to be the case, that the high temperature rate, A_1 , in the neighborhood of the transition point, would differ from the low temperature rate, A_2 , by a factor somewhat greater than 2. For if all the oxygen in the carbon dioxide that reacts goes to the monoxide, the high temperature rate must be represented by

$$C + CO_2 \longrightarrow 2CO$$

from which the factor 2 arises. In addition, since the carbon surface is cleaned up by the increased rate of decomposition, an increased rate of reaction is to be expected due to the increased availability of active surface. The latter consideration also accounts for the increased temperature coefficient, since the average energy of the surface available for reaction would be increased by the loss of the solid oxide, which was, presumably, most stable on the least saturated portions of the surface. Thus the high temperature rate A_1 may perhaps be represented by

$$C \div CO_2 \longrightarrow CO + C - O_{solid}$$

 $C - O_{solid} \longrightarrow CO$

where the second reaction follows so rapidly on the first that there is no accumulation of the solid oxide.

Summary

1. The measurement of the rate of a rapid heterogeneous reaction which usually is governed by diffusion conditions has been considered from a theoretical viewpoint. This discussion led to the development of a method which was used to determine the rate of reduction of carbon dioxide by graphite. The method involves the elimination of concentration gradients by increasing the gas velocity across the reacting surface until the velocity coefficient of the observed rate of reaction vanishes.

2. The rate of reduction of carbon dioxide has been measured in terms of cubic centimeters of carbon monoxide at N. T. P. produced per second from carbon dioxide at one atmosphere in contact with one square centimeter of graphite surface. It is given, for temperatures between 950 and 1300° , by the equation

$$\log A_1 = 5.07 - (38,700/4.575 T)$$

and for temperatures between $850 \ \mathrm{and} \ 950\,^{\mathrm{o}},$ by

 $\log A_2 = 3.40 - (32,360/4.575 T)$

3. The significance of the appearance of two stages in the oxidation of graphite by carbon dioxide and its relation to the surface oxide complex are discussed.

The Solubility of Hydrogen in Water at 0, 50, 75 and 100° from 25 to 1000 Atmospheres

BY R. WIEBE AND V. L. GADDY

This is a continuation of previous work.¹ The apparatus and method have been described. The hydrogen was 99.9 per cent. pure, the impurity being nitrogen. A correction was applied assuming that the amount of nitrogen dissolved was proportional to its mole fraction. Table I gives a summary of the experimental results; the previously published¹ values for the 25° isotherm are added for comparison. Figure 1 shows a plot of the results. A correction for the change of vapor pressure due to the gas pressure on the liquid was made in the manner already explained.¹ Table II shows values of the vapor pressure of water at 100° used in making this correction. These values are only approximate, but a relatively large error in the partial pressure of water (1) Wiebe, Gaddy and Heins, Ind. Eng. Chem., 24, 823, 927 (1982), This JOURNAL, 55, 947 (1983).

will make only a small correction in the final results. The total experimental error amounts to a few tenths of a per cent.

By a sensitive method of plotting deviations, the experimental data were smoothed with respect to both pressure and temperature to obtain interpolated solubility values. The results obtained by such interpolation are given in Table III. It was thought that an extrapolation of the results at 25 atmospheres to lower pressures by means of Henry's law, when corrected for deviations from the perfect gas law, would yield fairly accurate values for the absorption coefficient at one atmosphere. The following table gives the extrapolated values in terms of the Bunsen and Ostwald absorption coefficients² and shows also

for comparison the values of Winkler³ and at 25° an average value obtained from a table of best results published by Drucker and Moles.⁴ The value of Just was excluded from this average result since his values in general appear too high.⁵ The agreement with Winkler is fair except at the higher temperatures where his accuracy was least. There is perfect agreement with the average value of Drucker and Moles. It should be pointed out that when extrapolating solubility data to high pressures, a correction for the imperfection of the gas applied to Henry's law may lead to greater error than if none had been applied. The agreement in the case of nitrogen, for instance, is improved, whereas the results for hydrogen will be inade niuch worse.

ficulties at higher temperatures and deduced from their unpublished high temperature results the possibility of a minimum for the Bunsen absorption coefficient between 65 and 75° .

As Fig. 1 clearly shows the absorption coefficient (cc. of gas at S. T. P. per g. of water) shows a minimum. It should be pointed out, however, as has already been done by Just for instance,⁷ and as shown in Table IV, that the minima obtained by differently defined absorption coefficients are not identical. In some cases one coefficient may in fact show a minimum while the other may not.

It might be desirable to comment briefly on the temperature coefficient of solubility. Hildebrand⁸ states that on the basis of Raoult's law the solubility of a gas diminishes with rise in temperature. For gases above their critical temperatures this rule is very unreliable even qualitatively. In the nearly "ideal" case of hydrogen in benzene, the solubility of hydrogen increases with rise in temperature. For hydrogen in water, *e. g.*, the solubility diminishes only over part of the range.

Tammann⁹ attempted to explain the existence of minima in water on the basis of a hydration theory. But since minima occur in solvents other than water¹⁰ such special assumptions would not seem necessary.

Since Ostwald's absorption coefficient in dilute solutions should approach one practically at the critical temperature of the solvent¹¹ it would seem

> that all gases whose solubility diminishes with temperature over the known range should show a minimum at some higher temperature, while those whose solubility is known to increase with temperature might be thought to have passed the point of minimum at some lower temperature. Horiuti,¹² taking his own extensive data on the solubilities of hydrogen, nitrogen, carbon monoxide, oxygen and methane in various organic solvents, plotted the logarithm of the

Ostwald coefficient against the reciprocal of the absolute temperature and extrapolated to the critical temperature of the solvent. Several of his curves show a minimum within the experimental range and others may be expected to do so on the basis of their curvature. It seems, therefore, as was pointed out by Kuenen,¹³ that solubility minima are a phenomenon that can be deduced from the known behavior of mixtures and that the occurrence of minima is not necessarily dependent on the specific properties of the solvent or solute.

Finally a few words on attempts to calculate the solubility of gases, theoretically, may also be of interest. Van der Waals,¹⁴ using his conception of a simple substance whose equation of state is identical with that of the particular mixture to be treated, attempted to calculate the solubility of nitrogen in water using his equation of state. He obtained a value much too small and

(13) Kuenen, Proc. Roy. Soc. Edinburgh, 23, 312 (1900); Kuenen, "Verdampfung und Verflüssigung von Gemischen," Verlag Johann Ambrosius Barth, Leipzig, 1906, p. 82.

(14) Van der Waals-Kohnstamm, "Lehrbuch der Thermodynamik," Verlag Johann Ambrosius Barth, Leipzig, 1912, Vol. II, pp. 132-172. attributed this to the association of water and not to the various assumptions needed for the computation. Later on he¹⁵ pointed out that a correction for association would improve the agreement. Horiuti¹⁶ using empirical relations applied van der Waals' idea to the solubilities of gases in organic liquids. For gases above their critical temperatures, he was able to get only the right order of magnitude.

Summary

The solubility of hydrogen in water at 0, 50, 75 and 100° and from 25 to 1000 atmospheres has been determined. The solubility of hydrogen in water shows a minimum within the experimental range similar to that of nitrogen in water.

Existing data seem to show that minima are a general phenomenon that can be deduced from the known behavior of mixtures and not necessarily dependent on specific properties of the solvent or solute.

Heats of Solution and Heats of Reaction in Liquid Ammonia. I

By Charles A. Kraus and John A. Ridderhof¹

I. Introduction

Data relating to heats of solution of electrolytes in solvents other than water are almost completely lacking. There are available only several observations of Pickering² on the heat of solution of sodium iodide and lithium nitrate in alcohol. Both salts have markedly higher heats of solution in alcohol than in water. It seemed desirable to have data as to the heat of solution of salts in solvents other than water, particularly in solvents of lower dielectric constant. Ammonia seemed a very suitable solvent for this purpose, since many common salts are readily soluble in ammonia, while a good many important substances are soluble in ammonia that are not soluble in water. Numerous reactions, moreover, may be carried on in liquid ammonia which cannot be carried out in water; for example, reactions involving the alkali metals. In the present paper we report the results of a general survey of the field.

II. Apparatus and Method

Method.—Because of its high volatility, it is not possible to make calorimetric measurements with liquid ammonia according to the methods that may be employed in the case of water or other non-volatile liquids. It seemed possible, however, that by determining the ammonia vaporized as a result of the heat effect, the heat effect itself might be determined from the known heat of vaporization of liquid ammonia.

There are, of course, other effects entering, such as a change in the temperature of the calorimeter and its contents. These temperature changes are most conveniently measured by means of a suitable thermocouple. Since the boiling point of liquid ammonia is -33.35° , it was obviously necessary to employ a vacuum-jacketed calorimeter. For this purpose a vacuum-jacketed tube was employed, surrounded by a bath of boiling ammonia. Since the amount of ammonia evaporated gives the principal datum in connection with a determination of the heat effect, it is necessary to establish equilibrium between the liquid and the vapor. For this purpose, a stirrer must be provided which agitates the liquid-vapor
