Abstract. The application of the lattice Boltzmann model to simulating nonlinear propagative acoustic waves is considered. The lattice Boltzmann model, and its application to the study of nonlinear sound propagation, are discussed. Lattice Boltzmann simulations of the development of a shock front are performed when a sound wave is emitted from a high-amplitude sinusoidal source. For a number of parameters, representing different physical situations, the wave development is compared with inviscid shock theory and with the solution of Burgers' equation for a fully viscous fluid. The simulations show good agreement with Burgers' equation and with the inviscid theory when propagation at high Reynolds number is considered. These results suggest that the lattice Boltzmann model is a useful technique for studying a range of problems in nonlinear acoustics.

1. Introduction

The lattice Boltzmann model (LBM) has developed from the lattice gas automata (LGA) model [1–3] which considers the evolution of a number of idealized fluid 'particles' which move at unit speed on a regular grid subject to particle convection and simplified collision rules which conserve the total fluid mass and momentum. The main application of the LGA has been to fluid dynamics [4–6], however, sound propagation has also been considered. Frisch *et al* [2] showed that the LGA incorporates sound wave propagation in the small-perturbation limit. Numerical and theoretical evaluations of this LGA technique were performed by Margolus *et al* [7], Chen *et al* [8] and Lavallée [9]. The idea was also employed by Chen *et al* [10] who proposed a model to directly simulate a linear sound wave without treating the sound wave in the small-perturbation limit. The LGA approach to emulating sound waves was also developed by Sudo and Sparrow [11, 12] who considered sound propagation in one and two dimensions and who further developed their model to include dissipation [13]. These developments have led to a number of successful applications of the LGA to the study of acoustical problems: Numrich *et al* [14] considered underwater sound propagation, Stansell and Greated [15] simulated acoustic streaming in a pipe and Rothman [16] and Huang *et al* [17] modelled seismic *P*-waves in homogeneous and inhomogeneous media, respectively.

Despite the successful application of the LGA to many problems, both in fluid dynamics and in acoustics, there are a number of difficulties associated with LGA simulations. Two particular problems are the statistical noise associated with the simulation due to the small

number of ‘particles’ being considered, and the viscosity being limited to relatively high values. These both limited the range of application of the LGA, see, for example, [9, 15]. In an attempt to overcome these drawbacks LGA has evolved in a number of stages and developed into the LBM; details of the various steps can be found in, for example [18, 19]. The development of the LBM was driven mainly by its use in fluid dynamics, since the LBM can be shown [18] to mimic the incompressible Navier–Stokes and continuity equations. Recently, Buick *et al* [20] have applied the technique to simulate linear sound waves when the pressure variations are considered to be a small perturbation. Here we extend the scope of the simulations to consider nonlinear waves and show that the LBM method and the incompressible approximation are not limited to the linear regime. In all the simulations the amplitude of the density variation is no greater than 1% of the ambient density so that the incompressible LBM equations can be applied to a good approximation [20].

2. The lattice Boltzmann model

The LBM considered here evolves on a fixed hexagonal lattice. The sites on the lattice are joined by unit vectors e_i , where $i = 1, 2, \dots, 6$, while e_0 is defined to be the null vector (see figure 1). The simplified, discretized Boltzmann equation [21, 22] is given by

$$f_i(\mathbf{r} + e_i, t + \Delta t) - f_i(\mathbf{r}, t) = \Omega_i(\mathbf{r}, t) \quad i = 0, 1, \dots, 6 \quad (1)$$

where $f_i(\mathbf{r}, t)$ are the distribution functions along the links e_i at site \mathbf{r} and time t and $\Omega_i(\mathbf{r}, t)$ is the collision operator. The left-hand side of equation (1) is the convection operator and describes streaming of the distribution functions on the grid. This operator can be seen to be linear in velocity space. The simplification of the Boltzmann equation occurs in the form of the collision operator which is taken to be the Bhatnagar–Gross–Krook (BGK) approximation [21, 23, 24]:

$$\Omega_i(\mathbf{r}, t) = -\frac{1}{\tau}[f_i(\mathbf{r}, t) - \bar{f}_i(\mathbf{r}, t)] \quad (2)$$

where \bar{f}_i is the equilibrium distribution function and τ is the relaxation time. The form of Ω_i , given in equation (2), represents a relaxation of the distribution towards its equilibrium value and recovers the nonlinear form of the fluid, ensuring that the fully nonlinear Navier–Stokes equation is satisfied. The equilibrium distribution functions depend only on the fluid density, ρ , and velocity, \mathbf{u} , at each site which can be calculated from the distribution functions as

$$\rho = \sum_i f_i \quad (3)$$

and

$$\rho u_\alpha = \sum_i f_i e_{i\alpha} \quad (4)$$

where the Greek subscripts represent vector components and summation over repeated Greek indices is assumed. Thus the collision process requires only local information to introduce nonlinear effects into the simulation. Up to $O(u^2)$, we assume that the equilibrium distribution function has the general form [25],

$$\bar{f}_i(\mathbf{r}, t) = \begin{cases} \rho (A + B e_i \cdot \mathbf{u} + C (e_i \cdot \mathbf{u})^2 + D u^2) & i = 1, \dots, 6 \\ \rho (A_0 + D_0 u^2) & i = 0. \end{cases} \quad (5)$$

Figure 1. The hexagonal grid on which the simulations are performed. The vectors e_1, \dots, e_6 are unit vectors along the directions of the grid and e_0 is the null vector.

This expansion up to second order in \mathbf{u} ensures that the simulations have second-order accuracy, however, the expansion is only valid for small Mach numbers $M = u/c_s$, where c_s is the speed of sound in the medium. The constants A, A_0, \dots, D_0 can be found for the specific lattice being used and the required properties of the fluid. Here we require that the collisions conserve mass and momentum, that is

$$\rho = \sum_i \bar{f}_i \quad (6)$$

and

$$\rho u_\alpha = \sum_i \bar{f}_i e_{i\alpha} \quad (7)$$

and that the fluid is isotropic and exhibits Galilean invariance. These requirements are fulfilled by

$$A = \frac{1}{6}(1 - d_0) \quad A_0 = d_0 \quad B = \frac{1}{3} \quad C = \frac{2}{3} \quad D = -\frac{1}{6} \quad D_0 = -1 \quad (8)$$

where d_0 is an arbitrary constant. This determines the equilibrium distribution function which is applied here. In general, a different equilibrium distribution function can be used if different fluid properties are required.

The macroscopic equations can be derived from the lattice Boltzmann equations by performing a multiscale Chapman–Enskog expansion [2] in the time and space derivatives such that

$$\frac{\partial}{\partial t} \rightarrow \epsilon \frac{\partial}{\partial t_1} + \epsilon^2 \frac{\partial}{\partial t_2} \quad (9)$$

and

$$\frac{\partial}{\partial x} \rightarrow \epsilon \frac{\partial}{\partial x_1} \quad (10)$$

and the distribution function is expanded about the equilibrium value,

$$f_i \rightarrow \bar{f}_i + \epsilon f_i^{(1)} + \epsilon^2 f_i^{(2)} \quad (11)$$

where ϵ is the Knudsen number which must be small. If we further assume that the lattice spacing, e_i , and the time step, Δt , are small parameters, and of the same order as ϵ , then equation (1) can be Taylor expanded and combined with equation (2). Substituting the expression for the equilibrium distribution functions, equation (5), and the Chapman–Enskog expansions, equations (9)–(11), and retaining terms up to second order in ϵ we obtain [25]

the continuity and Navier–Stokes equations for an incompressible, isothermal fluid in two dimensions:

$$\partial_t \rho + \partial_\alpha \rho u_\alpha = 0 \quad (12)$$

and

$$\partial_t \rho u_\alpha + \partial_\beta \rho u_\beta u_\alpha = -\partial_\alpha \left[\frac{1}{2} (1 - d_0) \right] \rho + \nu \partial_\beta \partial_\beta \rho u_\alpha + \zeta \partial_\alpha \partial_\beta \rho u_\beta \quad (13)$$

where

$$\nu = \frac{1}{4} \left(\tau - \frac{1}{2} \right) \quad (14)$$

and

$$\zeta = \left(\tau - \frac{1}{2} \right) \left[\frac{1}{2} - \frac{1}{2} (1 - d_0) \right] \quad (15)$$

are the kinematic shear and bulk viscosities. The pressure term in equation (13) is $p = (1 - d_0)\rho/2$ which, for a perfect gas, gives the speed of sound as $c_s = [(1 - d_0)/2]^{1/2}$.

In deriving equations (12) and (13) there have been a number of assumptions made which restrict the application of the LBM. In the expansion of the equilibrium distribution function it is assumed that the Mach number $M = u/c_s$ is small; in the Taylor expansion of the Boltzmann equation the length and time scales of the simulation, e_i and Δt , are assumed to be small; finally, the density variation must also be assumed to be small since the equations of motion are for an incompressible fluid. Since we are dealing with a perfect gas where p is proportional to ρ we can write, for a progressive plane wave,

$$\frac{\rho'}{\rho_0} = \frac{u}{c_s} = M \quad (16)$$

where ρ' is a density variation due to the sound wave and ρ_0 is the ambient density. Here the low-Mach-number approximation and the incompressibility condition reduce to one constraint. The further constraint that e_i and Δt are small requires that the macroscopic scales of the wave are much larger than the microscopic scales of the grid, that is for a wave of wavelength λ and period T

$$|e_i| \ll \lambda \quad \text{and} \quad \Delta t \ll T. \quad (17)$$

This can always be achieved by selecting suitable values of λ and T .

It is worth noting that while the LBM satisfies the incompressible Navier–Stokes equation the simulated fluid can experience density variations. These arise from the definition of ρ , equation (3), which does not constrain ρ to be constant. In many fluid dynamics applications, for example pressure-driven Poiseuille flow, this is seen as a disadvantage since so-called compressibility errors are observed in a LBM simulation [26] and in many cases the pressure gradient is approximated by a body force to remove this effect [27]. Here we use this feature of the LBM in the limit that we consider only low Mach numbers.

3. Nonlinear acoustics

In this section we consider acoustic waves where the amplitude is large enough that nonlinear motion is observed, but where the restriction that the Mach number, $M = u/c_s$, is small, as is required for the lattice Boltzmann model to be applicable. Under these conditions nonlinear phenomena are locally small (of the order of M), however, the effects are cumulative and increase with the distance of propagation and will, after a sufficient propagation distance,

significantly distort the wave. To consider this we start from the Navier–Stokes and continuity equations and the equation of state of the fluid (see, for example, [28–30]):

$$\partial_t \rho + \partial_\alpha \rho u_\alpha = 0 \quad (18)$$

$$\rho [\partial_t u_\alpha + u_\alpha \partial_\beta u_\beta] = -\partial_\alpha p + \rho \nu \partial_\beta \partial_\beta u_\alpha + \rho \left[\zeta + \nu \left(1 - \frac{2}{D} \right) \right] \partial_\alpha \partial_\beta u_\beta \quad (19)$$

and

$$p' = c_s^2 \rho' + \frac{(\gamma - 1)c_s^2}{2\rho_0} \rho'^2 - \chi \left(\frac{1}{c_v} - \frac{1}{c_p} \right) \partial_\alpha u_\alpha \quad (20)$$

where D is the number of dimensions, χ is the coefficient of thermal conductivity, c_p and c_v are the specific heats at constant pressure and volume, $\gamma = c_p/c_v$ and the pressure and density (p and ρ) are, respectively, defined as the sum of the ambient (p_0 and ρ_0) and the perturbation (p' and ρ'). The kinematic shear and bulk viscosities and the speed of sound are ν , ζ and c_s , respectively, as before. Substituting the equation of state, equation (20), into the continuity and Navier–Stokes equations (18) and (19), expressing the pressure and the density as the sum of the ambient value and the perturbation, and neglecting the term $\rho' u_\beta \partial_\beta u_\alpha$ since it is $O(M^3)$ we obtain

$$\frac{\partial \rho'}{\partial t} + (\rho_0 + \rho') \frac{\partial u}{\partial x} + u \frac{\partial \rho'}{\partial x} = 0 \quad (21)$$

and

$$(\rho_0 + \rho') \frac{\partial u}{\partial t} + \rho_0 u \frac{\partial u}{\partial x} = -c_s^2 \frac{\partial \rho'}{\partial x} - \frac{2\epsilon c_s^2 \rho'}{\rho_0} \frac{\partial \rho'}{\partial x} + \rho_0 b \frac{\partial^2 u}{\partial x^2} \quad (22)$$

where $b = \zeta + (1 + 1 - 2/D)\nu + \chi(1/c_v - 1/c_p)/\rho_0$, $\epsilon = (\gamma + 1)/2$ and we have used one-dimensional notation since we are interested in the propagation of plane waves.

To proceed further it is not possible to consider a classical perturbation expansion of equations (21) and (22) using linear wave theory as a first-order approximation. This is because linear theory does not give a satisfactory first approximation, since no matter how small the initial amplitude the long-term behaviour will be nonlinear in the absence of dissipation. It is therefore necessary to use a multiple-scale method where x , t and $X = Mx$ are considered to be independent variables and $\partial/\partial x \rightarrow \partial/\partial x + M\partial/\partial X$. This allows a good description of the wave up to distances $x = O(1/M)$. Following this approach and introducing $\tau = t - x/c_s$, equations (21) and (22) can be shown to satisfy Burgers' equation [28]

$$\frac{\partial u}{\partial x} - \frac{\epsilon}{c_s^2} u \frac{\partial u}{\partial \tau} = \frac{b}{2c_s^3} \frac{\partial^2 u}{\partial \tau^2}. \quad (23)$$

Finally, it is convenient to change to dimensionless variables $q = u/U$, $\sigma = \epsilon M k x$ and $\theta = \omega \tau$ where U , ω and k are the initial velocity, angular frequency and wavenumber of the source and M has been redefined here as $M = U/c_s$. In these coordinates Burgers' equation is

$$\frac{\partial q}{\partial \sigma} - q \frac{\partial q}{\partial \theta} = \kappa \frac{\partial^2 q}{\partial \theta^2} \quad (24)$$

where

$$\kappa = \frac{1}{2\epsilon} \frac{1}{Re} \frac{1}{M} \quad (25)$$

and Re is the acoustical Reynolds number given by

$$Re = \frac{c_s}{bk}. \quad (26)$$

The dimensionless propagation parameter, σ , describes the development of the shock wave for $0 \leq \sigma \leq 1$. The shock formation distance for a sinusoidal sound wave with amplitude unity is $\sigma = 1$. That is, $\sigma = 1$ determines the distance at which a sinusoidal wave in an inviscid fluid is transformed into a discontinuous wave of sawtooth shape. In a viscous fluid the wave is transformed into an almost sawtooth shape, however, the action of viscous damping prevents a total discontinuity forming. Note that the multiple-scale method used in the derivation of Burgers' equation is valid for distances up to $x = O(1/M)$, that is, distances of the order of the shock formation distance $\sigma = 1$.

3.1. Solution of Burgers' equation

Here we consider the solution of Burgers' equation for two cases: firstly, the analytic solution for the special case for an inviscid medium where $\kappa = 0$, and, secondly, the numerical solution of the full Burgers' equation.

3.1.1. Inviscid fluid. We wish to solve the inviscid Burgers' equation

$$\frac{\partial q}{\partial \sigma} - q \frac{\partial q}{\partial \theta} = 0 \quad (27)$$

for the initial condition

$$q(\sigma, \theta)|_{\sigma=0} = f(\theta). \quad (28)$$

Following Crighton *et al* [29] we consider a curve in the (σ, θ) -plane for which θ is some definite function of σ . On this curve we have

$$\frac{dq}{d\sigma} = \frac{\partial q}{\partial \sigma} + \left(\frac{d\theta}{d\sigma}\right) \frac{\partial q}{\partial \theta} = 0 \quad \text{if} \quad \frac{d\theta}{d\sigma} = -q. \quad (29)$$

Let Γ be one such curve where q is constant, then Γ is the straight line $\theta = -q\sigma + \phi$. The point where this line cuts the θ -axis occurs when $\sigma = 0$, which gives $\phi = \theta$ or

$$q = f(\phi) \quad (30)$$

where ϕ is defined through

$$\phi = \theta + q\sigma. \quad (31)$$

Now, equation (27) preserves the parity and periodicity of the initial function. Thus, if we now consider the special case of a sinusoidal source, $f(\theta) = \sin \theta$, the solution of equation (27) must have the form

$$q(\sigma, \theta) = \sum_{n=1}^{\infty} a_n(\sigma) \sin(n\theta) \quad (32)$$

where

$$a_n(\sigma) = \frac{2}{\pi} \int_0^{\pi} q(\sigma, \theta) \sin n\theta \, d\theta. \quad (33)$$

Substituting in equations (30) and (31) and changing the variable of integration from θ to ϕ , equation (33) can be expressed as

$$a_n(\sigma) = \frac{2}{n\sigma} J_n(n\sigma) \quad (34)$$

where J_n is the Bessel function of order n . This gives the Fubini–Ghiron solution for the development of a shock in an inviscid fluid

$$q = \sum_{n=1}^{\infty} \frac{2}{n\sigma} J_n(n\sigma) \sin(n\theta). \quad (35)$$

This solution holds for $0 \leq \sigma \leq 1$ since for $\sigma > 1$ the θ – ϕ relationship is not one-to-one and the change of integration variable is not possible.

3.1.2. Numerical solution. We now turn our attention to the numerical solution of equation (24) [31]. To do this we consider a travelling wave of the form

$$q = \sum_{n=1}^{\infty} a_n(\sigma) \sin n\theta. \quad (36)$$

Considering first the nonlinear term:

$$q \frac{\partial q}{\partial \theta} = \left[\sum_{n=1}^{\infty} a_n(\sigma) \sin n\theta \right] \left[\sum_{m=1}^{\infty} m b_m(\sigma) \cos m\theta \right]. \quad (37)$$

Collecting together terms with the same frequency this can be rewritten as

$$q \frac{\partial q}{\partial \theta} = \frac{1}{2} \sum_{m=1}^{\infty} \left[m \sin m\theta \left(\sum_{p=1}^{m-1} \frac{1}{2} (a_p a_{m-p}) - \sum_{p=m+1}^{\infty} a_{p-m} a_p \right) \right]. \quad (38)$$

Calculating the other derivatives the solution of Burgers' equation reduces to solving the following set of first-order partial differential equations:

$$\frac{\partial a_n}{\partial \sigma} = n \left(\sum_{p=1}^{n-1} \frac{1}{2} (a_p a_{n-p}) - \sum_{p=n+1}^{\infty} a_{p-n} a_p \right) - \kappa n^2 a_n \quad (39)$$

where $a_1|_{\sigma=0} = 1$ and $a_n|_{\sigma=0} = 0$ for $n \geq 2$. This can be solved by truncating the series to N harmonics and solving the N equations using a variable-order variable-step Adams method [32, 33]. The solutions presented here were truncated at $N = 20$, although only the first six harmonics are plotted.

4. Numerical simulations

The development of the shock wave was simulated using the lattice Boltzmann model described in section 2. This was done using a grid consisting of λ sites in the x -direction and m sites in the y -direction, where λ is the wavelength of the sound wave being simulated and m is an arbitrary number. Periodic boundary conditions were applied at each of the grid edges. Since plane waves are being simulated the value of the pressure and the velocity, and hence the distribution functions, f_i , are the same on each column (x constant) and so the value of m is totally arbitrary. Here $m = 4$ was used. A sinusoidal source was mimicked by initializing

the grid with a sinusoidal pressure (density) and velocity variation. That is, the velocity and density were specified according to

$$\rho = \rho_0 + a \sin\left(\frac{2\pi x}{\lambda}\right) \quad (40)$$

and

$$u = \frac{ac_s}{\rho_0} \sin\left(\frac{2\pi x}{\lambda}\right). \quad (41)$$

The initial values of f_i at $t = 0$ were then calculated by substituting these values into equation (5). The constant d_0 in equation (8) can, in general, be varied to change the ratio of the shear and bulk viscosities; here it was fixed at $d_0 = \frac{1}{2}$. The value of the amplitude parameter a in equations (40) and (41) and the ambient density ρ_0 determine the Mach number: $M = a/\rho_0$. Here we choose $a = 0.1$ and $\rho_0 = 10$ giving $M = 0.01$ which satisfies the lattice Boltzmann constraint that $M \ll 1$. It is usual to express the intensity of a sound wave in terms of the sound pressure level rather than the Mach number. Comparing the simulations to a sound wave in air at atmospheric pressure, $M = 0.01$ corresponds to a pressure variation of 1×10^3 Pa which gives a sound pressure level [20] of $20 \log(1 \times 10^3 / 2 \times 10^{-5}) = 154$ dB SPL. The simulation is then allowed to evolve and the density and velocity measured at position $x = \lambda/2$ giving a time series record of the wave. The lattice exhibits periodicity and hence all other positions, for a particular phase, are equivalent. This differs from a typical experimental set-up and the theory in section 3 where a source is positioned in a medium and measurements are made at different positions giving a spatial record of the sound wave. Complete information for a particular phase can be obtained by measurements at different distances from the source at a single arbitrary time. The constant dispersion relation of our simulation ensures complete spacetime ergodicity and these two situations become completely equivalent. That is to say, measurements at time t and $t + \delta t$ from our simulations can equally be thought of as measurements at positions x and $x + \delta x$ where $x = c_s t$ and $\delta x = c_s \delta t$.

The LBM described in section 2 has an equation of state $p = c_s^2 \rho$ which corresponds to a fluid with $\gamma = 1$, with no thermal energy dissipation. This arises from the term $\partial_\alpha (1 - d_0) \rho / 2$ in equation (13) being equated to the term $\partial_\alpha p$ in the Navier–Stokes equation, with $c_s = [(1 - d_0)/2]^{1/2}$. We note that a different choice for the equilibrium distribution function, equation (5), could change the equation of state of the simulated fluid [34]. The dissipative term b is now expressed as $b = \nu + \zeta$ (since we are considering two dimensions) and the constant $\epsilon = 1$. Thermal dissipation effects can, however, be simulated using an effective viscosity which incorporates both viscous and thermal losses. This was not done here.

5. Simulation results

A typical set of results is shown in figure 2 which shows the variation in the normalized pressure with time during the formation of the shock wave. Initially the variation is approximately sinusoidal, however, this can be seen to change as the wave evolves. This distortion of the initial sine wave can be seen more clearly in figure 3 which shows a stack profile representing the normalized pressure of the wave plotted against the wave phase at different times. The change in the form of the oscillation can be clearly seen in figure 3.

In order to compare these results with the theoretical analysis we need to look at the growth and decay of the fundamental and higher harmonics within the waves. This was done by dividing the results into segments with length $3T$ in such a way that segment l contains

Figure 2. The measured pressure variation as a function of time for the first 16 periods of oscillation. This corresponds to the development of the shock front.

Figure 3. A stacked profile of the pressure variation as a function of the wave phase at selected times during the development of the shock front. The distortion of the initial sinusoidal variation to the ‘N’-shaped shock wave is clearly visible.

Figure 4. A typical example of the Fourier transform of a three-wavelength segment of the signal at selected times during the evolution of the shock wave. (a) represents the initial segment at $x = 3\lambda/2$ and shows most of the wave energy concentrated in the fundamental harmonic with the amplitude of the second and third harmonic starting to increase. (b) and (c) show the spectrum at later times and show the increasing prominence of the higher harmonics and the decrease of the fundamental harmonic as σ increases.

$(l - 1)T + 1 < t < (l + 2)T$. Each of these segments was then Fourier transformed and the resulting spectrum considered to represent the wave at $x = (l + \frac{1}{2})\lambda$. Typical results of such a procedure are shown in figure 4 which shows the change in the spectrum at selected distances from the source. As expected the amplitude of the higher harmonics is seen to increase with propagation distance, this is due to energy being transferred to these harmonics from the fundamental harmonic which is seen to decrease in amplitude. The change in the magnitude of each frequency component was extracted from the Fourier transform for waves with three different Reynolds numbers, $Re \simeq 1600, 1100$ and 160 . This was achieved using a fixed wavelength $\lambda = 500$ and varying the fluid viscosity using $\tau = 0.55, 0.57$ and 0.95 , respectively. In each case the Mach number was fixed at $M = 0.01$. These are shown in figure 5 for the first six harmonics along with the numerical solution of Burgers’ equation and the inviscid Fubini–Ghiron solution for comparison. In general, the simulation results show excellent agreement with the numerical solution of Burgers’ equation. There are, however, some regions where there is a small deviation. One source of error in the analysis is that we

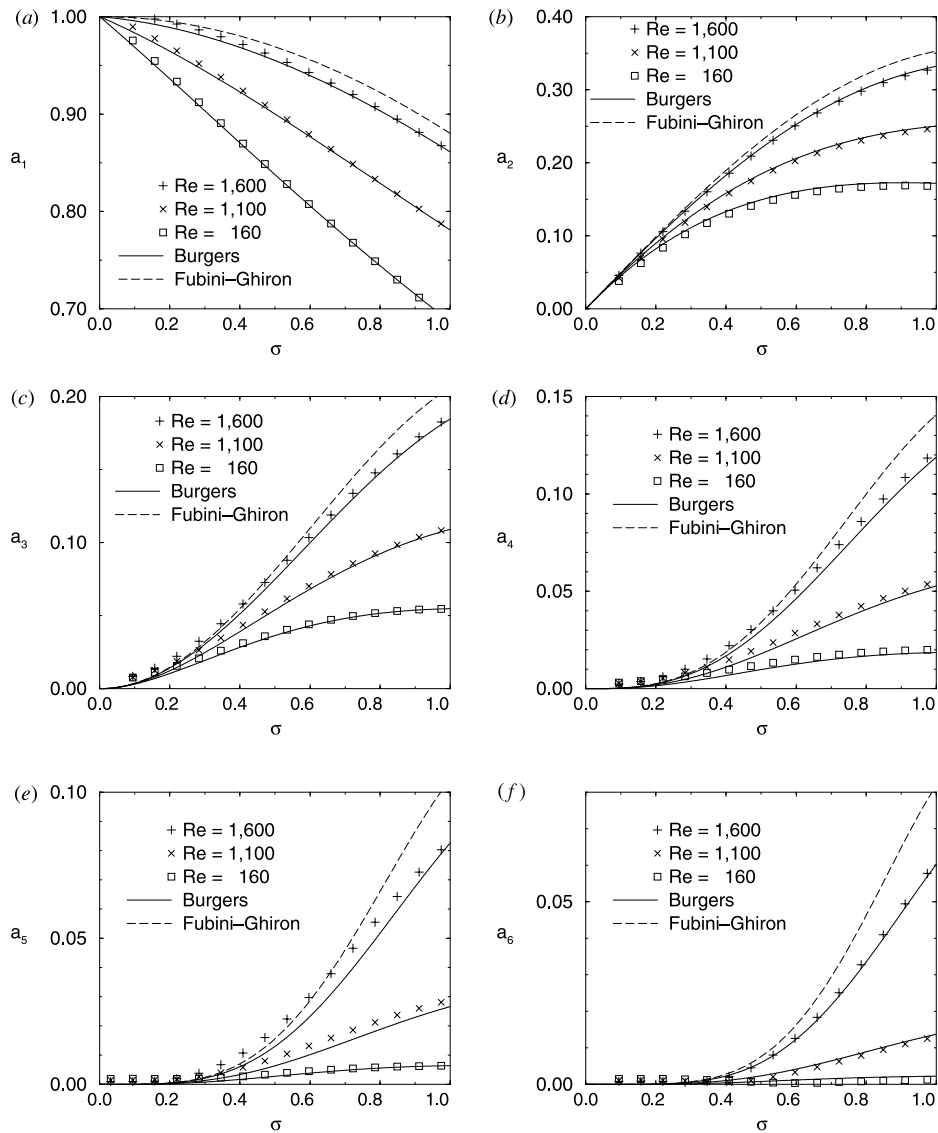

Figure 5. The variation in the relative amplitude of the first six harmonics for an initially sinusoidal nonlinear wave during the development of the shock front for three different Reynolds numbers, the Mach number is $M = 0.01$. In each case the numerical solution of Burgers' equation (24) is represented by a full curve. Also shown for comparison is the Fubini-Ghiron solution, equation (35), for each of the harmonics. (a) First harmonic; (b) second harmonic; (c) third harmonic; (d) fourth harmonic; (e) fifth harmonic and (f) sixth harmonic.

are performing the Fourier transform over three wavelengths during which there is a change in the amplitudes of the harmonics, both due to energy transfer between the harmonics and due to viscous damping. Therefore, the Fourier transform will not only contain peaks at the frequency of the harmonics, but also contributions due to the change in these amplitudes over the sample. This can be seen in figures 4(a) and (b) where the values between $n = 1$ and 2 and between $n = 2$ and 3 are not zero. These figures represent the early stages in the development of the

shock wave where there is the largest change in the amplitude of the harmonics. At later times, see figure 4(c), the change in the harmonic amplitudes is smaller and so is the value of the Fourier transform between the harmonics. In general, these additional contributions are small and, combined with numerical error, account for the small deviations observed, particularly when the harmonic amplitude is small; see, for example, figures 5(d)–(f) at small σ . As expected the results approach the inviscid Fubini–Ghiron solution as the Reynolds number increases.

6. Conclusion

The use of a BGK lattice Boltzmann model for simulating nonlinear propagative acoustic waves has been considered. It has been seen that a range of problems in nonlinear acoustics are within the dynamic range of the lattice Boltzmann model and the application of the technique has been demonstrated. This was done by simulating the development of a shock front from an initially sinusoidal nonlinear wave. The results of the simulation agreed well with theory, suggesting that the lattice Boltzmann model is indeed a useful approach to simulating nonlinear acoustical phenomena.

The simulations presented here have been limited to considering progressive waves in an unbound media. This is not a fundamental restriction of the technique which should be equally applicable to studying standing waves and propagation in a pipe where the action of the walls significantly influences the acoustics; indeed, the ability of the LBM to model complex boundary situations is well established. An investigation of this and the steady-state acoustic streaming flows set-up by the attenuation of a sound field in the boundary layer is currently in progress.
