#### Abstract

Single determinant ab initio molecular orbital theory has been applied to the study of the structures and relative energies of all possible singlet and triplet isomers of formula $\mathrm{C}_{3} \mathrm{H}_{2}$. Within the manifold of closed shell singlets, the $2 \pi$ electron aromatic cyclopropenylidene is found to be the most stable. Some $17 \mathrm{kcal} / \mathrm{mo}$ higher in energy is the acyclic system, vinylidenecarbene. The predicted equilibrium geometry of the most stable triplet isomer, propargylene, is not linear as was earlier supposed, but rather of $C_{2}$ symmetry. The calculations allow the rationalization of the observed EPR zero-field parameters in terms of such a structure while providing details which are not available from resonance studies. The next most stable triplet form is vinylidenecarbene ( $24 \mathrm{kcal} / \mathrm{mol}$ above propargylene). The calculated energies of cyclic triplet isomers are far higher. Finally comparison is drawn between the relative energies of the most stable form of each of the singlet and triplet manifolds. By an indirect approach, which utilizes the difference between the calculated and experimental singlet-triplet splitting in methylene, we have estimated that the lowest energy singlet isomer, cyclopropenylidene, is about $13 \mathrm{kcal} / \mathrm{mol}$ more stable than the best triplet form, propargylene, and hence must be considered the ground state of $\mathrm{C}_{3} \mathrm{H}_{2}$.

In recent years considerable attention has been given to the application of simple levels of ab initio molecular orbital theory to questions of structure and stability of small hydrocarbons, ${ }^{2}$ and positively charged hydrocarbon ions. ${ }^{2 \mathrm{a}, 3}$ Much of the earlier work was comparative in tenor, directed at establishing an overall level of confidence, against which one might render judgment on the theory's predictions in those instances where experimental data were unavailable. The considerable success with which these ventures have met compels us now to detail our collective studies on one such set of hydrocarbons, compounds of formula $\mathrm{C}_{3} \mathrm{H}_{2}$, on which quantitative structural and energetic data are all but completely lacking. Although only one of these hydrogen deficient species, the triplet state of prop-2-ynylidene (propargylene), has come under direct spectroscopic scrutiny, indirect "chemical" evidence suggesting the existence of derivatives of at least two others (propadienylidene and cyclopropenylidene) has emerged during the past decade. In addition, cyclopropyne, parent to the cycloalkyne series, has long been sought experimentally, though at present all such quests have proven unsuccessful.

Here we will be concerned primarily with the theoretical prediction of detailed geometrical structures and of relative isomer stability. The manifold of $\mathrm{C}_{3} \mathrm{H}_{2}$ isomers is, in at least one respect, more complicated than a number of previous systems investigated, for not only must we contend with closed shell species but also with the possibility of low-lying triplet arrangements. Thus, we shall be concerned not only with assigning which of the possible $\mathrm{C}_{3} \mathrm{H}_{2}$ isomers is the most stable singlet, but in addition shall be interested in the theory's prediction of the lowest energy member within the triplet manifold. Although the single determinant ab initio molecular orbital methods employed in the present work appear to be quite capable of properly ordering the stabilities of isomers within a given spin manifold, they are not as likely to be successful in choosing which of the lowest energy singlet or triplet species is actually the ground state of $\mathrm{C}_{3} \mathrm{H}_{2}$. In particular, it is anticipated that correlation effects, which are completely ignored within the framework of single determinant theory, will be
smaller for triplet states than for singlets.

## Quantum Mechanical Methods

Single determinant ab initio molecular orbital theory was used throughout. For singlet states, the closed-shell spin-restricted Hartree-Fock (RHF) procedure ${ }^{4}$ was employed, electrons being assigned to molecular orbitals in pairs. For triplet states, wave functions were obtained by the spin-unrestricted (UHF) procedure ${ }^{5}$ with two more $\alpha$ electrons than $\beta$ electrons. These are not pure triplet functions, but have some contamination from functions of higher spin multiplicity. As a consequence total energies computed at the UHF level will generally be lower than those obtained using a restricted Hartree-Fock procedure.

We have employed the STO-3G minimal basis set ${ }^{6}$ for the optimization of equilibrium geometries. The actual procedure is to select some starting geometry with a specified symmetry constraint and then to vary the remaining geometrical parameters until the energy is minimized. ${ }^{7}$ For some structures, it was found that release of the symmetry constraint led to further energy lowering toward some other structure, and full refinement was not then carried out. The resulting structures and the corresponding symmetry constraints are listed in Table I.

To assess relative isomer stabilities more accurately, single molecular orbital calculations at the extended 4-31G basis set level ${ }^{8}$ were then performed on each of these (STO-3G) equilibrium geometries. However, even at the 4-31G level, relative isomer energies are still subject to considerable error, in particular with regard to comparisons made between acyclic and small ring molecules. Therefore, in order to provide a still more accurate assessment of the relative stabilities of the $\mathrm{C}_{3} \mathrm{H}_{2}$ isomers, we have carried out a limited number of single calculations using the $6-31 \mathrm{G}$ * polarization basis set. ${ }^{9}$ Again the equilibrium geometries specified by the minimal basis set STO-3G method were employed. The complete set of energy data are to be found in Tables II and III for closed shell singlet and triplet species, respectively. All calculations have been

## Results and Discussion

We have endeavored to explore all possible isomers of $\mathrm{C}_{3} \mathrm{H}_{2}$ (closed shell singlet and triplet) in which each hydrogen is attached to a unique carbon. No evidence was found for structures with bridging hydrogen atoms. For systems with an acyclic carbon chain $\mathrm{C}_{1}-\mathrm{C}_{2}-\mathrm{C}_{3}$, possible positions of attachment of the two hydrogens are: (i) both at the same end (propadienylidene (I)); (ii) one in the middle, one at the end (propenediylidene (IIa, IIb)); (iii) one at each end (prop-2ynylidene (IIIa, IIIb)), (iv) both in the middle (propanediylidyne (IV). For cyclic structures, the possibilities are: (v) at the same position (cyclopropyne (V)); (vi) at different positions (cyclopropenylidene (VI)). We shall discuss the structures and relative energies for the singlet and triplet potential surfaces

in turn, postponing a comparative discussion of one with the other to the end.

## Singlet Isomers

The results, given in Table II, suggest that cyclopropenylidene (VI) is the most stable singlet isomer of $\mathrm{C}_{3} \mathrm{H}_{2}$. This conclusion is based on results at the $6-31 \mathrm{G}^{*}$ level. With the 4-31G basis the energies of propadienylidene (I) and cyclopropenylidene (VI) lie closer together. However, the greater energy lowering of the strained cyclic structure with the addition of $d$ functions is in line with corresponding findings for isomers of $\mathrm{C}_{3} \mathrm{H}_{4}$ and $\mathrm{C}_{3} \mathrm{H}_{6}{ }^{12}$ and is clearly important.

The geometrical structure for cyclopropenylidene (VI) shows considerable evidence of electron delocalization away from the $\pi$ orbital of the double bond and into the vacant $p$ function at the carbene center. As a consequence the two single

linkages have contracted (by $0.051 \AA$ from their value in cyclopropene) while the formal double bond has lengthened considerably (by $0.037 \AA$ from that in cyclopropene). The enhanced stability of the resulting $2 \pi$ electron cycle is evidenced by the energy of the isodesmic bond separation reaction ${ }^{13}$

$$
\begin{align*}
& \ddot{\Delta}+2 \mathrm{CH}_{4}+ \mathrm{CH}_{2}\left({ }^{2} \mathrm{~A}_{1}\right) \\

\end{align*}
$$

$\Delta E$ of the corresponding process for cyclopropene

on the other hand, indicates the considerable strain normally present in a three-membered ring. The unusually high stability of cyclopropenylidene, relative to its bond separation products, reminds us of a related system, the isoelectronic cyclopropenyl cation. ${ }^{3 a}$ Here the calculated energy required for bond separation (reaction 3 ) is actually negative though of much smaller

magnitude than that noted for cyclopropene (reaction 2).
The second most stable singlet isomer is propadienylidene (I, trivial name vinylidenecarbene). According to the

RHF/6.31G* energies, this lies some $17 \mathrm{kcal} / \mathrm{mol}$ above cyclopropenylidene (VI). The STO-3G calculated geometry is well represented by the valence structure

${ }^{2} \mathrm{~A}_{1}$
where the lengths of the double linkages have changed only slightly from the value in, say, allene ( $1.288 \AA$ at the STO-3G level). These geometric distortions are small, but in a direction which suggests involvement of zwitterionic forms such as:

The molecule has two $\pi$ electrons. Regarded as a singlet carbene, it would have a formally vacant $\pi$ atomic orbital on the carbene center. However, the two electrons in the neighboring $\pi$ double bond will move toward this vacancy, giving additional stability in terms of the structure $\mathrm{H}_{2} \mathrm{C}^{+}-\mathrm{C} \equiv \mathrm{C}^{-}$This high polarity is reflected in the large dipole moment (4.0 D at the $6-31 G^{*}$ level with $\mathrm{CH}_{2}$ at the positive end) for this isomer.

The third most stable closed shell singlet isomer is prop2 -ynylidene (trivial name propargylene) which is found to distort to an asymmetric structure well represented as ethynylmethylene.

Here, electron donation from the valence $\pi$ orbital of the triple bond into the vacant $p$ function at the carbene center results in lengthening of the former (multiple) linkage from its value

in, say, acetylene ( $1.168 \AA$ at the STO-3G level) accompanied by a shortening of the connecting single bond (from an STO3 G value of $1.537 \AA$ in a molecule like ethylidene ${ }^{14}$ ). Similar and somewhat larger geometrical effects have already been noted in the isoelectronic propargyl cation, ${ }^{3 a}$ due, in this instance, to interaction between the filled $\pi$ orbital of acetylene
and the vacant lobe at the carbonium center. An alternative, $C_{2 v}$ symmetry, form of singlet propargylene was also considered.

Upon release of the symmetry constraint it was noted to undergo collapse to the $C_{s}$ structure. However, it is possible that a local minimum of $C_{2 v}$ symmetry might exist for an open shell singlet species.

The remaining singlet structure is cyclopropyne (V) which has a much higher energy and is likely to be very unstable. At the $4-31 \mathrm{G}$ level it is $88 \mathrm{kcal} / \mathrm{mol}$ above cyclopropenylidene. No 6-31G* calculation was carried out on $V$, but, since both V and VI are three-membered rings, a similar large energy separation between them would be expected at this level.

## Triplet Isomers

On the triplet $\mathrm{C}_{3} \mathrm{H}_{2}$ surface, the results, given in Table III, indicate that prop-2-ynylidene (IIIa, trivial name propargylene) is the most stable form. Rather than being represented as an ethynyl group attached to methylene

the theoretical geometry seems to be better interpreted in terms of a diradical valence structure.

The lowest energy structure found for propargylene is one of $C_{2}$ symmetry. Here the carbon skeleton is close to linear ( $\angle C C C=167.1^{\circ}$ ), while the terminal hydrogens are attached with bond angles of $145.7^{\circ}$. One hydrogen rises out of the plane formed by the three carbons, the other descends below it. Finally, these two hydrogens are oriented so as to be nearly mutually perpendicular (dihedral angle $71.1^{\circ}$ ), the molecule taking on a W as opposed to U shaped geometry.

W shaped

Another way in which to visualize the theoretical equilibrium geometry of triplet propargylene is to consider it as having been

allene

triplet propargylene
derived from allene by removal of a vicinal pair of hydrogens. The $C_{2}$ axis present in both systems is easily recognized by looking straight down the $\mathrm{C}=\mathrm{C}=\mathrm{C}$ moiety.

allene

triplet propargylene

This element of symmetry is not destroyed by the further geometrical distortions undergone by propargylene (i.e., a closing of the dihedral angle between the terminal hydrogens, and a movement of the central carbon along the $C_{2}$ axis).

Experimentally, triplet propargylene was originally believed to possess a linear or nearly linear skeleton, based on the analysis of the EPR zero-field splitting parameters. ${ }^{15}$ In particular the observation that the anisotropy parameter, $E$, was vanishingly small was taken as evidence that the molecule possessed cylindrical symmetry (i.e., belonged to point groups $C_{\infty i}$ or $D_{\infty h}$ ). It was subsequently shown for triplet methylene, ${ }^{16}$ however, that rotation within the matrix could account for the observation of an apparent cylindrical axis in a nonlinear molecule.

Analogous considerations indicated that significant distortions of III from linearity could still allow relatively free rotation about the long axis of the molecule. Support for such distortions is found in earlier studies. ${ }^{17}$

In considering the zero-field parameters of III and its derivatives, the unpaired electrons were assigned to two perpendicular $\pi$ systems. ${ }^{17 a}$ Each of those $\pi$ systems would resemble that for the triplet ground state of vinylmethylene. The recent observation of the EPR of that species indicated nonlinear CCC and methylene carbon arrangements. ${ }^{17 \mathrm{~b}}$ Having the two HCC planes of III in an approximately perpendicular orientation was thus a possibility. When the geometry of the lowest triplet state was determined by minimizing the STO-3G energy the twisted W structure was the result. It was clear that such a structure is likely to experience only a small barrier to rotation about the long axis. Then, the measured asymmetry
parameter, $E_{\text {obsd }}$, equals $E_{\mathrm{f}} V / W_{2}$, where $E_{\mathrm{f}}$ is the parameter expected with no motion, $V$ is the twofold barrier to rotation due to interaction of the triplet with the matrix, and $W_{2}$ is the second excited rotational level for motion about the long axis. ${ }^{16}$ Consideration now turns to these three terms which determine $E_{\text {obsd }}$.
$W_{2}$ is inversely proportional to the moment of inertia about the long axis, $I$. The carbon atoms, because of their substantial mass and almost linear arrangement, are close to the axis. They therefore make only a small contribution to $I$. The hydrogen atoms are further away but their low mass again leads to a small contribution to the moment. The rotational energy levels will be rather widely spaced. From the geometry we determine that $W_{2} \approx 40 \mathrm{~cm}^{-1}$.

We do not have the information necessary to obtain an accurate value for the barrier to rotation, $V$. The shape of the cavity may resemble that of a dumbbell with the swinging hydrogens providing most of the barrier. A value similar to that observed with methylene ${ }^{16}$ seems reasonable, $\sim 10 \mathrm{~cm}^{-1}$.
$E_{\mathrm{f}}$ is expected to be much smaller than the $0.05 \mathrm{~cm}^{-1}$ for methylene because of several factors. Little contribution to the electron asymmetry arises from the central carbon as there is only a small spin density at that atom. Also, with an angle of $167^{\circ}$ the in-plane hybrid is almost a pure porbital and shows almost no asymmetry with respect to the perpendicular $C_{2} \pi$ orbital. Given the spin density at $\mathrm{C}_{1}$ or $\mathrm{C}_{3}$ and the HCC angle of $146^{\circ}$ we might expect the contribution to $E_{f}$ at one of the end carbons to be $\sim 0.01 \mathrm{~cm}^{-1}$. However, the dihedral angle of $71^{\circ}$ between the two HCC planes leads to extensive cancellation between the two ends of the molecule. The distribution of unpaired electrons appears to be approximately the same in two perpendicular directions and $E_{\mathrm{f}}$ is small, about $\sim 0.001 \mathrm{~cm}^{-1}$.

When rotation is considered, $E_{\text {obsd }}$ for IIIb should be $2 \times$ $10^{-4} \mathrm{~cm}^{-1}$. The widths of the EPR spectral lines are only able to give an upper limit to $E_{\text {obsd }}, \sim 0.002 \mathrm{~cm}^{-1}$. ${ }^{15 \mathrm{a}}$ The expected value is then considerably less than can be detected with the experiments reported hitherto and the available data are therefore compatible with IIIb.

The detection of an $E$ of $\sim 10^{-4} \mathrm{~cm}^{-1}$ by EPR studies in rigid matrices is likely to be difficult and even if observed could be due to site variations or asymmetries. A gas-phase resonance study would appear to be required for definitive results.

A number of other structural possibilities have been considered for triplet propargylene, but all were found to be of higher energy, and, including the $U$ shaped molecule of $C_{2}$ symmetry, unstable with respect to torsion of one or the other hydrogen about the carbon skeleton. In particular, planar forms of $C_{2 v}$ and $C_{s}$ symmetries and nonplanar geometries belonging to point groups $C_{s}$ and $C_{1}$ were all found to collapse, without activation to the $C_{2}$ structure.

The similarity of the overall (two-dimensional) rotational potential of triplet propargylene to that of methanediol ${ }^{18}$ is worthy of note. In both cases rotation of the terminal hydrogens around the heavy atom skeleton results in but a single minimum (or more precisely stated a pair of minimum energy forms related by the twofold symmetry axis). The equilibrium structure for the diol

does, however, have the hydroxy hydrogens placed in a manner which is quite different from the arrangement of the terminal CH's found in propargylene.

The second most stable triplet isomer is propadienylidene or triplet vinylidenecarbene. This is about $24 \mathrm{kcal} / \mathrm{mol}$ less stable than propargylene (a difference that is little changed by polarization functions). Unlike the corresponding singlet, triplet vinylidenecarbene is best viewed in terms of a diradical representation,

${ }^{3} \mathrm{~B}_{1}$
with one carbon-carbon linkage sizably longer than a normal double bond, the other somewhat shorter.

The remaining triplet structures including the cyclic forms V and VI are all much less stable than III or I. It is noteworthy that the effect of the $3 \pi$ electrons in cyclic conjugation in triplet cyclopropenylidene is clearly one of energetic destabilization, in striking contrast to the sizable stabilization afforded to the singlet species on account of its doubly occupied $\pi$ electron cycle. Indeed, $\Delta E$ of (4) is actually more negative than that

$$
\begin{gathered}
\triangle+2 \mathrm{CH}_{4}+\mathrm{CH}_{2}\left({ }^{3} \mathrm{~B}_{1}\right) \\
\longrightarrow 2 \mathrm{CH}_{3}-\mathrm{CH}\left({ }^{3} \mathrm{~A}^{\prime \prime}\right)+\mathrm{CH}_{2}=\mathrm{CH}_{2} \\
\Delta E(4-31 \mathrm{G})=-84.3 \mathrm{kcal} / \mathrm{mol}
\end{gathered}
$$

corresponding to the process of bond separation in cyclopropene.

## Relative Energies of Singlet and Triplet Isomers

As already noted in the introductory section, Hartree-Fock theory does not give satisfactory energy differences between singlet and triplet isomers, because correlation corrections are generally larger for closed shell singlets. This is evident for $\mathrm{CH}_{2}$ where the UHF/6-31G* theory gives the triplet state 31 $\mathrm{kcal} / \mathrm{mol}$ below the singlet, ${ }^{19}$ whereas the best available experimental evidence indicates a separation of about $10 \mathrm{kcal} /$ mol. ${ }^{20}$ Since satisfactory calculations of full correlation energies for $\mathrm{C}_{3} \mathrm{H}_{2}$ are beyond our scope at present, we can only estimate singlet-triplet differences by introducing an additional hypothesis.

For this purpose, we shall treat vinylidenecarbene (I) as an analogue of methylene and assume that the correction to be made to UHF/6-31G* singlet-triplet energy differences is the same for both. In other words, we assume that the energy of the reaction

$$
\begin{align*}
& \mathrm{H}_{2} \mathrm{C}=\mathrm{C}=\mathrm{C} \text { (singlet) }+\mathrm{H}_{2} \mathrm{C} \text { (triplet) } \\
& \longrightarrow \mathrm{H}_{2} \mathrm{C}=\mathrm{C}=\mathrm{C} \text { (triplet) }+\mathrm{H}_{2} \mathrm{C} \text { (singlet) } \tag{5}
\end{align*}
$$

is given correctly at the UHF/6-31G* level. Using the methylene results of Hariharan and Pople, ${ }^{19}$ this energy is +29.3 $\mathrm{kcal} / \mathrm{mol}$. Then, given a $10 \mathrm{kcal} / \mathrm{mol}$ experimental singlettriplet energy gap for methylene, the theory predicts that singlet vinylidenecarbene is more stable than the triplet by about $20 \mathrm{kcal} / \mathrm{mol}$. On the other hand, a direct comparison of the UHF/6-31G* energies gives the triplet lower by $1.5 \mathrm{kcal} / \mathrm{mol}$. The value arrived at by (5) is consistent with studies of derivatives of vinylidenecarbene by Hartzler, ${ }^{21}$ who concluded from their stereospecific addition to olefins, and in light of the Skell-Woodworth hypothesis, ${ }^{22}$ that they possessed singlet

Table IV. Proposed Heats of Formation of $\mathrm{C}_{3} \mathrm{H}_{2}$ Isomers

| Isomer |  | $\Delta H_{\mathrm{f}}{ }^{\circ}(298 \mathrm{~K})$ |
| :--- | :--- | :---: |
|  | Singlets |  |
| Cyclopropenylidene (VI) |  | 113 |
| Propadienylidene (I) |  | 130 |
|  | Triplets |  |
|  |  | 126 |
| Prop-2-ynylidene (IIIb) |  | 150 |

ground states. More recent and varied studies have repeatedly confirmed these trends.

If we accept the relative singlet energies from Table II and the relative triplet energies of Table III (at the 6-31G* level), we may now make comparisons between the two sets by lowering all singlet levels by about $21 \mathrm{kcal} / \mathrm{mol}$. Thus, we predict that the lowest energy isomer of $\mathrm{C}_{3} \mathrm{H}_{2}$ is singlet cyclopropenylidene (VI), this being about $13 \mathrm{kcal} / \mathrm{mol}$ more stable than the lowest triplet isomer (propargylene (III)).

## Heats of Formation

In conclusion, we make tentative proposals for the absolute heats of formation of the various singlet and triplet isomers. These will be based on the further hypothesis that the energy of the (singlet) isodesmic reaction

is given correctly by Hartree-Fock theory with the 6-31G* basis. Again using the results of this paper and ref 19, this energy is $74.2 \mathrm{kcal} / \mathrm{mol}$. Using values of $-16,102$, and 69 $\mathrm{kcal} / \mathrm{mol}$ for heats of formation of methane, singlet methylene, and cyclopropene, respectively, we deduce that the corresponding value for singlet cyclopropenylidene is $113 \mathrm{kcal} / \mathrm{mol}$. Combining this with the above discussion of relative energies, we propose the values listed in Table IV.

Note Added in Proof. Since this manuscript was written, a new experimental value of $19 \mathrm{kcal} / \mathrm{mol}$ for the singlet-triplet separation in methylene has come to our attention. ${ }^{23}$ If correct, this new result would alter the prediction made about the corresponding separation in $\mathrm{C}_{3} \mathrm{H}_{2}$. Our treatment would still predict that $\mathrm{C}_{3} \mathrm{H}_{2}$ has a singlet ground state, but that the corresponding triplet lies only $4 \mathrm{kcal} / \mathrm{mol}$ higher in energy.

# One- and Two-Configuration Hartree-Fock Limit Predictions for the Singlet-Triplet Separation in Methylene and Silylene 

James H. Meadows and Henry F. Schaefer III*<br>Contribution from the Department of Chemistry and Lawrence Berkeley Laboratory, University of California, Berkeley, California 94720. Received October 7, 1975

#### Abstract

A priori electronic structure theory has been applied to the lowest ${ }^{3} \mathrm{~B}_{1},{ }^{1} \mathrm{~A}_{1}$, and ${ }^{1} \mathrm{~B}_{1}$ states of $\mathrm{CH}_{2}$ and SiH . Very large basis sets of contracted Gaussian functions were employed. For $\mathrm{CH}_{2}$, the factors leading to different theoretical values of the ${ }^{3} \mathrm{~B}_{1}-{ }^{1} \mathrm{~A}_{1}$ energy separation are examined. For $\mathrm{SiH}_{2}$, the ${ }^{1} \mathrm{~A}_{1}$ state is predicted to lie below the ${ }^{3} \mathbf{B}_{1}$ state by $10 \mathrm{kcal} /$ mol.

The energy difference between the ${ }^{3} \mathrm{~B}_{I}$ and ${ }^{1} \mathrm{~A}_{\mid}$states of $\mathrm{CH}_{2}$ has been the subject of considerable experimental and theoretical research in recent years. In 1961 Herzberg established ${ }^{2 a}$ for the first time that the triplet state was the lower lying. However, since no singlet-triplet bands of $\mathrm{CH}_{2}$ have been analyzed, electronic spectroscopy does not yield a precise value of the separation. However, Herzberg suggested ${ }^{2 b}$ in 1966 that the singlet-triplet separation (to be called $\Delta E$ hereafter) should be less than $23 \mathrm{kcal} / \mathrm{mol}$. Since that time, essentially all experimental values have fallen into two groups, which may be referred to as the "high" values ${ }^{3-6}(8-9 \mathrm{kcal} /$ mol ) and the "low" values ${ }^{7-9}$ ( $0-3 \mathrm{kcal} / \mathrm{mol}$ ).

The three most reliable $a b$ initio theoretical studies ${ }^{10-12}$ reported to date all favor a high value for the singlet-triplet separation. The lowest theoretical $\Delta E$ of $9.2 \mathrm{kcal} / \mathrm{mol}$, predicted by Staemmler, ${ }^{12}$ was obtained using the independent electron pair approximation (IEPA) and a large contracted Gaussian basis set. Somewhat larger $\Delta E$ values ( $11.5^{10}$ and $14.1^{11} \mathrm{kcal}$ ) were obtained in the two variational studies. The present research was motivated by two theoretical suggestions made independently by Hay, Hunt, and Goddard ${ }^{10}$ and by Bender, Schaefer, Franceschetti, and Allen. ${ }^{11}$ The first of these is the understanding that $d$ functions on carbon significantly lower $\Delta E$. The second is the suggestion that the ${ }^{3} \mathrm{~B}_{1}$ state be approximated by a single configuration wave function

$$
\begin{equation*}
1 a_{1}^{2} 2 a_{1}^{2} 1 b_{2}^{2} 3 a_{1} l b_{1} \tag{1}
\end{equation*}
$$

while a two-configuration wave function

$$
\begin{equation*}
c_{1}\left(1 a_{1}^{2} 2 a_{1}^{2} 1 b_{2}^{2} 3 a_{1}^{2}\right)+c_{2}\left(1 a_{1}^{2} 2 a_{1}^{2} l b_{2}^{2} l b_{1}^{2}\right) \tag{2}
\end{equation*}
$$

be used to describe the ${ }^{1} \mathrm{~A}_{\mid}$state. And, in fact, comparison with
the extensive (both in terms of basis set and treatment of electron correlation ${ }^{13}$ ) theoretical treatments of Bender ${ }^{11}$ and Staemmler ${ }^{12}$ show these two features to be important ingredients in theoretical predictions of $\Delta E$. In general of course the reliable prediction of electronic excitation energies requires a fairly thorough treatment of electron correlation, usually via large scale configuration interaction (Cl). ${ }^{14}$ However, a simple rationalization of the apparent transparency of the correlation problem in this specific case is possible with reference to (1) and (2). We see that while the ${ }^{3} B_{\mid}$Hartree-Fock wave function treats the nearly degenerate $3 a_{1}$ and $1 b_{\text {o }}$ orbitals in an equivalent manner, the corresponding single-configuration $1 a_{1}{ }^{2} 2 a_{1}{ }^{2}$ $1 b_{2}{ }^{2} 3 a_{1}{ }^{2}$ for the ${ }^{1} A_{1}$ state ignores the $l b_{1}$ orbital entirely. Hence the second configuration $1 a_{1}{ }^{2} 2 a_{1}{ }^{2} 1 b_{2}{ }^{2} l b_{1}{ }^{2}$ may be required for a theoretical treatment comparable to the sin-gle-configuration description of the ${ }^{3} \mathrm{~B}_{1}$ state.

## Theoretical Details

The purpose of the present research was twofold. First, to obtain near-Hartree-Fock predictions for the methylene $\Delta E$ and therefore remove the basis set dependence of earlier theoretical work. ${ }^{15}$ Second, comparable calculations have been carried out for $\mathrm{SiH}_{2}$ (silylene), for which the singlet-triplet separation is currently rather uncertain. For carbon and silicon, the largest readily available Gaussian basis sets were used. The carbon ( 13 s 8 p ) primitive Gaussian set of van Duijneveldt ${ }^{16}$ was contracted to ( 9 s 6 p ) so as to maintain maximum flexibility in the valence region. That is, the five s functions with largest orbital exponents $\alpha_{i}$ were grouped together according to the carbon atomic is orbital, and an analogous procedure followed for the three carbon p functions with largest expo-
