# Molecular Orbital Theory of the Electronic Structure of Molecules. 34. Structures and Energies of Small Compounds Containing Lithium or Beryllium. Ionic, Multicenter, and Coordinate Bonding 

James D. Dill, ${ }^{12, b}$ Paul v. R. Schleyer, ${ }^{* 1 c}$ J. Stephen Binkley, ${ }^{1 d}$ and John A. Pople*1d<br>Contribution from the Departments of Chemistry, Princeton University, Princeton, New Jersey 08540, Carnegie-Mellon University, Pittsburgh, Pennsylvania 15213, the Institute of Organic Chemistry, University of Erlangen-Nuremberg, 8520 Erlangen, West Germany, and Physicalisch Chemisches Institut der Universität Basel, 2056 Basel, Switzerland. Received August 31, 1976

#### Abstract

A systematic set of 33 neutral molecules and molecular complexes is examined, each containing lithium or beryllium and one other heavy atom. These include singly bonded $\mathrm{MX}(\mathrm{M}=\mathrm{Li}, \mathrm{BeH})$ for all X of the first short period ( Li to F ), doubly bonded $\mathrm{BeY}\left(\mathrm{Y}=\mathrm{Be}, \mathrm{BH}, \mathrm{CH}_{2}, \mathrm{NH}, \mathrm{O}\right)$, hydrogen-bridged metal complexes $\mathrm{MH} \cdots \mathrm{M}^{\prime} \mathrm{H}\left(\mathrm{M}^{\prime}=\mathrm{Li}, \mathrm{BeH}, \mathrm{BH}_{2}\right)$, and coordinate donor-acceptor complexes $\mathrm{HM} \ldots \mathrm{D}\left(\mathrm{D}=\mathrm{NH}_{3}, \mathrm{OH}_{2}, \mathrm{FH}\right)$. Geometries are optimized at the STO-3G level followed by single 6-31G* calculations. Single bonds in MX molecules with lone pair X are predicted to be too short at STO-3G due to exaggerated $\mathrm{MX} \pi$ bonding. Bonds in $\mathrm{MM}^{\prime}$ and $\mathrm{MCH}_{3}$ species are long and relatively weak; the lengths of these appear to be well reproduced by the theory. Structures of MX compounds reflect optimum arrangements for $\pi$ bonding ( $\mathrm{NH}_{2}$ planar, OH linear). Lowest energy geometries of metal hydrides may be bound through two or three bridging hydrogen atoms. Three are favored in $\mathrm{LiBH}_{4}$ and $\mathrm{BeBH}_{5}$ and two in $\mathrm{Li}_{2} \mathrm{H}_{2}, \mathrm{LiBeH}_{3}$, and $\mathrm{Be}_{2} \mathrm{H}_{4}$.

In previous papers of this series, ${ }^{2-5}$ a major aim has been to develop a systematic and extensive "model chemistry" in which varieties of molecules are examined theoretically at a uniform level of approximation. In studying series of compounds, we do not require molecular descriptions which are accurate in an absolute sense but may employ reasonably inexpensive levels of theory to examine relationships among structures and energies. Early applications of this model have dealt largely with molecules well characterized experimentally and have served to calibrate the predictive ability of the theory. At this point, we may proceed with confidence into experimentally inaccessible or unexplored areas to model further structural and energetic trends.

The study of small compounds involving lithium and beryllium is a natural extension of previous work. While many of the structures in the present paper have not been observed experimentally as monomeric species, it is nevertheless worthwhile to examine these small compounds for comparison with those studied at the same level elsewhere. ${ }^{4,5}$ In fact, the present contribution fills one of the last major gaps in a complete model chemistry involving bonds between first-row elements. The set of molecules comprising this complete system is well defined and includes only neutral one- and two-heavyatom species, specifically the two hydrides LiH and $\mathrm{BeH}_{2}$, the
singly bonded molecules combining Li or HBe with any of the first-row radicals ( $\mathrm{Li}, \mathrm{BeH}, \mathrm{BH}_{2}, \mathrm{CH}_{3}, \mathrm{NH}_{2}, \mathrm{OH}, \mathrm{F}$ ), the molecular complexes combining LiH or $\mathrm{BeH}_{2}$ with first-row hydrides ( $\mathrm{LiH}, \mathrm{BeH}_{2}, \mathrm{BH}_{3}, \mathrm{CH}_{4}, \mathrm{NH}_{3}, \mathrm{OH}_{2}, \mathrm{FH}$ ), and the formally doubly bonded combinations of Be with $\mathrm{Be}, \mathrm{BH}, \mathrm{CH}_{2}$, NH, and O. For the formally doubly-bonded Be systems, both singlet and triplet states are considered.

Known compounds of lithium and beryllium span a wide range of structural types. ${ }^{6-9}$ Electron deficiency in these species is manifested in high degrees of association and solvation, while electronegativity differences lead to high degrees of ionic character in LiX and BeX bonds. Structures of lithium and beryllium compounds thus involve multicenter electron-deficient, coordinate, ionic, and covalent bonding. Depending on the surrounding medium, the organometallic system R-M (M $=\mathrm{Li}$ or BeR ) may be accurately represented as oligomeric ( $\mathrm{R}-\mathrm{M})_{n}$, base-coordinated $\mathrm{R}-\mathrm{M}(: \mathrm{B})_{n}$, or ionic $\mathrm{R}^{-} \mathrm{M}^{+}$. Gasphase structures are usually associated, consisting of small polyhedra of metal atoms bridged by organic radicals. However, in studying lithium and beryllium chemistry systematically, we begin with small (two-heavy-atom) systems in order to understand the nature of the various bond types, the corresponding bond strengths, and the factors which lead to molecular association.

${ }^{a}$ The notation " $-(\mathrm{H})_{n}--$ " indicates $n$ equivalent bridging hydrogens. A "- - " indicates a bond containing formally fewer than two electrons. See text. ${ }^{b}$ ln hartrees, at STO-3G optimized geometry. Unless stated otherwise, energies refer to singlet state. ${ }^{c}$ Energy (kcal mol ${ }^{-1}$, where 1 hartree $=627.53 \mathrm{kcal} \mathrm{mol}^{-1}$ ) relative to lowest energy isomer. ${ }^{d} \mathrm{H}-\mathrm{A}-\mathrm{B}-\mathrm{H}$ coplanar. ${ }^{e} \mathrm{H}-\mathrm{A}-\mathrm{B}-\mathrm{H}$ dihedral angle $=90^{\circ} . f$ Energy obtained by the UHF procedure of Pople and Nesbet (ref 16).

## Methods

Two levels of ab initio single-determinant molecular orbital theory were employed as in previous studies. ${ }^{2-4}$ First, the minimal STO-3G basis set, ${ }^{10}$ which includes a full set of p functions on Li and Be , was used together with standard molecular scaling factors for geometry optimizations. For each of the 47 structures listed in Table I, all independent geometrical parameters were varied until the energy was minimized. Minimum STO-3G energies are given in Table I, the corresponding geometries in Tables II and III. Also given are the final symmetry point groups assumed during each optimization, although in most cases a lower symmetry than that
specified was assumed at the outset. However, individual structures were not studied with respect to stability to all displacements, so that some may not represent the local potential minima. Not given in the tables are several metal hydride dimers calculated with partial geometry optimization. These are discussed below under the appropriate headings. In these systems, it was found after some variation of the most critical geometrical parameters that the dimer energy did not fall below the sum of monomer energies, and further study was deemed unnecessary.

Following STO-3G geometry optimizations, single calculations were carried out at the $6-31 \mathrm{G}^{*}$ level using the STO-3G

${ }^{a}$ Corresponding to the numbering in Table 1. ${ }^{b}$ Distances in ångströms, angles in degrees. For positions of numbered hydrogens and angles $\left(\mathrm{H}_{n}, \theta_{n}\right)$ refer to Figure 1 . No numbering is given when symmetry eliminates ambiguity.
geometries. In the 6-31G* basis set, ${ }^{11}$ d-type polarization functions on heavy atoms supplement an extended split-valence basis set ( $6-31 \mathrm{G}$ ), which has recently been developed for Li , Be , and $\mathrm{B},{ }^{12 \mathrm{a} . \mathrm{b}}$ and is specified elsewhere for $\mathrm{C}, \mathrm{N}, \mathrm{O}$, and $\mathrm{F} .{ }^{13}$ In the calculations involving beryllium compounds that are reported here, the new $6-31 G^{*}$ basis, derived from energy optimization of the beryllium ${ }^{3} \mathrm{P}$ excited state, has been used. ${ }^{12 \mathrm{~b}}$ Standard d exponents were used ( $\mathrm{Li}=0.2, \mathrm{Be}=0.4, \mathrm{~B}=0.6$, $C-F=0.8)$. Calculated $6-31 \mathrm{G}^{*}$ energies are given in Table 1.

The calculations reported in this paper were carried out with the "GAUSSIAN 70 " series of programs and modifications to it. ${ }^{11.14}$ Singlet states were computed using standard singledeterminant spin-restricted Hartree-Fock theory (RHF). ${ }^{15}$ Open-shell states were calculated using the spin-unrestricted Hartree-Fock (UHF) formalism of Pople and Nesbet. ${ }^{16}$

## Results

Geometries. Specifying structures of the types included in this paper, it is convenient to employ dashed lines to indicate a bond containing formally fewer than two electrons. Thus if M is a metal atom ( $\mathrm{Li}-\mathrm{B}$ ), D a lone-pair donor ( $\mathrm{N}-\mathrm{F}$ ), and H hydrogen, then "M- -D" represents a coordinate bond (Lewis acid-base interaction), "MH- -M" a single hydrogen bridge between metal atoms, and "M- $(\mathrm{H})_{n}--\mathrm{M}$ " a bridge of $n$ (equivalent) hydrogens. In this notation, diborane is designated $\mathrm{H}_{2} \mathrm{~B}-(\mathrm{H})_{2^{-}}-\mathrm{BH}_{2}$ and the hydrogen-bonded dimer of water as $\mathrm{HOH}--\mathrm{OH}_{2}$. Throughout this paper, structures are iden-
tified using this notation as well as by the numbers assigned in Table I.

In order to specify detailed geometries, we separate the complete list of molecules into two categories distinguishing those without bridging hydrogens (Table II) from those with (Table III). The former group is described with reference to the geometrical fragments in Figure 1. In order to visualize a particular structure, the right-hand fragment of Figure 1 is joined, without rotation from the plane of the paper, to one of the left-hand fragments (the numbered hydrogens in Table II specify which one). The assembled picture then has five hydrogens, some subset of which corresponds to the actual structure. The structure is determined from the specified symmetry, the molecular formula, and the correspondence between hydrogen numbers in Figure 1 and Table II.

Each hydrogen-bridged structure is described by one of the diagrams in Figure 2. In the figure, five general shapes are depicted, each having one to three equivalent bridging hydrogens $\mathrm{H}_{\mathrm{br}}$. In order to specify a bridged structure fully, the general shape ( $1-5$ ) is given along with letters ( $a, b, b^{\prime}$ ) indicating which of the terminal hydrogens drawn in the figure is present in the structure. All bridging hydrogens in the figure are present in each case. The digit-letter combination gives the structure type and is listed in Table III along with the symmetry. Also given are the bond lengths and terminal (HMH) angles, specified with reference to the labels in Figure 2. We now discuss the structures individually.

Lithium Compounds. (1) $\mathbf{L i H}$. Lithium hydride, having only

Figure 1. Molecular fragments defining geometrical parameters.
four electrons, has been a favorite among theoreticians as a test case for new quantum mechanical methods. Recent bibliographies of ab initio calculations ${ }^{17.18}$ list over 120 entries for LiH through 1973. These include the extensive study of first-row hydrides by Cade and Huo, ${ }^{19}$ in which the ground state Har-tree-Fock limit of LiH is determined ( -7.98731 hartrees) and the systematic configuration-interaction (CI) studies on diatomics by Fraga and Ransil, ${ }^{20}$ Bender and Davidson, ${ }^{21}$ and recently Meyer and Rosmus. ${ }^{22}$ All of these include reviews of previous work. Excited states of LiH have been investigated, ${ }^{23,24}$ and recent high-quality $\mathrm{Cl}^{25,26}$ and valence bond ${ }^{27,28}$ calculations have appeared. The lowest energy obtained to date appears to be that of Boys and Handy, ${ }^{29}$ who present a "transcorrelated" wave equation, obtaining $E=$ -8.063 hartrees compared to the experimental estimate ${ }^{19}$ of -8.070 .

Lithium hydride is known as an ionic NaCl -like solid ${ }^{30}$ and as a polar gas-phase monomer. The bond length in the latter ( $\left.r_{\mathrm{e}}=1.595 \AA\right)^{31}$ is somewhat larger than the STO-3G value of $1.510 \AA$ (Table II). On the other hand, the bond length calculated at $5-21 \mathrm{G}^{32}$ is too long ( $1.637 \AA$ ) as is that obtained from optimization at the Hartree-Fock limit ( $1.605 \AA$ ). ${ }^{19}$ This behavior is opposite that of hydrides of more electronegative atoms ( $\mathrm{CH}_{4}$ through FH ), where STO-3G generally overestimates ${ }^{3}$ while $4-31 G^{3}$ and higher basis sets ${ }^{33}$ underestimate $\mathrm{A}-\mathrm{H}$ distances. We find a regular trend along the first row:

3

4

5

Figure 2. Prototype molecules defining hydrogen positions.

STO-3G gives bond lengths too short (by $5.3 \%$ ) for LiH , improving until fairly precise for $\mathrm{CH}_{4}$, and then becoming too long (by $4.1 \%$ ) for FH . With the split valence bases, LiH is too long by $2.6 \%$, FH too short by $0.5 \%$.

The electronic properties of LiH have been determined with precision. ${ }^{34}$ The experimental dipole moment is $\mu_{\mathrm{e}}=5.828$ $\mathrm{D},{ }^{34 \mathrm{~b}}$ in the direction $\mathrm{Li}^{+} \mathrm{H}^{-}$. Our calculated values of 4.84 (STO-3G) and 5.74 (6-31G*) agree satisfactorily. It is ap-
propriate to mention that Mulliken population analysis ${ }^{35}$ of the STO-3G wave function indicates total atomic charges of -0.017 on $\mathrm{Li},+0.017$ on H , opposite the polarity implied by the dipole moment. This is to some extent an artifact of the population scheme, but it serves as an indication that the minimal basis set is unbalanced with regard to lithium. $p$ functions on lithium resemble polarization functions, providing a degree of flexibility not available to heavier atoms; in the population analysis, these orbitals are assigned an unrealistically high degree of electron density. Opposite problems are experienced in describing fluorine compounds at the minimal basis set level. ${ }^{36}$
(2) $\mathbf{L i}_{2}$. The lithium molecule (dilithium) is a simple homonuclear diatomic species which has also been popular among theoreticians. ${ }^{20,37-41} \mathrm{~A}$ thorough analysis of bonding in the first row $X_{2}$ systems ${ }^{4}$ demonstrates $\mathrm{Li}_{2}$ to have little interatomic p overlap, resulting in a long weak $\sigma$ bond. The experimental bond length ${ }^{31}$ is $2.672 \AA$, in good agreement with STO-3G (2.696), and represents the longest known (or calculated) single bond between first-row atoms in a two-heavy-atom species.
$(3,4) \mathrm{Li}_{2} \mathbf{H}_{2}$. Although there has been no experimental observation of a dimer of LiH , there is reason to believe that such a structure is stable. The evidence stems from previous theoretical studies of $\mathrm{Li}_{2} \mathrm{H}_{2}{ }^{26.42 .43}$ and from inference based on the gas-phase behavior of alkali halides. ${ }^{44.45}$ In the first category, Tyndall and Companion ${ }^{22}$ applied the semiempirical di-atomics-in-molecules (DIM) method to the $\mathrm{Li}_{2} \mathrm{H}_{2}$ potential surface, finding the $D_{2 h}$ dimer (3) to be less favorable than a nonplanar $C_{2 v}$ form resulting from perpendicular interaction of $\mathrm{Li}_{2}$ with $\mathrm{H}_{2}$. However, linear $\mathrm{Li}_{2} \mathrm{H}_{2}$ arrangements were found to decrease in stability $\mathrm{LiLiHH}>\mathrm{LiHHLi}>\mathrm{LiHLiH}$ $(=4)>\mathrm{HLiLiH}$, the first of these being more stable than either separated $\mathrm{Li}_{2}+\mathrm{H}_{2}$ or the $D_{2 h}$ dimer (3). These results appear contradictory to our own, but the accuracy of the DIM method is difficult to assess.

More recently, Kollman et al. ${ }^{43}$ have applied $a b$ initio and Cl methods to both dimers 3 and 4. Using a large basis of $s$ and p functions, they obtain $r=1.633 \AA$ and $E=-7.98262$ au for LiH itself. This bond length is close to that found at 4-31G $(5-21 \mathrm{G})^{32}$ but the energy is slightly lower than $6-31 \mathrm{G*}$. The geometries of $\mathbf{3}$ and 4 obtained by Kollman et al. are given in Table III along with STO-3G results. Their larger basis gives all bonds longer than STO-3G values and provides an interpretation of the linear dimer (4) which differs somewhat from ours, as discussed below.

The $D_{2 h}$ dimer has also been studied by Ahlrichs ${ }^{100 \mathrm{~b}}$ using a large basis set and the CEPA correlation method. The CEPA structure (Table III) is intermediate between the STO-3G geometry and that of Kollman et al. ${ }^{43}$

Our results suggest that the $D_{2 h}$ dimer (3) is the most stable form. In this, two LiH molecules are bound together in such a way that the $\mathrm{Li}-\mathrm{Li}$ distance ( $2.22 \AA$ ) is smaller than in $\mathrm{Li}_{2}$ ( $2.70 \AA$ ). Thus the three-center two-electron $\mathrm{Li}(\mathrm{H}) \mathrm{Li}$ bond is shorter than the two-center two-electron $\mathrm{Li}-\mathrm{Li}$ bond. Also upon dimerization the $\mathrm{Li}-\mathrm{H}$ monomer distances increase by $13 \%$ to $1.70 \AA$ in the dimer. There is precedent for these changes in the dimerization of $\mathrm{BH}_{3}$ to $\mathrm{B}_{2} \mathrm{H}_{6}$, in which bridging $\mathrm{B}-\mathrm{H}$ distances are significantly longer than terminal $\mathrm{B}-\mathrm{H}$ lengths, and the $\mathrm{B}-\mathrm{B}$ distance is similar to that calculated for planar $\mathrm{H}_{2} \mathrm{~B}-\mathrm{BH}_{2}{ }^{4}$

The linear LiH dimer (4) is bound by what is conceptually similar to a hydrogen bond but with opposite electronic properties. The principal binding force is the interaction of LiH dipoles which might be schematically represented as $\mathrm{Li}_{1} \rightarrow$ $\mathrm{H}_{1}(\delta-) \cdots(\delta+) \mathrm{Li}_{2} \rightarrow \mathrm{H}_{2}$, the hydrogen in the LiH monomers being negatively charged (unlike the hydrogens in the dimer of hydrogen fluoride which are positively charged). This type of binding can also be termed a "lithium bond" ${ }^{46}$ with the positive lithium taking the role of the electron-deficient species.

As the population analysis shows (see below), there is a net transfer of electrons from $\mathrm{Li}_{1}-\mathrm{H}_{1}$ to $\mathrm{Li}_{2}-\mathrm{H}_{2}$, leaving the $\mathrm{Li}-\mathrm{H}_{1}$ unit slightly deficient in electrons and causing a lengthening in the $\mathrm{Li}-\mathrm{H}_{1}$ bond to $1.56 \AA$ (at STO-3G) compared to 1.51 in LiH itself. An opposite effect is found in the study of Kollman et al., ${ }^{43}$ where additional $s$ and $p$ functions on $\mathrm{H}_{1}$ lead to an apparent charge buildup at that center according to a Mulliken population analysis, and $\mathrm{LiH}_{2}$ becomes longer while $\mathrm{LiH}_{1}$ remains constant. However, this discrepancy between their results and ours is evidently minor, since the two calculated dimerization energies agree closely (see discussion below). It is gratifying to note that the monomer-monomer separation $\left(\mathrm{H}_{1}--\mathrm{Li}_{2}\right)$ is in reasonable agreement between the two studies (Kollman $1.83 \AA$,STO-3G 1.77). In contrast, the corresponding distance in hydrogen-bonded systems is highly basis set dependent. For example, the $\mathrm{O}-\mathrm{O}$ distance in $\mathrm{H}_{2} \mathrm{O}$ --HOH changes from STO-3G to $4-31 \mathrm{G}$ to $6-31 \mathrm{G}^{*}$ as $2.73 \rightarrow$ $2.87 \rightarrow 2.99 \AA$ (exptl $=2.98$ ). ${ }^{47}$

Other linear arrangements were investigated with variation of all bond distances. These were $\mathrm{HLi}-\mathrm{-LiH}$ and $\mathrm{LiH}-\mathrm{HLi}$, neither of which became bound relative to 2 LiH . In addition, the $\mathrm{Li}_{1}-\mathrm{H}_{1}--\mathrm{Li}_{2}$ angle of $\mathbf{4}$ was varied and found to give an energy minimum at $180^{\circ}$.

The geometry of the bridged dimer 3 may be compared with known structures of alkali halide dimers. ${ }^{45,48-50}$ In the vapor phase, LiF (for example) exists primarily as planar cyclic $\mathrm{Li}_{2} \mathrm{~F}_{2},{ }^{50}$ which is approximately $62 \mathrm{kcal} \mathrm{mol}{ }^{-1}$ more stable than separated LiF monomers at $100^{\circ} \mathrm{C} .{ }^{45}$ Calculation of $\mathrm{Li}_{2} \mathrm{~F}_{2}$ at the STO-3G level ${ }^{51}$ gives a dimerization energy of $43.6 \mathrm{kcal} \mathrm{mol}^{-1}$ and a geometry of $\mathrm{Li}-\mathrm{F}=1.596 \AA, \mathrm{~F}-\mathrm{F}=$ $2.325 \AA, \angle \mathrm{~F}-\mathrm{Li}-\mathrm{F}=93.5^{\circ}$, and $\angle \mathrm{Li}-\mathrm{F}-\mathrm{Li}=86.5^{\circ}$. Like our calculated $\mathrm{Li}_{2} \mathrm{H}_{2}$ structure, this indicates that the lithiums lie within single-bonding distance of each other and demonstrates an increased $\mathrm{Li}-\mathrm{F}$ distance (from $1.56 \AA$ in the monomer ${ }^{52}$ ) upon dimerization. Similarly, an electron-diffraction structure of gaseous $\mathrm{Li}_{2} \mathrm{Cl}_{2}(\mathrm{Li}-\mathrm{Li}=2.64 \AA ; \mathrm{Cl}-\mathrm{Cl}=3.61 \AA ; \mathrm{Li}-\mathrm{Cl}=$ $2.23 \AA)^{48}$ shows the $\mathrm{Li}-\mathrm{Cl}$ distance to be longer than that of monomeric $\mathrm{LiCl}(2.02 \AA)$ but shorter than the $\mathrm{Li}-\mathrm{Cl}$ distance in the crystalline state $(2.57 \AA) .{ }^{48}$ In this sense our STO-3G structure for $(\mathrm{LiH})_{2}$ is reasonable in giving $\mathrm{LiH}=1.701 \AA$, between the known values of 1.595 for the LiH monomer ${ }^{31}$ and 2.043 for the crystal. ${ }^{53}$
(5) LiBeH . Like the $\mathrm{Li}-\mathrm{Li}$ single bond, a bond between Li and BeH is expected to be long and weak. We find a linear structure with $r_{\mathrm{Li}-\mathrm{Be}}=2.394 \AA$. In support of this is the ab initio study of Kaufman and Sachs on $\mathrm{BeLi}_{2},{ }^{54}$ in which the $\mathrm{Be}-\mathrm{Li}$ distance is found to be $2.56 \AA$ and the structure to be linear.
(6-9) $\mathrm{LiBeH}_{3}$. Mixed polymers containing lithium and beryllium are not unknown. The following stoichiometries have been reported: $\mathrm{LiBeR}_{3}{ }^{56}$ ( $\mathrm{R}=\mathrm{Ph}^{55}$ OAlk, $\mathrm{OSiMe}_{3}$ ), $\mathrm{Li}_{2} \mathrm{BeH}_{4},{ }^{57} \mathrm{Li}_{2} \mathrm{BeMe}_{4},{ }^{58} \mathrm{LiR}_{2} \mathrm{BeH}^{59}{ }^{59}$ Available x-ray data ${ }^{8 \mathrm{a} .58}$ on such systems indicate dibridged $\mathrm{Be}-(\mathrm{R})_{2}-\mathrm{Li}$ to be a common structural unit. Our findings concur, the structure $\mathrm{Li}--(\mathrm{H})_{2}--\mathrm{BeH}(6)$ being the best of the five geometries considered. In-plane dimerization of LiH and $\mathrm{BeH}_{2}$ is similar to $\mathrm{Li}_{2} \mathrm{H}_{2}$ or $\mathrm{B}_{2} \mathrm{H}_{6}$ formation. In the $\mathrm{C}_{2 v}$ form ( Li - $-(\mathrm{H})_{2^{-}}-$ BeH ) bonds to the bridging hydrogens from Li and Be are considerably longer than those in monomeric LiH or $\mathrm{BeH}_{2}$, while the $\mathrm{Li}-\mathrm{Be}$ distance is shorter than that in LiBeH . The terminal $\mathrm{Be}-\mathrm{H}$ distance is unchanged upon dimerization.

At somewhat higher energy is a $C_{3 v}$ structure, $\mathrm{Li}--(\mathrm{H})_{3}-\mathrm{Be}$ (7), having three equivalent bridging hydrogens. Here, bridge $\mathrm{Li}-\mathrm{H}$ and $\mathrm{Be}-\mathrm{H}$ distances are larger than in the doubly bridged form (6), while the $\mathrm{Li}-\mathrm{Be}$ distance is smaller.

Two linear forms (single bridges) were optimized. In these cases, in addition to the "lithium bond" in HLi- - $\mathrm{HBeH}(9)$, we have a "beryllium bond" in $\mathrm{LiH}--\mathrm{BeH}_{2}(8)$, the latter being slightly stronger. Geometry variations upon dimerization
leading to 8 and 9 are analogous to those leading to linear $(\mathrm{LiH})_{2}$. The LiH bond increases upon formation of LiH $\mathrm{BeH}_{2}$ but is unchanged in $\mathrm{HLi}-\mathrm{HBeH}$. The $\mathrm{Be}-\mathrm{H}$ length increases in the bridging position of $\mathrm{HLi}-\mathrm{HBeH}$ but is unchanged in the terminal position and in $\mathrm{LiH}--\mathrm{BeH}_{2} . \mathrm{Li}-\mathrm{Be}$ distances are roughly the same in both structures, $32 \%$ longer than the single bond distance in $\mathrm{Li}-\mathrm{BeH}$. $\mathrm{LiH}--\mathrm{BeH}_{2}$ (structure 8) is of $C_{2 v}$ symmetry and has a terminal $\mathrm{H}-\mathrm{Be}-\mathrm{H}$ angle of $139^{\circ}$, indicating a tendency toward $\mathrm{sp}^{2}$ hybridization at beryllium, which obtains charge from the interaction with LiH . The same $\mathrm{H}-\mathrm{Be}-\mathrm{H}$ bending occurs upon coordinate bond formation leading to donor $\rightarrow \mathrm{BeH}_{2}$ complexes, as discussed below.
(10) $\mathrm{LiBH}_{2}$. Lithioborane is an unknown derivative of $\mathrm{BH}_{3}$. Its calculated structure is planar $\left(C_{2 v}\right)$. The effect of substituting $\mathrm{BH}_{3}$ with a strong $\sigma$ donor is to reduce the HBH angle from its ideal $120^{\circ}$ value, so that the following trend is found along the series of substituted boranes $\mathrm{X}-\mathrm{BH}_{2}{ }^{4} \mathrm{HBH}=$ $112.6^{\circ}(\mathrm{X}=\mathrm{Li}), 114.9\left(\mathrm{BeH}\right.$, see below), $117.2\left(\mathrm{BH}_{2}\right.$ perpendicular), $118.5\left(\mathrm{CH}_{3}\right), 120.0(\mathrm{H}), 121.1\left(\mathrm{NH}_{2}\right), 121.0$ $(\mathrm{OH}), 121.0(\mathrm{~F})$. The $\mathrm{Li}-\mathrm{B}$ single bond is fairly long ( $2.19 \AA$ ) and not very strong.
(11-15) $\mathrm{LiBH}_{4}$. Lithium borohydride is a common reducing agent, the crystal structure of which indicates tetrahedral $\mathrm{BH}_{4}{ }^{-}$units surrounded by lithium ions with $r_{\text {Li- }}=2.47-2.56$ $\AA .{ }^{60}$ The more recent structure of $\mathrm{LiB}\left(\mathrm{CH}_{3}\right)_{4}$ is analogous ${ }^{61}$ and involves both dibridged $\mathrm{Li}--(\mathrm{Me})_{2}-\mathrm{B}$ and monobridged $\mathrm{Li}-$-(Me)- -B units but is apparently poorly described in terms of triple $\mathrm{Li}-(\mathrm{Me})_{3^{-}}-\mathrm{B}$ bridges.

The $\mathrm{LiH}-\mathrm{BH}_{3}$ potential surface we calculate is similar to that of $\mathrm{LiH}-\mathrm{BeH}_{2}$ but with some important differences. The calculated order of decreasing stability is triply bridged $\mathrm{Li}-$ $-(\mathrm{H})_{3}--\mathrm{BH}(11)>$ doubly bridged $\mathrm{Li}--(\mathrm{H})_{2}--\mathrm{BH}_{2}(12)>$ B-bonded $\mathrm{Li}-\mathrm{H}--\mathrm{BH}_{3}(13)>$ doubly bridged $\mathrm{HLi}-(\mathrm{H})_{2^{-}}$ $-\mathrm{BH}\left(\mathbf{1 4 )}>\mathrm{Li}\right.$-bonded $\mathrm{HLi}-\mathrm{HBH}_{2}$ (15). A triple hydrogen bridge is favored, unlike the beryllium systems, where Li - -$(\mathrm{H})_{2}-\mathrm{BeH}$ was preferred over $\mathrm{Li}--(\mathrm{H})_{3}-\mathrm{Be}$. Furthermore, doubly bridged $\mathrm{HLi}-(\mathrm{H})_{2}--\mathrm{BH}$ is bound relative to $\mathrm{HLi}+$ $\mathrm{BH}_{3}$, while the corresponding beryllium system ( $\mathrm{HLi}-(\mathrm{H})_{2^{-}}$ -Be ) was not. These preferences will be discussed below along with the dimerization energies.

Detailed geometries of structures 11-15 are as expected by extrapolation from other systems and may be summarized in two general statements. First, metal-metal distances in species having double or triple (but not single) bridging hydrogens are shorter than in covalent molecules having direct metal-metal bonds. Thus, for example, $\mathrm{Li}-\mathrm{B}$ distances increase as $\mathrm{Li}-$ -$(\mathrm{H})_{3}-\mathrm{BH}<\mathrm{Li}-(\mathrm{H})_{2}--\mathrm{BH}_{2}<\mathrm{LiBH}_{2}<\mathrm{LiH}--\mathrm{BH}_{3}$. Second, metal-hydrogen distances increase upon dimerization (relative to monomer values) for those hydrogens which become bridging but remain unchanged for terminal hydrogens.
(16) $\mathbf{L i C H}_{3}$. It is well established that methyllithium exists as a tetramer under standard conditions. ${ }^{7}$ The x -ray structure ${ }^{62}$ reveals a tetrahedral array of lithium atoms ( $r_{\mathrm{Li}-\mathrm{Li}}=2.56 \AA$ ) above each face of which is centered a methyl group ( $r_{\text {C-Li }}=$ $2.28 \AA$ ). However, at low temperature in an argon matrix, $\mathrm{CH}_{3} \mathrm{Li}$ has been observed as a monomer. ${ }^{63}$ The resulting infrared analysis yielded little structural information apart from the force constant for asymmetric deformation of the methyl group and a very rough estimate of the dipole moment ( $\mu=6$ D , assuming $r_{\mathrm{C}-\mathrm{Li}}=2.10 \AA$ ).

Theoretical studies, both semiempirical ${ }^{64-66}$ and $a b$ initio, ${ }^{66-69}$ have provided more detailed geometries for methyllithium and its aggregates, but only one of these studies ${ }^{70}$ included full geometry optimization. In most previous work, the methyl group in $\mathrm{LiCH}_{3}$ has been assumed to be strictly tetrahedral. We find at STO-3G that the methyl group, while not far from tetrahedral, is more pyramidal than that of any other $\mathrm{X}-\mathrm{CH}_{3}$ system for first-row X. Thus, STO-3G op-
timized values ${ }^{4.5}$ of the average HCH angle vary as $106.2^{\circ}$ $\left(\mathrm{LiCH}_{3}\right), 107.0^{\circ}\left(\mathrm{HBeCH}_{3}\right), 107.7^{\circ}\left(\mathrm{H}_{2} \mathrm{BCH}_{3}\right.$ perpendicular form) ${ }^{4} 108.2^{\circ}\left(\mathrm{H}_{3} \mathrm{CCH}_{3}\right), 108.2^{\circ}\left(\mathrm{H}_{2} \mathrm{NCH}_{3}\right), 108.1^{\circ}$ $\left(\mathrm{HOCH}_{3}\right), 108.3^{\circ}\left(\mathrm{FCH}_{3}\right)$, where unspecified conformations have staggered hydrogens.

Full STO-3G optimization of $\mathrm{LiCH}_{3}$ gives a C-Li distance of $2.009 \AA$. In an interesting study at STO-2G and STO-3G, Baird et al. ${ }^{67}$ find $r_{\mathrm{C}-\mathrm{Li}}=2.05 \AA$, but when $\mathrm{p} \pi$ orbitals on Li are removed the value becomes $2.09 \AA$. Fitzpatrick ${ }^{68}$ deduces considerable ionic character in the $\mathrm{C}-\mathrm{Li}$ bond since his calculated $r_{\text {C-Li }}=2.03 \AA$ is smaller than the value of 2.12 obtained from the sum of covalent radii $1 / 2 r_{\text {LiLi }}\left(\mathrm{Li}_{2}\right)+$ $1 / 2 \mathrm{rc}-\mathrm{c}\left(\mathrm{C}_{2} \mathrm{H}_{6}\right)$. All of these minimal-basis estimates are shorter than the $2.10 \AA$ proposed by Andrews ${ }^{63}$ on the basis of extrapolations of force constants and other data from known $\mathrm{Li}-\mathrm{X}$ monomers. However, an estimate of the $\mathrm{CH}_{3} \mathrm{Li}$ dipole moment ( 6 D ) made in the same way ${ }^{63}$ agrees well with that obtained at 6-31G* (5.71 D). The structure of methyllithium has been fully optimized at the $4-31 \mathrm{G} / 5-21 \mathrm{G}$ level; ${ }^{69 \mathrm{e}}$ the $\mathrm{C}-\mathrm{Li}$ bond actually shortens slightly, to $1.989 \AA$ and $\mathrm{C}-\mathrm{H}=1.092$ $\AA$, while the HCH angle increases from 106.2 to $107.3^{\circ}$. This differs somewhat from the recent results of Streitwieser et al., ${ }^{70}$ who employ three basis sets (STO-4G, split valence, and split valence + polarization) in a thorough examination of methyllithium. They find the C -Li distance to increase in going from minimal to split-valence levels. Their best basis, which includes d orbitals on carbon but not on lithium, gives $r_{\mathrm{C}-\mathrm{Li}}=$ $2.021 \AA, r_{\mathrm{C}-\mathrm{H}}=1.089 \AA$, and $\angle \mathrm{HCH}=105.8^{\circ}$. Altogether these comparisons suggest that the STO-3G structure for $\mathrm{CH}_{3} \mathrm{Li}$ is reasonably accurate.

Streitwieser et al. stress that there is very little covalent $\mathrm{C}-\mathrm{Li}$ bonding in methyllithium, but an opposite conclusion has been reached by Guest, Hillier, and Saunders. Much depends on how "ionic" or "covalent" character is defined. While we plan to study the problem of the natural bonding in lithium compounds in more detail, we have already emphasized that the peculiar structures adopted by polylithium compounds ${ }^{69 a-d}$ are better understood in terms of multicenter covalent bonding rather than "ion pair" character.
(17) $\mathrm{LiCH}_{5}$. The small degree of charge polarization in $\mathrm{C}-\mathrm{H}$ bonds of methane is sufficient to produce a weak interaction with LiH , giving $\mathrm{H}_{2} \mathrm{C}-(\mathrm{H})_{2}-\mathrm{LiH}$ (17). The same $\mathrm{C}-\mathrm{H}$ charge separation is responsible for the weak $\mathrm{CH}_{4}-$ - D hydrogen bonds calculated to exist when $\mathrm{D}=\mathrm{NH}_{3}, \mathrm{OH}_{2}$, and $\mathrm{FH}^{5.71}$ For $\mathrm{LiH}-\mathrm{CH}_{4}$, three conformations other than 17 were examined and found to lead to no binding between LiH and $\mathrm{CH}_{4}$; they were $\mathrm{HC}-(\mathrm{H})_{3}-\mathrm{LiH}, \mathrm{H}_{3} \mathrm{CH}-\mathrm{LiH}$, and $\mathrm{H}_{3} \mathrm{CH}-\mathrm{HLi}$. Note that the $\mathrm{CH}_{4}-\mathrm{LiH}$ system thus differs from the isoelectronic $\mathrm{BH}_{3}-\mathrm{BeH}_{2}$, which is not only bound as HB- $-(\mathrm{H})_{3}-$ - BeH but slightly favors that configuration over $\mathrm{H}_{2} \mathrm{~B}--(\mathrm{H})_{2}-\mathrm{BeH}$ (see below).

There is little change in geometry of either $\mathrm{CH}_{4}(r=1.083$ $\AA$ at STO-3G) or LiH ( $1.510 \AA$ ) upon complexation to form 17, $\mathrm{HLi}-(\mathrm{H})_{2}-\mathrm{CH}_{2}{ }^{\prime}$. $\mathrm{CH}^{\prime}$ distances are $1.083 \AA, \mathrm{C}-\mathrm{H}=$ $1.094 \AA, \mathrm{LiH}=1.509 \AA$, and the $\mathrm{H}^{\prime} \mathrm{CH}^{\prime}$ angle widens slightly to $113.1^{\circ}$. The Li-C distance is $2.486 \AA$, only $20 \%$ larger than the single bond distance in methyllithium. In contrast, the CO distance in the methane-water complex $\left(\mathrm{H}_{3} \mathrm{CH}-\mathrm{OH}_{2}\right)$ is $130 \%$ larger than that in methanol at STO-3G. ${ }^{5}$
(18) $\mathbf{L i N H}_{2}$. This compound is strongly basic, generating the amide ion $\left(\mathrm{NH}_{2}{ }^{-}\right)$in liquid ammonia, and is thus named lithium amide rather than lithioamine. ${ }^{6}$ A recent crystal structure ${ }^{72}$ gives $\mathrm{Li}-\mathrm{N}$ distances of 2.059-2.213 $\AA$ in the rather complicated packing arrangement. Though monomeric $\mathrm{Li}-$ $\mathrm{NR}_{2}$ units have not been reported, dimers exist as bridged $\mathrm{R}_{2} \mathrm{~N}$ - $-(\mathrm{Li})_{2}--\mathrm{NR}_{2}$ systems with bulky R groups such as $\mathrm{SiMe}_{3}{ }^{73}$

The STO-3G structure of $\mathrm{LiNH}_{2}$ is planar, with $\angle \mathrm{HNH}=$ $102.3^{\circ}$ and $\mathrm{Li}-\mathrm{N}=1.635 \AA$. A recent ab initio optimization ${ }^{74}$
gave $\angle \mathrm{HNH}=110^{\circ}, \mathrm{Li}-\mathrm{N}=1.782 \AA$ with a large polarized basis set. The discrepancy in HNH angle between STO-3G and the higher level is similar to many other cases, in which STO-3G generally underestimates while higher levels overestimate HXH angles. ${ }^{75}$ The discrepancy in bond lengths may be another manifestation of imbalance in the STO-3G basis due to the presence of $p$ functions on lithium.
$\mathrm{LiNH}_{2}$ has the same number of valence electrons as ammonia, which is pyramidal. When lithium is a ligand, however, its 2 s orbital is high in energy, diffuse, and mixes less effectively; at the same time its vacant $\mathrm{p} \pi$ orbitals may benefit by $\pi$ conjugation with ( $\mathrm{sp}^{2}$ ) nitrogen. In this case, the result is planar $\mathrm{LiNH}_{2}$, which seems reasonable considering the planarity of $\mathrm{HBeNH}_{2}$ (discussed below) and $\mathrm{H}_{2} \mathrm{BNH}_{2} .{ }^{4}$ This result is implicit in the Walsh rule that $\mathrm{H}_{2} \mathrm{AB}$ molecules are planar with fewer than 13 valence electrons. 76,77
(19) $\mathrm{LiNH}_{4}$. The interaction between LiH and $\mathrm{NH}_{3}$ represents a coordinate donor-acceptor bond similar to that in the more familiar $\mathrm{NH}_{3} \mathrm{BH}_{3} .{ }^{4}$ Alkyllithium compounds are generally chelated by two or more amine groups, with $\mathrm{Li}-\mathrm{N}$ distances ranging from 2.03 to $2.10 \AA$ in the crystal. ${ }^{78} \mathrm{We}$ find $\mathrm{HLi}--\mathrm{NH}_{3}(19)$ to have trigonal $C_{3 v}$ symmetry, with $\mathrm{Li}-\mathrm{N}$ $=1.944 \AA$. Neither LiH nor $\mathrm{NH}_{3}$ geometries are greatly perturbed by the coordinate interaction: for $\mathrm{NH}_{3}$, STO-3G gives $\angle \mathrm{HNH}=104.2^{\circ}, \mathrm{N}-\mathrm{H}=1.033 \AA,{ }^{5}$ while the corresponding values in $\mathrm{LiNH}_{4}$ are $\angle \mathrm{HNH}=105.7, \mathrm{~N}-\mathrm{H}=1.028$ $\AA$; the LiH distance changes only $0.004 \AA$ on complexation.
(20) $\mathbf{L i O H}$. Lithium hydroxide and a dimer assumed to have a $C_{2 h}$ structure ( $\mathrm{HO}--(\mathrm{Li})_{2}-\mathrm{OH}$ ) are known to exist in the gas phase ${ }^{79,80}$ but structural data are lacking. A reasonable estimate of the gaseous monomer structure based on rotational data is ${ }^{80}$ linear with $\mathrm{Li}-\mathrm{O}=1.582 \AA$ and $\mathrm{O}-\mathrm{H}$ assumed equal to the bond length in $\mathrm{H}_{2} \mathrm{O}(0.97 \AA)$. The STO-3G structure is linear and has a considerably shorter $\mathrm{Li}-\mathrm{O}$ bond of $1.432 \AA$ with $\mathrm{O}-\mathrm{H}=0.971 \AA$. An early theoretical study employing a double- $\zeta$ basis ${ }^{81}$ gave $r_{\mathrm{O}-\mathrm{Li}}=1.60 \AA$. In that study, the effects of removing $p$ functions from lithium were examined, but only with regard to the angular orientation, not on bond lengths. The molecule was found to be linear in agreement with the STO-3G structure. A more recent theoretical study ${ }^{82 a}$ assumed a value of $r_{\text {Li-O }}=3.02$ au but mistakenly reported the value as 5.71 au $(3.02 \AA) .{ }^{82 \mathrm{~b}}$

The better established experimental $\mathrm{Li}-\mathrm{O}$ distance in gaseous lithium oxide, $\mathrm{Li}_{2} \mathrm{O}$, may be cited for comparison. This molecule is linear ${ }^{49,83.84}$ with $\mathrm{Li}-\mathrm{O}=1.55^{83}-1.59 \AA .{ }^{84}$ The evidence seems to indicate that STO-3G gives an $\mathrm{Li}-\mathrm{O}$ bond length which is considerably too short, in line with the similar results for LiH and $\mathrm{LiNH}_{2}$

Both $\mathrm{Li}_{2} \mathrm{O}$ and LiOH have the same number of valence electrons as $\mathrm{H}_{2} \mathrm{O}$ which is bent. This is in agreement with Walsh's prediction that $\mathrm{AB}_{2}$ systems with not more than 16 valence electrons and ABH systems containing 10 or fewer valence electrons should be linear, while HAH systems with more than 4 valence electrons should be bent. These Walsh rules are based on the participation of $p$ functions in $\pi$ bonding in the linear forms. Another factor influencing the structure of alkali metal oxides is that charge separation leads to a large contribution from resonance forms such as $\mathrm{Li}^{+} \mathrm{O}^{2-} \mathrm{Li}^{+}$in which repulsion between the positive ions favors a linear geometry. ${ }^{81}$ On the other hand, the polarization of the $\mathrm{O}^{2-}$ ion by the positive charges favors a bent structure. This is because such charges (treated as points) lead to a nonvanishing electric field at the center of $\mathrm{O}^{2-}$ only if the molecule is bent. That competing factors are present is suggested by experimental observations that $\mathrm{Na}_{2} \mathrm{O}$ and $\mathrm{Cs}_{2} \mathrm{O}$ are nonlinear. ${ }^{85.86}$
(21) $\mathrm{LiOH}_{3}$. In the STO-3G structure of $\mathrm{HLi}--\mathrm{OH}_{2}$, the $\mathrm{Li}-\mathrm{O}$ axis forms an angle of $144^{\circ}$ with the plane of the water molecule. Additionally, the $\mathrm{H}-\mathrm{Li}-\mathrm{O}$ angle is $168^{\circ}$, so that the overall shape is cisoid (Figure 3). We find the $\mathrm{Li}-\mathrm{O}$ distance

Figure 3. Cisoid $\mathrm{HLiOH}_{2}$.
to be $1.765 \AA$, considerably shorter than the intermolecular distance in $\mathrm{HLi}--\mathrm{NH}_{3}(1.944 \AA)$. A similar decrease is found ${ }^{4}$ in going from $\mathrm{H}_{3} \mathrm{BNH}_{3}$ to $\mathrm{H}_{3} \mathrm{BOH}_{2}$. This cisoid structure is the only minimum found on the intermolecular potential surface. Rigid rotation by $180^{\circ}$ about the $\mathrm{Li}-\mathrm{O}$ line, giving a transoid structure, increases the energy $0.8 \mathrm{kcal} \mathrm{mol}^{-1}$. The lower energy of the cisoid form may be interpreted in terms of the interaction of dipole components perpendicular to the Li --O line.

For comparison we mention a recent study of $\mathrm{LiF}-\mathrm{H}_{2} \mathrm{O}$ by Clementi et al. ${ }^{87}$ using a very high quality basis set and presenting a detailed picture of the three-body potential surface of $\mathrm{Li}^{+}, \mathrm{F}^{-}$, and $\mathrm{H}_{2} \mathrm{O}$. A total of 250 geometrical arrangements were examined, but none in which $\mathrm{F}^{-}$was allowed to move out of the plane of the water molecule, such as would correspond to the STO-3G optimized geometry for $\mathrm{LiOH}_{3}$. The lowest energy arrangement among those studied was a $C_{2 i}$ configuration, $\mathrm{FLi}-\mathrm{OH}_{2}$, having $r_{\mathrm{O}-\mathrm{Li}}=1.89 \AA$. The structure of a related aqueous solution ( $\mathrm{LiCl}-\mathrm{H}_{2} \mathrm{O}$ ) has been investigated by an elegant x-ray and neutron-diffraction study. ${ }^{88}$
(22) LiF . Monomeric LiF is very precisely characterized experimentally, having $r=1.5639 \AA,{ }^{52} \mu=6.2841$ D ${ }^{89}$ Large basis sets give optimized values of $r_{\mathrm{LiF}}$ as $1.581^{87}$ to $1.528 \AA$ at the Hartree-Fock limit ${ }^{90}$ to $1.5637 \AA$ with extensive CI. ${ }^{91}$ However, STO-3G fares poorly, giving $r=1.407 \AA, \mu=3.12$ D, which again indicates that the minimal basis is not sufficiently balanced to describe LiX bonds adequately for electronegative X. In a previous comparison between STO-3G and experimental results on 69 bond lengths involving $\mathrm{H}, \mathrm{C}, \mathrm{N}, \mathrm{O}$, and $F,{ }^{5}$ the mean absolute deviation found was only $0.03 \AA$. Poorest results were seen for cations, excited states, and single bonds between the heaviest atoms ( $\mathrm{O}, \mathrm{F}$ ), the worst such example ( $\mathrm{F}_{2}$ ) having an STO-3G bond length $0.103 \AA$ shorter than the experimental. Now we find the deviation for LiF ( $0.157 \AA$ ) to be even greater. A combination of factors is responsible for this, among them the extensive flexibility at Li along with the lack of flexibility at $F$, both atoms having five orbitals to accommodate 3 vs . 9 electrons, and the use of averaged molecular scaling factors, a concept which does not allow strongly polarized bonds to be modelled accurately. These factors become less important with larger basis sets; at $6-31 \mathrm{G}^{*}$ the calculated dipole moment ( 5.57 D ) indicates a much more accurate representation.
(23) $\mathrm{LiFH}_{2}$. Like $\mathrm{LiOH}_{3}$ (21), the coordinately bound $\mathrm{HLi}-\mathrm{FH}$ system is nonlinear and thus parallels hydrogenbonded systems such as the HF dimer. ${ }^{5.47}$ The $\mathrm{H}-\mathrm{Li}-\mathrm{F}$ and $\mathrm{Li}-\mathrm{F}-\mathrm{H}$ angles are calculated to be 168.9 and $149.0^{\circ}$, with bonds in a cis arrangement. The intermolecular separation $r_{\text {Li- }}=1.627 \AA$ is shorter than in the $\mathrm{HLi}--\mathrm{OH}_{2}$ coordinate bond. A theoretical study of the related systems HF--LiF, $\mathrm{Li}-\mathrm{F}-\mathrm{LiF}$, and LiF- $-\mathrm{H}_{2}$ has been reported by Kollman et al. ${ }^{46}$ They found a cyclic structure for HFLiF although the linear form FH- -FLi was most stable. The ( LiF$)_{2}$ dimer was most stable in cyclic form. ${ }^{26 b, 43 b .46}$

Beryllium Compounds. (24) $\mathrm{BeH}_{2}$. Beryllium hydride has four valence electrons and is predicted by Walsh's rules ${ }^{76,77}$ to be linear, with sp hybridization at beryllium. This has been confirmed theoretically, ${ }^{92}$ although gaseous $\mathrm{BeH}_{2}$ has not been observed and in the solid state the arrangement of hydrogens about Be is nearly tetrahedral. ${ }^{30}$ The Hartree-Fock limit for $\mathrm{BeH}_{2}$ is estimated ${ }^{93}$ to be -15.7730 au ; correlation estimates are given in several recent studies ${ }^{92-95}$ the best of which ${ }^{95}$ gives a Be-H bond length of $1.334 \AA$ (with CI) and includes a review
of earlier studies. The STO-3G bond length is $1.291 \AA$. At $4-31 \mathrm{G} / 5-21 \mathrm{G}$ the value is $1.369 \AA .{ }^{32}$
$\mathrm{Be}_{2}$. The ground state of the Be atom ( ${ }^{( } \mathrm{S}$ ) has the closed shell configuration $(1 s)^{2}(2 s)^{2}$, so that there is no tendency for bond formation between two beryllium atoms. This has been examined theoretically elsewhere ${ }^{20,41.96 .97}$ and by us at STO-3G; the minimum energy obtained for $\mathrm{Be}_{2}$ was -28.70438 hartrees at $r=3.542 \AA$. This is only 0.39 kcal mol ${ }^{-1}$ below the STO-3G energy of two ${ }^{1} \mathrm{~S}$ Be atoms calculated with standard molecular scale factors. ${ }^{98}$ This is apparently an artifact of the limited STO-3G basis as this small binding energy disappears when larger basis sets are used. ${ }^{99}$
(25) $\mathrm{Be}_{2} \mathrm{H}_{2}$. This molecule bears the same relation to $\mathrm{BeH}_{2}$ as mercurous derivatives do to mercuric. It represents the simplest system with a $\mathrm{Be}-\mathrm{Be}$ single bond, as yet an unknown entity. The bond is characterized by features found in $\mathrm{Li}_{2}$ : little interatomic overlap and a large bond length ( $2.062 \AA$ at STO-3G). The structure is predicted to be linear, in accord with Walsh's rules.
(26) $\mathrm{Be}_{2} \mathrm{H}_{4}$. Three topologies were investigated but only one significantly bound dimer was located on the $\mathrm{BeH}_{2}-\mathrm{BeH}_{2}$ potential surface. This dimer 26 has a doubly bridged $\mathrm{HBe}-$ $-(\mathrm{H})_{2}-$ - BeH structure, as might be expected considering the stability of the analogues $\mathrm{Li}-(\mathrm{H})_{2^{-}}-\mathrm{Li}$ and $\mathrm{H}_{2} \mathrm{~B}-(\mathrm{H})_{2^{-}}-$ $\mathrm{BH}_{2}{ }^{4}$ This structure has been proposed on qualitative grounds by Pearson. A similar geometry obtained by Ahlrichs ${ }^{100}$ using a near-Hartree-Fock basis is given in Table III.

The trend noted previously in lithium hydrides appears to be a general one. In dimerization of $\mathrm{BeH}_{2}$, the Be atoms approach each other to $1.991 \AA$, within the single bond distance in $\mathrm{HBe}-\mathrm{BeH}$, while bridged $\mathrm{Be}-\mathrm{H}$ bonds become considerably longer ( $1.464 \AA$ ) than in $\mathrm{BeH}_{2}$. Terminal $\mathrm{Be}-\mathrm{H}$ bonds change little upon dimerization.

Also examined for $\mathrm{Be}_{2} \mathrm{H}_{4}$ were a $C_{2 i}$ "beryllium bonded" structure $\mathrm{HBeH}--\mathrm{BeH}_{2}$ and an unsymmetrical triply bridged form $\mathrm{HBe}-(\mathrm{H})_{3}-\mathrm{Be}$. The latter species was found to be unbound (with respect to two $\mathrm{BeH}_{2}$ moieties) after a partial optimization. The $C_{2 v}$ species, however, was found to be slightly bound by $\sim 0.4 \mathrm{kcal} \mathrm{mol}^{-1}$ after partial optimization, holding rigid $\mathrm{BeH}_{2}$ subunits, resulting in a $\mathrm{Be}-\mathrm{Be}$ distance of $4.214 \AA$. This small stabilization can be rationalized in terms of a qua-drupole-quadrupole interaction. There is some experimental support for the $D_{2 h}$ form; a similar geometry has been suggested for dimeric $\mathrm{Be}_{2} \mathrm{Cl}_{4}$, observed at $500^{\circ} \mathrm{C}$ to be the predominant oligomer of $\mathrm{BeCl}_{2}$ present in the gas phase. ${ }^{102}$ Also, x -ray structures of alkali metal dialkylberyllium hydrides ${ }^{59.103}$ indicate the presence of $\mathrm{R}_{2} \mathrm{Be}-(\mathrm{H})_{2}--\mathrm{BeR}_{2}$ units, isoelectronic with diborane-type structures $\mathrm{R}_{2} \mathrm{~B}--(\mathrm{H})_{2}-\mathrm{BR}_{2}$.
$(27,28) \mathrm{BeBH}$. For BeBH , two electronic states, ${ }^{3} \Pi$ and ${ }^{\prime} \mathrm{A}^{\prime}$, were studied. Formally, this species represents a $\mathrm{Be}=\mathrm{B}$ double bond. In the singlet state, however, bonding is relatively weak; the calculated bond length is long ( $1.966 \AA$ ) and the species is nonlinear with an $\mathrm{H}-\mathrm{B}-\mathrm{Be}$ angle of $120.5^{\circ}$. The singlet binding energy (relative to $\mathrm{Be}\left({ }^{1} \mathrm{~S}\right)^{126,98}$ and $\left.\mathrm{BH}\left({ }^{1} \Sigma^{+}\right)^{4}\right)$ is only 13.2 and $4.1 \mathrm{kcal}^{\mathrm{kcol}}{ }^{-1}$ with the STO-3G and $6-31 \mathrm{G}^{*}$ bases, respectively.

The geometry of the triplet state is found to be linear, with a substantially shorter $\mathrm{Be}-\mathrm{B}$ bond length ( $1.744 \AA$ ). At the STO-3G level, this state lies $56.7 \mathrm{kcal} \mathrm{mol}^{-1}$ below the ${ }^{1} \mathrm{~A}^{\prime}$ state and is bound by $69.9 \mathrm{kcal} \mathrm{mol}^{-1}$. At the $6-31 \mathrm{G}^{*}$ level, the triplet state is $41.6 \mathrm{kcal} \mathrm{mol}^{-1}$ below the singlet species and is bound by $45.7 \mathrm{kcal} \mathrm{mol}^{-1}$. It is therefore quite likely that the ground state is a triplet. It is interesting to note that the ${ }^{3} \Pi$ state obtained has only one $\pi$ electron. $\mathrm{A}^{3} \Sigma^{-}$state, with two $\pi$ electrons, was obtained at the STO-3G level but was found to lie some $39 \mathrm{kcal} \mathrm{mol}^{-1}$ above the ${ }^{3} \Pi$ state at the ${ }^{3} \Pi$ equilibrium geometry. This state was not studied further.
(29) $\mathrm{BeBH}_{3} . \mathrm{HBeBH}_{2}$, "beryllioborane", has been mentioned above in connection with the bond angle series in $\mathrm{XBH}_{2}$
systems. The structure is calculated to be planar, $C_{2 v}$. Beryl-lium-boron single bonding appears to be unreported elsewhere.
$(\mathbf{3 0}, \mathbf{3 1}) \mathrm{BeBH}_{5}$. We find at both the STO-3G and 6-31G* levels that triply bridged $\mathrm{HB}-(\mathrm{H})_{3}-\mathrm{BeH}(\mathbf{3 0})$ is very slightly favored over the doubly bridged form $\mathrm{H}_{2} \mathrm{~B}--(\mathrm{H})_{2}-\mathrm{BeH}(31)$. This agrees with calculations by Ahlrichs. ${ }^{105 a}$ The energy difference is sufficiently small ( $4.6 \mathrm{kcal} \mathrm{mol}{ }^{-1}$ at $6-31 \mathrm{G}^{*}$ ) that the two forms should be experimentally difficult to distinguish, as appears to be the case in several related systems. For example, recent electron diffraction data are unable to distinguish between doubly bridged $\mathrm{B}-(\mathrm{H})_{2^{-}}-\mathrm{Be}$ or triply bridged B - -$(\mathrm{H})_{3}-$ - Be units in cyclopentadienyl- $\mathrm{BeBH}_{4}{ }^{104}$ or $\mathrm{BeB}_{2} \mathrm{H}_{8} .{ }^{105}$ However, a methyl derivative of $\mathbf{3 0}, \mathrm{CH}_{3} \mathrm{BeBH}_{4}$, appears to involve only double hydrogen bridges. ${ }^{106}$

In addition to 30 and 31, four other $\mathrm{BeBH}_{5}$ structures were investigated. None was found to be significantly bound relative to $\mathrm{BH}_{3}$ and $\mathrm{BeH}_{2}$. Two are singly bridged species, HBeH $\mathrm{BH}_{3}\left(C_{3 c}\right)$ and $\mathrm{H}_{2} \mathrm{BH}--\mathrm{BeH}_{2}\left(C_{2 c}\right.$, with $\mathrm{BeH}_{2}$ and $\mathrm{BH}_{3}$ planes perpendicular). The third is the doubly bridged $\left(C_{2 v}\right)$ form $\mathrm{H}_{2} \mathrm{Be}--(\mathrm{H})_{2}-\mathrm{BH}$, and finally the $\left(C_{s}\right)$ triply bridged $\mathrm{Be}-(\mathrm{H})_{3}--\mathrm{BH}_{2}$, in which one of the three bridging hydrogens is distinct from the others. Partial geometry optimization was performed in each case.
$(32,33) \mathrm{BeCH}_{2}$. As with the other beryllium systems containing formal double bonds, we have considered two electronic states ( ${ }^{3} \mathrm{~B}_{1}$ and ${ }^{1} \mathrm{~A}_{1}$ ) for $\mathrm{Be}=\mathrm{CH}_{2}$. The $6-31 \mathrm{G}^{*}$ basis predicts a strongly bound ( $56.1 \mathrm{kcal} \mathrm{mol}{ }^{-1}$ ) ${ }^{3} \mathrm{~B}_{1}$ ground state and a slightly bound ${ }^{1} \mathrm{~A}_{1}$ state (relative to $\mathrm{CH}_{2}\left({ }^{3} \mathrm{~B}_{1}\right)+\mathrm{Be}\left({ }^{1} \mathrm{~S}\right)$ ) that lies $54.9 \mathrm{kcal} \mathrm{mol}^{-1}$ above the triplet. These results are consistent with the findings of Lamanna and Maestro ${ }^{107}$ who, based on a study using a moderate Gaussian sp basis, found $\mathrm{CH}_{2} \mathrm{Be}$ dissociation energies of 56.1 and $3.2 \mathrm{kcal} \mathrm{mol}^{-1}$ for the triplet and singlet states, respectively. Further, they concluded that the ${ }^{1} \mathrm{~A}_{1}$ state is very likely unbound relative to $\mathrm{CH}_{2}\left({ }^{3} \mathrm{~B}_{1}\right)$ and $\operatorname{Be}\left({ }^{1} \mathrm{~S}\right)$ when zero-point vibrational corrections are taken into account. However, the question of carbon-beryllium binding in $\mathrm{CH}_{2} \mathrm{Be}$ has been further pursued in a recent theoretical study ${ }^{108}$ with correlation corrections. This indicates substantial carbon-beryllium binding in both triplet and singlet states.

Both the singlet and triplet states are predicted to be of $C_{2 c}$ symmetry at the STO-3G level. The STO-3G Be-C bond length increases from 1.472 to $1.652 \AA$ on going from ${ }^{1} \mathrm{~A}_{1}$ to ${ }^{3} \mathrm{~B}_{1}$. Similar lengths of 1.498 and $1.651 \AA$ were reported by Lamanna and Maestro. The singlet $\mathrm{Be}=\mathrm{C}$ bond length falls in line with bond lengths calculated for other $\mathrm{X}=\mathrm{CH}_{2}$ systems. Calculated singlet double bond lengths ${ }^{4.5}$ decrease as X goes from boron to oxygen: $1.472 \AA\left(\mathrm{Be}=\mathrm{CH}_{2}\right), 1.339 \AA$ $\left(\mathrm{HB}=\mathrm{CH}_{2}\right), 1.306 \AA\left(\mathrm{H}_{2} \mathrm{C}=\mathrm{CH}_{2}\right), 1.273 \AA\left(\mathrm{HN}=\mathrm{CH}_{2}\right)$, $1.217 \AA\left(\mathrm{H}_{2} \mathrm{C}=\mathrm{O}\right)$.
(34) $\mathrm{BeCH}_{4}$. Methylberyllium hydride, $\mathrm{HBeCH}_{3}$, is not known as a monomer but exists only as a coordinated dimer, (S) $\mathrm{MeBe}-(\mathrm{H})_{2}-\mathrm{BeMe}(\mathrm{S})$, where $(\mathrm{S})$ is $\mathrm{NMe}_{3}, \mathrm{OEt}_{2}$, or other lone-pair donor complexed to beryllium. ${ }^{8 a}$ Structural data are available, however, concerning the disubstituted analogue, $\mathrm{Me}_{2} \mathrm{Be}$, which has been observed by electron diffraction as a gas-phase monomer. ${ }^{109}$ The following geometry was reported for $D_{3 h} \mathrm{Me}_{2} \mathrm{Be}$ (with STO-3G values for $\mathrm{C}_{3 v} \mathrm{HBeCH}_{3}$ in parentheses): $r_{\mathrm{Be}-\mathrm{C}}=1.698 \AA(1.691 \AA), \angle \mathrm{Be}-\mathrm{C}-\mathrm{H}=$ $113.9^{\circ}\left(111.8^{\circ}\right), r_{\mathrm{C}-\mathrm{H}}=1.127 \AA(1.085 \AA)$. The agreement is good. In previous theoretical studies of $\mathrm{HBeCH}_{3}{ }^{67}$ and $\mathrm{Be}\left(\mathrm{CH}_{3}\right)_{2}{ }^{64,66,68}$ strict tetrahedral geometry at $\mathrm{CH}_{3}$ was assumed but calculated Be -C distances were close to the STO3G value. One of these studies ${ }^{67}$ found dimerization to be slightly unfavorable, two $\mathrm{HBeCH}_{3}$ molecules being preferred by $4 \mathrm{kcal} \mathrm{mol}{ }^{-1}$ over $\mathrm{HBe}-(\mathrm{Me})_{2}-\mathrm{BeH}$. A fully optimized $4-31 \mathrm{G} / 5-21 \mathrm{G}$ structure of $\mathrm{CH}_{3} \mathrm{BH}$ is now available: ${ }^{69 \mathrm{e}} r_{\mathrm{Be}-\mathrm{C}}$ $=1.698 \AA, r_{\mathrm{Be}-\mathrm{H}}=1.335 \AA, r_{\mathrm{C}-\mathrm{H}}=1.089 \AA, \angle \mathrm{Be}-\mathrm{C}-\mathrm{H}=$
$111.8^{\circ}, E=-54.75469$ hartrees.
$\mathrm{BeCH}_{6}$. Several geometries were examined in an attempt to find a stable complex of methane and beryllium hydride a nalogous to $\mathrm{LiH}-\mathrm{CH}_{4}(\mathbf{1 7})$. However, none of the following was bound with respect to $\mathrm{BeH}_{2}$ plus $\mathrm{CH}_{4}$, after partial optimization: $\left(\mathrm{C}_{2 v}\right) \mathrm{H}_{2} \mathrm{Be}-(\mathrm{H})_{2}-\mathrm{CH}_{4}$, isostructural and isoelectronic with $\mathrm{B}_{2} \mathrm{H}_{6}$; triply bridged $\left(\mathrm{C}_{s}\right) \mathrm{H}_{2} \mathrm{Be}--(\mathrm{H})_{3}--\mathrm{CH}$; triply bridged $\left(C_{s}\right) \mathrm{HBe}-(\mathrm{H})_{3}-\mathrm{CH}_{2}$; beryllium bonded $\left(C_{s}\right)$ $\mathrm{H}_{2} \mathrm{Be}-\mathrm{HCH}_{3}$.
$(35,36) \mathrm{BeNH}$. Beryllium imide, BeNH, is formed upon pyrolysis of beryllium amide $\left(\mathrm{Be}\left(\mathrm{NH}_{2}\right)_{2}\right),{ }^{110}$ but no structural parameters have been reported. For this molecule, the ${ }^{3} \Pi$ state was studied in addition to the ${ }^{1} \Sigma^{+}$state. Both are found to be linear. The singlet has a sufficiently small $\mathrm{Be}-\mathrm{N}$ distance ( $1.288 \AA$ ) that it seems to involve a genuine multiple bond. The triplet state ( ${ }^{3} \Pi$ ), also of $C_{\infty}$ symmetry, has a somewhat longer $\mathrm{Be}-\mathrm{N}$ bond distance of $1.438 \AA$. Here, there are only three $\pi$ electrons (compared to the four in the ${ }^{1} \Sigma^{+}$state). Thus the lengthening of the $\mathrm{B}-\mathrm{N}$ bond may, in part, be attributed to the promotion of one of the ( $1 \pi$ ) orbital electrons to the ( $5 \sigma$ ) orbital thereby weakening one of the $\pi$ bonds. The triplet state is found to lie 29.1 and $33.1 \mathrm{kcal} \mathrm{mol}^{-1}$ below the singlet state with STO-3G and 6-31 G* bases, respectively. However, it is unclear at this time which state is the ground state; comparison of UHF triplets vs. RHF singlets can be misleading due to the preferential stabilization of triplets relative to singlets in the UHF formalism.
(37) $\mathrm{BeNH}_{3}$. Although monomeric beryllium monoamides are apparently not known, diamides have been reported. ${ }^{8 a}$ For example, gaseous ( $\left.\mathrm{SiMe}_{3}\right)_{2} \mathrm{~N}-\mathrm{Be}-\mathrm{N}\left(\mathrm{SiMe}_{3}\right)_{2}$ has been found ${ }^{111}$ to have $\mathrm{Be}-\mathrm{N}$ distances of $1.566 \AA$ in an allene-shaped framework. We find $\mathrm{HBeNH} \mathrm{N}_{2}$ to have a planar $C_{2 v}$ structure with $r_{\mathrm{Be}-\mathrm{N}}=1.457 \AA$, shorter than both the $1.53 \AA$ found by Baird et al. ${ }^{67}$ (at STO-2G) and the $1.566 \AA$ in the $\operatorname{Be}(\mathrm{N}-$ $\left.\left(\mathrm{SiMe}_{3}\right)_{2}\right)_{2}$ structure. Of course, this experimental value may be abnormally long due to steric crowding of the trimethylsilyl groups. It is noteworthy that $\mathrm{HBeNH}_{2}$ has a structure similar to that of the isoelectronic classical vinyl cation. ${ }^{5.112 .113}$
$(38,39) \mathrm{BeNH}_{5}$. Amine beryllium complexes are well known, ${ }^{8 \text { a }}$ but structural data are generally lacking for $1: 1$ adducts. A $\mathrm{Be}-\mathrm{N}$ coordinate bond length of $1.91 \AA$ has been found by x-ray diffraction for the bis quinuclidine adduct of $\mathrm{BeMe}_{2}\left[\mathrm{Me}_{2} \mathrm{Be}\left(\mathrm{NC}_{7} \mathrm{H}_{13}\right)_{2}\right]$, ${ }^{114}$ but unfortunately the structure of the simpler known adduct $\mathrm{Me}_{2} \mathrm{Be}--\mathrm{NMe}_{3}$ has not been reported. We have calculated two rotamers of $\mathrm{H}_{2} \mathrm{Be}--\mathrm{NH}_{3}$ : "cis", having a coplanar $\mathrm{H}-\mathrm{Be}-\mathrm{N}-\mathrm{H}$ arrangement (38), and "perpendicular" (39), rotated by $90^{\circ}$ from cis and reoptimized. The cis form is very slightly preferred over the perpendicular at both levels of calculation. The calculated $\mathrm{Be}-\mathrm{N}$ distance ( $1.747 \AA$ ) is longer than the corresponding calculated distance in the boron analogue $\mathrm{H}_{3} \mathrm{~B}--\mathrm{NH}_{3}\left(1.657 \AA\right.$ staggered ${ }^{4}$ ) but considerably shorter than $\mathrm{HLi}-\mathrm{NH}_{3}$ and the x-ray value cited above. In forming the amine beryllium complex, the geometry of $\mathrm{NH}_{3}$ is changed only slightly and the HBeH angle bends from 180 to $136^{\circ}$. These structures are analogous to those of the isoelectronic ethyl cation. ${ }^{5}$
$(40,41) \mathrm{BeO}$. Beryllium oxide has been the subject of several previous theoretical studies ${ }^{115-118}$ and the determination of the ground state has caused some difficulty. We have considered only two electronic states, ${ }^{3} \Pi$ and ${ }^{1} \Sigma^{+}$, in this study. The ${ }^{1} \Sigma^{+}$state is known experimentally ${ }^{119}$ to be the lowest singlet state (although Huo et al. ${ }^{117}$ report that the ${ }^{1} \Pi$ state is below the ${ }^{1} \Sigma^{+}$state when studied near the Hartree-Fock limit). The ${ }^{3} \Pi$ state appears to be the lowest triplet state but has to our knowledge never been observed experimentally. Based on theoretical considerations, Schaefer ${ }^{118}$ has concluded that the BeO ground state is ${ }^{1} \Sigma^{+}$. It is interesting to note that $C_{2}$, isoelectronic with BeO , is experimentally known ${ }^{120}$ to have a ${ }^{1} \Sigma_{\mathrm{g}}{ }^{+}$ ground state and first excited state of ${ }^{3} \Pi_{u}$. For BeO, both the

STO-3G and 6-31 $\mathrm{G}^{*}$ bases incorrectly predict that the ground state is ${ }^{3} \Pi$, presumably due to lack of correlation corrections.

The bond length for the ${ }^{1} \Sigma^{+}$state has been determined as $1.331 \AA$ (exptl), ${ }^{31} 1.313 \AA$ (first order wave function CI), ${ }^{118}$ $1.290 \AA$ (near Hartree-Fock), ${ }^{115}$ and $1.269 \AA$ (STO-3G). In the ${ }^{3} \Pi$ state, no experimental value is available. The theoretical bond lengths are $1.463 \AA$ (first order wave function CI), ${ }^{118}$ $1.447 \AA$ (near Hartree-Fock), ${ }^{115}$ and $1.435 \AA$ (STO-3G). As has been observed in other polar molecules, the STO-3G bond length is too short. The triplet state is found to be $28 \mathrm{kcal} \mathrm{mol}^{-1}$ below the singlet state at the $6-31 \mathrm{G}^{*}$ level. (Some caution must be exercised in interpreting singlet-triplet splittings derived solely from Hartree-Fock theory, as correlation corrections are likely to be important.) As has been noted elsewhere, ${ }^{20}$ convergence difficulties were encountered in obtaining the $6-31 \mathrm{G}^{*}$ wave function for the ${ }^{1} \Sigma^{+}$state. This problem was solved through use of special programs due to Seeger. ${ }^{20 c}$
(42) $\mathrm{BeOH}_{2}$. Hydroxyberyllium hydride is not known experimentally. Crystal data are, however, available for an ROBeR' tetramer, $\left[\mathrm{Me}_{3} \mathrm{SiOBeCH}_{3}\right]_{4}$; $^{121}$ it has Be and O atoms at alternate corners of a distorted cube, with $r_{\mathrm{Be}-\mathrm{O}}=$ $1.73 \AA$. We calculate the HBeOH monomer to have a linear structure with a short $\mathrm{Be}-\mathrm{O}$ bond ( $1.301 \AA$ ). This is similar to the isoelectronic molecules $\mathrm{HBNH}^{4}$ and HCCH .
$(43,44) \mathrm{BeOH}_{4}$. Beryllium-oxygen coordinate bonds are generally weaker than beryllium-nitrogen, ${ }^{122}$ and we calculate them to be shorter as well. The water- $\mathrm{BeH}_{2}$ system is isoelectronic with aminoborane ${ }^{4}$ and shows similar rotational behavior; in both cases, a planar $C_{2 v}$ form (43) is preferred over the $90^{\circ}$-rotated $C_{s}$ form (44). The $6-31 \mathrm{G}^{*}$ rotational barrier is $4.8 \mathrm{kcal} \mathrm{mol}^{-1}$. The $\mathrm{Be}-\mathrm{O}$ bond distance in the planar form is the smaller ( $1.582 \AA$ vs. $1.674 \AA$ rotated), reflecting additional $\pi$ bonding.
(45) HBeF. Alkaline earth halides have not been as extensively studied as alkali halides. In $\mathrm{BeF}_{2}$, the experimental structure is linear with $r_{\mathrm{BeF}}=1.430 \AA,{ }^{123}$ a value well reproduced by a near-Hartree-Fock calculation. ${ }^{124}$ Our structure for HBeF is linear with a B-F distance ( $1.299 \AA$ ) which is considerably shorter than in $\mathrm{BeF}_{2}$. Recently, a study of $\mathrm{CH}_{3} \mathrm{BeF}$ has been published ${ }^{125}$ giving a $\mathrm{Be}-\mathrm{F}$ length of 1.40 $\AA$. It is possible that some extra shortening in HBeF is due to additional $\pi$ bonding between Be and F since the beryllium atom does not accept any $\pi$ electrons from the other substituent in this case.
$(46,47) \mathrm{BeFH}_{3}$. The $\mathrm{BeH}_{2}-\mathrm{FH}$ complex falls in line with others. The $\mathrm{Be}-\mathrm{F}$ distance ( $1.588 \AA$ planar, $1.621 \AA$ rotated by $90^{\circ}$ ) is shorter than corresponding values in $\mathrm{H}_{2} \mathrm{Be}-\mathrm{OH}_{2}$ or $\mathrm{H}_{2} \mathrm{Be}-\mathrm{NH}_{3}$ but longer than in $\mathrm{H}_{3} \mathrm{~B}-\mathrm{FH} ;{ }^{4}$ the rotational behavior is as expected from the isoelectronic $\mathrm{H}_{2} \mathrm{BOH},{ }^{4}$ the planar form permitting $\pi$-electron delocalization and thus being strongly favored. Beryllium-fluorine coordinate bonds have not been discussed elsewhere.

## Standard Geometrical Models

We have often employed a set of standard bond lengths and angles when calculating large systems having well-defined structures. A standard set of lengths has been given previously for bonds between the atoms C to $\mathrm{F}^{126}$ and those involving $\mathrm{B},{ }^{4}$ and we now extend this to include $\mathrm{Li}-\mathrm{X}$ and $\mathrm{Be}-\mathrm{X}$ bonds.
A set of standard bond lengths is given in Table IV. These were obtained from STO-3G structures as well as the experimental and other theoretical data cited above. These lengths represent average distances regardless of hybridization at X . The single bond lengths apply only to monocoordinate lithium and dicoordinate beryllium, the latter having a standard X -$\mathrm{Be}-\mathrm{Y}$ angle of $180^{\circ}$. The values for $\mathrm{Li}-\mathrm{C}, \mathrm{Be}-\mathrm{H}$, and $\mathrm{Be}-\mathrm{C}$ have appeared previously. ${ }^{127}$

Table IV. Standard Bond Lengths for $\mathrm{Li}-\mathrm{X}$ and $\mathrm{Be}-\mathrm{X}^{a}$ Bonds

| Bond | Length, $\AA$ | Bond | Length, $\AA$ |
| :---: | :---: | :---: | :---: |
| Single Bonds |  |  |  |

${ }^{a}$ Standard $\mathrm{X}-\mathrm{Be}-\mathrm{Y}$ angle $=180^{\circ},{ }^{b}$ Standard values here refer to singlet states.

## Discussion

To facilitate discussion, it is convenient to subdivide the list of molecules according to bond type. In one category are the singly bonded $\mathrm{Li}-\mathrm{X}$ and $\mathrm{HBe}-\mathrm{X}$ and doubly bonded $\mathrm{Be}=\mathrm{X}$ systems involving covalent and ionic bonding. Dimers of LiH and $\mathrm{BeH}_{2}$ with Lewis acid hydrides $\left(\mathrm{LiH}, \mathrm{BeH}_{2}, \mathrm{BH}_{3}\right.$, and $\mathrm{CH}_{4}$ ) form a second category involving three-center twoelectron bonding. Finally, coordinate complexes of LiH and $\mathrm{BeH}_{2}$ with $\mathrm{NH}_{3}, \mathrm{OH}_{2}$, and FH represent a third bond type. In each of these categories, we shall discuss electron distributions and the nature of bonding.

We shall examine the electron distribution by Mulliken population analysis. ${ }^{35}$ This method has its drawbacks, especially in attempting to describe highly polar bonds. In LiX, for
example (with electronegative X ), the large, diffuse lithium orbitals overlap with smaller X orbitals in a region of space near the X nucleus, yet the Mulliken scheme assigns half the electrons in this overlap region to each atom. The result is an artificially large number of electrons assigned to lithium, making the $\mathrm{Li}-\mathrm{X}$ bond seem less polar, or more homogeneous, than is realistic. This problem is especially acute at the minimal STO-3G basis set level, particularly when p functions are included on lithium. Nevertheless the STO-3G populations do give some comparative information about electron displacements and they will be used unless otherwise indicated.

Single Bonds. Some Mulliken STO-3G overlap populations for $\mathrm{Li}-\mathrm{X}$ and $\mathrm{HBe}-\mathrm{X}$ molecules are given in Table V . The $\pi$-overlap population is the sum of the $\mathrm{p}_{x}-\mathrm{p}_{x}$ and $\mathrm{p}_{y}-\mathrm{p}_{y}$ overlap populations where the heavy atoms lie on the $z$ axis. The $\sigma$-overlap population is defined to be the sum of all overlap populations between the two heavy atoms involving $1 \mathrm{~s}, 2 \mathrm{~s}$, and $2 \mathrm{p}_{z}$ atomic functions.

In general, $\sigma$ overlap is reduced as the substituent X becomes more electronegative, and this is compensated by an increase in $\pi$ overlap. For both $\mathrm{Li}-\mathrm{X}$ and $\mathrm{HBe}-\mathrm{X}$ maximum $\pi$ overlap occurs when X is OH , and clearly it is to assure this that the OH group adopts a linear conformation. $\pi$ overlap is also high if X is $\mathrm{NH}_{2}$ or F , and the fact that values are nearly equal for these groups demonstrates the single lone pair on N to be roughly twice as effective as each of the two on $F$ at providing $\pi$ electrons.

Also given in Table V are total electron populations on Li and HBe and total electron transfer to Li and HBe for these singly bonded molecules. The total electron population on $\mathbf{M}$ is further subdivided into $\sigma$ and $\pi$ components. The $\pi$ component gives the total electron population residing in the $\mathrm{p}_{x}$ and $\mathrm{p}_{y}$ orbitals at M . The electron population in the remaining orbitals of the lithium or beryllium, plus the hydrogen orbital

${ }^{a}$ Experimental values in parentheses ( 0 K ), corrected for zero-point vibration, from data in ref $128 .{ }^{b} 6-31 \mathrm{G} *$ energies of nonmetal hydrides from ref $129, \mathrm{BH}_{3}$ from ref 4.
in the case $\mathrm{M}=\mathrm{HBe}$, gives rise to the $\sigma$ total electron population at M . The total electron transfer to M represents the fractional number of electrons transferred to M . Thus, in the case of $\mathrm{HBe}-\mathrm{F}$, the value -0.19 indicates that 0.19 electron has been transferred away from the HBe unit.

Some caution must be exercised in interpreting the results listed in Table V because the $\mathrm{p} \pi$ orbitals on lithium and beryllium are assigned excessive amounts of electron population in the STO-3G analysis. This effect is highly basis set dependent. In $\mathrm{Li}-\mathrm{F}$, for example, the STO-3G analysis indicates that the $\mathrm{p} \pi$ orbitals on the lithium have an electron population of 0.61 . The corresponding value at the $6-31 \mathrm{G}^{*}$ level is only 0.28 . As a result of this exaggerated $\pi$ population, the gross STO-3G population suggests too small a polarity for these bonds. The total $\sigma$ populations, on the other hand, are less dependent on the basis set and indicate that electrons move toward X in the $\sigma$ system with some back-donation in the $\pi$ system. In general, net electron transfer is toward X and leads to substantial dipole moments as shown in the last column of Table V .

Double Bonds $\mathrm{Be}=\mathbf{X}$. Population data on the four doubly bonded beryllium systems (both singlet and triplet states) are also given in Table V . This group of doubly bonded molecules can be logically subdivided into a group of ten-electron molecules (singlet and triplet $\mathrm{Be}=\mathrm{BH}$ ) and a group of twelveelectron molecules (the remaining doubly bonded systems, both singlet and triplet states). Further, it is useful to note that although varying point groups are represented $\left(C_{s}, C_{2}\right.$, and $C_{\infty}$ ), it is possible to define $\pi$-type orbitals as those having a node in the molecular plane and $\sigma$-type orbitals as those lacking such a node (in all cases, the heavy atoms lie on the $z$ axis, and if nonlinear, the hydrogens lie in the $x z$ plane). For $\mathrm{Be}=\mathrm{BH}$, the 10 -electron case, the low $\pi$ population for the singlet is readily explained by noting that the molecule has $C_{s}$ symmetry, and there are no occupied $\mathrm{a}^{\prime \prime}$ orbitals in the singlet configuration (the nonzero $\pi$ population arises from the fact that there are $\mathrm{a}^{\prime}$ orbitals having $\mathrm{p}_{x}$ character). The linear triplet, however, is formed by occupying one of the $\mathrm{a}^{\prime \prime}$ orbitals (becoming a $\pi$ orbital in the linear molecule), and consequently additional $\pi$ overlap is acquired. The 10 -electron systems are further characterized by the electron-acceptor nature of the beryllium atom at the STO-3G level. This effect is somewhat basis dependent, and at the 6-31 G* level, total electron transfer is away from the beryllium in the singlet (total electron transfer +0.04 ) and to the beryllium in the triplet (total electron transfer -0.05 ). Both singlet and triplet $\mathrm{Be}=\mathrm{BH}$ have moderate dipole moments, as might be expected by the small electron transfer values at the $6-31 G^{*}$ level. For the 12 -electron systems, the trends are largely reversed. The singlets are characterized by
having large $\pi$-overlap populations. There is, in each molecule, a significant reduction in $\pi$ overlap in going from the singlet to the triplet because in each case there is a reduction from four to three $\pi$-type orbitals. In all these 12 -electron systems, the total electron transfer is away from the beryllium. Further, the singlets are characterized by very large dipole moments, the triplets having only moderate dipole moments. In the singlet state of $\mathrm{Be}=\mathrm{CH}_{2}, \pi$ overlap is similar to that in ethylene ( 0.40 at STO-3G), and the total electron $\pi$ population indicates that the two $\mathrm{Be}=\mathrm{CH}_{2} \pi$ electrons are almost equally shared between Be and $\mathrm{C} . \pi$ overlap in $\mathrm{Be}=\mathrm{NH}$ and $\mathrm{Be}=\mathrm{O}$ indicates nearly triple bonding. In these, $\pi$ electrons are polarized toward Be with strong $\sigma$ donation in the opposite direction.

Heats of Hydrogenation. In previous studies, ${ }^{12}$ the Har-tree-Fock method with the $6-31 \mathrm{G}^{*}$ basis has been found to give good values for hydrogenation energies. In Table VI we list the theoretical energies for the hydrogenation reactions

$$
\begin{gathered}
\mathrm{LiX}+\mathrm{H}_{2} \rightarrow \mathrm{LiH}+\mathrm{XH} \\
\mathrm{HBeX}+\mathrm{H}_{2} \rightarrow \mathrm{BeH}_{2}+\mathrm{XH} \\
\mathrm{BeY}+2 \mathrm{H}_{2} \rightarrow \mathrm{BeH}_{2}+\mathrm{YH}_{2}
\end{gathered}
$$

The limited experimental data ${ }^{128}$ available are also given.
Variations in hydrogenation energies reflect strengths of $\mathrm{Li}-\mathrm{X}$ and $\mathrm{Be}-\mathrm{X}$ bonds relative to $\mathrm{H}-\mathrm{X}$. In general, negative hydrogenation energies indicate metal-metal single bonds to be weak, a result of high s character and little $\pi$ bonding. With lone-pair substituents, $\pi$ bonding leads to increased bond strengths, especially when two lone pairs are available ( $\mathrm{X}=$ OH or F ). A full study of bond dissociation energies in two-heavy-atom molecules will be presented in a future publication.

Multicenter Bonds. We now turn to the metal hydride dimers. Table VII gives the total atomic charges (from Mulliken STO-3G gross populations) for the structures we have considered. Atomic charges in $\mathrm{LiH}, \mathrm{BeH}_{2}$, and $\mathrm{BH}_{3}$ are also given in the table for comparison. The table is arranged with similar structures grouped together and in some cases entries are duplicated in order to permit easy comparisons.

Consider the charge reorganization in formation of a linear three-center two-electron bond, such as in dimerization of LiH to $\mathrm{Li}^{1}--\mathrm{H}_{\mathrm{br}}--\mathrm{Li}^{2}-\mathrm{H}^{2}$. The charge distributions in Table VII show $\mathrm{Li}^{1}$ to become highly positive in the dimer, while $\mathrm{Li}^{2}$ becomes negative. There is a slight accumulation of negative charge at the bridging hydrogen as well. Overall, charge shifts toward B in the AH- - B arrangement, just opposite the direction of polarization in hydrogen bonding. ${ }^{47}$ As the electron acceptor $\left(\mathrm{Li}^{2} \mathrm{H}^{2}\right)$ changes to $\mathrm{BeH}_{2}$ or $\mathrm{BH}_{3}$, more charge is

| 30 | $\mathrm{HBe}-(\mathrm{H})_{3}-\mathrm{BH}$ | 23.7 | 31.5 |

${ }^{a}$ Numbering and notation as in Table I. ${ }^{b}$ Energy relative to appropriate sum of $\mathrm{LiH}, \mathrm{BeH}_{2}$ (Table I), $\mathrm{BH}_{3}$ (ref 4), or $\mathrm{CH}_{4}$ (ref 3 and 129) energies.
transferred from $\mathrm{Li}^{1}$ via $\mathrm{H}_{\mathrm{br}}$ and is ultimately transmitted to terminal hydrogens. Similar charge shifts are seen in other singly hydrogen bridged dimers.

In structures having more than one bridging hydrogen, it is difficult to generalize the charge distributions in Table VII. Often hydrogens in bridging positions are more negative than in monomers, but this is not always true, particularly when neither of the heavy atoms is lithium. In unsymmetrical dimers, the more electropositive heavy atom generally provides charge to the other. Thus in $\mathrm{Li}-(\mathrm{H})_{2}-\mathrm{AH}$ or $\mathrm{Li}-(\mathrm{H})_{3}-\mathrm{A}(\mathrm{A}=\mathrm{Be}$ or BH ), lithium becomes positive while A and bridging hydrogens become negative.

Dimerization Energies. Table VIII gives the energies of hydrogen-bridged structures relative to the appropriate sums of monomer $\left(\mathrm{LiH}, \mathrm{BeH}_{2}, \mathrm{BH}_{3}, \mathrm{CH}_{4}\right)$ energies. A few general comments are in order concerning the ability of theory to reproduce binding energies of this type. A well-studied related
dimer known experimentally is diborane, $\mathrm{H}_{2} \mathrm{~B}-(\mathrm{H})_{2}--\mathrm{BH}_{2}$, for which the STO-3G dimerization energy of $\mathrm{BH}_{3}$ is 15.5 kcal $\mathrm{mol}^{-1}$, in reasonable agreement with the $6-31 \mathrm{G}^{*}$ value (20.5) and other theoretical determinations. ${ }^{4}$ However, the experimental value ${ }^{130}$ is around 36 . These and other calculations ${ }^{26 a, 131}$ are consistent with a large correlation energy change in comparing two $\mathrm{BH}_{3}$ moieties with $\mathrm{B}_{2} \mathrm{H}_{6}$. Similar conclusions have been reached for $\mathrm{BH}_{3}+\mathrm{BeH}_{2}$. Using an extensive sp basis and the IEPA method of determining correlation energies, Ahlrichs ${ }^{105 a}$ finds the following binding energies: for $\mathrm{HBe}--(\mathrm{H})_{3}-\mathrm{BH}(\mathbf{3 0}), 25.4 \mathrm{kcal} \mathrm{mol}^{-1}$ increasing to $39.9 \mathrm{kcal} \mathrm{mol}^{-1}$ with correlation (cf. 23.7 at STO-3G, 32.2 at $6-31 \mathrm{G}^{*}$ ); for $\mathrm{HBe}-(\mathrm{H})_{2^{-}}-\mathrm{BH}_{2}(31), 22.5$ or 33.0 with correlation (STO-3G gives $22.3,6-31 \mathrm{G}^{*}$ gives 27.6). Thus correlation differences seem to be important for hydrogenbridged structures, but the inclusion of $d$ functions is also clearly important.

Table IX. Charge Reorganization upon Acid $\left(\mathrm{LiH}, \mathrm{BeH}_{2}\right)-$ - Base $\left(\mathrm{NH}_{3}, \mathrm{OH}_{2}, \mathrm{FH}\right)$ Complexation ${ }^{a}$

| 43 | $\mathrm{H}_{2} \mathrm{Be}-\mathrm{OH}_{2}$ | 51.9 | 16.1 |
| 46 | $\mathrm{H}_{2} \mathrm{Be}--\mathrm{FH}$ | 43.2 | 4.5 |

${ }^{a}$ Energy of the reaction $\mathrm{H}_{n} \mathrm{~A}+\mathrm{BH}_{m} \rightarrow \mathrm{H}_{n} \mathrm{~A}-\mathrm{BH}_{m} .{ }^{b}$ Energies of $\mathrm{NH}_{3}, \mathrm{OH}_{2}$, and FH from ref 3 and 129 .

In contrast to the dimers involving boron, it has been found that the LiH dimer $\mathrm{Li}--(\mathrm{H})_{2}-\mathrm{Li}$ (3) is adequately described without correlation. Kollman et al. ${ }^{43}$ find the binding energy to be $47.2 \mathrm{kcal}^{\mathrm{mol}}{ }^{-1}$ with a near-Hartree-Fock basis, slightly decreasing (to $46.8 \mathrm{kcal} \mathrm{mol}^{-1}$ ) with inclusion of Cl . The values obtained by Ahlrichs ${ }^{26 \mathrm{a}}$ are more reliable: 47.3 kcal $\mathrm{mol}^{-1}$ (Hartree-Fock with large basis) and $48.3 \mathrm{kcal} \mathrm{mol}^{-1}$ (correlation corrections introduced with CEPA). Our values are similar, 44.0 and $46.8 \mathrm{kcal} \mathrm{mol}^{-1}$ at STO-3G and 6-31G*, respectively. In Kollman's study, ${ }^{43}$ the dimerization energy for linear ( LiH$)_{2}$ was found to be $26.0 \mathrm{kcal}_{\mathrm{mol}}{ }^{-1}$, in excellent agreement with our $6-31 \mathrm{G}^{*}$ value of $26.3 \mathrm{kcal}_{\mathrm{mol}}{ }^{-1}$. Apparently the lithium representation is sufficiently flexible without d functions, and correlation is less important for three-center bonds involving lithium than boron.

Finally, the effect of correlation has been studied ${ }^{100}$ on the $\mathrm{BeH}_{2}$ dimerization leading to $\mathrm{HBe}--(\mathrm{H})_{2}-\mathrm{BeH}$ (26). Using SCF only, the dimerization energy increases from 9.8 to 21.6 $\mathrm{kcal}^{\mathrm{mol}}{ }^{-1}$ with basis set expansion (compared to 19.6 at STO-3G and 24.5 at 6-31G*). Inclusion of correlation gives $27.9 \mathrm{kcal} \mathrm{mol}^{-1}$ and a final estimate of $31 \pm 6 \mathrm{kcal} \mathrm{mol}^{-1}$ is made when all data are considered. Thus $\mathrm{Be}_{2} \mathrm{H}_{4}$, predictably, is intermediate between $\mathrm{Li}_{2} \mathrm{H}_{2}$ and $\mathrm{B}_{2} \mathrm{H}_{6}$ with regard to correlation and d-function importance.

Table VIII shows the strongest linear MH- - $\mathrm{M}^{\prime}$ bond to be that in $\mathrm{LiH}-\mathrm{LiH}, 26.3 \mathrm{kcal}^{\mathrm{mol}}{ }^{-1}$. Other linear systems involve LiH and $\mathrm{BeH}_{2}$ or $\mathrm{BH}_{3}$ in one of two configurations, $\mathrm{LiH}-\mathrm{-M}$ or $\mathrm{MH}-\mathrm{Li}$; the first of these is favored in both cases. Thus LiH- $-\mathrm{BeH}_{2}$ (binding energy $=18.7 \mathrm{kcal}^{-1}{ }^{-1}$ ) is more stable than $\mathrm{HLi}-\mathrm{HBeH}\left(8.6 \mathrm{kcal} \mathrm{mol}^{-1}\right)$, and $\mathrm{LiH}-\mathrm{BH}_{3}$ is better than $\mathrm{HLi}--\mathrm{HBH}_{2}$ ( $23.0 \mathrm{vs} .3 .4 \mathrm{kcal}^{\mathrm{mol}}{ }^{-1}$ ). Apparently LiH is a better hydride donor than acceptor.
Similar patterns are seen in the di- and tribridged species. The highest binding energies are those involving lithium as "hydride donor", i.e., in the $\left[\mathrm{Li}-(\mathrm{H})_{n^{-}}-\right]_{\text {] configuration rather }}$
than $\left[\mathrm{HLi}-(\mathrm{H})_{n}-\mathrm{-}\right.$. Beryllium and boron, on the other hand, prefer configurations in which they have terminal hydrogens. In beryllium systems, $\mathrm{HBe}--(\mathrm{H})_{2}-\mathrm{Li}$ is preferred by 14 kcal $\mathrm{mol}^{-1}\left(6-31 \mathrm{G}^{*}\right)$ over $\mathrm{Be}--(\mathrm{H})_{3}-\mathrm{Li}$ and $\mathrm{Be}--(\mathrm{H})_{2}-\mathrm{LiH}$ is not bound at all. The situation among boron analogues is different: HB- -(H) $)_{3}-\mathrm{Li}$ is strongly bound and is 5 kcal better (6-31G*) than $\mathrm{H}_{2} \mathrm{~B}--(\mathrm{H})_{2}-\mathrm{Li}, \mathrm{HB}-(\mathrm{H})_{2}-\mathrm{LiH}$ is weakly bound, and there are no bound states involving boron without terminal hydrogens. In general it seems that boron gives more stable bridged dimers than beryllium, based on the binding energy orders $\mathrm{H}_{2} \mathrm{~B}--(\mathrm{H})_{2}-\mathrm{Li}>\mathrm{HBe}--(\mathrm{H})_{2}-\mathrm{Li}, \mathrm{H}_{2} \mathrm{~B}--$ (H) $2^{-}-\mathrm{BeH}>\mathrm{HBe}--\left(\mathrm{H}_{2}\right)-\mathrm{BeH}$, and $\mathrm{HB}--(\mathrm{H})_{3}-\mathrm{Li}>\mathrm{Be}-$ $-(\mathrm{H})_{3}-\mathrm{Li}$.

## Coordinate Bonds

Charge Distributions. In Table IX are given STO-3G values indicating the extent to which charge is reorganized upon complex formation, $\mathrm{H}_{n} \mathrm{M}+\mathrm{DH}_{m} \rightarrow \mathrm{H}_{n} \mathrm{M}-\mathrm{DH}_{m}$. If total atomic charges did not change in this process, " $\Delta q$ " values (Table IX) would be zero. Instead, complex formation results in a transfer of electron density from the donor molecule $\mathrm{NH}_{3}$, $\mathrm{OH}_{2}$, or FH to the acceptor LiH or $\mathrm{BeH}_{2}$. As the table shows, all atoms of the donor become more positive as all atoms of the acceptor become more negative, especially the metal atom. The total amount of charge transferred from donor to acceptor molecules is listed in Table IX; understandably, it decreases as the electronegativity of the donor increases, but changing the acceptor from $\mathrm{BeH}_{2}$ to LiH results in a decrease in charge transfer. Apparently the additional hydrogen on $\mathrm{BeH}_{2}$ allows distribution of greater negative charge.

Complexation Energies. The energies of complex formation are given in Table X. As noted elsewhere ${ }^{4}$ (for complexes of electron donors with $\mathrm{BH}_{3}$ ), the STO-3G basis gives poor complexation energies, as do extended basis sets without polarization functions. The effect of correlation has not been investigated, nor has any possible geometry change at higher levels of theory; it might well be that the intermolecular donor-acceptor distance is too short at STO-3G and that distances and binding energies would significantly increase with $6-31 \mathrm{G}^{*}$ geometry optimization.

Although we cannot fully assess the reliability of the 6-31G* binding energies, certain trends are clear from Table X. LiH is a better Lewis acid than $\mathrm{BeH}_{2}$ or $\mathrm{BH}_{3}$ ( $6-31 \mathrm{G}^{*}$ binding energies between $\mathrm{BH}_{3}$ and $\mathrm{NH}_{3}, \mathrm{OH}_{2}$, and FH are 21.3, 5.5, and $-7.7 \mathrm{kcal}^{-1 / 1}$, the last not bound at the STO-3G geometry ${ }^{4}$ ), while $\mathrm{NH}_{3}$ is a better base than $\mathrm{OH}_{2}$ or FH . It seems probable on the basis of the 6-31G* binding energies that the a mine- LiH or amine- $\mathrm{BeH}_{2}$ systems would be stable and observable in the gas phase, as amine boranes are. However, further theoretical study is required in order to establish firmly
the geometries and binding energies of such coordinately bound species.

## Conclusions

This study of lithium and beryllium compounds has led to a better understanding of bond types involving these electropositive atoms and has demonstrated some limitations of the theoretical model. The following general conclusions have been reached:
(1) Single metal-metal bonds are long and relatively weak. Bonds to lone-pair atoms are strong and short due to $\pi$ bonding, the magnitude of which is somewhat exaggerated at STO-3G leading to discrepancies between experimental and theoretical bond distances. In order to maximize $\pi$ bonding, $\mathrm{NH}_{2}$ adopts a planar conformation in $\mathrm{LiNH}_{2}$ and $\mathrm{HBeNH}_{2}$, while LiOH and HBeOH are linear.
(2) All systems containing formal $\mathrm{Be}=\mathrm{X}$ double bonds with the exception of $\mathrm{Be}_{2}$ are found to be bound both in singlet and triplet states.
(3) Doubly and triply bridged dimers of metal hydrides are generally more favorable than singly bridged forms. The fragments $\mathrm{Li}--$, $\mathrm{HBe}--$, and $\mathrm{H}_{2} \mathrm{~B}$ - - seem more apt to bridge than others with different numbers of terminal hydrogens.
(4) Coordinate bonds require $d$ functions for proper description and may also require geometries better than STO3G.

Acknowledgments. This research was supported by the National Science Foundation, Grants CHE75-09808 (Car-negie-Mellon University) and GP-29078X (Princeton University) and by the Fonds der Chemischen Industrie (Erlangen). Computer time was in part provided by Princeton and Carnegie-Mellon Universities. Mr. E. D. Jemmis is gratefully acknowledged for carrying out some of the computations in Munich, with the assistance of the Liebniz Rechenzentrum and the support of an award by the von Humboldt Foundation (to P.v.R.S.). Dr. Rolf Seeger assisted with the BeO and $\mathrm{LiFH}_{2}$ calculations, and additional input was provided by R. Whiteside, Y. Apeloig, J. B. Collins, and D. Poppinger. We thank a referee for constructive criticisms and useful suggestions.
