# Cleaving CC Bonds in Cyclopropenium Ions 

Eluvathingal D. Jemmis and Roald Hoffmann*<br>Contribution from the Department of Chemistry, Cornell University, Ithaca, New York 14853. Received September 19, 1979

#### Abstract

A cyclopropenium ion breaking one of its carbon-carbon bonds furnishes an orbital lemplate which can be exploited by sundry mononuclear and binuclear transilion metal fragments.

One of the many things that transition-metal complexes do, and we wish we knew better how to control it, is to cleave and form carbon-carbon bonds. In this paper one very specific CC bond breaking, that in cyclopropenium cations and cyclopropenones, is investigated theoretically. The case is special, but the theoretical methodology developed here lends itself to obvious extension.

We chose these three-membered rings for study in part because we understand the electronic structure of the organic moiety well and in part because the body of structural information on $\mathrm{C}_{3} \mathrm{R}_{3}$ and cyclopropenone complexes is just reaching the critical stage, revealing a continuum of bonding modes which may trace out a reaction coordinate for the insertion reaction.

The intrusion of a metal atom, with its associated ligands, into a CC bond of a strained three-membered ring may occur in either a single oxidative step, as in eq $1,{ }^{1}$ or following prior coordination of the organic ligand. Equation 2 represents perhaps the best characterized instance of this sequence. ${ }^{2,3}$

If coordination of the ring is a likely initial step, one is led to think about the ways in which a three-membered ring may be bound. Cyclopropenium complexes are not common, but we do have available structures in which the ring is $\eta^{3}, 3,{ }^{4-8} \eta^{2}$, 4, ${ }^{9}$ and $\eta^{1}, 5 .{ }^{10}$

On the completely ring-opened or metallocyclobutadiene

4
5
side we have the previously mentioned complexes $\mathbf{1}$ (and an analogous $\mathrm{RhCl}_{2}\left(\mathrm{PMe}_{2} \mathrm{Ph}_{2}\left(\mathrm{C}_{3} \mathrm{Ph}_{3}\right)^{12}\right)$ and 2. Then we encounter a fascinating group of bi- or polynuclear complexes with $\mathrm{C}_{3} \mathrm{R}_{3}$ or $\mathrm{C}_{2} \mathrm{R}_{2} \mathrm{CO}$ units sitting atop them ( $6,{ }^{13} 7,{ }^{14} \mathbf{8 , 1 5}$ 9, ${ }^{16}$ and $10^{17}$ ).

Are the three-membered rings in these complexes completely or only partially opened up? As the cyclopropenium ring is cleaved one CCC angle, $\theta$, opens up and the CC bond opposite, $R$, stretches. Less obvious, but important, is the fact that the orientation of the metal atom relative to the threecarbon plane changes. The metal is perpendicular to the plane

$6 R=P h$

7

$R=P h \quad 8 \quad R^{\prime}=N C^{\prime} B u$
$9 \mathrm{M}=\mathrm{Pd}, \mathrm{Pt}$

10
in the $\eta^{3}$ complexes, sometimes in that plane in the ring-opened metallocyclobutadienes. There are a number of ways of specifying this degree of freedom. We have chosen a parameter suited to a discussion of puckering on the metallocycle side, namely, the dihedral angle between the $\mathrm{C}_{1} \mathrm{MC}_{3}$ and $\mathrm{C}_{1} \mathrm{C}_{2} \mathrm{C}_{3}$ planes, $\varphi$. These variables are shown in 11 . Of course they do

11
not determine fully the geometry of the complex. Other distances and structural changes are interesting, for instance, the way the flanking bonds $\mathrm{C}_{1} \mathrm{C}_{2}$ and $\mathrm{C}_{2} \mathrm{C}_{3}$ follow the opening and the disposition of the substituents at $C_{1}$ and $C_{3}$. But we think that the deformation is well described by $\theta, R$, and $\varphi$, and for the known structures these are listed in Table I.

In the binuclear complexes two $\varphi$ angles are given, corresponding to the two kinds of metallocycle linkages that one could think of forming. It is clear from the structural data that the binuclear complexes are ring opened ( $\theta$ and $R$ just as great as in the metallocyclobutadienes) and yet $\varphi$ is not $180^{\circ}$. These $\mathrm{C}_{3}$ units straddle metal-metal bonds, as structures 6-10 indicate, an orientation that allows maximum interaction with both metals. They will be considered separately.

The number of mononuclear cyclopropenium complexes caught in the middle of the reaction, i.e., with $60<\theta<100^{\circ}$, $1.45<R<2.10 \AA$, is small. Nevertheless the data clearly suggest a reaction coordinate, CC bond breaking, drawn in 12.

The metal bonding partners differ in their capacity for pushing the three-membered ring to a definite place along that reaction

coordinate. How this comes about is next explored by us, using extended Hückel calculations whose details are provided in the Appendix. ${ }^{18}$

## Opening up a Cyclopropenium Cation

Our procedure is a transparent one. We will cleave a CC bond in $\mathrm{C}_{3} \mathrm{H}_{3}{ }^{+}$, the isolated organic molecule. The orbitals so obtained at various stages of the bond-breaking process will serve as electronic templates for transition metal fragment bonding partners. Sometimes we will turn the argument around, and ask what portion of the ring-opening surface will be stabilized by a specific metal fragment.

The geometrical change envisaged is an increase in $\theta, 13$,

13
coupled through the side CC bond length ( $1.40 \AA$ ) to the 1,3 separation $R$. The hydrogens at $\mathrm{C}_{1}$ and $\mathrm{C}_{3}$ were coupled to this motion by specifying that the $\mathrm{H}_{1}-\mathrm{C}_{1}-\mathrm{C}_{2}$ and $\mathrm{H}_{3}-\mathrm{C}_{3}-\mathrm{C}_{2}$ angles vary as $180^{\circ}-1 / 2 \theta$. The computed Walsh diagram (Figure 1) is a classical example of simple perturbation theory at work. ${ }^{19}$ At $\theta=60^{\circ}$ the $\pi$ orbitals of cyclopropenium fall into the familiar $\mathrm{a}_{2}{ }^{\prime \prime}$ below $\mathrm{e}^{\prime \prime}$ pattern. Not far above the occupied $\pi$ level the extended Hückel calculation places a degenerate $\mathrm{e}^{\prime} \sigma$ level. As $\theta$ departs from $60^{\circ}$, the symmetry is lowered from $D_{3 h}$ to $C_{2 v}$. The $\pi^{*}$ level splits, one component going up, one going down. The low-lying $\pi$ level is not much affected. The degenerate $\sigma$ level also splits. At large $\theta$ it is joined by a $\sigma^{*}$ level which has fallen rapidly in energy. At still greater $\theta \sigma$ and $\sigma^{*}$ cross-this is a well-understood consequence of through-bond coupling. ${ }^{19 \mathrm{a}}$ The destabilized $\sigma$ and stabilized $\sigma^{*}$ levels can also be thought of as the in- and out-of-phase combinations of the radical lobes of a didehydroallyl cation. Note that on the ring-opened side there are three orbitals lodged in the nonbonding region: $\sigma, \sigma^{*}$, and $\pi_{2}{ }^{*}$. Any bonding partner to the opened $C_{3} R_{3}$ must provide stabilizing interactions with these orbitals.

The hypothetical bonding partners that we would like to consider in the first instance are mononuclear transition metal fragments, $\mathrm{ML}_{n}$, and their isolobal replacements. More specifically we will examine bonding with $C_{4 v} \mathrm{ML}_{5}, C_{2 v} \mathrm{ML}_{4}, C_{3 v}$ $\mathrm{ML}_{3}$, and $C_{2 v} \mathrm{ML}_{2}$, as well as with their analogues in which a cyclopentadienyl ring replaces three carbonyls, $\mathrm{M}^{\prime} \mathrm{L}_{2} \mathrm{Cp}$, $\mathrm{M}^{\prime} \mathrm{LCp}$, and $\mathrm{M}^{\prime} \mathrm{Cp}$. The orbitals of these fragments should by now be familiar to our readers, ${ }^{20}$ and they are sketched in Figure 2. In the octahedral fragment geometries of $\mathrm{ML}_{5}, \mathrm{ML}_{4}$, and $\mathrm{ML}_{3}$ there are three levels down below, the remnants of the octahedral $\mathrm{t}_{2 \mathrm{~g}}$ set, and one, two, or three higher lying orbitals, the delocalized symmetry-adapted equivalents of the hybrids pointed toward the missing octahedral sites. Angular

Figure 1. A Walsh diagram for cleaving a single $C C$ bond in a cyclopropenium ion by opening up the angle opposite.
$\mathrm{ML}_{2}$ is different, having four low-lying orbitals and two hybrids above these. There is a second isolobal relationship between $\mathrm{d}^{10} \mathrm{ML}_{2}$ and $\mathrm{d}^{8} \mathrm{ML}_{4},{ }^{20 f}$ best approached by thinking about adding two axial ligands to $\mathrm{ML}_{2}$ or removing them from $\mathrm{ML}_{4}$. We are now ready for putting together the two pieces of the molecule.

## Bonding with a Cyclopropenium without Ring Opening, or, Haptotropic Shifts across a Three-Membered Ring

The secondary title of this section refers to our study of sigmatropic shifts in cyclopentadienyl complexes. ${ }^{2 \mid}$ Consider an $\mathrm{ML}_{n}$ group in transit across the face of a cyclopropenium, 14. Its location can be approximately described by the projection of the metal onto the ring plane, spanning sites marked $1 \eta, 2 \eta$, and $3 \eta$ in $\mathbf{1 5}$ to form obvious mnemonic connections to the $\eta^{1}, \eta^{2}$, and $\eta^{3}$ coordination implied.

14

15

The $\mathrm{ML}_{n}$ group will adopt the optimum position where there is most bonding interaction, and this will depend on the orbital pattern of $\mathrm{ML}_{n}$ and the electron count. Consider, for instance, $\mathrm{Co}(\mathrm{CO})_{3}$ or the isolobal NiCp . The higher lying $2 \mathrm{a}_{1}$ and 2 e orbitals of these fragments are a perfect match for $\mathrm{a}_{2}{ }^{\prime \prime}$ and $\mathrm{e}^{\prime \prime}$ $\pi$ orbitals of cyclopropenium if, and only if, the $M L_{n}$ fragment is $\eta^{3}$ bonded. The interaction diagram is shown schematically below in 16. The molecule is split up into neutral fragments. This is entirely arbitrary-we could just as well have interacted $\mathrm{C}_{3} \mathrm{H}_{3}{ }^{+}$and $\mathrm{NiCp}^{-}$, for in the one-electron molecular orbital theory we use the electron partitioning has no effects,

Were the MCp or $\mathrm{M}(\mathrm{CO})_{3}$ fragment moved off center to $2 \eta$ or $1 \eta$ sites, part of the important $\pi$-type interaction between

Figure 2. The frontier orbitals of $\mathrm{ML}_{5}, \mathrm{ML}_{4}, \mathrm{ML}_{3}$, and $\mathrm{ML}_{2}$ fragments.

16
the e orbitals would be lost. The trihapto bonding type is well represented by $\mathrm{C}_{3} \mathrm{R}_{3}$ complexes with $\mathrm{CpNi}, \mathrm{py}_{2} \mathrm{ClNi}$, and $\mathrm{Br}(\mathrm{CO})_{2} \mathrm{Ni}^{4-8}$ Incidentally a CH group will do as well, since it is isolobal with $\mathrm{d}^{9} \mathrm{ML}_{3}$. Which is hardly a surprise--we are discussing a peculiar way to form a tetrahedrane, a highly strained but respectable molecule. ${ }^{22}$

Now suppose that $\mathrm{ML}_{n}$ is $\mathrm{Mn}(\mathrm{CO})_{5}$. This has one electron more than $\mathrm{Cr}(\mathrm{CO})_{5}$ (Figure 2) and that electron is in a nicely oriented $\mathrm{a}_{1}$ hybrid. As $\mathrm{ML}_{n}$ makes a transit across a cyclopropenium ring it always interacts with $a_{2}{ }^{\prime \prime}$, but does so with one component of $e^{\prime \prime}$ only when it is off-center, and optimally so in the $\eta^{1}$ site. This is shown schematically in $\mathbf{1 7}$. The molecular type exists, not yet as $\left(\mathrm{C}_{3} \mathrm{R}_{3}\right) \mathrm{Mn}(\mathrm{CO})_{5}$ but as the isolobal $\eta^{1}\left(\mathrm{C}_{3} \mathrm{R}_{3}\right) \mathrm{Fe}(\mathrm{CO})_{2} \mathrm{Cp} .{ }^{10}$

The $\mathrm{ML}_{4}$ or $\mathrm{ML}_{2}$ cases are interesting because they are in principle intermediate between those discussed above. Where $\mathrm{ML}_{5}$ had a single $\sigma$-type orbital and $\mathrm{ML}_{3}$ had a $\sigma$ and two $\pi$ 's, $\mathrm{ML}_{2}$ and $\mathrm{ML}_{4}$ have one $\sigma$ and one $\pi$. The result is a fairly soft surface for motion across the cyclopropenyl ring, with an

Figure 3. Interaction diagram for $\left(\mathrm{C}_{3} \mathrm{R}_{3}\right) \mathrm{ML}_{2}$.
equilibrium geometry as in 18 . A complete discussion of the intricate surface for the interconversion of $\eta^{2}$ structures is given elsewhere. ${ }^{23}$ The observed structure of $\left(\mathrm{PPh}_{3}\right)_{2} \mathrm{Pt}\left(\mathrm{C}_{3} \mathrm{Ph}_{3}\right)^{+}$is indeed of the $\eta^{2}$ type, with two $\mathrm{Pt}-\mathrm{C}$ distances of 2.09 and one of $2.48 \AA .{ }^{9}$ Other $\left(\mathrm{C}_{3} \mathrm{R}_{3}\right) \mathrm{ML}_{2}$ complexes are known. ${ }^{5,24}$

## Metal-Assisted Ring Opening

Let us backtrack a moment to the $\left(\mathrm{C}_{3} \mathrm{R}_{3}\right) \mathrm{ML}_{2}$ complex, for it will have been noticed from Table I that it is the only structurally well-characterized example that we have which has $\theta$ and $R$ in the intermediate range. The ring is beginning to open up, though it has not gotten very far. Figure 3 shows an interaction diagram in the observed $\eta^{2}$ geometry. On top of several four-electron repulsive interactions the primary bonding is accomplished by the $\mathrm{ML}_{2} \mathrm{~b}_{2}$ level and one component of the cyclopropenium $\mathrm{e}^{\prime \prime} \pi_{2}{ }^{*}$ as shown in 19. Transfer of electrons to that $\pi^{*}$ is what stretches the $\mathrm{C}_{1}-\mathrm{C}_{3}$ bond to $1.58 \AA$, actually a distance somewhat longer than that observed in many $\mathrm{d}^{10}$ $\mathrm{ML}_{2}$ (olefin) complexes in which a similar interaction dominates.

Why does not the CC bond stretch any further? Let us compare the energies of the frontier orbitals of the two fragments in Figure 4. This reproduces the $\mathrm{C}_{3} \mathrm{R}_{3}$ levels along a bond-breaking coordinate and indicates the $\mathrm{ML}_{2} \mathrm{~b}_{2}$ level position by a dashed line. The orbitals which interact strongly carry a circle. If $\theta$ is increased further, the difference in energy between these orbitals would diminish, which is one factor that would strengthen interaction. There are also some four-electron repulsive interactions which appear to combine to hold the observed structure at an $\eta^{2}$ bonded point. In principle there is nothing barring the system from going on to open the ring further. Let us discuss this channel through the known ringopened $\mathrm{ML}_{4}$ complexes, whose orbitals resemble those of $\mathrm{ML}_{2}$, as mentioned above.

Figure 4. $\mathrm{C}_{3} \mathrm{R}_{3}$ levels as a funclion of $\theta$, solid lines, and the $\mathrm{ML}_{2} \mathrm{~b}_{2}$ level, dashed line. Circles identify interacting orbitals at observed geomerry.
$\mathrm{d}^{8} \mathrm{ML}_{4}$ reagents of the Vaska's complex type break the CC bond in a three-membered ring completely, achieving the metallocyclobutadiene geometry, 20.1,12 We have modeled their electronic structure by $(\mathrm{CO})_{4} \mathrm{Co}\left(\mathrm{C}_{3} \mathrm{H}_{3}\right)^{2+}$. The $\mathrm{d}^{8} \mathrm{ML}_{4}$ fragment has the three below two pattern exhibited in Figure 2. The important $b_{2}$ orbital can interact with $\pi_{2}{ }^{*}$, as in 21, when the ring plane is approximately orthogonal to the M-ring axis $\left(\varphi \sim 90^{\circ}\right)$. When $\varphi$ approaches $180^{\circ}$, the interaction is with $\sigma^{*}, 22$. At intermediate $\varphi \pi_{2}{ }^{*}$ and $\sigma^{*}$ mix through this interaction. It is clear that in the initial stages of the interaction, small $\theta$, the energy proximity criterion of perturbation theory ${ }^{19}$ favors $\pi_{2}{ }^{*}$. At $\theta \sim 104^{\circ} \sigma^{*}$ and $\pi_{2}{ }^{*}$ are of equal energy. Now the overlap criterion comes into play. At $\theta=100^{\circ}$ the group overlaps are $\left\langle\mathrm{b}_{2} \mid \pi_{2}{ }^{*}\right\rangle=0.239\left(\varphi=90^{\circ}\right),\left(\mathrm{b}_{2}\left|\sigma^{*}\right\rangle=0.272\right.$ $\left(\varphi=180^{\circ}\right.$ ). Increasing $\varphi$ is favored. The match of fragment orbitals in the metallocycle is shown in Figure 5.

The process by which an $\eta^{2}$-bonded cyclopropenium complex of $\mathrm{d}^{8} \mathrm{ML}_{4}$ or $\mathrm{d}^{10} \mathrm{ML}_{2}$ is converted to a metallocycle, i.e., the increase in $\theta$ and $\varphi$ along reaction path 12, is similar in detail to the disrotatory opening of a bicyclobutyl cation to cyclobutenyl cation, 23. This parallel has been noted by others as well. ${ }^{8}$ It is supported by the isolobal analogy ${ }^{20}$ that pairs $\mathrm{CH}_{2}$ with $\mathrm{Fe}(\mathrm{CO})_{4}$ or any $\mathrm{d}^{8} \mathrm{ML}_{4}$. A correlation diagram connecting the extremes of the reaction path is also easily drawn, and shows that the reaction is symmetry allowed.

## Bigger and Better

The binuclear or polynuclear complexes 6-10 obviously do an effective job of breaking a carbon-carbon bond: $\theta$ ranges

Figure 5 . $\mathrm{C}_{3} \mathrm{R}_{3}$ levels as a function of $\theta$, solid lines, and the $\mathrm{ML}_{4}$ frontier levels, dashed lines. Circles and squares identify interacting orbitals.

Figure 6. Construction of the orbitals of $\mathrm{Ni}_{2}(\mathrm{CO})_{4}$. The lower shaded blocks contain four filled orbitals in the monomer, eight in the dimer.
from 97.5 to $105^{\circ}$ and $R$ from 2.12 to $2.24 \AA$. In most cases the $\mathrm{C}_{3} \mathrm{R}_{3}$ unit nicely straddles the metal-metal bond, but this is not always so-notice the two disparate $\varphi$ angles in the $\operatorname{Pd}_{3}$ case, 9. ${ }^{16 \mathrm{~b}}$ The structures known are so complicated (and therefore intriguing) and unsymmetrical that we have had to limit ourselves to a symmetrical idealized complex, $(\mathrm{CO})_{4^{-}}$ $\mathrm{Ni}_{2}\left(\mathrm{C}_{3} \mathrm{H}_{3}\right)^{+}, \mathbf{2 4}$, a model for 7 and 8.

Figure 7. $\mathrm{C}_{3} \mathrm{R}_{3}$ levels as a function of $\theta$, solid lines, and the $\mathrm{Ni}_{2}(\mathrm{CO})_{4}$ frontier orbitals, dashed lines. The symbols identify interacting orbitals in the ring-opened geometry.

The frontier orbitals of a $\mathrm{d}^{10}-\mathrm{d}^{10} \mathrm{~L}_{2} \mathrm{MML}_{2}$ system are easily constructed from two $\mathrm{ML}_{2}$ fragments (Figure 6); in fact we have already done this in the context of a discussion of $\mathrm{Pt}(0)-\mathrm{Pt}(0)$ dimers. ${ }^{25}$ The $\mathrm{ML}_{2} \mathrm{~b}_{2}$ orbitals form two combinations that are metal-metal $\pi$ bonding and antibonding, respectively. Another valence orbital comes from a $\sigma$ bonding combination of the $3 a_{1}$ MOs which we will call $\sigma_{\text {hy }}$ to distinguish it from $\sigma$ of $\mathrm{C}_{3} \mathrm{H}_{3}{ }^{+}$. That the $\sigma_{\text {hy }}$ combination in the dimer is much lower than in the monomer is important in the bonding picture. These three $\mathrm{M}_{2} \mathrm{~L}_{4}$ orbitals, two filled, find a lovely match in three frontier orbitals of a ring-opened $\mathrm{C}_{3} \mathrm{H}_{3}{ }^{+}$, one filled, as shown in 25. A comparison (Figure 7) of the energies of the frontier orbitals of the fragments tells us that the bonding would have been less strong were the $\mathrm{C}_{3} \mathrm{H}_{3}+$ less open than was found experimentally.

Several alternative geometries were explored for $(\mathrm{CO})_{4}$ $\mathrm{Ni}_{2}\left(\mathrm{C}_{3} \mathrm{H}_{3}\right)^{+}$. Details are given in the microfilm edition of the journal. All are at higher energy than 24, but for some metal and ligand sets some of these geometries may become competitive.

The supplementary material in the microfilm edition also contains a discussion of cyclopropenone, cyclopropene, and cyclopropane as ligands analogous to cyclopropenyl cation. Here it is worthwhile to draw a comparison between ringopened $\mathrm{C}_{3} \mathrm{H}_{3}$ or cyclopropenone and an acetylene. These systems are in a sẹne isolobal, as shown in $\mathbf{2 6}$ below. At left are

three valence orbitals of the three-membered ring at large $\theta$, at right the four valence orbitals of an acetylene. The similarities jump to one's attention. One of the acetylene $\pi$ 's seems to have no cyclopropenium counterpart, but even that is not so--for the analogue is to be found in $\pi_{1}$, of $\mathrm{C}_{3} \mathrm{H}_{3}{ }^{+}$. There should be a chemistry of $C_{3} R_{3}$ and cyclopropenones as rich as that of acetylenes.

Supplementary Material Avallable: A discussion of cyclopropenone, cyclopropene, and cyclopropane complexes as well as alternative $\left(\mathrm{C}_{3} \mathrm{H}_{3}\right) \mathrm{M}_{2} \mathrm{~L}_{4}$ geometries (Table 2) ( 7 pages). Ordering information is given on any current masthead page.

## Appendix

All calculations were performed using the extended Hückel method. ${ }^{26}$ The $H_{i i}$ 's and orbital exponents were taken from previous work. ${ }^{27}$ The geometry of $\left(\mathrm{PH}_{3}\right)_{2} \mathrm{PtC}_{3} \mathrm{H}_{3}+$ (Figure 3) was adapted from the observed structure 4 by replacing the substituents on ligands by hydrogens ( $\mathrm{P}-\mathrm{H}=1.4, \mathrm{C}-\mathrm{H}=1.08$ $\AA$ ). The $\mathrm{Co}-\mathrm{C}$ and $\mathrm{C}-\mathrm{O}$ distances in the $\mathrm{Co}(\mathrm{CO})_{4}$ fragment were 1.9 and $1.13 \AA$ with an equatorial CCoC angle of $86^{\circ}$. The $\mathrm{Ni}_{2}(\mathrm{CO})_{4}$ fragment in 24 had the following bond lengths and angles: $\mathrm{Ni}-\mathrm{Ni}=2.52 \AA, \mathrm{Ni}-\mathrm{C}=1.8 \AA, \mathrm{C}-\mathrm{O}=1.14 \AA$, angle $\mathrm{NiNiC}=120^{\circ}$, angle $\mathrm{CNiC}=117^{\circ}$. The $\mathrm{C}_{3} \mathrm{H}_{3}$ geometry corresponded to various points in Figure $1(\mathrm{C}-\mathrm{C}=1.4$, $\mathrm{C}-\mathrm{H}=1.08 \AA$ ).
