# Theoretical Studies on the Singlet and Triplet Cyclopropylidene-Allene System 

Daniel J. Pasto,* Michael Haley, and Daniel M. Chipman*1<br>Contribution from the Department of Chemistry and the Radiation Laboratory, University of Notre Dame, Notre Dame, Indiana 46556. Received January 23, 1978

#### Abstract

Ab initio SCF calculations employing the STO-3G and 4-31G basis sets have been carried out with full geometry optimization on the singlet and triplet cyclopropylidene-allene systems. Triplet cyclopropylidene (1T) is calculated to be of lower energy than singlet cyclopropylidene (1S) by $8.4 \mathrm{kcal} / \mathrm{mol}$. Triplet allene is calculated to be a bent, planar species, being 8.0 $\mathrm{kcal} / \mathrm{mol}$ lower in energy than the linear, planar form. Both $\mathbf{1 S}$ and 1T undergo disrotatory ring opening, although the intimate details of the two processes differ greatly. In both cases substantial shortening of the $\mathrm{C}-\mathrm{C}$ bond lengths are observed as the ring opens. Barrier heights for the ring opening of 1 S and 1 T are calculated to be 18 and $19 \mathrm{kcal} / \mathrm{mol}$, respectively ( $4-31 \mathrm{G}$ level). The results of these calculations are significantly different from those reported previously, and the differences are discussed. The structures and ring-opening processes of 15 and 1 T are compared with those reported for the cyclopropyl cation and radical.

## Introduction

Our interest in the synthesis, structure, and chemical reactivity of allenes ${ }^{2}$ has led us to carry out a detailed theoretical study on the structures of singlet and triplet cyclopropylidene ( 1 S and 1 T , respectively) and allene ( 2 S and 2 T ) and their mode of interconversion as might be related to their photochemistry. ${ }^{3}$

1S

$1 T$

2TL

2 S

2TB

Prior to the initiation of this study, two somewhat conflicting reports on $\mathbf{1 S}$ and its conversion to $\mathbf{2 S}$ had appeared. Using orbital symmetry diagrams Borden ${ }^{4}$ originally suggested that 1S opened by a monorotatory process (see Figure 1), and that 1 T should not open. In a MINDO/2 study of the reaction of ${ }^{1}$ S carbon atoms with ethylene in which $1 \mathbf{S}$ is initially formed, the calculations of Dewar and co-workers ${ }^{5}$ indicated that in the process of opening of $\mathbf{1 S}$ to $\mathbf{2 S}$ methylene "rotation takes place only in the final stages of the reaction, the original unrotated geometry being retained in the transition state". The barrier height for the conversion of $1 \mathbf{S}$ to 2 S was calculated to be $50 \mathrm{kcal} / \mathrm{mol}$, although the authors acknowledged that this value was undoubtedly high because of the inability of MINDO/2 to accurately calculate the strain energies of small-ring compounds. In a later study using a newer version of MINDO/ 2 the barrier height for the conversion of 1 S to 2 S was calculated to be $13.7 \mathrm{kcal} / \mathrm{mol} .{ }^{6}$

During the course of the present study, the results of a Simplex-INDO study on the singlet and triplet energy surfaces of the cyclopropylidene-allene system appeared, ${ }^{7}$ certain of the results of which were inconsistent with those obtained in our calculations using STO-3G and 4-31G ab initio molecular orbital techniques. ${ }^{8}$ Because of substantial differences between the Dillon and Underwood results ${ }^{7}$ and ours, which will be discussed in later sections of this paper, the calculations were carried to completion. Very late in our study, ab initio calcu-
lations, including correlation energy corrections, on the geometry and rotational processes in singlet and triplet excited states of allene appeared ${ }^{9}$ which supported our results of STO-3G and 4-31G geometry optimization calculations. The following sections describe our results obtained by using the $a b$ initio program Gaussian $70^{8}$ along with a comparison with the results of previous calculations.

## Results and Discussion

Singlet Cyclopropylidene. The STO-3G fully geometry optimized $C_{2 v}$ structure of singlet cyclopropylidene ( $\mathbf{1 S}$ ) is shown in Figure 2,10 along with the STO-3G and $4-31 \mathrm{G}$ total energies. 1S lies in a fairly deep energy well $(\sim 18 \mathrm{kcal} / \mathrm{mol}$ at the $4-31 \mathrm{G}$ level relative to the transition state for ring opening; see Figure 5), and is higher in energy than triplet cyclopropylidene (1T) at its equilibrium geometry by $8.4 \mathrm{kcal} / \mathrm{mol}$ and is higher than 2 S by $74.2 \mathrm{kcal} / \mathrm{mol}$. These results are in distinct contrast to those reported by Dillon and Underwood, ${ }^{7}$ who claim that "there is no energy minimum at the point which corresponds to cyclopropylidene", and, furthermore, that $\mathbf{1 S}$ is of lower energy than 1T. It is not obvious whether Dillon and Underwood's lack of finding an energy minimum corresponding to 1 S is due to the type of calculations used (INDO) or to differences between the present STO-3G optimized geometry of 1S (Figure 2) and that assumed by Dillon and Underwood ${ }^{7}$ (C-C bond lengths of $1.31 \AA, \mathrm{C}_{1}-\mathrm{C}_{2}-\mathrm{C}_{3}$ bond angle of $60^{\circ}$, and with completely planar methylene groups). ${ }^{11}$ The report that 1 S is of lower energy than 1 T (by $22 \mathrm{kcal} / \mathrm{mol}$ ) is, however, not due to differences in geometry; it is the result of the type of calculations (INDO) employed. Our INDO calculations on the reported geometries of 1 S and 1 T , and on the STO-3G optimized geometries determined in this study, indicate that the INDO method does incorrectly predict that the singlet is of lower energy than the triplet. This inversion of relative energies is not unexpected in CNDO- and INDO-type calculations.

In 1 S the nonbonded pair of electrons is highly localized on $\mathrm{C}_{2}$ in an in-plane sp hybrid orbital in the highest occupied molecular orbital (HOMO) (see Figure 3). ${ }^{12}$ The lowest unoccupied molecular orbital (LUMO) consists almost entirely of the out-of-plane 2 pAO on $\mathrm{C}_{2}$.

Singlet Cyclopropylidene to Allene Interconversion. The mode of conversion of $\mathbf{1 S}$ to ground state, singlet allene (2S) has been investigated using complete geometry optimization STO-3G calculations at $10^{\circ}$ intervals of the $\mathrm{C}_{1}-\mathrm{C}_{2}-\mathrm{C}_{3}$ bond angle from 70 to $110^{\circ}$ and selected higher angles. At 70, 80, and $90^{\circ}$ the optimized geometries ${ }^{13}$ (see Table I) represent a

Figure 2. STO-3G geometry optimized structure of singlet cyclopropylidene and STO-3G and $4-31 \mathrm{G}$ energies.
disrotatory (D) ring-opening process, the disrotation of the methylene groups occurring synchronously with opening of the $C_{1}-C_{2}-C_{3}$ bond angle. During this $D$ process, the two methylenes develop considerable nonplanarity (see Figure 4). The rate of inward rotation of $\mathrm{H}_{1}$ and $\mathrm{H}_{3}$ lags considerably behind the outward rotation of $\mathrm{H}_{2}$ and $\mathrm{H}_{4}$. Inspection of the Mulliken overlap populations reveals that this effect is not due to an antibonding repulsion between $\mathrm{H}_{1}$ and $\mathrm{H}_{3}$, but arises from antibonding repulsions between the 1 S AO on the hydrogens and the AOs on the opposing carbon atoms.

At $100^{\circ}$ the lowest energy structure has a distorted perpendicular geometry (see Figure 4) derived by an apparent monorotatory ( $\mathbf{M}$ ) process from $1 \mathbf{S}^{14}$ (or conversely via a nonrotatory ( $\mathbf{N}$ ) process from $\mathbf{2 S}$ to $\mathbf{1 S}$ ). As in the $90^{\circ} \mathbf{D}$ structure, the distortion of the perpendicular methylene in the $100^{\circ}$ structure arises from repulsive antibonding interactions between the 1S AOs on $\mathrm{H}_{3}$ and $\mathrm{H}_{4}$ and the AOs on $\mathrm{C}_{1}$ and not from between $\mathrm{H}_{3}$ and $\mathrm{H}_{4}$ with $\mathrm{H}_{1}$. As the $\mathrm{C}_{1}-\mathrm{C}_{2}-\mathrm{C}_{3}$ bond angle increases the distortion of the methylene decreases, ultimately becoming planar (see Table I).

MO's of 2S

Figure 3. MOs of $\mathbf{1 S}$ and $\mathbf{2 S}$.

Figure 4. Geometries of the singlet species near the transition state for ring opening of $1 \mathbf{S}$. For structural parameters, see Table I.

Figure 5. Minimum energy surface for the conversion of $1 S$ to 2 . Points labeled $\overline{\mathbf{D}}, \overline{\mathbf{M}}, \overrightarrow{\mathrm{C}}$, and $\overline{\mathbf{N}}$ are the energies of the structures formed by D, M, $\mathbf{C}$, and $\mathbf{N}$ ring-opening processes from $1 \mathbf{S}$, the $\mathbf{N}$ point being off scale. The points labeled $\mathbf{N}$ are the energies of the nonrotatory ring closing process from $\mathbf{2 S}$.

The lowest energy D structure at $100^{\circ}$, optimized by maintaining a vertical plane of symmetry, is of considerably higher energy than the $\mathbf{M}$ (from 1S) structure at $100^{\circ}$ (see Figure 5). Unconstrained optimization of the $\mathrm{H}-\mathrm{C}-\mathrm{C}-\mathrm{C}$ dihedral angles in the $\mathbf{D}$ structure resulted in a smooth conversion to the $100^{\circ} \mathbf{M}$ (from $\mathbf{1 S}$ ) structure indicating that the $100^{\circ} \mathbf{D}$ structure does not lie in an energy minimum. Similarly, a $90^{\circ}$ $\mathbf{M}$ (from 1S) structure is of much higher energy than the $90^{\circ}$ D structure, and similarly does not lie in an energy minimum. It must be concluded, therefore, that the $\mathbf{D}$ (from 1S) and $\mathbf{N}$ (from 2S) energy valleys are not separated by an energy maximum but must intersect between $\mathrm{C}_{1}-\mathrm{C}_{2}-\mathrm{C}_{3}$ bond angles of 90 and $100^{\circ}$.

${ }^{a}$ Arrows between columns indicate crossovers of the MOs.

Figure 6. 4-31G geometry optimized structure of triplet cyclopropylidene 1T.

Calculations were then carried out at an intermediate angle of $94.5^{\circ}$ giving the fully geometry optimized structure shown in Figure 4 in which the $C_{1}$ methylene has rotated to a nearly coplanar orientation while the $\mathrm{C}_{3}$ methylene has reversed its direction of rotation and is nearly perpendicular to the $\mathrm{C}_{1}-$ $\mathrm{C}_{2}-\mathrm{C}_{3}$ plane. The energy of this structure is slightly lower than that at $90^{\circ}(0.3 \mathrm{kcal} / \mathrm{mol})$ and we conclude that the transition state must lie between the 90 and $94.5^{\circ}$ structures. It should be noted that the energy surface in the direction of the reaction coordinate near the transition state is rather flat, the rotational processes of the methylenes being associated with rather low dihedral angle rotational (bending) force constants (0.3-1.1 $\times 10^{-4} \mathrm{M}$ dyn $/ \AA$ ).

The conversion of $\mathbf{1 S}$ to $\mathbf{2 S}$ therefore involves three distinct processes: (a) initial disrotatory opening proceeding almost to the transition state; (b) a rapid transformation from the disrotatory structure to distorted monorotatory (from 1S) structure between $C_{1}-C_{2}-C_{3}$ bond angles of 90 and $100^{\circ}$; and (c) nonrotatory conversion of the $100^{\circ}$ structure to allene by opening of the $C_{1}-C_{2}-C_{3}$ bond angle with flattening of the out of plane methylene group. The final $4-31 \mathrm{G}$ energy calculations indicate a barrier height of $\sim 18 \mathrm{kcal} / \mathrm{mol}$ and an overall exoergicity of $\sim 74 \mathrm{kcal} / \mathrm{mol}$ for the ring-opening process.

The transformation of the MOs of singlet cyclopropylidene to allene have been determined by correlating the character of the MO wave functions. (The energies of the MOs are listed in Table II.) Several features are noteworthy. The most dramatic changes in energy occur in those MOs of 1 S which are undergoing conversion to the $\pi$ and $\pi^{*}$ MOs of allene, those changes occurring just before and at the transition state. Several orbital crossings also occur (indicated in Table II by the arrows between columns). The ninth $\mathrm{a}_{1} \mathrm{MO}$ of $\mathbf{1 S}$ crosses the tenth MO and shortly after the transition state becomes nearly degenerate with the 11 th $\mathrm{a}_{1} \mathrm{MO}$ in forming the degenerate $\pi$ MOs of allene. The tenth $\mathrm{b}_{1} \mathrm{MO}$ of 1 S crosses both the ninth and eighth MOs becoming the seventh MO in allene consistent with its becoming the $2 \mathrm{p}_{z} \sigma$-type MO.

Overall, the ring opening of $\mathbf{1 S}$ to $\mathbf{2 S}$ is a net $90^{\circ}$ monorotatory or $45^{\circ}$ conrotatory process, the former being identical with that suggested earlier by Borden on the basis of simple orbital symmetry correlation considerations; ${ }^{4}$ however, the more intimate details of the process are not revealed by such considerations. The nonrotatory ( $\mathbf{N}$ ) process, until after the transition state, followed by monorotation to orthogonal allene predicted by the MINDO/ 2 calculations ${ }^{6}$ is not consistent with the results of the present calculations. Similarly, the initial disrotatory opening followed by reversal to a nonrotated transition state followed by a conrotatory conversion to (planar) allene as predicted by INDO calculations ${ }^{7}$ is not in agreement with the present results.

The rotatory process described herein is fully consistent with the stereochemical aspects of the ring opening of optically active cyclopropylidenes ${ }^{15}$ in which the direction of rotation of the methylene groups is determined by steric interactions

in the initial disrotatory opening of $\mathbf{1 S}$ as illustrated in the following equations.

Triplet Cyclopropylidene (1T). The 4-31G fully optimized structure of 1 T is shown in Figure 6 (see also Table III). ${ }^{16} \mathrm{As}$ pointed out earlier, 1 T lies at lower energy than 1 S by 8.4 $\mathrm{kcal} / \mathrm{mol}$ at the $4-31 \mathrm{G}$ level. The calculated unrestricted Hartree-Fock wave function of 1 T is essentially pure triplet as indicated by the $\left\langle S^{2}\right\rangle$ value of 2.010 (as compared to 2.000 for a pure triplet).

The highest singly occupied molecular orbital (HSOMO) consists almost entirely (Mulliken population of 0.947) of a contribution from the $2 \mathrm{p}_{\mathrm{y}} \mathrm{AO}$ on $\mathrm{C}_{2}$ (see Figure 7). The other unpaired electron occupies an in-plane MO with populations of 1.047 and -0.035 on $C_{2}$ and $C_{1}\left(C_{3}\right)$, respectively.

Triplet Allene (2T). Initial STO-3G geometry optimization calculations on triplet allene suggested that 2T was a bent planar species. However, the calculations indicated that there were significant contributions of higher spin states to the nominal triplet wave function $\left(\left\langle S^{2}\right\rangle=2.189\right)$. This initially caused concern in view of the fact that the most stable form of triplet allene had been reported by Dillon and Underwood ${ }^{7}$ to be a linear planar species. The contribution of other spin states of similar energy, but significantly different geometry, in our calculations could have conceivably resulted in optimization to a structure not representative of triplet allene. Geometryoptimized $4-31 \mathrm{G}$ calculations, however, resulted in essentially the same structure but indicated a significantly lower contribution of other spin states to the wave function $\left(\left\langle S^{2}\right\rangle=2.130\right)$.

${ }^{a}$ Parenthesized percentages are percent ring opening from 1T to 2TB.

Figure 8. Minimum energy surface for conversion of 1 T to 2TB and on to 2TL (right energy scale in hartrees) and HSOMOs energies (left scale in hartrees).

During the final stages of these calculations the results of an unrestricted Hartree-Fock 6-31G calculation including correlation energy corrections appeared also indicating that the lowest energy form of 2 T had a bent planar structure. ${ }^{9}$ Our value of $138.1^{\circ}$ for the $\mathrm{C}_{1}-\mathrm{C}_{2}-\mathrm{C}_{3}$ bond angle in 2 T is quite close to that of $135.4^{\circ}$ found in the more extensive calculations, ${ }^{9}$ with the bent structure being lower in energy than the linear structure. The result reported by Dillon and Underwood ${ }^{7}$ was obtained using the INDO technique which does, in fact, incorrectly predict that a linear planar structure is lower in energy than the bent planar form of 2 T .
The HSOMO of 2 TB is a nonbonding $\pi$ allyl-type MO (see Figure 7), while the second SOMO is an in-plane MO with dominant contribution from the AOs on $\mathrm{C}_{2}$. The Mulliken populations on $C_{1}, C_{2}$, and $C_{3}$ are $0.70,-0.40$ and 0.70 for the HSOMO and $0.11,0.77$, and 0.11 for the second SOMO, respectively. The linear planar allene triplet lies $8.0 \mathrm{kcal} / \mathrm{mol}$

${ }^{a}$ Orbital energies are given in hartrees. The dominant character of the orbitals is indicated in parentheses.
higher in energy (4-31G level). The SOMOs are illustrated in Figure 7, the HSOMO being an antibonding allyl-type MO perpendicular to the plane of the molecule, while the second SOMO is an in-plane, nonbonding allyl-type MO.

Interconversion of 1T and 2T. The energy surface connecting 1T and planar, bent triplet (2TB) was calculated at $10 \%$ intervals between 20 and $80 \%$ ring opening, and at 150,160 , and $170^{\circ}$ for the conversion of 2 TB to the linear, planar form 2TL and is shown in Figure 8. ${ }^{16}$ Although the total energy surface is smooth and appears normal, a detailed analysis of the character and energies of the SOMOs shows a dramatic discontinuity between 30 and $50 \%$ ring opening ( 85.5 and $99.9^{\circ}$, respectively) (see Figure 8 and Table IV). The in-plane $\sigma$ SOMO initially rapidly decreases in energy up to $85.5^{\circ}$ owing
to a decrease in the bonding between $C_{1}$ and $C_{3}$ as the ring opens. At $99.9^{\circ}$, however, it is at considerably lower energy. At $92.7^{\circ}$ ( $40 \%$ ring opening) the character of the SOMOs is highly mixed, showing neither dominant $\sigma$ nor $\pi$ character. Furthermore, the energies of the SOMOs (indicated by $\odot$ in Figure 8) are not close to those expected for the $\sigma$ - and $\pi$-type SOMOs. These results appear to be due to mixing of the $\sigma$ - and $\pi$-type SOMOs which are accidentally nearly degenerate at $92.7^{\circ}$ at which point the calculations were carried out. (The dashed lines in Figure 8 show the correlations between the $\sigma$ and $\pi$-type MOs.) Although this mixing greatly affects the character and energies of the SOMOs, it does not affect the total energy of the system.

Another discontinuity which occurs in this same region, but which is not related to that discussed above, is observed in the values of $\left\langle S^{2}\right\rangle$. The value of $\left\langle S^{2}\right\rangle$ remains constant at $\sim 2.010$ up to $85.5^{\circ}$ indicating a nearly pure triplet wave function. At $92,7^{\circ}$ the value of $\left\langle S^{2}\right\rangle$ is $2.307^{16}$ which steadily decreased to 2.130 at 2TB. Full geometry optimization using both the STO-3G and 4-31G basis sets gives essentially identical structures, even though the $\left\langle S^{2}\right\rangle$ values are significantly different ( 2.540 and 2.307 , respectively). We therefore believe that the calculations provide a valid description of the triplet geometry. The only significant effects that removal of the spin contamination might have would be to possibly push the transition state to a slightly higher $\mathrm{C}_{1}-\mathrm{C}_{2}-\mathrm{C}_{3}$ angle and to make small changes in the shape of the energy curve just beyond the transition state.
The ring opening of $\mathbf{1 T}$ to 2 TB occurs initially via an essentially nonrotatory process which rapidly changes to a disrotatory process in, or very shortly after, the transition state. The barrier height for this process is estimated to be $\sim 19$ $\mathrm{kcal} / \mathrm{mol}$ ( $4-3 \mathrm{I}$ G level) and occurs near $88^{\circ}$, or $\sim 33 \%$ ringopened structure. As the $\mathbf{N}$ process approaches the transition state the methylenes approach nearly planar configurations. After entering the disrotatory phase the methylenes become distinctly nonplanar, the rotation of the inner hydrogens lagging behind that of the outward rotating hydrogens (see Figure 9). As in the disrotatory opening of $\mathbf{1 S}$, this nonplanarity is due to repulsive interactions between the 1 S AOs on $\mathrm{H}_{1}\left(\right.$ or $\left.\mathrm{H}_{3}\right)$ and the AOs on $\mathrm{C}_{3}$ (or $\mathrm{C}_{1}$ ). As the $\mathrm{C}_{1}-\mathrm{C}_{3}$ distance increases during the ring-opening process this repulsion decreases and the methylenes become planar.

The opening of 1 T therefore occurs in basically three phases: (a) a nonrotatory process up to the nearly planar transition state with a $C_{1}-C_{2}-C_{3}$ bond angle of almost $90^{\circ} ;(b)$ a rapid disrotatory motion around the transition state to give a nonplanar structure; and (c) ring opening with gradual flattening of the methylenes to give the bent planar triplet allene. The $4-31 \mathrm{G}$ energy calculations indicate a barrier height of $\sim 19$ $\mathrm{kcal} / \mathrm{mol}$ and an overall exoergicity of $\sim 37 \mathrm{kcal} / \mathrm{mol}$ for the ring-opening process.

Although the much cruder INDO calculations ${ }^{7}$ also predict a nonrotatory process up to $90^{\circ}$, further details of the transformation are quite inconsistent with the present results. The INDO results indicate disrotation between 90 and $105^{\circ}$ to produce an all-planar transition state at about $105^{\circ}$ with a barrier height of $74 \mathrm{kcal} / \mathrm{mol}$, proceeding to planar-linear triplet allene, with an overall endoergicity of $35 \mathrm{kcal} / \mathrm{mol}$ !

Comparison of $1 S$ and 1T with the Cyclopropyl Cation and Radical. It is interesting to compare the structures, mode of ring opening, and the activation energies for the ring opening of 1 S and 1 T with the results reported for the cyclopropyl

Figure 9. Geometries of the triplet species near the transition state.
cation and radical. ${ }^{17} 1 \mathrm{~S}$ can be considered to be derived from the cyclopropyl cation by removal of a proton from the cationic center, the electrons which were previously considered to be associated with the $\mathrm{C}-\mathrm{H}$ bond becoming the nonbonding pair of electrons in $\mathbf{1 S}$. Thus, the MOs of the two species should be very similar. In keeping with this notion, both systems undergo disrotatory ring opening in which the disrotation of the methylene groups occurs synchronously with the ring-opening process. The barrier height for ring opening of the cyclopropyl cation has been calculated ${ }^{17}$ to be $1.3 \mathrm{kcal} / \mathrm{mol}$ (double $\zeta$ basis with limited configuration interaction) ${ }^{18}$ compared to our result of $18 \mathrm{kcal} / \mathrm{mol}$ for $\mathbf{1 S} .{ }^{19}$ The optimized bond lengths in the cyclopropyl cation are calculated to be $1.40 \AA$, considerably shorter than those in 1 S of $1.507 \AA$ for $\mathrm{C}_{1}-\mathrm{C}_{2}$ and $\mathrm{C}_{2}-\mathrm{C}_{3}$. (It must be recognized, however, that bond lengths calculated by the STO-3G method are slightly longer than experimentally observed bond lengths. Nonetheless a significant difference still exists.)

In 1 T , an electron has been transferred from the in-plane $\sigma \mathrm{MO}$ to the vacant $2 \mathrm{p} \pi \mathrm{AO}$ on $\mathrm{C}_{2}$ of 1 S resulting in a shortening of the $C_{1}-C_{2}$ and $C_{2}-C_{3}$ bonds to $1.459 \AA$. This shortening can be rationalized on the basis of a decrease in the dominant repulsion between the nonbonded (single) $\sigma$ electron on $\mathrm{C}_{2}$ and the electrons of the $\mathrm{C}_{1}-\mathrm{C}_{2}$ and $\mathrm{C}_{2}-\mathrm{C}_{3}$ bonds. 1T can be related to the cyclopropyl radical by removal of a hydrogen atom from the latter, and, thus again, similarities between the two systems should exist. Both 1T and the radical are predicted to undergo overall disrotatory ring opening. However, in contrast to 1 S and the cation, the ring opening and disrotation of the methylenes in 1T and the radical do not occur synchronously. The initial ring opening of 1 T and the radical occurs in a nonrotatory manner with the disrotation process beginning at, or shortly after, the transition state. Assuming that the MOs of the radical are very nearly the same as those of the cation (application of Koopman's theorem) ${ }^{20}$ the activation energy for opening of the radical has been calculated ${ }^{17}$ to be 35 $\mathrm{kcal} / \mathrm{mol}$ compared to our result of $19 \mathrm{kcal} / \mathrm{mol}$ for the opening of 1 T .

(10) Our presently calculated structure is slightly different from that calculated for 15 previously (W. A. Lathan, L. Radom, P. C. Hariharan, W. J. Hehre, and J. A. Pople, Fortschr. Chem. Forsch., 40, 1 (1973)) with $\angle C_{1}-C_{2}-C_{3}$
of $58.3^{\circ}, C_{1}-C_{2}$ bond length of $1.530 \AA, C-H$ bond length $1.081 \AA$, and $\angle \mathrm{H}-\mathrm{C}-\mathrm{H}$ angles of $113.8^{\circ}$
(11) Dewar and co-workers derived $\mathrm{C}_{1}-\mathrm{C}_{2}$ and $\mathrm{C}_{2}-\mathrm{C}_{3}$ bond lengths of 1.428 $\AA, C_{4}-C_{2}-C_{3}$ bond angle of $62.6^{\circ}, C_{2}-C_{1}-H$ bond angles of $119.7^{\circ}$, and $\mathrm{H}-\mathrm{C}-\mathrm{C}-\mathrm{C}$ dihedral angles $\sim 110^{\circ}$ using the Simplex-MINDO/2 procedure (see ref 6).
(12) This MO description is different from that implied in ref 6 in which the nonbonded pair of electrons is depicted as occupying a 2 p AO on $\mathrm{C}_{2}$.
(13) In the geometry optimization calculations at $90^{\circ}$ each $\mathrm{H}-\mathrm{C}-\mathrm{C}$ bond angle and $\mathrm{H}-\mathrm{C}-\mathrm{C}-\mathrm{C}$ dihedral angle was optimized individually producing a structure with perfect $C_{s}$ symmetry. Final calculations at $90^{\circ}$, as weil as those at 70 and $80^{\circ}$, were carried out by coupling symmetry related bond lengths, bond angles and dihedral angles.
(14) At $100^{\circ}$ the $\mathrm{H}-\mathrm{C}$ bond lengths, $\mathrm{H}-\mathrm{C}-\mathrm{C}$ bond angies, and $\mathrm{H}-\mathrm{C}-\mathrm{C}-\mathrm{C}$ dihedral angles were indlvidually optimized. After two complete cycies of optimization, the predicted geometry was approaching that with a plane of symmetry coincident with the $\mathrm{C}_{1}-\mathrm{C}_{2}-\mathrm{C}_{3}$ plane. Instead of cyciling further, the $\mathrm{H}_{3}-\mathrm{C}_{3}$ and $\mathrm{H}_{4}-\mathrm{C}_{3}$ bond lengths, $\mathrm{H}_{3}-\mathrm{C}_{3}-\mathrm{C}_{2}$ and $\mathrm{H}_{4}-\mathrm{C}_{3}-\mathrm{C}_{2}$ bond angles, and the $\mathrm{H}_{3}-\mathrm{C}_{3}-\mathrm{C}_{2}-\mathrm{C}_{4}$ and $\mathrm{H}_{4}-\mathrm{C}_{3}-\mathrm{C}_{2}-\mathrm{C}_{4}$ dihedral angles were symmetry coupled and optimized. This latter procedure was used at angles of $120-180^{\circ}$.
(15) For a thorough review of the stereochemical aspects of the ring opening of cyclopropylidenes see ref 7.
(16) Although in general the structures were optimized using the STO-3G minimal basis set, the results of the STO-3G calculations on the triplet energy surface indicated considerably greater contributions of higher spin states to the tripiet wave function than in the 4-31G extended basis set as indicated by the value of $\left\langle S^{2}\right\rangle$, particularly from $40 \%$ ring opening to aliene. Therefore, 4-31G geometry optimization calculations were carried out on

1T, at $40 \%$ ring opening, and for bent planar allene. The geometries resulting from these calculations, however, were only negligibly different from the STO-3G optimized structures, and geometry optimization at the other points on the triplet surface were carried out using the STO-3G basis set with the final energies being calculated using the 4-31G extended basis set.
(17) P. Merlet, S. D. Peyerimhoff, R. J. Buenker, and S. Shih, J. Am. Chem. Soc., 96, 959 (1974).
(18) Incorporation of Cl in the calculations for the cyclopropyl cation resulted in only silght lowering of the activation energy, 1.6 to $1.3 \mathrm{kcal} / \mathrm{mol}$ for the disrotatory process and 86.3 to $78.5 \mathrm{kcal} / \mathrm{mol}$ for the conrotatory process.
(19) Because of the small effect of incorporation of Cl on the energies in the cyclopropyl cation caiculations it was not considered worthwhile to incorporate Cl into the present calculations.
(20) The application of Koopmans' theorem to the cation and radical pair in ref 17 assumes that the two species have identical structures, i.e., planar cation and radical centers. However, in the case of the cyclopropyl radical, $E P R^{2 \dagger}$ and stereochemical studies ${ }^{22}$ involving the cyclopropyl radical have been interpreted in terms of a nonplanar radical center with a low energy barrier to inversion. This does not invalidate the comparisons made between 1T and the cyclopropyl radical as during the ring opening of the cyclopropyl radical planarity must be achieved along the reaction coordinate. Such a change in geometry would result in an increase in the activation energy for ring opening of the radical over that calculated on the basis of a planar radical in ref 17.

# Ab Initio Molecular Orbital Study of the Geometries, Properties, and Protonation of Simple Organofluorides ${ }^{1}$ 

William L. Jorgensen* and Michael E. Cournoyer

Contribution from the Department of Chemistry, Purdue University, West Lafayette, Indiana 47907. Received January 12, 1978

#### Abstract

SCF calculations with minimal, STO-3G, and extended, 4-31G, basis sets have been used to study the geometries and properties of the simple alkyl fluorides, HF to $t-\mathrm{BuF}$, and vinyl fluoride. Particular emphasis is placed on examining the corresponding protonated fluorides in order to better understand the gas-phase behavior of these species as well as to provide insight into the solvation of carbonium ions in a superacid medium such as liquid HF. In contrast to an earlier study of alkyl chlorides, computed properties for the protonated fluorides are poorly described with the minimal basis set calculations. This necessitates limited geometry optimization at the $4-31 \mathrm{G}$ level to obtain reasonable agreement with experimental proton affinities and carbonium ion- FH dissociation energies $\left(\Delta E_{\mathrm{s}}\right.$ ). The small $\Delta E_{\mathrm{s}}$ values ( $<8 \mathrm{kcal} / \mathrm{mol}$ ) for protonated isopropyl and tert-butyl fluorides account for the inability to observe these ions in ICR experiments and provide evidence for the weak solvation of secondary and tertiary carbonium ions in superacid solutions. It is also found that an HF binds to bisected ethyl cation more strongly than the bridged ethyl cation by $4 \mathrm{kcal} / \mathrm{mol}$. Although this is consistent with previous work, the conclusion could be modified by a more sophisticated theoretical treatment. As an exception, vinyl fluoride is predicted to protonate on carbon rather than fluorine; the reason is illuminated by a simple frontier orbital analysis. Various correlations involving the properties of the fluorides are noted, while differences in the behavior of chlorides and fluorides can usually be ascribed to the greater basicity and weaker electronegativity of chlorine.

The current interest in chemistry in the gas phase ${ }^{2}$ and in superacid media ${ }^{3}$ prompted a series of theoretical studies on the properties and protonation of alkyl chlorides. ${ }^{4}$ Both semiempirical and ab initio molecular orbital calculations were used to explore the origins of variations in proton affinities and in the interactions between carbonium ions and HCl . The present work extends the analyses to alkyl fluorides and their protonated analogues. This order of presentation may at first seem unusual; however, it resulted from the fact that neither semiempirical nor ab initio calculations with minimal basis sets yield adequate descriptions of protonated fluorides, whereas both approaches are suitable for the study of neutral and protonated alkyl chlorides. ${ }^{4}$ As discussed below, greater sophistication is necessary in the ab initio calculations to obtain energetic results in reasonable agreement with experiment for protonated alkyl fluorides.
The detailed purposes of this paper are: (1) to examine the structures and thermodynamic stability of protonated alkyl
fluorides in the gas phase; (2) to determine the extent of interaction between various carbonium ions and HF as a primitive model for solvation in a superacid medium; and (3) to seek out correlations involving the properties of the fluorides and to compare the results with similar data for chlorides. The molecules treated are the simple alkyl fluorides, HF to $t$ - BuF , vinyl fluoride, and their protonated derivatives. The method of analysis employs single determinant, ab initio molecular orbital calculations with both a minimal STO-3 $\mathrm{G}^{\text {5a }}$ basis set and the extended, split-valence $4-31 \mathrm{G}^{5 b}$ basis. The computations were performed using the GAUSSIAN/74 program ${ }^{6}$ on the CDC/6500 system at Purdue.

Several significant findings were made in the course of this research. Consistent with other studies of the protonation of bases containing first-row elements, ${ }^{7}$ the protonated fluorides are much too bound at the STO-3G level which is witnessed by proton affinities (PAs) that are too high by $40-60 \mathrm{kcal} / \mathrm{mol}$. The consequent errors in the geometries of the ions cause
