretical structural characteristics for 1,2-dihydro- and 1,4-dihydro-1,2,4,5-tetrazines are in good agreement with available experimental facts.

## Introduction

Pyramidalizations in nonplanar hydrocarbons have attracted much attention for their structural characteristics, physicochemical properties, and chemical reactions, and the topics have been reviewed on pyramidalized alkenes, strained bridgehead alkenes, and related compounds. ${ }^{1-6}$ Further, the planarity or nonplanarity of conjugated dienes, especially of the second stable conformer of 1,3-butadiene, aroused considerable discussion both theoretically and experimentally. ${ }^{7-11}$ On the other hand, a conformational criterion for aromaticity and antiaromaticity was put forth by Raber et al. such that, relative to planar reference geometries, a folding of the molecular skeleton in aromatic and antiaromatic systems results in large endothermic and exothermic changes, respectively. ${ }^{12}$ On the basis of the criterion, a series of eight $\pi$-electron, six-membered ring systems examined are shown to be highly flexible and therefore classified as nonaromatic rather than antiaromatic within ab initio RHF calculations with the 6-21G basis set.

Among eight $\pi$-electron monocyclic compounds, cyclooctatetraene is the prototype that takes a nonplanar tub structure of $D_{2 d}$ symmetry with alternate long and short bonds. ${ }^{13,14}$ It is so far believed that a planar bond-alternated structure of $D_{4 h}$ symmetry should be deformed into the tub structure to relax the bond angle strain in the eight-membered ring and the internuclear repulsion between vicinal hydrogen atoms. We made previously an energy component analysis of the pseudo-Jahn-Teller (JT) distortion from planarity to elucidate the origin for energetic stability of the nonplanar tub structure. ${ }^{15,16}$ It is shown that the tub structure owes its stability essentially to an energy lowering of the electron-nuclear attractive term. Recently, we have studied the nature of the pseudo-JT distortion

[^0]from planarity in the ground states of cycloheptatriene, heptalene, and heptafulvalene. ${ }^{17}$ Despite their marked differences in molecular shape, it is found that the cause of nonplanarity is all ascribed to an energy lowering of the electron-nuclear attractive term. It is worth noting that Boyd et al. put forth the following question on the basis of the results obtained for the methane and borane cation radicals regarding the first-order JT distortions; ${ }^{18,19}$ Is it generally true that the pure JT effect leads to a contraction of the electron cloud and to a concomitant decrease in the nuclear-electron attraction energy and to an increase in the interelectronic and internuclear repulsion energies?

It seems that no essential difference should exist between the first-order JT and pseudo-JT effects, at least in the sense that the former deals with the geometric instability of degenerate electronic states and the later merely with that of nearly degenerate electronic states. In this context, the purpose of this study is to examine whether an energy lowering of the electronnuclear attractive term should be a common phenomenon when a conjugated molecule undergoes the pseudo-JT distortion from planarity. This is because the total energy of a molecule is composed of the four energy components and, accordingly, there is every reason to believe that the stability should result from an energy term other than the electron-nuclear attractive term. Using ab initio MCSCF method with $6-31++\mathrm{G}(\mathrm{d}, \mathrm{p})$ basis set, we explore the nature of pseudo-JT distortion from planarity by dealing with the following eight $\pi$-electron heterocyclic conjugated systems (Figure 1): hydro-pyrizinyl anion (1), 1,2-dihydro-1,2-diazine (2), 1,3-dihydro-1,3-diazine (3), 1,4-dihydropyrazine (4), 1,2-dihydro-1,2,4,5-tetrazine (5), and 1,4-dihydro-1,2,4,5-tetrazine (6). It is noted that $\mathbf{1 - 3}$ are still unknown compounds but derivatives of $\mathbf{4}$ and $\mathbf{5}$ and the parent compound $\mathbf{6}$ have been reported to take nonplanar conformations by X-ray structure analyses. ${ }^{20,21}$

Figure 1. Molecular skeletons and numbering of atoms for $\mathbf{1 - 6}$. The $z$ axis is taken to be the main molecular axis in the $C_{2 v}$ and $C_{s}$ point groups, to be the $C_{2}$ rotational axis in the $C_{2}$ point group, and to be perpendicular to the molecular plane in the $C_{2 h}$ point group.

## MCSCF Calculations

To describe the ground state properly, we make use of the full-optimized reaction space (FORS) multiconfiguration selfconsistent field (MCSCF) method with the $6-31++G(d, p)$ basis set. ${ }^{22-26}$ To take into account an essential part of the static correlation among $\pi$ and $\sigma$ electrons upon the structural change from a symmetric planar to a distorted nonplanar structure, we employ here 8 orbitals and 12 electrons as the active space in the MCSCF calculations. That is, all inner valence $\pi$ orbitals are included commonly for $\mathbf{1 - 6}$ because they result in $\sigma$ orbitals at the distorted nonplanar structure. As for $\sigma$ orbitals, however, two orbitals are included that are lying near the $\pi$ orbitals in energy: namely, they correspond to the two highest occupied $\sigma$ orbitals for $\mathbf{1 - 4}$ and to the two lone-pair orbitals of N atoms for 5-6.

To locate the geometrical structures corresponding to a true energy minimum, preliminary geometrical optimizations are performed by assuming the symmetric planar structures with the RHF/6-31++G(d,p) method. After geometrical optimizations, vibrational analyses are carried out to inquire as to whether each symmetric structure should be a true energy minimum on the singlet potential energy surface of the ground state. Further, structural optimizations are performed for the relevant less symmetric structures, provided that imaginary frequencies would appear in the accompanying vibrational analyses. By repetition of the procedures, we locate the true energy minimum and transition structures using the RHF method. Subsequently, all of the stationary structures are reoptimized by means of the MCSCF/6-31++G(d,p) method to see whether the above predictions should be acceptable within this level of theory. Except for frequency calculations, our discussion given below is based on the results obtained by the MCSCF calculations.

## Energy Partitioning Scheme

Energy components included in the total energy are important essentially for discussing the leading terms responsible for the pseudo-JT distortion from planarity in the present molecules, and hence we give here a brief review of the energy partitioning scheme. ${ }^{27}$ The total energy of a molecular system is expressed as the sum of the electronic energy $E^{\mathrm{el}}$ and the internuclear repulsion energy $V_{\mathrm{nn}}$. The $E^{\mathrm{el}}$ term comprises the kinetic energy $T$ and the potential energy $V$, the latter being further partitioned into the electron-nuclear attraction energy $V_{\text {en }}$ and the interelectronic repulsion energy $V_{\text {ee. }}$. That is, the total energy can be written as given below.

$$
E=T+V_{\mathrm{en}}+V_{\mathrm{ee}}+V_{\mathrm{nn}}
$$

Following the molecular virial theorem for the stationary structures, ${ }^{28-31}$ the energy difference between a less symmetric and a symmetric structure is readily given as $-\Delta T$ or $\Delta V / 2$, the quantity being negative. In terms of the energy components comprised in the potential energy, the energy difference is expressed as given below.

$$
\Delta E=\left(\Delta V_{\mathrm{en}}+\Delta V_{\mathrm{ee}}+\Delta V_{\mathrm{nn}}\right) / 2
$$

From the leading contributor that should lead to the energy lowering of a less symmetric structure, it may be possible to classify the molecules. Namely, a molecule can be referred to as the electron-nuclear attractive, the interelectronic repulsive, or the internuclear repulsive type, as it owes its stability from an energy lowering of the corresponding energetic term. Because the kinetic energy is raised, in principle, in the pseudo-JT structural changes, no kinetic energy type should appear as the classification of the pseudo-JT stabilization.

All calculations are carried out by means of the quantum chemistry code GAMESS ${ }^{22}$ in which new subroutines for the energy component analysis are included.

## Results and Discussion

Transition and Energy Minimum Structures. The vibrational analyses with the RHF method show that at the symmetric $C_{2 v}$ structure of $\mathbf{1}$, three imaginary frequencies corresponding to out-of-plane $b_{2}$ nuclear deformations appear. It follows that the structure optimizations starting with the three $b_{2}$ nuclear deformations all converge into the same nonplanar $C_{s}$ structure. At the symmetric $C_{2 v}$ structure of 2, there appear three imaginary frequencies corresponding to two $b_{2}$ and $b_{1}$ nuclear deformations. The structure optimizations show that the former two lead to the same nonplanar $C_{2}$ structure and the latter to a nonplanar $C_{s}$ structure. Moreover, because the resulting $C_{s}$ structure has one imaginary frequency corresponding to a nuclear deformation of a" symmetry, it is distorted into a nonsymmetric $C_{1}$ structure. Comparison of the total energy finds the $C_{2}$ structure to be the real minimum and the $C_{1}$ structure to be a local minimum on the potential energy surface. The symmetric $C_{2 v}$ structure of $\mathbf{3}$ exhibits a second-order saddle point with regard to $b_{1}$ and $b_{2}$ nuclear deformations. The geometry optimizations lead to a nonplanar $C_{2}$ structure for the former and to a nonplanar $C_{s}$ structure for the latter. Subsequently, the resulting $C_{2}$ and $C_{s}$ structures each have one imaginary frequency corresponding to b and $\mathrm{a}^{\prime \prime}$ nuclear deformations, respectively. Eventually, the geometrical optimizations starting with the respective nuclear deformations are converged into just the same $C_{1}$ structure. At the $D_{2 h}$ structure of 4, there appear two imaginary frequencies corresponding to $b_{1 g}$ and $b_{2 g}$ nuclear deformations, i.e., the anti

Figure 2. Side views of the $C_{s}$ conformation and the $C_{2}, C_{s}$, and $C_{1}$ conformations obtained using the atomic coordinates of the optimized structures for $\mathbf{1}$ and 2, respectively. Black and gray circles indicate C and N atoms, respectively.
and syn folding motions of N -hydrogens. The geometry optimizations lead to a nonplanar $C_{2 h}$ structure for the former and to a nonplanar $C_{2 v}$ structure for the latter, with the result that both structures have comparable energies (vide infra). The symmetric $C_{2 v}$ structure of $\mathbf{5}$ exhibits three imaginary frequencies corresponding to two $a_{2}$ and $b_{1}$ nuclear deformations. The former two lead to just the same $C_{2}$ structure and the latter to a $C_{s}$ structure. Further, the resulting $C_{s}$ structure has one imaginary frequency corresponding to a nuclear deformation of a" symmetry, and it is transformed into the aforesaid $C_{2}$ structure by the nuclear deformation. Notice that this transformation does not correspond to the pseudo-JT structural change. Frequency analyses find the $C_{2}$ structure to be the true minimum and the $C_{s}$ structure to be the transition structure for the inversion process occurring in the interconversion between the two equivalent $C_{2}$ structures. The symmetric $C_{2 h}$ structure of 6 exhibits a second-order saddle point with regard to $a_{u}$ and $b_{g}$ nuclear deformations and, hence, the pseudo-JT distortions lead to $C_{2}$ and $C_{i}$ structures, respectively. Because all of the frequencies for the resulting $C_{2}$ and $C_{i}$ structures are positive definite, both are found to be stationary points on the potential energy surface. Comparison of the total energy reveals that the $C_{2}$ structure is the global minimum and the $C_{i}$ structure is a local minimum.

It can be pointed out that the heterocyclic conjugated molecules 1-6 display a variety of structural changes by the pseudo-JT effects. This should be responsible for the molecules being the eight $\pi$-electron, six-membered ring systems as given below. From the perturbational MO (PMO) approach, ${ }^{32}$ the molecules are regarded as perturbed benzenes with eight $\pi$ electrons, formed by replacement of CH -group(s) in benzene by NH-group(s) and/or N atom(s), where a degeneracy of the LUMOs in benzene is removed by such exchanges. Because the extra two $\pi$ electrons are assigned to the resulting LUMO, ${ }^{33}$ the ground state would exhibit in this sense an unfavorable electronic situation at the symmetric planar structure. Such being the case, there is good possibility for some lower electronically excited states lying at relatively lower energy regions from the ground state. Accordingly, a nuclear distortion of proper symmetry should mix the ground state and a low-lying excited state and thereby lowers the ground-state energy. ${ }^{34}$ This is equivalent to saying that the relevant force constant becomes negative and, hence, the pseudo-JT distortion from planarity should take place spontaneously.

Structural and Electronic Characteristics. Table 1 presents the fully optimized geometrical parameters regarding bond lengths and bond angles around $\mathrm{N}(\mathrm{C})$ atoms for the various structures of $\mathbf{1 - 6}$ calculated by the MCSCF/6-31++G(d,p)

Figure 3. Side views of the $C_{2}, C_{s}$, and $C_{1}$ conformations obtained using the atomic coordinates of the optimized structures for $\mathbf{3}$.
method. Figures $2-5$ display the side views of nonplanar structures obtained by using atomic coordinates. In Table 2 are listed atomic populations obtained at the respective structures by means of Mulliken's population analysis. ${ }^{35}$

The $C_{2 v}$ structure of $\mathbf{1}$ takes a so-called quinoid form with a double-bond fixation on the opposing $\mathrm{C} 2-\mathrm{C} 3$ and $\mathrm{C} 5-\mathrm{C} 6$ bonds, which is supported from the pattern of charge distribution. That is, significantly large negative charges are localized on N1 ( -0.49 ) and $\mathrm{C} 4(-0.88) .{ }^{36}$ On symmetry reduction from $C_{2 v}$ to $C_{s}$, a negative charge flows into $\mathrm{C} 2(\mathrm{C} 6)$ from C 4 , with the result that the negative charge of C4 is eventually reduced to one-half its initial value (Table 2). At the same time, both N1 and C4 atoms are displaced above a molecular plane of the symmetric structure, whereby the N -hydrogen is bent up on the axial position and the C 4 -hydrogen is pointed to the equatorial position (Figure 2). Of special notice is the finding that the sum of bond angles around N 1 is $324.4^{\circ}$. Clearly, this angle is less than that of $328.4^{\circ}$ in a pure $\mathrm{sp}^{3}$-hybridized atom, and the anion 1 adopts a typical boat $C_{s}$ conformation with the pseudo-JT stabilization energy of $16.7 \mathrm{kcal} / \mathrm{mol}$.

The $C_{2 v}$ structure of $\mathbf{2}$ shows a marked double-bond fixation on $\mathrm{C} 3-\mathrm{C} 4$ (C5-C6), and the adjacent N atoms each carry a negative charge of -0.37 . The $C_{s}$ structure with almost a planar ring form exhibits a more pronounced bond fixation on the CC bond, in conjunction with an increase in negative charges on C3 (C6) and a decrease in negative charges on C4 (C5). Distortion of the $C_{s}$ structure into the twisted $C_{1}$ structure is accompanied by a shortening of the NN bond, with the result that the sum of the bond angles around N 1 is reduced to $326.8^{\circ}$ from $337.2^{\circ}$. On going from $C_{2 v}$ to $C_{2}$, on the other hand, the NN bond is twisted relative to $\mathrm{C} 4-\mathrm{C} 5$, the $\mathrm{C} 6-\mathrm{N} 1-\mathrm{N} 2-\mathrm{C} 3$ moiety is charged negatively, and the two N -hydrogens are directed almost to the axial positions. That is, the stable $C_{2}$ structure takes a twisted boat conformation, where the sum of the bond angles around N 1 is $337.9^{\circ}$. A marked distinction between the twisted $C_{2}$ and $C_{1}$ structures (Figure 2) is a spatial arrangement of the N1-hydrogen, so that the two appear to constitute mutually the conformational isomers arising from an inversion of the N1 atom. Relative to the symmetric $C_{2 v}$ structure, the pseudo-JT stabilization energy amounts to $9.9 \mathrm{kcal} /$ mol for the $C_{s}$ structure, $18.3 \mathrm{kcal} / \mathrm{mol}$ for the $C_{1}$ structure, and $21.6 \mathrm{kcal} / \mathrm{mol}$ for the $C_{2}$ structure.

The $C_{2 v}$ structure of $\mathbf{3}$ takes an antiquinoid form, possessing a rather long N3-C4 (N1-C6) and large negative charges on $\mathrm{N} 1(\mathrm{~N} 3)$ and $\mathrm{C} 4(\mathrm{C} 6)$. In the $C_{s}$ structure with a very shallow boat form (Figure 3), the C4- and C6-hydrogens are slightly bent downward, but a bond fixation is relaxed somewhat on N3-C4 with a decrease in negative charge on C4. Very similar features are also observed for the $C_{2}$ structure with a nearly planar ring form. In contrast, the puckered $C_{1}$ structure exhibits a pronounced structural change in comparison with those in the

Figure 4. Side views of the $C_{2 v}$ and $C_{2 h}$ conformations and the $C_{2}$ and $C_{s}$ conformations obtained using the atomic coordinates of the optimized structures for 4 and $\mathbf{5}$, respectively.
$C_{s}$ and $C_{2}$ structures. A marked bond fixation appears on the periphery of the six-membered ring, N1 takes a nearly pure $\mathrm{sp}^{3}$ pyramidal configuration because of the sum of the associated bond angles being $330.6^{\circ}$, and the negative and positive charges are sizeably relaxed on C 2 and C 4 , respectively. The stabilization energy due to the pseudo-JT effect is $2.2 \mathrm{kcal} / \mathrm{mol}$ for the $C_{s}$ structure, $3.4 \mathrm{kcal} / \mathrm{mol}$ for the $C_{2}$ structure, and $15.8 \mathrm{kcal} /$ mol for the $C_{1}$ structure. In the former two, the relevant energy lowerings are relatively small, which are referable to the structural changes arising mainly from out-of-plane deviations of the H atoms.

The symmetric $D_{2 h}$ structure of 4 adopts a quinoid form, showing that the two opposite CC bonds have double bond character and $\mathrm{N} 1(\mathrm{~N} 4)$ is charged negatively with a value of -0.54 . In the distorted $C_{2 h}$ and $C_{2 v}$ structures, the structural parameters regarding bond distances as well as the bond angles around N 1 are almost the same between the two: the former takes almost a planar ring form with anti-folded positions of N -hydrogens, while the latter does a very shallow boat form with syn-folded positions of N -hydrogens (Figure 4). It is notable that relative to the $D_{2 h}$ structure, the negative charge on N 1 is reduced by 0.121 and 0.125 for the $C_{2 h}$ and $C_{2 v}$ structures, respectively. Concomitantly, the pseudo-JT stabilization energies are calculated to be 6.2 and $6.4 \mathrm{kcal} / \mathrm{mol}$ for the $C_{2 h}$ and $C_{2 v}$ structures, respectively. Because the two structures have comparable energies, a preferred structure is not conceivable within the present MCSCF calculations. ${ }^{37,38}$ Besides, the activation energy of the interconversion reaction between the two structures is rather small, and the pseudo-JT effect may be of a dynamical rather than a static nature. It is noted, however, that a tetraaryl derivative of $\mathbf{4}$ is known to take a boat conformation by X-ray structure analysis. ${ }^{21,39,40}$

The symmetric $C_{2 v}$ structure of $\mathbf{5}$ exhibits a double-bond fixation on the $\mathrm{N} 2-\mathrm{C} 3-\mathrm{N} 4(\mathrm{~N} 1-\mathrm{C} 6-\mathrm{N} 5)$ moiety, but in the $C_{s}$ and $C_{2}$ structures the bond fixation is smoothed out on $\mathrm{N} 2-$ $\mathrm{C} 3(\mathrm{~N} 1-\mathrm{C} 6)$ and the sum of the bond angles around N 1 is about $339^{\circ}$. One of the differences between the $C_{s}$ and $C_{2}$ structures is a spatial arrangement of the two N -hydrogens (Figure 4). In the $C_{s}$ structure with a nearly planar ring form, both N hydrogens are bent upward, while in the $C_{2}$ structure with a twisted boat conformation, they are on the axial positions, one tending upward and the other downward. The stabilization energies which favor the less symmetric $C_{s}$ and $C_{2}$ structures are calculated to be 7.1 and $17.1 \mathrm{kcal} / \mathrm{mol}$, respectively. In this context, the activation energy is estimated to be $10.0 \mathrm{kcal} / \mathrm{mol}$ for the isodynamic inversion process occurring in the interconversion between the two equivalent $C_{2}$ structures. The geometrical parameters for the $C_{2}$ structure are in qualitatively accord with the values observed for its diphenyl derivative. ${ }^{20}$

The symmetric $C_{2 v}$ structure of $\mathbf{6}$ shows a double-bond

Figure 5. Side views of the $C_{2}$ and $C_{i}$ conformations obtained using the atomic coordinates of the optimized structures for 6 .
fixation on the $\mathrm{N} 2-\mathrm{C} 3-\mathrm{N} 4$ ( $\mathrm{N} 1-\mathrm{C} 6-\mathrm{N} 5$ ) moiety, while in the $C_{i}$ and $C_{2}$ structures the bond fixation is entirely smoothed out on $\mathrm{C} 3-\mathrm{N} 4(\mathrm{~N} 1-\mathrm{C} 6)$. In the $C_{i}$ structure with a nearly planar ring form (Figure 5), the two N -hydrogens are displaced above and below from a molecular plane of the symmetric structure, respectively. On the other hand, the $C_{2}$ structure takes a boat conformation, where both the pyrrole-type N atoms are displaced above from the molecular plane. The stabilization energy which favors a less symmetric structure is calculated to be $2.5 \mathrm{kcal} /$ mol for the $C_{i}$ structure and $8.0 \mathrm{kcal} / \mathrm{mol}$ for the $C_{2}$ structure. In detail, the experimental boat structure shows a slight distortion from $C_{2}$ to $C_{1}$, but this may be responsible for crystal packing forces, as is often the case. For all that, the theoretical geometrical parameters regarding bond distances in the $C_{2}$ structure reproduce the X-ray experimental data considerably well. ${ }^{20}$ Moreover, the sum of the calculated bond angles around N 1 (N4) is $337.3^{\circ}$, in good agreement with the observed value of $339^{\circ}$.

Rehybridization of Nitrogen. It will be pertinent to refer to a possible relationship between the rehybridization of nitrogen and the pseudo-JT distortion from planarity. As noted above, each N atom carries a large negative charge in the symmetric planar structure as compared in the less symmetric structure. In some detail, the negative charge is larger for pyrrole-type nitrogen than for pyridine-type nitrogen in $\mathbf{5}$ and $\mathbf{6}$. Moreover, the sum of bond angles around pyrrole-type nitrogen is less than $360^{\circ}$, which gives a strong indication of the $\mathrm{sp}^{3}$-pyramidal hybridization. Upon rehybridization from $\mathrm{sp}^{2}$ to $\mathrm{sp}^{3}$, a reorganization of the $\sigma$ and $\pi$ electron clouds occurs around the relevant N atom. Since the resulting lone-pair electron cloud should be oriented far apart from the nearest neighbor electron clouds in CN and NH bonds, the rehybridization will bring about a decrease in the interelectronic repulsive interactions between them. Further relief may be afforded to the repulsive interactions, provided that the excess charge density on pyrrole-type nitrogen is reduced to some extent. This is equivalent to an expansion of the electron cloud to other sites, ${ }^{41}$ so that with a negative charge relaxation the molecule will change its shape from the planar to the nonplanar structure. As typical examples belonging to this category, $\mathbf{4}$ and $\mathbf{6}$ can be cited. In the $C_{2 v}$ structure of 4, the sum of bond angles around nitrogen is reduced by $21.2^{\circ}$, relative to the $D_{2 h}$ structure, with a decrease in charge density by about 0.13 (e). In this sense, it appears that a charge relaxation on nitrogen should plays an important role in the pseudo-JT distortion from planarity. A similar change in hybridization is observed on the carbon of $\mathbf{1}$. In the structural change from $C_{2 v}$ to $C_{s}$, the sum of bond angles around C 4 is reduced by $6.4^{\circ}$ with a decrease in charge density by about 0.44 (e). But, it should be emphasized that the rehybridization itself is not necessarily the decisive factor for the overall pseudo-JT stabilization as given below, because a pyramidalization causes a skeletal folding and hence leads to an enhancement of the interelectronic repulsive interactions by virtue of the proximity between the electron clouds in bonds.

Energy Component Analysis of the Ground States. Table 3 shows the total and partitioned energies at the symmetric and less symmetric structures as well as the relative energy differences between them. In general, it is seen that the energy terms

${ }^{a}$ Numbering of atoms is shown in Figure 1. Bond lengths and bond angles are in angstroms and degrees. ${ }^{46}$
are highly sensitive to changes in molecular geometry and have mutually opposite signs to the pseudo-JT stabilization.

The Hydropyrizinyl Anion (1). Distortion of the planar $C_{2 v}$
structure to the boat $C_{s}$ structure is accompanied by a small amount of the totally symmetric expansion of the six-membered ring. The associated changes in bond length are given below,

TABLE 2: Atomic and Bond Populations at the Symmetric and Distorted Structures of 1-6
$\left.\begin{array}{cccccc}\hline & & \begin{array}{c}\text { structure } \\ \text { molecule }\end{array} & \text { position } \\ \text { point group) }\end{array}\right)$
where the signs + and - denote, respectively, a lengthening and a shortening of the bonds relative to the $C_{2 v}$ structure: N1$\mathrm{C} 2(+0.015 \AA), \mathrm{C} 2-\mathrm{C} 3(+0.009 \AA)$, and C3-C4 ( $-0.013 \AA$ ). Because of a folding of the molecular skeleton, the nuclei and the electron cloud should become spatially close together and, hence, the electrostatic interactions should be largely enhanced in the $C_{s}$ structure. In conformity with this expectation, the distortion leads to large energy changes of the attractive and repulsive interaction terms. Actually, the former term is lowered in energy, while the latter terms are raised in energy. Further, it is observed that the kinetic term is slightly raised in energy, in accord with the requirement arising from the molecular virial theorem. This is briefly accounted for in terms of the kinetic energy pressure of electrons: ${ }^{42-45}$ the less room the electron
has to move about in, the higher will be the kinetic energy. Since a folding of the molecular skeleton brings about a confinement of the electron movement, it results in an energy raise of the kinetic term in comparison with the $C_{2 v}$ structure. In conclusion, it can be said that the boat $C_{s}$ structure of $\mathbf{1}$ owes its energetic stability to the energy lowering of the electronnuclear attractive term $V_{\text {en }}$ and the other terms are in the opposite direction to the stability.

1,2-Dihydro-1,2-diazine (2). As noted in the preceding section, the molecule suffers two types of the pseudo-JT effects, one being from $C_{2 v}$ to $C_{1}$ and the other from $C_{2 v}$ to $C_{2}$. (i) On distortion from $C_{2 v}$ to $C_{1}$, the structural changes take place in two stages. As a whole, the first step $\left(C_{2 v} \rightarrow C_{s}\right)$ is attributable to an expansion of the six-membered ring, holding the ring to almost planar: $\mathrm{N} 1-\mathrm{N} 2(+0.032 \AA), \mathrm{N} 2-\mathrm{C} 3(+0.030 \AA), \mathrm{C} 3-$ $\mathrm{C} 4(-0.004 \AA), \mathrm{C} 4-\mathrm{C} 5(-0.016 \AA), \mathrm{C} 1-\mathrm{H} 1(+0.010 \AA), \mathrm{C} 3-$ $\mathrm{H} 3(+0.001 \AA)$, and $\mathrm{C} 4-\mathrm{H} 4(+0.001 \AA)$. Evidently, this will lead to the prediction that the repulsive terms $V_{\mathrm{nn}}$ and $V_{\mathrm{ee}}$ should be lowered in energy, whereas the attractive term $V_{\text {en }}$ should be raised in energy. Interestingly, the second step $\left(C_{s} \rightarrow C_{1}\right)$ offers a contrast with the first one in that the net structural change presents a contraction of the six-membered ring coupled with its folding. A simple analysis with regard to the bond distances between the $C_{s}$ and $C_{1}$ structures reveals that $\mathrm{N} 1-\mathrm{N} 2$ is shortened by $0.037 \AA, \mathrm{~N} 2-\mathrm{C} 3$ is lengthened by $0.005 \AA, \mathrm{C} 3-$ C 4 is lengthened by $0.008 \AA$, and C4-C5 is shortened by 0.003 $\AA$ in a totally symmetric fashion. Besides, the asymmetric $\mathrm{a}^{\prime \prime}$ nuclear deformation is operative such that $\mathrm{N} 2-\mathrm{C} 3$ is shortened by $0.019 \AA, \mathrm{C} 3-\mathrm{C} 4$ is lengthened by $0.002 \AA$, and the remaining two bonds are lengthened and shortened so that each set of the displacement vectors may satisfy the symmetry. However, N1N 2 and $\mathrm{C} 4-\mathrm{C} 5$ remain unchanged in length by symmetry. Accordingly, the skeletal folding accompanied by a contraction of the electron cloud should give rise to the energy changes of the individual terms opposite to those in the first step. Indeed, it is seen that the attractive term $V_{\text {en }}$ is lowered in energy, whereas the repulsive terms $V_{\mathrm{nn}}$ and $V_{\text {ee }}$ are raised in energy. Regarding the overall distortion from $C_{2 v}$ to $C_{1}$, it may be safely said that the molecular skeleton is contracted in a totally symmetric fashion, the associated changes in bond length being given as follows: $\mathrm{N} 1-\mathrm{N} 2(-0.005 \AA), \mathrm{N} 2-\mathrm{C} 3(-0.067 \AA)$, $\mathrm{C} 3-\mathrm{C} 4(+0.004 \AA)$, and $\mathrm{C} 4-\mathrm{C} 5(-0.014 \AA)$. Comparison of each term in energy between the $C_{2 v}$ and $C_{1}$ structures reveals that the skeletal contraction is actually reflected in an energy lowering of the attractive term. From this viewpoint, it can be said that the stability of $C_{1}$ structure originates from an energy lowering of the electron-nuclear attractive term $V_{\text {en }}$. (ii) On the structural changes from $C_{2 v}$ to $C_{2}, \mathrm{~N} 2-\mathrm{C} 3$ is lengthened by $0.038 \AA$, while the remaining peripheral bonds are slightly shortened. This shows that almost no net changes in bond distance take place regarding the peripheral bonds, while a negative charge is transferred to the twisting $\mathrm{C} 3-\mathrm{N} 2-\mathrm{N} 1-\mathrm{C} 6$ moiety. On account of a twisting of the six-membered ring, the nuclei should come to lie in close proximity to the electron clouds. As is to be expected, this is virtually reflected on an energy lowering of the attractive term. Thus, it is concluded that the energetic stability of $C_{2}$ structure should arise from the electron-nuclear attractive term $V_{\text {en }}$.

1,3-Dihydro-1,3-diazine (3). The pseudo-JT effects from $C_{2 v}$ to $C_{1}$ take place through two paths, one being via the $C_{s}$ structure and the other via the $C_{2}$ structure. (i) In the first step $\left(C_{2 v} \rightarrow C_{s}\right)$, the changes in bond distance correspond to an expansion of the six-membered ring as given below: $\mathrm{C} 2-\mathrm{N} 3(+0.008 \AA)$, $\mathrm{N} 3-\mathrm{C} 4(-0.001 \AA)$, and $\mathrm{C} 4-\mathrm{C} 5(+0.018 \AA)$. It is thus

${ }^{a}$ Energies are in hartrees. ${ }^{b}$ Differences of the total energy in kcal/mol relative to the symmetric structure.
predicted that the skeletal expansion should result in an energy lowering of the internuclear and interelectronic repulsive terms. In the second step $\left(C_{s} \rightarrow C_{1}\right)$, the molecular skeleton is slightly expanded symmetrically relative to the $C_{s}$ structure: $\mathrm{C} 2-\mathrm{N} 3$ $(+0.083 \AA), \mathrm{N} 3-\mathrm{C} 4(-0.084 \AA)$, and $\mathrm{C} 4-\mathrm{C} 5(+0.017 \AA)$. At the same time, the asymmetric $a^{\prime \prime}$ nuclear deformation is operative such that $\mathrm{C} 2-\mathrm{N} 3$ is shortened by $0.041 \AA, \mathrm{~N} 3-\mathrm{C} 4$ is shortened by $0.042 \AA, \mathrm{C} 4-\mathrm{C} 5$ is lengthened by $0.056 \AA$, and the remaining bonds are shortened and lengthened so that each set of the displacement vectors may satisfy the symmetry. Moreover, the molecular skeleton is folded with the structural changes. This implies that the energy variation of the attractive and repulsive terms should be affected by the opposing two factors, one being an expansion of the ring and the other a folding of the skeleton. In such a case, it is hard to predict the energy variation of the terms in question. However, that the attractive term is indeed lowered and the repulsive terms are raised in energy can be presumed to be due the fact that the contribution from the latter is larger than the former. It should be remarked that, owing to the competition between the two factors, each change of the terms is rather small in energy as
compared with the other cases. (ii) In another path, the first step ( $C_{2 v} \rightarrow C_{2}$ ) as well as the second one ( $C_{2} \rightarrow C_{1}$ ) cause almost the same structural and energy changes as those observed in (i). The first step indicates an expansion of the six-membered ring: $\mathrm{C} 2-\mathrm{N} 3(+0.008 \AA), \mathrm{N} 3-\mathrm{C} 4(-0.003 \AA)$, and $\mathrm{C} 4-\mathrm{C} 5$ $(+0.019 \AA)$. It is thus predictable that the internuclear and interelectronic repulsive terms should be lowered in energy. In the second step, the ring is slightly expanded symmetrically relative to the $C_{2}$ structure, followed by a folding of the molecular skeleton: C2-N3 ( $+0.083 \AA$ ), N3-C4 ( $-0.082 \AA$ ), and $\mathrm{C} 4-\mathrm{C} 5(+0.016 \AA)$. In this case too, the numerical values in Table 3 indicate clearly that to the energy variation of the individual terms, the contribution from the skeletal folding is larger than that from the skeletal expansion. In short, the stability of the $C_{2}$ structure is due to an energy lowering of the repulsive terms $V_{\mathrm{nn}}$ and $V_{\text {ee }}$, while the stability of the $C_{1}$ structure is ascribed to an energy lowering of the attractive term $V_{\text {en }}$. It is further noted that, irrespective of the above pathways, the overall pseudo-JT distortion from $C_{2 v}$ to $C_{1}$ gives rise to a folding of the molecular skeleton as well as a slight symmetrical expansion of the six-membered ring: $\mathrm{C} 2-\mathrm{N} 3(+0.083 \AA), \mathrm{N} 3-\mathrm{C} 4$
$(-0.082 \AA)$, and $\mathrm{C} 4-\mathrm{C} 5(+0.016 \AA)$. From this viewpoint, it may be said that the stability of $C_{1}$ structure should originate from an energy lowering of the electron-nuclear attractive term $V_{\text {en }}$.

1,4-Dihydropyrazine (4). Taking the bond distances at the $D_{2 h}$ structure as the reference values, it is found that the molecular skeleton of the antifolded $C_{2 h}$ structure is expanded symmetrically, with the six-membered ring being held almost planar. The associated changes in bond length are given as follows: N1-C2 (+0.012 A), C2-C3 (-0.002 A), N1-H1 $(+0.010 \AA)$, and $\mathrm{C} 2-\mathrm{H} 2(+0.002 \AA)$. Because the skeletal expansion leads to an expansion of the electron cloud, the interelectronic repulsive interactions should be largely reduced in energy. As is shown in Table 3, the internuclear and interelectronic repulsive terms are actually lowered in energy, where an energy lowering of the latter term is partly responsible for a negative charge relaxation on $\mathrm{N} 1(\mathrm{~N} 4)$. On the other hand, the electron-nuclear attractive term is raised in energy due to the factors mentioned above. The same is also found for the $C_{2 v}$ structure with regard to the structural changes as well as the associated variation of each energy term. In conclusion, it can be said that the energetic stability of $C_{2 h}$ and $C_{2 v}$ structures should arise from an energy lowering of the internuclear and interelectronic repulsive terms $V_{\mathrm{nn}}$ and $V_{\mathrm{en}}$.

1,2-Dihydro-1,2,4,5-tetrazine (5). Upon the pseudo-JT distortion from $C_{2 v}$ to $C_{s}$, almost all the bonds including CH and NH bonds are lengthened as given below: N1-N2 $(+0.026 \AA)$, $\mathrm{N} 2-\mathrm{C} 3(+0.027 \AA), \mathrm{C} 3-\mathrm{N} 4(-0.004 \AA), \mathrm{N} 4-\mathrm{N} 5(-0.010 \AA)$, $\mathrm{N} 1-\mathrm{H} 1(+0.010 \AA)$, and $\mathrm{C} 3-\mathrm{H} 3(+0.001 \AA)$. Concurrently, the adjacent N -hydrogens are bent up from the planar sixmembered ring. Owing to an expansion of the molecular skeleton, the two repulsive terms $V_{\mathrm{nn}}$ and $V_{\text {en }}$ should contribute to the stability of $C_{s}$ structure. In the transformation from $C_{s}$ to $C_{2}$, the planar six-membered ring is deformed into a twisted conformation, the changes in bond distance being given as follows: $\mathrm{N} 1-\mathrm{N} 2(-0.029 \AA), \mathrm{N} 2-\mathrm{C} 3(+0.010 \AA), \mathrm{C} 3-\mathrm{N} 4$ $(+0.005 \AA), \mathrm{N} 4-\mathrm{N} 5(-0.017 \AA)$. Because the structural change corresponds to a contraction of the six-membered ring together with its twisting, it is readily predicted that the electron-nuclear attractive term is lowered in energy, while the repulsive terms are raised in energy. In accord with this expectation, the twisted $C_{2}$ structure is actually lowered in energy by the electronnuclear attractive term $V_{\text {en }}$. In the pseudo-JT distortion from $C_{2 v}$ to $C_{2}$, the associated changes in bond distance are given as follows: $\mathrm{N} 1-\mathrm{N} 2(-0.003 \AA), \mathrm{N} 2-\mathrm{C} 3(+0.037 \AA), \mathrm{C} 3-\mathrm{N} 4$ $(+0.001 \AA), \mathrm{N} 4-\mathrm{N} 5(-0.027 \AA), \mathrm{N} 1-\mathrm{H} 1(+0.012 \AA)$, and C3-H3 $(+0.001 \AA)$. In this case, no appreciable changes in bond distance are observed on the whole, but the hydrazine moiety is twisted relative to the $\mathrm{N} 4-\mathrm{N} 5$ bond. Note that since a twisting of the ring brings about the proximity between the nuclei and electron clouds, the electron-nuclear attraction energy should be lowered in energy. On the contrary, the repulsive interaction terms should be raised in energy because of the proximity between the nuclei and between the electron clouds. It can be given as a conclusion that a preference of the $C_{2}$ structure over the $C_{2 v}$ structure comes from an energy lowering of the electron-nuclear attractive term $V_{\text {en }}$.

1,4-Dihydro-1,2,4,5-tetrazine (6). In the pseudo-JT structural changes from $C_{2 h}$ to $C_{i}$, almost all of the bonds are lengthened, the associated changes in bond distance being given as follows: $\mathrm{N} 1-\mathrm{N} 2(+0.004 \AA), \mathrm{N} 2-\mathrm{C} 3(-0.001 \AA), \mathrm{C} 3-\mathrm{N} 4$ $(+0.017 \AA)$, and $\mathrm{N} 1-\mathrm{H} 1(+0.006 \AA)$. At the same time, the two N -hydrogens are directed spatially to the antifolded positions, relative to the almost planar six-membered ring. In
short, the nuclear deformation corresponding to a slight skeletal expansion should lower the interelectronic and internuclear repulsive interactions. As expected, the stability of $C_{i}$ structure would arise actually from an energy lowering of the two repulsive terms $V_{\mathrm{nn}}$ and $V_{\mathrm{ee}}$. In the pseudo-JT structural changes from $C_{2 h}$ to $C_{2}$, a skeletal expansion is also observed, the associated changes in bond distance being given as follows: $\mathrm{N} 1-\mathrm{N} 2(+0.010 \AA), \mathrm{N} 2-\mathrm{C} 3(-0.002 \AA), \mathrm{C} 3-\mathrm{N} 4(+0.022 \AA)$, $\mathrm{N} 1-\mathrm{H} 1(+0.007 \AA)$, and $\mathrm{C} 3-\mathrm{H} 2(+0.001 \AA)$. In contrast with the above case ( $C_{2 h} \rightarrow \mathrm{C}_{\mathrm{i}}$ ), the pyrrole-type N 1 and N 4 atoms are displaced above a molecular plane of the symmetric structure, so that the six-membered ring is deformed into a shallow boat conformation, followed by a charge transfer from N1 (N4) to the nearest-neighbor atoms. Just as in the case $\left(C_{s} \rightarrow C_{1}\right)$ of $\mathbf{3}$, it may be presumed here that to the energy variation of the terms of interest, the contribution from a folding of the six-member ring should be larger than that from an expansion of the skeleton. From this standpoint, the attractive term $V_{\text {en }}$ should be lowered in energy, while the repulsive terms $V_{\mathrm{nn}}$ and $V_{\mathrm{ee}}$ should be raised in energy. As is actually listed in Table 3, the assumption that a folding of the molecular skeleton should affect largely the energy variations is shown to hold for this case also. As a consequence, it can be said that the energetic stability of the $C_{2}$ structure arises from an energy lowering of the electron-nuclear attractive term $V_{\mathrm{en}}$ and the others are in the opposite direction to the stability.

## Conclusion

This study shows that the energy component analyses are highly informative to elucidate what happens inside the molecule when it undergoes the pseudo-JT distortion. It is found that the variation of the attractive and repulsive terms is considerably large in energy, but they are out of phase with each other. Examination of the energy components reveals that the pseudoJT stabilization is classified into two cases, one in which the stability of nonplanar structure results from a lowering of the electron-nuclear attraction energy and the other in which the associated stability arises from a lowering of the internuclear and interelectronic repulsion energies. For one thing, the pseudoJT stabilization from $C_{2 v}$ to $C_{s}$ in $\mathbf{1}$ originates from an energy lowering of the electron-nuclear attractive term, due to a proximity between the nuclei and electron clouds arising from a folding of the ring. For another, 4 undergoes the pseudo-JT distortions from $D_{2 h}$ to $C_{2 h}$ and $C_{2 v}$, and the stability of both structures arises from an energy lowering of the two repulsive terms, due to an expansion of the molecular framework along with a charge relaxation on N atoms. In the remaining molecules, the case differs somewhat in several respects, but the type of pseudo-JT stabilization can be classified into one of the above two cases. As to $\mathbf{6}$, for example, the pseudo-JT stabilization from $C_{2 h}$ to $C_{2}$ arises from an energy lowering of the electron-nuclear attractive term, whereas the distortion into the local minimum $C_{i}$ structure takes place with an energy lowering of the two repulsive terms. From these results, we can draw a conclusion that an energy lowering of the electronnuclear term should not be a common phenomenon when a molecule undergoes the pseudo-JT distortion from planarity. It is of interest to note that, as the energy terms responsible for the pseudo-JT stabilization combine, no instances other than the above two cases are in fact observed, at least in the present molecules. ${ }^{47}$ In summary, it can be said that the dominant energy components leading to the pseudo-JT stabilization are different from molecule to molecule and, even within a molecule, they differ from one case to another when it will settle at some stationary points by the pseudo-JT distortions.

Finally, it is noted that it will be desirable for representing the ground state properly to take into account much larger active spaces than the present eight orbitals and 12 electrons in the MCSCF calculations. However, because the differences of the total energy and the components between the symmetric and distorted structures are considered in this work, we conjecture that the likely effects on the energy terms at the different structures would be virtually canceled when estimating the relevant energy differences. ${ }^{18,48}$ We thus hope that the essence of the conclusions for $\mathbf{1 - 6}$ will not be impaired, even if much larger active spaces are included in the MCSCF calculations.

(36) From the PMO approach, the anion 1 is regarded as formed by replacement of one CH -group in benzene by NH -group and by addition of one electron, whereby a degeneracy of the LUMOs in benzene is lifted. The extra two $\pi$-electrons are assigned to the resulting LUMO with large atomic-orbital coefficients on two opposite positions and, as a result, C 4 has a large negative charge. Indeed, the atomic population of 6.8773 is made up of the $\sigma$ and $\pi$ components of 5.1825 and 1.6948, respectively.
