# On the Temple lower bound for eigenvalues 

L M DELVES<br>Department of Computational and Statistical Science, University of Liverpool, Liverpool L69 3BX, UK

MS received 6 March 1972

#### Abstract

In the first part of this paper we examine the relation between the Temple, Weinstein and Stevenson bounds for an arbitrary eigenvalue of a Hamiltonian H. We show that, in a sense which we define, the Temple and Stevenson bounds are numerically equivalent, while the Weinstein bound is inferior to either.

In the second part, the Temple bound is reformulated and it is shown that the usual restriction on its validity may be relaxed; the relaxation leads to rather more convenient calculations in the presence of excited states, but not to improved lower bounds. A numerical example demonstrating the extension is given.

## 1. Introduction

There exists a large number of methods for computing lower bounds on the eigenvalues of an hermitian operator $H$. These methods differ in their ease of computation; in their efficiency for a given class of trial functions; and in the input knowledge they assume. This knowledge may be either of the structure of $H$ (such as a split of the form $H_{0}+V$ for soluble $H_{0}$ ) or of the approximate position of adjacent eigenvalues.

We consider here only the 'classical' lower bounds, which introduce the operator $H^{2}$ and assume some knowledge of the level spacing. The best known of these are the formulae of Temple, Stevenson, and Weinstein. These are usually quoted only for the ground state, but apply equally well to excited states; we can write them in the conventional form as follows. For a given (normalized) trial function $\Psi$ we define

$$
\begin{align*}
& \eta=(\Psi, H \Psi) \\
& \delta^{2}=(H \Psi, H \Psi) \tag{1}
\end{align*}
$$

Then lower bounds to the $p$ th ordered eigenvalue of $H$ are given by :
Weinstein (1934)

$$
\begin{equation*}
E_{p} \geqslant E_{\mathrm{W}}=\eta-\left(\delta^{2}-\eta^{2}\right)^{1 / 2} \tag{2a}
\end{equation*}
$$

provided

$$
\begin{equation*}
\eta \leqslant \frac{1}{2}\left(E_{p}+E_{p+1}\right) \tag{2b}
\end{equation*}
$$

Temple (1928a, 1928b)

$$
\begin{equation*}
E_{p} \geqslant E_{\mathrm{T}}(\alpha)=\eta-\frac{\delta^{2}-\eta^{2}}{\alpha-\eta} \tag{3a}
\end{equation*}
$$

provided that

$$
\begin{equation*}
\eta<\alpha \leqslant E_{p+1} \tag{3b}
\end{equation*}
$$

Stevenson (1938)

$$
\begin{equation*}
E_{p} \geqslant E_{\mathrm{S}}(\beta)=\beta-\left(\beta^{2}-2 \beta \eta+\delta^{2}\right)^{1 / 2} \tag{4a}
\end{equation*}
$$

provided that

$$
\begin{equation*}
\beta \leqslant \frac{1}{2}\left(E_{p}+E_{p+1}\right) . \tag{4b}
\end{equation*}
$$

These formulae differ both in their accuracy for a given trial function, and in their ease of optimization when this contains a number of linear parameters. Their accuracy has been compared by a number of authors. In $\S 2$ we add to these comparisons, and we hope clarify the situation in which one or other will yield the better results. In § 3 we compare the computational convenience of the methods, and in particular rederive the Temple bound in a convenient form which allows us to ease the restriction ( $3 b$ ). A calculation on helium which demonstrates this is discussed.

## 2. Relation between the Temple, Weinstein and Stevenson bounds

The bounds (3), (4), (5) have been compared by a number of authors, with varying conclusions. These variations stem from the presence of the parameters $\alpha, \beta$ in $E_{\mathrm{T}}, E_{\mathrm{S}}$; both $E_{\mathrm{T}}$ and $E_{\mathrm{S}}$ are monotonic increasing functions of these parameters, which are therefore taken in practice to be as large as possible. It is easy to make different assumptions concerning the 'possible size' which affect the detailed comparisons. We remark further on this below.

## 2.1. $E_{\mathrm{W}}$ and $E_{\mathrm{S}}$

The Weinstein bound can be viewed as a special case of the Stevenson bound for the choice $\beta=\eta$

$$
E_{\mathrm{W}}=E_{\mathrm{S}}(\eta)
$$

Hence we have as remarked by Walmsley (1967)

$$
\begin{equation*}
E_{\mathrm{S}}(\beta) \geqslant E_{\mathrm{W}} \quad \text { if } \beta \geqslant \eta \tag{5a}
\end{equation*}
$$

## 2.2. $E_{\mathrm{W}}$ and $E_{\mathrm{T}}$

It is straightforward to derive the identity

$$
E_{\mathrm{T}}(\alpha)-E_{\mathrm{W}}=\frac{\left(\delta^{2}-\eta^{2}\right)^{1 / 2}}{\alpha-\eta}\left\{(\alpha-\eta)-\left(\eta-E_{\mathrm{W}}\right)\right\} .
$$

The denominator in this expansion is positive, as is the factor $\left(\delta^{2}-\eta^{2}\right)^{1 / 2}$. We therefore conclude that

$$
E_{\mathrm{T}}>E_{\mathrm{W}}
$$

provided that

$$
\begin{equation*}
\alpha-\eta>\eta-E_{\mathbf{w}} \tag{5b}
\end{equation*}
$$

Comment: Both the inequalities ( $5 a$ ), ( $5 b$ ) may be violated in particular calculations; however, the calculations will then inevitably be very inaccurate. We recall that $\eta$ should approximate $E_{p}$ while in a practical calculation we will choose $\beta$ as close to $\left(E_{p}+E_{p+1}\right) / 2$ as possible. In terms of the level spacing $\Delta=E_{p+1}-E_{p}$ we may therefore write the second inequality in ( $5 a$ ) approximately in the form

$$
\begin{equation*}
\eta-E_{p} \leqslant \frac{1}{2} \Delta \tag{5c}
\end{equation*}
$$

Moreover, in a practical calculation $\alpha$ will be chosen as close as possible to $E_{p+1}$. Hence if $\eta$ is close to $E_{p}$, the second inequality in ( $5 b$ ) becomes approximately

$$
\begin{equation*}
\Delta \geqslant \eta-E_{\mathrm{w}} \tag{5d}
\end{equation*}
$$

Thus $E_{\mathrm{W}}$ is worse than either $E_{\mathrm{S}}$ or $E_{\mathrm{T}}$ provided only that the calculation has an accuracy comparable with or better than the spacing between energy levels. This is a rather modest accuracy to aim at in most circumstances. Worse, inequality ( $5 c$ ) is a condition for the validity of the Weinstein bound; hence, to a good approximation, we may say that $E_{\mathrm{w}}$ is never preferable whenever it is valid.

## 2.3. $E_{\mathrm{S}}$ and $E_{\mathrm{T}}$

There has been some confusion over the relation between $E_{\mathrm{S}}$ and $E_{\mathrm{T}}$ in the past. Kato (1949) has shown that, if the only available information is given by $\eta, \delta$ and $E_{1}$, then $E_{\mathrm{T}}\left(E_{1}\right)$ is the best possible uniform bound in the sense that, for all systems and some $\Psi_{\mathrm{T}}$, the Temple bound may be exact (see also Schmid and Schwager 1968). Walmsley (1967) on the other hand has derived the straightforward algebraic identity.

$$
E_{\mathbf{S}}\left(E_{p}+\alpha\right) \geqslant E_{\mathrm{T}}(\alpha)
$$

provided

$$
\begin{equation*}
\eta \leqslant \alpha \leqslant E_{p+1} \tag{6}
\end{equation*}
$$

and concludes that the Stevenson bound is uniformly better than the Temple. This conclusion rests on the assumption that the comparative choice of parameters $\beta=E_{p}+\alpha$ is valid; however, the numerical implementation of such a comparison involves knowing $E_{p}$, and Schmid and Schwager (1968) have tartly remarked that this knowledge leads to the best of all lower bounds : $E_{\mathrm{L}}=E_{p}$. In practice, the choice of $\alpha$ requires prior knowledge of a lower bound on $E_{p+1}$; the choice of $\beta$ requires in addition a lower bound on $E_{p}$. We can perform one consistent comparison by either taking $E_{\mathrm{T}}$ as this input lower bound, or by a self consistent procedure in which we set $\beta=E_{\mathrm{S}}+\alpha$. In either case it is straightforward to derive the following identity (Schmid et al 1963):

$$
\begin{equation*}
E_{\mathrm{S}}\left(E_{\mathrm{T}}+\alpha\right)=E_{\mathrm{S}}\left(E_{\mathrm{S}}+\alpha\right)=E_{\mathrm{T}}(\alpha) \tag{7}
\end{equation*}
$$

This equation indicates a close relation between $E_{\mathrm{S}}$ and $E_{\mathrm{T}}$. We now ask which would be preferable, for any legitimate choice of $\alpha, \beta$, if we are to attempt a calculation of high accuracy. For such a calculation, or sequence of calculations, we have $E_{\mathrm{S}}, E_{\mathrm{T}}, \eta \simeq E_{p}$.

We write $E_{\mathrm{S}}=\eta-\Delta_{\mathrm{S}}, E_{\mathrm{T}}=\eta-\Delta_{\mathrm{T}}$ and compute the ratio $\Delta_{\mathrm{S}} / \Delta_{\mathrm{T}}$. We first rewrite $E_{\mathrm{S}}$ in the form

$$
\begin{align*}
E_{\mathrm{S}} & =\beta-\left(\beta^{2}-2 \beta \eta+\delta^{2}\right)^{1 / 2} \\
& =\beta-(\beta-\eta)\left(1+\frac{\delta^{2}-\eta^{2}}{(\beta-\eta)^{2}}\right)^{1 / 2} \\
& =\eta-\frac{\delta^{2}-\eta^{2}}{2(\beta-\eta)}+\frac{\left(\delta^{2}-\eta^{2}\right)^{2}}{8(\beta-\eta)^{3}}+\mathrm{O}\left(\delta^{2}-\eta^{2}\right)^{3} \tag{8}
\end{align*}
$$

Whence we find immediately

$$
\begin{equation*}
\frac{\Delta_{\mathrm{S}}}{\Delta_{\mathrm{T}}}=\frac{(\alpha-\eta)}{2(\beta-\eta)}\left(1-\frac{\delta^{2}-\eta^{2}}{4(\beta-\eta)^{2}}+\mathrm{O}\left(\delta^{2}-\eta^{2}\right)^{2}\right) \simeq \frac{\alpha-\eta}{2(\beta-\eta)} . \tag{9}
\end{equation*}
$$

Now the ratio (9) is finite, and to first order independent of the accuracy of the trial function $\Psi_{\mathrm{T}}$ (which enters only via $\eta$ ). Thus, for any $\alpha, \beta$ a sequence of calculations with increasing number of terms in $\Psi_{\mathrm{T}}$ (for example) will yield identical convergence rates from $E_{\mathrm{S}}$ and $E_{\mathrm{T}}$. Moreover, any choice of $\alpha, \beta$ close to their 'optimal' values will make the ratio (9) close to unity. This is not so for the Weinstein bound; the corresponding ratio $\Delta_{\mathrm{W}} / \Delta_{\mathrm{T}}$ becomes infinite in this limit, and hence $E_{\mathrm{W}}$ converges more slowly than either $E_{\mathrm{T}}$ or $E_{\mathrm{S}}$.

### 2.4. Input and output bounds

Despite these results, there will be many situations in which the Temple bound is poor, and in which the Stevenson and Weinstein bounds appear better; the calculations of Walmsley (1967) form such a case. This gain is then essentially illusory. Both $E_{\mathrm{S}}$ and $E_{\mathrm{W}}$ require for their validity information which we can interpret as an input lower bound on the eigenvalue $E_{p}$. For $E_{\mathrm{W}}$ this is given by ( $2 b$ ), which may be written

$$
E_{p} \geqslant 2 \eta-E_{p+1}=E_{\mathrm{WI}} \quad \text { (Weinstein input bound). }
$$

While any given choice of the parameter $\beta$ yields a similar input bound for $E_{\mathrm{S}}$

$$
E_{p} \geqslant 2 \beta-E_{p+1}=E_{\mathrm{SI}} \quad \text { (Stevenson input bound). }
$$

If the output bounds $E_{\mathrm{W}}, E_{\mathrm{S}}$ lie below the input bounds $E_{\mathrm{WI}}, E_{\mathrm{SI}}$, it cannot be said that we have gained much. The discussion above then shows that this will always be so whenever $E_{\mathrm{w}}, E_{\mathrm{S}}$ are better than $E_{\mathrm{T}}$.

We illustrate this remark with numerical results from a calculation in the threenucleon system ${ }^{3} \mathrm{H}$ with the Hamada-Johnston potential (Hamada and Johnston 1962). The upper and Temple lower bounds $E_{\mathrm{u}}$ and $E_{\mathrm{T}}$ for this work have been published (Delves and Hennell 1971); the latter are very bad. Table 1 gives these bounds, and also the input and output Stevenson and Weinstein bounds, for several wavefunctions. For this calculation $E_{p+1}$ represents the two-body deuteron energy, and is known; the upper bound appeared to be converging to -6.5 MeV . The input $E_{\mathrm{SI}}$ determines $\beta$. and has been set at -10 MeV , well below this. We see from table 1 that indeed we get less out of $E_{\mathrm{W}}$ and $E_{\mathrm{S}}$ than we put into them, although they are attractively higher than $E_{\mathrm{T}}$.

Table 1. Bounds for the energy $E\left({ }^{3} \mathrm{H}\right)$ with the Hamada-Johnston potential

| $N$ | $\Psi$ | $\begin{aligned} & \text { Ritz } \\ & E_{\mathrm{u}} \end{aligned}$ | Temple$E_{\mathrm{T}}$ | Weinstein |  | Stevenson |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  |  |  | Input $E_{\mathrm{WI}_{\mathrm{I}}}$ | Output $E_{\mathrm{w}}$ | $\begin{aligned} & \text { Input } \\ & E_{\mathrm{SI}} \end{aligned}$ | Output $E_{\mathrm{S}}$ |
| 6 | $\Psi_{u}$ | -4.73 | -294.0 | $-7.2$ | $-31.7$ | $-10.0$ | -33.1 |
|  | $\Psi_{L}$ | -3.66 | -187.6 | $-5.1$ | -20.0 | $-10.0$ | -22.6 |
| 13 | $\Psi_{u}$ | $-5.60$ | -429.4 | -9.0 | -43.5 | $-10.0$ | -44.0 |
|  | $\Psi_{\text {L }}$ | -3.78 | -129.4 | $-5.3$ | $-17.8$ | $-10.0$ | -20.3 |
| 23 | $\Psi_{u}$ | $-5.72$ | $-359.5$ | -9.2 | -41.0 | $-10.0$ | -41.3 |
|  | $\Psi_{L}$ | $-3.80$ | $-67.0$ | -5.4 | -13.8 | -10.0 | $-16.4$ |
| 66 | $\Psi_{4}$ | $-6.40$ | -206.2 | $-10.6$ | -35.3 | $-10.0$ | $-35.0$ |
|  | $\Psi_{L}$ | -3.93 | -41.2 | -5.6 | -11.9 | $-10.0$ | -14.4 |

These results come from the calculation of (Delves and Hennell 1971). $N$ is the number of linear parameters in the trial function; $\Psi_{u}$ and $\Psi_{L}$ represent trial functions whose linear parameters have been optimized for the upper $\left(E_{\mathrm{u}}\right)$ and Temple lower $\left(E_{\mathrm{T}}\right)$ bounds respectively. $E_{\mathrm{WI}}, E_{\mathrm{SI}}$ are the input bounds $\left(2 b^{\prime}\right),\left(4 b^{\prime}\right)$ for the Weinstein and Stevenson lower bounds $E_{\mathrm{w}}, E_{\mathrm{s}}$.

## 3. Extension of the Temple bound

We now rederive the Temple bound in a computationally convenient form. The Schrödinger equation for an eigenvalue $E$ is

$$
(H-E) \Psi=0
$$

We write this in the form

$$
(L-\gamma) \Psi=0 \quad L=H-\alpha \quad \gamma=E-\alpha
$$

whence premultiplying by the operator $L$ we find

$$
\begin{equation*}
\left(L-\epsilon L^{2}\right) \Psi=0 \quad \epsilon=1 / \gamma . \tag{10}
\end{equation*}
$$

This equation is formally similar to the original Schrödinger equation, since the operator $L^{2}$ is positive definite (we exclude the case that $\alpha$ is an eigenvalue of $H$ ). A linear trial function $\Psi_{\mathrm{T}}=\Sigma_{i=1}^{N} a_{i}^{(N)} h_{i}$ with $N$ terms leads to the finite matrix equation for $\epsilon^{(N)}, a^{(N)}$ :

$$
\begin{equation*}
\left(L_{(N)}-\epsilon^{(N)} L_{(N)}^{2}\right) a^{(N)}=0 \tag{11}
\end{equation*}
$$

Moreover, the Hylleraas-Undheim theorem holds for the pair (10), (11); that is, if we order the eigenvalues $\epsilon_{i}$ and approximations $\epsilon_{i}^{(N)}$

$$
\begin{align*}
& \epsilon_{1} \leqslant \epsilon_{2} \leqslant \epsilon_{3} \ldots \\
& \epsilon_{1}^{(N)} \leqslant \epsilon_{2}^{(N)} \leqslant \ldots \tag{12}
\end{align*}
$$

Then

$$
\begin{equation*}
\epsilon_{i}^{(N)} \geqslant \epsilon_{i} \quad i=0,1,2, \ldots, N . \tag{13}
\end{equation*}
$$

Now the ordering (12) induces a mapping between the $\epsilon_{i}$ and the (ordered) $E_{i}$. Let us suppose that $\epsilon_{i}=1 /\left(E_{j_{i}}-\alpha\right)$; then (13) reads

$$
\begin{equation*}
\epsilon_{i}^{(N)} \geqslant \frac{1}{E_{j_{1}}-\alpha} . \tag{13a}
\end{equation*}
$$

Now if $E_{j_{i}}<\alpha$, the right hand side is negative. If $\epsilon_{i}^{(N)}$ is positive, (13a) is then not very useful. If $\epsilon_{i}^{(N)}$ is negative, we invert the inequality to read

$$
\begin{equation*}
E_{j_{i}} \geqslant \alpha+\frac{1}{\epsilon_{i}^{(N)}} \quad E_{j}<\alpha \quad \epsilon_{i}^{(N)}<0 \tag{14}
\end{equation*}
$$

Equation (14) has the form of the Temple bound. To see this, let us choose (as is usual)

$$
E_{1}<\alpha<E_{2} .
$$

Then there exists only one negative $\epsilon_{i}=\epsilon_{1}$; and $E_{j_{i}}=E_{1}$. Moreover, the solution of (11) yields the Rayleigh quotient

$$
\begin{aligned}
\epsilon_{1}^{(N)} & =\frac{\boldsymbol{a}^{\mathbf{T}(N)} L_{(N)} \boldsymbol{a}^{(N)}}{\boldsymbol{a}^{\mathbf{T}(N)} L_{(N)}^{2} \boldsymbol{a}^{(N)}} \\
& =\frac{\eta-\alpha}{\delta^{2}-2 \alpha \eta+\alpha^{2}}
\end{aligned}
$$

whence (14) may be put in the form (3).
However, we may use (14) to ease the restriction (3b) on the parameter $\alpha$. Let us suppose that $E_{p}<\alpha<E_{p+1}$; there are then $p$ negative eigenvalues $\epsilon_{i}$. Moreover, the correspondence between the first $p \epsilon_{i}$ and $E_{j_{\mathrm{i}}}$ is as follows:

$$
\left(\epsilon_{1}, E_{p}\right) \quad\left(\epsilon_{2}, E_{p-1}\right) \quad\left(\epsilon_{3}, E_{p-2}\right) \ldots\left(\epsilon_{p}, E_{1}\right) .
$$

Let us suppose that there are $q \leqslant p$ negative eigenvalues $\epsilon_{i}^{(N)}, i=1 \ldots q$. Then these $q$ eigenvalues yield via (14) lower bounds on $E_{p}, E_{p-1} \ldots E_{p-q+1}$. For a 'sufficiently good' trial function we shall have $q=p$; we then have in particular a lower bound on the ground state $E_{1}$ using the Temple formula with a value of $\alpha>E_{2}$. If $q<p$, the lower bounds which we obtain can however be expected to be rather poor; the numerical results below show clearly that they then tend to be approximations to $E_{q} \ldots E_{1}$, although of course valid lower bounds to $E_{p} \ldots E_{p-q+1}$. We may use this extension to find improved lower bounds on any eigenvalue : we compute the eigenvalues $\epsilon_{i}^{(N)}$ for increasing $\alpha$, checking meanwhile that the appropriate number of negative $\epsilon_{i}^{(N)}$ exists. We illustrate the extension with a calculation on the $1^{1} \mathrm{~S}$ and $2^{1} \mathrm{~S}$ states of the helium atom, using the basis $\exp \left\{-S\left(l r_{1}+m r_{2}+n r_{12}\right)\right\}$. The calculation was performed using a general purpose program which has been described elsewhere (Delves and Kalotas 1968). The first three eigenvalues of this system are in atomic units

$$
E\left(1^{1} S\right)=-2.9037243 \quad E\left(2^{1} S\right)=-2.1459681 \quad E\left(3^{1} S\right)=-2.0612558
$$

Calculations were performed using 40 and 60 term functions, with $\alpha=-2.06128 \simeq E\left(3^{1} S\right)$. The results are shown in figure 1 as a function of the scale parameter $S$. For small values of the scale ( $S \leqq 2.0$ ) only one negative eigenvalue $\epsilon_{1}^{(N)}$ was found. This then yields via (14) a lower bound on $E\left(2^{1} \mathrm{~S}\right)$; however, it is evident from figure 1 that it is in fact a rather good approximation to $E\left(1^{1} \mathrm{~S}\right)$ and an extremely poor lower bound to $E\left(2^{1} \mathrm{~S}\right)$.

Figure 1. Temple lower bounds for the singlet states of the helium atom using a basis $\exp \left\{-S\left(l r_{1}+m r_{2}+n r_{12}\right)\right\}$ with $N=40$ and 60 terms. The reference energy $\alpha$ used is $\alpha=-2.06128 \simeq E\left(3^{1} S\right) ; \epsilon_{1}, \epsilon_{2}$ are the algebraically smallest and second smallest eigenvalues of equation (11). These lead to lower bounds on $E\left(2^{1} \mathrm{~S}\right)$ and $E\left(1^{1} \mathrm{~S}\right)$ respectively. Note that the definition in terms of their ordering induces a break in the curves of $\epsilon_{1}, \epsilon_{2}$ as a function of the scale $S$, and that for small $S \epsilon_{1}$ yields a good approximation to $E\left(1^{1} S\right)$ rather than to $E\left(2^{1} \mathrm{~S}\right)$.

This result is to be expected, on continuity grounds. For larger scale factors, we found two negative $\epsilon_{i}^{(N)}$ for both $N=40$ and $N=60$, and hence obtained lower bounds on both $E\left(1^{1} \mathrm{~S}\right)$ and $E\left(2^{1} \mathrm{~S}\right)$. The best lower bounds found in this way are shown in table 2 , together with the values obtained for the 'conventional' Temple bound using $\alpha=-2 \cdot 146 \simeq E\left(2^{1} S\right)$.

Table 2. Temple lower bounds for the helium atom

| State | $1^{1} \mathrm{~S}$ | $2^{1} \mathrm{~S}$ |
| :--- | :--- | :--- |
| $E$ exact | -2.9037243 | -2.1459681 |
| $N=40, \alpha=-2.06128$ | -2.90411 | -2.15328 |
| $N=60, \alpha=-2.06128$ | -2.90373 | -2.14605 |
| $N=40, \alpha=-2.146$ | -2.90388 | - |
| $N=60, \alpha=-2.146$ | -2.90372 | - |

The last figure in each result may be in error by one unit due to round-off errors.

## 4. Discussion

The conventional results above show clearly that there is a nett loss in accuracy for the ground state from the use of the generalization given for the Temple bound. In this sense the gain has been negative. However, we have the advantage that it is no longer
necessary to know the number or location of the excited states of the system used. For any choice of the parameter $\alpha$ (such that there is only a finite number of levels below $\alpha$ ), a calculation with increasing $N$ will 'eventually' yield the full number of bound states and hence a lower bound on these low-lying levels. The form (14) is also useful in that it leads, via (11), to a straightforward optimization of the linear parameters in the trial function. A similar formalism exists for the Stevenson bound, by replacing (10) by the equation

$$
\left(L^{2}-\gamma^{2}\right) \Psi=0 \quad L=H-\beta \quad \gamma=E-\beta
$$

In practice, the Stevenson and Temple bounds are therefore essentially equivalent in both convenience and in results; the Temple bound then has the advantage that its side conditions do not involve the eigenvalue to be computed. The Weinstein bound on the other hand does not appear to lead to such straightforward optimization procedures, and despite suggestions to the contrary (Goodison 1967) would seem to have little to recommend it as a procedure for bounding excited states.

## Acknowledgments

This research was partly financed by SRC Grant NG207 to the University of Liverpool for work on the quantum mechanical three-body system. The calculations were performed on the ICL Atlas computer at SRC, Chilton. I am grateful to the staff of the Atlas Laboratory for their assistance with running and for the allocation of time.
