# Transits across a Cyclopentadienyl: Organic and Organometallic Haptotropic Shifts 

Nguyên Trong Anh, Mihai Elian, and Roald Hoffmann*<br>Department of Chemistry, Cornell University, Ithaca, New York 14853. Received March 14, 1977

#### Abstract

Organic and organometallic haptotropic shifts in cyclopentadienyl compounds CpX are analyzed by studying the motion of an $\mathrm{X}^{+}$across the face of a $\mathrm{C}_{5} \mathrm{H}_{5}^{-}$ring. The ligand in transit, $\mathrm{X}^{+}$, may be $\mathrm{H}^{+}, \mathrm{CH}_{3}{ }^{+}, \mathrm{XH}_{3}{ }^{+}(\mathrm{X}=\mathrm{Si}, \mathrm{Ge}, \mathrm{Sn})$, $\mathrm{Mn}(\mathrm{CO})_{3}{ }^{+}, \mathrm{Li}^{+}, \mathrm{CuR}^{+}$, and $\mathrm{CH}_{2}{ }^{2+}$ and $\mathrm{CH}_{2}$, the latter serving as models for $\mathrm{BR}_{2}{ }^{+}, \mathrm{AlR}_{2}{ }^{+}$and $\mathrm{NR}_{2}{ }^{+}, \mathrm{PR}_{2}{ }^{+}$as well. The $\mathrm{Cp}^{-}$ offers donor orbitals of a + e symmetry. The interactions of the ligand may be dominated by an acceptor orbital of symmetry type a $\left(\mathrm{H}^{+}, \mathrm{CH}_{3}{ }^{+}\right)$in which case $\eta^{2}$ and $\eta^{2}$ geometries are favored, or a set of acceptor orbitals of a + e symmetry $\left(\mathrm{Mn}(\mathrm{CO}) 3^{+}\right.$, $\left.\mathrm{Li}^{+}, \mathrm{CuR}^{+}\right)$, the e component of which greatly stabilizes the most symmetrical $\eta^{5}$ coordination. The lower the energy of the e acceptor set and the better the overlap with its Cp counterpart, the more are $\eta^{2}$ and $\eta^{5}$ stabilized relative to $\eta^{1}$. In the case of $\mathrm{XH}_{3}+(\mathrm{X}=\mathrm{C}, \mathrm{Si}, \mathrm{Ge}, \mathrm{Sn})$ an e acceptor orbital moves to lower energy as one proceeds down the group, and this is responsible for the decreasing barrier for sigmatropic shifts in $\mathrm{CpXH}_{3}$. The $\mathrm{XH}_{2}$ case, which yields a number of interesting collapse structures, is a nalyzed in detail for $\mathbf{X}$, a main group center.

Contrast the interaction of a cyclopentadienide anion and a proton with the interaction of the same anion and a $\mathrm{Mn}(\mathrm{CO})_{3}{ }^{+}$fragment. Both result in stable molecules: cyclopentadiene (1) and $\eta^{5}-\mathrm{CpMn}(\mathrm{CO})_{3}$ (2). But what a difference

1

2
in the equilibrium geometries of these end products of the interaction! If we focus our attention on the cyclopentadienide site where the interacting partner settles down, then the proton chooses a position near to one carbon of the ring, but the $\mathrm{Mn}(\mathrm{CO})_{3}{ }^{+}$fragment sits directly over the center of the ring. The ramifications of this differential are the concern of this paper. We will examine the interaction of a cyclopentadienide $\left(\mathrm{C}_{5} \mathrm{H}_{5}{ }^{-}, \mathrm{Cp}\right.$ ) ion with an interacting group $\mathrm{X}, \mathrm{X}=\mathrm{H}^{+}, \mathrm{CH}_{3}{ }^{+}$, $\mathrm{SiR}_{3}{ }^{+}, \mathrm{Mn}(\mathrm{CO})_{3}{ }^{+}, \mathrm{CH}_{2}{ }^{2+}, \mathrm{CH}_{2}$. The result will consist of some conclusions concerning the equilibrium geometry of CpX as well as the relative energetics of the various haptotropic reactions of this species. ${ }^{1,2}$

Consider the passage of the interacting group X across the face of a Cp molecule, moving as indicated in $\mathbf{3}$ in a plane

parallel to the Cp ring. Let the distance $d$ be a separation at which there is sizable interaction between the frontier orbitals of X and the $\mathrm{Cp} \pi$ system. For a surface so constrained the asymmetric unit that need be calculated consists of the shaded area in $\mathbf{4}$, and two of the three boundaries of that area are contained in a transit along a line shown in projection in 5. Mirror symmetry is maintained at all points. The numbers $n \eta$ shown along that line are convenient labels invoking a connection to the inorganic $\eta^{n}$ notation ${ }^{2}$ for denoting an approximate coordination geometry. In order to avoid confusion with structure numbers and ring carbon numbers, we have labeled the various sites along the transit line as $1 \eta, 2 \eta, \ldots, 5 \eta$. The site labeled $1 \eta$, or some geometry near it, corresponds to $\eta^{\prime}$ or simple $\sigma$ interaction, such as we have in the collapse product cyclopentadiene. The $\eta^{5}$ site $5 \eta$ is where one better come up with maximum stabilization for $\mathrm{X}=\mathrm{Mn}(\mathrm{CO})_{3}{ }^{+}$. The site labeled $2 \eta$ positions $X$ over the center of a bond, and obviously will describe the important transition state region for a sigmatropic shift of a system like cyclopentadiene. $3 \eta$ and $4 \eta$ are not so easily defined. Experimentally, slippage of Cp rings from $\eta^{5}$ coordination is often observed and $\eta^{3}$ or $\eta^{4}$ coordination may or may not be invoked. Somewhat arbitrarily we define $3 \eta$ at the intersection of the transit line with the line joining C-2 and $\mathrm{C}-5$ projected on the transit plane. The tetrahapto coordination site is most ambiguous (it could be near $3 \eta$ or near $5 \eta$ ), and so we will not label any position as such.

The analysis will consist of an inspection of interaction diagrams for the orbitals of Cp and X , as the ligand X and its position along the transit are varied. The qualitative arguments based on symmetry and overlap are supported by extended Hückel calculations whose details are given in the Appendix. The reader should be aware that this is an approximate method

Figure 1. Overlaps between a H 1 s orbital and the two lower cyclopentadienyl $\pi$ orbitals that it interacts with. For $\left(H\left|\chi_{2}\right\rangle\right.$ the absolute value of the overlap is plotted.
with well-documented deficiencies, and that the conclusions drawn therefrom should be considered as qualitative ones.

We begin with the well-known $\pi$ orbitals of $\mathrm{C}_{5} \mathrm{H}_{5}^{-}$shown in $6 .{ }^{3}$ For an X group passing above Cp the crucial features of

these orbitals are their nodal characteristics: no angular nodes in the lowest nondegenerate orbital $\chi_{1}$, one angular node in the next pair $\chi_{2}$ and $\chi_{3}$, the highest occupied molecular orbitals (HOMO) of the molecule, and two nodes in the higher lying, unoccupied set, $\chi_{4}$ and $\chi_{5}$. The degenerate orbitals are so chosen as to be symmetric ( $\chi_{2}, \chi_{4}$ ) or antisymmetric ( $\chi_{3}, \chi_{5}$ ) with respect to the mirror plane maintained in the transit.

CpH . When X is $\mathrm{H}^{+}$, the orbital it bears is obviously symmetric with respect to the mirror plane. The chemically significant two-electron bonding interactions will be between that empty 1 s orbital and the occupied orbitals of Cp . Of course, it is a formality that we partition the system as $\mathrm{C}_{5} \mathrm{H}_{5}{ }^{-}$and $\mathrm{X}^{+}$; the analysis could just as well have been carried through with a pair of radicals, or even $\mathrm{C}_{5} \mathrm{H}_{5}{ }^{+}$and $\mathrm{X}^{-}$. The position of the hydrogen in the mirror plane limits its interaction in general to $\chi_{1}$ and $\chi_{2}$ of $C p$, and in the special site $5 \eta$ just to $\chi_{1}$. The important interactions are summarized in 7.
Counting the number of interactions alone, one would decide against the $5 \eta$ site. A doubt might linger that the overlap of the H ls orbital with $\chi_{1}$ could be significantly larger in the $5 \eta$ position than elsewhere. We are working here within the usual framework of a one-electron perturbation theory, where the energy of interaction between two orbitals is expected to go as

$$
\Delta E=\left|H_{i j}\right|^{2} /\left(E_{i}-E_{j}\right)
$$

Figure 2. Computed total energies for $\mathrm{H}^{+}, \mathrm{CH}_{3}{ }^{+}, \mathrm{SiH}_{3}{ }^{+}$, and $\mathrm{Mn}(\mathrm{CO})_{3}{ }^{+}$ moving across the face of a cyclopentadienyl. For $\mathrm{SiH}_{3}{ }^{+}$two curves are shown, one without 3d orbitals, the other with 3d orbitals included with parameters described in the Appendix. All curves are referred to an arbitrary zero of energy at the $1 \eta$ site.

and $H_{i j}$ is in some way related to the overlap. ${ }^{4}$ Figure 1 plots the group overlaps between $\chi_{1}, \chi_{2}$ and a hydrogen 1 s orbital passing in a plane $1.11 \AA$ above the Cp ring plane. Not only is the $5 \eta$ site disfavored on both overlap and energy (see 7) grounds, but it is also clear that $1 \eta$ and $2 \eta$ or their environs are the favored points on the transit. This is confirmed in Figure 2 which shows the computed total energy of the CpH system. The lowest energy is at $1 \eta$, which were it allowed further degrees of freedom would certainly collapse to cyclopentadiene. The next higher energy point is $2 \eta$, indicating in another way the well-known fact that hydrogen migration in cyclopentadiene occurs by a symmetry-allowed [1,5] sigmatropic shift. ${ }^{5-7}$ The observed activation energy for the rearrangement is 24.3 $\mathrm{kcal} / \mathrm{mol} .{ }^{6 \mathrm{c}}$ The calculated difference in energy between $1 \eta$ and $2 \eta$ is $\sim 10 \mathrm{kcal} / \mathrm{mol}$, considerably smaller. However, we have not allowed the other geometrical parameters in the two structures to relax, and this geometrical relaxation (as well as a better computational method than ours) is necessary to obtain a reasonable theoretical estimate for the activation energy. ${ }^{7}$

Figure 3. The molecular orbitals of a methyl group.
$\mathrm{CpMn}(\mathrm{CO})_{3}$. The valence orbitals of a $\mathrm{d}^{6} \mathrm{Mn}(\mathrm{CO})_{3}{ }^{+}$fragment are well known. ${ }^{8-11}$ As shown in 8 , they consist of a trio

of filled orbitals, the remnant of the octahedral $t_{2 g}$ set. Above these are three acceptor orbitals, of $a_{1}+e$ symmetry, beautifully hybridized to provide maximum interaction with other ligands. When the $\mathrm{Mn}(\mathrm{CO})_{3}{ }^{+}$is positioned at $5 \eta$, the $\mathrm{a}_{1}+\mathrm{e}$ acceptor set is perfectly set up to mix with all three Cp orbitals. As the $\mathrm{Mn}(\mathrm{CO})_{3}{ }^{+}$moves away from $5 \eta$ toward either $1 \eta$ or $2 \eta$, the net overlap suffers, especially that of $e_{x}$ with $\chi_{2}$. This has the energetic consequences shown in Figure 2. The $\mathrm{Mn}(\mathrm{CO})_{3}{ }^{+}$ fragment prefers $5 \eta$, as it should. It is difficult to point to any definitive experimental information to test whether a distortion from $5 \eta$ toward $1 \eta$ is easier than toward $2 \eta$. Our calculations do not indicate a large energy differential between the two deformation modes.
$\mathrm{CpXH}_{3}$. We next consider the motion of an $\mathrm{XH}_{3}$ group, X $=\mathrm{C}$ or Si , across the face of a Cpring. The motivation here is the knowledge that migration of a methyl group is more difficult than that of a hydrogen atom ( $\Delta G^{\ddagger}$ in 1,1-dimethylcyclopentadiene $=41.8 \mathrm{kcal} / \mathrm{mol}^{12}$ ), but that the activation energy for other group 4 migrating centers ${ }^{13}$ is considerably lower $\left(\Delta G^{\ddagger}=15.2 \mathrm{kcal} / \mathrm{mol}\right.$ for $\mathrm{Si}\left(\mathrm{CH}_{3}\right)_{3},{ }^{13 \mathrm{a}} 13.3 \mathrm{kcal} / \mathrm{mol}$ for $\mathrm{Ge}\left(\mathrm{CH}_{3}\right)_{3},{ }^{13 \mathrm{~b}} 6.6 \mathrm{kcal} / \mathrm{mol}$ for $\left.\mathrm{Sn}\left(\mathrm{CH}_{3}\right)_{3}{ }^{13 \mathrm{~b}}\right)$.

The familiar orbitals of a methyl group ${ }^{14}$ are shown in Figure 3. Those of another $\mathrm{XH}_{3}$ group ( $\mathrm{X}=\mathrm{Si}, \mathrm{Ge}, \mathrm{Sn}, \mathrm{Pb}$ ) will differ from these in a number of well-understood ways. First there will be an effect of the decreasing electronegativity of X as one proceeds down the group. ${ }^{14}$ This will shift levels in energy; for instance, the crucial LUMO of an $\mathrm{XH}_{3}{ }^{+}$group, the $2 a_{1}$ orbital, will be at higher energy for Si than for C. A second effect of electronegativity will be to cause shifts in electron density within the orbitals. An important orbital in the subsequent discussion will turn out to be the hyperconjugating $\mathrm{X}-\mathrm{H} \sigma^{*}$ combination 2 e . As one progresses down the group this will become more localized on the X atom. A second
effect, not independent of the first one, is that of the weaker and longer X-H bonds. This will decrease the energy of the 2 e as one moves down the group. A third effect is that of hypothetical participation in bonding of d orbitals on $\mathrm{Si}, \mathrm{Ge}, \mathrm{Sn}, \mathrm{Pb}$. This is a problem of long standing. ${ }^{15}$ These orbitals (3d for Si , 4 d for Ge, etc.) are clearly there, but we have no way of knowing if they are sufficiently contracted and at sufficiently low energy to play a significant acceptor role. If they do get involved then among them is a pair of the same symmetry as the 2 e set, $x z$ and $y z$. The 2 e set will be further stabilized by interaction with d orbitals.

Figure 2 shows a very sharp curve for the motion of a $\mathrm{CH}_{3}{ }^{+}$ (pyramidal) across the face of a Cp ring. The methyl axis was kept perpendicular to the Cp plane throughout the transit. The general behavior of the curve parallels that for $\mathrm{H}^{+}$, but both the higher energy of the $5 \eta$ position and the $1 \eta-2 \eta$ difference are increased for the methyl case. A fragment molecular orbital analysis ${ }^{16}$ shows that the essential pattern is set by the methyl LUMO $2 a_{1}$, playing the same role as the hydrogen $1 s$ orbital discussed earlier. This was to be expected. That the energy changes more sharply along the transit for $\mathrm{CH}_{3}{ }^{+}$compared to $\mathrm{H}^{+}$may be traced to four-electron destabilizing interaction between $\mathrm{la}_{1}$ and le and various $\mathrm{Cp} \sigma$ and $\pi$ orbitals. These are greater in $5 \eta$ than $1 \eta$ or $2 \eta$, and of course do not have an analogue in the $\mathrm{H}^{+}$case.

An $\mathrm{SiH}_{3}{ }^{+}$group shows a much softer energy curve for transit across a Cp face. The calculation which led to the curve shown in Figure 2 did not include 3d orbitals on Si. The relative destabilization of $5 \eta$ is much less in the silyl case compared to methyl, and is even lower than for a migrating hydrogen. The $1 \eta-2 \eta$ difference, which should be related to the activation energy for the allowed 1,5 -sigmatropic shift, is lower for silyl than for methyl. This is in accord with the experimental data quoted above. However, the $\mathrm{SiH}_{3} 1 \eta-2 \eta$ difference is greater than for H , which is not in accord with experimental findings, at least for $\mathrm{Si}\left(\mathrm{CH}_{3}\right)_{3} .{ }^{13 \mathrm{a}} \mathrm{CNDO} / 2$ and MINDO/ 2 calculations by Shchembelov and Ustynyuk, ${ }^{7 \mathrm{a}}$ which allow for geometrical relaxation, order the $\mathrm{H}, \mathrm{CH}_{3}$, and $\mathrm{SiH}_{3}$ activation energies correctly.

In the $\mathrm{SiH}_{3}$ case the major factor shaping the curve is once again the $2 \mathrm{a}_{1}$ orbital, which favors $1 \eta$ and $2 \eta$ sites. The same repulsive terms which we mentioned in the methyl case are also present here. But there is a new factor at work in the silyl case, and it is responsible for the lowered energy of the $5 \eta$ geometry. The fragment molecular orbital analysis shows that the 2 e orbitals in the $\mathrm{SiH}_{3}{ }^{+}$fragment interact much more strongly than the corresponding levels in $\mathrm{CH}_{3}{ }^{+}$. They do so both because they are lower in energy and they overlap better; such are the consequences of the electronegativity and bond length effects mentioned above as one progresses down the group. The more the 2 e orbitals interact, the more is $5 \eta$ stabilized. Whatever stabilization occurs at $5 \eta$ is also "remembered", at least in part, at the $2 \eta$ site. There one member of the $2 e$ set has the correct pseudo-symmetry to interact with $\chi_{3}$.

We now return to the effect of d orbitals on Si . As we said above, it is difficult to estimate the extent to which 3d orbitals on Si are involved. We can, however, get an idea of the effect of these orbitals by including them in the calculations with parameters (exponent and $H_{i i}$ ) which allow them to mix strongly with other orbitals. When we do this, the most important effect is that the 2 e orbitals are stabilized as a result of p-d mixing which relieves their antibonding character and, most important for the rearrangement surface, hybridizes the p orbitals so that they point away from the silyl hydrogens and toward the Cp ring. This is shown below for one member of the 2 e set. The result is an increased stabilizing interaction between

2 e and the degenerate Cp orbital, maximized in the $5 \eta$ geometry. The energy of $5 \eta$ decreases relative to $2 \eta$. With d orbitals contracted and low in energy we can get the energies of the two alternative transition states to be comparable. The 3d parameters that it takes to do this are not realistic ones, in our opinion. ${ }^{17}$ However, the trend is clear.

The conclusion of the previous discussion comparing $\mathrm{CH}_{3}{ }^{+}$ and $\mathrm{SiH}_{3}{ }^{+}$is that an important role is played by the hyperconjugating 2 e orbitals of the $\mathrm{XH}_{3}{ }^{+}$group. This set of levels is expected to play a more important role as one moves down group 4, with all three factors enumerated (electronegativity decrease, bond length increase, increasing d participation) probably playing a role. It is not inconceivable to us that by the time one gets to Sn or Pb not much energy will separate $1 \eta, 2 \eta$, and $5 \eta$ sites. As indirect evidence for this supposition one might cite the lowered sigmatropic shift activation energies given above, ${ }^{13}$ the existence of $\eta^{5} \mathrm{Cp}_{2} \mathrm{Sn}$ and $\mathrm{Cp}_{2} \mathrm{~Pb}$ in the vapor phase, ${ }^{18}$ mixed $\eta^{5}$ and $\eta^{4}$ coordination for $\mathrm{Cp}_{2} \mathrm{~Pb}$ in the solid phase, ${ }^{19}$ and a slightly slipped $\eta^{5}$ geometry for CpSnX in the solid. ${ }^{20}$

One is tempted to summarize the $\mathrm{XH}_{3}{ }^{+}$trend as one moves down the group, 2 e interacting more and more, by saying that $\mathrm{XH}_{3}{ }^{+}$is beginning to resemble $\mathrm{Mn}(\mathrm{CO})_{3}{ }^{+}$, the $2 \mathrm{a}_{1}$ and 2 e orbitals of $\mathrm{XH}_{3}{ }^{+}$taking the place of the empty $e+a_{1}$ orbitals of the transition metal carbonyl fragment. This is not quite right, for in $\mathrm{XH}_{3}{ }^{+}$the 2 e always stays above $2 \mathrm{a}_{1}$, whereas in $\mathrm{Mn}(\mathrm{CO})_{3}{ }^{+}$the e orbital is always lower.

In some ways the $\mathrm{XH}_{3}{ }^{+}$trend is more an approach to $\mathrm{Li}^{+}$, $\mathrm{BeX}^{+}$, or $\mathrm{CuL}^{+}$than to $\mathrm{M}(\mathrm{CO})_{3}{ }^{+}$. We have not discussed the $\mathrm{Li}^{+}$case here, but the analysis is obvious. In addition to the $\mathrm{Li}^{+}$ 2 s orbital, playing a role analogous to an $\mathrm{H}^{+}$is or the $\mathrm{XH}_{3}{ }^{+}$ $2 a_{1}$, there is a set of relatively low-lying $2 p$ orbitals. One combination of these, $\mathrm{p}_{x}, \mathrm{p}_{y}$, is of e symmetry and has the limiting appearance of the 2 e set of $\mathrm{XH}_{3}{ }^{+}$. The geometry of CpLi is not definitely known, but calculations ${ }^{21 a-d}$ predict an $\eta^{5}$ structure. That is also the gas-phase structure of $\mathrm{CpTl}{ }^{21 e}$ and CpIn. ${ }^{21 f}$
$\mathrm{CpCuL}, \mathrm{L}=$ phosphine, molecules are well-characterized molecules with an $\eta^{5}$ geometry. ${ }^{22} \mathrm{We}$ have not carried out any calculations on this system, but the orbitals of a $\mathrm{CuL}^{+}$group are easily constructed, 9 . In addition to a filled $d$ band there

is a hybrid orbital pointing toward the Cp ring and two p orbitals above it. The availability of an a $+e$ acceptor set favors the $\eta^{5}$ coordination. The electronic structure of a $\mathrm{BeX}^{+}(\mathrm{X}=$ halide) fragment is similar, of course with the $d$ orbitals omitted. CpBeX possess an $\eta^{5}$ geometry. ${ }^{23 a}$ However, our picture of the electronic structure of these compounds cannot be complete, for subtle quantitative factors obviously influence whether an $\eta^{5}$ ground-state geometry is achieved. CpHgX (X $=$ halide) species, which should electronically resemble CpCuPR 3 , are not $\eta^{5}$ but $\eta^{1}$, and rearrange readily by sequential 1,2 shifts. ${ }^{23 \mathrm{~b}}$

In concluding this discussion of group $4 \mathrm{CpXH}_{3}$ systems, we note two matters. First these molecules exhibit interesting distortion in their ground-state geometries; namely, that with

Figure 4. The molecular orbitals of a methylene group.
$\mathrm{X} \neq \mathrm{C}$ the carbon ring is sometimes nonplanar. ${ }^{24}$ There must be a low barrier to out-of-plane deformations of the Cp ring. This was not considered in our studies, which assumed a planar carbon ring. A second point is that in addition to other theoretical considerations on sigmatropic shifts in cyclopentadiene and related organometallic systems ${ }^{25}$ there is in the literature a very interesting correlation of photoelectron spectroscopy, theory, and the kinetic parameters of sigmatropic rearrangements. Cradock, Ebsworth, and co-workers ${ }^{26}$ correlate the fluxionality of the molecules with the extent of mixing of the lowest diene $\pi$ with the $\mathrm{Si}-\mathrm{C}$ bonding orbital. The same mixing influences the splitting between the $\pi$ levels. The approach is in a sense complementary to ours, for whereas we focus on the transition state, these workers seek correlations between ground-state properties and ease of sigmatropic rearrangement.

CpXL2. Let us begin with a model $\mathrm{CH}_{2}{ }^{2+}$ or $\mathrm{CH}_{2}$ group passing across the cyclopentadienyl face. The organic ligand and its charge may seem unusual until one examines the possible "collapse products" of such a transit. These might be 10-12.10 as a cation is the well-characterized bicyclo[3.1.0]-

hexenyl system, 11 the less well-known but still realistic bicyclo[2.1.1] cation or anion, and 12 a possible transition state geometry for a degenerate sigmatropic rearrangement of $\mathbf{1 0}$, or a cation or anion in its own right. Isoelectronic with $\mathrm{CpCH}_{2}^{-}$ would be $\mathrm{CpNH}_{2}$ which in turn is related to $\mathrm{CpPF}_{2}$, whose fluxionality is established. ${ }^{27}$ Isoelectronic with $\mathrm{CpCH}_{2}{ }^{+}$would be $\mathrm{CpBH}_{2}$, to which a number of other group 3 cyclopentadienyls $\left(\mathrm{CpXR}_{2}, \mathrm{X}=\mathrm{Al}, \mathrm{Ga}, \mathrm{In}\right)$ are related. ${ }^{28.29}$

The orbitals of a methylene group are well known ${ }^{14}$ and are shown schematically in Figure 4. The critical orbitals in our discussion will be the directed hybrid $2 a_{1}$ and the 2 p orbital orthogonal to the $\mathrm{CH}_{2}$ plane, $l \mathrm{~b}_{1}$. In the context of a general discussion of methylenes these have been called $\sigma$ and p , respectively. ${ }^{30} \sigma$ and p are both empty if the fragment is $\mathrm{CH}_{2}{ }^{2+}$, and $\sigma$ is filled while $p$ remains empty for a $\mathrm{CH}_{2}$ fragment.

It is further important to distinguish two orientations of the methylene plane relative to the Cp vertical mirror plane. We shall refer to "in-plane" geometries, when the $\mathrm{CH}_{2}$ lies in the vertical symmetry plane of the cyclopentadienyl (13) and

Figure 5. Computed total energies for $\mathrm{CH}_{2}{ }^{2+}$ and $\mathrm{CH}_{2}$ transits across the face of a $\mathrm{Cp}^{-}$. Solid line $=$in-plane orientation; dashed line $=$perpendicular orientation. The arbitrary energy zero is chosen at the most stable $2 \eta$, in-plane, geometry of both $\mathrm{C}_{2}{ }^{2+}$ and $\mathrm{CH}_{2}$.
"perpendicular", when these planes are mutually orthogonal (14).

13

14

The results of extended Hückel calculations on the four transits, $\mathrm{CH}_{2}$ and $\mathrm{CH}_{2}{ }^{2+}$, in-plane and perpendicular, are shown in Figure 5. Let us analyze the shape of these curves, beginning with the $\mathrm{CpCH}_{2}{ }^{+}$case. The $\mathrm{CH}_{2}{ }^{2+}$ fragment has two important acceptor orbitals, $\sigma$ and p. Interaction with $\sigma$ is no different from the $\mathrm{H}^{+}$or $\mathrm{XH}_{3}{ }^{+}$cases, and leads to an energy factor greatly favoring $1 \eta$ and $2 \eta$. This sets the main feature of the energy curve along the transit coordinate. However, superimposed on this one has the effect of the acceptor function $p$, which depending on its orientation can mix with one or the other member of the degenerate $C p e_{1}$ set. These interactions, shown in 15 and 16, are maximal (and

15

16
equal to each other) at $5 \eta$. They are not equal when the $\mathrm{CH}_{2}$ moves away from $5 \eta$. Detailed calculations show that the symmetric function, derived from 16 and corresponding to a "perpendicular" methylene, always has a smaller overlap than the antisymmetric function. This is responsible for the steady destabilization of the perpendicular transit, relative to the inplane one, that may be seen in Figure 5. The difference in overlap may be appreciated from a drawing of the interactions at $2 \eta$, shown in 17 and 18 . In 17 there is clearly retained a substantial overlap, while in 18 the "local" overlap with p or-

17

18

19
bitals at $\mathrm{C}_{3}$ and $\mathrm{C}_{4}$ is zero, and only the smaller long-distance overlap with $C_{1}, C_{2}$, and $C_{5}$ remains.

An intriguing feature of the calculations is that for the more stable in-plane $\mathrm{CH}_{2}$ orientation the $2 \eta$ site is at lower energy than $1 \eta$. This is a direct consequence of the better overlap in 17 than 19 , and is consistent with the stability of the collapse product, the bicyclo[3.1.0] hexyl cation. It is also consistent with the observed geometry of $\mathrm{CpAl}\left(\mathrm{CH}_{3}\right)_{2},{ }^{29}$ a molecule related to the hypothetical $\mathrm{CpBH}_{2}$ which is isoelectronic to $\mathrm{CpCH}_{2}{ }^{+}$. CNDO/ 2 and ab initio SCF-MO calculations by Haaland and co-workers ${ }^{29,31}$ on $\mathrm{CpAlR}_{2}$ also prefer such a geometry and, as we would also infer, find substantial barriers to twisting the $\mathrm{AlR}_{2}$ group by $90^{\circ}$.

The $1 \eta$ site models a transition state for the degenerate sigmatropic rearrangement of the bicyclo[3.1.0]hexenyl cation. This [ 1,4 ] sigmatropic shift should proceed with inversion at the migrating carbon, ${ }^{5}$ a prediction that has been experimentally confirmed. ${ }^{32}$ The required geometry is the one we have called in-plane. Ab initio calculations by Hehre ${ }^{33}$ put this conformation of a cyclopentadienyl carbinyl $9-12 \mathrm{kcal} / \mathrm{mol}$ below an alternative in which the $\mathrm{CH}_{2}$ group is twisted by $90^{\circ}$, which would be modelled by our perpendicular geometry.

An interesting problem is the absence in the calculation of any low-energy region around $3 \eta$, which might be an indication of a collapse to 11, a molecule for which a perfectly reasonable valence structure may be drawn. Indeed one can draw a correlation diagram interrelating the $3 \eta$ site orbitals with the orbitals of 11. There is no level crossing along the way. It appears that the reason why the existence of a collapse channel leading to $\mathbf{1 1}$ is not indicated by the energy curve is that such a collapse requires great geometrical deformations. There are signs of incipient bonding in the overlap populations, but not in the energy.

We next turn to the $\mathrm{CpCH}_{2}{ }^{-}$systems, formally constructed from the interaction of $\mathrm{Cp}^{-}$with a neutral $\mathrm{CH}_{2}$. While a singlet methylene would have the $\sigma$ orbital doubly occupied, we cannot assume that this is so in $\mathrm{CpCH}_{2}{ }^{-}$. As was mentioned above, both $\sigma$ and p interact with the Cp orbitals, and the interaction of $\sigma$ is much the stronger. Thus while $\sigma$ may be below p in an isolated methylene, in $\mathrm{CpCH}_{2}{ }^{-}$the antibonding combinations represented schematically by $\sigma-\lambda \chi(\mathrm{Cp})$ and $\mathrm{p}-\lambda^{\prime} \chi(\mathrm{Cp})$ order themselves in such a way that the latter, shown in $\mathbf{2 0}$ or 21, is at lower energy. This is the orbital occu-

20

21
pied by the two additional electrons as one goes from $\mathrm{CpCH}_{2}{ }^{+}$ to $\mathrm{CpCH}_{2}{ }^{-}$. Recall that the maximum overlap of $p$ with the appropriate symmetry Cp orbital, whether one is in the inplane or the perpendicular geometry, is at the $5 \eta$ site. This is then the site of maximum antibonding in $\mathrm{CpCH}_{2}{ }^{-}$, with the result that relative to $\mathrm{CpCH}_{2}{ }^{+}$all curves become sharper. Figure 5 clearly shows this.

In the in-plane conformation the overlap in question is consistently greater than in the perpendicular geometry. This was discussed above (see 17 and 18). In $\mathrm{CpCH}_{2}^{-}$, where the antibonding combination $\mathbf{2 0}$ or $\mathbf{2 1}$ is filled, that geometry which offers least overlap will be least destabilized. Therefore we would expect the in-plane and perpendicular alternatives for

Table I. Extended Hückel Parameters

| Orbital |  | $H_{i j}, \mathrm{eV}$ | Exponent ${ }^{a}$ |
| :--- | :--- | :--- | :--- |
| H | 1 s | -13.60 | 1.300 |
| C | 2 s | -21.40 | 1.625 |
|  | 2 p | -11.40 | 1.625 |
| Si | 3 s | -17.30 | 1.383 |
|  | 3 p | -9.20 | 1.383 |
|  | 3 d | -6.00 | 1.383 |
| Mn | 4 s | -9.75 | 0.970 |
|  | 4 p | -5.89 | 0.970 |
|  | 3 d | -11.67 | $5.150(0.51391)$ |
|  |  |  | $1.700(0.69291)$ |
| $\mathrm{C}^{b}$ | 2 s | -24.26 | 1.625 |
|  | 2 p | -9.32 | 1.625 |
| $\mathrm{C}^{c}$ | 2 s | -25.48 | 1.625 |
|  | 2 p | -10.48 | 1.625 |
| $\mathrm{O}^{d}$ | 2 s | -30.31 | 2.275 |
|  | 2 p | -11.31 | 2.275 |
| $\mathrm{H}^{d}$ | 1 s | -12.08 | 1.300 |

${ }^{a}$ Two exponents are listed for Mn , with corresponding coefficients of the double- $\zeta$ expansion in parentheses. ${ }^{b}$ For cyclopentadienyl carbons in $\mathrm{CpMn}(\mathrm{CO})_{3 \cdot}{ }^{\text {c }}$ For carbonyl carbons in $\mathrm{CpMn}(\mathrm{CO})_{3}$. ${ }^{d}$ In $\mathrm{CpMn}(\mathrm{CO})_{3}$.
$\mathrm{CpCH}_{2}-$ to lie closer to each other in energy than they do in $\mathrm{CpCH}_{2}{ }^{+}$, and this is also seen in Figure 5.

So far we have considered only the repulsive four-electron interactions between $p$ and $\chi_{2}$ or $\chi_{3}$ of Cp . But in addition one can have attractive interactions with unfilled Cp orbitals $\chi_{4}$ and $\chi_{5}$. These do not mix much in our analysis, in part because they are at high energy, in part because their pseudo-symmetry (two angular nodes) does not match the pseudo symmetry of the p orbital (one angular node). We do find some of this effect in the perpendicular $1 \eta$ site. Note incidentally that at $1 \eta$ the perpendicular conformation for $\mathrm{CpCH}_{2}{ }^{-}$is still at higher energy than the in-plane one. This is not in accord with the orbital symmetry prediction for a transition state for a [ 1,4 ] sigmatropic shift with retention, but may be the result of an incomplete geometry optimization.

The general ordering in energy of $1 \eta$ and $2 \eta$, in-plane and perpendicular, conformations in $\mathrm{CpCH}_{2}{ }^{-}$may not be reliably given by these calculations. Lowest in energy is the in-plane $2 \eta$ geometry. For species related to $\mathrm{CpCH}_{2}{ }^{-}$, such as $\mathrm{CpNR}_{2}$ or $\mathrm{CpPF}_{2}$, this would correspond to a zwitterionic structure 22. There is nothing wrong with this one, but perhaps the alternative 23, which is not charge-separated, looks better. In the

22

23
case of $\mathrm{CpPF}_{2}$ the equilibrium geometry is $\eta^{1}$. This molecule is no doubt strongly pyramidal at the phosphorus, so that our trigonal $\mathrm{CH}_{2}$ group will not be a good model for the energetics of sigmatropic shifts in this case.

Other Organometallic Groups. A great deal has been learned about haptotropic rearrangements in organometallic compounds containing Cp rings and transition metal centers, from the elegant work of Cotton as well as others. ${ }^{1,34}$ The molecules best understood experimentally, $\mathrm{Cp}_{2} \mathrm{Fe}(\mathrm{CO})_{2}, \mathrm{Cp}_{4} \mathrm{Ti}$, and $\mathrm{Cp}_{3} \mathrm{MoNO}$, present a fairly complicated picture theoretically because of the low symmetry of the fragment coordinated to the Cp ring. We do not wish to examine these molecules in this initial paper but will return to them in the future. For the moment we are satisfied with having achieved a basic understanding of the factors governing the potential energy surface for haptotropic shifts across a cyclopentadienyl of both organic and organometallic groups.

Acknowledgment. We are grateful to the Committee on International Exchange of Persons (Senior Fulbright-Hays Program) which made possible the stay of M.E. (from the Institute of Organic Chemistry, Bucharest, Romania) at Cornell University. The permanent affiliation of N.T.A. is with the Laboratoire de Chimie Théorique, Université de Paris-Sud, Orsay, France. We appreciate the assistance of R. Weber and P. K. Mehrotra with the calculations, T. Albright for advice, J. Jorgensen for the drawings, and R. Albright for the production of the manuscript. The suggestion of using the term "haptotropic" is due to Peter Hofmann. Our work was generously supported by the National Science Foundation.

## Appendix

All calculations were of the extended Hückel type, ${ }^{35}$ with a "weighted $H_{i j}$ " formula ${ }^{36}$ used for approximating the offdiagonal matrix elements. The parameters which we used are given in Table I. $\mathrm{CpMn}(\mathrm{CO})_{3}$ was a special case in that we cycled to self-consistency on the charges of all the atoms, including $\mathrm{C}, \mathrm{O}$, and H . The Coulomb integrals for those atoms thus differ from the $\mathrm{C}, \mathrm{O}, \mathrm{H}$ parameters used for the other CpX calculations. However, a repetition of the $\mathrm{CpMn}(\mathrm{CO})_{3}$ calculation with the other parameters shows no substantial differences. The Mn 3d function was taken as a linear combination of two Slater functions. ${ }^{37}$

In all computations the Cp ring had $\mathrm{CC} 1.418 \AA, \mathrm{CH} 1.111$ $\AA . \mathrm{CH}_{3}$ and $\mathrm{SiH}_{3}$ groups were tetrahedral: $\mathrm{CH} 1.10 \AA, \mathrm{SiH}$ $1.521 \AA$. The methyl group moved $1.54 \AA$, the silyl group 1.87 $\AA$ above the Cp plane. The methylene group had CH $1.111 \AA$, angle $\mathrm{HCH} 116^{\circ}$, and moved $1.54 \AA$ above the Cp plane. The $\mathrm{Mn}(\mathrm{CO})_{3}$ group was taken as an octahedral fragment, MnC $1.80 \AA$, CO $1.15 \AA$, which made the transit at $1.80 \AA$ above the Cpring.

(2) The "hapto"' notation was introduced by F. A. Cotton, J. Am. Chem. Soc., 90,6230 (1968). We use here the new descriptor "haptotropic", an obvious extension of "sigmatropic", The latter refers specifically to $\sigma$ bond shifts, while the former carries the more general connotation of changing coordination type.
