| $p-\mathrm{CF}_{3}$ | $1.00^{b}$ | $4.90 \times 10^{6}$ |
| $3,5-\left(\mathrm{CF}_{3}\right)_{2}$ | $1.00^{b}$ | $3.47 \times 10^{8}$ |
| $\mathrm{CH}_{3}$ | $1.00^{b}$ | $9.3 \times 10^{7}$ |
| H | $1.00^{c}$ | $9.8 \times 10^{13}$ |

${ }^{a}$ Reference 8, 9. ${ }^{b}$ Corrected from 70\% dioxane to $80 \%$ acetone. ${ }^{9}$ c Corrected from tosylate in acetic acid to p-nitrobenzoate in $50 \%$ acetone. ${ }^{9}$

volysis of 7 -norbornenyl derivatives (7) where $\pi$-participation is significant, ${ }^{8}$ and much larger than $\rho^{+}$for 7 -norbornyl (8), Hence the $\pi \sigma$-participation from the cyclopropane ring is a linear function of the electron demand of the incipient carbonium ion center.

The rates of solvolysis of 1 are compared with the 7 -norbornyl $p$-nitrobenzoates (2) ${ }^{8,9}$ and are listed in Table II. The relative rate data reveal that with increasing electron demand at the cationic center the rates of solvolysis of the pentacyclic derivatives (1) increase markedly relative to the rates of the corresponding 7 -norbornyl derivatives (2).

It is interesting to note that very low 9-methyl/9-hydrogen (127) and 9-phenyl/9-methyl (14) ratios are evident in this system (Table I). These values should be compared with the very large methyl/hydrogen $\left(1.23 \times 10^{8}\right)^{10}$ and phenyl/methyl ratios $\left(2.3 \times 10^{5}\right)^{11}$ observed in the solvolysis of the parent 7 -norbornyl derivatives. The low methyl/hydrogen and phenyl/methyl ratios can be attributed to the fact that the cation is so stabilized by $\pi \sigma$-participation that it makes relatively little demand upon substituents for further stabilization. Similar diminished methyl/hydrogen (420) ${ }^{12}$ and phenyl/methyl ratios (9.5) ${ }^{11}$ are also observed in the solvolysis of 7 -norbornenyl derivatives (7) where the solvolysis proceeds through $\pi$-participation.

The major product of solvolysis of 9-phenyl-9-pentacyclo[4,3.0, $\left.0^{2,4} .0^{3,8}, 0^{5,7}\right]$ nonyl $p$-nitrobenzoate ( $1, \mathrm{R}=\mathrm{Ph}$ ) in $80 \%$ aqueous acetone at $75^{\circ} \mathrm{C}$ after ten half-lives is the unrearranged tertiary alcohol ( $95 \%$ ). The solvolysis also furnished a minor amount, $5 \%$, of the secondary alcohol.

In conclusion, both the application of the tool of increasing electron demand and the low methyl/hydrogen and phenyl/ methyl ratios observed in the solvolysis of 1 unambiguously support the earlier conclusion that the solvolysis of this system proceeds with carbon ( $\pi \sigma$ )-participation. However, it should be pointed out that the application of the same criteria to $2-$ norbornyl fails to reveal such participation under solvolytic conditions. ${ }^{13,14}$

## Reduction of Excited Singlet State Acetone by 2-Propanol

Sir:
While the intermediacy of the $n \pi^{*}$ triplet states ( $\mathrm{T}_{1}$ ) of alkanones in their photoreductions by hydrogen donors is well established, less is known about the reactivities of the corresponding $n \pi^{*}$ singlet states $\left(\mathrm{S}_{1}\right)$. Theory ${ }^{1,2}$ predicts similar reactivities for $S_{1}$ and $T_{1}$, in keeping with the quenching of adamantanone fluorescence by hydrogen donors. ${ }^{3}$ The $S_{1}$ reaction may be less efficient, however, since ground state educts and radical pair product lie on a common energy hypersurface, and return to the ground state can compete with radical pair formation. ${ }^{1,2}$ Wagner's finding of no ${ }^{4}$ or only little ${ }^{5}$ 2-propanol formation during reaction of excited acetone with tributylstannane under conditions where only $S_{1}$ should react may point to a low efficiency of the $S_{1}$ reaction. However, this explanation conflicts with the unit quantum yield of 2-propanol formation under conditions where both $\mathrm{S}_{1}$ and $\mathrm{T}_{1}$ states of acetone react with the stannane. ${ }^{4,5}$

Extending our studies ${ }^{6}$ on the acetone/2-propanol photosystem we have now observed the formation of the photoreduction product pinacol from a singlet reaction of excited acetone, and confirm that $S_{1}$ and $T_{1}$ states are about equally reactive towards 2-propanol.

Samples ( $560 \mu \mathrm{l}$ ) of three different reaction mixtures consisting of (a) 5 M 2 -propanol plus 5 M 2 -propanol- $d_{6}$ in di-tert-butyl peroxide, (b) 1 M acetone plus 10 M 2 -propanol- $d_{6}$

Table I, Yields of Pinacols

${ }^{a}$ Di-tert-butyl peroxide. ${ }^{b}$ Absolute concentrations in $10^{-3} \mathbf{M}, \pm 5 \%$, relative concentrations $\pm 1 \%$, result of two independent runs and more
than two GLC analysis each. ${ }^{c}$ Excess pinacol $\left[R_{H}-R_{D}\right]_{C}=\left[R_{H}-R_{D}\right]-\left[R_{H}-R_{H}\right]-\left[R_{D}-R_{D}\right]$.
in acetonitrile, (c) 1 M acetone- $d_{6}$ plus 10 M 2 -propanol in acetonitrile were exposed for 5 min at $(26 \pm 1)^{\circ} \mathrm{C}$ in septum closed NMR tubes to the filtered light of a Philips SP 1000-W lamp $^{7}$ ( $295<\lambda<360 \mathrm{~nm}$, absorbed flux ca, $10^{17}$ quanta $^{-1}$ ). The yields of the three pinacols $\mathrm{R}_{\mathrm{H}}-\mathrm{R}_{\mathrm{H}}, \mathrm{R}_{\mathrm{H}}-\mathrm{R}_{\mathrm{D}}$, and $\mathrm{R}_{\mathrm{D}}-\mathrm{R}_{\mathrm{D}}$ $\left(\mathrm{R}_{\mathrm{H}}=\left(\mathrm{CH}_{3}\right)_{2} \mathrm{COH}, \mathrm{R}_{\mathrm{D}}=\left(\mathrm{CD}_{3}\right)_{2} \mathrm{COH}\right)$ were then determined by quantitative GLC. ${ }^{8}$ As evident from Table I, for the photoreduction systems the yield of $\mathrm{R}_{\mathrm{H}}-\mathrm{R}_{\mathrm{D}}$ exceeds the sum of the yields of $R_{H}-R_{H}$ and $R_{D}-R_{D}$ by about $10 \%$ whereas no excess $\mathrm{R}_{\mathrm{H}}-\mathrm{R}_{\mathrm{D}}$ is found in the peroxide/2-propanol/2-propa-nol- $d_{6}$ mixture.

To analyze this finding we first consider the peroxide system, Here $R_{H}$ and $R_{D}$ are generated independently from each other by reaction of primary tert-butoxy radicals with the propanols. They terminate by combination (rate constants $k_{\mathrm{HH}}, k_{\mathrm{HD}}$, and $k_{\mathrm{DD}}$ ) to the pinacols $\mathrm{R}_{\mathrm{H}}-\mathrm{R}_{\mathrm{H}}, \mathrm{R}_{\mathrm{H}}-\mathrm{R}_{\mathrm{D}}$, and $\mathrm{R}_{\mathrm{D}}-\mathrm{R}_{\mathrm{D}}$ and by disproportionation to acetones and 2-propanols (in part via the acetone enols). ${ }^{6}$ The ratio of pinacol yields $\left[R_{H}-R_{D}\right]^{2} /$ $\left[R_{H}-R_{H}\right] \cdot\left[R_{D}-R_{D}\right]$ is given by

$$
\begin{equation*}
\frac{\left[\mathrm{R}_{\mathrm{H}}-\mathrm{R}_{\mathrm{D}}\right]^{2}}{\left[\mathrm{R}_{\mathrm{H}}-\mathrm{R}_{\mathrm{H}}\right]\left[\mathrm{R}_{\mathrm{D}}-\mathrm{R}_{\mathrm{D}}\right]}=\frac{k_{\mathrm{HD}}{ }^{2}}{k_{\mathrm{HH}} k_{\mathrm{DD}}} \frac{\left(\int \mathrm{R}_{\mathrm{H}} \mathrm{R}_{\mathrm{D}} \mathrm{~d} t\right)^{2}}{\int \mathrm{R}_{\mathrm{H}}^{2} \mathrm{~d} t \cdot \int \mathrm{R}_{\mathrm{D}}^{2} \mathrm{~d} t} \tag{1}
\end{equation*}
$$

where the integrations extend over the reaction period. Now, since ${ }^{9}$

$$
\begin{equation*}
\left(\int \mathrm{R}_{\mathrm{H}} \mathrm{R}_{\mathrm{D}} \mathrm{~d} t\right)^{2} \leq \int \mathrm{R}_{\mathrm{H}}{ }^{2} \mathrm{~d} t \cdot \int \mathrm{R}_{\mathrm{D}}^{2} \mathrm{~d} t \tag{2}
\end{equation*}
$$

we have

$$
\begin{equation*}
\frac{\left[\mathrm{R}_{\mathrm{H}}-\mathrm{R}_{\mathrm{D}}\right]^{2}}{\left[\mathrm{R}_{\mathrm{H}}-\mathrm{R}_{\mathrm{H}}\right]\left[\mathrm{R}_{\mathrm{D}}-\mathrm{R}_{\mathrm{D}}\right]} \leq \frac{k_{\mathrm{HD}}{ }^{2}}{k_{\mathrm{HH}} k_{\mathrm{DD}}} \tag{3}
\end{equation*}
$$

Both sides of eq 2 and 3 are equal if the concentrations of $R_{H}$ and $R_{D}$ are proportional to each other, ${ }^{9}$ for instance for stationary radical concentrations. In view of the low conversion (Table I) $\mathrm{R}_{\mathrm{H}} \sim \mathrm{R}_{\mathrm{D}}$ can be safely assumed for the peroxide system. Thus the observed value $\left[\mathrm{R}_{\mathrm{H}}-\mathrm{R}_{\mathrm{D}}\right]^{2} /\left[\mathrm{R}_{\mathrm{H}}-\mathrm{R}_{\mathrm{H}}\right]$ [ $\left.R_{D}-R_{D}\right]=3.97$ should be close to the true value of $k_{\mathrm{HD}^{2}}$ ] $k_{\mathrm{HH}} k_{\mathrm{DD}} .{ }^{10}$

For the photoreduction systems the ratios $\left[R_{H}-R_{D}\right]^{2} /$ $\left[\mathrm{R}_{\mathrm{H}}-\mathrm{R}_{\mathrm{H}}\right]\left[\mathrm{R}_{\mathrm{D}}-\mathrm{R}_{\mathrm{D}}\right]$ ar considerably larger than 3.97 (Table I). Because of eq 3 this must mean that the excess yield of [ $\mathrm{R}_{\mathrm{H}}-\mathrm{R}_{\mathrm{D}}$ ] is not formed in radical reactions describable by usual kinetic rate laws. Since in these systems $R_{H}$ and $R_{D}$ are generated simultaneously we conclude that the excess $\mathrm{R}_{\mathrm{H}}-\mathrm{R}_{\mathrm{D}}$ is due to combination in primary geminate radical pairs and reflects a cage effect.
The multiplicity of the primary pairs follows from a triplet quenching experiment: Acetonitrile solutions of acetone- $d_{6}$ ( 1 M ) and 2-propanol ( 10 M ) containing cis-1,3-pentadiene $(\mathrm{Q})$ were exposed as described above. For $[\mathrm{Q}]=0.12 \mathrm{M}$ not even traces of $R_{H}-R_{H}$ and $R_{D}-R_{D}$ were formed, yet $R_{H}-R_{D}$ was obtained with a yield of $(1,44 \pm 0,15) \times 10^{-3} \mathrm{M}$. Within the error limits this yield was found unquenchable also for higher quencher concentrations ${ }^{12}\left(0.12 \leq[\mathrm{Q}] \leq 1.4 \mathrm{M}, k_{\mathrm{q}} \tau\right.$ $\left.=(0.04 \pm 0.04) \mathrm{M}^{-1}\right)$, and this proves that it must be formed
in a photoreduction from the singlet $S_{1}$ state. ${ }^{13}$ Further we note that the unquenchable fraction of $\mathrm{R}_{\mathrm{H}}-\mathrm{R}_{\mathrm{D}}$ is practically equal to the excess fraction found in the absence of quencher (Table I). This shows that primary pairs derived from the $T_{1}$ photoreduction do not lead to effective cage product formation.

The quantum yield of pinacol formation $\phi_{\mathrm{P}}$ was determined for solutions of 0.1 M acetone in 2-propanol and 0.1 M acetone plus $1,0 \mathrm{M} 2$-propanol in acetonitrile. Both systems gave $\phi_{\mathbf{P}}$ $=0.105 \pm 0.005$ at $25^{\circ} \mathrm{C}$ and $300 \mathrm{~nm} .{ }^{15}$ If we accept this value for the systems of Table I then the fractions of excess $R_{H}-R_{D}$ correspond to quantum yields of pinacol formation in $\mathrm{S}_{1}$ cage reactions of $\phi_{\mathrm{P}} \mathrm{SC}=0.0048$ (acetone system) and $\phi_{\mathrm{P}} \mathrm{SC}=$ 0,0063 (acetone- $d_{6}$ system), respectively ( $\pm 10 \%$ ). Further, knowledge of $\phi_{\mathrm{P}}$ and the ratio of disproportionation to combination of the radicals $\left(7.8 \pm 1.5^{16}\right)$ leads to a quantum yield for acetone photoreduction to radicals, $\phi_{\mathrm{R}}=0.92 \pm 0.19$. From these results ranges for the rate constant $k_{\mathrm{q}}{ }^{\mathrm{S}}$ of acetone $\mathrm{S}_{1}$ quenching by 2-propanol I and for the efficiency (probability) $P_{\text {rad }}$ of radical pair formation during this process may be estimated. We assume that quenching and intersystem crossing ( $k^{\mathrm{ST}}$ ) are the only reactions available to $\mathrm{S}_{\text {I }}$ and have

$$
\begin{equation*}
\phi_{\mathrm{P}}^{\mathrm{SC}}=\frac{k_{\mathrm{q}}^{\mathrm{S}}[\mathrm{I}]}{k_{\mathrm{q}}^{\mathrm{S}}[\mathrm{I}]+k^{\mathrm{ST}}} P_{\mathrm{rad}} P_{\mathrm{cage}} P_{\mathrm{com}} \tag{4}
\end{equation*}
$$

where in addition to the previously defined quantities $P_{\text {cage }}$ is the probability that the radicals react in the cage rather than diffuse apart and $P_{\text {com }}$ is the probability that the radicals couple rather than disproportionate. We further assume that acetone $T_{1}$ is completely reduced to radicals, from which

$$
\begin{equation*}
\phi_{\mathrm{R}}=1-\frac{k_{\mathrm{q}}^{\mathrm{S}}[\mathrm{I}]}{k_{\mathrm{q}}^{\mathrm{S}}[\mathrm{I}]+k^{\mathrm{ST}}}\left(1-P_{\mathrm{rad}}\right) \tag{5}
\end{equation*}
$$

follows. For the evaluation of $P_{\text {rad }}$ from eq 4 and 5 we take $0.0045 \leq \phi_{\mathrm{P}} \mathrm{SC} \leq 0.0065,0.73 \leq \phi_{\mathrm{R}} \leq 1.00$, and $0.10 \leq P_{\text {com }}$ $\leq 0.14$ as reasonable ranges from the experimental data, and adopt $0.5 \leq P_{\text {cage }} \leq 1.0$ as usual for $S_{\mid}$pair reactions. ${ }^{17}$ This gives $0.107 \leq P_{\mathrm{rad}} \leq 1$, i.e,, an efficiency range of 10 to $100 \%$ for the $S_{1}$ reaction. With the known rate constant for intersystem crossing ${ }^{18} k^{\mathrm{ST}}=5 \times 10^{8} \mathrm{M}^{-1} \mathrm{~s}^{-1}$ and the above range for $P_{\text {rad }}$ the rate constant for quenching then becomes $2.8 \times$ $10^{7} \geq k_{\mathrm{q}}^{\mathrm{S}} \geq 2.4 \times 10^{6} \mathrm{M}^{-1} \mathrm{~s}^{-1}$, low values for $P_{\mathrm{rad}}$ corresponding to high values for $k_{\mathrm{q}} \mathrm{S}$ and vice versa.

Our lower limit for $k_{\mathrm{q}} \mathrm{S}$ agrees with the rate constant for the quenching of adamantanone fluorescence by 2-propanol ${ }^{3}$ (1.9 $\times 10^{6} \mathrm{M}^{-1} \mathrm{~s}^{-1}$ ) and is similar to the rate constant for photoreduction of acetone $\mathrm{T}_{1}$ by 2 -propanol ${ }^{14}\left(1 \times 10^{6} \mathrm{M}^{-1} \mathrm{~s}^{-1}\right)$. This indicates that the reactivities and efficiencies of acetone $\mathrm{S}_{1}$ and $\mathrm{T}_{1}$ may be roughly equal. More generally, acetone $\mathrm{S}_{1}$ either has a reactivity towards 2-propanol which is similar to that of acetone $T_{1}$ and leads to radicals with unit efficiency or it reacts with a higher rate constant but less efficiently. These results differ from those obtained by Wagner ${ }^{4}$ for the acetone/tributylstannane system, and we cannot offer an explanation for this difference.

Acknowledgment. We thank Professor K. Grob, EMPA, Dübendorf, for his generous gift of the GLC column, Mrs. I. Verhoolen for the GLC experiments, and Dr. N. Neuner-Jehle, Givaudan-Esrolko, Dübendorf, for the GLC/MS result. We also appreciate helpful advice on the analysis by Professor P. J. Wagner, East Lansing.

(12) GLC/MS examination of the solution after irradiation in the presence of 0.74 M cis-1,3-pentadiene confirmed the identity of $\mathrm{R}_{\mathrm{H}}-\mathrm{R}_{\mathrm{D}}$.
(13) The dominant mechanisms ${ }^{14}$ for the decay of acetone $T_{1}$ are quenching by [Q], for which we assume $k_{Q}{ }^{\top}=5 \times 10^{9} \mathrm{M}^{-1} \mathrm{~s}^{-1}$, and photoreduction by 2-propanol ${ }^{3.14}$ with $k_{\mathrm{q}}{ }^{\top}=1 \times 10^{6} \mathrm{M}^{-1} \mathrm{~s}^{-1}$. At 10 M 2 -propanol $[\mathrm{Q}]=$ 1.4 M results in a 700 -fold decrease of the photoreduction yield as compared to the unquenched reaction. Yet the yield of unquenchable $R_{H}-R_{D}$ is only a factor 20 lower than the sum of pinacol yields in the unquenched reaction. For $[\mathrm{Q}]=0.12 \mathrm{M}$ some chemical quenching ${ }^{3}$ of the radicals by cis-1,3-pentadiene must be invoked to explain the complete lack of $\mathrm{R}_{\mathrm{H}}-\mathrm{R}_{\mathrm{H}}$ and $R_{0}-R_{0}$.

## Isolation and Identification of Cross-Linked Nucleosides from Nitrous Acid Treated Deoxyribonucleic Acid

Sir:
Treatment of DNA with nitrous acid covalently cross-links the two strands of the double helix. ${ }^{1,2}$ This reaction leads to inactivation ${ }^{3}$ and perhaps to deletion mutations ${ }^{4}$ in bacteriophage. The chemical structure of the cross-links has not been determined, although this knowledge is needed in the study of DNA repair processes. ${ }^{5}$ A recent suggestion that the cross-links arise from the reaction of aldehyde groups, liberated by depurination, with amino groups on the opposite chain ${ }^{6}$ has now been withdrawn. ${ }^{3}$ We have approached this problem directly, by isolating cross-linked nucleosides from nitrous acid treated DNA. We wish to propose I and tentatively, II, as the structures of two such products.

Calf thymus DNA ( 500 mg ) was treated with $1 \mathrm{M} \mathrm{NaNO}_{2}$ at pH 4.2 and $25^{\circ} \mathrm{C}$ for 24 h . At the end of this time, the product ( $T_{\mathrm{m}} 75^{\circ} \mathrm{C}$ ) had at least one cross-link per molecule,

I

II
a, $\mathrm{R}=2$-deoxy- $\beta$-D-ribofuranosyl 5 '-phosphate b, $\mathrm{R}=2$-deoxy- $\beta$-D-ribofuranosyl
even after sonication, as measured by the ultraviolet assay for reversible denaturation. ${ }^{1,2}$ The product was freed of salt by dialysis, and hydrolyzed with deoxyribonuclease I and snake venom phosphodiesterase. The mixture was fractionated by DEAE-Sephadex chromatography using a LiCl gradient in the presence of 7 M urea. ${ }^{7}$ Mononucleotides were eluted, followed by dXMP, and then a series of small peaks containing the cross-linked dinucleotide Ia, and oligonucleotides resulting from inhibition of enzymatic hydrolysis of the modified DNA. Each of these latter peaks was desalted, ${ }^{8}$ treated with alkaline phosphatase, and subjected to Sephadex G-25 chromatography, in water. This procedure converted Ia (Ve/Vo 1.0) to Ib (Ve/Vo 1.9). The mobility of the oligonucleotide peaks (Ve/ Vo 1.0) was not altered substantially by this treatment, as they retained internal phosphates.

Compound Ib (yield $12.5 \mathrm{~A}_{290}$ units) was homogeneous in an anion exchange high pressure liquid chromatography system, and had the following properties: $\lambda_{\max }(\mathrm{nm}) 260,300(\mathrm{pH}$ 2.5), 292 ( pH 7.0 ), 250, 260, $290(\mathrm{pH} 13) ; \mathrm{p} K_{\mathrm{a}}$ values, 5.6 and 10.8, the NMR (in $\mathrm{D}_{2} \mathrm{O}$, Fourier transform) showed an aromatic proton ( $\delta 8.1$ ) and a set of peaks due to deoxyribose ${ }^{9}$ in a $1: 1$ ratio. The compound resisted reduction by sodium dithionite, which excluded the presence of nitro, nitroso, azo, azoxy, or diazoamino functions. The $\mathrm{p} K_{\mathrm{a}}$ of Ib was shifted from 5.6 to 7.8 in the presence of glyoxal, ${ }^{10}$ which suggested the presence of the adjacent $\mathrm{N}-1$ and amino functions of guanine,

After trimethylsilylation ${ }^{11}$ the mass spectrum ${ }^{12}$ of Ib showed a molecular weight of 1021 , which from comparison with the trimethylsilyl $-d_{9}$ derivative ${ }^{13}(\mathrm{M}=1075)$ gave a molecular weight of free Ib of 571 . Measurement of exact mass (1021.4426, found) supported $\mathrm{C}_{20} \mathrm{H}_{16} \mathrm{~N}_{9} \mathrm{O}_{8}\left(\mathrm{SiMe}_{3}\right)_{7}$ (1021.4436, calcd), corresponding to two deoxyguanosine molecules minus $\mathrm{NH}_{3}$. The principal fragmentation pathway showed sequential loss of each sugar moiety with hydrogen rearrangement to give $m / e 761$ and 501 , which are analogous to common nucleoside reactions ${ }^{14}$ and militate against a sugar-sugar linkage. N,O-Permethylation $\left(\mathrm{CD}_{3}\right)^{15}$ produced a similar mass spectrum ( $M=618$ ) in which the base-base linkage was maintained in the principal fragment ions, as required for the proposed structure. Treatment of Ib with $\mathrm{D}_{2} \mathrm{O}$ for 1 h at $80^{\circ} \mathrm{C}$ resulted in 2 amu shifts for all base-containing ions, in accord with two unsubstituted C-8 moieties.

Structure Ib is consistent with the properties and origin of the compound, as well as the known thermal and base stability of the cross-links induced by nitrous acid in DNA. ${ }^{16}$ To confirm its origin, we allowed 500 mg of dGMP to react with nitrous acid under the conditions used for DNA, and isolated 8.2 A $_{290}$ units of Ia, after a DEAE-Sephadex workup. A possible mechanism for the formation of I involves diazotization of a guanine amino group, and attack at the position by a second
