# Solvent Effects in the Complexation of [2]-Cryptands and Related Monocycles with Transition- and Heavy-Metal Cations 

F. Arnaud-Neu, B. Spiess, and M. J. Schwing-Weill*<br>Contribution from the Ecole Nationale Supèrieure de Chimie de Strasbourg, Université Louis Pasteur, ERA 166, 67000 Strasbourg, France. Received December 28, 1981

#### Abstract

Potentiometric and spectrophotometric results on the complexation of transition- and heavy-metal cations by the bicyclic cryptands 211,221 , and 222 and the related monocycles 21 and 22 in water, methanol ( MeOH ), dimethyl sulfoxide ( $\mathrm{Me}_{2} \mathrm{SO}$ ), and propylene carbonate ( PC ) are discussed. The complexes formed in solution are strongly influenced by the solvent: the mononuclear 1:1 complexes are in some cases accompanied by dinuclear $2: 1$ and/or protonated mononuclear $1: 1: 1$ complexes. With $1: 1$ complexes, it is shown that (i) for a given complex the stability sequence is $\mathrm{Me}_{2} \mathrm{SO}<\mathrm{H}_{2} \mathrm{O}<\mathrm{MeOH}<\mathrm{PC}$, (ii) for a given cation the variation of the stability with the cryptand cavity size is parallel in all solvents, and (iii) a strong macrobicyclic effect is displayed in all solvents by the larger $\mathrm{Pb}^{2+}$ and $\mathrm{Ag}^{+}$cryptates whereas no significant cryptate effect is found with transition cations. The generalized extrathermodynamic assumption involving cryptates recently proposed in the literature appears to be generally not consistent with the $\mathrm{Ph}_{4} \mathrm{As}^{+} / \mathrm{Ph}_{4} \mathrm{~B}^{-}$assumption, with divalent as well as with monovalent cations. The transfer activity coefficients of divalent cryptates are calculated from the present data by using the literature values of the transfer activity coefficients of the uncomplexed cryptands and of the free cations.

The diazapolyoxamacrobicycles, or [2]-cryptands, first synthesized by Dietrich, Lehn, and Sauvage in 1969 and represented in Figure 1, are well-known for their ability to form $1: 1$ inclusion complexes, or cryptates, with metallic cations. ${ }^{1-4}$
The thermodynamics of complexation in solution of 211,221 , and 222 has been mainly studied with alkali and alkaline-earth cations in water and in various nonaqueous solvents. The main potentiometric and calorimetric studies are due to Lehn et al., ${ }^{5.6}$ Schneider et al., ${ }^{7-9}$ Kolthoff et al., ${ }^{10.11}$ Bessiere et al.. ${ }^{12,13}$ and Abraham et al. ${ }^{14-17}$ The complexation of $\mathrm{Ag}^{+}$and $\mathrm{Tl}^{+}$has been investigated by Anderegg in aqueous medium ${ }^{18}$ and by most of the previous authors both in water and in some nonaqueous solvents. ${ }^{7,8,11,12,16-19}$ However, no systematic investigation of the complexation of transition- and heavy-metal cations by [2]cryptands in various solvents had been undertaken before our own studies ${ }^{20-24}$ of the complexation of the bicyclic ligands 211,221 ,

[^0]and 222 and the related monocyles 21 and 22 (Figure 1) in water, ${ }^{20}$ methanol, ${ }^{21,22} \mathrm{Me}_{2} \mathrm{SO}$, ${ }^{24}$ and PC. ${ }^{23,24}$

We report here some new results concerning water and $\mathrm{Me}_{2} \mathrm{SO}$ media and discuss the complete set of our potentiometric and spectrophotometric results. ${ }^{20-24}$ As each of the monocyclic ligands is one of the cycles of the bicyclic [2]-cryptands, our results allow a comparison of the complexing properties of both class of macrocycles, which is of special interest when two ligands of comparable cavity sizes are compared, such as 221 and 21 or 222 and 22 (see caption of Table II). Before our work, the complexation of 21 and/or 22 with transition- and heavy-metal cations had only been studied in aqueous medium with $\mathrm{Cu}^{2+},{ }^{26} \mathrm{Cd}^{2+},{ }^{18,26}$ $\mathrm{Ag}^{+}$, and $\mathrm{Hg}^{2+18}$ and more recently in $95 / 5$ methanol with $\mathrm{Co}^{2+}$, $\mathrm{Ni}^{2+}, \mathrm{Cu}^{2+}, \mathrm{Zn}^{2+}$, and $\mathrm{Cd}^{2+} .{ }^{19}$

## Results

The overall stability constants $\beta_{x y z}$ for the general equilibrium 1 between a cation $\mathrm{M}^{n+}$, a macrocycle L , and protons is given by

$$
\begin{equation*}
x \mathrm{M}^{n+}+y \mathrm{H}^{+}+z \mathrm{~L} \rightleftharpoons \mathrm{M}_{x} \mathrm{H}_{y} \mathrm{~L}_{z}^{(n x+y)+} \tag{1}
\end{equation*}
$$

eq 2. $\beta_{x y z}$, which is a concentration ratio, is an apparent overall

$$
\begin{equation*}
\beta_{x y z}=\left[\mathbf{M}_{x} \mathrm{H}_{y} \mathrm{~L}_{z}^{(n x+y)+}\right] /\left[\mathrm{M}^{n+}\right]^{x}\left[\mathrm{H}^{+}\right]^{y}[\mathrm{~L}]^{z} \tag{2}
\end{equation*}
$$

stability constant. But in the particular case of the formation of 1:1 macrocyclic complexes ( $x=z=1, y=0$ ), as already pointed out by Popov and Lehn, ${ }^{4}$ the value of the apparent stability constant can be assimulated to the thermodynamic stability constant, provided that the ionic strength is not too high, i.e., that the activity factors of the cations do not depend upon their ionic radius. In fact, Popov has shown that the ionic strength $I$ does not modify the stability constants of the complex of crown ethers in methanol up to $I=0.05$. ${ }^{28}$
The technique employed in water was pH measurement (complexation of $\mathrm{Hg}^{2+}$ by 211,221 , and 21 and $\mathrm{Ag}^{+}$by 221 ). In $\mathrm{Me}_{2} \mathrm{SO}$, potentiometric methods were mainly used with a cop-per-selective electrode for the copper complexes and a silver

electrode for the lead complexes. Some of the results obtained with copper were also confirmed by visible-near-IR spectrophotometry. More experimental details are given in the Experimental Section.

Our potentiometric data have been refined by the computer programs SCOGS ${ }^{29}$ or MINIQUAD. ${ }^{30}$ The spectrophotometric data collected at various wavelengths were analyzed by the matrix-rank treatment of Hugus and El -Awady, ${ }^{31}$ which provides the minimum number of species to take into account for the interpretation of the whole set of data. The stability constants and the electronic spectra of the various species in solution have been calculated by the general program Letagrop-spefo. ${ }^{32}$ Figure 2 summarizes some of our previously published results concerning the $1: 1$ complexes given in this paper. The newly determined overall stability constants are listed in Table I with their 95\% confidence interval $\pm 2 \sigma$, and some of them are visualized in Figure 2.

Our previous and new results show that in all cases studied we find $1: 1$ mononuclear species, sometimes accompanied in the protic solvents by protonated $1: 1: 1$ species ( $\mathrm{Cu}^{2+}$ and $\mathrm{Zn}^{2+}$ ). More unexpected is the evidence for binuclear $2: 1$ complexes found in some cases, i.e., in methanol, with all studied cations except $\mathrm{Zn}^{2+}$, and in PC , with $\mathrm{Pb}^{2+}$. Obviously, these binuclear complexes cannot be real inclusion bimetallic complexes as, for instance, the so-called "bis-tren" complexes synthetized by Lehn ${ }^{33}$ and studied in solution by Martell et al..$^{34}$ the cavities of the ligands studied in this work are too small to encapsulate two cations, even the smallest transition cations. Consequently, either both cations are bound outside the cavity or one is inside and the other outside the cavity.

If we now focus our interest on the $1: 1$ mononuclear complexes, the following questions may be answered: (i) what are the medium effects upon the stability constants, (ii) is any size effect observable, as in the case of alkali and alkaline-earth cations, ${ }^{5}$ and (iii) is there evidence for any macrobicyclic effect, i.e., any enhancement of stability of the complexes of bicyclic ligands, compared to the analogue complexes of monocyclic ligands of comparable cavity sizes?
(i) Figure 2 clearly demonstrates that with the five cations $\mathrm{Ag}^{+}$, $\mathrm{Pb}^{2+}, \mathrm{Cd}^{2+}, \mathrm{Cu}^{2+}$, and $\mathrm{Zn}^{2+}$, the stability sequence for a given complex increases in the order $\mathrm{Me}_{2} \mathrm{SO}<\mathrm{H}_{2} \mathrm{O}<\mathrm{MeOH}<\mathrm{PC}$. It is of interest to point out that in their recent study of alkali

[^2]

Figure 2. Logarithms of the stability constants for $\mathrm{Ag}^{+}, \mathrm{Pb}^{2+}, \mathrm{Cd}^{2+}$, $\mathrm{Cu}^{2+}$, and $\mathrm{Zn}^{2+}$ l:1 cryptates vs. the ratio $R$ of the cation ionic radius to the ligand cavity radius.
cation cryptates, Cox et al., ${ }^{9}$ Kolthoff and Chantooni, ${ }^{10}$ Yee et al., ${ }^{25}$ and Bessiere et al. ${ }^{13}$ also find that the stability sequence is identical for all alkali cations but that the stability in water is always lower than in $\mathrm{Me}_{2} \mathrm{SO}$. Thus the stability sequence depends on the type of the cation and is not the same for alkali cation cryptates as for transition- or heavy-metal cation cryptates.
(ii) Concerning size effects, Figure 2 shows evidence of two facts: for a given cation the variation of the stability with the cavity size of the ligand is parallel in all solvents. This conclusion was also reached by Cox et al. ${ }^{9}$ with the monovalent alkali cations, for which they find a selectivity pattern independent of the solvent. A pronounced stability maximum is displayed in all cases by the cryptand 221 except for $\mathrm{Cu}^{2+}$ in water and $\mathrm{Me}_{2} \mathrm{SO}$, where $\mathrm{Cu}-$ $(211)^{2+}$ is the most stable complex. Such a situation is quite understable for the larger $\mathrm{Ag}^{+}$and $\mathrm{Pb}^{2+}$ cations, which fit best inside the cavity of 221 , as can be seen on Figure 2 from the ratio $R$ of the cation ionic radius to the cavity radius. But for the smaller cations $\mathrm{Cu}^{2+}$ and $\mathrm{Zn}^{2+}$, one could have expected on the basis of size considerations, a stability maximum to be reached with the cryptand 211 . When this is not observed it can be due to the partially covalent character of the bonds between the transition cations and the ligands heteroatoms.
(iii) As shown in Table II, in which 221 is compared to 21 and 222 to 22 , a strong bicyclic or cryptate effect is displayed in all solvents by the larger cations $\mathrm{Pb}^{2+}$ and $\mathrm{Ag}^{+}$, and the effect is always more important with 221 than with 222 . For both cations, the smallest effect is observed in $\mathrm{Me}_{2} \mathrm{SO}$. On the contrary, with the smaller copper cation, the macrobicyclic effect is nearly negligible, and even reversed in $\mathrm{Me}_{2} \mathrm{SO}$. No significant macrobicyclic effect was found with the other transition cations.

Table II. The Macrobicyclic Effect

| cations | ligands | water | methanol | $\mathrm{Me}_{2} \mathrm{SO}$ | PC |
| :--- | :--- | :---: | :---: | ---: | ---: |

|  | $222 / 22$ | 0.63 | 0.11 | -0.32 |  |

${ }^{a} 221 / 21=\log \beta_{101}\left(M(221)^{n+}\right)-\log \beta_{101}\left(M(21)^{n+}\right)$ and $222 / 22=$ $\log \beta_{101}\left(\mathrm{M}(222)^{n+}\right)-\log \beta_{101}\left(\mathrm{M}(22)^{n+}\right)$. Cavity sizes from CPK molecular models: ${ }^{20} 221$ (1.10 A), 21 ( $1.0 \AA$ ), 222 ( $1.40 \AA$ ), 22 ( $1.40 \AA$ ).

## Discussion

The stability constants of $1: 1$ alkali cryptates in various solvents have been used in the past 3 years to test the validity of the new extrathermodynamic assumption involving cryptates proposed by Bessiere et al. ${ }^{12,13}$ in which a cryptand L and a cryptate $\mathrm{ML}^{n+}$ undergo the same solvation changes upon transfer from a reference solvent $\mathrm{S}_{0}$ to a solvent S provided that $\mathrm{ML}^{n+}$ is a real inclusion complex.

If $\gamma_{S_{0}}{ }^{S}(i)$ is the transfer activity coefficient of the species $i$ when transferred from $S_{0}$ to S , Bessiere's generalized assumption may be written

$$
\begin{equation*}
\gamma_{\mathrm{S}_{0}} \mathrm{~S}^{\mathrm{S}}\left(\mathrm{ML}^{n+}\right)=\gamma_{\mathrm{S}_{0}} \mathrm{~S}^{\mathrm{S}}(\mathrm{~L}) \tag{3}
\end{equation*}
$$

Quite rigorously, and independent of any extrathermodynamic assumption, the difference between the logarithms of the formation constants of a cryptate $\mathrm{ML}^{n+}$ in the solvents S and $\mathrm{S}_{0}$ is equal to the logarithm of the transfer activity coefficient of the cation $\mathrm{M}^{n+}$ plus the difference $\delta_{\mathrm{S}_{0}} \mathrm{~S}$ between the transfer activity coefficients of the cryptand and the cryptate:

$$
\begin{gather*}
\Delta_{\mathbf{S}_{0}}{ }^{\mathbf{S}}=\log \beta(\mathbf{S})-\log \beta\left(\mathbf{S}_{0}\right)=\log {\gamma_{\mathbf{S}_{0}}}^{\mathbf{S}}\left(\mathbf{M}^{n+}\right)+\delta_{\mathbf{S}_{0}} \mathbf{S}  \tag{4}\\
\delta_{\mathbf{S}_{0}} \mathbf{S}=\log \gamma_{\mathbf{S}_{0}} \mathbf{S}^{\mathbf{S}}(\mathrm{L})-\log \gamma_{\mathbf{S}_{0}} \mathbf{S}^{\mathbf{S}}\left(\mathrm{ML}^{n+}\right) \tag{5}
\end{gather*}
$$

According to Bessiere's proposal, $\delta_{\mathrm{S}_{0}} \mathrm{~S}$ should be equal to 0 , and the experimental value of $\Delta_{\mathbf{S}_{0}}{ }^{\mathbf{S}}$ should be equal to the transfer activity coefficient of the cation $\mathrm{M}^{n+}$, regardless of the solvents $S_{0}$ and $S$ used. Thus, if valid, the assumption should have the great advantage of providing a new method for the determination of transfer activity coefficients of cations. This method would find its most interesting application with divalent cations, as the measurement of their transfer activity coefficients based upon other extrathermodynamic assumptions is often subject to serious restrictions. ${ }^{35}$

Of course, one cannot prove whether an extrathermodynamic assumption is right or not, but one can compare the results derived from two different extrathermodynamic assumptions and analyze whether they are self-consistent or not.

In this respect, all conclusions concerning the transfer properties of the cryptates of the monovalent alkali, $\mathrm{Ag}^{+}$and $\mathrm{Tl}^{+}$, cations imply the well-known and widely used tetraphenylarsonium tetraphenylborate assumption: $\gamma_{\mathrm{S}_{0}}{ }^{\mathrm{S}}\left(\mathrm{Ph}_{4} \mathrm{As}^{+}\right)=\gamma_{\mathrm{S}_{0}}{ }^{\mathrm{S}}\left(\mathrm{Ph}_{4} \mathrm{~B}^{-}\right)^{36}$ for the estimation of $\gamma_{\mathrm{S}_{0}}{ }^{\mathbf{S}}\left(\mathrm{M}^{+}\right)$.

The first conclusions were established with the ligand 222 and the cations $\mathrm{K}^{+}, \mathrm{Ag}^{+}$, and $\mathrm{Tl}^{+}$, which fit closely inside the cavity of the cryptand. The quantity $\delta_{S_{0}}$ S was found to be equal to 0 only if $S_{0}$ and $S$ are two dipolar aprotic solvents. ${ }^{7.10}$ If the reference solvent $\mathrm{S}_{0}$ is water and S is a dipolar aprotic solvent, $\delta_{\mathrm{H}_{2} \mathrm{O}} \mathrm{S}$ is found to be approximately constant for these cations, whatever $S(\delta=$ 3.75 according to ref 7 ), whereas a slightly different value was found for the smaller $\mathrm{Na}^{+}$cation. ${ }^{10}$ If the transfer occurs between water and methanol, no constancy of $\delta_{\mathrm{H}_{2} \mathrm{O}} \mathrm{MeOH}$ was observed, probably due, as suggested by Kolthoff et al. ${ }^{10}$ and by Abraham et al., ${ }^{14-18}$ to the hydrophobic solvation of $\mathrm{LM}^{n+}$ in water and to a lesser extent to the fact that methanol is an H-bonding solvent. The detailed investigations of Abraham and co-workers, all devoted

[^3]to the transfer of monovalent 222 cryptates from water to methanol, confirm that for this case Bessiere's assumption is not consistent with the $\mathrm{Ph}_{4} \mathrm{As}^{+} / \mathrm{Ph}_{4} \mathrm{~B}^{-}$assumption: strong deviations are observed for the small $\mathrm{Li}^{+}$cation and for the large $\mathrm{Cs}^{+}$cation.

Further studies concerning the complete series of alkali cations and the other cryptands 221 and $211^{8,9,11}$ are in agreement with the above conclusions and point out the fact that the constancy of $\delta_{S_{0}}$ S only applies to the real inclusive cryptates defined by Popov and Lehn. ${ }^{4}$

The transfer properties of divalent cation cryptates have been much less studied. Only transfers from water to PC and DMF (dimethylformamide) of $\mathrm{CaL}^{2+}(\mathrm{L}=211,221 \text {, and } 222)^{9}$ and transfer of $\mathrm{BaL}^{2+}(\mathrm{L}=222$ and dibenzo-222) from water to methanol ${ }^{11}$ have been investigated very recently. Both studies suggest large differences between the solvation of cryptates of monovalent and divalent cations.
In the present state of investigations about the extrathermodynamic assumption involving cryptates, our results bring forth the following new contributions; (i) they concern more cryptates of divalent cations $\left(\mathrm{Pb}^{2+}, \mathrm{Cu}^{2+}, \mathrm{Cd}^{2+}\right)$ and (ii) they enable a comparison between the transfer properties of bicyclic and monocyclic diazapolyoxamacrocyclic complexes. This latter point is of particular interest for testing the validity of Bessiere's assumption, as there is no obvious reason why it should also apply to complexes of monocyclic ligands where the cation is certainly much less shielded from the solvent than in cryptates.

Table III gives our experimental $\Delta$ values for the transfers from water to methanol, PC , and $\mathrm{Me}_{2} \mathrm{SO}$.
(a) At first sight, the $\Delta$ values concerning the bicyclic ligands seem, in most cases, to be roughly independent of the nature of the cryptand. The only exceptions concern $\mathrm{Pb}(211)^{2+}$, which has a very different behavior than $\mathrm{Pb}(221)^{2+}$ and $\mathrm{Pb}(222)^{2+}$, and the cadmium cryptates of 221 and 222 , for which no constancy of $\Delta_{\mathrm{H}_{2} \mathrm{O}} \mathrm{MeOH}$ is observed. One could be tempted to explain the particular behavior of $\mathrm{Pb}(211)^{2+}$ by the fact that it is not an inclusive complex, but the same could also be said for $\mathrm{Ag}(211)^{+}$, which however does not display any singular behavior. Other factors probably have to be considered to explain the particular behavior of $\mathrm{Pb}(211)^{2+}$. The relative constancy of $\Delta$ displayed by most of the bicyclic systems investigated in this work enables the definition of mean $\Delta$ values for bicyclic systems, noted $\bar{\Delta}_{B}$, which can be calculated with their experimental uncertainty (see Table III).

The results concerning the monocyclic systems are interesting in two respects. First, as with bicyclic ligands, for a given transfer and a given cation, $\Delta$ is often independent of the nature of the ligand, except for lead complexes transferred from water to PC ( $\Delta_{\mathrm{H}_{2} \mathrm{O}} \mathrm{PC}$ being respectively equal to 2.8 and 4.7 for 21 and 22 ) and for silver complexes transferred from water to $\mathrm{Me}_{2} \mathrm{SO}$ ( $\Delta_{\mathrm{H}_{2} \mathrm{O}} \mathrm{Me}_{2} \mathrm{SO}$ being respectively -0.7 and -1.7 for 21 and 22 ). When possible, the mean $\bar{\Delta}_{\mathrm{M}}$ values for the monocyclic systems are also given in Table III. Second, for the transfers from water to methanol, the $\bar{\Delta}_{\mathrm{M}}$ values are not significantly different from the corresponding $\bar{\Delta}_{\mathrm{B}}$ values, whereas both sets of values are significantly different for transfers from water to $\mathrm{Me}_{2} \mathrm{SO}$. This observation confirms that Bessiere's assumption is more justified for transfers to dipolar aprotic solvents than to methanol and extends this conclusion to divalent cations. Our $\bar{\Delta}_{M}$ values for transfers from $\mathrm{H}_{2} \mathrm{O}$ to $\mathrm{Me}_{2} \mathrm{SO}$ are less negative than the corresponding $\bar{\Delta}_{\mathrm{B}}$ values (see Table III). According to eq 4 and 5 , if $\bar{\Delta}_{\mathrm{M}}>\bar{\Delta}_{\mathrm{B}}$, the quantity $\log \gamma_{\mathrm{H}_{2} \mathrm{O}} \mathrm{Me}_{2} \mathrm{SO}(\mathrm{L})-\log \gamma_{\mathrm{H}_{2} \mathrm{O}} \mathrm{Me}_{2} \mathrm{SO}\left(\mathrm{ML}^{n+}\right)$ is greater for the monocyclic systems than for the bicyclic ones. Consequently, with $\mathrm{L}_{\mathrm{B}}$ and $\mathrm{L}_{\mathrm{M}}$ being respectively the bicyclic and the monocyclic diazapolyoxamacrocycles,

$$
\begin{align*}
& \log \gamma_{\mathrm{H}_{2} \mathrm{O}}{ }^{\mathrm{Me}_{2} \mathrm{SO}}\left(\mathrm{~L}_{\mathrm{B}}\right)-\log \gamma_{\mathrm{H}_{2} \mathrm{O}} \mathrm{Me}_{2} \mathrm{SO}\left(\mathrm{~L}_{\mathrm{M}}\right)< \\
& \quad \log \gamma_{\mathrm{H}_{2} \mathrm{O}}{ }^{\mathrm{Me}_{2} \mathrm{SO}}\left(\mathrm{ML}_{\mathrm{B}}{ }^{n+}\right)-\log \gamma_{\mathrm{H}_{2} \mathrm{O}}{ }^{\mathrm{Me}_{2} \mathrm{SO}}\left(\mathrm{ML}_{\mathrm{M}^{n+}}\right) \tag{6}
\end{align*}
$$

Thus upon transfer from water to $\mathrm{Me}_{2} \mathrm{SO}$, the difference in the solvation changes undergone by the free mono- and bicyclic diazapolyoxamacrocycles is less important than for corresponding complexes.

Table IV shows a comparison between the mean $\bar{\Delta}_{B}$ values and

the most reliable literature values for $\log \gamma_{\mathrm{H}_{2} \mathrm{O}}{ }^{\mathrm{S}}\left(\mathrm{M}^{n+}\right)$ derived from the $\mathrm{Ph}_{4} \mathrm{As}^{+} / \mathrm{Ph}_{4} \mathrm{~B}^{-}$assumption. In the few cases in which both quantities are known, two remarks can be made: (i) $\bar{\Delta}_{\mathrm{B}}$ and $\log$ $\gamma_{\mathrm{H}_{2}} \mathrm{O}^{\mathrm{S}}\left(\mathrm{M}^{n+}\right)$ are always the same sign and (ii) they are not of equal magnitude. This confirms the conclusion previously established for the transfer from water to a solvent $S$ of monovalent cryptates ( $\delta_{\mathrm{H}_{2} \mathrm{O}} \mathrm{S}^{\mathrm{S}} \neq 0$ ) and extends it to the divalent copper cryptates. It is regrettable that no value for $\gamma_{\mathrm{H}_{2} \mathrm{O}} \mathrm{s}\left(\mathrm{Pb}^{2+}\right)$ based upon the $\mathrm{Ph}_{4} \mathrm{As}^{+} / \mathrm{Ph}_{4} \mathrm{~B}^{-}$assumption can be found in the literature and that, consequently, our data on lead complexes cannot be further discussed. The only case for which we find a $\bar{\Delta}_{\mathrm{B}}$ value not very different from $\log \gamma_{\mathrm{S}_{0}}{ }^{\mathrm{s}}\left(\mathrm{M}^{n+}\right)$ concerns silver cryptates transferred from water to methanol. A similar agreement between both quantities has also been found recently by Kolthoff and Chantooni for the transfer of $\mathrm{Ba}(222)^{2+}$ from water to methanol (see Table IV). As this transfer is precisely the case in which Bessiere's assumption seems to be less applicable, the observed agreement is probably fortuitous. ${ }^{11}$

${ }^{a}$ From ref $9 .{ }^{b}$ Data from ref 11. ${ }^{c}$ Mean value of the data from ref 15,9 , and $11 .^{d}$ Data from ref 35.

The constant value $\delta_{\mathrm{H}_{2} \mathrm{O}} \mathrm{S}=3.75$ proposed by Gutknecht and co-workers ${ }^{7}$ for the transfer of monovalent cryptates from water to a dipolar aprotic solvent applies very well to our results, as it provides, for $\mathrm{Ag}^{+}$, a value of $\left(\bar{\Delta}_{\mathrm{B}}-3.75\right)$ close to $\log \gamma_{\mathrm{H}_{2} \mathrm{O}} \mathrm{s}\left(\mathrm{Ag}^{+}\right)$ (with $\mathrm{S}=\mathrm{PC}$ or $\mathrm{Me}_{2} \mathrm{SO}$ ). For the transfer from water to $\mathrm{Me}_{2} \mathrm{SO}$ of copper cryptates, we find a positive value of $\delta_{\mathrm{H}_{2} \mathrm{O}} \mathrm{Me}_{2} \mathrm{SO}=-3.9$ $+8.8=4.9$, which is significantly larger than 3.75 . But no further information about the magnitude of $\delta_{\mathrm{H}_{2}} \mathrm{~S}$ for divalent cations cryptates ( S being a dipolar aprotic solvent) can be obtained for the moment, as the transfer activity coefficients $\gamma_{\mathrm{H}_{2} \mathrm{O}} \mathrm{S}$ of $\mathrm{Pb}^{2+}$ and $\mathrm{Ca}^{2+}$, for which stability constants of the cryptates in various solvents are available, have not yet been determined on the basis of the $\mathrm{Ph}_{4} \mathrm{As}^{+} / \mathrm{Ph}_{4} \mathrm{~B}^{-}$assumption.
(b) A sharper analysis of the individual $\Delta$ values for each complex (listed in Table III) can be attempted by taking into account the determinations of the transfer activity coefficients of the free cryptands, recently performed by Abraham et al., ${ }^{15}$

Cox et al., ${ }^{9}$ and Kolthoff et al. ${ }^{11}$ (see Table V). The knowledge of $\log \gamma_{\mathrm{H}_{2} \mathrm{O}}{ }^{\mathrm{S}}\left(\mathrm{M}^{n+}\right)$, according to the $\mathrm{Ph}_{4} \mathrm{As}^{+} / \mathrm{Ph}_{4} \mathrm{~B}^{-}$assumption, and of $\log \gamma_{\mathrm{H}_{2} \mathrm{O}} \mathrm{S}(\mathrm{L})$ enables the calculation of $\log \gamma_{\mathrm{H}_{2} \mathrm{O}}{ }^{\mathrm{S}}\left(\mathrm{ML}^{n+}\right)$ from eq 4 and 5. Table $V$ gives the calculated values of log $\gamma_{\mathrm{H}_{2} \mathrm{O}}{ }^{\mathrm{S}}\left(\mathrm{ML}^{n+}\right)$ for the cryptates of $\mathrm{Ag}^{+}$and of the divalent cations $\mathrm{Cu}^{2+}$ and $\mathrm{Cd}^{2+}$. Literature values for the 222 cryptates of $\mathrm{Ba}^{2+}$, $\mathrm{Na}^{+}, \mathrm{K}^{+}$, and $\mathrm{Tl}^{+}$are listed in Table V for comparison purposes.

For the transfer from water to methanol, $\log \gamma_{\mathrm{H}_{2} \mathrm{O}} \mathrm{MeOH}_{\left(\mathrm{ML}^{+}\right)}$ is found to be negative for alkali cations cryptates, ${ }^{11}$ the monocharged cryptates being more solvated in methanol than in water. We find a positive and quite large $\log \gamma_{\mathrm{H}_{2} \mathrm{O}}{ }^{\mathrm{MeOH}}\left(\mathrm{ML}^{2+}\right)$ value for $\mathrm{Cu}^{2+}$ and $\mathrm{Cd}^{2+}$ cryptates, respectively about 3 and 5-7. Thus, on the basis of the $\mathrm{Ph}_{4} \mathrm{As}^{+} / \mathrm{Ph}_{4} \mathrm{~B}^{-}$assumption, the cryptates of $\mathrm{Cu}^{2+}$ and $\mathrm{Cd}^{2+}$ are more solvated in water than in methanol, as also found for the free ligands and the free divalent cations. The difference $\delta=\log \gamma(\mathrm{L})-\log \gamma\left(\mathrm{ML}^{n+}\right)$, which measures the deviation from Bessiere's proposal, is negative for cryptates of $\mathrm{Cu}^{2+}$ and $\mathrm{Cd}^{2+}$ and is positive for the monovalent cryptates. The absolute value of $\delta$, though, is not higher for $\mathrm{Cu}^{2+}$ cryptates than for some alkali cation cryptates, and in both cases, Bessiere's assumption is not consistent with the tetraphenylarsonium assumption.

The values of $\log \gamma_{\mathrm{H}_{2} \mathrm{O}}{ }^{\mathrm{MeOH}}$ ( $\mathrm{ML}^{n+}$ ) obtained by Kolthoff and Chantooni ${ }^{11}$ and by us for barium and silver cryptates, respectively, are intermediate between the results for alkali cation cryptates and for $\mathrm{Cu}^{2+}$ and $\mathrm{Cd}^{2+}$ cryptates, $\log \gamma_{\mathrm{H}_{2} \mathrm{O}}{ }^{\mathrm{MeOH}}\left(\mathrm{ML}^{n+}\right) \neq 0$, and the apparent agreement with Bessiere's assumption observed in these cases is probably fortuitous.

Our data for the transfer from water to dimethyl sulfoxide show that $\log \gamma_{\mathrm{H}_{2} \mathrm{O}}{ }^{\mathrm{MeSO}}\left(\mathrm{M}(222)^{n+}\right)$ is negative for $\mathrm{Ag}^{+}$and $\mathrm{Cu}^{2+}$ cryptates, as it is for the free cations. Both the free cations and the cryptates are more solvated in $\mathrm{Me}_{2} \mathrm{SO}$ than in water, whereas the free 222 is more solvated in water than in $\mathrm{Me}_{2} \mathrm{SO}$. Nevertheless, the solvation changes are more important for the free cations than for the cryptates.

The situation is different for the transfer of silver cryptates from water to $P C$, as $\log \gamma_{\mathrm{H}_{2} \mathrm{O}}{ }^{\mathrm{PC}}\left(\mathrm{Ag}(222)^{+}\right)$and $\log \gamma_{\mathrm{H}_{2}} \mathrm{OC}^{\mathrm{PC}}\left(\mathrm{Ag}^{+}\right)$ are of opposite sign: the free silver cation, as uncomplexed 222 is more solvated in water, whereas the cryptate $\mathrm{Ag}(222)^{+}$is more solvated in PC than in water. This last result is surprising, considering that PC is ordinarily a poor solvating solvent for cations. From the results of Cox et al., ${ }^{9}$ the same conclusion can be reached for $\mathrm{Na}(222)^{+}: \log \gamma_{\mathrm{H}_{2} \mathrm{O}}{ }^{\mathrm{PC}}\left(\mathrm{Na}(222)^{+}\right)=-3.8$ with $\log$

## Experimental Section

The preparation and purification of the chemicals and solvents as well as the experimental techniques used for all studies in water, methanol, and propylene carbonate and for the study of $\mathrm{Ag}^{+}$complexes in $\mathrm{Me}_{2} \mathrm{SO}$ have been described in our earlier papers. ${ }^{20-24}$
The copper perchlorate solvate in $\mathrm{Me}_{2} \mathrm{SO}$ was prepared from Cu $\left(\mathrm{ClO}_{4}\right)_{2} \cdot 6 \mathrm{H}_{2} \mathrm{O}$ (Alfa-Ventron p a) that had been dried at $70^{\circ} \mathrm{C}$ under reduced pressure for 12 h before being dissolved in $\mathrm{Me}_{2} \mathrm{SO}$. The solution thus obtained was concentrated by evaporation under 15 mmHg at 80 ${ }^{\circ} \mathrm{C}$. The solvate, which precipitated on cooling, was recrystallized three times and dried under 1 mmHg for 12 h . The carbon and hydrogen content (respectively 16.62 and $4.14 \%$ ) correspond to the tetrasolvate $\mathrm{Cu}\left(\mathrm{ClO}_{4}\right)_{2} \cdot 4 \mathrm{Me}_{2} \mathrm{SO}$ (theoretical composition: $\mathrm{C}, 16.69 ; \mathrm{H}, 4.17$ ).

The copper complexes in $\mathrm{Me}_{2} \mathrm{SO}$ were studied with a copper cation selective electrode, in the following electrochemical cell:

$$
\mathrm{Cu}_{x} \mathrm{Ag}_{y} \mathrm{~S} \mid \mathrm{Cu}\left(\mathrm{ClO}_{4}\right)_{2}\left(c_{\mathrm{c}_{\mathrm{C}}}\right),
$$

$$
\mathrm{Et}_{4} \mathrm{NClO}_{4} 0.1 \mathrm{M}^{2} \mathrm{Et}_{4} \mathrm{NClO}_{4} 0.1 \mathrm{M}_{\|} \mid \mathrm{Et}_{4} \mathrm{NClO}_{4} 0.09 \mathrm{M},
$$ $\mathrm{AgClO}_{4} 0.01 \mathrm{M} \mid \mathrm{Ag}_{5}$

In the range $10^{-5} \mathrm{M}<\mathrm{Cu}^{2+}<10^{-2} \mathrm{M}$, the slope of the linear plot $E$ $=f\left(\log \left[\mathrm{Cu}^{2+}\right]\right)$ was found to equal 0.0290 V instead of the theoretical slope 0.0296 V , as already noticed by Coetzee and Istone. ${ }^{35}$ The stability constants thus determined are in good agreement with those obtained by spectrophotometry.
The lead complexes in $\mathrm{Me}_{2} \mathrm{SO}$ were determined by a competition method with $\mathrm{Ag}^{+}$by using a silver electrode in the following electrochemical cell:

$$
\begin{aligned}
& \mathrm{Ag}_{\mathrm{s}} \mid \mathrm{AgClO}_{4}\left(c_{\mathrm{Ag}^{\prime}}\right), \mathrm{Pb}\left(\mathrm{ClO}_{4}\right)_{2}\left(c_{\mathrm{pb}_{\mathrm{P}}}\right), \\
& \mathrm{Et}_{4} \mathrm{NClO}_{4} 0.1{\mathrm{M} \| \mathrm{Et}_{4} \mathrm{NClO}_{4} 0.1 \mathrm{M}| | \mathrm{Et}_{4} \mathrm{NClO}_{4} 0.09 \mathrm{M},}_{\mathrm{AgClO}_{4} 0.01 \mathrm{M} \mid \mathrm{Ag}_{5}}
\end{aligned}
$$

After calibration of the silver electrode in the range $5 \times 10^{-5} \mathrm{M}<\mathrm{Ag}^{+}$ $<10^{-2} \mathrm{M}$, the ligand solution (about $5 \times 10^{-2} \mathrm{M}$ ) was added stepwise with a $1-\mathrm{mL}$ "Manostat" microburet to a solution of anhydrous silver perchlorate ( $2 \times 10^{-3} \mathrm{M}$ ) and lead nitrate ( $10^{-3} \mathrm{M}$ ). After each addition, the system was stabilized within less than 1 min .

All experiments were performed in $40-\mathrm{mL}$ thermostated quartz cells at $25^{\circ} \mathrm{C}$ under argon flushing, and with a total ionic strength of $10^{-1} \mathrm{M}$ adjusted by $\mathrm{Et}_{4} \mathrm{NClO}_{4}$.
