## LETTER TO THE EDITOR

# Self-avoiding walks with nearest- and next-nearest-neighbour steps 

J Oitmaa $\dagger$<br>Department of Physics, University of Alberta, Edmonton, Alberta, T6G 2JI Canada

Received 21 April 1980

#### Abstract

Self-avoiding walks of 12 steps and fewer have been enumerated for the square lattice, for the case in which steps can occur between both nearest-neighbour and next-nearest-neighbour lattice sites. The appropriate two-variable generating function diverges along a critical line with a constant exponent $\gamma \sim \frac{4}{3}$, in agreement with general universality expectations.

The properties of self-avoiding walks (chains) on a regular lattice are of theoretical interest, as a general problem in lattice statistics. Their interest in physics stems mainly from their use in polymer physics, as models of polymer chains which incorporate excluded-volume effects. Self-avoiding walks also provide the largest contribution to the high-temperature susceptibility of the Ising model and are consequently of interest in the field of critical phenomena. A review by Domb (1969) gives an extensive discussion of the field.

Exact enumerations of short chains (up to $\sim 10-20$ steps) have been carried out for all of the regular two- and three-dimensional lattices, primarily at King's College, London (Martin et al 1967, Sykes et al 1972). From this work it has been well established that the chain generating function $C(x)$ has a power-law singularity at a 'critical point' $x_{c}$ with asymptotic behaviour $C(x) \sim A\left(1-x / x_{c}\right)^{-\gamma}$. The critical exponent $\gamma$ appears to be universal and has values close to, and possibly exactly equal to, $\frac{4}{3}$ and $\frac{7}{6}$ in two and three dimensions respectively. The amplitude $A$ and the critical point $x_{\mathrm{c}}$ vary from lattice to lattice.

All of the previous studies have considered self-avoiding walks with only nearestneighbour steps, or chains with only nearest-neighbour links. It is possible to consider a more general problem, in which next-nearest-neighbour steps are also permitted. As part of a study of the Ising model with nearest- and next-nearest-neighbour interactions, we have enumerated such chains with up to and including 12 links on the square lattice. This Letter presents the data and a numerical analysis of the appropriate two-variable generating function. The enumeration was carried out directly, using the University of Alberta Amdahl 470 computer, and took about $3 \frac{1}{2}$ hours of cPu time.

We denote by $c_{m, n}$ the number of chains consisting of $m$ nearest-neighbour links and $n$ next-nearest-neighbour links. Table 1 gives the values of these coefficients for the

[^0]Table 1. Values of $c_{m, n}$-the number of chains with $m$ nearest-neighbour and $n$ next-nearest-neighbour steps, for the square lattice.

square lattice (for $m+n \leqslant 12$ ). A generating function can be defined by

$$
\begin{equation*}
C(x, y)=\sum_{m, n=0}^{\infty} c_{m, n} x^{m} y^{n} \tag{1}
\end{equation*}
$$

with $c_{0,0}=1$. For $y=0$ (or equivalently for $x=0$ ) the problem reduces to the usual one of chains with only nearest-neighbour links. We expect that the function $C(x, y)$ will diverge along a critical line in the ( $x, y$ ) plane with a characteristic exponent $\gamma$ which, according to general ideas of universality, should remain constant along this line.

Techniques for numerical analysis of such power series have been used with considerable success in the field of critical phenomena (see e.g. Gaunt and Guttmann 1974), and we have used these methods to determine the position of the critical line and to estimate the value of the exponent $\gamma$. We introduce polar coordinates $(z, \theta)$ and analyse single-variable series in $z$ for fixed values of $\theta$. For fixed $\theta$ the generating function is expected to have the asymptotic behaviour

$$
\begin{equation*}
C(z) \sim A(\theta)\left(1-z / z_{\mathrm{c}}(\theta)\right)^{-\gamma} . \tag{2}
\end{equation*}
$$

The series are most amenable to analysis by Padé approximants, and in table 2 we give some details for the case $\theta=45^{\circ}$. Results of similar consistency are obtained for

Table 2. Series analysis for $\theta=45^{\circ}$.

other values of $\theta$, and yield the locus of the critical line in the $(x, y)$ plane as shown in figure 1. Ratio analysis is complicated by the presence of odd-even oscillations, characteristic of bipartite lattices. These oscillations are due to interfering negative singularities and are most pronounced near $\theta=0^{\circ}$ and $\theta=90^{\circ}$. The ratio results are consistent with but less precise than the Padé results. Estimates of the exponent $\gamma$ are marked by a high degree of consistency, and provide strong evidence for the hypothesis that $\gamma$ is constant along the entire critical line, and takes the value $\gamma=1.333\left(=\frac{4}{3}\right)$.

It is hoped that these results may be of some interest to workers in the field of lattice statistics. They are certainly of relevance in the study of the Ising model with nearestand next-nearest-neighbour interactions on the square lattice, and this topic will be discussed in a future publication. It is not clear whether chains of this type have any useful application in polymer problems.

Figure 1. The locus of the line of singularities of the generating function $C(x, y)$ in the $(x, y)$ plane. The uncertainty is estimated to be considerably less than the drawn width of the line.

This work was carried out while the author held a visiting appointment at the University of Alberta. He thanks members of the Department of Physics for their hospitality and support.
