# Vibrational Spectra, Conformations, and Potential Functions of Cycloheptane and Related Oxepanes ${ }^{1}$ 

David F. Bocian and Herbert L. Strauss*<br>Contribution from the Department of Chemistry, University of California, Berkeley, California 94720. Received September 7, 1976

#### Abstract

The vibrational spectra of cycloheptane, oxepane, and 1,3-dioxepane are presented and assigned with particular emphasis on the skeletal bending vibrations. The assignments and normal coordinate calculations show that the three molecules have twist-chair conformations as their lowest energy forms. The cycloheptane and 1,3 -dioxepane exist as twist-chairs ( $C_{2}$ symmetry) and the oxepane exists as two asymmetric ( $C_{1}$ symmetry) $d l$ pairs of $t w i s t$-chairs of approximately equal energy. The vibrational spectra can be interpreted on the basis of rigid conformations. A model potential is developed which is used in the following paper to calculate the conformational properties of these ring molecules.

## I. Introduction

The conformations of saturated ring compounds have long been of interest to chemists and many methods have been employed in an attempt to determine their geometries and relative energies. The equilibrium structures of a large number of three-, four-, five-, and six-membered rings have been well characterized by the powerful techniques of electron diffraction and microwave spectroscopy, and more indirectly, by vibrational analysis. Although the equilibrium structures of small saturated ring molecules have been characterized by these methods, the seven-membered rings present difficulties that have, so far, prevented an experimental determination of their lowest energy conformations. However, extensive conformational energy calculations have been done on the seven-membered rings and these have led to an identification of four basic conformations ${ }^{2-6}$-the chair, boat, twist-chair, and twist-boat. The determination of the relative energies and geometries of these four forms has proved extremely difficult; consequently, we have undertaken a detailed vibrational investigation of cycloheptane and the cyclic ethers oxepane and 1,3-dioxepane (Figure 1).

We discuss the vibrational analysis in a number of steps. First we present the experimental spectra and provide an assignment of the low-frequency skeletal modes based on the potential functions and structures we have previously used to fit some preliminary data. ${ }^{7}$ We then refine the potential function to give a better fit to the skeletal frequencies. This potential function also provides a basis for describing the conformations of the seven-membered rings and this detailed description is to be found in the following paper. ${ }^{8}$ Finally, the calculated geometries of the conformations are used together with standard vibrational potential functions ${ }^{9-11}$ (quadratic terms only) to assign the entire vibrational spectrum of each molecule. In practice, of course, we went through several cycles of this procedure to arrive at our final results. We conclude that the lowest energy conformations of these molecules are the twist-chairs illustrated in Figure 1.

## II. Vibrational Spectra and Assignment of Vibrational Frequencies

There have been no detailed infrared or Raman studies of cycloheptane or the oxepanes. Several investigators have, however, reported vibrational spectra of these molecules and offered some very qualitative interpretations. No Raman spectrum of oxepane appears to have been reported, and reports of the Raman spectra of the other molecules lack polarization data.

Our starting point is to characterize the eight ring-bending modes of the three molecules studied. These deformations are
shown schematically for cycloheptane in Figure 2, which is drawn as if the ring were planar ( $D_{7 h}$ symmetry). In this representation there are four vibrations whose motion is essentially out-of-plane ( $\omega_{1}-\omega_{4}$ ) and four whose motion is in-plane $\left(\omega_{5}-\omega_{8}\right)$. Despite the fact that the seven-membered rings deviate greatly from planarity, the designations "in-plane" and "out-of-plane" remain approximately correct and will be retained. A summary of the irreducible representations of the ring-bending deformations is presented in Table I along with their infrared and Raman selection rules in several relevant symmetries.

The approximate separability of the low-frequency motions of the ring from other vibrations in the molecule has been demonstrated by normal coordinate calculations on cyclohexane and other six-membered rings. ${ }^{10-12}$ The calculations indicate that five of the six lowest frequency vibrations of these molecules are almost entirely associated with bending deformations of the ring. The sixth is also primarily a ring-bending vibration, but contains appreciable contributions from the motions of the methylene groups. This information can be extrapolated to predict that only the two highest frequency deformations of a seven-membered ring will show significant mixing with the higher frequency vibrations. The validity of this hypothesis is verified by the full normal coordinate calculations which will be discussed later.

Before presenting the vibrational spectra of the sevenmembered rings in detail, it is useful to state some conclusions: A summary of the ring-bending assignments for all three molecules is presented in Tables II-IV. Also included in the tables are the calculated ring-bending frequencies and the observed and calculated far-infrared intensities. The calculated vibrational frequencies are those of the minimum energy twist-chair conformers whose structures are shown in Figure 1. For each of the structures, the $C$ axis of inertia is approximately the out-of-plane coordinate and for the forms with $C_{2}$ symmetry, the $A$ inertial axis corresponds to the symmetry axis. The exact geometries of the lowest energy forms as well as their energies relative to the other conformations of the ring can be found in the following paper. ${ }^{8}$ Both the frequencies and the structures of the twist-chairs were determined from our ring-bending potential function, whose exact form will be discussed at length later. The vibrational frequencies were calculated as in our work on six-membered rings. ${ }^{12,13 \mathrm{a}}$ Since the potential function is based on a model in which the lowfrequency vibrations are treated as pure ring-bending motions, no attempt was made to fit the $\omega_{7}$ and $\omega_{8}$ vibrations, which are appreciably mixed with motions of the methylene groups. For all three molecules, the calculated frequencies of $\omega_{7}$ and $\omega_{8}$ are higher than those observed. This is consistent with the con-

${ }^{a}$ The notation of ref 9 is used in the table. ${ }^{b}$ For the nonplanar heterocycles there are also boat, twist-boat, chair, and twist-chair conformers which have no symmetry. For these cases all eight vibrations are both IR and Raman active and belong to the irreducible representation A of the symmetry group $C_{1}$. ${ }^{c}$ The designations " A " and "I" indicate active and inactive vibrations, respectively. The polarized Raman bands are marked with a lower case " $p$ ".

straints imposed on the ring-bending motions by our model, since inclusion of the methylene motions can only shift the calculated frequencies of $\omega_{7}$ and $\omega_{8}$ downward. The far-infrared intensities were calculated using a bond-dipole model which includes both $\mathrm{C}-\mathrm{H}$ and $\mathrm{C}-\mathrm{O}$ dipoles. The $\mathrm{C}-\mathrm{H}$ dipole is assumed to be $-1 / 3$ that of a $\mathrm{C}-\mathrm{O}$ dipole. For the oxygencontaining compounds only minor changes in the intensities result if the $\mathrm{C}-\mathrm{H}$ dipole contributions are neglected.
Experiment. Cycloheptane and 1,3-dioxepane were obtained as reagent-grade solvents from Aldrich Chemical Co., Inc., and oxepane was obtained as a reagent-grade solvent from Chemical Samples Co., Inc. Gas chromatographic analysis revealed no impurities and all spectra were recorded without further purification of the chemicals. The samples used for

gas-phase spectra were stored under vacuum after the air had been removed from the compounds by several freeze-pumpthaw cycles.

All infrared spectra in the region $4000-400 \mathrm{~cm}^{-1}$ were recorded on a Beckman IR-12 infrared spectrometer. The vapor-phase spectra were taken at a sample pressure of approximately 10 Torr at path lengths varying from 10 cm to 10 m in a Beckman variable path-length multipass cell equipped

Table IV. Observed and Calculated Ring-Bending Frequencies of Oxepane

${ }^{a}$ The Roman numerals refer to Figure $1 .{ }^{b}$ These frequencies are taken from the spectra of the liquid. ${ }^{c}$ These bands are severely overlapped and their individual intensities cannot be measured. The observed intensity is the sum of the intensities of the $\omega_{4}$ and $\omega_{6}$ bands for both conformers. ${ }^{d}$ These frequencies were not fit with ring-bending potential function; see text.

Cycloheptane Vapor 53 Degrees $0.6 \mathrm{~cm}^{-1}$ Resolution

Figure 3. Far-infrared spectrum of cycloheptane ( $400-75 \mathrm{~cm}^{-1}$ ). Average of six samples and six background spectra: 17 -Torr pressure; $39-\mathrm{m}$ path length; temperature $53^{\circ} \mathrm{C}$. The bands at 123,335 , and $395 \mathrm{~cm}^{-1}$ are barely visible on this spectrum.

Figure 4. Low-frequency Raman spectrum of cycloheptane. The very weak shoulder at $347 \mathrm{~cm}^{-1}$ is not visible on this drawing.
with KBr windows. All liquid-phase spectra were recorded as neat films on CsI plates, with the exception of cycloheptane, whose spectrum was recorded at a path length of 1 mm in KBr cells.

The liquid-phase spectra in the region $400-33 \mathrm{~cm}^{-1}$ were recorded on a Beckman IR-11 far-infrared spectrometer. The spectra of oxepane and 1,3-dioxepane were recorded in $1-\mathrm{mm}$ path length Beckman polyethylene liquid cells on $20 \%$ (by volume) solutions in cyclohexane. The spectrum of cycloheptane was obtained on the neat liquid in $5-\mathrm{mm}$ path length polyethylene cells. For oxepane and 1,3-dioxepane, the reference cell contained cyclohexane, and for cycloheptane the reference cell was empty.

The vapor-phase far-infrared spectra in the region from 400 to $10 \mathrm{~cm}^{-1}$ were obtained on a RIIC FS-520 Michelson interferometer, which has been modified as described in the theses of Borgers, Greenhouse, and Pickett. ${ }^{13}$ Mylar beam splitters of $1 / 4$ - and 1 -mil thickness were used to examine the regions $400-75$ and $75-10 \mathrm{~cm}^{-1}$, respectively. All spectra were taken at a sample pressure of approximately 10 Torr and a path length of 39 m in a specially constructed variable pathlength multipass White-type cell ${ }^{14}$ with high-density polyethylene windows.

The Raman spectra of all the molecules were recorded as neat liquids at an excitation wavelength of $5145 \AA$. A Coherent Radiation Model CR-2 argon ion laser served as the source of incident radiation, while spectral resolution was achieved with a Spex Industries double monochrometer. The spectra of cycloheptane and 1,3-dioxepane were obtained with the aid of J. M. Scherer and Sima Kint, while the spectrum of oxepane was recorded in our own laboratory.

Cycloheptane. The liquid-phase infrared and Raman spectra of cycloheptane have been reported by Wheeler and Mateos ${ }^{15}$

Figure 5. Far-infrared spectrum of 1,3 -dioxepane ( $400-75 \mathrm{~cm}^{-1}$ ). Average of six samples and six background spectra: 17-Torr pressure; 39-m path length.

and Bazhulin et al., ${ }^{16}$ respectively, while the liquid spectrum in the far-infrared region has been examined by Lord. ${ }^{17}$ In all cases the spectra observed in our laboratory have agreed with those reported by the previous investigators.

The vapor-phase far-infrared spectrum of cycloheptane was examined with the Michelson interferometer at room temperature. Under these conditions the vapor pressure of the molecule was found to be insufficient to yield any absorption above that of the background. In order to observe any spectral features, it was necessary to reexamine the spectrum at $53^{\circ} \mathrm{C}$, which gave a sample pressure of approximately 17 Torr. Even at this temperature the spectrum was observed to be extremely weak; a broad, moderately intense band centered at $273 \mathrm{~cm}^{-1}$ is its only prominent feature (Figure 3). A more careful examination of the vapor spectrum, together with an examination of the liquid far-infrared, revealed additional extremely weak absorptions centered at approximately 123,335 , and $395 \mathrm{~cm}^{-1}$. No absorptions were observed in the region $75-10 \mathrm{~cm}^{-1}$, the region in which absorption would be expected if the molecule were undergoing free or nearly free pseudorotation.

The low intensity of the cycloheptane spectrum can be explained in terms of approximate symmetry arguments analogous to those we used for cyclohexane. ${ }^{12}$ For planar cycloheptane, the eight ring-bending vibrations transform in four degenerate pairs, belonging to the irreducible representations $\mathrm{E}_{2}{ }^{\prime \prime}, \mathrm{E}_{3}{ }^{\prime \prime}, \mathrm{E}_{2}{ }^{\prime}$, and $\mathrm{E}_{3}{ }^{\prime}$ of the symmetry group $D_{7 h}$ (Figure 2, Table I), and are infrared inactive. Although the twist-chair conformers are distorted from a $D_{7 h}$ plane, the vibrations remain weak. Their relative intensities can be explained by examining the form of the normal coordinates. The out-of-plane
vibrations $\omega_{1}-\omega_{4}$ have most of their motion in the out-of-plane direction parallel to the molecular $C$ axis. The vibrations $\omega_{2}$ and $\omega_{4}$ are of $A$ symmetry in the $C_{2}$ group (twist-chair) and thus can only produce dipole changes along the $A$ molecular axis. The $\omega_{1}$ and $\omega_{3}$ vibrations produce dipole changes along the $C$ molecular axis and consequently the intensities of the $\omega_{1}$ and $\omega_{3}$ bands are much larger than the intensities of the $\omega_{2}$ and $\omega_{4}$ bands. The same argument accounts for the relative intensity of the $\omega_{1}$ band of 1,3-dioxepane as compared to the $\omega_{2}$ band and the $\omega_{3}$ band compared to the $\omega_{4}$ band (Table III).

Since the $\omega_{2}$ and $\omega_{4}$ vibrations are totally symmetric, they, as well as the $\omega_{5}$ and $\omega_{7}$ vibrations, should be observed as polarized Raman bands. The examination of the low-frequency Raman spectrum of cycloheptane (Figure 4) does, indeed, reveal two polarized bands at positions which do not correspond to bands in the gas-phase infrared, a weak band at $182 \mathrm{~cm}^{-1}$ and a strong, sharp line at $320 \mathrm{~cm}^{-1}$. It was first thought that the $320-\mathrm{cm}^{-1}$ line might be the same band as that observed at $335 \mathrm{~cm}^{-1}$ in the infrared, but the $335-\mathrm{cm}^{-1}$ band is the depolarized shoulder which appears on the $320-\mathrm{cm}^{-1}$ line. The $182-$ and $320-\mathrm{cm}^{-1}$ bands are assigned as $\omega_{2}$ and $\omega_{4}$ and the infrared absorptions at 123 and $335 \mathrm{~cm}^{-1}$ are attributed to the other two out-of-plane vibrations $\omega_{1}$ and $\omega_{3}$. Examination of the cyclohexane frequencies suggests that the $\mathrm{E}_{2}$ frequencies are lower than the $\mathrm{E}_{3}$ frequencies, so that the $273-\mathrm{cm}^{-1}$ band is assigned as $\omega_{6}$ and the strong polarized Raman band at 400 $\mathrm{cm}^{-1}$ as $\omega_{5}$. The two highest skeletal bending modes are assigned with $\omega_{7}$ at $515 \mathrm{~cm}^{-1}$, since the Raman band is polarized, and the remaining $\omega_{8}$ at $490 \mathrm{~cm}^{-1}$. These arguments are not unambiguous, but are confirmed by the detailed normal coordinate calculations and by consistent results for all three of the seven-membered rings.

1,3-Dioxepane. The infrared and Raman spectra of liquid 1,3-dioxepane have been reported by Tarte et al. ${ }^{18}$ and are in complete agreement with those recorded in our laboratory. As is true for cycloheptane, no vapor-phase spectra have been previously reported for 1,3-dioxepane.

The vapor-phase far-infrared spectrum of 1,3-dioxepane was examined in the region $400-10 \mathrm{~cm}^{-1}$ on the Michelson interferometer under the conditions previously discussed. As was the case for cycloheptane, no extremely low-frequency absorptions, which might be indicative of a freely interconverting molecule, were observed. Unlike cycloheptane, however, 1,3-dioxepane spectra recorded at room temperature at a sample pressure of 10 Torr showed fairly intense absorptions in the region $400-75 \mathrm{~cm}^{-1}$. This is to be expected, since the substitution of the highly electronegative oxygen atoms for methylene groups removes the approximate electrical symmetry achieved in cycloheptane. The far-infrared spectrum of 1,3-dioxepane is shown in Figure 5 and the low-frequency Raman spectrum in Figure 6. Both of these spectra are similar to those of cycloheptane and can be assigned in an analogous fashion.

Oxepane. The mid-infrared spectrum of liquid oxepane was

Figure 7. Far-infrared spectrum of oxepane ( $400-75 \mathrm{~cm}^{-1}$ ). Average of six samples and six background spectra: 17-Torr pressure; $39-\mathrm{m}$ path length.

Figure 8. Low-frequency Raman spectrum of oxepane.
reported by Kirrmann and Hamaide ${ }^{19}$ in 1957, but no Raman or vapor-phase infrared spectrum of this molecule is available in the literature. As was the case for cycloheptane and 1,3dioxepane, our vapor-phase infrared spectra of oxepane below $75 \mathrm{~cm}^{-1}$ revealed no absorptions which might be indicative of a freely interconverting molecule. The spectrum in the region $400-75 \mathrm{~cm}^{-1}$ is exceptionally rich, however, and appears to be much more complex than that of either of the other two molecules (Figure 7). Prominent fine structure is evident on a number of bands and the very intense absorption centered at approximately $290 \mathrm{~cm}^{-1}$ appears to be a composite of three or possibly four overlapping bands. In the liquid far-infrared spectrum, the $290-\mathrm{cm}^{-1}$ band splits quite clearly into two bands of approximately equal intensity at 278 and $297 \mathrm{~cm}^{-1}$ with much weaker shoulders at 310 and $325 \mathrm{~cm}^{-1}$. The resolving of the $290-\mathrm{cm}^{-1}$ band in the liquid phase is probably due to several factors, such as the collapse of vibration-rotation structure and changes in the relative intensities of the overlapping bands. In addition to the multiple bands at $290 \mathrm{~cm}^{-1}$, vapor-phase mid-infrared spectra recorded at a sample pressure of 13 Torr and a path length of 1 m clearly reveal that the two highest frequency ring-bending vibrations at 555 and 508 $\mathrm{cm}^{-1}$ occur as doublets split by approximately $10 \mathrm{~cm}^{-1}$. A number of other mid-infrared bands also appear split, and those which are not are considerably broader than their counterparts in either cycloheptane or 1,3-dioxepane. All of this evidence strongly suggests that oxepane exists in two stable conformations.
The low-frequency Raman spectrum of oxepane (Figure 8) retains many of the general features of the cycloheptane and 1,3-dioxepane spectra. In contrast to the far-infrared, no bands are clearly doubled, but several are quite broad. Attempts at splitting the $417-, 352-$, and $325-\mathrm{cm}^{-1}$ lines, as well as the symmetric ring-breathing vibration at $752 \mathrm{~cm}^{-1}$, proved unsuccessful; but the line widths at half maximum for these bands were measured to be approximately four times those of the analogous lines in cycloheptane and 1,3-dioxepane.

Our ring-bending potential function predicts two stable conformations for oxepane. ${ }^{8}$ The calculations indicate that
these forms are both twist-chairs (Figure 1), which are of approximately equal energy, and that there exists a $2-\mathrm{kcal} / \mathrm{mol}$ barrier to interconversion between the two forms. The calculated frequencies and intensities of the ring-bending vibrations of the two forms, when viewed together, successfully account for the complexities found in the oxepane spectrum. The quartet of bands is due to the overlapping $\omega_{4}$ and $\omega_{6}$ vibrations of both conformers, while the nondoubled bands at 417 and 357 $\mathrm{cm}^{-1}$ are a result of the near coincidence of the two $\omega_{5}$ and $\omega_{3}$ vibrations, respectively. The low-frequency normal coordinate calculations also indicate that both $\omega_{1}$ and $\omega_{2}$ should be doubled, but no splitting of these bands is observed. The intensity calculations reveal, however, that $80 \%$ of the intensity of the $\omega_{2}$ band is due to conformer II, while $75 \%$ of the intensity of the $\omega_{1}$ band is due to conformer I (Table IV). In light of this fact, it is not unreasonable that the weaker members of each of the pairs of bands are not seen.

Since both of the stable oxepane conformations have no symmetry, all Raman bands would be expected to be at least partly polarized. However, the low-frequency Raman spectrum of oxepane exhibits both polarized and approximately depolarized bands analogous to those of cycloheptane and 1,3dioxepane.

Nonfundamental Low-Frequency Vibrations. Several nonfundamental vibrations are also observed in the low-frequency spectra of cycloheptane, oxepane, and 1,3-dioxepane. The frequencies and possible assignments of these vibrations are summarized in Table V. Several of these bands can be successfully assigned as sum and difference bands between comparable ring-bending vibrations in more than one of the molecules. For example, the spectra of both cycloheptane and 1,3-dioxepane have bands assignable as the difference between $\omega_{7}$ and $\omega_{2}$, while oxepane and 1,3-dioxepane have bands assignable as the sum of $\omega_{2}$ and $\omega_{4}$. In addition, the oxepane and 1,3-dioxepane spectra have bands which are not consistent with sums, differences, or overtones of the ring-bending frequencies exclusively. A weak shoulder appears in the 1,3-dioxepane spectrum at $470 \mathrm{~cm}^{-1}$ which has a counterpart in oxepane at $436 \mathrm{~cm}^{-1}$ (Figures 6 and 8). Both of these bands are assignable as the difference between $\omega_{7}$ and a ring-stretching vibration. The oxepane band is quite broad, with a frequency spread of approximately $20 \mathrm{~cm}^{-1}$, while the 1,3 -dioxepane band is considerably narrower. This is consistent with the doubling observed for the $\omega_{7}$ band in oxepane (Table IV), since the difference band is probably a composite of the bands arising from both of the stable oxepane conformers.

One other relatively intense band is observed in both the infrared and Raman spectra of 1,3-dioxepane. Although this band could be assigned as a difference frequency between any one of several of the ring-bending vibrations and a ring stretch, the band seems too strong to be a difference band. There is some possibility the band is due to an unusually low-frequency C-H rocking vibration, but the normal coordinate calculations for 1,3-dioxepane (Table VII) do not indicate that a defor-

Table V. Correlation Table for Nonfundamental Vibrations ${ }^{a}$

mation of this type should occur anywhere in this frequency region. It is also unlikely that the band is one of the two highest frequency ring-bending vibrations, since the intensities and polarizations of the 1,3 -dioxepane bands at 606 and $516 \mathrm{~cm}^{-1}$ are much more consistent with those of the $\omega_{7}$ and $\omega_{8}$ vibrations in the other two molecules.

Normal Coordinate Calculations. In order to assign the higher frequency vibrations and to test the validity of the assumption concerning the separability of these vibrations from the low-frequency motions, conventional normal coordinate calculations were carried out for each of the molecules studied. The inverse kinetic energy matrix, $G$, was set up using the internal coordinates of Wilson, Decius, and Cross, ${ }^{9}$ and the geometries determined by our conformational calculations. ${ }^{8}$ The force fields used were the saturated hydrocarbon force field of Snyder and Schachtschneider ${ }^{10}$ and the aliphatic ether force field of Snyder and Zerbi. ${ }^{11}$ The secular equation was solved using the $F G$ matrix method of Wilson, using the computer programs of Schachtschneider. ${ }^{20}$ The application of Snyder and Zerbi's force field to 1,3-dioxepane is not possible without some additional assumptions, and whenever necessary we used the force constant for the valence coordinate most like the needed force constant. For example, the force constant for the OCC angle bend was also used for the OCO angle bend of 1,3-dioxepane.

The results of the normal coordinate calculations are presented in Tables VI-VIII. The fits obtained are not nearly as good as those for the model compounds used by Snyder and Schachtschneider and Snyder and Zerbi to determine the force fields, but they are surprisingly good considering the approximations made before application to the seven-membered rings was possible. As is the case for the model compounds, the low-frequency vibrations are those whose calculated values agree most poorly with experiment. For all the molecules, however, only the two highest frequency ring-bending vibrations show significant mixing with the motions of the methylene groups. The relative separability of the in- and out-ofplane deformations of the ring is also maintained and these motions retain much of their ideal character. In the results for oxepane both stable conformations are included. The calculations indicate that many of the higher energy motions in the two conformers have frequencies which are nearly coincident, consistent with the failure to observe clearly doubled lines for many of these vibrations. Most of the bands calculated to have splittings $>5 \mathrm{~cm}^{-1}$ are observed to be doubled.

## III. Determination of Conformation and Potential Function for Ring Bending

The determination of a ring-bending potential function for the seven-membered rings was complicated by the fact that the geometries of the minimum energy forms were not known. Although most conformational calculations indicate the twist-chair to be the most stable form, ${ }^{2-6}$ it is not clear a priori that this should be the lowest energy conformer. Conventional normal coordinate calculations are of little aid in the determination of conformation, since only very approximate fits can be obtained for those frequencies most sensitive to the con-
formation. Additionally, we have found that the higher frequency vibrations of the seven-membered rings are fairly insensitive to the conformation. Thus, mid-infrared spectra can be successfully interpreted in terms of either a boat- or chairlike conformer. None the less, some useful information can be extracted from conventional normal coordinate calculations. These show that good agreement can only be obtained with the observed Raman polarizations in the mid-frequency range if the molecule is taken to be in a twisted conformation ( $C_{2}$ symmetry).

Our criteria for determining a ring-bending potential function are two: First, the potential must accurately reproduce the observed ring-bending frequencies of all three molecules. Second, this potential, when used as the basis for conformation calculations, must yield minimum energy structures consistent with the observed spectroscopic data. The actual details of the conformational calculations using our ring-bending potential function are presented in the following paper. ${ }^{8}$

The potential function used for our conformational and low-frequency vibrational calculations is

$$
\begin{align*}
V= & \sum_{i=1}^{7}\left[H\left(\psi_{i}-\psi_{i}^{0}\right)^{2}+F\left(\psi_{i}-\psi_{i}^{0}\right)\left(\psi_{i+1}-\psi_{i+1}^{0}\right)\right. \\
+ & T \cos \tau_{i}+D \cos 2 \tau_{i}+K\left(\psi_{i}-\psi_{i}^{0}\right)\left(\psi_{i+1}-\psi_{i+1}^{0}\right) \\
& \left.\times \cos \tau_{i}+\sum_{\substack{j=i+3 \\
\bmod 7}}^{\bmod 7} \sum_{m=1}^{4}\left(A e^{-r_{i j m} / r_{0}}-B / r_{i j m^{6}}^{6}\right)\right] \tag{1}
\end{align*}
$$

In this equation, the $\psi_{i}$ are the values of the seven ring bond angles and the $\psi_{i}{ }^{0}$ are the equilibrium values they would have if the ring were opened. The $\tau_{i}$ are the torsional angles of the ring. The $r_{i j m}$ are the distances between the hydrogen atoms attached to the carbon atoms indexed $i$ and $j$. The index $m$ labels the four distances between the hydrogens on these atoms. For the ethers, $r_{i j m}$ also represents the distance between the oxygen atom (indexed $i$ ) and the hydrogens on carbon atom $j$. For the special case of the hydrogen-oxygen interaction, the index $m$ runs from 1 to 2 .

In our calculations all the carbon-carbon bond lengths were fixed at $1.532 \AA$ and the carbon-hydrogen bond lengths at $1.110 \AA$. The carbon-oxygen bond lengths were taken as 1.43 $\AA .^{13 a}$ The HCH bond angle was fixed at $107^{\circ} .^{7}$ The values of the $\psi_{i}{ }^{0}$ were the same as those used by Pickett and Strauss in their determination of a ring-bending potential function for cyclohexane and a number of oxanes. ${ }^{12}$

The complete set of parameters for eq 1 , used in our calculations, is summarized in Table IX. Since the potential constants were obtained by fitting the low-frequency vibrational motions only, they are effective potential constants which in other potential functions would be modeled by a large number of nonbonded interactions (carbon-carbon, carbon-hydrogen, carbon-oxygen, etc.). For this reason many of our constants are quite different from those determined from conventional normal coordinate calculations. ${ }^{10,11}$

Pickett and Strauss found that a potential function containing only $H, F, T$, and a onefold torsional term, $U$, is sufficient for a successful conformational and low-frequency vi-

[^0]brational treatment of the six-membered rings. ${ }^{12,21}$ For cyclic molecules larger than cyclohexane, however, it is clear that more terms must be added to the potential function. Calculations on cyclooctane show that a potential with just $H, F, T$,
and $U$ terms leads to untenable conformations with unreasonably small 1,5 -hydrogen-hydrogen distances. ${ }^{22}$ A 1,5hydrogen repulsive term must therefore be added to the potential function. The terms $H, F, T$, and $U$ should correlate 1,2-

${ }^{a}$ See Table VI for notation.
and 1,3 -hydrogen-hydrogen interactions, but it is unclear a priori how these terms correlate the 1,4 -interactions in the seven-membered rings. Calculations show, however, that 1,4 -nonbonded interaction terms can have a significant effect on both the relative energies ${ }^{7}$ and vibrational frequencies of the various conformations. If a potential function containing only $H, F, T$, and $U$ terms is used for the seven-membered rings, the boats are the preferred structures by several kilocalories per mole, while inclusion of nonbonded terms makes the chairs more favorable. Vibrational calculations for the seven-membered rings using the six-membered ring potential function reveal that the low frequencies of the chair forms are in qualitative agreement with experiment, while those of the boat are totally inconsistent. The calculated out-of-plane frequencies of the boat conformers deviate by nearly $70 \mathrm{~cm}^{-1}$ from those observed, while the calculated intensities of the vibrations are an order of magnitude different from their actual values. No simple adjustment of the parameters $H, F, T$, and $U$ can bring the frequencies of the boats into agreement with experiment.
A number of different approaches could be taken in modi-
fying the six-membered ring potential function to provide a better fit to the data. We have chosen to add a nonbonded term, to replace the onefold torsional term, $U$, by a twofold term, $D$, and to add a bend-torsion interaction constant, $K$ (eq 1). With minor modification, the values of $H, F$, and $T$ are taken to be the same as for the six-membered rings. The parameter $B$ of the nonbonded part of the potential is set at the value estimated for van der Waals interactions. ${ }^{7}$ A number of choices are available for the parameters $A$ and $r_{0}{ }^{3,23,24}$ and we have used the relatively soft potential of Abe et al., ${ }^{23}$ which raises the boat conformers about $0.5 \mathrm{kcal} / \mathrm{mol}$ above the chair forms and has only a small effect on the calculated skeletal bending frequencies. The onefold torsional term, $U$, used for cyclohexane was found to have little effect on the properties of the seven-membered rings, so a twofold term was added instead. This term raises the energy of the boat forms some more and has a small effect on the frequencies. The value of $D$ cannot be determined with much accuracy because of the insensitivity of the frequencies to changes in $D$. As a final adjustment to our potential function, an angle bending-torsion interaction term, $K$, is added. A term of this form has been used by Warshel and

Lifson in their conformational and vibrational treatment of cyclopentane, cyclohexane, and a number of $n$-alkanes, ${ }^{25}$ and inclusion of terms in $K(\mathrm{CCCC})$ and $K(\mathrm{CCCO})$ results in a general improvement of the fits of the in-plane frequencies. No significant improvements were noted upon inclusion of $K(\mathrm{CCOC})$ or $K(\mathrm{COCO})$ terms, however, so these are not included in our potential function.

In order to obtain the calculated ring-bending frequencies listed in Tables II-IV, a few additional modifications are necessary in the six-membered ring potential function. These involve small adjustments in the values of $H, F$, and $T$ for the
valence coordinates involving only the carbon atoms. Our CCC angle bending force constant is about $10 \%$ larger than that of Pickett and Strauss, ${ }^{12}$ while our threefold CCCC torsional parameter is approximately $40 \%$ smaller. The large change in $T$ is somewhat artificial, however, occurring for the most part because of the addition of the twofold term. The barrier height of our torsional well is only $14 \%$ less than that of Pickett and Strauss. The six-membered ring potential function does not differentiate between the angle bending interaction terms $\mathrm{CCC}-\mathrm{CCC}$ and $\mathrm{CCC}-\mathrm{CCO}$. For the seven-membered rings, the fits of the in-plane frequencies improve considerably if the sign of the CCC-CCC term is reversed and its absolute value increased by about $50 \%$. No adjustments were found necessary in the potential constants $H, F$, or $T$ for any of the valence coordinates involving the oxygen atoms.

## IV. Conclusions

We conclude that the lowest energy conformation of cycloheptane, 1,3-dioxepane, and oxepane are the twist-chair forms shown in Figure 1. The skeletal bending modes are fit by the potential function of eq 1 and Table IX, and this potential function also determines the structures and relative energies of the various conformations. Using our calculated structures, standard vibrational potential functions fit the entire range of vibrational frequencies. It should be emphasized that the conclusion that the molecules are twist-chairs does not depend on the details of the potential function. Indeed, a rather different potential function developed by Warshel ${ }^{26}$ gives similar results for the low frequencies and the conformations. The low frequencies are used to further refine our potential
function and this in turn leads to more precise conclusions about the properties of the various conformations of the seven-membered rings, as discussed in the following paper.

# Conformational Structure and Energy of Cycloheptane and Some Related Oxepanes ${ }^{1}$ 

David F. Bocian and Herbert L. Strauss*<br>Contribution from the Department of Chemistry, University of California, Berkeley, California 94720 . Received September 7, 1976

#### Abstract

Calculations of the low-energy conformations of cycloheptane, 1,3-dioxepane, and oxepane are presented. The calculations use the potential function derived using the vibrational information in the preceding paper. The various paths for conformational interconversion are characterized and the chair-twist-chair pseudorotation paths are mapped. The results of the calculations are compared with NMR results and with rotational Raman spectra, and with the results of previous calculations. The available evidence leads to a consistent picture of the seven-membered rings, with the twist-chairs as the lowest energy conformations.

## I. Introduction

The determination of the relative energies and geometries of the cycloalkanes has been an ongoing challenge to chemists. The conformations of the smaller ring molecules have been well characterized, but the determination of the properties of molecules of seven ring atoms and larger has proved to be more difficult. Calculations based on empirically determined potential functions have suggested the main features to be expected in the seven-membered rings ${ }^{2-6}$ and have identified four basic conformations-the chair, the boat, the twist-chair, and the twist-boat. ${ }^{7}$ In a previous paper, ${ }^{7}$ we presented a detailed account of the conformational properties of cycloheptane using a potential function derived from an analysis of the vibrational spectra of six-membered rings. ${ }^{8}$ Now we have been able to analyze the vibrational spectra of cycloheptane, 1,3-dioxepane, and oxepane. The vibrational spectra show that each of these molecules exist in twist-chair conformations. Oxepane exists as a set of $d l$ pairs of two different twist-chairs with no elements of symmetry; 1,3-dioxepane and cycloheptane exist as single twist-chairs containing single twofold symmetry axes. We have used this information and the vibrational frequencies to modify our original potential function. In this paper, we present calculations of the conformational properties of these molecules
using our new potential function. The transformations among the conformations are visualized using methods we described previously. ${ }^{7}$

Comparison is made to new NMR data and to other experiments that contain some structural information. We first present the results of the conformational energy calculations, then an account of the details of the determination of the potential function, and finally, an account of comparison with other data. We have interpreted the spectrum of one other seven-membered ring molecule, cycloheptanone. The barrier to pseudorotation in cycloheptanone is significantly lower. The same model we present here also fits the properties of cycloheptanone in detail, but we discuss the cycloheptanone in a separate paper because the lower barrier changes the observable spectra dramatically. ${ }^{10}$

## II. Conformational Energy Surfaces

In our previous paper on cycloheptane, ${ }^{7}$ we described a set of coordinates for the seven-membered rings which are especially suited for conformational calculations. These coordinates are similar to those which have been described in detail for cyclopentane, ${ }^{11}$ cyclohexane, ${ }^{12,13}$ and for rings in general. ${ }^{14}$ In this coordinate system, the $z$ or out-of-plane displacements

[^0]:    ${ }^{a}$ Abbreviations: v , very; s, strong; m, medium; w, weak; p, polarized; dp, depolarized. ${ }^{b}$ Key to the notation for the vibrational motion. The motions involving the bond and torsional angles of the ring are denoted by $\theta$ and $\tau$, respectively. R denotes the stretching of a ring bond. The motions of the methylene group are defined with respect to the plane formed by three consecutive ring atoms, where the methylene group of interest is located at the central atom. These motions are defined as follows: scissoring, the two protons move out of the plane in opposite directions; twisting, the two protons move in the plane in opposite directions; wagging, the two protons move in the plane in the same direction; rocking, the two protons move out of the plane in the same direction. Only the major contributions to the vibrational motion are listed in the tables. For the ring skeleton, numerical values are given (parentheses), and these represent the percentage contribution of the major diagonal elements of the force constant matrix to the vibrational frequency.
