Received 25 January 1999, in final form 10 May 1999

Abstract. We show that the response to an electric field, in models of the integral quantum Hall effect, is analytic in the field and has *isolated essential singularity* at zero field. We also study the breakdown of Chern numbers associated with the response of Floquet states. We argue, and give evidence, that the breakdown of Chern numbers in Floquet states is a discontinuous transition at zero field. This follows from an observation, of independent interest, that Chern numbers for finite-dimensional Floquet operators are generically zero. These results rule out the possibility that the breakdown of the Hall conductance is a phase transition at finite fields for a large class of models.

1. Introduction

The principal motivation for the present work is the question: is the breakdown of the integer quantum Hall effect a (quantum) phase transition? Since the Hall conductance in the adiabatic limit is identified with a Chern number, the question can also be phrased as: is the breakdown of Chern numbers a phase transition?

Experimentally, [9, 4, 5, 12, 18, 8, 19, 23] the breakdown of the Hall effect at finite driving currents is signalled by the onset of dissipation, and is accompanied by hysteresis and complex dynamical behaviour. The critical current and voltage depend, in general, on the geometry of the system, the temperature and on the magnetic field. It has been suggested that a phase diagram for the breakdown resembles the phase diagram of superfluidity [19].

Is there a theoretical basis for identifying breakdown with a phase transition? Naively, one can argue either way. In a class of models of the integer Hall effect the Hall conductance (at zero temperature and in the limit of linear response) is related to a Chern number [21]. Chern numbers, being integers, depend discontinuously, if at all, on parameters in the Hamiltonian. So, if the strength of the external electric field was just like any other parameter in the Hamiltonian, one would expect the breakdown of the Hall conductance to be discontinuous and at non-zero field. This would say that the breakdown of the Hall effect is indeed a quantum phase transition at finite fields.

On closer inspection one realizes that this line of reasoning cannot be quite right. For, if it was, then the Hall conductance would also remain precisely quantized for small but finite values of the electric field. This would imply that there are no corrections to the quantization—not even exponentially small correction. Common wisdom is that while there are no power corrections to the integral Hall conductance, there are exponentially small corrections [13]. As we shall explain in detail, and this is going to be a key point of our analysis, the strength of the

driving electric field (or the driving emf) is a special parameter which affects the Hamiltonian and the evolution in a way that is structurally different from say, the strength of the magnetic field or the disorder potential.

A simple and common argument, with some experimental support, says that the breakdown occurs at finite driving fields so that the critical field, \mathcal{E}_c , scales like $B^{3/2}$, where B is the strength of the magnetic field. This estimate follows from comparison of the energy gap in Landau levels with the voltage drop on a magnetic length. The breakdown is then attributed to tunnelling between Landau levels. This argument does not directly address the question if the breakdown is a phase transition. It also has a weakness in that the Landau Hamiltonian with constant electric and magnetic fields is explicitly soluble and does not show breakdown. For other theories of the breakdown see e.g. [22] and references therein.

To address the breakdown as a quantum phase transition, a handle on the conductance at finite fields is needed. This goes beyond linear response and Kubo's formulation.

In this work we shall concentrate on the breakdown of the Hall conductance, rather than the breakdown that occurs in the dissipative conductance in the Hall effect. This is done for two reasons. The first is that we are interested in breakdown that occurs in Chern numbers, for which the Hall conductance is a basic paradigm. The second is for concreteness sake. Some parts of what we say can be transcribed, *mutatis mutandis*, for the dissipative conductance.

We find no theoretical support to the hypothesis that the breakdown in the Hall effect is a phase transition at *finite fields*. Rather, we find support to the claim that the conductance has an *essential singularity at zero fields*, which can, of course, manifest itself into what resembles a phase transition.

In section 2 we show that the strength of the driving electric field (or emf), \mathcal{E} , can be related to a timescale τ . In section 3 we show that the expectation value of a (bounded) observable, in particular, the current density in tight-binding models of non-interacting electrons, is an analytic function of \mathcal{E} with an essential singularity at $\mathcal{E} = 0$ when $\mathcal{E}t$ is kept fixed. In section 4 we consider the analytic properties of a natural notion of transport for a class of model Hamiltonians which, in the limit of linear response, reduces to the usual notion of conductance that coincides with a Chern number. We show that this observable is analytic in \mathcal{E} with an essential singularity at $\mathcal{E} = 0$. It is interesting that the absence of phase transition at finite fields can be shown for the same class of models where one can prove quantization. In section 5 we study the Harper model for which we present numerical results. In section 7 we study Chern numbers associated with Floquet states, their properties and their interpretation as Hall conductance of the Floquet states. In section 8 we study the breakdown of Chern numbers associated to Floquet states. We show that the breakdown is discontinuous and argue that it occurs at zero fields, $\mathcal{E} = 0$. In section 9 we describe numerical evidence that supports the claim that non-zero Chern numbers for Floquet states are unstable against perturbations in the Hamiltonian.

2. Driving fields interpreted as a timescale

Because gauge invariance allows one to impose one condition on the scalar and vector potential, it is always possible to choose a gauge where the *external* electric and magnetic fields are described only by the vector potential \vec{A} . In order to produce an electric field this potential has to be time dependent. Assume that this dependence is characterized by some timescale τ as $\vec{A}(\vec{x}, t/\tau)$. Suppose now that we scale time so that $t = \tau s$. The Maxwell equation gives the external electric field, (in scaled time), as

$$\vec{E}(\vec{x}, s) = -\frac{1}{\tau c} \partial_s \vec{A}(\vec{x}, s). \quad (1)$$

With \vec{A} fixed, weak electric fields correspond to large τ while strong electric fields correspond to small τ . In systems that are otherwise time independent, τ interpolates between weak and strong fields. A similar argument can be made about the emf, which is a line integral of the electric field.

The identification of the timescale τ with the strength of the external driving, be it the electric field or an emf, is not a new idea, of course. It lies at the heart of the identification of the adiabatic limit with linear response. What is perhaps new here is that we want to use this correspondence for any driving, and in particular identify strong driving fields and large emfs with short timescales. Equation (1) suggests that we write

$$\mathcal{E} = \left(\frac{\hbar}{e}\right) \frac{1}{\tau} \tag{2}$$

where \mathcal{E} is a measure of the strength of the driving field. We have put fundamental constants into this relation so that (in cgs units) \mathcal{E} has the dimensions of an emf (or voltage). Because lattice models also have a natural length scale—the lattice spacing—one can choose constants so that \mathcal{E} has the dimensions of an electric field. The identification of the strength of the field with an inverse timescale is central to our considerations and turns out to have consequences for transport. The first and easy consequence is that the question of phase transition in, say, the Hall conductance as a function of the driving electric field, can be phrased as a question about the analytic properties of the Hall conductance as a function of τ . The second consequence is discussed in the next section.

3. Analyticity of observables in τ

The identification of the timescale with the strength of the driving makes the driving field, be it an electric field or an emf, a special parameter in the Hamiltonian. This can be seen from the form of the Schrödinger equation for the time evolution operator in scaled time:

$$i\dot{U}_\tau(s) = \tau H(\vec{A}(s))U_\tau(s) \quad U_\tau(0) = 1. \tag{3}$$

The τ dependence of the Hamiltonian is linear, and *a fortiori*, analytic in τ , irrespective of how H depends on \vec{A} . This has the following consequences.

Proposition 1. *Suppose that $H(\vec{A}(s))$ is bounded and self-adjoint, then $U_\tau(s)$ and $U_\tau^\dagger(s)$ are both entire functions of τ .*

Proof. The first part follows from a standard argument about the absolute convergence of the Dyson series for U_τ . The second assertion is a consequence of the fact that, for real τ , U_τ^\dagger satisfies

$$i\dot{U}_\tau^\dagger(s) = -\tau U_\tau^\dagger(s)H(\vec{A}(s)) \quad U_\tau^\dagger(0) = 1. \tag{4}$$

The Dyson series implies that one can extend $U_\tau^\dagger(s)$ to an entire function of τ . □

We now have the following corollary.

Corollary 2. *Suppose that I is a (fixed) bounded operator, and ψ a (τ -independent) initial state then:*

$$I(\tau, s) = \langle \psi | U_\tau^\dagger(s) I U_\tau(s) | \psi \rangle \tag{5}$$

is an entire function of τ .

This leads to the main result of this section.

Theorem 3. Let $H(\bar{A})$ be bounded self-adjoint operator. Let I be a bounded observable, then, its expectation value $\langle I \rangle(\mathcal{E}, s)$ is an analytic function of \mathcal{E} with isolated essential singularity at $\mathcal{E} = 0$ and with Laurent expansion

$$\langle I \rangle(\mathcal{E}, s) = \sum_{n=0}^{\infty} \frac{a_n(s)}{\mathcal{E}^n} \quad (6)$$

with infinitely many of the $a_n \neq 0$ (except if $\langle I \rangle$ is a constant).

Proof. From proposition 1, $\langle I \rangle(\mathcal{E}, s)$ is an analytic function whose Taylor expansion about $\tau = 0$ is absolutely convergent with a radius of convergence that is infinitely large. The expansion cannot have positive powers of \mathcal{E} , for if it did, the response at $\tau = 0$ would not be analytic. The singularity at the $\mathcal{E} = 0$ must be essential for if it was a pole then the response would diverge as $\tau \rightarrow \infty$ along any direction. But, the response is bounded on the real τ -axis by the self-adjointness of the Hamiltonian. It follows that the response cannot have a pole of finite order at $\mathcal{E} = 0$. \square

Remarks.

- (i) It is important for the conclusion of the theorem to hold that the scaled time s is kept finite. If one lets $s \rightarrow \infty$ then analyticity in τ may be lost.
- (ii) We have restricted ourselves to bounded Hamiltonians and bounded observables. This is because phase transitions are normally a long-wavelength, low-energy phenomenon. Some parts of the theorem can also be extended to unbounded Schrödinger-type Hamiltonians provided some care is taken about questions of domains of operators.
- (iii) The smooth dependence of the evolution in τ is not really special to quantum mechanics. It also holds in classical mechanics under slightly stronger conditions, namely that $\partial_p H$ and $\partial_x H$ are both bounded functions (provided the initial state is analytic in τ).
- (iv) A classical model that shows breakdown of analyticity in a constant electric field is the washboard potential with initial state at rest at a local minimum. When \mathcal{E} is sufficiently small, the velocity stays zero for all times. When \mathcal{E} passes a threshold the particle accelerates indefinitely. This is not a counterexample to the analyticity of observables because the initial state in the washboard potential is \mathcal{E} dependent in a non-analytic way.
- (v) Two prototype functions for $\langle I \rangle$ that satisfy the conclusion of the theorem are $\exp(-c/\mathcal{E}^2)$ and $\sin(c/\mathcal{E}^2)$.
- (vi) The theorem has an interesting implication to the question of power law corrections to linear response. It follows from the theorem that if $\langle I \rangle$ has an asymptotic expansion in powers of $\mathcal{E} \in \mathbb{R}_+$ at $\mathcal{E} = 0$ then this expansion must vanish identically. One may wonder if the absence of power law corrections to linear response is a valid conclusion of equation (6). It is not, as one can see from the second prototype example in (v), where an asymptotic expansion in powers of $\mathcal{E} \in \mathbb{R}_+$ does not exist.
- (vii) Absence of power corrections to linear response in quantized Hall conductance has been proven rigorously for the quantum Hall effect by Klein and Seiler [13]. Their proof uses an adiabatic theorem to all orders, to show that an asymptotic expansion exists and a clever trick that shows that the coefficients must vanish. The theorem above can be used to replace their clever trick.

In tight-binding models the current operator, for finitely many interacting electrons or the current density operator for infinitely many non-interacting electrons, is bounded. It follows that the currents in such models have an essential singularity at $\mathcal{E} = 0$, but are analytic at non-zero \mathcal{E} provided the time $t\mathcal{E}$ is kept fixed.

4. Breakdown of Chern numbers

In this section we consider the breakdown of an observable associated with quantized charge transport. Quantized charge transport occurs for a class of Hamiltonians in the adiabatic limit. This class of Hamiltonians includes models of the quantum Hall effect, and in particular includes the Harper model. It also includes certain models of the Hall effect with electron–electron interactions. The observable that we consider reduces to the Hall conductance in the limit of linear response, and coincides with a Chern number. In this section we discuss the analytic properties of this observable with τ .

The model Hamiltonians for which quantization occurs have the following structure [20, 21]: $H(\phi, k)$ is a self-adjoint Hamiltonian that depends periodically on two real, dimensionless parameters, ϕ and k , with period 2π . $H(\phi, k)$ may be associated with a *finite multiparticle* system, where ϕ and k are external parameters, for example, two Aharonov–Bohm fluxes. Alternatively, $H(\phi, k)$ may be a Bloch-type Hamiltonian in two dimensions describing *infinitely many non-interacting* electrons, where ϕ and k are two Bloch momenta. In either case, we shall require that for fixed ϕ and k the Hamiltonian $H(\phi, k)$ has a discrete spectrum with no eigenvalue crossing. For the sake of simplicity we assume that the ϕ and k dependence is smooth and that $H(\phi, k)$ is a bounded operator such as a tight-binding model and its multiparticle generalizations.

The time dependence comes from a time dependence of ϕ on a timescale τ †. We suppose that $\phi(s)$ is a smooth, monotonically non-decreasing function of s with $\phi(s) = 0$ in the past, $s < 0$, and $\phi(s) = 2\pi$, in the future, $s \geq 2\pi$. H is therefore time dependent only on a finite interval of (scaled) time $[0, 2\pi]$.

Since $\partial_k H$ is the current operator in these models the total charge transported by the action of ϕ is

$$Q(\tau; \psi) = \frac{\tau}{2\pi} \int_0^{2\pi} dk \int_0^\infty ds \left\langle U_\tau(s, k)\psi(k) \left| \frac{\partial H(\phi(s), k)}{\partial k} \right| U_\tau(s, k)\psi(k) \right\rangle \quad (7)$$

with an initial condition ψ that is an eigenstate of $H(\phi, k)$ for $s = 0$.

There are several special things that happen in the adiabatic limit. First, Q coincides with the Hall conductance defined via Kubo’s formula [20, 21]. Second, it is independent of the functional form of ϕ (provided ϕ satisfies the limiting conditions). Third, since in the adiabatic limit there is no current once the driving stops, i.e. when $\dot{\phi} = 0$, Q can also be written as

$$Q(s; \tau, \psi) = \frac{\tau}{2\pi} \int_0^{2\pi} dk \int_0^s ds' \left\langle U_\tau \psi \left| \frac{\partial H}{\partial k} \right| U_\tau \psi \right\rangle \quad (8)$$

provided $s \geq 2\pi$. Q is always a measure of the charge transport, but its identification with a conductance is valid, in general, only in the adiabatic limit‡.

Applying the results of the previous section we see that the breakdown of the Chern number Q is smooth, and has no phase transition at finite fields. Due to the prefactor τ in equation (8), $a_0 = 0$ in equation (6).

It is interesting that for the class of models where one can prove that Q is quantized in the adiabatic limit, one can also show that it is an analytic function of the field away from $\mathcal{E} = 0$. (For model Hamiltonians with infinitely many interacting electrons there is, at present, no proof of quantization either.)

† Here ϕ plays the role of \bar{A} of the previous section.

‡ Equation (8) implies that Q vanishes in the limit $\tau \rightarrow 0$, i.e. in the limit of *large* external fields, contrary to common experience. One reason for this is that tight-binding models are unreasonable when the external fields are large on an atomic scale. We shall take the point of view that the breakdown is a low field phenomenon that is divorced from the asymptotic behaviour at very large fields.

There are now three possibilities. The first, and perhaps simplest, is that the breakdown of the Hall effect is a consequence of an essential singularity at zero field. The second is that the breakdown of the Hall effect is associated with the limit $s \rightarrow \infty$. And the third is that the breakdown is a property of infinitely many interacting electrons. We shall examine the second possibility in section 7.

5. Example: Hall conductance in the Harper model

The Harper model is the simplest, non-trivial, model where one can study the breakdown of the Hall effect in detail, at least numerically. The model is associated with a square lattice, \mathbb{Z}^2 ; an external *homogeneous* magnetic field B , and *homogeneous* electric field \mathcal{E} pointing in the x direction. We choose a gauge so that the electric field is described by a time-dependent vector potential. After separation of the variable, the model is described by a Hamiltonian on \mathbb{Z} parametrized by one Bloch momentum, k . The Hamiltonian action on the vector $\Psi \in \ell^2(\mathbb{Z})$, while the electric field is acting, is

$$e^{i\mathcal{E}t}\Psi_{x+1} + e^{-i\mathcal{E}t}\Psi_{x-1} + 2\cos(Bx+k)\Psi_x \quad k \in [-\pi, \pi] \quad x \in \mathbb{Z}. \quad (9)$$

For rational magnetic field $B = 2\pi p/q$ with $p, q \in \mathbb{Z}$ the Hamiltonian is periodic in x , with period q . One then classifies the solutions by a second Bloch momentum, $\ell \in [-\pi, \pi]$ so that $\Psi_{x+q} = \exp(-i\ell)\Psi_x$. Fixing periodic boundary conditions is achieved by the unitary transformation $\Psi_x \rightarrow e^{i\frac{\ell}{q}x}\Psi_x$. So, finally, the requisite form of the Harper Hamiltonian we shall study is

$$(H(\phi, k)\Psi)_x = e^{i\phi}\Psi_{x+1} + e^{-i\phi}\Psi_{x-1} + 2\cos\left(2\pi\frac{p}{q}x+k\right)\Psi_x$$

$$\Psi_{x+q} = \Psi_x \quad \phi(t) = \begin{cases} \frac{\ell}{q} & \text{if } t < 0 \\ \mathcal{E}t + \frac{\ell}{q} & \text{if } 0 < t < \frac{2\pi}{\mathcal{E}} \\ 2\pi + \frac{\ell}{q} & \text{otherwise.} \end{cases} \quad (10)$$

This corresponds to a $q \times q$ Hermitian matrix, periodic in ϕ and k . The driving electric field, \mathcal{E} , is related to the adiabaticity parameter τ , by (2) (in units where $e = \hbar = 1$). In this example $\phi(s)$ is continuous and piecewise linear. As a consequence the electric field is discontinuous in time. It is easy to modify the model so that the electric field is switched on and off continuously. We have also examined such models and the behaviour is qualitatively similar to models with discontinuous switching.

For $p = 1, q = 3$, the Harper Hamiltonian is a 3×3 matrix. Its Chern numbers are $\{3, 3, -6\}$. Figure 1 shows the charge transport, $Q(2\pi; \tau, \psi)$, as a function of the applied field. The graph has a rich and complex structure, but no sharp breaking. Substantial deviation from integral quantization occurs near $\tau = 5$.

6. Long-time limit and Floquet states

In this section we consider the long-time limit of observables, in time-periodic (finite-dimensional) Hamiltonians. An example is the current density operator in tight-binding models, such as the Harper model, driven by a time-independent electric field. One advantage of using a time-dependent representation over the time-independent representation is that

Figure 1. The Hall conductance of the 3×3 Harper Hamiltonian as a function of the adiabaticity parameter τ .

one has to deal with finite-dimensional matrices. In the time-independent representation the matrices are infinite dimensional.

In the theory of time-periodic Hamiltonians Floquet states [7, 16, 6] play a role analogous to that of eigenstates for time-independent operators. We shall see that the long-time (Abelian) limit of observables in time-periodic systems is related to the expectation value of the observable in Floquet states.

Consider a time-periodic, self-adjoint, finite-dimensional matrix Hamiltonian $H(s+2\pi) = H(s)$. The Harper model of section 5 is an example except that now the electric field is time independent for all (positive) times $s \geq 0$.

Let F denote the unitary evolution over one cycle

$$F = U(2\pi). \tag{11}$$

The time evolution for $n \in \mathbb{Z}$ periods is clearly

$$F^n = U(2n\pi). \tag{12}$$

We assume that F is a finite-dimensional, non-degenerate matrix. Its spectral representation is then

$$F = \sum_n e^{iE_n} |\psi_n^F\rangle \langle \psi_n^F|. \tag{13}$$

E_n are the *quasienergies*, and $|\psi_n^F\rangle$ the eigenvectors of F .

Consider the observable associated to the bounded operator I (e.g. the current density operator in tight-binding models). Let ψ be the initial state of the system at $s = 0$, then the Abelian, long-time limit of the expectation value of I , when ψ evolves according to the Schrödinger evolution, is

$$\lim_{M \rightarrow \infty} \frac{1}{M} \sum_{j=1}^M \langle I(2\pi j) \rangle = \lim_{M \rightarrow \infty} \frac{1}{M} \sum_{j=1}^M \langle F^j \psi | I | F^j \psi \rangle =$$

$$\begin{aligned}
&= \sum_{l,n} \langle \psi_n^F | I | \psi_l^F \rangle \langle l | \psi \rangle \langle \psi | n \rangle \left(\lim_{M \rightarrow \infty} \frac{1}{M} \sum_{j=1}^M e^{i(E_l - E_n)j} \right) \\
&= \sum_l |\langle \psi | \psi_l^F \rangle|^2 \langle \psi_l^F | I | \psi_l^F \rangle. \tag{14}
\end{aligned}$$

The long-time behaviour is a weighted sum of the expectation value of the operator I in Floquet states, i.e. $\langle \psi_l^F | I | \psi_l^F \rangle$.

In particular, if one now defines the Hall conductance as the ratio of the Hall current density to the electric field in the long-time limit, then the breakdown of the Hall effect is related to analytic properties of the expectation value of the current density operator in Floquet states. This is the subject of the following sections.

7. Transport in Floquet states

In this section we recall, and extend, results of Ferrari [10] that relate the Hall conductance of Floquet states to their Chern number and the winding numbers of their quasienergies.

Consider a time-periodic, self-adjoint, finite-dimensional matrix Hamiltonian $H(s + 2\pi, k) = H(s, k)$, which depends analytically on s and k . The Harper model of section 5 is an example except that now the electric field is time independent for all (positive) times. s is, as before, the scaled time.

We define the Floquet operator as the unitary evolution over one cycle

$$F_\tau(s, k) = U_\tau(s + 2\pi, k) U_\tau^\dagger(s, k). \tag{15}$$

The Floquet theorem can be expressed as

$$F_\tau(s + 2\pi, k) = F_\tau(s, k). \tag{16}$$

We assume that F_τ is a finite-dimensional matrix. It therefore has a discrete spectrum and its spectral representation is

$$F_\tau(s, k) = \sum_n e^{iE_n(s, k; \tau)} \mathcal{P}_n(s, k; \tau). \tag{17}$$

E_n are the *quasienergies*, and \mathcal{P} are the eigenprojections. We shall denote by $|\psi_\tau^F\rangle$ a unit eigenvector of F_τ .

Lemma 4. *For a Floquet operator generated by a bounded and analytic $H(s, k)$:*

- (1) *The quasienergies are independent of s , $E_n(s, k; \tau) = E_n(k; \tau)$.*
- (2) *The eigenfunctions (eigenprojections) obey the Schrödinger (Heisenberg) equations*

$$i\partial_s |\psi_\tau^F(s, k)\rangle = \tau H(s, k) |\psi_\tau^F(s, k)\rangle \tag{18}$$

$$i\partial_s \mathcal{P}(s, k; \tau) = \tau [H(s, k), \mathcal{P}(s, k; \tau)]. \tag{19}$$

- (3) *$F_\tau(s, k)$ is an entire function of τ and an analytic function of s and k .*

Proof. The Floquet operator satisfies

$$F_\tau(s, k) = U_\tau(s, k) F_\tau(0, k) U_\tau^\dagger(s, k) \tag{20}$$

so its eigenvalues are independent of s . The eigenfunctions and eigenprojections transform in the same way:

$$|\psi_\tau^F(s, k)\rangle = U_\tau(s, k) |\psi_\tau^F(0, k)\rangle \tag{21}$$

$$\mathcal{P}(s, k; \tau) = U_\tau(s, k) \mathcal{P}(0, k; \tau) U_\tau^\dagger(s, k) \tag{22}$$

from which the second assertion follows. The third item follows from proposition 1. \square

F depends on s , τ and k . Because of equations (20) the s variable is uninteresting. It is a basic fact of perturbation theory [11] that if a (normal) operator depends analytically on two variables (or more), one can choose, in general, at most one variable so that the eigenvectors and eigenvalues are real analytic. We choose real analyticity in the k variable. The price one has to pay for this is twofold. First, the τ dependence of the projections will, in general, be discontinuous at crossings[†] and the second is that the 2π periodicity in k may be lost. (One cannot assume that \mathcal{P} is both real analytic and 2π periodic in k .) But, it is $2\pi N$ periodic for some finite N . If there are no crossing then $N = 1$.

A result of Ferrari [10] identifies the Chern numbers of Floquet eigenstates with the charge they transport and relates the Chern number of Floquet states to the winding number of the quasienergies. This identification will play a key role in the next section where we discuss breakdown.

Proposition 5. *Let $F_\tau(0, k)$ be a finite-dimensional Floquet operator, which is unitary for real values of τ and k , and analytic in both. Fix τ and label the spectrum so that $\mathcal{P}_\tau(0, k)$ is real analytic in k with period $2\pi N$. Then:*

- (1) *The quasienergies $E(k; \tau)$ and the associated eigenfunctions $|\psi_\tau^F(s, k)\rangle$ are simultaneously real analytic in k and s .*
- (2) *The conductance associated to non-interacting electrons that fill a k -band of Floquet states is a Chern number multiple of $1/N$:*

$$Q(\tau; \psi_\tau^F) = \frac{1}{2\pi N} \text{Im} \int_0^{2\pi} ds \int_0^{2\pi N} dk \left\langle \frac{\partial \psi_\tau^F}{\partial s} \left| \frac{\partial \psi_\tau^F}{\partial k} \right. \right\rangle \in \frac{\mathbb{Z}}{N}. \tag{23}$$

- (3) *$Q(\tau; \psi_\tau^F)$ is also the winding number of the corresponding eigenvalue,*

$$Q(\tau; \psi_\tau^F) = -\frac{E(2\pi N; \tau) - E(0, \tau)}{2\pi N}. \tag{24}$$

- (4) *$Q(\tau, \psi_\tau^F) = 0$ for all $\mathcal{E} > 2 \max_{s,k \in [0, 2\pi]} \|H(s, k)\|$.*

Proof. The first assertion follows from the real analyticity of the projection, (21), and standard facts from perturbation theory [11]. The second assertion follows from

$$\tau \left\langle \psi_\tau \left| \frac{\partial H}{\partial k} \right| \psi_\tau \right\rangle = \tau \frac{\partial}{\partial k} \langle \psi_\tau | H | \psi_\tau \rangle + \text{Im} \left\langle \frac{\partial \psi_\tau}{\partial k} \left| \frac{\partial \psi_\tau}{\partial s} \right. \right\rangle. \tag{25}$$

The observable on the left-hand side of this identity is the ratio of the current to the driving electric field (in each k channel). This means Q is a conductance. The identity (25) is a consequence of integration by parts, the equation of motion, and the periodicity in k . The quantization of Q follows by integrating over the period in k and using standard facts about Chern numbers. Using the identity

$$\left(F_\tau^\dagger \frac{\partial F_\tau}{\partial k} \right) (0, k) = -i\tau \int_0^{2\pi} U_\tau^\dagger(s, k) \left(\frac{\partial H}{\partial k} \right) U_\tau(s, k) ds \tag{26}$$

and equation (17)

$$\langle \psi_\tau^F(0, k) | (F_\tau^\dagger \partial_k F_\tau)(0, k) | \psi_\tau^F(0, k) \rangle = i \partial_k E(k; \tau) \tag{27}$$

gives assertion (3). Item (4) follows from the observation that the winding vanishes if $\max |E(k; \tau)| < \pi$. The maximum can be achieved when all the terms in the Dyson expansion

[†] This can be seen already for the 2×2 matrix function $\tau \sigma_x + k \sigma_z$ where σ are the Pauli matrices.

of the evolution operator have the same eigenstate for their maximal eigenvalue and all the eigenvalues are summed up with the right signs. It follows that

$$|E| \leq 2\pi \tau \max \|H\| \quad (28)$$

which implies item (4). \square

Finally, we note that for the adiabatic limit, $\mathcal{E} = 0$, eigenstates of the Hamiltonian are also Floquet eigenstates. This shows that for $\mathcal{E} = 0$ the Chern number for Floquet states is the Hall conductance of linear response when $H(s, k)$ is the Hamiltonian for the Hall effect.

8. Breakdown in Floquet states

In the previous section it was shown that the Hall conductance in Floquet states, for any field strength \mathcal{E} , is related to the Chern number of the state. Since the Chern numbers are integers, this implies that the breakdown in Floquet states is always discontinuous: a quantum phase transition. For $\mathcal{E} = 0$ the conductance for Floquet states coincides with the Hall conductance of linear response but when \mathcal{E} is large enough Q vanish. This forces a discontinuous breakdown.

At first, it appears that one can argue that a breakdown must occur for some finite value of \mathcal{E} because Chern numbers do not change under small deformations of the bundle of eigenstates, and so if the Chern number is non-zero at zero field, should it not also be non-zero for small fields?

To understand how the breakdown occurs we first make the observation that non-zero Chern numbers for Floquet operators always come with level crossings.

Theorem 6. *Let $F_\tau(0, k)$ be a finite-dimensional Floquet operator, which is unitary for $\tau, k \in \mathbb{R}$, and analytic in both. Label the spectrum of F_τ so that $\mathcal{P}_\tau(0, k)$ is real analytic in k with period $2\pi N$. If any Chern number is non-zero then F_τ has eigenvalue crossing for some value of k .*

Proof. By general principles, the sum of all the Chern numbers for any finite-dimensional matrix, such as F_τ , must vanish. Hence, if there is a positive Chern number for one of the states of F_τ , there must also be a negative Chern number for some other state. The quasienergy with a positive winding must then cross the one with negative winding. \square

This leads to a puzzle that has Chern on one side, and Wigner and von-Neumann (WVN) on the other: WVN [17][†] say that eigenvalue crossings tend to be unstable, unless the dimension of parameter space is three or more[‡]. The relevant parameter space for the Floquet operators is the τ - k space which has dimension two. This implies that crossings are unstable. On the other hand Chern numbers give a topological characterization of the bundle of eigenstates and are stable under continuous deformations of the bundle. Who wins?

The winners, we claim, are WVN. It is, of course, true that continuous deformations of the bundle keep the Chern number fixed. But, there is no reason why continuous deformations of the Hamiltonian or a variation in τ , should lead to continuous deformations of the bundle of eigenstates. By perturbation theory a small deformation in the Hamiltonian can result in a discontinuous change of the bundle at points of crossing. Since the non-zero Chern number for Floquet states always comes with an eigenvalue crossing, the bundles always lie at the boundary of the region of stability. As a consequence, generically at least, Chern numbers for Floquet operators[§] should be zero and the breakdown should therefore occur at $\mathcal{E} = 0_+$.

[†] The English translation can be found in the appendix of [14].

[‡] In the complex case, which is the case relevant here.

[§] At least, those of the class we study here, that depend on a single variable k .

Experimentally, the breakdown of the Hall effect is continuous and consequently, the breakdown of Floquet states does not appear to be an appropriate theory for the breakdown of the Hall effect. This suggests that the breakdown is not a large time phenomenon. Nevertheless, the breakdown in Floquet states is an interesting chapter in the theory of breakdown of Chern numbers.

9. Unstable Chern numbers

We have seen in theorem 6 that non-zero Chern numbers for Floquet operators always come with eigenvalue crossings. The question whether Floquet operators do or do not have stable non-zero Chern numbers, is equivalent to the question whether Floquet operators do or do not have stable eigenvalue winding and crossing.

9.1. Fragile Winding

A simple example, that we owe to B Simon, illustrates how topological objects that are normally associated with stability become fragile in the context of eigenvalue problems. Consider the unitary

$$F_\tau(s = 0, k) = \begin{pmatrix} \cos(1/\tau)e^{ik} & \sin(1/\tau) \\ -\sin(1/\tau) & \cos(1/\tau)e^{-ik} \end{pmatrix}. \tag{29}$$

F has a unit determinant so its two eigenvalues are determined by a single angle ϕ . Clearly $\cos \phi = \cos(1/\tau) \cos k$. For $1/\tau = \pi n$ the two eigenvalues have winding numbers ± 1 as k goes through a period. But, for most values of τ the two eigenvalues repel at 0 and π , and have zero winding. Winding numbers that arise from an eigenvalue problem are not stable.

9.2. The paradigm

The basic paradigm of line bundles associated with Chern numbers ± 1 comes from Berry’s example of spin $\frac{1}{2}$ in a magnetic field. Berry’s spin $\frac{1}{2}$ model describes a 2×2 Hamiltonian that is parametrized by the two sphere. In the study of Floquet operators and adiabatic transport, one is interested in families parametrized by the 2-torus. The question is how to pick a family of 2×2 Hamiltonians on a 2-torus with Chern numbers ± 1 . A nice geometric way (figure 2) to think about the family is to consider the pull-back of Berry’s spin $\frac{1}{2}$ on the 2-sphere, by the Gauss map from the 2-torus to the 2-sphere with degree one[†].

A useful fact about the quasienergies of 2×2 Floquet operators with determinant 1 is that $E_1 = -E_2$. Hence, gap closure occurs only at $E = 0$ and $E = \pm\pi$. A stable non-zero Chern number then requires a stable crossing at both at $E = 0$ and $E = \pm\pi$. Since this feature considerably simplifies the numerical analysis the 2×2 Hamiltonian on the torus should also be traceless.

An example of a periodic, traceless 2×2 matrix Hamiltonian with Chern numbers ± 1 is

$$H_1(s, k) = \frac{1}{\sqrt{\sin(s)^2 + |a|^2}} \begin{pmatrix} \sin(s) & a \\ \bar{a} & -\sin(s) \end{pmatrix} \tag{30}$$

with

$$a = \cos\left(k + \frac{\pi}{4}\right) + i \cos\left(k - \frac{\pi}{4}\right) + (1 + i)(\cos(s) + 1). \tag{31}$$

[†] We thank I Klich for pointing this out.

Figure 2. A map from the 2-torus (φ, θ) to the sphere (the unit vector pointing from θ to φ). The linking number is the degree of the map.

Figure 3. Gap widths of the Floquet operators from H_1 . The solid curve is for the gap near $E = \pi$, the dashed curve is for the gap near $E = 0$.

The Floquet operator associated to this Hamiltonian has to be calculated by numerical integration of the Schrödinger equation (3). This Floquet is our basic paradigm. Now, if non-zero Chern numbers for Floquet operators are generically unstable, this will manifest itself in the opening of gaps at π and 0. The gaps are shown in figure 3 and are consistent with the claim that Chern numbers of the Floquet operator are generically zero.

9.3. Another toy model

We have also carried out extensive numerical studies of the following toy model of a 2×2 traceless periodic matrix family:

$$H_2(s, k, \varepsilon) = \frac{1}{\sqrt{a^2 + (b + \varepsilon)^2 + c^2}} \begin{pmatrix} a & b - ic + \varepsilon \\ b + ic + \varepsilon & -a \end{pmatrix} \quad (32)$$

$$a = \cos(k) \quad b = \cos(s) \quad c = \cos(s + k).$$

This Hamiltonian is inspired to some extent by the Harper model on a triangular lattice [1]. It has the following features:

- (i) For all $s, k, \varepsilon \neq \pm 1$ the spectrum is constant $\text{Spec}(H_2(s, k, \varepsilon)) = \{-1, 1\}$.

Figure 4. Plot of the minimal quasienergy gap versus τ for $\varepsilon = 0$. Notice the logarithmic y -scale. The calculation accuracy was of order 10^{-8} . The circles represent the calculation points which are spaced non-uniformly.

- (ii) The Chern numbers associated with the eigenvectors of $H_2(s, k, \varepsilon)$ are ± 2 for $-1 < \varepsilon < 1$ and zero otherwise[†].

We have added an extra parameter, ε so that the associated Floquet operator, $F_\tau(0, k; \varepsilon)$, depends on three variables, $\{\tau, k, \varepsilon\}$. The reason for including ε shall become clear below.

What should one expect for the Floquet operator based on WVN's genericity argument? Since (the unitary) $F_\tau(0, k; \varepsilon)$ depends on three real variables, one expects isolated points in the $\{\tau, k, \varepsilon\}$ space where there is crossing. In other words, for some special values of ε one expects to find crossing, while for most values of ε , there should be no crossing, and all Chern numbers should vanish. This turns out to be the case.

Here too the Floquet operator has to be calculated by numerical integration of the Schrödinger equation (3).

For $\varepsilon = 0$ the crossing at $E = 0$ is stable for all τ . The gap at $E = \pm\pi$ is plotted in figure 4. As can be seen, for most values of τ the gap is wider than the numerical tolerance. This gap is usually very small. It is easy to mistake these small gaps for crossings.

Near integers values of τ the gap width decreases rapidly. At these points the gaps seem to close, up to our numerical accuracy, and the winding numbers change from zero to ± 2 .

These results are in conflict with both the putative stability of Chern numbers, and the WVN instability of crossing. It is in conflict with Chern, as non-zero Chern numbers appear to occur at isolated points on the τ -axis rather than intervals. It is also in conflict with WVN, for, by the no-crossing rule one expects no crossing in the τ - k plane at all. The model would be consistent with WVN if the point $\varepsilon = 0$ turns out to be a special point. Although we do not know if and why $\varepsilon = 0$ is special, one expects WVN to fail for *some* ε , and a test would be to see if the crossings disappear when we wiggle away from $\varepsilon = 0$.

For non-zero values of ε both gaps close at $E = 0, \pi$ indeed disappear, as is seen in figure 5, and WVN are vindicated.

For more numerical results and description for some of the numerical procedures see [15].

[†] This can be seen by examining sections of the bundle.

Figure 5. Gap widths of the Floquet operators from H_2 with $\varepsilon = 0.2$. The solid curve is for the gap near $E = \pm\pi$, the dashed curve is for the gap near $E = 0$.

Figure 6. The quasienergies $E(k)$ of the Floquet operator associated with the 3×3 Harper Hamiltonian for $\tau = 1.5, 2.5$.

In conclusion, the numerical results for both toy models are in agreement with WVN and with our argument that Chern numbers for Floquet operators are generically zero.

9.4. The Harper model

We have also numerically studied the question of stability of Chern numbers for the Floquet operator that is associated with the Harper model.

Telling a true crossing from an avoided crossing in a numerical study is often a challenge. Often one finds complicated pictures where it is difficult to tell with certainty which is really the case since even real gaps tend to be very small. This is illustrated by numerical results for the Harper model with $p = 1$ and $q = 3, 4$, see figures 6 and 7.

Our numerical results are consistent with the assertion that the Harper model has some stable crossings. It is an open problem to prove or disprove this.

Figure 7. The quasienergies $E(k)$ of the Floquet operator associated with the 4×4 Harper Hamiltonian for $\tau = 1.5, 5.0$.

Figure 8. The 2-torus which is used to enclose the crossing line. Notice that s is a cyclic parameter, so the cylinder closes to a torus.

10. Failure of Berry’s method to detect Floquet crossings

One reliable method to identify crossing of *self-adjoint* matrices, is to compute a Chern number (in the Hermitian case) or the Longuet–Higgins phase (in the symmetric case) [2, 3]. Unfortunately, this method does not work for the kind of Floquet operators that we consider, as we now proceed to explain.

Because of the s independence of the spectrum an isolated crossing would look like the line of constant k and τ as in figure 8. The associated Chern number involves the surface of integration, a 2-torus of (s, θ) , as shown in figure 8.

Using similar arguments as in equations (23) and (24) we find

$$\text{ch}(\mathcal{P}) = -\frac{1}{2\pi} \int_0^{2\pi} \partial_\theta E(\theta) d\theta = -\frac{E(2\pi) - E(0)}{2\pi}. \tag{33}$$

Since the surface lies away from any crossing the winding number of all eigenvalues must be the same. Since the Chern numbers sum to zero, the winding must be zero too. Chern numbers are therefore not useful to identify the crossing of Floquet operators.

11. Conclusion

Transport coefficients *in linear response theory*, such as the Hall conductance, can, in general, undergo a phase transition as functions of *parameters* in the Hamiltonian. This is because, in the linear regime, the conductance can be expressed in terms of the spectral data of the Hamiltonian. Spectral data may, and in general will, lose smoothness near eigenvalue crossing and allow for the loss of analyticity.

The breakdown in Chern numbers associated with the Hall conductance in finite fields seen in figure 1 is not associated with loss of analyticity at finite fields but with an essential singularity at zero fields.

One way to have Chern numbers undergo a phase transition with the applied field is to define them by a spectral problem. This is the case for Chern numbers of Floquet states. An external time-independent electric field, in an appropriate gauge, leads to a tight-binding Hamiltonian that is periodic in time and admits Floquet analysis. The Hall conductance in Floquet states reduces to a spectral problem for the Floquet operator. This holds for any value of the driving field, and not just in the linear response regime. Because of this, changing the field can lead to a non-smooth behaviour of the conductance when eigenvalues of the Floquet operator cross. We argue that the Chern numbers of Floquet operators are generically zero, because non-zero Chern numbers come with eigenvalue crossings. Non-zero Chern numbers are unstable to small variations in the Hamiltonian and the breakdown occurs at zero fields.

In conclusion we can say that we find no theoretical reason for the breakdown of the Hall effect to be a quantum phase transition at nonzero fields, although we do not rule this out for more complicated models such as models of infinitely many interacting particles. In addition we observe that under the condition where one can show that the charge transport is quantized, one can also show that it is an analytic function of the field with an essential singularity at zero field.
