Abstract
Semigroups describing the time evolution of open quantum systems in finite-dimensional spaces have generators of a special form, known as Lindblad generators. The simple generators, characterized by only one operator, are analyzed. The complete set of all the stationary states is presented in detail, including a formula to calculate a stationary state from the generating operator. Also the opposite task can be fulfilled, to construct an evolution leading to a prescribed stationary state.

1. Introduction

Complete positivity is an essential property of maps acting on states of open quantum systems, representing their change in time. It was in the 1970s, starting with [K71], when this has been discovered. In the following, the generators of semigroups formed by maps with this property have been identified for finite-dimensional systems, and also for infinite systems, provided a strong continuity property is assumed in addition to complete positivity, [GKS76, L76]; they are now known as 'Lindblad generators'. The interest at that time has been mainly in connection with non-equilibrium thermodynamics, see [D76, S80, AF01, BP02] and references therein.

New interest has arisen recently in connection with quantum engineering of small systems, and it seems necessary to enlarge our knowledge about such semigroups. So we proceed in the analysis of these completely positive semigroups, acting on states for systems with *finite-dimensional* Hilbert spaces. We are interested in characterizing both the set of invariant states and the paths of changing states. The early results on invariance stated in [S76, F78, S80] concern systems under special conditions on the set of generators. We give more general detailed insight, not needing these restricting conditions. Pioneering work has been done by K Dietz [D03, D04, D05], identifying 'superselection sectors', discussing the change in time

of entropy and presenting a formula which relates a stationary state to the operator which appears in a simple generator. In the present paper, his findings are imbedded into a complete mathematical characterization. In addition we shed some light on the approach to equilibrium, on the geometry of the paths in the set of states.

There are three types of physical processes one wants to describe: decay, dissipation and decoherence. Decay of excited states leads—in an idealized model—to a complete annihilation of some subspaces of the Hilbert space. Dissipation, on the other hand, leads to a spreading of the state over a large space, getting more mixed, in case it started as a pure state. It is somehow the counterpart to decay and also to conservation laws. In reality and also in our studies both of these effects occur simultaneously, and conservation laws may impose some structuring. Decoherence in a wide sense is dephasing; in a preferred basis the off-diagonal elements of the density matrix are diminishing and finally vanishing. Each type of these processes has its mathematical expression in properties of the quantum-dynamical semigroup's generator.

In this paper, we concentrate on simple generators, the building blocks for generators of general completely positive semigroups—a characterization of complete positivity is presented in the appendix. For two-dimensional systems, a.k.a. qubits, we present a detailed description. In a companion paper, we extend our interest to the general quantum-dynamical semigroups on finite-dimensional Hilbert spaces.

Our starting point, the connection with the earlier studies, is the result of [GKS76, L76].

Proposition 1 (generators of semigroups). *Every generator of a semigroup of completely positive trace preserving maps $\mathcal{T}^t : \rho(s) \mapsto \rho(s+t)$ for $t \geqslant 0$ on the set of finite-dimensional density matrices ρ can be written in the form*

$$\dot{\rho} = \mathcal{D}(\rho) = -\mathrm{i}[H, \rho] + \sum_\alpha \mathcal{D}_{h^\alpha}(\rho), \qquad where \quad H = H^\dagger, \tag{1}$$

where the dissipative parts, the $\mathcal{D}_{h^\alpha}$, are as follows.

Definition 2 (simple generators).

$$\mathcal{D}_h(\rho) = h\rho h^\dagger - \tfrac{1}{2}(h^\dagger h\rho + \rho h^\dagger h). \tag{2}$$

The commutator with a Hamiltonian alone generates a unitary time evolution, which is well known in principle. We concentrate on the other building blocks, the simple generators $\mathcal{D}_h$ and the evolutions they generate.

It is well known that the division of $\mathcal{D}$ into a sum of several simple generators is not unique. Different sets of operators h^α can be attributed to a given generator $\mathcal{D}$. The attribution of a single h to a simple generator on the other hand is mostly unique, with few exceptions. The method of proof for this statement uses a structuring of the Hilbert space and of the operator h, which reflects some characteristic properties of the simple $\mathcal{D}$. These methods are presented in section 3.1, At the end of the same section the mentioned uniqueness is stated in lemma 7 and then proved.

Our analysis starts with studying the decompositions of h, and their relations to the action of the generator. It turns out that the time evolution of ρ in the convex set **S** of density matrices can be analyzed by studying the action of $\mathcal{D}$ on the boundary of **S**, which is the set of density matrices with rank less than the dimension of the Hilbert space. The structure of the operator h and the corresponding structuring of the Hilbert space are here of prime importance. Only a density matrix the support of which is an eigenspace of h does not dissipate in first order of t into higher dimensional subspaces. Therefore, we call these faces of **S** which are formed by ρ with support being an eigenspace or a generalized eigenspace of h the 'lazy faces'. An even stronger condition marks certain eigenspaces and the corresponding faces as enclosures. No

path $\rho(t)$ leads into or out of them, some conservation laws are valid. A closer look on the action of $\mathcal{D}_h$ on density matrices in special faces lets us determine precisely the complete set of stable, 'stationary', states. These results are presented in theorem 15. A note on naming: in the literature the characterization of a state as 'invariant', 'stable' or 'stationary' is used, each one meaning $\dot{\rho} = 0$. In this paper, we favor 'stationary', and we are sloppy in not differentiating 'state' and 'density matrix'.

Further analysis, making a detour using the dual time evolution of the operators and the Kadison inequality, leads to the insight that there are no periodic evolutions, no circular paths for the $\rho(t)$. All paths in the space **S** lead to the stationary states. The entropy of the states along a path may increase or decrease and may even pass through several local maxima and minima.

Some examples, most of them with qubits, demonstrate the findings of our analysis.

At various places, we have to do calculations concerning a splitting of the Hilbert space into two orthogonal subspaces. The elaborated formulas are collected in appendix A.2.

2. The set of generators

2.1. Basic properties of the generator's actions

By inspection of definition 2, it is obvious that the semigroups generated by the superoperators $\mathcal{D}_h$ preserve the trace and selfadjointness of matrices:

$$\frac{\mathrm{d}}{\mathrm{d}t}\mathrm{Tr}\rho(t) = \mathrm{Tr}[\mathcal{D}(\rho(t))] = 0, \qquad \frac{\mathrm{d}}{\mathrm{d}t}\sigma^\dagger(t) = \mathcal{D}(\sigma^\dagger(t)) = [\mathcal{D}(\sigma(t))]^\dagger. \tag{3}$$

To see that they also preserve positivity, we look at the parts of the simple $\mathcal{D}_h$ separately. The first part, mapping a positive ρ to a non-negative operator $h\rho h^\dagger$, causes an increase of ρ. The second part causes a decrease of the eigenvalues. The argument goes as in proving the Feynman–Hellmann theorem and provides the following proposition.

Proposition 3 (a differential inequality). *If $r(t)$ is a non-negative eigenvalue of $\rho(t)$, its change in time is bounded from below as*

$$\dot{r}(t) \geqslant -\|h\|^2 r(t). \tag{4}$$

Proof. Differentiating the eigenvalue equation $\rho(t)\psi(t) = r(t)\psi(t)$,—Rellich's theorem guarantees that all terms are analytic functions—and using $\langle\psi|\dot\psi\rangle = 0$ gives

$$\begin{aligned}
\dot{r}(t) = \langle\psi|\dot\rho|\psi\rangle &= \langle\psi|\left(h\rho h^\dagger - \tfrac{1}{2}(h^\dagger h\rho + \rho h^\dagger h)\right)|\psi\rangle \\
&\geqslant -\tfrac{1}{2}\langle\psi|(h^\dagger h\rho + \rho h^\dagger h)|\psi\rangle \\
&= -\langle\psi|h^\dagger h|\psi\rangle r(t).
\end{aligned} \tag{5}$$

$\square$

This implies that the positive eigenvalues r_j of the density operator obey in the course of time the inequality

$$r_j(t) \geqslant \exp(-\|h\|^2 t) \cdot r_j(0) > 0, \tag{6}$$

and positive eigenvalues stay positive. By continuity of the time evolution, zero eigenvalues cannot get negative, the positivity of density matrices is preserved.

So the evolutions do not leave **S**. Moreover, there exist stationary states, i.e. states which do not change in the course of time.

Proposition 4 (existence of stationary states)**.** *For each simple generator $\mathcal{D}_h$ there exists a stationary state ρ_∞ satisfying $\mathcal{D}_h(\rho_\infty) = 0$. If h has zero as an eigenvector, each state with support in the zero subspace is stationary. If h does not have zero as an eigenvalue, one may construct a stationary state by*

$$\rho_\infty = (h^\dagger h)^{-1}/\mathrm{Tr}[(h^\dagger h)^{-1}]. \tag{7}$$

Proof. If $\rho = \sum_j r_j|\phi_j\rangle\langle\phi_j|$ where $h|\phi_j\rangle = 0$, obviously $h\rho = 0, \rho h^\dagger = 0$ and therefore $\mathcal{D}_h(\rho) = 0$ hold. For h without zero as an eigenvector, consider the polar decomposition $h = U|h|$, where $|h| = \sqrt{h^\dagger h}$ and $U = h|h|^{-1}$. The evolution equation for $\rho_\infty = |h|^{-2}/\mathrm{Tr}[|h|^{-2}]$ is

$$\dot{\rho}_\infty = U|h|\rho_\infty|h|U^\dagger - \tfrac{1}{2}(|h|^2\rho_\infty + \rho_\infty|h|^2) = (U \cdot U^\dagger - \mathbb{1})/\mathrm{Tr}[|h|^{-2}] = 0. \qquad \square$$

This relation between h and ρ_∞ has already been given in [D03]. The questions of uniqueness and of attraction to paths of other states are answered in theorems 15 and 17.

2.2. Superoperators

In the following, it will be useful to endow the linear space of matrices with an inner product $\langle\sigma|\rho\rangle = \mathrm{Tr}\sigma^\dagger\rho$, and consider matrices as elements of this space, the *Hilbert–Schmidt, HS space*. In the middle of the set of density matrices **S** is the maximally mixed state $\omega = \mathbb{1}/\dim(\mathcal{H})$. The square distance $\|\rho - \omega\|^2$ is related to the 'Fermi entropy' $\mathrm{Tr}\rho(\mathbb{1} - \rho)$, on which we make some remarks in subsection 4.3.

Consider a generator $\mathcal{D}$ as a superoperator acting on the HS space. In this respect the semigroup which it generates can be extended to a group. For negative t the trace and selfadjointness of matrices are still preserved, but not the positivity.

The *adjoint $\mathcal{D}^\dagger$* can be looked upon as generator of the *dual time evolution* of observables in the *Heisenberg picture*.

$$\mathcal{D}_h^\dagger(f) = h^\dagger f h - \tfrac{1}{2}(h^\dagger h f + f h^\dagger h). \tag{8}$$

Preservation of the trace of density operators corresponds to preservation of the unity under the dual time evolution of observables, the semigroup generated by $\mathcal{D}^\dagger$ is 'unital'. (That both $\mathcal{D}$ and $\mathcal{D}^\dagger$ are unital and trace preserving occurs, if h is a normal operator.)

Diagonalizability of $\mathcal{D}$ is rather exceptional. Nevertheless there exists for each $\mathcal{D}$ its set of eigenvalues $\{\lambda\}$, equal to the set of zeros of the characteristic polynomial $\det(\mathcal{D} - \lambda\mathbb{1})$, a set of proper eigenmatrices $\{\sigma\}$, obeying $\mathcal{D}\sigma = \lambda\sigma$, and, in some cases of degeneracy, generalized eigenmatrices, obeying $(\mathcal{D} - \lambda)^n\sigma = 0$. As in any set of linear differential equations, any $\rho(t)$ can be expanded into a sum of such $\sigma \cdot e^{\lambda t} \cdot \mathrm{Polynomial}(t)$. Some general properties of eigenvalues and eigenmatrices are presented in subsection 3.4. Examples and special cases will be presented for two-dimensional systems in subsection 4.2.

The generators $\mathcal{D}$, defined in proposition 1, with $H = 0$ form a convex cone. The simple generators make the extremal rays. Nevertheless closure adds the generators of unitary groups.

Proposition 5. *Generators of unitary time evolution can arise as limit of simple Lindbladian generators.*

Proof. Define $h(\lambda) := 2\lambda^{-1}\mathbb{1} - \mathrm{i}\lambda H$ where $H^\dagger = H$. Consider the limit $\lambda \to 0$:

$$\mathcal{D}_{h(\lambda)}(\rho) = -\mathrm{i}[H, \rho] + \lambda^2\mathcal{D}_H(\rho) \quad \to \quad -\mathrm{i}[H, \rho]. \tag{9}$$

$$\square$$

Note that the norm of $h(\lambda)$ diverges, but $\mathcal{D}_{h(\lambda)}$ converges in norm. So it is to be expected that a thorough inspection of the extremal rays, containing the building blocks, the simple generators, will give a good basis for the analysis of all GKS-Lindblad generators.

3. Simple generators

3.1. Splitting, decomposition, structure

We consider the generators $\mathcal{D} = \mathcal{D}_h$, defined in definition 2. To analyze their properties it is convenient to find structures on two levels. The structure in the large concerns a kind of enclosure: subspaces of $\mathcal{H}$ with the property that the system can neither leave nor enter any of them in the course of time. (These subspaces are related to the superselection sectors in [D04].) P is a projector onto such a subspace if and only if it obeys

$$[P, h] = 0. \tag{10}$$

Each operator h appearing in a generator $\mathcal{D}_h$ can be decomposed as

$$h = \bigoplus_j h_j \tag{11}$$

with a decomposition of the Hilbert space $\mathcal{H} = \bigoplus_j \mathcal{H}_j$ into mutually orthogonal subspaces $\mathcal{H}_j = P_j \mathcal{H}$, where each h_j acts on $\mathcal{H}_j$ and is not further decomposable.

Aim and purpose of this decomposition in the large is to reduce the analysis of the superoperator's action on any ρ to the analysis to the split action on the blocks $P_j \rho P_j$ and $P_j \rho P_\ell$. It is

$$\mathcal{D}_h(P_j \rho P_j) = h_j \rho h_j^\dagger - \tfrac{1}{2}\big[h_j^\dagger h_j \rho - \rho h_j^\dagger h_j\big] = \mathcal{D}_{h_j}(P_j \rho P_j), \tag{12}$$

for the diagonal blocks in the decomposition of ρ into block matrices $P_j \rho P_\ell$. The off-diagonal blocks give the phase relations between the enclosure-like subspaces.

$$\mathcal{D}_h(P_j \rho P_\ell) = h_j \rho h_\ell^\dagger - \tfrac{1}{2}\big[h_j^\dagger h_j \rho - \rho h_\ell^\dagger h_\ell\big]. \tag{13}$$

In the case of an appearance of equivalent parts h_j there is the possibility of *unitary reshuffling* the corresponding subspaces: Collect the set of equivalent parts as $h_1, \ldots, h_N$, i.e.

$$\forall \{j, \ell\} \subset \{1, \ldots, N\} \quad \exists \text{ unitary} \quad U_{j\ell} : h_j = U_{j\ell} h_\ell U_{j\ell}^\dagger.$$

Represent their sum $h_1 \oplus \cdots \oplus h_N$ as a tensor product $\mathbb{1}_N \otimes h_1$ acting in $\mathbb{C}^N \otimes \mathcal{H}_1$. The action of a unitary operator $V \oplus \mathbb{1}$ in this tensorial representation gives a unitary reshuffling of eigenspaces $\mathcal{H}_j$.

Proposition 6 (splitting of operators and of spaces)**.** *The splitting $h = \bigoplus_j h_j$ with a set of orthogonal projectors P_j which commute with h is unique, except for a unitary reshuffling of eigenspaces $\mathcal{H}_j = P_j \mathcal{H}$ on which equivalent parts h_j are acting.*

The action of the generator splits as

$$\mathcal{D}_h(P_j \rho P_\ell) = P_j \mathcal{D}_h(\rho) P_\ell. \tag{14}$$

Proof. By induction, one may find a maximal set of mutually commuting orthogonal projectors P_j, all commuting with h: if there exists one P commuting with h, one may start with the set $\{P, \mathbb{1} - P\}$. Then one searches for a further splitting $P = P_2 + P_3$, P_j commuting with h. If such a further splitting exists, one replaces P by P_2 and P_3. The same for $\mathbb{1} - P$, and then further splittings of P_j, and so on. At the end of this procedure, one has the splitting $\mathcal{H} = \bigoplus_j P_j \mathcal{H}$, and $h = \bigoplus_j P_j h P_j$, which cannot further be refined.

Now collect piecewise all the mutually equivalent parts $h_{j_1}, \ldots, h_{j_{n(j)}}$ as $\mathbb{1}_{n(j)} \otimes h_{j_1}$ acting in $\mathbb{C}^{n(j)} \otimes \mathcal{H}_{j_1}$. All the possible families $\{P_j\}$ of projectors can be observed in this way: the operator h commutes with each projector onto $\mathcal{V} \otimes \mathcal{H}_{j_1}$, where $\mathcal{V}$ is any subspace of $\mathbb{C}^{n(j)}$, and h commutes with no other projector.

The split action of the parts on diagonal and off-diagonal blocks of ρ, stated in equations (12) and (13), is obvious. □

This decomposition is an important step in the analysis of the time evolution. An algebraist's point of view is that the projectors commuting with h create a subalgebra of conserved observables, $\mathcal{D}^{\dagger}(P_j) = 0$. The law of conservation implies that the probability for the system to remain in an enclosing subspace $P_j \mathcal{H}$ is constant in time. The evolution inside the subspace is determined by the action of $\mathcal{D}_{h_j}$. Studying the total action of D_h consists of determining the action of single $\mathcal{D}_{h_j}$ with indecomposable h_j, and studying the evolution of the phase relations between different subspaces $\mathcal{H}_j$. The indecomposable parts acting on diagonal blocks of ρ are studied in sections 3.2 and 3.3, The evolution of the phase relations, represented in the off-diagonal blocks $P_j \rho P_\ell$, is discussed in sections 3.3 and 4.1.

The *structure on the second level* is related to representations of an indecomposable h—which may enter in the large as an indecomposable part h_j—in a *Schur triangulated form*, as an upper triangular matrix, see e.g. [L69]: on the diagonal are the eigenvalues in arbitrary sequence, below the diagonal there are only zeros. An indecomposable h of dimension greater than 1 is not diagonalizable, one has to be aware of the generalized concepts: the eigenspaces and generalized eigenspaces are subspaces $P\mathcal{H}$ with projectors P, with the characterizing property

$$hP = PhP. \tag{15}$$

These P are orthogonal projectors, $P = P^2$; each one-dimensional P projects onto a proper eigenvector. These eigenvectors are in general not mutually orthogonal. The eigenspaces and generalized eigenspaces are spanned by the proper and the generalized eigenvectors, $\psi_{\lambda,j,0}$ and $\psi_{\lambda,j,m}$, of h:

$$(h - \lambda)\psi_{\lambda,j,0} = 0, \qquad (h - \lambda)\psi_{\lambda,j,m} = \psi_{\lambda,j,m-1}.$$

Note that a generalized eigenspace containing $\psi_{\lambda,j,m}$ has to contain also all the $\psi_{\lambda,j,\mu}$ with $\mu < m$.

To be sure about the relevance of the properties of h for the action of $\mathcal{D}_h$ it is helpful to study the uniqueness of attributing h to a given simple generator. Already here the method of Schur triangulation appears as an important tool.

Lemma 7. *If it is possible to write a generator D as a simple $\mathcal{D}_h$, the attribution of h is unique up to a phase factor, unless h is a 'normal', i.e. diagonalizable, operator.*

Proof. The strategy of the proof is to consider the equations $\dot{\rho} = \mathcal{D}_h(\rho)$ for the given h, with a set of properly chosen matrices ρ as determining the operator k which shall give the same $\dot{\rho}$, by $\dot{\rho} = \mathcal{D}_k(\rho)$. The condition of non-diagonalizability of the given h can hold only for $n = \dim(\mathcal{H}) \geqslant 2$. The proper choice of ρ requires a proper choice of the basis vectors, giving a triangular matrix representation of h and enabling a proof by induction on the rank of ρ. If the given h has a generalized eigenvector $\psi_{\lambda,1}$, choose the basis for its decomposition and its Schur triangulation in such a way that $\psi_{\lambda,0}$ is the first basis vector and $\psi_{\lambda,1}$ is the second one. If h has only proper eigenvectors, then, because of its non-diagonalizability, there must be a non-orthogonal pair of them, $\psi_{\lambda,0}$ and $\psi_{\mu,0}$. Choose this pair to form the first two basis vectors: $\psi_{\lambda,0}$ and the normalized $\psi_{\mu,0} - \gamma \psi_{\lambda,0}$, where $\gamma = \langle \psi_{\lambda,0} | \psi_{\mu,0} \rangle$. Then we proceed by

induction on the dimension of the space and use the chosen basis. We refer to the formulas presented in appendix A.2.

For dimension 2, the action of $\mathcal{D}$ on the matrix $\rho = \begin{pmatrix} r & q \\ q^\dagger & s \end{pmatrix}$ with $q = 0$ and $s = 0$ determines $c = 0$ for the matrix $k = \begin{pmatrix} a & b \\ c & d \end{pmatrix}$. The action on ρ with $r = q = 0$ determines first $|b|$, which is not zero, due to the proper choice of the basis vectors. Then via $\dot{q} = a^\dagger b r$ it determines $a^\dagger b$. Finally, acting on ρ with $r = q = 0$, by $\dot{q} = \left(bd^\dagger - \frac{1}{2} a^\dagger b \right) s$ it determines $bd^\dagger$. So the matrix k is determined up to a phase as $k = h$.

For higher dimensions use the block matrix form, as in appendix A.2, with $\text{rank}(A) = \text{rank}(R) = n - 1$, where $S = s$ and $D = d$ are numbers, $B = |b\rangle$ and $Q = |q\rangle$ are vectors. The action on a ρ with $|q\rangle = 0$ and $s = 0$ is $\dot{R} = \mathcal{D}_A(R)$ and—there is the induction hypothesis—this determines A up to a phase. Note that $\dot{R} \neq 0$, so $A \neq a\mathbb{1}$. The action on this ρ is also $\dot{s} = 0$, determining $C = 0$ and $|\dot{q}\rangle = RA^\dagger|b\rangle$. Choosing a phase for A, the action on ρ with $R = 0$, $|q\rangle = 0$ determines $|b\rangle$ via $\dot{R} = |b\rangle s \langle b|$ and via $|\dot{q}\rangle$ from before; and it determines d via $|\dot{q}\rangle = s(d^\dagger|b\rangle - \frac{1}{2} A^\dagger|b\rangle)$ in case $|b\rangle \neq 0$. If $|b\rangle = 0$, consider the action on a ρ with $|q\rangle \neq 0$: $|\dot{q}\rangle = d^\dagger A|q\rangle - \frac{1}{2}[A^\dagger A + |d|^2]|q\rangle$. This is a quadratic equation for the number d, but there are at least two different equations for the components of $|q\rangle$ to determine d. So the proof of uniqueness is completed for nondiagonalizable h. $\square$

If h is a diagonal operator, all the matrix elements of ρ evolve in time independently of each other,

$$\dot{\rho}_{i,j} = \left[h_i h_j^\dagger - \frac{1}{2}(|h_i|^2 + |h_j|^2) \right]\rho_{i,j},$$

the diagonal of ρ is invariant in time. Only diagonal k in $\mathcal{D}_k$ can give the same evolution. But there are not always enough equations to determine the matrix elements on the diagonal of k. There remains some freedom in choosing k with $|k_i - k_j| = |h_i - h_j|$ and $\text{Im}\left(k_i k_j^\dagger\right) = \text{Im}\left(h_i h_j^\dagger\right)$ in special cases, e.g. if there are not more than two different values of h_j, or if all h_j are real. But the qualitative structure of possible k is fixed: it is determined that it is a diagonal operator in the same basis, with the same degeneracies.

3.2. At the boundary of the set of states

It turns out that the time evolution of ρ in the set **S** can be analyzed by studying the action of $\mathcal{D}$ on the boundary, the set of density matrices with rank less than the dimension of the Hilbert space. Referring to inequality (6), we note that it implies one of the central observations:

Lemma 8 (no purifying in finite time). *The rank of $\rho(t)$ cannot decrease.*

An observation of almost sure increase of the rank serves as a companion to this exclusion of a decrease.

Lemma 9. *Consider $\rho(t)$ with $\text{rank}(\rho(0)) < \dim(\mathcal{H})$. At least one eigenvalue which is zero for $\rho(0)$ becomes strictly positive in first order in t, if and only if the range of $\rho(0)$ is not an eigenspace or a generalized eigenspace of h.*

Proof. Consider the analytic expansion of $\rho(t)$ and its eigenvalues $r(t)$, using the eigenvectors related to them, and consider the terms linear in t.

$$\dot{r}(0) = \langle\psi|\dot{\rho}(0)|\psi\rangle.$$

Write h in Schur triangulated form, such that the upper left part R (we use here the notation of appendix A.2) acts as a matrix of full rank in the range of $\rho(0)$. Use the block matrix

equation (A.9), with R the restriction of ρ to its range, ϕ an eigenvector to the eigenvalue zero, so it is not in the range of R and

$$\dot{r}(0) = \langle\phi|\dot{S}(0)|\phi\rangle = \langle\phi|CRC^{\dagger}|\phi\rangle. \tag{16}$$

Observe that, according to (15), the range of $\rho(0)$ is a (generalized) eigenspace, iff $C = 0$. Since R is of full rank there is at least one ϕ giving a strict increase $\dot{r} > 0$, iff $C \neq 0$. $\qquad\square$

Note the *correspondence* between *subspaces* of the Hilbert space $\mathcal{H}$ and *faces* of the set of states **S**: each face consists of density matrices whose range is some subspace of $\mathcal{H}$. Since all subspaces of $\mathcal{H}$ cannot be eigenspaces of a non-constant operator, the corresponding faces form a zero-set in the boundary of the set of states. Here comes the structure of the operator h into play.

Definition 10. *We define each face which corresponds to an eigenspace or a generalized eigenspace of h as a* lazy face. *In a formal notation: if P is the projector onto the range of ρ, and if P fulfils property (15) i.e. $hP = PhP$, then, and only then, ρ is in a lazy face.*

The reason for this definition is lemma 9, and its strengthening in lemma 11. Eigenvalues $r(t)$ which are zero for $t = 0$ do not increase in first, not even in second order in t if $\rho(0)$ is in a lazy face. They may increase in third or a higher order, or not at all. Examples will be presented in subsection 4.2.

Lemma 11. *Consider $\rho(t)$ with $\rho(0)$ in a lazy face. Each eigenvalue $r(t)$ beginning as $r(0) = 0$ does not increase in first and not in second order in t.*

Proof. The eigenvalue equation $\rho(t)\psi(t) = r(t)\psi(t)$ has to hold in each order of t. Consider the splitting $\psi = \chi \oplus \phi$, with $\chi(0) = 0$, the block matrix form presented in appendix A.2, with $C = 0$, $Q(0) = 0$, $S(0) = 0$, and the Taylor expansions. For the blocks of ρ we need

$$R(t) = R + O(t), \quad Q(t) = -\tfrac{1}{2}RA^{\dagger}Bt + O(t^2), \quad S(t) = \tfrac{1}{2}B^{\dagger}ARA^{\dagger}Bt^2 + O(t^3). \tag{17}$$

The first order of the eigenvalue equation, $\dot{\rho}(0)\psi(0) + \rho(0)\dot{\psi}(0) = \dot{r}(0)\psi(0)$, gives two equations, one for the vector component orthogonal in the range of $\rho(0)$,

$$-\tfrac{1}{2}B^{\dagger}AR\chi(0) = \dot{r}(0)\phi(0) \quad \Rightarrow \quad \dot{r}(0) = 0,$$

and one for the component in the range of $\rho(0)$

$$-\tfrac{1}{2}RA^{\dagger}B\phi(0) + R\dot{\chi}(0) = 0 \quad \Rightarrow \quad \dot{\chi}(0) = \tfrac{1}{2}A^{\dagger}B\phi(0).$$

The last implication uses the invertibility of R, due to its full rank. From the second-order equation we need only the part in the subspace orthogonal to the range of $\rho(0)$: $\tfrac{1}{2}\ddot{\rho}(0)\psi(0) + \dot{\rho}(0)\dot{\psi}(0) + \tfrac{1}{2}\rho(0)\ddot{\psi}(0) = \tfrac{1}{2}\ddot{r}(0)\psi(0)$ gives

$$\tfrac{1}{4}B^{\dagger}ARA^{\dagger}B\phi(0) - \tfrac{1}{2}B^{\dagger}AR\dot{\chi}(0) + 0 = \tfrac{1}{2}\ddot{r}(0)\phi(0) \quad \Rightarrow \quad \ddot{r}(0) = 0,$$

since the terms on the left-hand side cancel when the identity for $\dot{\chi}(0)$ is used. $\qquad\square$

There is a way to geometrically characterize the action of $\mathcal{D}$ on the states in a face. Define the mid-point ω_f of the face as

$$\omega_f = \frac{1}{n}\sum_j |\phi_j\rangle\langle\phi_j|,$$

where ϕ_j form a basis of the n-dimensional subspace corresponding to the face. Consider the projection of the path $\rho(t)$ in the Euclidean space of Hermitian matrices onto the line which

connects ω_f with the maximally mixed state ω in the center of **S**. This projection gives a special coordinate for the HS vector pointing from ω_f to $\rho(t)$:

$$\mathrm{Tr}[(\rho(t) - \omega_f)(\omega - \omega_f)] = \frac{1}{n}\mathrm{Tr}[S(t)]. \tag{18}$$

Only for lazy faces does this coordinate not grow linearly in *t*. It grows quadratically in *t*, see (17), so this geometrical characterization is not as strong as the statements on the eigenvalues made in lemma 11.

In the next section, we explain in detail how an appearance of zero as an eigenvalue for *h* has consequences in the investigations on the set of invariant states. They can be elements of the corresponding lazy face. Concerning the dimension of such a face we state as a remark the following lemma.

Lemma 12. *An indecomposable operator h of rank n cannot have more than n/2 proper eigenvectors to a degenerate eigenvalue.*

Proof. Write *h* in a triangulated form and use *m* proper eigenvectors to the degenerate eigenvalue λ as the first *m* basisvectors.

$$h = \begin{pmatrix} A & B \\ 0 & D \end{pmatrix},$$

where $A = \lambda \mathbb{1}_m$. The rectangular matrix *B* cannot have more rows than columns, i.e. $m \leqslant n - m$; otherwise, the rows could not be linearly independent and there would be a unitary transformation of the *m*-dimensional proper eigenspace such that $m - (n - m)$ rows of the transformed *B* would be zero, contradicting the undecomposability of *h*. $\qquad \square$

3.3. Stationary states

The upshot of the investigations on the action of $\mathcal{D}_h$ at the border is the following two complementary propositions.

Proposition 13 (quitting the boundary). *$\mathcal{D}_h$ has no stationary state at the boundary if h is indecomposable and does not have zero as an eigenvalue.*

Proof. Consider ρ at the boundary, write it as a block matrix (notation as in appendix A.2 with *R* a matrix of full rank, i.e. *R* has no zero-eigenvalues, $Q = 0$ and $S = 0$. If $C \neq 0$, use equation (A.9), which implies $\dot{S} \neq 0$. Otherwise, apply equation (A.11): $\dot{Q} = RA^\dagger B \neq 0$, since neither *R* nor $A^\dagger$ have zero eigenvalues and $B \neq 0$ because of the non-splitting property of *h*. $\qquad \square$

But otherwise, one of the lazy faces may be an *attractive face*.

Proposition 14 (eigenvalues zero are attractive). *If h is indecomposable and has zero as an eigenvalue, then the proper eigenspace to this eigenvalue zero corresponds to a face with stationary states. This face is an attractor, and no other state is stationary.*

Proof. If ρ is in this face, obviously $h\rho = 0$, $\rho h^\dagger = 0$ and therefore $\mathcal{D}_h(\rho) = 0$ hold. On the other hand, if ρ is not in this face, one analyzes $P^\perp \rho P^\perp$, where *P* is the projector onto the proper eigenspace belonging to the eigenvalue zero of *h*. Use the triangulated block matrix form presented in appendix A.2, with $A = 0$ acting on the zero-subspace, with $C = 0$, and $S = P^\perp \rho P^\perp$. Equation (A.12) reduces to $\dot{S} = \mathcal{D}_D(S) - \frac{1}{2}[B^\dagger B S + S B^\dagger B]$, and $\frac{\mathrm{d}}{\mathrm{d}t}\mathrm{Tr}[S] =$

$-\text{Tr}[BSB^\dagger]$. Looking at $S_\infty = \lim_{T\to\infty} \frac{1}{T}\int_0^T S(t)\mathrm{d}t$, which must be stationary in time, we find that both terms have to vanish separately in $\dot{S}_\infty = \mathcal{D}_D(S_\infty) - \frac{1}{2}[B^\dagger B S_\infty + S_\infty B^\dagger B] = 0$.

First, assume h does not have improper eigenvectors to the eigenvalue zero. This means that all the zeros in the diagonal of the triangulated h appear in A and $D = P^\perp h P^\perp$ is without zero-eigenvalues. Since h is indecomposable, $B \neq 0$. If ρ has $S \neq 0$, then, as is stated in proposition 13, $\mathcal{D}_D(S) \neq 0$ unless S is a matrix of full rank without zero eigenvalues; but then $B^\dagger B S + S B^\dagger B \neq 0$, acting as emptying out the subspace which is orthogonal to the zero-subspace, and leading to $S = 0$.

Now it remains to consider h with improper eigenvectors to the eigenvalue zero. These zeros appear in the diagonal of $D = P^\perp h P^\perp$, at least one of them as a proper eigenvalue of D, which acts in $P^\perp \mathcal{H}$, a space of lower dimension than that where h acts. We make an induction on the dimension of the Hilbert space. The induction hypothesis is that the sub-subspace $\mathcal{K}$ spanned by the proper eigenvectors for the zeros of D makes an attractive face for $\check{S}(t)$, which is defined by $\frac{\mathrm{d}}{\mathrm{d}t}\check{S} = \mathcal{D}_D(\check{S})$, one part of the time evolution of $S(t)$. The stationary S_∞ vanishes on $\mathcal{H} - \mathcal{K}$. But the sub-subspace $\mathcal{K}$ is an improper eigenspace for h, for each $|\psi\rangle \in \mathcal{K}$ one has $B|\psi\rangle \neq 0$. So $\frac{\mathrm{d}}{\mathrm{d}t}\text{Tr}[S(t)] = -\text{Tr}[BS(t)B^\dagger] \neq 0$ for each S which does not vanish on $\mathcal{K}$, and $P^\perp \mathcal{H}$ is emptied out in the course of time. $\square$

Theorem 15 (all the stationary states for simple generators).

(1) Dissipation. If h is indecomposable and has no zero-eigenvalues, there is a unique stationary state in the interior. It is

$$\rho_\infty = (h^\dagger h)^{-1}/\text{Tr}[(h^\dagger h)^{-1}]. \tag{19}$$

(2) Decay. If an indecomposable h does have zero-eigenvalues, the stationary states form an attractive face, corresponding to the space spanned by the zero-eigenvalues.

(3) Elementary dephasing. If, in the other extreme, h is diagonalizable, the set of invariant states is the set of density matrices commuting with h.

(4) Stationary splitting. If h is decomposable, $h = \bigoplus_j h_j$, each h_j indecomposable, the direct sums of stationary states ρ_j of its parts form the set of all the stationary states which do not have phase relations between the independent subspaces $\mathcal{H}_j$.

(5) Dephasing of parts. If h is decomposable, there is a set of invariant phase relations $\rho_{j,\ell}$ between the subspaces which are domains of definition of h_j and h_ℓ, if and only if either both h_j and h_ℓ have zero-eigenvalues, or $h_j \cong h_\ell$. In the first case the invariant off-diagonal block matrices are $\rho_{j,\ell} = \sum_{\alpha,\beta} c_{\alpha,\beta}|v_{j,\alpha}\rangle\langle w_{\ell,\beta}|$ where the $|v_{j,\alpha}\rangle$ and $|w_{\ell,\beta}\rangle$ are the proper zero-eigenvectors of h_j and h_ℓ. In the second case any invariant phase relation $\rho_{j,\ell}$ is equivalent to ρ_j multiplied with some complex number, where $\rho_j \cong \rho_\ell$ is the stationary state of $\mathcal{D}_{h_j}$.

Proof. (a) The stationarity of ρ_∞ has been stated and proved in proposition 4 and in its proof. Suppose there were two different stationary states, ρ_0 and ρ_∞. By linearity of the evolution equation, the whole line $\rho_0 + \lambda(\rho_\infty - \rho_0)$ would consist of invariant matrices. But this line would intersect the boundary where there are no stationary states, see proposition 13.

(b) See proposition 14.

(c) That $[h, \rho] = 0$ implies $\mathcal{D}_h(\rho) = 0$ is obvious. The off-diagonal elements obey $\dot{\rho}_{i,j} = (h_i^* h_j - \frac{1}{2}(|h_i|^2 + |h_j|^2))$, which is not zero, if $h_i \neq h_j$. For details on the decrease of phase relations $\rho_{i,j}$ in this case see subsection 4.1.

(d) That is the combination of the previous results, using proposition 6.

(e) Any density matrix ρ for the whole Hilbert space $\mathcal{H}$ can be considered as a big block matrix with entries $\rho_{j,\ell}$, corresponding to the splitting of $\mathcal{H} = \bigoplus_j \mathcal{H}_j$ defined in

proposition 6. Each $\rho_{j,\ell}$ has a time evolution on its own, without any mixing with the other blocks. The stationary diagonal elements $\rho_{j,j}$ have been identified in (a)–(d). Knowledge about them, together with the general preservation of positivity, helps us to find possible invariant off-diagonal blocks $\rho_{j,\ell}$. So, for any pair h_j, h_ℓ of indecomposable parts of h, we look at a state ρ restricted to the subspace $\mathcal{H}_j \oplus \mathcal{H}_\ell$.

First assume that h_j has zero as an eigenvalue. Since positivity is preserved as $t \to \infty$, and since stationary elements $\rho_{j,j}$ reside on the subspace spanned by zero-eigenvectors, an invariant $\rho_{j,\ell}$ must also obey $h_j \rho_{j,\ell} = 0$. Its time evolution is $\dot{\rho}_{j,\ell} = -\frac{1}{2}\rho_{j,\ell} h_\ell^\dagger h_\ell$, and this can vanish only if $\rho_{j,\ell} h_\ell = 0$. Invariant phase relations exist therefore only if also h_ℓ does have zero eigenvectors. The stationary $\rho_{j,\ell}$ can then be expanded in ket-bra products of zero-eigenvectors.

Now consider the case that both h_j and h_ℓ are indecomposable and do not have zero as an eigenvalue. Assume that an invariant $\rho_{j,\ell} \neq 0$ exists. Keeping the diagonal blocks $\rho_{j,j}$ and $\rho_{\ell,\ell}$ fixed, given by the unique stationary states determined by h_j and h_ℓ, multiplied with any nonzero weights, the off-diagonal elements can be chosen with some factor λ, as $\lambda \rho_{j,\ell}$ and $\rho_{\ell,j} = \lambda^* \rho_{j,\ell}^\dagger$, such that the whole ρ is at the boundary of the set of states. Now we refer to the formulas stated in appendix A.2, formula (A.9) and the following lines. As is shown there, the density matrix, now represented by R acting on a subspace, is invariant only if $C = 0$ and also $RA^\dagger B = 0$. Now R has no zero-eigenvalues, and A has a subset of the whole set of diagonal elements of $h_j \oplus h_\ell$ as eigenvalues, also without zeros. So $B = 0$ must hold. But then $h_j \oplus h_\ell \cong \begin{pmatrix} A & 0 \\ 0 & D \end{pmatrix}$ commutes with the projector $P = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}$. Since neither h_j nor h_ℓ commute on their domains of definition $P_j \mathcal{H}$ and $P_\ell \mathcal{H}$ with anything else but the constant operators, the only possibility for such a nontrivial P is the unitary equivalence of h_j with h_ℓ: $h_j = V h_\ell V^\dagger$, $\quad V \cdot V^\dagger = \mathbb{1}_j$,

$$ P = p\mathbb{1}_j + \sqrt{p(1-p)}V + \sqrt{p(1-p)}V^\dagger + (1-p)\mathbb{1}_\ell. $$

This unitary equivalence implies then the equivalence of the invariant blocks with some factors, equivalence of $c_j \cdot \rho_{j,j}$ with $c_{j,\ell} \cdot \rho_{j,\ell}$ and $c_\ell \cdot \rho_{\ell,\ell}$. $\square$

We may reformulate the results, so that equivalent parts are collected as factors in a tensor product: if one knows the stationary states $\rho_{j,\alpha}$ for an indecomposable h_j, one knows all possible states for $\mathbb{1} \otimes h_j$; they are $\sum_\alpha \sigma_\alpha \otimes \rho_{j,\alpha}$, for any positive matrix σ_α which has $\mathrm{Tr}[\sigma_\alpha] = 0$. Stationary phase relations between the parts may exist.

In the case of an indecomposable h with no zero-eigenvalues it can be shown, as a companion to proposition 14, that the unique stationary state is an attractor. See subsection 3.4.

Parts (a) and (b) of theorem 15 and formula (19) allow for an inversion, constructing an operator h in such a way that the evolution generated by $\mathcal{D}_h$ has to lead to a given state ρ.

Theorem 16 (construction of a simple evolution leading to a given state). *For ρ either a pure state or a state with a density matrix of full rank, but non-constant, there exist dynamical semigroups with a simple GKS–Lindblad generator which have the given ρ as the unique stationary state.*

Proof. In case ρ is a pure state, take an indecomposable h with just one zero eigenvalue, so that $h\rho = 0$. This may be, for example, $h = \sum_j |\phi_j\rangle\langle\phi_{j+1}|$, with $|\phi_0\rangle\langle\phi_0| = \rho$.

In case ρ is a matrix of full rank, construct $h = U|h|$ with $|h| = \rho^{-1/2}$, as it has to be according to formula (19). This h is decomposable iff there exists a nontrivial projector P commuting with h. This commutation implies also the commutation of P with $h^\dagger$, with

$|h|^2 = h^\dagger h$ and with $|h|$. Since this $|h|$ has no zero eigenvalue and is invertible, P has also to commute with U. As commuting operators, P and $|h|$ have common eigenvectors ϕ_j, such that $|h| = \sum_j r_j^{-1/2} |\phi_j\rangle\langle\phi_j|$, and $P = \sum_{j\in I} |\phi_j\rangle\langle\phi_j|$. Now one has to consider a unitary operator U which mixes all the eigenspaces of $|h|$ belonging to different eigenvalues. This may be, for example, $U = \sum |\phi_j\rangle\langle\phi_{j+1}| + |\phi_N\rangle\langle\phi_0|$, where N is the dimension of the Hilbert space. Such a U does not commute with any P of the sort which commutes with h, and h is indecomposable.
$\square$

For exceptional ρ, not pure but not invertible, and also for the maximally mixed ω, it is possible to find a semigroup with this ρ as a stationary state; however, it will not be the unique one.

3.4. The geometry of paths

The geometric characterization of the paths $\rho(t)$ is equivalent to the algebraic characterization of the superoperator $\mathcal{D}$, determining its eigenvalues, its proper eigenspaces and also the generalized eigenspaces. Logical arguments can work in both directions, from geometry to algebra or vice versa.

On the geometrical side, we know that positivity of ρ is preserved, that the compact set **S** of states is mapped into itself. The algebraic consequence for $\mathcal{D}$ is that there is no eigenvalue with strictly positive real part. The detailed argument for this fact can be seen in the following discussion which is needed for deeper analysis.

The reflection $\sigma \leftrightarrow \sigma^\dagger$ is compatible with the action of $\mathcal{D}$, i.e. $\mathcal{D}(\sigma^\dagger) = [\mathcal{D}(\sigma)]^\dagger$. The consequences are: if an eigenvalue λ of $\mathcal{D}$ is a real number, the accompanying eigenmatrix and generalized eigenmatrices—if there exist any—can be chosen as selfadjoint. Each pair of a complex eigenvalue λ together with the eigenmatrix σ has a mirror companion in the pair λ^* and $\sigma^\dagger$. For the set of selfadjoint matrices this implies that for each complex number z the matrix $\tau_z = z\sigma + z^*\sigma^\dagger$ lies on a path $\tau_z(t)$ which is a spiral. The imaginary part of λ determines the time T of revolution, the real part gives the change of the HS-norm.

$$T := 2\pi/\mathrm{Im}(\lambda), \qquad \tau_z(T) = e^{2\pi\mathrm{Re}(\lambda)T}\tau_z. \tag{20}$$

Now consider any ρ in the interior of **S**, and some number ε, such that

$$\rho_\pm = \rho \pm \varepsilon\tau_z \tag{21}$$

are both inside of **S**. Their distance changes exponentially in time,

$$\|\rho_+(t) - \rho_-(t)\| = \|\rho_+(0) - \rho_-(0)\| \cdot e^{2\pi\mathrm{Re}(\lambda)t}.$$

But both of them remain in **S**, their distance cannot increase, $\mathrm{Re}(\lambda) \leqslant 0$.

It remains to discuss the cases of $\mathrm{Re}(\lambda) = 0$. We know for sure that stationary states exist. They are eigenmatrices to the eigenvalue $\lambda = 0$. We state the absence of other cases as the following theorem.

Theorem 17 (no circular paths). *There are no circular paths in the HS-space of matrices; there are no eigenvalues λ of $\mathcal{D}$ on the imaginary axis except $\lambda = 0$.*

Proof. We decompose the Hilbert space $\mathcal{H} = \bigoplus_j P_j\mathcal{H}$ and the operator $h = \sum_j P_j h P_j$ into indecomposable parts, as stated in proposition 6. For matrices σ we use the block matrix decomposition $\sigma = \sum_{j,\ell} P_j \sigma P_\ell$ and observe the mutual independence of evolutions for the blocks, $\mathcal{D}(P_j \sigma P_\ell) = P_j \mathcal{D}(\sigma) P_\ell$. So the search for eigenmatrices can be done by considering single block matrices.

First we consider h_j having zero as an eigenvalue. We know by proposition 14 that all the states $P_j \rho P_j$ move to the attractive face, where nothing changes in time any more. Now consider the path $\rho_+(t)$ starting with $\rho_0 + \varepsilon \tau_+$, as in equation (21). $\rho_0(t)$ moves to a ρ_∞ on the attractive face, as $t \to \infty$. Also $\rho_+(t)$ has to stay inside of **S**, moving to the attractive face, where there can be no circular path. So also $\rho_+(t)$ has to approach ρ_∞, so $\mathrm{Re}(\lambda) < 0$, strictly. The path may have the structure of a tornado.

For a matrix $\sigma = P_j \rho P_\ell$, giving the phase relation between $\mathcal{H}_j$ and $\mathcal{H}_\ell$, we know that it has to move to the subspace of matrices obeying $h_j \sigma = 0$, because of preserving positivity for states on the domain $\mathcal{H}_j \oplus \mathcal{H}_\ell$. For such a σ the time evolution is dictated as $\dot{\sigma} = -\frac{1}{2} \sigma h_\ell^\dagger h_\ell$. This gives either exponential decrease in time, or invariance, or a combination of both, but no circular path, no nonzero eigenvalue of $\mathcal{D}$ on the imaginary axis.

Now it remains to consider those $\sigma = P_j \sigma P_j$ and $\sigma = P_j \sigma P_\ell$ where neither h_j nor h_ℓ do have zero as an eigenvalue. Here we turn to study the adjoint $\mathcal{D}^\dagger$. It determines the time evolution in the Heisenberg picture. Its set of eigenvalues is the complex conjugated set of eigenvalues of $\mathcal{D}$, so these sets are actually identical.

We use the Kadison inequality, [K52] (See appendix A.2),

$$\Phi_t(F^\dagger F) \geqslant \Phi_t(F^\dagger)\Phi_t(F) \tag{22}$$

which holds for the mapping $F \mapsto \Phi_t(F)$ of time evolution in the Heisenberg picture.

Consider an eigenmatrix $F = P_\ell F P_j$, with $\mathcal{D}^\dagger(F) = \lambda F$. The adjoint $F^\dagger$ is an eigenmatrix with eigenvalue λ^* Assume $\lambda = \mathrm{i}r$ with $r \in \mathbb{R}$. Then $\Phi_t(F^\dagger)\Phi_t(F) = (\mathrm{e}^{-\mathrm{i}rt} F^\dagger)(\mathrm{e}^{\mathrm{i}rt} F) = F^\dagger F$. The matrix $F^\dagger F$ maps $\mathcal{H}_j$ into $\mathcal{H}_j$ and is positive. Take the projector onto an eigenvector with the largest eigenvalue, which is $\|F^\dagger F\|$, as a density matrix ρ, and switch for the moment between the Schrödinger and the Heisenberg pictures:

$$\mathrm{Tr}[\rho(t) F^\dagger F] = \mathrm{Tr}[\rho \Phi_t(F^\dagger F)] \geqslant \mathrm{Tr}[\rho F^\dagger F] = \|F^\dagger F\|. \tag{23}$$

The mean value over the time $\geqslant 0$ has to give the stationary state $\bar{\rho}$ on $\mathcal{H}_j$, which is unique and has no zero eigenvectors in $\mathcal{H}_j$, see theorem 15.

$$\mathrm{Tr}[\bar{\rho} F^\dagger F] = \lim_{T \to \infty} \frac{1}{T} \int_0^T \mathrm{Tr}[\rho(t) F^\dagger F] \geqslant \|F^\dagger F\|. \tag{24}$$

On the other hand, obviously $\mathrm{Tr}[\bar{\rho} F^\dagger F] \leqslant \|F^\dagger F\|$, so $\mathrm{Tr}[\bar{\rho} F^\dagger F] = \|F^\dagger F\|$. In a basis where $\bar{\rho}$ is diagonal, the matrix representing $F^\dagger F$ has therefore all diagonal elements equal to its norm, which implies vanishing of all the off-diagonal elements, so $F^\dagger F = \|F^\dagger F\| \mathbb{1}_j$.

If $\ell \neq j$ one finds also $FF^\dagger = \|FF^\dagger\| \mathbb{1}_\ell$ by doing analogous investigations. A first consequence is that the existence of such an eigenmatrix is possible only if $\mathcal{H}_j$ and $\mathcal{H}_\ell$ have equal dimension. With $FF^\dagger F = F\|F^\dagger F\| = \|FF^\dagger\|F$ we conclude $\|F^\dagger F\| = \|FF^\dagger\|$, so $V := F/\sqrt{\|F^\dagger F\|}$ is a unitary operator if $\mathcal{H}_j = \mathcal{H}_\ell$; and it is an isometry between $\mathcal{H}_j$ and $\mathcal{H}_\ell$ if these are different subspaces. We turn back to the Heisenberg picture and multiply the evolution equation (8) for V from the left by $V^\dagger$:

$$V^\dagger \mathcal{D}^\dagger(V) = V^\dagger h_\ell^\dagger V h_j - \tfrac{1}{2} V^\dagger h_\ell^\dagger h_\ell V - \tfrac{1}{2} V^\dagger V h_j^\dagger h_j = V^\dagger \lambda V = \mathrm{i}r \mathbb{1}_j. \tag{25}$$

We insert $VV^\dagger$ between $h_\ell^\dagger$ and h_ℓ, define $\hat{h}_\ell = V^\dagger h_\ell V$, take the trace and read it as an equation for inner products in the HS-space:

$$\langle \hat{h}_\ell | h_j \rangle = \tfrac{1}{2}(\langle \hat{h}_\ell | \hat{h}_\ell \rangle + \langle h_j | h_j \rangle) + \mathrm{i}rn, \tag{26}$$

where $n = \dim(\mathcal{H}_j)$. For $j = \ell$ we can conclude immediately that $\lambda = \mathrm{i}r = 0$. For $j \neq \ell$ this follows from the Cauchy Schwarz inequality and the inequality between the geometric and the arithmetic mean

$$|\langle \hat{h}_\ell | h_j \rangle| \leqslant \|\hat{h}_\ell\| \|h_j\| \leqslant \tfrac{1}{2}(\|\hat{h}_\ell\|^2 + \|h_j\|^2). \tag{27}$$

$\square$

4. Special systems and examples

4.1. Dephasing

The stable phase relations between indecomposable parts have been identified in theorem 15. In some special cases, we can state details on the integrated evolution: one may restrict the study to indecomposable parts. We use the same notation as in appendix A.2, applied to the operators in the subspace $\mathcal{H}_j \oplus \mathcal{H}_\ell$, writing $A = h_j$ and $D = h_\ell$ for the parts of h. The phase relations are expressed in $Q = \rho_{j,\ell}$. They evolve, according to equation (A.11), as

$$\dot{Q} = AQD^\dagger - \frac{1}{2}(A^\dagger A Q + Q D^\dagger D). \tag{28}$$

(1) Looking at a diagonalizable h, with $A = a$ and $D = d$ just numbers, the phase relations, the off-diagonal elements of ρ, evolve according to equation (28) as

$$\frac{\mathrm{d}}{\mathrm{d}t}q = -\frac{1}{2}(|a - d|^2 + (a^*d - ad^*))q, \tag{29}$$

giving exponential decrease, $|q(t)| = \exp(-|a-d|^2)q(0)$, together with a phase rotation.

(2) Consider $D = h_\ell$ having zero-eigenvectors and $QD^\dagger = 0$. Then

$$\dot{Q} = -\frac{1}{2}A^\dagger A Q.$$

Expand $Q = \sum_\alpha c_\alpha Q_\alpha$ with $A^\dagger A Q_\alpha = a_\alpha Q_\alpha$. Exponential decrease is the consequence:

$$Q(t) = \sum_\alpha \mathrm{e}^{-ta_\alpha/2} Q_\alpha. \tag{30}$$

(3) Consider $\mathcal{H}_\ell$ as one-dimensional, with $h_\ell = d$, and the other part $h_j = A$ as indecomposable. Then equation (28) implies monotone decrease of $\mathrm{Tr}(Q^\dagger Q)$:

$$\frac{\mathrm{d}}{\mathrm{d}t}\mathrm{Tr}(Q^\dagger Q) = -\mathrm{Tr}(Q^\dagger[(A^\dagger - d^\dagger)(A - d)]Q) \leqslant 0. \tag{31}$$

This inequality is strict, unless d is an eigenvalue of A and the columns of Q are corresponding eigenvectors. In the case of $(A - d)Q = 0$ this first-order derivative of $\|Q\|^2$ vanishes. Nevertheless one gets

$$\dot{Q} = \left(|d|^2 - \frac{1}{2}A^\dagger d - \frac{1}{2}|d|^2\right)Q = \frac{1}{2}d(d^* - A^\dagger)Q \neq 0, \tag{32}$$

since A is an indecomposable h_j, so A and $A^\dagger$ have no common eigenvalues. There is no stationary phase relation. The second-order derivative of $Q^\dagger Q$ in t is also zero, but the third-order derivative is strictly negative.

To make the calculation transparent, we consider Q as an element $|Q\rangle$ of the Hilbert–Schmidt-space, with the inner product $\langle P|Q\rangle = \mathrm{Tr}(P^\dagger Q)$. Time-derivative is a super-operator $\mathcal{D}$, mapping $|Q\rangle$ to $|\dot{Q}\rangle$. In the formulas we use the same letter A for the special super-operator which we define as $A|Q\rangle := |AQ\rangle$, as for the operator in $\mathcal{H}$.

$$|\dot{Q}\rangle = \mathcal{D}|Q\rangle = \left[-\frac{1}{2}(A^\dagger - d^*)(A - d) + \frac{1}{2}(Ad^* - A^\dagger d)\right]|Q\rangle. \tag{33}$$

Its adjoint operator is

$$\langle \dot{Q}| = \langle Q|\mathcal{D}^\dagger = \langle Q|\left[-\frac{1}{2}(A^\dagger - d^*)(A - d) - \frac{1}{2}(ad^* - A^\dagger d)\right]. \tag{34}$$

In this formalism we get $\frac{\mathrm{d}}{\mathrm{d}t}\mathrm{Tr}Q^\dagger Q = \langle Q|(\mathcal{D}^\dagger + \mathcal{D})|Q\rangle$ and

$$\frac{\mathrm{d}^n}{\mathrm{d}t^n}\mathrm{Tr}Q^\dagger Q = \sum_{m=0}^{n}\binom{n}{m}\langle Q|\mathcal{D}^{\dagger^m}\mathcal{D}^{n-m}|Q\rangle. \tag{35}$$

The assumption $AQ = \mathrm{d}Q$ gives $(\mathcal{D}^\dagger + \mathcal{D})|Q\rangle = 0$ and its adjoint, $\langle Q|(\mathcal{D}^\dagger + \mathcal{D}) = 0$. Now we write the second and first derivatives, using (35), as

$$\frac{\mathrm{d}^2}{\mathrm{d}t^2}\mathrm{Tr}Q^\dagger Q = \langle Q|\left((\mathcal{D}^\dagger + \mathcal{D})\mathcal{D} + \mathcal{D}^\dagger(\mathcal{D}^\dagger + \mathcal{D})\right)|Q\rangle = 0,$$

and, using $|Q\rangle\langle Q|/\|Q\|^2 < \mathbb{1}$,

$$\begin{aligned}
\frac{\mathrm{d}^3}{\mathrm{d}t^3}\mathrm{Tr}Q^\dagger Q &= \langle Q|((\mathcal{D}^\dagger + \mathcal{D})\mathcal{D}^2 + \mathcal{D}^\dagger(\mathcal{D}^\dagger + \mathcal{D})\mathcal{D} + \mathcal{D}^{\dagger^2}(\mathcal{D}^\dagger + \mathcal{D}))|Q\rangle \\
&= \langle Q|\mathcal{D}^\dagger(\mathcal{D}^\dagger + \mathcal{D})\mathcal{D}|Q\rangle = -\langle Q|\mathcal{D}^\dagger(A^\dagger - d^*)(A - d)\mathcal{D}|Q\rangle \\
&\leqslant -\langle Q|\mathcal{D}^\dagger(A^\dagger - d^*)|Q\rangle\langle Q|(A - d)\mathcal{D}|Q\rangle/\|Q\|^2 \\
&= -\left\|\frac{1}{2}d(d^* - A^\dagger)Q\right\|^4/\|Q\|^2 \Big\|^2 < 0,
\end{aligned}$$

with a strict inequality, as in equation (32).

We *warn* of thinking to generalize these examples. There is in general no monotone decrease of phase relations, not in the form of a decrease of the HS-norm of Q. Some remarks are stated in subsection 4.3.

4.2. Two-dimensional systems

We present the stationary states, the investigations on the eigenvalues and eigenmatrices of $\mathcal{D}$, and make remarks on the paths.

If h is constant, then $\mathcal{D}_h$ is zero. This case is nevertheless worth mentioning. In the way of decomposing a larger system it may appear as a restriction to a subspace. The constant h is then active in the evolution of the phase relations with other subspaces.

For non-constant h consider the triangulated representation

$$h = \begin{pmatrix} a & b \\ 0 & d \end{pmatrix}. \tag{36}$$

- If **b = 0** there are four eigenmatrices of $\mathcal{D}_h$,

$$\begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \quad \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}, \quad \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \quad \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix},$$

the first two belonging to the eigenvalue 0, the other two to $\lambda = \frac{1}{2}|a - d|^2 + \frac{1}{2}(a^*d - ad^*)$ and to λ^*. Each diagonal ρ is constant in time, dephasing occurs as stated in subsection 4.1(a).

- For any h with **b ≠ 0** there is a unique normed stationary state ρ, with

$$\rho = \begin{pmatrix} r & q \\ q^* & s \end{pmatrix}, \quad r = 1 - s, \quad s = \frac{|a|^2}{|a|^2 + |b|^2 + |d|^2}, \quad q = \frac{-a^*b}{|a|^2 + |b|^2 + |d|^2}. \tag{37}$$

This is easily seen by considering equations (A.10)–(A.12) in the simpler form with numbers instead of matrix-blocks; and it is, of course, consistent with equation (19).

Any kind of ρ can appear as a stationary state for some $\mathcal{D}_h$, except the maximally mixed $\omega = \mathbb{1}/2$. The stationary ρ_0 is a pure state if $a = 0$ or $d = 0$.

Concerning all the eigenvalues λ of $\mathcal{D}_h$ and its eigenmatrices $\sigma = \begin{pmatrix} r & q \\ p & s \end{pmatrix}$, we note that the preservation of the trace takes the form $\dot{s} + \dot{r} = \lambda(r + s) = 0$. The case $\lambda = \lambda_0 = 0$ involves the unique stationary state. The other eigenmatrices belong to $\lambda_i \neq 0$ and have $r + s = 0$. By using equations (A.11)–(A.13), together with this condition $\mathrm{Tr}\sigma = 0$, one gets the eigenvalue equation $\dot{\sigma} = \mathcal{D}_h(\sigma) = \lambda\sigma$ in the form

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{pmatrix} q \\ p \\ s \end{pmatrix} = \begin{pmatrix} ad^* - \|h\|_2^2/2 & 0 & bd^* \\ 0 & a^*d - \|h\|_2^2/2 & b^*d \\ -\frac{1}{2}ab^* & -\frac{1}{2}a^*b & -|b|^2 \end{pmatrix}\begin{pmatrix} q \\ p \\ s \end{pmatrix} = \lambda\begin{pmatrix} q \\ p \\ s \end{pmatrix}. \tag{38}$$

The remaining eigenvalues of $\mathcal{D}$ are the zeros of the characteristic polynomial for the 3×3 matrix appearing in this equation.

• For $\mathbf{a} = \mathbf{0}$ there are only real eigenvalues. They are $\lambda_1 = -|b|^2$, $\lambda_2 = \lambda_3 = -\|h\|_2^2/2$, the eigenmatrices are

$$\sigma_1 = \begin{pmatrix} |b|^2 - |d|^2 & 2bd^* \\ 2b^*d & |d|^2 - |b|^2 \end{pmatrix}, \qquad \sigma_2 = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \qquad \sigma_3 = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}. \tag{39}$$

For $a = 0$ and $|b| = |d| \neq 0$ all three zeros of the characteristic polynomial coincide, and the eigenmatrix σ_1 is no longer linearly independent of σ_2 and σ_3. But there is now a generalized eigenmatrix

$$\hat{\sigma}_1 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix},$$

satisfying the equation $\mathcal{D}(\hat{\sigma}_1) + |b|^2\hat{\sigma}_1 = |b|^2(\sigma_2 + \sigma_3)$.

• For $a \neq 0, b \neq 0, d \neq 0$ (note that $d = 0$ is equivalent to $a = 0$) the three eigenvalues of $\mathcal{D}$ which are not zero have to be calculated by finding the zeros of the characteristic polynomial for the matrix appearing in (38), a polynomial of third order. A simple case occurs when a and d are real numbers and either b or bi is also real. In these cases, one real eigenvalue is $\lambda_1 = -(|a - d|^2 + |b|^2)/2$, and the corresponding eigenmatrix σ_1 is, in case b is real, the selfadjoint matrix $\sigma_1 = \begin{pmatrix} 0 & i \\ -i & 0 \end{pmatrix}$. In case b is imaginary it is $\sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$.

• Quitting the boundary, starting from the *lazy state* $\rho(0) = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}$: the eigenvalue $e(t)$ to the density matrix $\rho(t)$, starting as $e(t) = 0$, can be analyzed in its behavior as an analytic function. Its Taylor expansion gives, as has been stated and proved in lemma 11, $\dot{e}(t) = 0$ and $\ddot{e}(t) = 0$. Continuing the procedure of solving the eigenvalue equation term by term according to the order of t^n gives

$$\frac{d^3}{dt^3}e(t)|_{t=0} = \frac{1}{2}|a|^2|b|^2|a - d|^2.$$

Also this third-order derivative vanishes if $a = d$, whereas, in this case

$$\frac{d^4}{dt^4}e(t)|_{t=0} = \frac{7}{8}|a|^2|b|^6.$$

4.3. Mixing and demixing

The mixing property of a state can change, in the course of time, in any direction for general h. The case of dissipation can start with a pure state and will end up in a mixed state. In the case of decay, when h has only one eigenvector to the eigenvalue zero, each mixed state will decay and approach the pure decay product. The path in **S** can also start from the boundary and go through the maximally mixed state ω, the following evolution will then act as purifying. This means increase of entropy, followed by its decrease. Such cases have been found numerically in [NTP07] and in [D04]. If such an up-and-down process appears in parallel fashion in two parts of the system, the phase relations between them can also show this non-monotonic behavior.

One may imagine a fast decay procedure with up–down evolution of entropy in a subspace, followed by a slower procedure, going over to another subspace. What is the end product of the first decay is then decaying again. It is of course possible that these happenings repeat several times, giving several ups and downs of entropy. From the mathematicians point of view there is the question of forming functions by superpositions of a finite number of exponential functions. In reality these things happen in nuclear processes.

5. Summary and conclusion

We consider the quantum-dynamical semigroups representing time evolutions of open systems with finite-dimensional Hilbert space. In this paper, we concentrate on semigroups with a simple GKS–Lindblad generator. An inequality concerning the decay of eigenvalues is recognized as an important clue to the behavior of mixed states near the boundary of the set of states; the rank cannot decrease in finite time. The complementary clue is a study on the increase of the rank of $\rho(t)$, eigenvalues which start at zero getting positive. There are few exceptions to an increase in first order $\sim t$. For this analysis the characterization of structures is essential, representing the operator h which is used to build the generator $\mathcal{D}_h$ as an upper triangular matrix. In relation to the subspaces appearing as eigenspaces to h we define, in one-to-one correspondence, certain faces of **S**, the convex set of states, as 'lazy' faces, since the rank of the ρ in such a face does not increase in first order $\sim t$.

The three basic ways of non-invertible time evolution in physics, i.e. dissipation, decay and decoherence/dephasing are mirrored in the mathematical structures of h and of the generator $\mathcal{D}_h$, and the decomposition of h is the basis for a complete characterization of all the stationary states, including a concrete formula. We have moreover characterized the dephasing as not allowing circular paths of states, and we have characterized the stationary states as attractive. With a view on applications in 'quantum engineering' we stated a possibility of inverting the task: find an evolution which leads to a given state. This task can be fulfilled for each state with one exception: the maximally mixed state.

Hereupon we demonstrated the findings on two-dimensional systems.

Appendix

A.1. Complete positivity

Dynamical maps of **S** into **S** have to preserve the trace. The dual maps are then 'unital' i.e. they map $\mathbb{1}$ to $\mathbb{1}$.

Stinespring's theorem states that ϕ mapping $\mathcal{B}(\mathcal{H})$ to $\mathcal{B}(\mathcal{H})$ is completely positive and unital iff

$$
\begin{aligned}
&\exists \mathcal{H}_2, \quad \exists U = (U^\dagger)^{-1} \quad \text{on} \quad \mathcal{H} \otimes \mathcal{H}_2, \quad \exists \rho_2 \in \mathbf{S}(\mathcal{H}_2) \\
&\forall F: \quad \Phi(F) = \mathrm{Tr}_2 \quad ((\mathbb{1} \otimes \rho_2) \cdot U^\dagger \cdot (F \otimes \mathbb{1}) \cdot U).
\end{aligned}
\tag{A.1}
$$

The predual map, acting on a state represented by the density matrix $\rho \in \mathcal{B}(\mathcal{H})$, is therefore

$$
\rho \mapsto \mathrm{Tr}_2(U \cdot (\rho \otimes \rho_2) \cdot U^\dagger).
\tag{A.2}
$$

From a physicists point of view, (A.1) or (A.2) are the relevant equations for a quantum dynamical map, where $\mathcal{B}(\mathcal{H})$ is the algebra of observables for a system, and $\rho_2 \in \mathbf{S}(\mathcal{H}_2)$ is the state of the 'reservoir'. So we actually do not need the mathematicians definition of complete positivity. In the following, we use only (A.1) instead.

Proposition 18 (the Kadison inequality). *If Φ is a unital completely positive map $\mathcal{B}(\mathcal{H}) \to \mathcal{B}(\mathcal{H})$, then for each $F \in \mathcal{B}(\mathcal{H})$ there holds the inequality*

$$
\Phi(F^\dagger F) \geqslant \Phi(F^\dagger)\Phi(F).
\tag{A.3}
$$

Proof. By doubling the 'reservoir'-space $\mathcal{H}_2$ to $\mathcal{H}_2 \otimes \mathcal{H}_2$ one can consider the state ρ in $\mathcal{B}(\mathcal{H}_2)$ as the restriction of an entangled pure state, with a state vector Ψ in $\mathcal{H}_2 \otimes \mathcal{H}_2$. Letting U act

on $\mathcal{H} \otimes \mathcal{H}_2 \otimes \mathcal{H}_2$ one can reformulate (A.1) as

$$\Phi(F) = \langle \Psi | U^\dagger \cdot (F \otimes \mathbb{1} \otimes \mathbb{1}) \cdot U | \Psi \rangle. \tag{A.4}$$

Now using $|\Psi\rangle\langle\Psi| < \mathbb{1}$ in $\Phi(F^\dagger) \cdot \Phi(F)$ gives the Kadison inequality. $\qquad\square$

If one feels uneasy with the abstract algebraic notation, one may read (A.4) as

$$\langle \phi | \Phi(F) | \psi \rangle = \langle \phi \otimes \Psi | U^\dagger \cdot (F \otimes \mathbb{1} \otimes \mathbb{1}) \cdot U | \psi \otimes \Psi \rangle, \tag{A.5}$$

and use a set $|\phi_n\rangle$ of basis vectors in $\mathcal{H}$ to write the product $\Phi(F^\dagger) \cdot \Phi(F)$ in matrix notation, and insert $\sum_n |\phi_n \otimes \Psi\rangle\langle\phi_n \otimes \Psi| < \mathbb{1}$ between $\Phi(F^\dagger)$ and $\Phi(F)$.

A.2. Block matrices

Consider a splitting of $\mathcal{H}$ into subspaces, $\mathcal{H} = \mathcal{H}_1 \oplus \mathcal{H}_2$. Write vectors $\psi = \chi \oplus \phi$ as $\binom{\chi}{\phi}$ and write operators acting in $\mathcal{H}$ as block matrices:

$$h = \begin{pmatrix} A & B \\ C & D \end{pmatrix} \tag{A.6}$$

$$\rho = \begin{pmatrix} R & Q \\ Q^\dagger & S \end{pmatrix}. \tag{A.7}$$

The action of $\mathcal{D}_h : \quad \rho \quad \mapsto \quad \dot\rho = \begin{pmatrix} \dot R & \dot Q \\ \dot Q^\dagger & \dot S \end{pmatrix}. \tag{A.8}$

We need two special cases.

The first one is the case of density matrices ρ with rank less than the dimension of the Hilbert space:

$$\text{If} \quad Q = 0 \quad \text{and} \quad S = 0, \qquad \text{then} \quad \dot S = CRC^\dagger. \tag{A.9}$$

The second special case with no restriction on ρ uses the Schur–Toeplitz triangulation, [L69], of the generating matrix h: If $C = 0$, then

$$\dot R = \mathcal{D}_A(R) + BSB^\dagger + AQB^\dagger + BQ^\dagger A^\dagger - \tfrac{1}{2}[QB^\dagger A + A^\dagger BQ^\dagger] \tag{A.10}$$

$$\dot Q = AQD^\dagger + BSD^\dagger - \tfrac{1}{2}[A^\dagger AQ + QB^\dagger B + QD^\dagger D + RA^\dagger B + A^\dagger BS] \tag{A.11}$$

$$\dot S = \mathcal{D}_D(S) - \tfrac{1}{2}[B^\dagger BS + SB^\dagger B + B^\dagger AQ + Q^\dagger A^\dagger B]. \tag{A.12}$$

For a general matrix

$$\sigma = \begin{pmatrix} R & Q \\ M & S \end{pmatrix},$$

which is in general not selfadjoint, we have to replace $Q^\dagger$ in (A.10) and in (A.12) by M, and we also need

$$\dot M = DMA^\dagger + DSB^\dagger - \tfrac{1}{2}[MA^\dagger A + B^\dagger BM + D^\dagger DM + B^\dagger AR + SB^\dagger A]. \tag{A.13}$$
