#### Abstract

The product distribution of the reaction of acetic acid, $\mathrm{CH}_{3} \mathrm{COOH}$, with hydroxyl radicals, OH , was studied experimentally and theoretically. Mass-spectrometric measurements at 290 K and 2 Torr of He of the $\mathrm{CO}_{2}$ yield versus the loss of acetic acid yielded a branching fraction of $64 \pm 14 \%$ for the abstraction of the acidic hydrogen as follows: $\mathrm{CH}_{3} \mathrm{COOH}+\mathrm{OH} \rightarrow \mathrm{CH}_{3} \mathrm{COO}+\mathrm{H}_{2} \mathrm{O} \rightarrow \mathrm{CH}_{3}+\mathrm{CO}_{2}+\mathrm{H}_{2} \mathrm{O}$. A quantum chemical and theoretical kinetic analysis showed that the abstraction of the acidic hydrogen is enhanced relative to the abstraction of $-\mathrm{CH}_{3}$ hydrogens because of the formation of a strong pre-reactive H -bonded complex, where the H -bonds are retained in the H -abstraction transition state. The potential energy surface of the reaction is explored in detail, and the reaction products of the individual channels are identified. The theoretical product branching is found to be critically dependent on the energetic and rovibrational differences between the H -abstraction transition states.

## Introduction

For the $\mathrm{HO}_{x}$ budget in the atmosphere, oxygenated volatile organic compounds (VOCs) are important species, even when present only in trace concentrations. Among the oxygenates, acetic acid $\left(\mathrm{CH}_{3} \mathrm{COOH}\right)$ has recently been recognized as an important species in the troposphere. The primary sources of acetic acid in the atmosphere are the reaction of peroxy acetyl radicals $\left(\mathrm{CH}_{3} \mathrm{C}(\mathrm{O}) \mathrm{OO}{ }^{\circ}\right)$ with $\mathrm{HO}_{2}$ and $\mathrm{CH}_{3} \mathrm{O}_{2}{ }^{1}$ and direct emission from biomass burning. ${ }^{2}$ The latter process is thought to make an important contribution to the high concentration (up to 2 ppbv ) of acetic acid observed in the tropical upper troposphere, ${ }^{3}$ even accounting for dissolution of acetic acid into rain. Very recently, at the low temperatures of the tropical tropopause, the fast equilibrium $\mathrm{HO}_{2}+\left(\mathrm{CH}_{3}\right)_{2} \mathrm{CO} \leftrightarrow\left(\mathrm{CH}_{3}\right)_{2} \mathrm{C}-$ $(\mathrm{OH}) \mathrm{OO}^{\bullet}$ followed by reaction with NO and then the subsequent fast decomposition $\left(\mathrm{CH}_{3}\right)_{2} \mathrm{C}(\mathrm{OH}) \mathrm{O}^{\bullet} \rightarrow \mathrm{CH}_{3}+\mathrm{CH}_{3} \mathrm{COOH}$ has been proposed ${ }^{4}$ as an additional source of acetic acid. In view of the reported levels of acetic acid concentrations, $\mathrm{CH}_{3} \mathrm{COOH}$ can be assumed to be a non-negligible source of methyl peroxy radicals, ${ }^{3}$ thereby influencing the oxidative capacity of the upper troposphere.

The sources and sinks of acetic acid are not fully understood and quantified; thus there are inconsistencies in current atmospheric models. It is believed that the major acetic acid sink in the free and upper troposphere is the gas-phase reaction with the OH radical. So far, only a few studies have been performed on this particular reaction. The reaction can proceed through two reaction channels, both of which are H -abstractions; one channel leads to $\mathrm{CH}_{3}$ and $\mathrm{CO}_{2}$ and the other channel to ${ }^{\circ} \mathrm{CH}_{2}-$ COOH . Like the reaction of OH with ketones and aldehydes, ${ }^{5-10}$ addition on the carbonyl double bond $(\mathrm{C}=\mathrm{O})$ does not contribute significantly.

[^0]\[

$$
\begin{gather*}
\mathrm{CH}_{3} \mathrm{COOH}+{ }^{\bullet} \mathrm{OH} \rightarrow \mathrm{CH}_{3} \mathrm{C}(\mathrm{O}) \mathrm{O}^{\bullet}+\mathrm{H}_{2} \mathrm{O} \rightarrow \mathrm{CO}_{2}+ \\
{ }^{\bullet} \mathrm{CH}_{3}+\mathrm{H}_{2} \mathrm{O}  \tag{1a}\\
 \tag{1b}\\
{ }^{\bullet} \mathrm{CH}_{2} \mathrm{COOH}+\mathrm{H}_{2} \mathrm{O}
\end{gather*}
$$
\]

The $\mathrm{CH}_{3} \mathrm{C}(\mathrm{O}) \mathrm{O}^{\bullet}$ radical will decompose rapidly into ${ }^{\bullet} \mathrm{CH}_{3}+$ $\mathrm{CO}_{2}$ with a barrier of only some $5 \mathrm{kcal} \mathrm{mol}{ }^{-1,11}$ this process should occur on a nanosecond-to-microsecond time scale in all atmospheric conditions. The subsequent atmospheric oxidation of the radicals will always lead to $\mathrm{CH}_{2} \mathrm{O}+\mathrm{CO}_{2}$ as the final products, in atmospheric conditions with sufficiently high levels of NO ; this was confirmed experimentally. ${ }^{12}$ The ${ }^{\circ} \mathrm{CH}_{3}$ radicals will, as usual, be converted to $\mathrm{CH}_{2} \mathrm{O}$, and the ${ }^{\circ} \mathrm{CH}_{2} \mathrm{COOH}$ radical will react with $\mathrm{O}_{2}$ and NO to form a $\beta$-substituted alkoxyradical $\left({ }^{\circ} \mathrm{OCH}_{2} \mathrm{COOH}\right)$. The dissociation of this radical, forming $\mathrm{CH}_{2} \mathrm{O}$ and HOCO , is expected to have a barrier of about 3 kcal $\mathrm{mol}^{-111}$; HOCO , in turn, will oxidize to $\mathrm{CO}_{2} \cdot{ }^{13}$ In less oxidative conditions with lower NO concentrations, the chemistry will shift to peroxy radical reactions and (hydro)peroxides may be formed. Even if the final products are the same for both channels, the existence of two initial reaction channels affects the overall rate coefficient of the $\mathrm{CH}_{3} \mathrm{COOH}+\mathrm{OH}$ reaction and its temperature and pressure dependence. For other acids, the final atmospheric degradation products of the different initial reaction channels might be nonidentical.
Experimental data on the temperature dependence of the rate coefficient of the title reaction are scarce and sometimes contradictory: both negative ${ }^{14,15}$ and positive ${ }^{16}$ temperature dependencies are observed between 229 and 446 K . The current recommended value at 298 K is $8 \times 10^{-13} \mathrm{~cm}^{3}$ molecule ${ }^{-1}$ $\mathrm{s}^{-1},{ }^{17,18}$ while the most recent experimental study by Butkovskaya et al. ${ }^{15}$ on the overall rate constant between 229 and 300 K at 200 Torr of $\mathrm{N}_{2}$ showed an overall rate constant at 298 K of $6.6 \times 10^{-13} \mathrm{~cm}^{3}$ molecule ${ }^{-1} \mathrm{~s}^{-1}$ and a pronounced negative temperature dependence in good agreement with earlier results by Singleton et al. ${ }^{14}$ Some information on the branching fraction
$k_{1 \mathrm{a}} / k_{1}$ and the reaction mechanism is also available. On the basis of isotope effects and the significantly lower reactivity of the dimer, Singleton et al. ${ }^{14}$ concluded that abstraction of the acidic hydrogen is the dominant channel; their observations agree ${ }^{14,19}$ with a two-channel mechanism involving hydrogen-bonded complexes and H -abstraction enhanced by tunneling through a potential energy barrier. The direct product measurements for reaction channel 1a by Butkovskaya et al. ${ }^{15}$ yielded a branching fraction $k_{1 \mathrm{a}} / k_{1}$ of $64 \pm 17 \%$ for $\mathrm{T}=229-300 \mathrm{~K}$ and 200 Torr of $\mathrm{N}_{2}$, based on the observed yield of $\mathrm{CO}_{2}$ as a primary reaction product.

In this work, the branching fraction for the reaction of acetic acid with OH was determined experimentally at 290 K and 2 Torr of He by measuring the $\mathrm{CO}_{2}$ yield from reaction 1a. In addition, a complementary theoretical investigation of the $\mathrm{CH}_{3}-$ $\mathrm{COOH}+\mathrm{OH}$ reaction was performed; it supports the experimental product data, clarifies the intricate molecular mechanisms of this complex process, and reveals the crucial role of the various intermediate hydrogen-bonded complexes involved.

## Experimental Study

Experimental Setup and Conditions. A multistage fast-flow reactor coupled to a molecular beam sampling mass spectrometry (MBMS) apparatus was used in this study. The fused-silica reactor consists of a cylindrical tube (internal radius $R$ of 1.35 cm ) equipped with a microwave sidearm and a set of two independently movable coaxial central injector tubes. The experimental setup and the cleaning procedure with final HFpassivation in order to suppress radical losses on the reactor walls have been described before. ${ }^{20}$ The gas at the reactor exit is sampled through a 0.3 mm pinhole in the tip of a quartz cone, which gives access to three differentially pumped vacuum chambers. The resulting molecular beam is mechanically modulated by means of a chopper to allow phase-sensitive detection, and then it enters the last chamber which houses an axial electron-impact ionizer and a high-sensitivity Extranuclear quadrupole mass spectrometer. A lock-in amplifier separates the beam signal from the background signal.

Hydroxyl radicals are generated via the reaction $\mathrm{H}+\mathrm{NO}_{2}$ $\rightarrow \mathrm{NO}+\mathrm{OH}$. Hydrogen atoms are formed upstream in a 75 W microwave discharge through a $\mathrm{H}_{2} / \mathrm{He}$ mixture and are reacted with $\mathrm{NO}_{2}$ added through the outer central tube. The H -atoms are always in (slight) excess over $\mathrm{NO}_{2}$. Acetic acid is fed into the reactor through the inner central tube. He was used as the carrier gas in all cases. Gases and liquids were used without further purification. He ( $99.9996 \%$, Air Products) was used as the carrier gas for the discharge sidearm of the reactor, and He ( $99.995 \%$, Indugas) was the main carrier gas for the inner and outer central tubes. The other gases were $\mathrm{H}_{2}$ ( $5.0 \%$ in UHP He , Air Liquide), $\mathrm{CO}_{2}\left(99.97 \%\right.$, Messer), and $\mathrm{NO}_{2}(2.5 \%$ in UHP He, Air Products). Acetic acid (liquid) was of pro analysi quality ( $100 \%$, Merck).

Methodology. To determine the relative importance of the two reaction channels for $\mathrm{CH}_{3} \mathrm{COOH}+\mathrm{OH}$, we quantitatively measured one of the primary reaction products formed, namely, $\mathrm{CO}_{2}$, for various initial concentrations of acetic acid and OH . The branching fraction of channel 1a, $k_{1 a} / k_{1}$, can be determined directly from the measured $\mathrm{CO}_{2}$-product concentration and the decrease in acetic acid concentration from the reaction with OH . Because of the multiple secondary reactions involving OH , one cannot use the decrease in the concentration of this species to determine the branching fraction. $\mathrm{CO}_{2}$ production and $\mathrm{CH}_{3}-$ COOH consumption were confirmed to be valid sensors for $k_{1 a} /$ $k_{1}$ through kinetic modeling with the Facsimile software, ${ }^{21}$ as detailed below.

Absolute concentrations of $\mathrm{NO}_{2}$ as the titrant gas and $\mathrm{CO}_{2}$ as the calibrant gas were derived from the measured flows (regulated by flow controllers) of certified high-purity gas mixtures and the total pressure in the reactor. The initial concentration of hydroxyl radicals, $[\mathrm{OH}]_{0}$, resulting from the reaction of $\mathrm{NO}_{2}$ with an excess of H atoms, was taken to be equal to the added $\left[\mathrm{NO}_{2}\right]_{\text {add }}$, neglecting OH -losses because of the OH self-reaction and $\mathrm{OH}+\mathrm{H}$ recombination on the reactor walls. Note that $[\mathrm{OH}]_{0}$ is not a critical quantity in this determination of $k_{19} / k_{1}$. The $[\mathrm{OH}]_{0}$ values in these experiments were in the range of $5 \times 10^{12}$ to $5 \times 10^{13}$ molecules $\mathrm{cm}^{-3}$. $\mathrm{CO}_{2}$ was measured at an ionizing-electron energy $E_{\mathrm{el}}=25 \mathrm{eV}$. The $\mathrm{CO}_{2}{ }^{+}$mass spectrometric signals were duly corrected, by blanc measurements, for a small $m / e=44$ background contribution from trace $\mathrm{CO}_{2}$ in the gas mixtures and found to be independent of added $\mathrm{CH}_{3} \mathrm{COOH}$. The detection limit of $\mathrm{CO}_{2}$, defined as the standard deviation on the intercept of the calibration curve divided by the sensitivity, was around $3.0 \times$ $10^{11}$ molecules $\mathrm{cm}^{-3}$ of $\mathrm{CO}_{2}$.
The gas-phase concentration of the $\mathrm{CH}_{3} \mathrm{COOH}$ reactant was obtained through a different procedure. A small He gas flow was bubbled through liquid acetic acid in a glass container thermostated at 290 K ; He was introduced through a diffuser plate so that small gas bubbles were formed to ensure a high mass transfer of acetic acid into the gas phase. Typically, flows of 200-1200 sccm of He were used. The flow of He through the liquid $\mathrm{CH}_{3} \mathrm{COOH}$ was kept constant by using a flow controller to ensure a constant concentration of acetic acid throughout each experiment, as confirmed by the constant mass spectrometric $\mathrm{CH}_{3} \mathrm{COOH}$ signals ( $m / e=60$ and $E_{\mathrm{el}}=25 \mathrm{eV}$ ). To calculate the gas-phase concentration, the weight loss of $\mathrm{CH}_{3}-$ COOH over a period of several hours was measured at a constant bubbling He flow, as used in the pertinent experiments. Stable concentrations of $\mathrm{CH}_{3} \mathrm{COOH}$ between $10^{13}$ and $10^{14}$ molecules $\mathrm{cm}^{-3}$ were easily obtained. Using the mass spectrometric signal $i_{\mathrm{CH}_{3} \mathrm{COOH}^{+}}$and the absolute concentration $\left[\mathrm{CH}_{3}{ }^{-}\right.$ $\mathrm{COOH}]_{\mathrm{s}}$ calculated from the mass loss per unit time, we can derive the sensitivity of acetic acid as $S_{\mathrm{CH}_{3} \mathrm{COOH}}=i_{\mathrm{CH}_{3} \mathrm{COOH}^{+}} /$ $\left[\mathrm{CH}_{3} \mathrm{COOH}\right]_{\mathrm{s}}$. It must be noted that the dimerization of acetic acid in the gas phase is of no significance under the conditions of this study, given the low $\left[\mathrm{CH}_{3} \mathrm{COOH}\right]$ values. A similar procedure for the calibration of acetic acid has been used before ${ }^{22}$ in studies of the reactions of ketones with OH .

Results. The branching fraction, $k_{1 a} / k_{1}$, of the $\mathrm{CO}_{2}$-forming channel was determined from the concentration of the $\mathrm{CO}_{2}$ formed ( $\left[\mathrm{CO}_{2}\right]_{\text {formed }}$ ) and the decrease in the concentration of acetic acid $\left(\left[\mathrm{CH}_{3} \mathrm{COOH}\right]_{\text {react }}\right)$ upon reaction with OH

$$
k_{1 \mathrm{a}} / k_{1}=\left[\mathrm{CO}_{2}\right]_{\text {formed }} /\left[\mathrm{CH}_{3} \mathrm{COOH}\right]_{\text {react }}
$$

The reaction conditions were changed by varying the initial concentrations of both the reactants. The initial $\left[\mathrm{CH}_{3} \mathrm{COOH}\right]_{0}$ was varied between $2.5 \times 10^{13}$ and $1 \times 10^{14}$ molecules $\mathrm{cm}^{-3}$, and for each $\left[\mathrm{CH}_{3} \mathrm{COOH}\right]_{0}$, the initial $[\mathrm{OH}]_{0}$ was changed in a range of $5 \times 10^{12}$ to $5 \times 10^{13}$ molecules $\mathrm{cm}^{-3}$. All experiments were performed at 290 K and 2 Torr of total pressure (He is main bath gas), and the reaction time between the reactants, OH and $\mathrm{CH}_{3} \mathrm{COOH}$, was kept constant at $\sim 6 \mathrm{~ms}$. The results are summarized in Table 1. Because of the sometimes rather small decrease in the signal of acetic acid when reacting with OH , the spread of the individual branching fraction results is sometimes rather large. By averaging over all experiments, we determined the branching fraction of reaction 1a to be $64 \%$ with a standard deviation of $14 \%$. Our experimental value of $64 \pm$ $14 \%$ for the branching fraction of the $\mathrm{CO}_{2}$-reaction channel is

${ }^{a}$ The reaction time was 6 ms .

Figure 1. Branching fraction $k_{1 \mathrm{a}} / k_{1}$ for the reaction between OH and acetic acid at 290 K and 2 Torr as a function of the initial concentration of acetic acid, $\left[\mathrm{CH}_{3} \mathrm{COOH}\right]_{0}$. At a given $\left[\mathrm{CH}_{3} \mathrm{COOH}\right]_{0}$, the initial $[\mathrm{OH}]_{0}$ ranged from $2 \times 10^{12}$ to $2 \times 10^{13}$ molecules $\mathrm{cm}^{-3}$; the plot shows the average (symbol) with standard deviation (error bar) of the branching fraction measurements over this $[\mathrm{OH}]_{0}$ range.
nearly identical to the value reported very recently by Butkovskaya et al., ${ }^{15} 64 \pm 17 \%$.

To check for possible secondary reactions which could influence the determination of the branching fraction, the dependence of the branching fraction data on the initial acetic acid and the initial OH concentration was checked by sorting the branching fraction results as functions of the initial concentrations. These dependencies are depicted in Figures 1 and 2 ; no meaningful effect on the experimentally determined branching fraction can be discerned as a function of either the initial $\mathrm{CH}_{3} \mathrm{COOH}$ concentration or the initial concentration of OH.

Figure 2. Branching fraction $k_{1 \mathrm{a}} / k_{1}$ of the reaction between OH and acetic acid at 290 K and 2 Torr as a function of the initial OH concentration, $[\mathrm{OH}]_{0}$. At a given $[\mathrm{OH}]_{0}$, the initial $\left[\mathrm{CH}_{3} \mathrm{COOH}\right]_{0}$ ranged from $2.5 \times 10^{13}$ to $1.1 \times 10^{14}$ molecules $\mathrm{cm}^{-3}$; the plot shows the average (symbol) with standard deviation (error bar) of the branching fraction measurements over this $\left[\mathrm{CH}_{3} \mathrm{COOH}\right]_{0}$ range.

Kinetic Modeling. The acetic acid-OH reaction system was also investigated by means of kinetic modeling with the Facsimile software ${ }^{21}$ using a kinetic model, with 26 reactions and 27 different species, that describes our experimental conditions accurately. The most important reactions in the model are given in Table 2. Given the low reactivity of the vinoxyresonance stabilized ${ }^{\circ} \mathrm{CH}_{2} \mathrm{COOH}$ radical (inc. toward $\mathrm{CH}_{3}$ COOH ), the lack of easily accessible $\mathrm{CO}_{2}$-forming reactions from this radical (in the absence of $\mathrm{O}_{2} / \mathrm{NO}$ ), and its low concentration, secondary reactions of ${ }^{\bullet} \mathrm{CH}_{2} \mathrm{COOH}$ are unlikely to affect the $\mathrm{CH}_{3} \mathrm{COOH}$ and $\mathrm{CO}_{2}$ concentrations and need not be included in the model. The kinetic simulation was done with an overall rate constant ${ }^{23}$ for the $\mathrm{CH}_{3} \mathrm{COOH}+\mathrm{OH}$ reaction of $7.8 \times 10^{-13} \mathrm{~cm}^{3}$ molecule ${ }^{-1} \mathrm{~s}^{-1}$ and a branching fraction of

${ }^{a}$ Overall rate constant $k_{1}=7.8 \times 10^{-13} \mathrm{~cm}^{3}$ molecule ${ }^{-1} \mathrm{~s}^{-123}$ and branching $k_{1 \mathrm{a}}=64 \% .{ }^{15}$
$64 \%$ for 1a, as obtained experimentally in this work and the work of Butkovskaya et al. ${ }^{15}$ Various initial concentrations of acetic acid and OH were used. The concentration of the bath gas He was fixed at $5 \times 10^{16}$ molecule $\mathrm{cm}^{-3}$.

From these kinetic modeling calculations, we learned that the branching fraction value derived from $\left[\mathrm{CH}_{3} \mathrm{COOH}\right]_{\text {react }}$ and $\left[\mathrm{CO}_{2}\right]_{\text {formed }}$ is only slightly influenced by secondary reactions, i.e., an underestimation between 2 and $3 \% . \mathrm{CO}_{2}$, a primary reaction product of reaction channel 1 a , does not participate in important secondary reactions in our experimental conditions and, therefore, can be used reliably to determine the relative importance of channel 1a. The reaction responsible for the slight underestimation is the reaction between acetic acid and ${ }^{1} \mathrm{CH}_{2}$ (Table 2) with singlet $\mathrm{CH}_{2}$ formed in the secondary reaction of OH with ${ }^{\circ} \mathrm{CH}_{3}$ radicals. As the predicted underestimation is significantly less than the experimental error, this slight bias was neglected in this report.

An alternative approach deriving the branching fraction from $\left[\mathrm{CO}_{2}\right]_{\text {formed }}$ relative to $[\mathrm{OH}]_{\text {reacted }}$ would lead to a pronounced underestimation of the branching fraction, namely, an underestimation by a factor of 5 based on the reaction currently included in the model. This is a result of OH not only reacting with acetic acid but also being removed by fast secondary reactions, such as the reaction with ${ }^{\circ} \mathrm{CH}_{3}$, a primary product. The reaction of ${ }^{\bullet} \mathrm{CH}_{3}$ with OH forms singlet $\mathrm{CH}_{2}$ among other species which leads to further secondary removal of OH .

## Theoretical Study

The $\mathrm{CH}_{3} \mathrm{COOH}+\mathrm{OH}$ reaction can proceed via the following three mechanisms: (1) OH -addition to the carbon of the $\mathrm{C}=\mathrm{O}$ group in acetic acid, (2) hydrogen abstraction from the methyl group, and (3) H -abstraction from the -COOH group. The first channel, OH -addition to the carbonyl bond, is expected to be a minor channel: for both aldehydes ${ }^{5-8}$ and ketones ${ }^{9,10}$ significant barriers were found for this channel. As the methyl $\mathrm{C}-\mathrm{H}$ bond strength ( $98 \pm 2 \mathrm{kcal} \mathrm{mol}^{-1}$ ) is weaker by about $12 \mathrm{kcal} \mathrm{mol}^{-1}$ when compared to that of the acidic $\mathrm{O}-\mathrm{H}$ bond $(110 \pm 2 \mathrm{kcal}$ $\left.\mathrm{mol}^{-1}\right),{ }^{29,30}$ one expects the H -abstraction from the methyl group to be, by far, the dominant reaction channel. However, experimental evidence (e.g., refs 14 and 15 and this work) indicates that it is, in fact, the acidic H that is being abstracted for an important, even dominant, fraction. Hence, ab initio/DFT calculations and theoretical kinetic analyses are required to elucidate the mechanism of the $\mathrm{CH}_{3} \mathrm{COOH}+\mathrm{OH}$ reaction.

All ab initio and DFT calculations described below were done employing the Gaussian-98 program. ${ }^{31}$ The theoretical kinetic
calculations involved both RRKM-ME analyses, ${ }^{32-34}$ using the URESAM program, ${ }^{35}$ and transition state theory (TST) ${ }^{36-38}$ calculations, including tunneling corrections. ${ }^{39}$

Quantum Chemical Characterization. The stationary points, both mimima and transition states, on the potential energy surface (PES) of the $\mathrm{CH}_{3} \mathrm{COOH}+\mathrm{OH}$ reaction were located using the B3LYP method ${ }^{40,41}$ in combination with the $6-311++G-$ (2df,2pd) basis set. To improve the accuracy of the relative energies for quantitative predictions and kinetic analysis, a modified version of the G2M(CC,MP2) method ${ }^{42}$ was used to calculate single point energies. In our modification, the original $6-311 \mathrm{G}(\mathrm{d}, \mathrm{p})$ and $6-311+\mathrm{G}(3 \mathrm{df}, 2 \mathrm{p})$ basis sets were replaced by the correlation-consistent aug-cc-pVDZ and aug-cc-pVTZ basis sets, respectively, which include diffuse orbitals to improve the description of long-range effects, such as hydrogen bonds. It is expected that the relative energies calculated with our modified G2M(CC,MP2) method approach those at the CCSD(T)/aug-$\mathrm{cc}-\mathrm{pVTZ}$ level. The relative energies calculated at the various levels of theory from the B3LYP optimized geometries are listed in Table 3. The G2M energies were used to construct the PES, which is shown in Figure 3. As seen in Table 3, the B3LYP energies agree reasonably with $\operatorname{CCSD}(\mathrm{T})$ and G2M for most of the structures; the differences are about $1-5 \mathrm{kcal} \mathrm{mol}^{-1}$. An important exception to this is TS3, which shows a large difference from about $8 \mathrm{kcal} \mathrm{mol}^{-1}$ at the B3LYP/6-311++G(2df,2pd) level to about $13 \mathrm{kcal} \mathrm{mol}^{-1}$ at the B3LYP/6-31G$\left(d_{5 d}, \mathrm{p}\right)$ level when compared to the results from $\operatorname{CCSD}(\mathrm{T})$ and G2M. The values at the $\operatorname{CCSD}(\mathrm{T})$ level of theory are in good agreement, within $\sim 0.5 \mathrm{kcal} \mathrm{mol}^{-1}$, with those of the G2M method; the single exception is a $2 \mathrm{kcal} \mathrm{mol}^{-1}$ difference for one set of products, $\mathrm{CH}_{3}+\mathrm{H}_{2} \mathrm{CO}_{3}$.

TS1, TS2, and TS3 (Figure 3) are key transition states. They are the rate-determining transition states, and they control the product distribution. In view of the exceptional behavior of TS3 in the preceding calculations, we further investigated these key transition states using both B3LYP-DFT and MP2 levels of theory with various basis sets. Their relative energies were then refined using the G2M(CC,MP2) method described above. The values calculated at the various levels of theory are summarized in Table 4. ${ }^{43}$ In comparison with the values obtained from the $\operatorname{CCSD}(\mathrm{T})$ and G2M methods, the values from the B3LYP method underestimate the barrier height while those from the MP2 method overestimate it. The MP2 and B3LYP relative energies for the TS suffer from well-known defects, e.g., an underestimation of H -abstraction energy barriers for B3LYPDFT. The $\operatorname{CCSD}(\mathrm{T})$ and G2M values on the respective MP2 and B3LYP geometries agree well with each other for TS1 and TS2: the largest discrepancy is less than $0.5 \mathrm{kcal} \mathrm{mol}^{-1}$ indicating that the $\operatorname{CCSD}(\mathrm{T})$ and G2M methods work well for both optimized geometries; therefore, the relative energies do not depend strongly on the optimized geometries. However, a discrepancy up to $1.6 \mathrm{kcal} \mathrm{mol}^{-1}$ between the G2M//MP2 and G2M//B3LYP levels was found for TS3.

Finally, the G3 theory, ${ }^{44}$ which is based on MP2/6-31G(d) geometries, was also applied. The relative energies at the G3 level of theory for TS1, TS2, and TS3 are about $2 \mathrm{kcal} \mathrm{mol}^{-1}$ higher than those at the G2M(CC,MP2) level but reproduce the TS1/TS2/TS3 near-isoergicity of the G2M//MP2 results. However, if we use the barrier heights computed with G3 theory, we derive absolute rate constants which are much too small when compared to those from the experimental data. The barrier heights calculated with the G2M(CC,MP2) method yield absolute rate constants in much better agreement with the experimental data.

Discussion of the Reaction Mechanism. The three reaction mechanisms for the $\mathrm{CH}_{3} \mathrm{COOH}+\mathrm{OH}$ reaction are as follows: addition/fragmentation, H -abstraction from $-\mathrm{CH}_{3}$, and H abstraction from the OH group. The addition of OH on the carbon of the $\mathrm{C}=\mathrm{O}$ group forms a $\mathrm{CH}_{3} \mathrm{C}(\mathrm{OH})_{2} \mathrm{O}^{\bullet}$ radical intermediate, Com8 (Figure 3), via TS5 with a barrier height of $9.5 \mathrm{kcal} \mathrm{mol}^{-1}$. TS5 is the highest entrance transition state, about $5.5-7.0 \mathrm{kcal} \mathrm{mol}^{-1}$ higher than the abstraction transition states (TS1, TS2, and TS3). As a consequence, this channel is too slow to compete with the H -abstraction channels at atmospheric temperatures and will, therefore, not be important. Many internal rotameric forms exist for the addition product, each with different H -bonds and different relative energies. All rotameric forms of $\mathbf{C o m 8}$ can decompose to $\mathrm{CH}_{3}+\mathrm{H}_{2} \mathrm{CO}_{3}$ via TS6 with barrier heights of about $6.1 \mathrm{kcal} \mathrm{mol}^{-1}$.

The dominant channels in the $\mathrm{CH}_{3} \mathrm{COOH}+\mathrm{OH}$ reaction are the abstraction mechanisms. To access the actual abstraction transition states, the OH radical will first approach acetic acid to form H-bonded complexes of which we characterized several. Some of these complexes are energetically above the $\mathrm{CH}_{3} \mathrm{COOH}$ +OH reactants (Figure 4) and are formed from the complexation of OH with the higher-energy non- H -bonded rotamer of acetic acid. H -Bond breaking in acetic acid faces a barrier of $11.6 \mathrm{kcal} \mathrm{mol}^{-145}$ with the TS much higher in energy than those for both the addition and abstraction channels, and the non- $\mathrm{H}-$ bonded acetic acid rotamer lies about $5 \mathrm{kcal} \mathrm{mol}^{-1}$ above the most stable rotamer. Hence, these complexes are kinetically unimportant at atmospheric temperatures. Three energetically much more favorable H -bonded $\mathrm{CH}_{3} \mathrm{COOH}-\mathrm{OH}$ complexes are shown in Figure 3; Com1, Com2, and Com3 are 5.1, 3.1, and $7.3 \mathrm{kcal} \mathrm{mol}^{-1}$ below the reactants, respectively, with Com3 being the most stable because of its two hydrogen bonds. The $\mathrm{CH}_{3} \mathrm{COOH}-\mathrm{OH}$ complexes can interconvert comparatively easily, e.g., Com1 isomerizes to Com3 via TS4 with a barrier height of only $0.9 \mathrm{kcal} \mathrm{mol}^{-1}$; these rearrangement transition states lie below the energy level of the initial reactants and well below the transition states for chemical reaction. Hence, these complexes should establish a mutual equilibrium and an equilibrium with the noncomplexed reactants much faster than the chemical H -abstraction reactions take place, especially at the relevant atmospheric temperatures. Given that Com3 is the most stable rotamer, it will contribute the most to the thermal equilibrium population and is, therefore, the key species in the initial complexation of OH with $\mathrm{CH}_{3} \mathrm{COOH}$. The initial complexation occurs through a long-range barrierless association,
and a quantitative theoretical kinetic treatment of this association and the reverse dissociation would probably require trajectory dynamic calculations on an accurate PES. Such calculations are computationally prohibitively expensive and of little relevance to the scope of this paper given the expected fast equilibria as detailed above. Different H -abstraction channels are accessible depending on the position of the OH radical in the complex. According to TST, when the complexes are in thermal (quasi) equilibrium with each other and the reactants, the rates of reaction through these different channels should be controlled (quasi) uniquely by the energies and partition functions of the three transition states (TS1, TS2, and TS3) and of the initial reactants.

If one starts from the $\mathrm{CH}_{3} \mathrm{COOH}-\mathrm{OH}$ complexes $\mathbf{C o m} 1$ and Com2, a 1,5-H-shift via TS1 and TS2 with barrier heights of 8.9 and $6.8 \mathrm{kcal} \mathrm{mol}^{-1}$ (both about $4 \mathrm{kcal} \mathrm{mol}^{-1}$ above the reactants) leads to the ${ }^{\circ} \mathrm{CH}_{2} \mathrm{COOH}-\mathrm{H}_{2} \mathrm{O}$ complexes $\mathbf{C o m 6}$ and Com7. These chemically activated complexes dissociate readily to ${ }^{\bullet} \mathrm{CH}_{2} \mathrm{COOH}+\mathrm{H}_{2} \mathrm{O}$.

A $1,5-\mathrm{H}$-shift in the most stable $\mathrm{CH}_{3} \mathrm{COOH}-\mathrm{OH}$ complex, Com3, via TS3 with a barrier height of $9.7 \mathrm{kcal} \mathrm{mol}^{-1}$ (between 1.5 and $3.5 \mathrm{kcal} \mathrm{mol}^{-1}$ above the reactants) leads to Com4, a weakly bonded complex of $\mathrm{H}_{2} \mathrm{O}$ and $\mathrm{CH}_{3} \mathrm{C}(\mathrm{O}) \mathrm{O}^{\bullet}$, which will dissociate spontaneously to the separated products $\mathrm{H}_{2} \mathrm{O}+$ $\mathrm{CH}_{3} \mathrm{C}(\mathrm{O}) \mathrm{O}^{*}$, especially since the complex inherits a large internal energy from the H -shift reaction. $\mathrm{CH}_{3} \mathrm{C}(\mathrm{O}) \mathrm{O}^{*}$, in turn, is also chemically activated and dissociates easily to $\mathrm{CH}_{3}+$ $\mathrm{CO}_{2}$ with a barrier of only $2.3 \mathrm{kcal} \mathrm{mol}^{-1}$, according to the present results. Earlier calculations confirmed this low barrier to dissociation, predicting a barrier of about $5 \mathrm{kcal} \mathrm{mol}^{-1} .{ }^{11}$ There are other complexes of $\mathrm{H}_{2} \mathrm{O}$ with $\mathrm{CH}_{3} \mathrm{C}(\mathrm{O}) \mathrm{O}^{\bullet}$, such as Com 5 with two hydrogen bonds. This structure is $3.9 \mathrm{kcal} \mathrm{mol}^{-1}$ more stable than the separated products, $\mathrm{H}_{2} \mathrm{O}+\mathrm{CH}_{3} \mathrm{C}(\mathrm{O}) \mathrm{O}^{*}$, but can only be formed directly through higher-energy pathways (Figure 4), making these complexes less important for roomtemperature gas-phase kinetics. In an aqueous medium, such as aerosol particles, however, complexes such as Com5 could be formed using $\mathrm{H}_{2} \mathrm{O}$ from the solvent bulk and could affect the kinetics of the system somewhat even if the final products, $\mathrm{CH}_{3}+\mathrm{H}_{2} \mathrm{O}+\mathrm{CO}_{2}$, remain the same after Com5 fragmentation via TS8 with a barrier height of $2.7 \mathrm{kcal} \mathrm{mol}{ }^{-1}$.

Kinetics of the Product Distribution. Despite the wellestablished fact that a carboxylic $\mathrm{O}-\mathrm{H}$ bond is substantially stronger than a $\mathrm{C}-\mathrm{H}$ bond, the results from both our experiment and Butkovskaya et al. ${ }^{15}$ indicate that abstraction of the acidic hydrogen is faster than abstraction of the methyl hydrogens. The key feature of the potential energy surface enabling this result is the strong hydrogen bond between the OH-radical and the -COOH group in acetic acid, $>7 \mathrm{kcal} \mathrm{mol}^{-1}$, which remains intact and equally strong in the transition state for abstracting the acidic hydrogen. The geometries of the transition states for methyl H -abstraction on the other hand show much weaker, if any, H -bond interactions between the OH -radical and the acidic group, despite the existence of pre-reactive H -bonded complexes, since the OH-radical needs to reposition itself to create optimal orbital overlap with the methyl hydrogens to enable their abstraction. Hence, H -bonding in the acidic H -abstraction lowers this TS strongly, even to the point where the relative energies of methyl and acidic H -abstraction TSs become roughly comparable and even somewhat favor acidic H -abstraction. The RRKM-ME analyses for this reaction system indicate that this is a necessary condition to explain the experimentally observed product distribution supported, in turn, by the high-level quantum chemical G2M calculations. Further RRKM-ME

Figure 4. B3LYP/6-311+ $+\mathrm{G}(2 \mathrm{df}, 2 \mathrm{pd})$ potential energy surface for the reaction of OH with the high-energy rotamer of acetic acid.
branching ratio sensitivity analyses with respect to the relative energies of the two types of H -abstraction showed that the branching is critically dependent on the relative energies of TS1 and TS2 on one hand versus TS3 on the other.

Unfortunately, while the highest levels of theory used in this work agree within a few tenths of a kilocalories per mole on the barrier heights of TS1 and TS2 for methyl H -abstraction, the relative energy of TS3 for acidic H -abstraction is subject to a much larger uncertainty $\left(\sim 1.5 \mathrm{kcal} \mathrm{mol}^{-1}\right)$. The large uncertainty results in a wide margin of error for the RRKMME or TST predictions at room temperature; the predictions indicate that acidic H -abstraction is certainly competitive with methyl H -abstraction but that branching fractions of $10-90 \%$ and beyond can be obtained depending on the set of input parameters used. Since the uncertainty involves the lowest-lying transition state, there are also large errors on the predicted absolute rate coefficient for the $\mathrm{CH}_{3} \mathrm{COOH}+\mathrm{OH}$ reaction. As such, the quantum chemical data available at this time qualitatively support the experimental observations but are unable to quantitatively predict or support the branching ratio and absolute rate coefficients with a reasonable level of accuracy.

We attempted to obtain a better estimate for the relative energy of TS3 by optimizing the theoretically predicted branching ratio, using TST, to match the experimental fraction of $64 \%$; in this optimization, the relative energies of TS1 and TS2 were kept constant. On the basis of the B3LYP-DFT vibrational frequencies (used unscaled), an optimal fit for the TS3 relative energy of $3.08 \mathrm{kcal} \mathrm{mol}^{-1}$ above the $\mathrm{C}_{3} \mathrm{HCOOH}+\mathrm{OH}$ reactants was obtained; the use of the MP2 wavenumbers (scaled by $0.9748)^{43}$ and a relative energy of $1.68 \mathrm{kcal} \mathrm{mol}^{-1}$ yielded the
best correspondence. This reverses the relative ordering of the G2M//MP2 versus G2M//B3LYP TS3 energies, and the uncertainty of the relative energy remains about $1.4 \mathrm{kcal} \mathrm{mol}^{-1}$. The lower barrier height for the optimization using MP2 frequencies is indicative of the more rigid TS3 transition state characterized at this level of theory in comparison to that of B3LYP. Also, the B3LYP imaginary wavenumbers differ strongly between TS1/TS2 $\left(\sim 700 i \mathrm{~cm}^{-1}\right)$ and TS3 $\left(\sim 1300 i \mathrm{~cm}^{-1}\right)$, so that the inclusion of a tunneling correction, modeled using an asymmetric Eckart barrier, ${ }^{39}$ alters the predicted ratio by a factor of $\sim 3.5$. In contrast, the MP2 imaginary wavenumbers are much higher but closer together (all within $1900 i-2200 i \mathrm{~cm}^{-1}$ ) so that the inclusion of tunneling hardly affects the relative contributions. The predicted temperature dependence of the branching, calculated after tuning the 290 K branching to $64 \%$ by adjusting the TS3 barrier height, also differs between the two sets of vibrational data: the B3LYP vibrational characteristics lead to a steeper $T$-dependence ( $32 \%$ at $400 \mathrm{~K}, 82 \%$ at 250 K , and $96 \%$ at 210 K ), while the MP2 data have a less pronounced temperature dependence ( $48 \%$ at $400 \mathrm{~K}, 70 \%$ at 250 K , and $76 \%$ at 210 K ). Note that both methods agree that the contribution of acidic H -abstraction increases with lower temperature. The data from Butkovskaya et al. ${ }^{15}$ seem to suggest a very slightly decreasing contribution (4\% decrease from 298 to 250 K ), although this change is dwarfed by the experimental error (about $17 \%$ absolute) and, therefore, might be an artifact. Using the relative energies for TS1, TS2, and TS3 obtained by fitting the product distribution as detailed above, we attempted to optimize the absolute barrier heights by optimizing the [TS1,TS2,TS3] set of barrier heights simultaneously so that the

Figure 5. Arrhenius plot of the total rate coefficients $k_{1}(T)$. The reference line is the modified Arrhenius expression ${ }^{15}$ obtained from experimental data by Butkovskaya et al. ${ }^{15}$ and Singleton et al. ${ }^{14}$ The theoretical results were obtained by adjusting the barrier heights for TS1, TS2, and TS3 so that TST calculations on the product distribution and absolute rate coefficient, using the rovibrational data from B3LYPDFT and MP2 calculations, match the experimental data.

TST-predicted total absolute rate coefficient at 298 K matches the experimentally observed rate coefficient, $k_{1}(298 \mathrm{~K})$, of 6.6 $\times 10^{-13} \mathrm{~cm}^{3}$ molecule ${ }^{-1} \mathrm{~s}^{-1} .{ }^{14,15}$ The adjusted barrier heights obtained in this two-step procedure yield TST rates that match both the experimental total rate coefficient and the experimental product distribution at 298 K. Using the B3LYP-DFT rovibrational data, we found an optimal correspondence for barrier heights of $1.20,0.90$, and $0.28 \mathrm{kcal} \mathrm{mol}^{-1}$ for TS1, TS2, and TS3, respectively; for the MP2 set of rovibrational data, we obtained barrier heights of $3.28,3.28$, and $1.27 \mathrm{kcal} \mathrm{mol}^{-1}$, respectively. The overall rate coefficients obtained at both levels of theory are shown in Figure 5 and compared to the experimental data. Both curves show a negative temperature dependence, in agreement with the experimental data. The temperature dependence using MP2 wavenumbers is significantly steeper than that of the experimental data which might suggest that the high imaginary wavenumbers obtained at the MP2 level of theory result in an overcorrection for tunneling. The B3LYP-based rate coefficient matches the experimental curve better at lower $T$, but its curvature is a bit too pronounced so that the high-temperature data are overestimated some. For both sets of rovibrational data, the optimization of the barrier heights to fit the experimental data required significant changes from the native energies or single point G2M energies, both absolute and relative.

Our theoretical treatment of the temperature dependence of the branching ratio and absolute rate coefficient is far from complete and should include, among other things, a more detailed treatment of the tunneling effects and the impact of the $-\mathrm{CH}_{3}$ internal rotor. Earlier theoretical work on the acetone +OH reaction ${ }^{10}$ already showed that tunneling from pre-reactive complexes has an important effect on the relative importance of different reaction channels. However, a more detailed theoretical kinetic analysis has little predictive value until the uncertainties on the H -abstraction characteristics, in particular TS3, are resolved. The G2M energies prior to ZPE correction are identical for the reactants for both methods but differ by $0.92 \mathrm{kcal} \mathrm{mol}^{-1}$ for TS3. This indicates that MP2 and B3LYP disagree on the geometry of this transition state. Furthermore, the ZPE correction from reactants to TS3 also differs by 0.58 $\mathrm{kcal} \mathrm{mol}^{-1}$, further escalating the energy difference, and is indicative of a difference in TS rigidity between the two levels of theory. The difference in rigidity can also be seen from the difference in barrier height upon matching the predicted product
distribution to the observed branching (see above). In addition, the disagreement in frequency analysis between MP2 and B3LYP is borne out by the large differences in imaginary wavenumbers, affecting both the absolute and relative tunneling corrections. At present, it seems that neither the MP2/6$311++G(2 d, 2 p)-$ nor B3LYP/6-311++G(2df,2pd)-based data are of sufficient accuracy to fully conform to the experimental data. Such discrepancies can only be resolved by higher-level geometry optimizations and frequency analysis, which is computationally very expensive. We will address these issues in later theoretical work.

The potential energy surface available here is sufficiently accurate to predict the nature of the products finally formed for each of the entrance channels. Also, it shows that abstraction of the acidic hydrogen is energetically feasible and competitive with abstraction of the methyl hydrogens despite the difference in bond strength. The relative energies of the key transition states TS1, TS2, and TS3 are characterized within $1.5 \mathrm{kcal} \mathrm{mol}^{-1}$, but as both the absolute and the relative rates of reaction through these transition states are too sensitive to the exact value, a definitive quantitative prediction of the temperature-dependent overall rate coefficient and branching ratio is not possible as yet.

## Conclusions

An experimental study of the branching ratio of the $\mathrm{CH}_{3}{ }^{-}$ $\mathrm{COOH}+\mathrm{OH}$ reaction at 290 K and 2 Torr of He showed a branching ratio of $64 \pm 14 \%$ for the abstraction of the acidic hydrogen based on the amount of $\mathrm{CO}_{2}$ formation by that product channel compared to the amount of acetic acid consumed. This result is in excellent agreement with recent experimental work by Butkovskaya et al. ${ }^{15}$ Quantum chemical calculations on the potential energy surface of the title reaction show that its kinetics and product distribution, in particular the acidic H -abstraction, are greatly enhanced and largely controlled by the formation of very stable H -bonded pre-reaction complexes. From these H -bonded complexes, the reaction proceeds by H -abstraction reactions where abstraction of the acidic hydrogen is competitive with abstraction of the methyl hydrogen despite the large difference in bond strength. The addition of OH onto the carbonyl double bond is predicted to be negligible at room temperature. The products formed in each of the reaction channels are characterized. Theoretical prediction of the tem-perature-dependent absolute rate coefficient and product branching is critically sensitive to the characteristics of the acidic H -abstraction transition state, TS3, and will be examined in more detail in a follow-up study.

Acknowledgment. This work was carried out in part in the frame of the Belgian research program on Global Change and Sustainable Development, funded by the Federal Office for Scientific, Technical and Cultural Affairs, and of the FP5 program of the European Commission (Environment, project Utopihan-Act). The authors are also indebted to the Fund for Scientific Research-Flanders (postdoctoral mandate and research project) and to the KULeuven Research Council (OT and GOA).

Supporting Information Available: Geometries, energies and vibrational wavenumbers of all of the structures discussed in this text or displayed in the figures at the B3LYP and MP2 levels of theory. This information is available free of charge via the Internet at http://pubs.acs.org.
