**Abstract.** Activation energies for crystallization of 50 Li<sub>2</sub>O–40 P<sub>2</sub>O<sub>5</sub>–10 Nb<sub>2</sub>O<sub>5</sub>–*x* Fe<sub>2</sub>O<sub>3</sub> glasses, with *x* = 0, 5 and 10 mol%, were determined by differential thermal analysis (DTA). The structure was investigated by infrared and Mössbauer spectroscopy. Samples with *x* = 5 mol% of Fe<sub>2</sub>O<sub>3</sub> show larger activation energy (160.9 kJ mol<sup>-1</sup>). Absorptions at P–O–P, P=O, P–O<sup>-</sup> and PO<sub>4</sub> units are present in these glasses. P=O absorptions disappear at compositions with *x* = 5 and 10 mol% of Fe<sub>2</sub>O<sub>3</sub>, which shows absorption around 571 cm<sup>-1</sup>, attributed to FeO<sub>6</sub> units. According to Mössbauer results high spin Fe<sup>3+</sup> and Fe<sup>2+</sup> at distorted octahedral sites are present in samples with *x* = 5 and 10 mol% of Fe<sub>2</sub>O<sub>3</sub>, thus working as a network modifier.

### 1. Introduction

Phosphate glasses have been studied extensively in recent years. Vitreous phosphoric anhydride (P<sub>2</sub>O<sub>5</sub>) does not have sufficient hygroscopic resistance to be used alone. Its structure is based on distorted tetrahedral (PO<sub>4</sub>). One interest is in the use of P<sub>2</sub>O<sub>5</sub> as a network former and the possibility of forming a vitreous matrix with, for example, alkali metals (M = Li, Na) in system M<sub>2</sub>O–Nb<sub>2</sub>O<sub>5</sub>–P<sub>2</sub>O<sub>5</sub> [1]. The introduction of P<sub>2</sub>O<sub>5</sub> into binary alkali silicate glasses has profound effect on their structure, particularly at high concentrations [2]. Phosphates of alkali metals grouping at different degrees of complexity such as isolated PO<sub>4</sub><sup>3-</sup> tetrahedra, two tetrahedra joined and long chains or rings of PO<sub>4</sub><sup>3-</sup>. These materials combine to form M<sub>3</sub>PO<sub>4</sub> (orthophosphate), M<sub>4</sub>P<sub>2</sub>O<sub>7</sub> (pyrophosphate) and MPO<sub>3</sub> (pyrophosphate) [3]. For niobium phosphate glasses, with 2 mol% of Fe<sub>2</sub>O<sub>3</sub> used as impurity, LiNbO<sub>3</sub> can be crystallized inside the glass structure to form a glass–ceramic [4]. Lithium niobate, LiNbO<sub>3</sub>, is a ferroelectric material, with Curie temperature of 1210 °C, with high efficiency for second harmonic generation and widely used as an optoelectronic device as in planar wave guides [5]. In the glass system Li<sub>2</sub>O–P<sub>2</sub>O<sub>5</sub>–Nb<sub>2</sub>O<sub>5</sub>, doped with 2 mol% of Fe<sub>2</sub>O<sub>3</sub>, iron ions are distributed in octahedral sites, and Fe<sup>3+</sup> is predominant compared with Fe<sup>2+</sup> [6]. In the present work, differential thermal analysis (DTA) was used to determine activation energy of crystallization and physical characteristics of the studied glass system. Infrared (IR) and Mössbauer spectroscopy were used to study the effect of Fe<sub>2</sub>O<sub>3</sub> concentration on Li<sub>2</sub>O–P<sub>2</sub>O<sub>5</sub>–Nb<sub>2</sub>O<sub>5</sub>–Fe<sub>2</sub>O glasses with the aim of understanding the function of the iron in the physical properties of this system.

## 2. Experimental procedure

Glasses in the  $\text{Li}_2\text{O}-\text{P}_2\text{O}_5-\text{Nb}_2\text{O}_5-\text{Fe}_2\text{O}_3$  system were prepared from reagent grade ammonium phosphate ( $\text{NH}_4\text{H}_2\text{PO}_4$ ), lithium carbonate ( $\text{Li}_2\text{CO}_3$ ) and niobium oxide ( $\text{Nb}_2\text{O}_5$ ) with iron oxide  $\text{Fe}_2\text{O}_3$  as an impurity, by mixing reagents in appropriate proportions and heating them in platinum crucibles in an electric furnace. To prevent excessive boiling and consequent loss of mass, the water and ammonia in  $\text{NH}_4\text{H}_2\text{PO}_4$  were removed by pre-heating the mixture at  $200^\circ\text{C}$  for several hours before the fusion. The mixture was subsequently melted at  $1150^\circ\text{C}$  for 1 h. The melt was then poured into a stainless steel mould and pressed between two stainless steel plates. The mould and plates were pre-heated to  $300^\circ\text{C}$ . The glasses prepared are  $(50 \text{ Li}_2\text{O}-40 \text{ P}_2\text{O}_5-10 \text{ Nb}_2\text{O}_5):x \text{ Fe}_2\text{O}_3$ , with  $x = 0, 5$  and  $10 \text{ mol\%}$ . The glassy state in the quenched samples was confirmed by x-ray diffraction (XRD) analyses at room temperature using  $\text{Cu K}\alpha$  radiation. The glass transition temperature ( $T_g$ ), temperature of onset crystallization ( $T_x$ ) and melting temperature ( $T_m$ ) were determined by DTA, at heating rate of  $10^\circ\text{C min}^{-1}$  using STA-409 Netzsch apparatus. The DTA measurements were performed using a platinum crucible in air and a constant sample weight of  $40 \text{ mg}$  was used for all measurements. The glass densities were determined by the Archimedes method, using distillate water as immersion liquid. The IR spectra of the glasses were investigated using KBr pellets made from a mixture of powder for each glass composition investigated. The IR spectra were measured from  $1400$  to  $400 \text{ cm}^{-1}$  with a Bomem MB-102 spectrometer. To determine activation energy for crystallization ( $E$ ), samples were crystallized at four heating rates,  $\phi$  ( $5, 10, 15$  and  $20^\circ\text{C min}^{-1}$ ). The data were analysed using the Kissinger equation [7],

$$\ln(T_p^2/\phi) = E/RT_p + \text{constant}$$

where  $T_p$  is a temperature corresponding to the maximum of the DTA crystallization peak and  $R$  is the gas constant. The activation energy was calculated from a plot of  $\ln(T_p^2/\phi)$  versus  $1/T_p$ .

The Mössbauer absorption spectra as obtained in standard transmission geometry, using a radioactive source of  $^{57}\text{Co}$  in Rh matrix. Measurements were carried out at room temperature on powder samples with absorber thickness  $1.9 \text{ mg}$  of natural iron per  $\text{cm}^2$ . The spectra were evaluated using the Normos fitting program that makes use of a set of Lorentzian quadrupole doublets with fixed width and isomer shift and computes the contribution of each curve to the absorption spectra by a least squares procedure. All the isomer shifts ( $\delta$ ) quoted are relative to metallic iron ( $\alpha\text{-Fe}$ ). The theory of Mössbauer spectroscopy is described in the literature [8].

## 3. Results and discussion

### 3.1. DTA measurements

Several DTA measurements, at four heating rates  $\phi$  (heating rate between  $5$  and  $20^\circ\text{C min}^{-1}$ ), were performed for  $(50 \text{ Li}_2\text{O}-40 \text{ P}_2\text{O}_5-10 \text{ Nb}_2\text{O}_5)-x \text{ Fe}_2\text{O}_3$ , with  $x = 0, 5$  and  $10 \text{ mol\%}$ , glasses with the aim to determine activation energy  $E$ . With the maximum crystallization  $T_p$  obtained from these DTA data and respective heating rate  $\phi$ , figure 1 was plotted. Figure 1 shows a plot of  $\ln(T_p^2/\phi)$  versus  $1/T_p$ , for samples with  $x = 0, 5$  and  $10 \text{ mol\%}$  of  $\text{Fe}_2\text{O}_3$ . The activation energy  $E$  was calculated from angular coefficients to linear fits in figure 1. Table 1 summarizes the activation energy for  $(50 \text{ Li}_2\text{O}-40 \text{ P}_2\text{O}_5-10 \text{ Nb}_2\text{O}_5)-x \text{ Fe}_2\text{O}_3$  glasses and others physical characteristics such as density ( $\rho$ ),  $T_g$ ,  $T_x$

**Figure 1.** Plot of  $\ln(T_p^2/\phi)$  versus  $1/T_p$  of the 50  $\text{Li}_2\text{O}$ -10  $\text{P}_2\text{O}_5$ -10  $\text{Nb}_2\text{O}_5$ - $x$   $\text{Fe}_2\text{O}_3$  glasses for determination of activation energy. Points are experimental data and line are fitting at  $x = 0$  mol% (○),  $x = 5$  mol% (△) and  $x = 10$  mol% of  $\text{Fe}_2\text{O}_3$  (□).

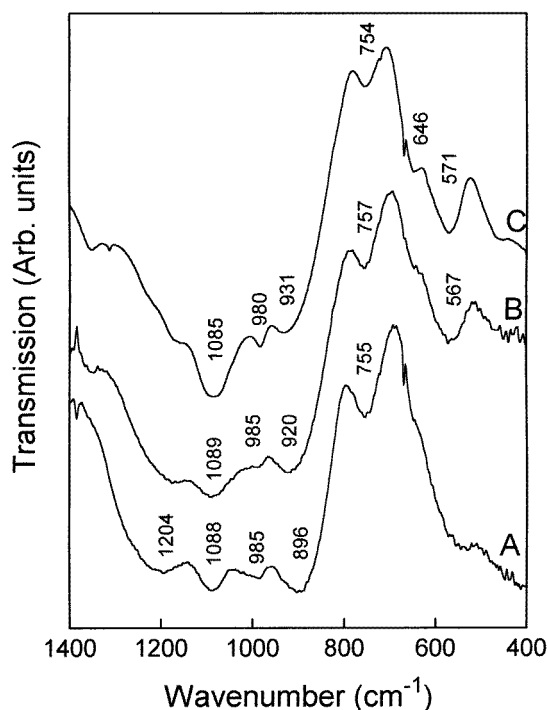

and  $T_m$ . As we can see, the results show that sample with  $x = 5$  mol% of  $\text{Fe}_2\text{O}_3$  has a maximum of activation energy ( $E = 160.9 \text{ kJ mol}^{-1}$ ). The values of  $E$  determined in the present work for lithium niobophosphate glasses (table 1) are smaller than disilicate glass (250 to 290  $\text{kJ mol}^{-1}$ ), for example, reported by others [9, 10]. Activation energy was calculated at samples as prepared because, as expected, the activation energy is practically independent of the nucleation temperature and concentration of nuclei in the glass [9]. Thus, for any nucleation temperature between glass transition ( $T_g$ ) and crystallization onset ( $T_x$ ) temperatures, it is expected that activation energy will be the same. Glass stability can be determined qualitatively by the difference  $\Delta T = T_x - T_g$ . As shown in table 1, the sample without  $\text{Fe}_2\text{O}_3$  ( $x = 0$ ) on the glass matrix is the most stable glass, with  $\Delta T = 159$   $^{\circ}\text{C}$ . The introduction of  $\text{Fe}_2\text{O}_3$  in the glass matrix  $\text{Li}_2\text{O}$ - $\text{P}_2\text{O}_5$ - $\text{Nb}_2\text{O}_5$  decreases thermal stability in this glass (table 1) and increases the density from  $2.60 \text{ g cm}^{-3}$  to  $3.00 \text{ g cm}^{-3}$ .

### 3.2. Infrared spectroscopy (IR)

Phosphate glasses are composed of  $\text{PO}_4$  tetrahedra, which consist of long chains or rings of  $\text{PO}_4$  sharing corners. In this work we will use the results of Corbridge and Lowe [11] and Muller [12] to interpret the IR of the phosphate glasses. According to Muller [12], absorption of the  $\text{P}=\text{O}$  group is around  $1282$ - $1205 \text{ cm}^{-1}$  in polymeric phosphate chains. The stretching bands of  $\text{P}-\text{O}^-$  (NBO—non-bridging oxygen) are around  $1150$ - $1050 \text{ cm}^{-1}$  and  $950$ - $900 \text{ cm}^{-1}$ . Absorption at  $800$ - $720 \text{ cm}^{-1}$  is due to  $\text{P}-\text{O}-\text{P}$  vibrations (BO—bridging

**Table 1.** Physical characteristics of the 50 Li<sub>2</sub>O–40 P<sub>2</sub>O<sub>5</sub>–10 Nb<sub>2</sub>O<sub>5</sub>–*x* Fe<sub>2</sub>O<sub>3</sub> glasses, obtained at a heating rate of 10 °C min<sup>-1</sup>.

Glass composition	Density $\rho$ (g cm <sup>-3</sup> )	Glass transition temperature $T_g$ (°C)	Crystallization temperature $T_x$ (°C)	Melting temperature $T_m$ (°C)	Activation energy $E$ (kJ mol <sup>-1</sup> )
$x = 0$ mol%	2.60	398	557	642	96.3
$x = 5$ mol%	2.86	433	545	729	160.9
$x = 10$ mol%	3.00	461	560	728	149.4

**Figure 2.** Infrared spectra of 50 Li<sub>2</sub>O–40 P<sub>2</sub>O<sub>5</sub>–10 Nb<sub>2</sub>O<sub>5</sub>–*x* Fe<sub>2</sub>O<sub>3</sub> glasses at  $x = 0$  mol% (A),  $x = 5$  mol% (B), and  $x = 10$  mol% of Fe<sub>2</sub>O<sub>3</sub> (C).

oxygen). The bands below 600 cm<sup>-1</sup> are due to the bending mode of the PO<sub>4</sub> units in phosphate glasses.

Figure 2 shows the IR spectra of the lithium niobophosphate glasses with  $x = 0$ , 5 and 10 mol% of Fe<sub>2</sub>O<sub>3</sub>. Spectrum in figure 2(A) shows the IR spectra of the lithium niobophosphate glass without Fe<sub>2</sub>O<sub>3</sub>. The bands 1204 cm<sup>-1</sup> (P=O), 1088 cm<sup>-1</sup>, 985 cm<sup>-1</sup> and 896 cm<sup>-1</sup> (P–O<sup>-</sup>), 755 cm<sup>-1</sup> (P–O–P) and 543 cm<sup>-1</sup> (PO<sub>4</sub> units) are present. With the introduction of the Fe<sub>2</sub>O<sub>3</sub> in the glass matrix, in the proportion of 5 mol% and 10 mol%, figure 2(B) and (C) respectively, the resonance around 1204 cm<sup>-1</sup> disappears. On the other hand, new bands around 567 cm<sup>-1</sup> and 571 cm<sup>-1</sup> appear (figure 2(B) and (C)).

Osaka *et al* [13] have shown that the PO<sub>4</sub> unit has two bridging oxygen bonds along with two non-bridging oxygen bonds as P=O and P–O<sup>-</sup>. Therefore, the IR spectra are split into two bands with higher energy and a lower energy band. However, the iron niobophosphate

glasses studied in this work did not show splitting into these two bands. The absence of the  $1204\text{ cm}^{-1}$  band in figure 2(B) and (C) may be associated with conversion of the P=O double bond into as bridging oxygen. The shift to higher frequency for the P-O<sup>-</sup> vibration, from  $896\text{ cm}^{-1}$  to  $931\text{ cm}^{-1}$  (table 2), may be due a large ionic nature of Fe-O bonds. Similar behaviour was observed by Mogus-Milankovic and Day [14] for iron phosphate glasses.

**Table 2.** Frequency ( $\text{cm}^{-1}$ ) for IR absorptions in  $50\text{ Li}_2\text{O}-40\text{ P}_2\text{O}_5-10\text{ Nb}_2\text{O}_5-x\text{ Fe}_2\text{O}_3$  glasses.

Vibrations	Frequency ( $\text{cm}^{-1}$ )		
	$x = 0\text{ mol}\%$	$x = 5\text{ mol}\%$	$x = 10\text{ mol}\%$
P-O-P (BO)	755	757	754
P=O	1204	NO	NO
P-O <sup>-</sup> (NBO)	1088, 985 and 896	1089, 985 and 920	1085, 980 and 931
FeO <sub>4</sub>	NO	NO	646
FeO <sub>6</sub>	NO	567	571

NO: not observed; NBO: non-bridging oxygen; BO: bridging oxygen.

In order to elucidate the coordination of iron for glasses studied in this work, IR spectra of Fe<sub>2</sub>O<sub>3</sub> and its compounds were considered. There are two characteristic FeO<sub>6</sub> octahedral bands,  $\nu_3$  at  $580\text{--}550\text{ cm}^{-1}$  and  $\nu_4$  at  $470\text{ cm}^{-1}$ . The vibrations of FeO<sub>4</sub> tetrahedra are at  $660\text{--}625\text{ cm}^{-1}$  [15]. Thus, absorption around  $646\text{ cm}^{-1}$ , clearly present in figure 2(C), may be ascribed to the vibrations of FeO<sub>4</sub> tetrahedra. The presence of the absorption bands at  $567\text{ cm}^{-1}$  and  $571\text{ cm}^{-1}$ , figure 2(B) and (C) respectively, indicates the existence of octahedral iron FeO<sub>6</sub>. Table 2 summarizes the absorption bands from figure 2. Abreu *et al* published very recently [16] a work studying the effect of a high level of Fe<sub>2</sub>O<sub>3</sub> doping ( $x \geq 10\text{ mol}\%$ ) concentration in the iron niobophosphate glasses, studied by Mössbauer and infrared spectroscopy. The results show that Fe<sup>3+</sup> and Fe<sup>2+</sup> ions are distributed in octahedral sites and that bands around  $587\text{ cm}^{-1}$ ,  $503\text{ cm}^{-1}$  and  $480\text{ cm}^{-1}$  are associated with existence of octahedral iron FeO<sub>6</sub>. The measurements also indicate that LiFePO<sub>4</sub> and  $\alpha\text{-Fe}_2\text{O}_3$  crystalline phases are present for high iron content samples ( $x = 40$  and  $x = 50\text{ mol}\%$ ). In our present study we are concerned with the low level of doping of Fe<sub>2</sub>O<sub>3</sub> ( $0 \leq x \leq 10\text{ mol}\%$ ).

### 3.3. Mössbauer spectroscopy

Figure 3 shows the Mössbauer spectra for samples with  $x = 5$  and  $10\text{ mol}\%$  of Fe<sub>2</sub>O<sub>3</sub>. All the spectra in figure 3 can be interpreted as the superposition of two broad doublets. The more intense doublet can be assigned, based on isomer shift and quadrupole splitting value, to high spin Fe<sup>3+</sup> (ferric iron), and the less intense to high spin Fe<sup>2+</sup> (ferrous iron) [17]. We used a set of 60 Lorentzian doublets, 30 to fit the contribution to the spectrum due to Fe<sup>3+</sup> and 30 for Fe<sup>2+</sup>. The Lorentzian half width has been fixed at  $0.12\text{ mm s}^{-1}$ , which is typical of a spectrum of standard metallic iron.

In table 3 are listed the Mössbauer parameters, isomer shift ( $\delta$ ), the most probable values of quadrupole splitting ( $\Delta_{max}$ ) and relative area population ( $A$ ) obtained from the fit. According to Dyar [18] the Fe<sup>3+</sup> ions in a octahedral coordination, present the Mössbauer parameter isomer shift ( $\delta$ ) with values between  $0.35$  and  $0.55\text{ mm s}^{-1}$  relative to metallic iron, whereas for a tetrahedral coordination the  $\delta$  value between  $0.20$  and  $0.30\text{ mm s}^{-1}$ . For the Fe<sup>2+</sup> ions, values of  $\delta$  below  $1.0\text{ mm s}^{-1}$  relative to metallic iron, are associated with

**Figure 3.** Mössbauer spectra of samples of  $x = 5$  and  $x = 10$  mol%. (●) Experimental points and the continuous line is the theoretical fitting.

**Table 3.** Mössbauer parameters of the 50 Li<sub>2</sub>O–40 P<sub>2</sub>O<sub>5</sub>–10 Nb<sub>2</sub>O<sub>5</sub>– $x$  Fe<sub>2</sub>O<sub>3</sub> glasses. In this table  $\delta$  (mm s<sup>-1</sup>),  $\Delta$  (mm s<sup>-1</sup>) and  $A$  (%), are the isomer shift, quadrupole moment and area, respectively.

Sample	Fe <sup>2+</sup>			Fe <sup>3+</sup>		
	$\delta$ (mm s <sup>-1</sup> )	$\Delta$ (mm s <sup>-1</sup> )	$A$ (%)	$\delta$ (mm s <sup>-1</sup> )	$\Delta$ (mm s <sup>-1</sup> )	$A$ (%)
$x = 5$	1.08	2.51	31	0.37	0.67	69
$x = 10$	1.05	2.50	26	0.40	0.70	74

tetrahedral coordination. The Mössbauer parameter quadrupole splitting ( $\Delta$ ) is also useful for evaluating the coordination number since a distorted tetrahedral site is characteristically less symmetric than a distorted octahedral site, therefore different values of  $\Delta$  should be obtained. However it is observed [18] that coordination number should be primarily determined from  $\delta$  values.

Recently Day *et al* [19] report results in iron phosphate glasses studied by Mössbauer spectroscopy where the valence states of iron ions in several iron phosphate glasses were studied. It was observed that the general coordination of the majority of iron ions appears to be distorted octahedral. However the Mössbauer spectra do not totally exclude the presence of some tetrahedrally coordinated iron ions in the iron phosphate glasses.

In this work, for the  $\text{Fe}^{3+}$  ion, the values of  $\delta$  range from 0.37 to 0.40  $\text{mm s}^{-1}$  and for the  $\text{Fe}^{2+}$  ion the values are between 1.08 and 1.05  $\text{mm s}^{-1}$ , for  $x = 5$  and 10 mol% of  $\text{Fe}_2\text{O}_3$  respectively. Therefore we can assume that both ions are sites of distorted octahedral coordination, i.e. they are network modifiers. The quadrupole splitting values are also in agreement with this interpretation. Table 3 also shows the relative area population ( $A$ ) for both  $\text{Fe}^{2+}$  and  $\text{Fe}^{3+}$  ions. As we can see, for both samples  $\text{Fe}^{3+}$  is predominant compared with the  $\text{Fe}^{2+}$  population.

**Figure 4.** Quadrupole splitting distribution for  $\text{Fe}^{3+}$  and  $\text{Fe}^{2+}$  at the octahedral sites. (Samples  $x = 5$  and  $x = 10$  mol%.)

Figure 4 shows the probability distributions of the Lorentzian doublets versus quadrupole splitting ( $\Delta$ ) for  $\text{Fe}^{3+}$  and  $\text{Fe}^{2+}$  ions in samples with  $x = 5$  and 10 mol% of  $\text{Fe}_2\text{O}_3$ . As we can see the distributions show different maxima of the quadrupole splitting distribution, which are associated with different distortions of the octahedral symmetry around the iron ions. The position of the  $\Delta_{max}$  represents the most probable value of the quadrupole splitting of the site. For samples with  $x = 5$  the  $\text{Fe}^{2+}$ , which are just 31% of the total iron, occupy two distinct sites. The site with  $\Delta_{max} = 2.51 \text{ mm s}^{-1}$  is the one with highest probability. The  $\text{Fe}^{3+}$  in this samples (69% of the total iron) show the most probable value  $\Delta_{max} = 0.67 \text{ mm s}^{-1}$ . For samples with  $x = 10$  mol% the  $\text{Fe}^{2+}$ , which represent 26% of the total iron, occupy two distinct sites with the most probable  $\Delta_{max} = 2.50 \text{ mm s}^{-1}$ . The  $\text{Fe}^{3+}$  (74% of the total iron) on the other hand, presents the most probable  $\Delta_{max} = 0.70 \text{ mm s}^{-1}$ .

#### 4. Conclusions

Iron niobophosphate glasses were investigated in the present work with DTA analysis, infrared and Mössbauer spectroscopy, to investigate the effect of the increasing concentration of Fe<sub>2</sub>O<sub>3</sub> in the glass matrix. Results show that the activation energy for crystallization increases with the increase of Fe<sub>2</sub>O<sub>3</sub> in the glass matrix. The sample with 5 mol% of Fe<sub>2</sub>O<sub>3</sub> shows the maximum activation energy. Infrared spectra clearly indicate the presence of the P=O, P–O–P and P–O<sup>−</sup> bands. Samples with Fe<sub>2</sub>O<sub>3</sub> do not show bands associated with P=O. This absence may be associated with conversion of the P=O double bond into a bridging oxygen. High spin Fe<sup>2+</sup> and Fe<sup>3+</sup> (which are present in samples with  $x = 5$  and 10 mol% of Fe<sub>2</sub>O<sub>3</sub>) are assumed to be at sites of distorted octahedral coordination (network modifier).
