Received September 21, 1984

#### Abstract

Within the last decade, the ternary molybdenum chalcogenides have played a major role in superconductivity: opening of the ternary superconductor range, competition between superconductivity and magnetism. It is mainly due to the pseudomolecular nature of the $\mathrm{Mo}_{6} \mathrm{X}_{8}$ unit. In these materials, the $\mathrm{Mo}_{6}$ cluster plays the electron-acceptor role and the number of valence electrons per molybdenum atom is related to the Mo-Mo intracluster bonding. The increase of this valence electron concentration (VEC) per molybdenum in new ternary chalcogenides corresponds to larger and larger clusters. These new extended clusters belong to a very large family containing the general $\mathrm{Mo}_{3 n} X_{3 n+2}$ ( $n \geq 2$ ) block unit. The tridimensional stacking of these building blocks provides more and more large channels and leads to a more and more anisotropic character of their physical properties. © 1985 Academic Press, Inc.

## Introduction

The ternary molybdenum chalcogenides $M_{x} \mathrm{Mo}_{6} X_{8}(X=\mathrm{S}, \mathrm{Se}, \mathrm{Te} ; M=$ a cation ), so called "Chevrel phases," have stimulated a great amount of interest because of their outstanding remarkable properties.

These chalcogenides were considered by Matthias et al. (1) as the first superconducting ternary system having high critical temperatures, reaching 15 K for the $\mathrm{PbMo}_{6} \mathrm{~S}_{8}$ compound. These compounds have helped open the way to the research of new ternary superconductors. The upper critical field

[^0]$H_{\mathrm{c}_{2}}$ of the $\mathrm{Pb} / \mathrm{Mo} / \mathrm{S}$ compound ( $\mathrm{H}_{\mathrm{c}_{2}} \sim 60 \mathrm{~T}$ ) is, so far, the highest value observed in any class of superconductors; it exceeds by more than 20 T , the highest value reported for the $\mathrm{Nb}_{3} \mathrm{Ge}$ binary $(2,3)$. Another center of interest is the interplay between superconductivity and magnetism at low temperatures in the rare earth molybdenum chalcogenides: the coexistence of superconductivity and antiferromagnetism or the competition between superconductivity and ferromagnetism. Another property is the high and reversible mobility of the $M^{n+}$ counterions ( $\mathrm{Cu}, \mathrm{Li}, \mathrm{Fe}, \mathrm{Ni} .$. ) allowing one to carry out reversible topotactic redox reactions (4). This property is used to make new metastable binary or ternary molybdenum chalcogenides $(5,6)$. The originality of this family resides in the
fact that they are ternary cluster-based superconductors, providing the beginning for an intense activity in the field of new clus-ter-based materials (7). It seems that the clustering of the transition metal atoms has been found to be a feature common to ternary high $-T_{\mathrm{c}}$ superconductors and is therefore a contributing factor to the high critical temperatures.

The purpose of this paper is to describe briefly the structural aspects of the $M_{x}$ $\mathrm{Mo}_{6} \mathrm{X}_{8}$ compounds and new extended cluster compounds and to exhibit the relationships between the valence electron concentration per molybdenum and the size of the cluster.

## Structural Aspects of the $\boldsymbol{M}_{x} \mathrm{Mo}_{6} \boldsymbol{X}_{8}$ Compounds

The $M_{x} \mathrm{Mo}_{6} X_{8}$ ternary molybdenum chalcogenides are a very large family of compounds (more than 100 compounds where $M$ stands for about 40 elements and $X$ a chalcogen atom) made up from the $\mathrm{Mo}_{6} X_{8}$ quasirigid building blocks (5):

Each $\mathrm{Mo}_{6} X_{8}$ block unit is constituted from an octahedral molybdenum $\mathrm{Mo}_{6}$ cluster (slightly elongated along the threefold axis) where the faces are bridged by eight chalcogen atoms forming a pseudocube like the $\mathrm{Mo}_{6} \mathrm{Cl}_{8}$ unit of molybdenum dichloride. These cubic units are directly interconnected via short Mo- $X$ intercluster bonds arising from tilting of the units: every Mo atom in one octahedral cluster, located at the center of a chalcogen square face of one unit, is bonded to another chalcogen in a neighboring unit. The five Mo- $X$ distances are nearly equal ( $\mathrm{Mo}-\mathrm{S} \sim 2.5 \AA$ ). The stacking and bridging of these $\mathrm{Mo}_{6} \mathrm{X}_{8}$ units makes possible the Mo-Mo intercluster bonding. These Mo-Mo intercluster distances depend strongly upon the nature of the $M$ element and the $X$ chalcogen; for instance, they vary from 3.1 to $3.3 \AA$ in the

Fig. 1. Projection onto the ( $11 \overline{2} 0$ ) hexagonal plane of the $\mathrm{SnMo}_{6} \mathrm{~S}_{8}$ compound.
sulfides and are $20 \%$ larger than the intracluster Mo-Mo distances ( $\sim 2.7 \AA$ ) (Fig. 1).

These Mo-Mo interactions are relatively weak as proved by band structure calculations (7) but are very important for electronic properties of these materials. The two main cavities form tridimensional channels running along the chains of weakly coupled octahedral clusters and are either empty (binaries) or partially filled by the counterions like tin ions.

## The Valence Electron Concentration (VEC) and Related Properties

The large electronegativity differences between the two metals $M$ and Mo and the nonmetal chalcogen imply the occurrence of the charge transfer within the structure.

Fig. 2. The decrease of the Mo-Mo intracluster distance $d_{1}$ as a function of the charge transfer (or the VEC) (after Ref. (7)).

We are going to consider this charge transfer from the $M$ elements to the $\mathrm{Mo}_{6}$ cluster or better, the number of the valence electrons on the molybdenum atoms, the socalled VEC (valence electron concentration), which are available for the Mo-Mo intracluster bonding (8). In the first approximation, for instance, in the $\mathrm{PbMo}_{6} \mathrm{~S}_{8}$ compound, the lead atom transfers its two $p$ electrons to the $\mathrm{Mo}_{6} \mathrm{~S}_{8}$ unit, giving the $\mathrm{Pb}^{2+}$ ion, and the sulfur atoms accept 2 electrons to fill their $p$-states ( $\mathrm{S}^{2-}$ ); so there remain 22 electrons per $\mathrm{Mo}_{6}$ cluster or a VEC equal to 3.66 electrons per molybdenum. So, in the binary $\mathrm{Mo}_{6} \mathrm{~S}_{8}$, the VEC is 20 electrons per $\mathrm{Mo}_{6}$ cluster or $3.33 e^{-}$per Mo , the electronpoorest compound with the least regular cluster whereas in the $\mathrm{Cu}_{x} \mathrm{Mo}_{6} \mathrm{~S}_{8}$ solid solution, the $\mathrm{Cu}_{4} \mathrm{Mo}_{6} \mathrm{~S}_{8}$ compound with a VEC of $24 e^{-}$per cluster or $4 e^{-}$per molybdenum is the electron-richest compound and has the most regular $\mathrm{Mo}_{6}$ cluster. It seems that the counting of the VEC is also a measure of the Mo-Mo intracluster bonding. Actually, if we plot the Mo-Mo intracluster distance $d_{1}$ parallel to the direction of the threefold axis versus the charge transfer or
the number of valence electrons per cluster or per molybdenum (VEC), we obtain a good relationship between both variables (Fig. 2). The larger the charge transfer from the $M$ element onto the cluster (from an increased content or charge of the $M$ element) is or the VEC, the shorter the MoMo intracluster bonding $d_{1}$ becomes, and the more the $\mathrm{Mo}_{6}$ cluster is regular. In fact, the $\mathrm{Mo}_{6}$ cluster plays the role of an elec-tron-acceptor.
Furthermore, the band structure calculations, related to the pseudomolecular aspect of the structure, show the Fermi level falls in narrow bands that mainly arise from the $4 d$-molybdenum character. That narrow band is completely filled with 24 electrons per cluster or 4 electrons per Mo. Thus, an increase of the VEC from 20 to 24 electrons corresponds to a gradual filling of this conduction band.
One consequence of this gradual filling is the stability of the compounds. Really, the binary $\mathrm{Mo}_{6} \mathrm{~S}_{8}$ compound containing $20 e^{-}$ per cluster (the most elongated $\mathrm{Mo}_{6}$ cluster) is a metastable compound (it decomposes at $470^{\circ} \mathrm{C}$ ); it cannot be made through heat-
ing of its constitutive elements at high temperature, but only by deintercalation (9). So, if we change the VEC by substitution of two bromine or iodine atoms for two of sulfur, we obtain the pseudobinaries $\mathrm{Mo}_{6} \mathrm{~S}_{6} \mathrm{Br}_{2}$ and $\mathrm{Mo}_{6} \mathrm{~S}_{6} \mathrm{I}_{2}$ at high temperatures containing 22 electrons per cluster or a VEC equal to 3.66 electrons per Mo atom (10). These compounds are high- $T_{\mathrm{c}}$ superconductors ( 13.8 and 14 K , respectively) and have the same VEC that the two better ternary superconductors $\left(\mathrm{PbMo}_{6} \mathrm{~S}_{8}, \mathrm{SnMo}_{6} \mathrm{~S}_{8}\right)$. The synthesis of new pseudobinaries at high temperatures has been carried out, for instance, for the semiconducting pseudobinary $\left(\mathrm{Mo}_{2} \mathrm{Re}_{4}\right) \mathrm{S}_{8}$ with 24 electrons per cluster and a filled $d$-band (11).

## New Extended Clusters in Other Ternary Molybdenum Chalcogenides

Some general conclusions can be drawn when we consider obtaining new extended clusters in the ternary molybdenum chalcogenides: the number of valence electrons (VEC) available for Mo-Mo bonding must be increased to allow an increase in the number of the metallic bonding. In other words, the formal oxidation state will be lowered; i.e., the compounds will become more and more reduced and the ratio $X / \mathrm{Mo}$ will become lower and lower. Of course, the VEC will be a function of the charge transfer and the number of the counterions.

A considerable number of Mo-cluster chalcogenides closely related to the $\mathrm{Mo}_{6} X_{8}$ structure have been prepared at high temperatures. The syntheses of the ternary molybdenum chalcogenides have been performed using appropriate mixtures of Mo powder, $\mathrm{Mo} \mathrm{X}_{2}$ or $\mathrm{Mo}_{6} \mathrm{X}_{8}$ chalcogenide and $M$ element in the form of metallic grains ( $M$ $=\mathrm{Ag}, \mathrm{In}, \mathrm{Tl})$, binary compounds ( BaS ), or ternary compounds ( $M_{2} \mathrm{MoS}_{4}$ or $M_{2} \mathrm{Mo}_{6} X_{6}$ ) in evacuated silica tubes or sealed molybdenum crucibles.

The $M_{2} \mathrm{Mo}_{6} \mathrm{~S}_{6}$ phases ( $M=$ alkali metal)
can be obtained by different methods: reduction of $M \mathrm{MoS}_{2}$ under $\mathrm{H}_{2}$ flow at $950^{\circ} \mathrm{C}$ (12) or by solid-solid reaction between $M_{2} \mathrm{MoS}_{4}, \mathrm{MoS}_{2}$, and Mo powder in evacuated sealed silica tubes. The $M_{2} \mathrm{Mo}_{6} X_{6}(X=$ $\mathrm{Se}, \mathrm{Te}$ ) alkali metal phases are also synthesized by cationic exchange in a temperature gradient $\left(500^{\circ} \mathrm{C}\right.$-room temperature) according to the reaction $(5,6,13)$

$$
\begin{array}{rl}
\mathrm{In}_{2} \mathrm{Mo}_{6} X_{6}+2 & \mathrm{MCl} \xrightarrow{\text { between } 500 \text { and } 800^{\circ} \mathrm{C}} \\
& M_{2} \mathrm{Mo}_{6} X_{6}+2 \mathrm{InCl} \uparrow
\end{array}
$$

The new $M_{2 n-2} \mathrm{Mo}_{6 n} X_{6 n+2}$ series have been prepared from mixtures of $M_{2} \mathrm{Mo}_{6} X_{6}$ and $\mathrm{Mo}_{6} X_{8}$ phases ( $X=\mathrm{Se}$ ) (or $\mathrm{MoS}_{2}$ and Mo powder):

$$
\begin{aligned}
&(n-1) M_{2} \mathrm{Mo}_{6} X_{6}+ \mathrm{Mo}_{6} X_{8} \\
& M_{2 n-2} \mathrm{Mo}_{6 n} X_{6 n+2}
\end{aligned}
$$

The reaction is carried out in sealed molybdenum crucibles at $1300-1500^{\circ} \mathrm{C}$ (14). This method allows one to obtain single crystals of these later compounds and likewise, the pseudo-one-dimensional $\quad M_{2} \mathrm{Mo}_{6} X_{6}$ alkali metal compounds. The lattice parameters and the volumes of the unit cells in the new $M_{2 n-2} \mathrm{Mo}_{6 n} X_{6 n+2}$ series and the $M_{2} \mathrm{Mo}_{6} X_{6}$ compounds are reported in Tables I and II, respectively. The detailed structural pa-

rameters from single crystals are available in Ref. (14).

The principle of cluster condensation in the ternary molybdenum chalcogenides is based on the sharing of opposite faces of
the Mo-cluster octahedra when the ratio $X /$ Mo is decreased. All of these new cluster units derive from a linear progressive condensation of the $\mathrm{Mo}_{6} \mathrm{X}_{8}$ units along the ternary axis: as shown in Fig. 3, the $\mathrm{Mo}_{9} X_{11}$ and the $\mathrm{Mo}_{12} X_{14}$ units, the new $\mathrm{Mo}_{18} X_{20}$, $\mathrm{Mo}_{24} X_{26}, \mathrm{Mo}_{30} X_{32}$ block units, and then the limit of the series $(n=\infty)\left|M_{6 / 2} X_{6 / 2}\right|_{\infty}^{1}$ in a one-dimensional chain.

The units all belong to the same very general unit:

$$
\mathrm{Mo}_{3 n} X_{3 n+2} \quad(n \geq 2)
$$

This general formula allows a fragmental decomposition of the units. In fact, the $\mathrm{Mo}_{6} \mathrm{X}_{8}$ cubic unit observed along the threefold axis can be viewed as two $\mathrm{Mo}_{3} X_{3}$ starshaped planes ( $n=2$ ) capped by two chalcogen atoms on the threefold axis. Then, the $\mathrm{Mo}_{9} X_{11}$ unit ( $n=3$ ), the $\mathrm{Mo}_{12} X_{14}$ unit ( $n$ $=4$ ), and so on . . . can be, respectively, described as a stacking of three $\mathrm{Mo}_{3} \mathrm{X}_{3}$ starlike planes, four $\mathrm{Mo}_{3} X_{3}$ star-like planes, and so on . . . , always capped by two chalcogen atoms to give discrete units.

The Mo-Mo and Mo chalcogen intracluster distances in these longer clusters are like the intracluster distances in the $M_{x} \mathrm{Mo}_{6} X_{8}$ compounds. Apart from the infinite unit, the Mo terminal atoms $\left(\mathrm{Mo}_{3}\right.$

plane) in the top and bottom layers of these finite clusters have the same surroundings as the six Mo atoms of the $\mathrm{Mo}_{6} \mathrm{X}_{8}$ unit.

Each one of the six Mo terminal atoms is located to the center of square of chalcogen atoms and is interconnected to another unit by short Mo- $X$ intercluster bonds; this packing allows some Mo-Mo intercluster contacts. In the terminal $\mathrm{Mo}_{3} \mathrm{X}_{3}$ planes, the Mo atom has nine coordinated atoms: four Mo atoms and four $X$ atoms of the same unit and one $X$ chalcogen atom of a neighboring unit; the $X$ chalcogen atom has four metal neighbors: three Mo atoms of the same unit and one Mo atom of a different unit. In the central $\mathrm{Mo}_{3} X_{3}$ planes, the Mo atom has 10 coordinated atoms: six Mo atoms and four $X$ atoms in the same unit but no contacts with any atoms in the surrounding unit; the X atom has four Mo neighboring atoms of the same unit.

We can remark that the metal-ligand environment is the same as the ligand-metal
environment in the central plane: each atom is surrounded by four butterflyshaped different atoms, this allowing onedimensional polymerization.
The limit term of this series ( $n=\infty$ ) (Fig. 3) is $\left(\mathrm{Mo}_{3} X_{3}\right)_{\infty}^{1}$ and contains quasi-infinite columns of face-sharing $\mathrm{Mo}_{6}$ octahedra and contains only the central $\mathrm{Mo}_{3} \mathrm{X}_{3}$ planes.

## Relationships between the VEC and the Size of the Extended Cluster

In Table III are summarized the results on the new extended clusters. It is seen that the lowering of the formal oxidation state of the Mo atom or the increase of the valence electron concentration per Mo atom together with the decrease of the ratio $X / \mathrm{Mo}$ and the charge transfer from the $M^{n+}$ counterions are well related to the size of the extended clusters. We have already seen that in the first chalcogenides, the ratio $X /$

Fig. 4. Projection onto the ( $11 \overline{2} 0$ ) hexagonal plane of the $\mathrm{Tl}_{2} \mathrm{Mo}_{9} \mathrm{~S}_{11}$ compound.

Mo is 1.33 and the charge of the $\mathrm{Mo}_{6} X_{8}$ unit can vary from 0 to $4^{-}$, corresponding to 20 and 24 electrons per $\mathrm{Mo}_{6}$ cluster. For the ratio $X /$ Mo equal to $1.26_{7}$, we have two kinds of compounds in which two types of building blocks coexist: $\mathrm{Mo}_{6} X_{8}$ and $\mathrm{Mo}_{9} X_{11}$ units. Based on the assumption of the variation in the negative charge (from 0 to 4) of the $\mathrm{Mo}_{6} X_{8}$ unit as the $M_{x} \mathrm{Mo}_{6} X_{8}$ compounds, and accounting for the charge transfer of the indium or barium counterions, the formal Mo-electron number found on the $\mathrm{Mo}_{9} X_{11}$ unit will be between 30 and 36 electrons per Mo , cluster. This corresponds to the same range of the VEC per Mo atom as before ( 3.33 to $4 e^{-}$). For the ratio $11 / 9$ or $1.22_{2}$, we have therefore two kinds of compounds: one containing the only $\mathrm{Mo}_{9} \mathrm{Se}_{11}$ unit in $\mathrm{Ag}_{3.6} \mathrm{Mo}_{9} \mathrm{Se}_{11}$ (15) with almost 4 electrons per Mo and the other one,
$\mathrm{Tl}_{2} \mathrm{Mo}_{9} \mathrm{~S}_{11}$, where both $\mathrm{Mo}_{6} \mathrm{X}_{8}$ and $\mathrm{Mo}_{12} X_{14}$ units cocrystallize. With the same assumption as before, the $\mathrm{Mo}_{12}$ cluster will count between 44 and $48 e^{-}$, corresponding to a VEC range between 3.66 and 4 electrons per Mo atom.
The new condensed cluster selenides synthesized recently by Gougeon (14) are obtained by further reduction of the $X / \mathrm{Mo}$ ratio. The ratio in these lies between $1.16_{7}$ and $1.06_{6}$ as the new clusters become larger and larger: the $\mathbf{M o}_{12}, \mathbf{M o}_{18}, \mathbf{M o}_{24}$, and $\mathbf{M o}_{30}$ clusters are more and more extended and are multiples of the primary $\mathrm{Mo}_{6}$ octahedra. The new $\left(\mathrm{Mo}_{12} \mathrm{Se}_{14}\right),\left(\mathrm{Mo}_{18} \mathrm{Se}_{20}\right)$, $\left(\mathrm{Mo}_{24} \mathrm{Se}_{26}\right)$, $\left(\mathrm{Mo}_{30} \mathrm{Se}_{32}\right)$ units have twofold, fourfold, sixfold, and eightfold negative formal charges, respectively, and a VEC per Mo atom increasing from $3.83,4,4.08$ to 4.13 , respectively. It is a stepwise condensation of the $\mathrm{Mo}_{6} X_{8}$ units.

At the end of the linear condensation of these units, the infinite limit chain $\left|\mathrm{Mo}_{6 / 2} X_{6 / 2}\right|_{\infty}^{1}$ has a $1-$ negative charge for each planar $\mathrm{Mo}_{3} X_{3}$ unit in the $\mathrm{Tl}_{2} \mathrm{Mo}_{6} \mathrm{Se}_{6}$ compound, and it corresponds to 13 electrons per $\mathrm{Mo}_{3}$ plane and a VEC of 4.33 per Mo atom.

What is the structural tridimensional arrangement of these different condensed clusters? The different stacking of the $\mathrm{Mo}_{6} X_{8}$ and $\mathrm{Mo}_{9} X_{11}$ block units provides two families of superconducting-type compounds: $\mathrm{In}_{2} \mathrm{Mo}_{15} \mathrm{Se}_{19}$ and $\mathrm{In}_{\sim 3} \mathrm{Mo}_{15} \mathrm{Se}_{19}$ (16, 17). The $M_{2} \mathrm{Mo}_{9} \mathrm{~S}_{11}$ compounds ( $M=\mathrm{K}, \mathrm{Tl}$ ) do not contain the $\mathrm{Mo}_{9} X_{11}$ unit but the two mixed $\mathrm{Mo}_{6} \mathrm{~S}_{8}$ and $\mathrm{Mo}_{12} \mathrm{~S}_{14}$ units where onehalf of the $\mathrm{Mo}_{6} \mathrm{~S}_{8}$ units are replaced by the $\mathrm{Mo}_{12} \mathrm{~S}_{14}$ units of the same ( $\overline{3}$ ) point symmetry (18). The sequence along the $c$ hexagonal axis is $\mathrm{Mo}_{6} \mathrm{~S}_{8}-\mathrm{Tl}-\mathrm{Tl}-\mathrm{Mo}_{12} \mathrm{~S}_{14}$ (Fig. 4). The different length of the $\mathrm{Mo}_{12} \mathrm{~S}_{14}$ unit with respect to the $\mathrm{Mo}_{6} \mathrm{~S}_{8}$ unit leaves large vacant sites between two units along the $c$ hexagonal axis where two thallium monovalent ions are located.

The new compounds in the $M_{2 n-2}$

Fig. 5. Projection onto the (11 $\overline{2} 0$ ) hexagonal plane of the $M_{2 n-2} \mathrm{Mo}_{6 n} X_{6 n+2}$ series. $\mathrm{Mo}_{6} \mathrm{Se}_{8}$ (a), $\mathrm{Cs}_{2}$ $\mathrm{Mo}_{12} \mathrm{Se}_{14}$ (b), $\mathrm{Rb}_{4} \mathrm{Mo}_{18} \mathrm{Se}_{20}$ (c), $\mathrm{Cs}_{6} \mathrm{Mo}_{24} \mathrm{Se}_{26}$ (d), and $\mathrm{Cs}_{8} \mathrm{Mo}_{30} \mathrm{Se}_{32}$ (e).
$\mathrm{Mo}_{6 n} X_{6 n+2}$ family crystallize in the same space group $R \overline{3}$ as do the $M_{x} \mathrm{Mo}_{6} X_{8}$ phases. These compounds are richer and richer in molybdenum atoms (the ratio of chalcogen to Mo decreases) and contain longer and longer units with more and more extended clusters. Every $\mathrm{Mo}_{6} \mathrm{X}_{8}$ unit is replaced by the condensed $\mathrm{Mo}_{6 n} X_{6 n+2}$ unit of the $\overline{3}$ same symmetry. These condensed units create larger and larger tridimensional channels which run along the three rhombohedral axes (Fig. 5). Of course, more large cations like alkali metals Rb , Cs occur in these channels along the threefold axis with increasing content.

The first results on the transport properties performed on single crystals of the $\mathrm{Cs}_{2}$ $\mathrm{Mo}_{12} \mathrm{Se}_{14}$ and $\mathrm{Cs}_{6} \mathrm{Mo}_{24} \mathrm{Se}_{26}$ ternary selenides show that these exhibit superconducting transitions ( $T_{\mathrm{c}} \sim 4$ and 3 K , respectively) though the $\mathrm{Cs}_{6} \mathrm{Mo}_{24} \mathrm{~S}_{26}$ compound shows a drastic metal-insulator
transition at 112 K in the resistivity associated with a structural transition.
This lengthening of these units leads directly to the one-dimensional compounds with the $\mathrm{Tl}_{2} \mathrm{Mo}_{6} \mathrm{Se}_{6}$-type structure $(19,20)$. In this type of compound, there are no terminal Mo atoms because there are no capped chalcogen ligands on the threefold axis and no square-face ligands. Thus, there are no close contacts between the different chains as in the previous clusters (intercluster distances $\sim 6.30 \AA$ ).

These infinite $\left(\mathrm{Mo}_{6 / 2} \mathrm{Se}_{66}\right)_{\infty}^{1}$ chains are separated by the Tl monovalent ions and $\mathrm{Se}-\mathrm{Se}$ van der Waals contacts (Fig. 6). Thus the resistivity measurements performed on single crystals indicate a very high anisotropy ( $\rho_{\perp} / \rho_{\|}$above 1000). This result fits with the anisotropy of the critical field of the superconducting $\mathrm{Tl}_{2} \mathrm{Mo}_{6} \mathrm{Se}_{6}$ compound ( $T_{\mathrm{c}} \sim 6 \mathrm{~K}$ ) (21-23).

On the contrary, the low resistivities of

Fig. 6. Projection onto the (11 $\overline{2} 0)(a)$, and ( 0001 ) (b) hexagonal planes of the $\mathrm{Tl}_{2} \mathrm{Mo}_{6} \mathrm{Se}_{6}$ structure.
the alkali metal compounds at room temperature ( $\rho_{\mathrm{RT}} \sim 0.1$ to $1 \mathrm{~m} \Omega \mathrm{~cm}$ ) increase strongly at low temperature (below 70 K ) by factors of $10^{3}$ to $10^{8}$.

These results have opened up a lot of research on many cluster compounds. Some recent results provide hope for establishing a solution-phase chemistry such as the well-known chemistry of the $\mathrm{Mo}_{6} \mathrm{Cl}_{8}^{4+}$ ion.
