#### Abstract

The crystal structure of $\mathrm{Ba}_{2} \mathrm{~V}_{3} \mathrm{O}_{9}$ has been determined and refined to final $R$ and $R_{w}$ values of 0.025 and 0.028 from 1562 independent single crystal reflections. It crystallizes in the space group $P 2_{1} / m$ with $a=9.302(1) \AA, b=5.969(1) \AA, c=8.118(1) \AA$, and $\beta=113.96(1)^{\circ}$. The structure consists of one-dimensional rutile-type chains of edge-sharing $\mathrm{VO}_{6}$ octahedra parallel to the $b$ axis. The $\mathrm{VO}_{4}$ tetrahedra share corners with $\mathrm{VO}_{6}$ octahedra of a single rutile-type chain to form one-dimensional $\left[\mathrm{V}_{3} \mathrm{O}_{9}\right]_{\infty}^{4-}$ columns which are held together by $\mathrm{Ba}^{2+}$ ions. In this mixed valence compound $\mathrm{V}^{4+}$ and $\mathrm{V}^{5+}$ ions are distributed in an ordered way in octahedra and tetrahedra, respectively. In the almost perfect $\mathrm{O}_{6}$ octahedron the vanadium atom is off-center so that it forms a short vanadyl $\mathrm{V}=\mathrm{O}$ bond of $1.686(3) \AA$, typical of a $\mathrm{V}^{4+}$ ion. This compound is a barium vanadyl vanadate $\mathrm{Ba}_{2}(\mathrm{VO})\left(\mathrm{VO}_{4}\right)_{2}$. It is the first example of isolated rutile-type chains found with $\mathrm{V}^{4+}$ ions. Magnetic susceptibility measurements show that this phase is an antiferromagnet with $T_{\mathrm{N}} \cong$ 58 K . At about 20 K magnetic anisotropy causes a canted spin arrangement. © 1996 Academic Press, Inc.

## INTRODUCTION

Mixed valence vanadium compounds are important in solid state chemistry because the many oxidation states lead to a variety of crystal structures and nonstoichiometric phases. They exhibit complex magnetic and electrical properties. Recently Mentre and Abraham (1) discovered two new compounds in the $\mathrm{Pb}-\mathrm{V}-\mathrm{O}$ system,

[^0]$\mathrm{Pb}_{1.32} \mathrm{~V}_{8.35} \mathrm{O}_{16.7}$ and $\mathrm{PbV}_{6} \mathrm{O}_{11}$. The former adopts a hol-landite-related structure with lead atoms and $\mathrm{VO}_{4}$ tetrahedra occupying the large tunnels of the $\mathrm{V}_{8} \mathrm{O}_{16}$ hollandite framework. The structure of the latter is closely related to that of $A \mathrm{~V}_{6} \mathrm{O}_{11}$ compounds $(A=\mathrm{Na}, \mathrm{Sr})$ which crystallize with an $R$-type hexagonal ferrite structure (2-4). A solid solution phase $\mathrm{BaV}_{10-x} \mathrm{O}_{17}(0.10 \leq x \leq$ 0.65 ) has been described that also displays a modified hollandite structure whose tunnels accommodate alternately Ba and O atoms. The tunnel O atoms generate octahedral sites which are statistically occupied by V atoms, thus causing the wide solid-solution range (5). Bouloux et al. (6) have reported a hollandite-type phase $\mathrm{Ba}_{x} \mathrm{~V}_{8} \mathrm{O}_{16},(1.20 \leq x \leq 1.36)$, and very recently Kanke et al. (7) refined the crystal structure of the tetragonal priderite-type compound $\mathrm{Ba}_{1.09} \mathrm{~V}_{8} \mathrm{O}_{16}$. These phases contain both trivalent and tetravalent vanadium cations. The recently described $\mathrm{Ba}_{8} \mathrm{~V}_{7} \mathrm{O}_{22}$ is the first example of a vandium oxide phase in which all three oxidation states of vanadium, $\mathrm{V}^{3+}, \mathrm{V}^{4+}$, and $\mathrm{V}^{5+}$, coexist (8). Although barium trivalent or tetravalent vanadyl phosphates and arsenates have been described (9-15), no barium vanadyl(IV) vanadate has been characterized to date.

During our attempts to prepare barium mixed-valence vanadium oxides, single crystals whose composition corresponded to $\mathrm{Ba}_{2} \mathrm{~V}_{3} \mathrm{O}_{9}$ were often obtained. This compound was first synthesized by Bouloux et al. (6) and was shown to crystallize in the monoclinic system, but its crystal structure was not determined. The chemical composition seems to indicate the presence of $\mathrm{V}^{4+}$ and $\mathrm{V}^{5+}$ and we undertook a single crystal X-ray diffraction structure determination as well as magnetic and IR studies. The results of these experiments show that indeed the compound is a barium vanadyl(IV) vanadate, $\mathrm{Ba}_{2}(\mathrm{VO})\left(\mathrm{VO}_{4}\right)_{2}$.

## EXPERIMENTAL

## Synthesis

$\mathrm{Ba}_{2} \mathrm{~V}_{2} \mathrm{O}_{7}$ was obtained by heating a mixture of $\mathrm{BaCO}_{3}$ (Aldrich 98\%) and $\mathrm{V}_{2} \mathrm{O}_{5}$ (Aldrich $99.6 \%$ ) in a $2: 1$ molar ratio at $750^{\circ} \mathrm{C}$ for 5 days. $\mathrm{V}_{2} \mathrm{O}_{3}$ was obtained by reducing $\mathrm{V}_{2} \mathrm{O}_{5}$ in hydrogen at $850^{\circ} \mathrm{C}$. Bouloux et al. (6) prepared $\mathrm{Ba}_{2} \mathrm{~V}_{3} \mathrm{O}_{9}$ by solid state reaction between $\mathrm{Ba}_{2} \mathrm{~V}_{2} \mathrm{O}_{7}$ and $\mathrm{VO}_{2}$. In our experiments $\mathrm{VO}_{2}$ was prepared in situ, thus $\mathrm{Ba}_{2} \mathrm{~V}_{2} \mathrm{O}_{7}, \mathrm{~V}_{2} \mathrm{O}_{5}$, and $\mathrm{V}_{2} \mathrm{O}_{3}$ were mixed in a $4: 1: 1$ molar ratio. About 0.3 g of the mixture was introduced into a gold tube, sealed in an evacuated silica tube, and then heated at $900^{\circ} \mathrm{C}$ for 48 h . Regrinding and reheating was needed to achieve a single phase product as evidenced by the match of the powder X-ray diffraction pattern with that reported for $\mathrm{Ba}_{2} \mathrm{~V}_{3} \mathrm{O}_{9}$ (16).

Single crystals were obtained from the same mixture heated at $1010^{\circ} \mathrm{C}$, cooled at $4^{\circ} \mathrm{C} / \mathrm{h}$ to $850^{\circ} \mathrm{C}$, and then furnace cooled. Red, acicular, crystals were obtained. Bouloux et al. (6) reported the lattice parameters and space group from Weissenberg photographs and indexed the X-ray diffraction powder data using a nonstandard, $B$-centered monoclinic cell with $a=8.108(6) \AA, b=5.970(4) \AA$, $c=17.02(1) \AA$, and $\beta=91.96(10)^{\circ}$. We transformed to a primitive cell and the lattice parameters reported in Table 1 resulted from a least-squares refinement of an indexed powder X-ray diffraction pattern obtained with a Siemens D5000 diffractometer equipped with a graphite crystal diffracted-beam monochromator and $\mathrm{Cu} K \alpha$ radiation.

## Single Crystal X-Ray Analysis

Preliminary Weissenberg photographs confirmed the $2 / m$ diffraction symmetry. The data collection parameters are reported in Table 1. Intensities were corrected for Lorentz-polarization effects. Absorption corrections were applied using the analytical method of De Meulenaer and Tompa (17). The density was determined with a AccuPyc 1330 He gas displacement pycnometer. The systematic absences $k=2 n+l$ for $0 k 0$ are consistent with space groups $P 2_{1}$ (No. 4) and $P 2_{1} / m$ (No. 11). The structure was successfully solved and refined in $P 2_{1} / \mathrm{m}$. The coordinates of the barium atoms were determined from a three dimensional Patterson synthesis. Difference Fourier syntheses calculated at subsequent stages located the vanadium and oxygen atoms. Atom $V(3)$ was statistically distributed over its crystallographic site. The refinement of the coordinates and the anisotropic displacement parameters shown in Tables 2 and 3 converged to $R=0.025, R_{\mathrm{w}}=0.028$, Table 1. Values of the scattering factors for neutral atoms were obtained from (18) and the anomalous dispersion corrections from Cromer and Liberman (19). The full matrix least squares refinements were performed with a local mod-

${ }^{a} B_{\text {eq }}$ is defined by $B_{\text {eq }}=4 / 3 \sum_{i} \Sigma_{j} \beta_{i j} a_{i} a_{j}$.
netic susceptibilities were measured with a Quantum Design DC SQUID magnetometer over the range $10-300 \mathrm{~K}$ for zero-field-cooled (ZFC) samples and over the range $300-10 \mathrm{~K}$ for field-cooled (FC) samples. The measurements for ZFC were taken by equilibrating the sample at 10 K , switching on a magnetic field of 3 kOe , and recording the magnetization as a function of temperature to 300 K . With the applied field on, measurements of susceptibility were then continued while the sample was cooled from 300 to 10 K to obtain FC data.

## DISCUSSION

Selected bond distances and bond angles are given in Table 4. A projection of the structure along the $b$ axis is shown in Fig. 1. V(1) and $V(2)$ are tetrahedrally coordinated to oxygen and $V(3)$ is in an octahedral environment.

The $\mathrm{V}(3) \mathrm{O}_{6}$ octahedra form linear, rutile-type, edge-sharing chains parallel to $\mathbf{b}$. The $\mathrm{V}(1) \mathrm{O}_{4}$ and $\mathrm{V}(2) \mathrm{O}_{4}$ tetrahedra share corners with the $\left[\mathrm{V}(3) \mathrm{O}_{4}\right]_{\infty}$ chains to constitute infinite, one-dimensional columns of the formula $\left[\mathrm{V}_{3} \mathrm{O}_{9}\right]_{\infty}^{4-}$, (Fig. 2). The columns are held together by Ba ions.

Rutile chains are found both in low-temperature and high-temperature forms of vanadium dioxide. In the tetragonal high-temperature form the six $\mathrm{V}-\mathrm{O}$ distances are nearly equal and the $\mathrm{V}-\mathrm{V}$ separation is 2.87 A . Below $69^{\circ} \mathrm{C}, \mathrm{VO}_{2}$ transforms to the monoclinic variety in which the chains of cations sharing octahedral edges have alternating short, $2.62 \AA$, and long, $3.17 \AA$, separations creating a charge density wave. The $\mathrm{VO}_{6}$ octahedra in the two forms display different distortions. In the tetragonal case the distance between the bridging oxygen atoms shortens in order to minimize the electrostatic repulsion between $\mathrm{V}^{4+}$ ions. The $\alpha$ ratio, the distance between bridging anions to

FIG. 1. The $\mathrm{Ba}_{2} \mathrm{~V}_{3} \mathrm{O}_{9}$ structure projected on (010).
the average of the remaining interanion separations along octahedral edges, is close to 0.9 . In the monoclinic form, the bridging oxygen atoms are displaced from each other, allowing the formation of $\mathrm{V}-\mathrm{V}$ metal bonds across the octahedral edge and $\alpha$ is 0.97 (21). In $\mathrm{Ba}_{2} \mathrm{~V}_{3} \mathrm{O}_{9}$ the bridging $\mathrm{O}(6)-\mathrm{O}(7)$ bond is shortened and $\alpha$ is 0.92 . Thus the structure is essentially ionic and no metal-metal bonds are present. However, $\mathrm{V}(3)$ is displaced from the center of the octahedron toward $\mathrm{O}(6)$ and the $\mathrm{V}(3)-\mathrm{O}(6)$ distance, 1.686(3) $\AA$, is characteristic of a double $\mathrm{V}=\mathrm{O}$ bond. This distance is about $0.30 \AA$ shorter than the four equatorial $\mathrm{V}-\mathrm{O}$ bonds ranging from $1.981(3)$ to $2.048(2) \AA$. The $\mathrm{V}(3)-\mathrm{O}(6)$ bond trans to the double bond is $2.240(3) \AA$.

FIG. 2. The column $\left[\mathrm{V}_{3} \mathrm{O}_{9}\right]_{\infty}^{4-}$ in $\mathrm{Ba}_{2} \mathrm{~V}_{3} \mathrm{O}_{9}$.

FIG. 3. The $\mathrm{V}(3)$ displacement within a single rutile-type chain in $\mathrm{Ba}_{2} \mathrm{~V}_{3} \mathrm{O}_{9}$.

The $\mathrm{V}(3)$ atom is disordered and occupies a site randomly displaced from the $(0,0,1 / 2)$ octahedron center toward the two $\mathrm{O}(6)$ atoms. In one rutile-type chain two adjacent $\mathrm{V}(3)$ atoms need to be related by a $2_{1}$ axis and the $\mathrm{V}(3)$ displacement is cooperative intrachain but not interchain, leading to a $\mathrm{V}(3)-\mathrm{V}(3)$ distance of 3.007 (1) $\AA$ (Fig. 3). If this is not the case it would lead to the unlikely configuration $\mathrm{O}=\mathrm{V}=\mathrm{O}$. The long $\mathrm{V}-\mathrm{V}$ distance doesn't allow vanadium $t_{2 g}$ orbitals to overlap leading to a localized electron system. Indeed, $\mathrm{Ba}_{2} \mathrm{~V}_{3} \mathrm{O}_{9}$ is an insulator between room temperature and 30 K . Random displacement of the $\mathrm{V}(3)$ atoms in the octahedra occurs among the columns. If V(3) were displaced toward the same $\mathrm{O}(6)$ atom for all the columns the space group becomes $P 2_{1}$. Refinement in $P 2_{1}$ led to greater values of $R=0.036$ and $R_{\mathrm{w}}=0.044$ in spite of a greater number of refined parameters, 127. This model can be safely rejected on the basis of the Hamilton ratio test $R_{127,1435,0.005} \approx 1.05$ as compared to the observed ratio 1.57 (18).

The $\mathrm{V}(1) \mathrm{O} 4$ and $\mathrm{V}(2) \mathrm{O} 4$ tetrahedra share corners with the VO6 octahedra. The $\mathrm{V}(1) \mathrm{O} 4$ tetrahedra are bidentate, bridging two adjacent VO6 octahedra through $\mathrm{O}(2)$. The $\mathrm{V}(2) \mathrm{O} 4$ tetrahedra share $\mathrm{O}(7)$ with the octahedra. The $\mathrm{O}(6)$ oxygen atom of the vanadyl bond is unshared. Within tetrahedra the $\mathrm{V}-\mathrm{O}$ distances to oxygen atoms shared with VO6 octahedra are longer than the V-O distances to unshared oxygen atoms (Table 4). The average V-O bond lengths for $V(1)$ and $V(2)$ atoms, 1.71(6) and 1.72(9) $\AA$, respectively, are in good agreement with the sum of ionic radii of $\mathrm{V}^{5+}$ in C.N.IV and $\mathrm{O}^{2-}, 1.73 \AA$, whereas the average $\mathrm{V}(3)-\mathrm{O}$ bond length of $2.0 \AA$ agrees with $r\left[\mathrm{~V}^{4+}\right.$ (C.N.VI)] $+r\left(\mathrm{O}^{2-}\right)=1.96 \AA$ (22). These results strongly suggest that $\mathrm{V}(1)$ and $\mathrm{V}(2)$ are $\mathrm{V}^{5+}$ and $\mathrm{V}(3)$ is $\mathrm{V}^{4+}$. Moreover bond-length and bond-strength calculations using the method of Brown and Shannon (23) and the data of Brown and Altermatt (24) give bond valence sums for $\mathrm{V}(1)=$
5.14, $\mathrm{V}(2)=5.09$, and $\mathrm{V}(3)=3.81$, indicating that $\mathrm{V}(1)$ and $\mathrm{V}(2)$ are pentavalent and that $\mathrm{V}(3)$ is tetravalent. Based on these results this mixed valence vanadium oxide is a vanadyl(IV) vanadate and the chemical formula can be written as $\mathrm{Ba}_{2}\left(\mathrm{~V}^{4+} \mathrm{O}\right)\left(\mathrm{V}^{5+} \mathrm{O}_{4}\right)_{2}$.
$\mathrm{Ba}(1)$ is coordinated by 10 oxygen atoms with an average $\mathrm{Ba}-\mathrm{O}$ distance of $2.86(15) \AA$ while $\mathrm{Ba}(2)$ is coordinated by six oxygen atoms forming a distorted octahedron with an average $\mathrm{Ba}-\mathrm{O}$ distance 2.75(3) Å with a seventh oxygen atom at $3.190(4) \AA$ (Fig. 4). The bond valence sums for $\mathrm{Ba}(1)$ and $\mathrm{Ba}(2)$ are 2.32 and 1.78 , respectively, and the underbonding for $\mathrm{Ba}(2)$ may be the cause of the larger value of the displacement parameter.
$\mathrm{Ba}_{2}(\mathrm{VO})\left(\mathrm{VO}_{4}\right)_{2}$ is the first example of a vanadium compound containing isolated rutile-type chains linked to tetrahedra. In $\mathrm{VO}_{2}$, the rutile chains are connected to each other by corner sharing (Fig. 5a); in hollandite and hol-landite-related compounds the rutile chains share edges to form double strings and the double strings are connected at their corners to form a $\left[\mathrm{V}_{8} \mathrm{O}_{16}\right]$ framework structure (Fig. 5b). In the hollandite-related structure $\mathrm{Pb}_{1.32} \mathrm{~V}_{8.35}$ $\mathrm{O}_{16.70}$, extra $\mathrm{VO}_{4}$ tetrahedra occupy the large tunnels of the [ $\mathrm{V}_{8} \mathrm{O}_{16}$ ] framework and are attached to the $\mathrm{VO}_{6}$ octahedral framework (1). Isolated rutile chains are found with metal ions other than vanadium in compounds of formula $A_{2} \mathrm{MO}_{4}$, e.g., in $\mathrm{Pb}_{2} \mathrm{PtO}_{4}$ (25), in which the rutile chains are connected only by $A^{2+}$ ions (Fig. 5c).

Different types of one-dimensional chains separated by $\mathrm{Ba}^{2+}$ cations are also found in the vanadyl phosphate compounds $\mathrm{Ba}_{2}(\mathrm{VO})\left(\mathrm{PO}_{4}\right)_{2} \cdot \mathrm{H}_{2} \mathrm{O}$ (11) and $\mathrm{Ba}_{8}(\mathrm{VO})_{6}$ $\left(\mathrm{HPO}_{4}\right)_{11} \cdot 3 \mathrm{H}_{2} \mathrm{O}(14)$. In the former, vanadium atoms are disordered on a site displaced from the octahedron center to an apex oxygen forming a short $\mathrm{V}=\mathrm{O}$ bond ( $1.580 \AA$ ) and a long trans $\mathrm{V}-\mathrm{O}$ bond. Although the two oxygen atoms of the $\mathrm{O}=\mathrm{V}-\mathrm{O}$ moiety are crystallographically related, they represent either an $\mathrm{O}=\mathrm{V}$ oxygen or an oxygen of a water molecule. The latter compound exhibits two types of one-dimensional chains involving independent $\mathrm{V}(1)$ and $\mathrm{V}(2)$ octahedral atoms. The $\mathrm{V}(1) \mathrm{O}_{6}$ octahedron doesn't show evidence of a short $\mathrm{V}=\mathrm{O}$ bond but the $\mathrm{V}(1)$ site is believed to be an average of superimposed $O-V=O$

FIG. 4. The oxygen environment around $\mathrm{Ba}(1)$ and $\mathrm{Ba}(2)$.

FIG. 5. Rutile-type chains (a) connected at corners, e.g., $\mathrm{VO}_{2}$, (b) edge-shared in a hollandite framework, and (c) isolated in $A_{2} \mathrm{MO}_{4}$ compounds.
and $\mathrm{O}=\mathrm{V}-\mathrm{O}$ configurations. In the $\mathrm{V}(2) \mathrm{O}_{6}$ octahedron a short vanadyl bond ( $1.596 \AA$ ) is observed. Recently, several barium vanadyl-arsenates, -phosphates, and -hydrogenophosphates have been studied and they exhibit various frameworks; e.g., $\mathrm{Ba}(\mathrm{VO})_{2}\left(\mathrm{AsO}_{4}\right)_{2}$ and its isomorph $\mathrm{Sr}(\mathrm{VO})_{2}\left(\mathrm{AsO}_{4}\right)_{2}$ consist of one-dimensional cationic tunnels, the framework being composed, as in $\mathrm{Ba}_{2} \mathrm{~V}_{3} \mathrm{O}_{9}$, of edge sharing $\mathrm{VO}_{6}$ octahedra, but in these two isostructural compounds only one $\mathrm{O}-\mathrm{O}$ edge is shared between two $\mathrm{VO}_{6}$ octahedra forming $\mathrm{V}_{2} \mathrm{O}_{10}$ dimers with two intradimer $\mathrm{V}=\mathrm{O}$ bonds of $1.59 \AA$ (13). An example of a two-dimensional structure containing $\mathrm{V}=\mathrm{O}$ bonds, $1.605 \AA$, is provided by $\mathrm{Ba}(\mathrm{VO})\left(\mathrm{PO}_{4}\right)\left(\mathrm{H}_{2} \mathrm{PO}_{4}\right) \cdot \mathrm{H}_{2} \mathrm{O}$ in which $\mathrm{V}^{4+} \mathrm{O}_{6}$
octahedra and $\mathrm{PO}_{4}$ groups are linked by corners into anionic layers (12). Finally, two types of tetravalent vanadium $\mathrm{V}=\mathrm{O}$ groups are present in the three-dimensional framework of $\mathrm{Ba}(\mathrm{VO})_{2}\left(\mathrm{PO}_{4}\right)_{2}$ with bond lengths 1.603 and 1.611 Å (10).

It is important to emphasize that the octahedral $\mathrm{V}^{4+}=\mathrm{O}$ bond in $\mathrm{Ba}(\mathrm{VO})\left(\mathrm{VO}_{4}\right)_{2}, 1.686(3) \AA$, is significantly longer than in the previously mentioned barium vanadyl compounds. The same effect is also observed when comparisons are made with the square pyramidal vanadyl(IV) ion present in mixed valence vanadium oxides such as $\mathrm{Cs}_{2} \mathrm{~V}_{5} \mathrm{O}_{13}(26)(\mathrm{V}=\mathrm{O}=1.607 \AA), \mathrm{K}_{2} \mathrm{~V}_{3} \mathrm{O}_{8}(27)(\mathrm{V}=\mathrm{O}=$ $1.582 \AA$ ), and the recently published intercalated vanadyl vanadate $\left(\mathrm{V}^{4+} \mathrm{O}\left(\mathrm{V}^{5+} \mathrm{O}_{4}\right) \cdot 0.5\left[\mathrm{CH}_{3} \mathrm{~N}_{2} \mathrm{H}_{12}\right]\right.$ (28). In this compound, two $\mathrm{V}^{4+} \mathrm{O}_{5}$ vanadyl square pyramids share an edge to form $\mathrm{V}_{2} \mathrm{O}_{8}$ dimers similar to those observed in compounds derived from carnotite such as $\left(\mathrm{Na}_{1-x} \mathrm{~K}_{x}\right) \mathrm{UO}_{2}$ $\left(\mathrm{V}_{2} \mathrm{O}_{8}\right)$ in which the $\mathrm{V}=\mathrm{O}$ bond distances are $1.579 \AA$ (29). Many other new barium vanadium oxides, phosphates, or hydrogenophosphates such as $\mathrm{Ba}\left(\mathrm{VO}_{2}\right) \mathrm{PO}_{4}(30)$, $\mathrm{Ba}_{8} \mathrm{~V}_{7} \mathrm{O}_{22}$ (8), and $\mathrm{Ba}\left[\mathrm{V}_{2}\left(\mathrm{HPO}_{4}\right)_{4}\right] \cdot \mathrm{H}_{2} \mathrm{O}$ (15) have been recently synthesized, notably by hydrothermal synthesis, but they don't exhibit short $\mathrm{V}=\mathrm{O}$ vanadyl bonds.

## Infrared Spectroscopy

The IR data for $\mathrm{Ba}_{2} \mathrm{~V}_{3} \mathrm{O}_{9}$ show typical bands associated with orthovanate $\mathrm{V}-\mathrm{O}$ and vanadyl $\mathrm{V}=\mathrm{O}$ resonances (Fig. 6). The classical vibrations of the tetrahedral $\mathrm{VO}_{4}^{3-}$ ion, $\nu 1, \nu 3$, and $\nu 4$, are observed. They can be empirically assigned on the basis of previous results on orthovanadate compounds (31-34). Thus, the $944-838 \mathrm{~cm}^{-1}$ and the $490-$ $400 \mathrm{~cm}^{-1}$ multiplets are attributed to asymmetric stretching, $\nu 3$, and symmetric bending, $\nu 4$, vibrations, respectively. The ratio of the average intensity of the two-multicomponent peaks to the $\nu 1$ sharp band intensity has been found to be close to 1 for orthovanadates with the apatite structure (34). Such considerations applied to our case indicate a $705 \mathrm{~cm}^{-1}$ symmetric stretching $\nu 1$ vibration. The remaining sharp band which appears at $770 \mathrm{~cm}^{-1}$ is assigned to the $\mathrm{V}=\mathrm{O}$ stretching vibration and is lower in energy with respect to other vanadyl compounds $(10,14,35)$.

## Magnetic Measurements

Figure 7 shows the plot of $\chi$ and $\chi^{-1}$ vs $T$. The reversibility of the ZFC and FC data indicate that the magnetic susceptibility is not history dependent. From room temperature to about 100 K , the inverse susceptibility can be modeled by the Curie-Weiss relationship, $\chi^{-1}=\left(T-T_{\mathrm{c}}\right) /$ $C$. The diamagnetic corrections were neglected. A least squares fit yielded $C=0.512 \mathrm{emu} \mathrm{K} / \mathrm{mol} \mathrm{Oe}$ and $T_{\mathrm{c}}=$ -132.5 K . The calculated value $\mu_{\text {eff }}=2.0 \mu_{\mathrm{B}}$ per formula unit is slightly higher than the expected value of 1.73 for $\mathrm{a} \mathrm{V}^{4+}$ spin-only ion and is due to a spin-orbital contribution.

FIG. 6. Infrared spectrum of $\mathrm{Ba}_{2} \mathrm{~V}_{3} \mathrm{O}_{9}$.

FIG. 7. Temperature dependencies of magnetic susceptibility (circles) and inverse susceptibility (triangles) of a polycrystalline $\mathrm{Ba}_{2} \mathrm{~V}_{3} \mathrm{O}_{9}$ specimen.

The compound is an antiferromagnet with $T_{\mathrm{N}}=-58 \mathrm{~K}$. The change at about 20 K could indicate the presence of a small amount of a paramagnetic impurity. On the other hand it might be due to a ferromagnetic exchange coupling that causes a canted-spin arrangement of the $\mathrm{V}^{4+}$ ions along the rutile chains (Fig. 3). Three possible interactions can induce this kind of noncolinear spin arrangement in $\mathrm{Ba}_{2} \mathrm{~V}_{3} \mathrm{O}_{9}$ :

1. Metal-metal double exchange through $2 p^{6}$ oxygen orbitals, but this is unlikely because of the single $4+$ valence of the vanadium ions along the $b$ axis.
2. Dzyaloshinski-Moriya interactions $(36,37)$ are not possible because of the centrosymmetric space group.
3. The presence of magnetic anisotropy is the most likely explanation for the spin canting away from the antiferromagnetic spin alignment. Indeed, the existence of a double vanadyl bond between octahedral $\mathrm{V}^{4+}$ and a bridging oxygen splits the $3 t_{2 g}$ low energy orbitals into one with lower energy occupied by the $d^{1}$ electron and two empty orbitals at slightly higher energy. Thus overlapping $2 p^{6}$ orbitals generate a strong anisotropy in the octahedral crystal field tilting the antiferromagnetically aligned spins along the zigzag vanadyl chains. Similar behavior has been observed in $\mathrm{Ba}_{8}(\mathrm{VO})_{6}\left(\mathrm{HPO}_{4}\right)_{11} \cdot 3 \mathrm{H}_{2} \mathrm{O}$ but cannot be justified in the same way because of the long $\mathrm{V}-\mathrm{O}-\mathrm{P}-\mathrm{O}-\mathrm{V}$ superexchange between $\mathrm{V}^{4+}$ (14).

## SUMMARY

The crystal structure of a previously reported compound, $\mathrm{Ba}_{2} \mathrm{~V}_{3} \mathrm{O}_{9}$, was determined and its IR spectrum and magnetic susceptibility were investigated. The compound is a vanadyl vanadate, $\mathrm{Ba}_{2}(\mathrm{VO})\left(\mathrm{VO}_{4}\right)_{2}$. Edge sharing octahedra have attached to them tetrahedra to form a free standing column of composition $\mathrm{V}_{3} \mathrm{O}_{9}^{4-}$. The octahedra are occupied by $\mathrm{V}^{4+}$ that are slightly displaced from the octahedron center to form a $\mathrm{V}=\mathrm{O}$ double bond to one oxygen and the tetrahedra are occupied by $\mathrm{V}^{5+}$. The IR spectrum is consistent with the presence of a vandyl group. The magnetic susceptibility shows that the material has CurieWeiss behavior between 100 K and room temperature and a $\mu_{\text {eff }}=2 \mu_{\mathrm{B}}$ with $T_{\mathrm{N}}$ about 58 K . At about 20 K a ferromagnetic component becomes important to give rise to spin canting. The crystal structures of $\mathrm{Sr}_{2} \mathrm{~V}_{3} \mathrm{O}_{9}$ and isostructural $\mathrm{Pb}_{2} \mathrm{~V}_{3} \mathrm{O}_{9}$ are now under investigation.
