 $U_4Mo_5Si_3$ and $U_4Cr_6Si_2$ have been synthesized by argon arcmelting the elemental combinations and annealing at 1400°C. The homogeneity domains of $U_4Mo_{5+x}Si_{3-x}$ and $U_4Cr_{6+y}Si_{2-y}$ have been established by X-ray powder and single-crystal diffraction analysis and range from x = 0 to 1 and from y = -0.5to 1. Single-crystal X-ray studies have shown that the transition metal and the silicon are both distributed on the two sites occupied by zinc in the Laves phase MgZn₂ (*6h* and 2*a* positions in *P*6₃/*mmc*). Magnetic investigations of these compounds revealed temperature-independent paramagnetism as a result of the very short uranium–uranium distance found in the structure determinations. © 1996 Academic Press, Inc.

INTRODUCTION

As part of our systematic study of phase relationships in the U-Mo-Si system at 1400°C (1), we have prepared the ternary uranium molybdenum silicide U₄Mo₅Si₃. The existence of this compound and also U₄Fe₆Si₂, U₄Cr₆Si₂, $U_4Mn_5Si_3$, and $U_4Co_6Si_2$, which have the MgZn₂ structure type (2, 3), was reported in the 1960s by Sikirica and Ban (4) and Kusma and Nowotny (5, 6). In this structural type (space group $P6_3/mmc$), magnesium is in the 4f position and zinc occupies crystallographic sites of multiplicity 6 and 2. It was postulated that, in $U_4Cr_6Si_2$, the transition metal occupies a 6h position and silicon a 2a position. On the other hand, the formulation U₄Mo₅Si₃ suggests a disorder on the 6h and 2a positions and therefore the existence of a homogeneity domain. In the present paper we describe the preparation, the structural chemistry, and the magnetic behavior of $U_4Mo_5Si_3$ and $U_4Cr_6Si_2$.

EXPERIMENTAL DETAILS

The pseudo-ternary phases $U(Mo_xSi_{1-x})_2$ and $U(Cr_ySi_{1-y})_2$ have been synthesized by argon arc-melting

ingots of the elements. In order to avoid oxidation due to slightly surface-oxidized molybdenum and chromium, those two metals were first melted individually once. To ensure homogeneity, the alloy pellets were turned over and remelted several times. The weight losses were below 0.5 wt%. Various compositions ranging between 4:6:2 and 4:5:3 were prepared and a homogeneity domain was revealed for the molybdenum and the chromium compounds by X-ray diffraction. Small single crystals were obtained by heating the arc-melted pellets at high temperature (~1500°C) for few hours followed by slow cooling.

Single-crystal X-ray diffraction studies were performed using an automatic Enraf–Nonius CAD 4 four-circle diffractometer with graphite monochromated MoK α radiation ($\lambda = 0.71069$ Å). The lattice parameters were obtained by least-squares refinement of the setting angles of 25 reflections. Details of the intensity data collection and crystallographic data are summarized in Table 1. Intensities were corrected for Lorentz and polarization effects. After isotropic refinement, an empirical absorption correction was performed by means of the DIFABS program (7). All calculations were carried out on a VAX 3100 microcomputer using the SDP crystallographic software packages (8). The structure was refined in the space group $P6_3/mmc$, with the positions of all atoms being assigned by analogy with the structure of MgZn₂.

STRUCTURAL CHEMISTRY

Crystal Structure of U₄Mo₅Si₃

The uranium atom was found to occupy the 4*f* position $(\frac{1}{3}, \frac{2}{3}, z)$. The electronic densities calculated from a difference Fourier analysis revealed some statistical distribution of molybdenum and silicon on the 6*h* (*x*, 2*x*, $\frac{1}{4}$ and the 2*a* (0, 0, 0) crystallographic sites: four molybdenum and two silicon atoms are located on the 6*h* site and one molybdenum and silicon atom on the 2*a* site. This result is in disagreement with that previously obtained from powder data (6), in which an ordered distribution of transition metals and silicon over the 6*h* and 2*a* positions, respectively, was

assumed. After refinement, the final residual value was R = 0.018. The final position and thermal parameters are listed in Table 2 and selected interactomic distances are presented in Table 3.

The crystal structure of $U_4Mo_5Si_3$ is shown in Fig. 1. It can be seen that the alternating layers of molybdenum (or silicon) and uranium follow the sequence X2-U-X1-U-X2-U-X'1-U-X2 (X = molybdenum or silicon). The uranium atom is surrounded by 16 atoms, which form a Friauf polyhedron (2, 9) previously described by Komura and Tokunaga in (10). The 6h and 2a sites have icosahedral coordinations.

One of the interesting aspects of this structure is the existence of a very short uranium–uranium distance (3.127 Å), close to that existing in metallic uranium (3.10 Å). This implies a strong delocalization of the 5*f* electrons of uranium, and thus one can expect a temperature-independent paramagnetic behavior for this compound.

Crystal Structure of U₄Cr₆Si₂

The structures of three crystals grown from mixtures with nominal starting compositions 4:6:2, 4:6:2, and

TABLE 3Interatomic Distances (Å) for $U_4Mo_5Si_3$ (X = Mo or Si)

U-3 <i>X</i> 1 6 <i>X</i> 1 1U	3.0926(3) 3.1086(6) 3.1271(8)	X1–2X1 2X2 2X1	2.612(1) 2.662(1) 2.761(1)	X2–6X1 6U	2.662(1) 3.1536(1)
3 <i>X</i> 2 3U	3.1536(1) 3.3036(3)	2U 4U	3.0926(3) 3.1086(6)		

4:5:3 have also been refined from single-crystal X-ray diffraction data. The results are summarized in Tables 4, 5, and 6. Rather poor quality of crystals 1 and 3 resulted in weaker diffraction intensities and higher final *R* values. Structure factor tables are available from the authors upon request.

In each case, the uranium atom is situated in the 4*f* position $(\frac{1}{3}, \frac{2}{3}, z)$. The site occupancy refinements for the $6h(x, 2x, \frac{1}{4})$ and 2a(0, 0, 0) positions gave the following atomic distributions:

	Crystal 1	Crystal 2	Crystal 3
6h site (X1)	5 Cr + 1 Si	6 Cr	4.7 Cr + 1.3 Si
2a site (X2)	1 Cr + 1 Si	1 Cr + 1 Si	0.8 Cr + 1.2 Si
Formula	$U_4Cr_6Si_2$	U ₄ Cr ₇ Si	$U_4Cr_{5.5}Si_{2.5}$

Taking into account these structural results, we can assume that the homogeneity domain spreads at least from U_4Cr_7Si to $U_4Cr_{5.5}Si_{2.5}$. As with $U_4Mo_5Si_3$, uranium–uranium metal bonds are also inferred in these crystals, with the shortest U–U distance (2.939 Å) existing for the composition $U_4Cr_{5.5}Si_{2.5}$.

MAGNETISM

The magnetic properties have been studied in the temperature range 5–300 K using a SQUID magnetometer and are summarized in Fig. 2.

$U_4 Mo_5 Si_3$

As shown in Fig. 2, $U_4Mo_5Si_3$ exhibits a temperatureindependent paramagnetism between 10 and 300 K ($\chi_m \sim$

TABLE 2 Atomic Parameters for $U_4Mo_5Si_3$ (X = Mo or Si)

Note. $B = (\frac{4}{3}) \sum_{i,j} \beta_{i,j} a_i \cdot a_j$. The coefficients for anisotropic thermal measurements are expressed as $\exp -[h^2 \beta_{11} + k^2 \beta_{22} + l^2 \beta_{33} + hk \beta_{12} + hl \beta_{13} + kl \beta_{23}]$. Standard deviations in the least significant digits are given in parentheses.

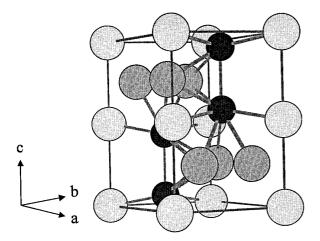

FIG. 1. Perspective view of the crystal structure of $U_4Mo_5Si_3$ (X = Mo or Si; X1, dark gray circles; X2, gray circles; U, black circles). Bonding distances shorter than 3.2 Å around uranium atoms are shown.

 4.3×10^{-3} emu/mole). As stated above, this behavior is consistent with the existence of very short uranium– uranium bonds in this structural type. The small increase of the susceptibility below 10 K is probably due to the presence of magnetic impurities. The absence of magnetic interactions at low temperature is confirmed by the curve of magnetization versus magnetic field at 5 K (Fig. 2, insert), which is linear and reversible.

$U_4Cr_6Si_2$

The magnetic behavior of $U_4Cr_6Si_2$ (as well as of $U_4Cr_{5.5}Si_{2.5}$) is similar to that found for $U_4Mo_5Si_3$, with

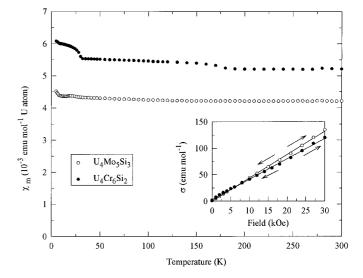

FIG. 2. Susceptibility per uranium atom vs temperature for $U_4Mo_5Si_3$ and $U_4Cr_6Si_2$. Magnetization vs field is also shown.

a temperature-independent paramagnetism of 5.5×10^{-3} emu/mole. The slight variation of the susceptibility at about 170 K and below 25 K is thought to be due to impurities.

CONCLUSION

The parameters of the atomic positions of the Lavesphase-type compounds $U_4(Mo_xSi_{1-x})_8$ and $U_4(Cr_xSi_{1-x})_8$ have been refined, and it has been found that, in both cases, the transition metal and the silicon are distributed over the two sites occupied by zinc in the Laves phase

MgZn₂. The homogeneity domain which results from this fact is larger in the system U–Cr–Si (U₄Cr_{5.5}Si_{2.5}–U₄Cr₇Si) than in the system U–Mo–Si (U₄Mo₅Si₃–U₄Mo₆Si₂) (1). The magnetic properties of these compounds are consistent with their structural characteristics: the very short uranium–uranium distances involve a very strong 5f-5f overlap, with metallic bonding and therefore the absence of a localized moment. As a consequence, measurements at very low temperature (<1 K) should be interesting to check for the possible occurrence of superconductivity.
