

isoenergetic with the  $\text{Ru}^{2+}$  Fermi level. This condition requires that their energy levels be about 2.5 V below the Fermi level of the hydrocarbon chain. It is difficult to imagine, however, the sort of molecular organization that would lead to orbital stabilization to this extent. Ultimately, electron transfer may prove to be more appropriately described in terms of superexchange-type coupling mechanisms, e.g., as discussed by Jortner.<sup>5a</sup> In this regard, both the phosphatidylcholine monomers and alkyl substituent chain of the ruthenium coordination complex used in these studies possess olefinic unsaturation, the relatively low-lying unoccupied orbitals of which might engage in electronic mixing with donor and acceptor orbitals. Current research is directed

at characterizing the rate-influencing factors inherent in the ligand and membrane molecular structures.

## Infrared Spectra of $\text{MeMn}(\text{CO})_5$ and $\text{MeRe}(\text{CO})_5$ Species: Methyl Group Geometry and the Effects of Internal Rotation

C. Long,<sup>1a</sup> A. R. Morrisson,<sup>1b</sup> D. C. McKean,\* and G. P. McQuillan

Contribution from the Department of Chemistry, University of Aberdeen, Aberdeen AB9 2UE, Scotland. Received June 14, 1984

**Abstract:** Infrared spectra in the CH and CD stretching regions are reported for various  $\text{MeMn}(\text{CO})_5$  and  $\text{MeRe}(\text{CO})_5$  species. Interpretation is made in terms of a freely internally rotating methyl group whose individual bond-stretching force constants vary during the rotation. The "average" "isolated" CH stretching frequencies of 2955.0 and 2934.6  $\text{cm}^{-1}$  observed in the  $\text{CHD}_2$  spectra are used to predict  $r_0^{\text{CH}}$  values of 1.095, Å (Mn) and 1.098, Å (Re), respectively, HCH angles,  $A_0$ , and  $D^\circ_{298}(\text{C-H})$  values. The CH bonds are of medium strength, that in the Re compound being slightly weaker than the Mn one and displaying an inverse relationship to  $D(\text{M-CH}_3)$ .

The methyl pentacarbonyls of manganese and rhenium have been the subject of a number of structural studies, involving gas-phase electron diffraction<sup>2,3</sup>, X-ray diffraction and incoherent inelastic neutron scattering,<sup>4</sup> and vibrational spectroscopy.<sup>4-8</sup> These have left uncertain two structural features associated with the methyl group, its geometry, and its internal rotational motion. The disordered structure of the Mn crystal meant that no geometric information could be obtained from the X-ray study, while the hydrogen positions were not located by the electron-diffraction experiments.<sup>2,3</sup> This situation may be remedied through a study of the CH stretching region of the  $\text{CHD}_2$  species, from whose "isolated" CH stretching frequencies, bond lengths and HCH angles may be predicted by the use of correlation graphs.<sup>9a,b</sup>

Prior evidence relating to the internal rotation problem in the Mn compound is of three kinds. A Raman line at 174  $\text{cm}^{-1}$  and part of a broad IINS feature at 169  $\text{cm}^{-1}$ , both in the crystal at 10 K, have been assigned to a torsional mode of the  $\text{CH}_3$  group.<sup>4</sup> As discussed below, this would be impossible with a  $V_{12}$  potential term and would require a high barrier of  $>350 \text{ cm}^{-1}$  with a  $V_4$  one. The second and third observations are from infrared spectra and apparently conflict with each other. The antisymmetric

stretching mode of the methyl group is split into two components in the gas phase, while in solution and in the solid it presents a single broad band whose width varies little with temperature.<sup>6</sup> The latter observation leads to an estimate of the barrier height of  $944 \pm 175 \text{ cm}^{-1}$ .<sup>24</sup>

Here again the infrared study of partially deuterated species may throw some light, at the cost, however, of introducing a further complication. Previous work in this field<sup>8a</sup> has revealed a variety of circumstances in which CH bonds within a methyl group vary in strength according to their angular position within the molecule. Where internal rotation is restricted, these have straightforward effects in the spectra. Infrared bands appear at frequencies corresponding to bonds in each of the various potential minima. However, for the case of low barriers, as in  $\text{MeNO}_2$ ,  $\text{MePh}$ ,<sup>10,11</sup>  $\text{MeBF}_2$ ,  $\text{MeBCl}_2$ ,  $\text{Me}_3\text{B}$ , and  $(\text{MeBO})_3$ ,<sup>12</sup> the spectra and their interpretation are more complex. Theoretical treatments of a  $\text{CH}_3$  group and of a  $\text{CHD}_2$  one rotating against an infinitely heavy, planar skeleton, as in the above molecules, have been given by Sheppard and Woodman<sup>13</sup> and Cavagnat and Lascombe<sup>11</sup> (hereafter SW and CL, respectively).

Taken together, this prior work yields strong evidence for a variation of CH bond strength during the essentially free internal rotation in the above cases. While no corresponding theory exists for the vibration-rotation transitions of a methyl group rotating against a  $C_{4v}$  skeleton, as in the pentacarbonyls, features similar to the earlier ones may reasonably be expected to occur if the barrier is likewise very low. Since this work is little known, it will be necessary to give a more detailed review of it before we can conduct a meaningful discussion of the pentacarbonyl spectra.

Vibrational Spectra of  $\text{Me}_2\text{M}$ ,  $\text{MeXY}_2$ , and  $\text{MeXYZ}$  (Planar Skeleton) Systems

(a) **High-Barrier Case (Local  $C_s$  Symmetry).** In systems such as  $\text{CH}_3\text{CHO}$ ,  $\text{CH}_3\text{CH}=\text{CH}_2$ ,<sup>14</sup> and *o*-xylene<sup>15</sup> there is a relatively high barrier to internal rotation of the methyl group which adopts a conformation in which one bond, designated  $\text{CH}_s$  or  $\text{CH}_\parallel$  lies in the skeletal plane of the molecule, and the other two lie above and below it, respectively ( $\text{CH}_a$ ), but not of course in a plane at right angles to the skeletal one for which we reserve the symbol  $\text{CH}_\perp$ . Two  $\nu^{\text{as}}(\text{CH})$  bands<sup>16</sup> are seen, the higher frequency one due to  $\text{CH}_s$  and the lower to the two  $\text{CH}_a$  bonds. These may be identified by means of their band contours, or through the use of the frequency sum rule<sup>17</sup> for CH stretches:  $\sum_i^3 \nu^{\text{as}}(\text{CH}) = \sum_i^3 \nu(\text{CH}_3)$ . Use of this rule of course necessitates initially correcting the  $\text{CH}_3$  group frequencies for the universal Fermi resonances, on  $\nu_s(\text{CH}_3)$  especially. A slightly more sophisticated approach is to interrelate the  $\nu^{\text{as}}(\text{CH})$  and  $\nu(\text{CH}_3)$  frequencies through the "3 × 3" refinement<sup>18</sup> which essentially deduces stretch-stretch interaction force constants from the displacements of the  $\nu_{\text{as}}(\text{CH}_3)$  frequencies from the  $\nu^{\text{as}}(\text{CH})$  ones.<sup>19</sup> If an incorrect assignment has been made, anomalous values of these interaction constants appear.

(b) **Low-Barrier Systems.** (i)  **$\text{Me}_2\text{M}$  Systems (M = Zn, Cd, Hg).** In this series of molecules, the barrier to internal rotation is very low indeed and the perpendicular bands of the  $\text{CH}_3$  or  $\text{CD}_3$  species exhibit K spacings characteristic of a single, freely internally rotating methyl group. No variation of CH stretching force constant with orientation seems likely, and the  $\text{CHD}_2$  spectrum is in agreement with this.<sup>20</sup> As seen in Figure 1, for  $\text{Zn}(\text{CHD}_2)_2$ , the CH stretching band is hybrid in nature, with both parallel and perpendicular components, the latter showing broad Q branches with a spacing appropriate for a single  $\text{CHD}_2$  rotor.

(ii)  **$\text{CHD}_2\text{XY}_2$  Systems.** The vibration-internal rotation levels and the resulting infrared and Raman spectra have been treated by CL.<sup>11</sup> The effect of a change in CH force constant during the internal rotation is introduced through a large  $V_2$  term and a smaller  $V_4$  term which are added to the small  $V_6$  term derived from the conventional barrier to rotation. A curious result of this in the two cases studied, i.e.,  $\text{CHD}_2\text{NO}_2$  and  $\text{CHD}_2\text{Ph}$ , is that the minimum in the torsional potential in the ground vibrational state is determined by the zero-point energy of the single CH bond, which is a minimum when this bond is at right angles to the skeletal plane ( $\text{CH}_\perp$ ). The torsional potential barrier in the first excited vibrational state is derived almost wholly from the  $V_2$  and  $V_4$  terms and is much greater than that in the ground state, but not so great as to prevent many transitions occurring to states well above the barrier, both in the Raman isotropic scattering spectrum and in the infrared. The former yields a frequency which is an *average* over all torsional angles, and the same average band appears with a type A contour in the infrared from the component of the dipole derivative parallel to the top axis. A small number of transitions from the ground torsional states give rise to Raman and infrared bands at the frequency  $\nu(\text{CH}_\perp)$ , the infrared one having a type C contour. Components of  $(\partial\mu/\partial r)_{\text{CH}}$  perpendicular to the top axis produce two irregular series of frequencies respectively above and below  $\nu(\text{CH})^{\text{av}}$ . Thus far theory and experiment agree satisfactorily. Earlier infrared spectra of  $\text{CHD}_2\text{BY}_2$  compounds,<sup>12</sup> however, were fundamentally different in appearance from those of  $\text{CHD}_2\text{NO}_2$  or  $\text{CHD}_2\text{Ph}$  in that two broad bands of similar intensity were seen in each case, the lower one of which in several instances had a contour recognizably type

Figure 1. Infrared spectrum of  $\text{Zn}(\text{CHD}_2)_2$  in the gas phase (resolution  $0.12 \text{ cm}^{-1}$ ) showing parallel and perpendicular components of the hybrid  $\nu(\text{CH})$  band, the latter with K spacing characteristic of a freely internally rotating  $\text{CHD}_2$  group with unvarying force constant.<sup>20</sup>

C in character. The Raman spectrum in each case consisted of a single, broad, often asymmetric line intermediate in frequency between those of the two infrared bands. The relationship between these frequencies suggested that the Raman one was  $\nu(\text{CH})^{\text{av}}$ , as in the  $\text{CHD}_2\text{NO}_2$  and  $\text{CHD}_2\text{Ph}$  cases, whereas the upper and lower infrared bands represented  $\nu(\text{CH}_\parallel)$  and  $\nu(\text{CH}_\perp)$ , respectively, arising from the *x* and *y* components of  $(\partial\mu/\partial r)_{\text{CH}}$ .<sup>21</sup> The absence of  $\nu(\text{CH})^{\text{av}}$  in the infrared was attributed to a negligible *z* component of  $(\partial\mu/\partial r)_{\text{CH}}$ , which idea is supported by the absence or low intensity of  $\nu_s(\text{CH}_3)$  in the  $\text{CH}_3\text{BY}_2$  infrared spectra. The principal weakness of the above interpretation is the lack of any theoretical basis for assigning the higher band as  $\nu(\text{CH}_\parallel)$  since existing theory predicts only an irregular series of K lines above  $\nu(\text{CH})^{\text{av}}$ , whose center of gravity is indeterminate.<sup>22</sup> There seems little doubt, however, that in all these molecules the CH bond strength is a maximum in the skeletal plane ( $\nu(\text{CH}_\parallel)$ ), and a minimum at right angles to it ( $\nu(\text{CH}_\perp)$ ).

(iii)  **$\text{CH}_3\text{XY}_2$  Species.** If one assumes a  $\cos 2\phi$  ( $V_2$ ) variation in the strength of each individual CH bond, the 3 × 3 refinement shows that the  $\text{CH}_3$  group has three different vibration frequencies which remain essentially constant for different chosen internal rotation angles, the higher two of course being essentially anti-symmetric motions. For the conformation I in Figure 2A the symmetry coordinates  $2r_1 - r_2 - r_3$  and  $r_2 - r_3$  describe the higher and lower antisymmetric stretches, respectively (the former approximately, the latter exactly): however, after a 90° rotation in which II is reached, the frequencies have been reversed. This situation is the one treated by SW<sup>13</sup> for the case of a  $\text{CH}_3$  group, also rotating against an infinitely heavy framework, the in-plane higher frequency  $\nu_{\text{as}}(\parallel)$  and the out-of-plane lower one  $\nu_{\text{as}}(\perp)$  being assumed to be precisely constant.<sup>23</sup> The perturbation to the vibration-internal rotation levels, which is produced by this change in vibration frequency of a particular symmetry coordinate during internal rotation, causes a hole to develop in the perpendicular type band which would have arisen if the two vibrations had been degenerate. No K transitions in fact occur within the limits  $\nu^{\text{av}} \pm \frac{1}{2}\Delta\nu$  which describe the maximum ( $\nu_{\text{as}}(\text{CH}_3)(\parallel)$ ) and minimum ( $\nu_{\text{as}}(\text{CH}_3)(\perp)$ ) frequencies, respectively. For fast rotation, at high

(19) This is another example of an "energy factored" force field more familiar as applied to CO stretches in organometallic compounds.

(20) McKean, D. C.; McQuillan, G. P.; Thompson, D. W. *Spectrochim. Acta, Part A* **1980**, *36A*, 1009.

(21)  $\text{BMe}_3$  appears to be a special case not readily interpretable on any model.

(22) Since in the model assumed the  $\text{XY}_2$  portion is assumed to be infinitely heavy.

(23) Calculation of the  $\nu_{\text{as}}(\text{CH}_3)$  frequencies with both  $V_2$  and  $V_4$  terms as found in  $\text{CHD}_2\text{NO}_2$  and  $\text{CHD}_2\text{Ph}$ <sup>11</sup> leads to two frequencies which are far from being constant during rotation, the variation in each being about  $20 \text{ cm}^{-1}$ . This would necessitate a modification of the SW treatment.

**Figure 2.** The description of the high ( $\nu_1$ ) and low ( $\nu_2$ )  $\nu_{as}(\text{CH}_3)$  vibrations for various internal rotation angles,  $\phi$ , over a half cycle: (A)  $\text{CH}_3\text{XY}_2$  and (B)  $\text{CH}_3\text{XY}_4$  systems.

K values, the K spacings settle down to those expected for a normal perpendicular band with  $\nu_0 = \nu^{av} \pm A(1 - 2\zeta)$ . The treatment does not take into account the overall rotation of the molecule so that quantitative prediction of actual band contours is not possible. However, in all planar  $\text{MeXY}_2$  systems, type C contours may be expected from transitions in the neighborhood of  $\nu_{as}(\text{CH}_3)(\perp)$ , while those near  $\nu_{as}(\text{CH}_3)(\parallel)$  give rise to type B contours in  $\text{MeNO}_2$ ,  $\text{MePH}$ , and  $\text{MeBF}_2$  but a type A one in  $\text{MeBCl}_2$ . The extent to which such contours may be discerned is discussed by Dempster, Powell, and Sheppard,<sup>24</sup> in connection with the spectra of  $\text{C}_6\text{H}_5\text{-CD}_3$  and  $\text{C}_6\text{D}_5\text{-CH}_3$ , and appears to depend on the magnitude of the vibrational splitting [ $\nu_{as}(\parallel) - \nu_{as}(\perp)$ ] relative to the K line separation, which of course reflects the inertial constant of the rotating group. Thus, much better defined A-, B-, or C-type contours are expected, and usually found, for  $\text{CD}_3$  species than for  $\text{CH}_3$  ones. The well-defined centers of such contours surely then define  $\nu_{as}(\parallel)$  and  $\nu_{as}(\perp)$ . An important conclusion from this work therefore is that observation of characteristic A-, B-, or C-type contours for  $\nu_{as}(\text{XY}_3)$  motions does *not* mean that internal rotation is necessarily restricted.

This splitting of  $\nu_{as}(\text{CH}_3)$  or  $\nu_{as}(\text{CD}_3)$  due to force constant variation is in contrast to the SW analysis of the effect of a conventional  $V_6$  barrier on a  $\nu_{as}(\text{CH}_3)$  mode whose degeneracy remains unlifted. Here holes develop on each side of the band center as the barrier is raised, but the intensity at the center increases at the same time. This suggests that where it is hard to tell from the  $\text{CHD}_2$  spectrum whether the effects seen are due to a conventional  $V_6$  barrier or to a  $V_2/V_4$  variation in vibration frequency, a choice might be made from the appearance of the  $\nu_{as}(\text{CH}_3)$  spectrum.

The ultimate aim should of course be to integrate the information from both  $\nu_{as}(\text{CH}_3)$  and  $\nu(\text{CHD}_2)$  spectra. Efforts to do this on a purely vibrational basis, through the "3 x 3" refinement, have been made<sup>12</sup> but cannot be said to be successful, in so far as the data can only be fitted, and that not too well, by angular variations in the stretch-stretch interaction force constants which

**Figure 3.** Plots of selected  $\nu(\text{CH})$  and  $\nu(\text{CD})$  values for  $\text{CH}_3$ ,  $\text{CH}_2\text{D}$ , and  $\text{CHD}_2$  groups as a function of rotation angle,  $\phi$ , over a half cycle of change for the parameters of case 2, Table I.

are so large as to be implausible.

(iv) **Extension to  $\text{MeXY}_5$  Systems ( $M = \text{Mn, Re}; Y = \text{CO}$ ).** We note first that a further infrared study of the carbonyl stretching regions of these compounds, in the gas phase, shows no sign of any departure of the skeleton from  $C_{4v}$  symmetry.<sup>25</sup> Thus the degeneracy of the e species fundamental remains unlifted, to within about  $1 \text{ cm}^{-1}$  as seen in Figure 9 for  $\text{CH}_3\text{Re}(\text{CO})_5$ . There is no reason therefore to suppose that a torsional barrier of order less than 12 ( $V_{12}$ ) can be present in a symmetrical ( $\text{CH}_3$ ) methyl group.

For a  $\text{CHD}_2$  group, a variation in the individual CH force constant will lead to a  $V_4$  term with the possibility also of a smaller  $V_8$  term, by analogy with the  $V_3$  and  $V_6$  components of the  $\text{CHD}_2\text{NO}_2$  potential. Again, by analogy with  $\text{MeNO}_2$ , the  $V_4/V_8$  terms should greatly exceed the  $V_{12}$  one of conventional origin.

The plane of the  $V_4$  barrier is hard to predict. If the variation in individual CH bond strength is determined mainly by the relative positions of the nuclei, then by analogy with  $\text{MeXY}_2$  systems the maximum strength, and therefore the barrier, would occur when the CH bond eclipses an equatorial CO bond. If by contrast repulsive interactions between CH bonding electrons and filled  $\pi$ -type orbitals are the dominant effect in weakening the CH bond, as has been suggested for propene,<sup>14</sup> then two effects have to be considered, involving the  $d_{xy}$  and  $d_{xz}$ ,  $d_{yz}$  pair, respectively. All three of these d orbitals are filled, apart from donation to the  $\pi$  orbitals of the carbonyls. The  $d_{xz}$ ,  $d_{yz}$  pair is much closer to the CH bonds than the  $d_{xy}$  orbital, which lies in the equatorial plane, and will be coplanar with the CH and CO bonds in the eclipsed conformation. Repulsive interactions will therefore involve mainly the  $d_{xz}$  and  $d_{yz}$  orbitals, so that the CH bonds are likely to be weakest in the eclipsed conformation and strongest when staggered.

It will be apparent that we approach the problem with a VSEPR type model in mind, rather than by invoking hyperconjugation. The latter may represent a satisfactory MO description of the phenomena, but it cannot be seen to be directly related to terms

<sup>a</sup> $f_i = f_0 + f_4 \cos 4(\phi + \delta_i) + f_8 \cos 8(\phi + \delta_i)$  where  $f_0 = 4.7765$ ,  $f_4 = 0.0874$  for both cases above, and  $\delta_i = 0^\circ, 120^\circ$ , and  $240^\circ$  for  $i = 1, 2$ , and  $3$ . Throughout,  $f' = 0.026$ . The value of  $f_4$  yields maximum and minimum values of  $\nu_1(\text{CHD}_2)$  agreeing approximately with the observed wings. This may represent an overestimate (see text). <sup>b</sup>Over  $15^\circ$  in  $\phi$  for CH<sub>3</sub>, CD<sub>3</sub>,  $45^\circ$  for CHD<sub>2</sub> and CH<sub>2</sub>D. <sup>c</sup>Computed  $\nu(\text{CD}) \times 1.011$  to offset anharmonicity. <sup>d</sup>The minima and maxima in  $\nu_1, \nu_2$ , and  $\nu_3$  do not always occur at the same value of  $\phi$ . <sup>e</sup>Excited and ground-state energies ( $\text{cm}^{-1}$ ) in the three CH/CD stretching vibrations.

in the Hamiltonian and therefore does not supply a *reason* for the effect.

The effect of a  $V_4$  variation in the individual CH stretching force constant on the vibrations of a CH<sub>3</sub> group is illustrated in Figure 3 and Table I, which includes also the effect of an added  $V_8$  contribution. Three frequencies result, which in the absence of the  $V_8$  term are essentially constant, as in CH<sub>3</sub>XY<sub>2</sub> systems. However, a particular symmetry coordinate now yields the same frequency every  $90^\circ$ , as seen in Figure 2B. Thus it is no longer possible to associate the higher antisymmetric stretching frequency with one particular direction (say,  $x$ ) and the lower such frequency with the  $y$  direction, as in CH<sub>3</sub>XY<sub>2</sub> and the SW model.<sup>26</sup> It would be surprising, however, if the resulting spectrum were not similar to that predicted by the SW model, namely, a perpendicular band with no transitions inside the limits  $\nu_{\text{as}}(\text{max}) - \nu_{\text{as}}(\text{min})$ .

For a CH<sub>3</sub>XY<sub>3</sub> molecule where  $\nu_{\text{as}}(\text{CH}_3)$  remains degenerate, and the methyl group suffers a  $V_{12}$  potential, calculations of energy levels have been made for  $V_{12}$  barriers in the range  $1\text{--}10 \text{ cm}^{-1}$ ,<sup>27</sup> and the results for a CD<sub>3</sub> group are illustrated in Figure 4, for states derived from  $K = 0\text{--}6$ . The values differ very little from those for  $V_3$  or  $V_6$  barriers, and like them, they increase linearly with increase in  $V_{12}$ , the spacings remaining unchanged. However, the first  $K$  level to be split by the perturbation is the  $K = 6$  one, in contrast to the  $K = 3$  one in the  $V_6$  case. The resulting spectrum should resemble that of Figure 4 of ref 13 except that the holes on each side of the center develop further out than in the CH<sub>3</sub>XY<sub>2</sub> case, having even more intensity in between.

We note finally that for these methyl pentacarbonyl compounds, the substituent dimensions are such that the molecules are approximately spherical tops for whose infrared bands PQR-type contours should be found with PR spacing of about  $10 \text{ cm}^{-1}$ , having no marked dependence on the orientation of the dipole derivative within the skeleton of the molecule. For the parallel bands, the PR separations calculated from the electron-diffraction dimensions, using the formula of Gerhard and Dennison,<sup>28</sup> are  $9.5 \text{ (Mn)}$  and  $8.9 \text{ cm}^{-1}$  (Re), respectively.

### Experimental Section

Infrared spectra in the gas phase were obtained on a Nicolet 7199 FTIR spectrometer, with a resolution of  $0.12\text{--}0.5 \text{ cm}^{-1}$ , using gas cells of  $10\text{--}20 \text{ cm}$  length or a multiple reflection cell with path lengths up to  $11 \text{ m}$ , gas pressures being in the range from  $1 \text{ torr}$  up to the vapor pressure at room temperature. Infrared crystal spectra were obtained from films deposited on a CsI window at  $78 \text{ K}$  with use of a Perkin-Elmer

Figure 4. Internal rotation energy levels for a CD<sub>3</sub> group with  $A = 2.614 \text{ cm}^{-1}$ , experiencing a  $V_{12}$  sinusoidal barrier.

225 spectrometer. Samples were prepared by reacting the appropriately labeled methyl iodide with  $\text{NaM}(\text{CO})_5$  in tetrahydrofuran.

### Results

The frequencies observed for the various  $\text{MeM}(\text{CO})_5$  species are listed in Tables II (Mn) and III (Re), respectively.

Figure 5 compares the gas-phase infrared spectra of CH<sub>3</sub>-Mn(CO)<sub>5</sub> and CH<sub>3</sub>Re(CO)<sub>5</sub>, respectively, in the CH stretching region. The spectrum of CH<sub>3</sub>Mn(CO)<sub>5</sub> is as reported earlier.<sup>6</sup> The origin of the bands at  $3010.0$  and  $2950.2 \text{ cm}^{-1}$ , earlier identified as components of  $\nu_{\text{as}}(\text{CH}_3)$ ,<sup>6</sup> is confirmed by their shifts of  $10$  and  $11.5 \text{ cm}^{-1}$ , respectively, on <sup>13</sup>C substitution. By contrast, the <sup>13</sup>C shifts on  $\nu_s(\text{CH}_3)$  and  $2\delta_s(\text{CH}_3)$  at  $2917.6$  and  $2830.7$  are much smaller,  $4.5$  and  $5.5 \text{ cm}^{-1}$ , respectively.

The spectrum of the rhenium compound has all the features of the manganese one but in addition has a weak broad asymmetric band centered at  $\sim 2967 \text{ cm}^{-1}$ , also with a <sup>13</sup>C shift appropriate to  $\nu_{\text{as}}(\text{CH}_3)$ . Both  $\nu_s(\text{CH}_3)$  bands have an incipient PQR-type contour. The smaller separation of the  $\nu_s(\text{CH}_3)$  and  $2\delta_s(\text{CH}_3)$  Re bands is in keeping with the stronger intensity of the latter

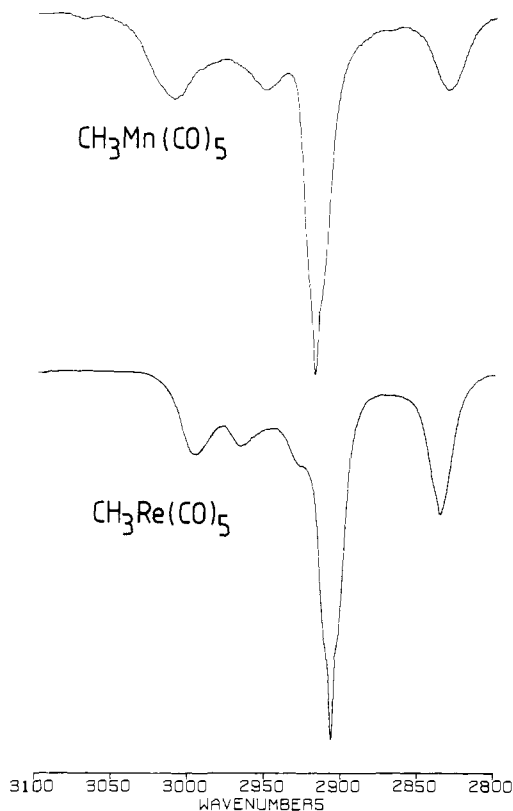

Figure 5. Infrared spectra of gaseous  $\text{CH}_3\text{Re}(\text{CO})_5$  (resolution  $0.5\text{ cm}^{-1}$ ) and  $\text{CH}_3\text{Mn}(\text{CO})_5$  (resolution  $0.25\text{ cm}^{-1}$ ),  $\nu(\text{CH})$  region.

Figure 6. Infrared spectra of gaseous  $\text{CHD}_2\text{Re}(\text{CO})_5$  and  $\text{CHD}_2\text{Mn}(\text{CO})_5$ , (resolution as for Figure 5),  $\nu(\text{CH})$  region.

relative to the former, and increased Fermi resonance.

Figure 6 shows the infrared gas-phase spectra of the two  $\text{CHD}_2$  compounds. Each has a relatively strong PQR-type band with exactly the spacings predicted above for a symmetric top parallel band, and in addition there are broad weak wings on each side, spaced almost symmetrically.

Figure 7. Infrared spectrum of gaseous  $\text{CH}_2\text{DMn}(\text{CO})_5$ , (resolution  $0.5\text{ cm}^{-1}$ ),  $\nu(\text{CH})$  region.

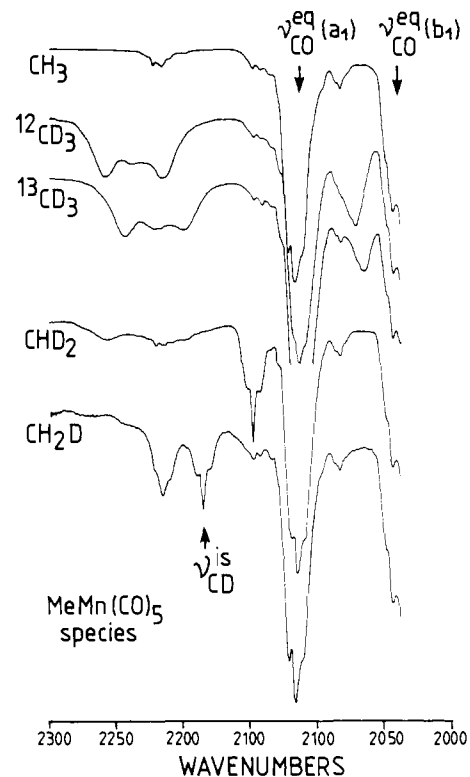

Figure 8. Infrared spectra of gaseous  $\text{MeMn}(\text{CO})_5$  species,  $\nu(\text{CD})$  region (resolutions:  $^{12}\text{C}$  samples,  $0.12\text{--}0.5\text{ cm}^{-1}$ ;  $^{13}\text{C}$  samples,  $1\text{ cm}^{-1}$ ). Both active  $a_1$ ,  $\nu(\text{CO})$ , and "inactive"  $b_1$ ,  $\nu(\text{CO})$ , fundamental bands are also seen. (See also ref 25.)

Figure 7 shows the spectrum of  $\text{CH}_2\text{DMn}(\text{CO})_5$  in the gas phase. This contains two weak broad bands at high frequency, and a third stronger one with shape reminiscent of  $\nu_s(\text{CH}_3)$ , at  $2940.6\text{ cm}^{-1}$ .

The infrared spectra in the CD stretching region are complicated by the presence of both fundamentals and combinations arising from the CO stretching vibrations. The spectra of the Mn compounds are compared in Figure 8.  $\nu_{\text{as}}(\text{CD}_3)$  is associated with the peaks at  $2256.8$ ,  $2237$ , and  $2213.5\text{ cm}^{-1}$ , which all appear to move about  $14\text{ cm}^{-1}$  on  $^{13}\text{C}$  substitution. There may be slight interference from the carbonyl combination band which in the  $\text{CH}_3$  compound has two maxima at  $2222$  and  $2215\text{ cm}^{-1}$ . The latter probably reappear in the  $\text{CHD}_2$  compound as the maxima at  $2219.6$  and  $2213\text{ cm}^{-1}$ .

<sup>a</sup> Excluding  $\nu(\text{CO})$  fundamentals. In brackets, <sup>13</sup>C shifts. <sup>b</sup> Resolution 0.25  $\text{cm}^{-1}$ . <sup>c</sup> Resolution  $\sim 1 \text{ cm}^{-1}$ . <sup>d</sup> Reference 6. <sup>e</sup> Resolution 0.12  $\text{cm}^{-1}$ . <sup>f</sup> Resolution 0.5  $\text{cm}^{-1}$ .

A band in the  $\text{CD}_3$  compound at 2071  $\text{cm}^{-1}$  with a marked <sup>13</sup>C shift of 5.5  $\text{cm}^{-1}$  must be associated with  $\nu_s(\text{CD}_3)$ . It is, however (see below), much too low for an unperturbed  $\nu_s(\text{CD}_3)$  frequency. The  $\text{CHD}_2$  compound has two broad features in the 2200–2260  $\text{cm}^{-1}$  region, the lower of which is badly overlapped by the probable combination band, plus a well-defined PQR band at 2147.5  $\text{cm}^{-1}$ . The latter frequency coincides exactly with that of a very weak combination band in the  $\text{CH}_3$  and  $\text{CD}_3$  spectra, raising the possibility that it may be the same combination but with greatly enhanced intensity due to breakdown of selection rules following the asymmetric substitution. The  $\text{CH}_2\text{D}$  spectrum shows what may be the same effect—a band at 2214.8  $\text{cm}^{-1}$  which could be merely an enhanced version of the 2215- $\text{cm}^{-1}$  band seen in the  $\text{CH}_3$  spectrum. The PQR-type band at 2184.5  $\text{cm}^{-1}$  is clearly the CD stretching counterpart of the parallel  $\nu(\text{CH})$  band in the  $\text{CHD}_2$  spectrum. Any wings that it might possess are obscured by neighboring bands.

Figure 9 shows the spectra of  $\text{CH}_3\text{Re}(\text{CO})_5$  and  $\text{CD}_3\text{Re}(\text{CO})_5$  (<sup>12</sup>C and <sup>13</sup>C) in the region 2300–1900  $\text{cm}^{-1}$ . This shows all the  $\nu(\text{CO})$  fundamentals and certain combinations, including one at 2216.8  $\text{cm}^{-1}$  in the  $\text{CH}_3$  compound. The latter coincides with the central maximum of three peaks clearly due mainly to  $\nu_{as}(\text{CD}_3)$ , at 2241, 2219, and 2193.5  $\text{cm}^{-1}$  in the <sup>12</sup> $\text{CD}_3$  compound. In the <sup>13</sup> $\text{CD}_3$  the highest peak at 2223  $\text{cm}^{-1}$  is clearly enhanced in intensity by reason of this combination, while the <sup>13</sup> $\text{CD}_3$  shoulder at 2204  $\text{cm}^{-1}$  is evidence that  $\nu_{as}(\text{CD}_3)$  on its own exhibits a central maximum.

Changes in the band contour near 2120  $\text{cm}^{-1}$  are presumably due to the intervention of  $\nu_s(\text{CD}_3)$ .

There may also be extra absorption in the  $\text{CD}_3$  spectrum near 2080  $\text{cm}^{-1}$ .

**Crystal Phase.** Figure 10 shows the spectra of the  $\text{CH}_3\text{Mn}$  and  $\text{CHD}_2\text{Mn}$  compounds, and Figure 11 shows the rhenium compounds. In both  $\text{CH}_3$  compounds the  $\nu_{as}(\text{CH}_3)$  region features a broad band with two likely components. In the Mn compound, the higher frequency band is much more intense than the lower, whereas in the Re compound, the lower band is on initial deposition (spectrum a) slightly stronger than the higher frequency one. Annealing (spectrum b) reverses the intensities. The  $\text{CHD}_2$  bands in both cases are broad, the Mn one showing a weak sharp maximum at 2953  $\text{cm}^{-1}$ , in addition to the broad one at 2966  $\text{cm}^{-1}$ . The shift of intensity toward higher frequency seen in  $\nu_{as}$ -

$(\text{CH}_3)(\text{Re})$  upon annealing is reproduced also in the  $\text{CHD}_2\text{Re}$  spectrum where the maximum moves up about 9  $\text{cm}^{-1}$ .

### Discussion

Our first attempt to analyze the spectra will be based on the frequency sum rule. We must first estimate corrections to  $\nu_s(\text{CH}_3)$  for Fermi resonances involving  $2\delta_{\text{as}}(\text{CH}_3)$  and  $2\delta_s(\text{CH}_3)$ . These we make by borrowing  $W$  values of 34  $\text{cm}^{-1}$  from  $\text{CH}_3\text{Cl}$ <sup>29</sup> and of 40  $\text{cm}^{-1}$  from  $\text{CH}_3\text{F}$ <sup>30</sup> for the two resonances, respectively. The displacements to  $\nu_s(\text{CH}_3)$  from  $2\delta_{\text{as}}(\text{CH}_3)$  alone are then calculated to be 16.4 (Mn) and 24.8  $\text{cm}^{-1}$  (Re), respectively. The higher value for the Re compound is in keeping with the altered intensity ratio and frequency separation observed for it.

Bands due to  $2\delta_s(\text{CH}_3)$  were not identified, but they may be expected near 2370  $\text{cm}^{-1}$  in both cases. The further shift on  $\nu_s(\text{CH}_3)$  due to  $2\delta_s(\text{CH}_3)$  is then estimated to be about 3  $\text{cm}^{-1}$ . We therefore predict  $\nu_s^\circ(\text{CH}_3)$  at 2898 (Mn) and 2879  $\text{cm}^{-1}$  (Re), respectively.

In calculating the frequency sum for the  $\text{CH}_3$  group, we take the highest and lowest frequencies of the band due to  $\nu_{\text{as}}(\text{CH}_3)$ , in each case, plus  $\nu_s^\circ(\text{CH}_3)$  and divide by three to obtain the "average" CH stretching frequencies of 2953 (Mn) and 2936  $\text{cm}^{-1}$  (Re). These averages are remarkably close to the centers of the observed parallel-type bands at 2955.0 (Mn) and 2934.6  $\text{cm}^{-1}$  (Re), in the  $\text{CHD}_2$  compounds, which constitutes strong prima facie evidence for the assignment of the latter as average fre-

quencies. The same interpretation then follows for the band at 2184.5  $\text{cm}^{-1}$  in the  $\text{CH}_2\text{DMn}(\text{CO})_5$  spectrum, whose frequency relative to the  $\text{CHD}_2\text{Mn}$  band yields an acceptable anharmonicity factor of 1.007.<sup>31</sup>

Two possibilities then arise for these "average frequency" bands. The first is that they represent a CH bond whose force constant is constant and independent of internal rotation angles. Any torsional barrier must then arise from the conventional origin with the first term expected to be a  $V_{12}$  one. If this term were negligible then the  $\nu_{\text{as}}(\text{CH}_3)$  band should have the appearance of a normal perpendicular band with  $K$  spacing characteristic of the freely rotating  $\text{CH}_3$  group with an  $A$  value of about 5  $\text{cm}^{-1}$ . Moreover the  $\text{CHD}_2$  band would be hybrid in character, and its perpendicular component would be similar to the  $\nu_{\text{as}}(\text{CH}_3)$  one, but with  $K$  spacing reflecting the smaller  $A$  value of about 3.2  $\text{cm}^{-1}$  for the  $\text{CHD}_2$  group, exactly as seen in the infrared spectrum of  $(\text{CHD})_2\text{Zn}$  in Figure 1.<sup>20</sup> Clearly neither of these bands has the expected appearance. However, the wings on the  $\text{CHD}_2$  band have so wide a spacing that it is difficult to resist the conclusion that they derive from an internally rotating  $\text{CHD}_2$  group. That these wings are present as *maxima* then implies that a barrier exists to internal rotation.

With use of the same argument as was employed in the case of carbon monoxide in a quinol clathrate,<sup>32</sup> the height of the barrier is approximately the rotational energy at the wing maximum, which is 59  $\text{cm}^{-1}$  for a  $K$  value of 4.3. Preliminary calculations suggest that this barrier is more likely to be of  $V_4$  than of  $V_{12}$  origin, since the lowest energy levels and wave functions for a  $V_{12}$  potential are much more rotational in character than those of a  $V_4$  one, whose lowest levels are distinctly torsional in nature. The  $V_4$  potential according to the earlier discussion would derive from a varying CH force constant, whose average value gives rise to the parallel  $\text{CHD}_2$  band.

The appearance of the  $\nu_{\text{as}}(\text{CH}_3)$  band appears to discriminate sharply between the two possible origins of the torsional barrier. A  $V_{12}$  potential introduces holes centered on transitions to  $K = 6$  levels, on each side of a strong central maximum. The absence of the latter in the  $\text{CH}_3\text{Mn}(\text{CO})_5$  spectrum, with instead a widely spaced doublet, can only be interpreted in terms of a splitting of the  $\nu_{\text{as}}(\text{CH}_3)$  degeneracy, with consequences as in the SW model, and such a splitting, we believe, invariably stems from a CH force constant variation.

<sup>a</sup> HCH angles as in Table VI. <sup>b</sup> Computed frequencies × 1.011 to alleviate CH/CD anharmonicity differences.

There are, however, weak central maxima on the  $\nu_{\text{as}}(\text{CD}_3)$ (Mn) and  $\nu_{\text{as}}(\text{CH}_3)$ (Re) bands, and possibly also in the  $\nu_{\text{as}}(\text{CD}_3)$ (Re) one. These could indicate the existence of a small  $V_{12}$  barrier. By analogy with toluene and nitromethane, this is unlikely to exceed  $\sim 5 \text{ cm}^{-1}$ . The ground ( $K = 0$ ) state lies below the barrier in all cases, and for a  $\text{CD}_3$  group the  $K = 1$  state lies at or below the barrier for a height  $> 5 \text{ cm}^{-1}$  (Figure 4). The possibility of intensity derived from  $\Delta K = 0$  transitions then arises. There is, however, an alternative source of intensity near the center of a  $\nu_{\text{as}}(\text{CH}_3)$  band. There is no reason why the dipole derivative of a CH bond should be invariant during internal rotation, and one can imagine an overall dipole derivative for the whole group developing a component parallel to the top axis, which would lead to  $\Delta K = 0$  transitions. Either mechanism might be expected to be more prominent in the Re compound where the carbon-metal bond is significantly stronger than that in the Mn compound, leading to greater interaction between the methyl group as a whole and the metal d orbitals.

The conclusion that a variation in  $\nu(\text{CH})$  with rotation angle is responsible for the strange appearance of both  $\text{CHD}_2$  and  $\text{CH}_3$  spectra also enables us to understand the spectra in condensed phases. The great breadth of both  $\nu(\text{CHD}_2)$  and  $\nu_s(\text{CH}_3)$  bands in the solid and the relatively low sensitivity of the latter both in solid and in solution to temperature variation is readily explained if the breadth is due largely to force constant variation and not to free internal rotation. It then becomes unnecessary to assume the unrealistically high barrier of  $\sim 944 \text{ cm}^{-1}$  deduced by Dempster et al.<sup>24</sup>

It will be apparent that it would be very hard to reconcile our picture of a low ( $< 10 \text{ cm}^{-1}$ )  $V_{12}$  barrier in the ground state of a  $\text{CH}_3$  group with the supposed torsional frequency of  $174 \text{ cm}^{-1}$  in the crystal phase.<sup>4</sup> We observe first that the harmonic oscillator approximation

$$V_n = \nu_i^2 / n^2 B$$

is valueless for situations where  $B$  and  $n$  are large, although for a smaller value of  $n$  such as 3 it gives a barrier of  $\sim 635 \text{ cm}^{-1}$ , not far below the one estimated by Cavagnat of  $\sim 710 \text{ cm}^{-1}$ .<sup>27</sup> For  $n = 6$ , the first excited torsional state, which derives from the levels  $K = 3, 4, 5$ , and 6, is still split by about  $61 \text{ cm}^{-1}$  when  $V_6 = 400 \text{ cm}^{-1}$ , and no well-defined torsional frequency could be expected.<sup>27</sup> For  $n = 12$ , an enormous barrier would be needed before well-defined torsional levels would appear, deriving as they do each from seven  $K$  levels. It is difficult to resist the conclusion that torsional-rotational transitions in the crystal must be spread over a wide region of the spectrum and thus remain undetected.

It remains to attempt a semiquantitative interpretation of the  $\text{CH}_3$  and  $\text{CHD}_2$  frequencies, which may also help us to understand the  $\text{CH}_2\text{D}$  spectrum.

**3 × 3 Refinement Calculations.** We first attempt to fit average  $\text{CHD}_2$  and  $\text{CH}_3$  frequencies, derived from transitions well above

Table V. Methyl Group  $\nu_{\text{as}}$  and  $\nu(\text{CHD}_2)$  Splittings ( $\text{cm}^{-1}$ )<sup>a</sup>

<sup>a</sup> Gas phase except where otherwise indicated. <sup>b</sup> Reference 14. <sup>c</sup> Reference 33. <sup>d</sup> Reference 10 and 11. <sup>e</sup> Reference 12. <sup>f</sup> This work.

the barrier, with two parameters, one diagonal stretching and one off-diagonal stretch-stretch interaction constant. For the latter, if we take the average of the two extreme  $\nu_{\text{as}}(\text{CH}_3)$  frequencies to represent  $\nu_{\text{as}}^{\text{av}}(\text{CH}_3)$ , we obtain the results under (1) of Table IV. For the Mn compound, the value of  $f'$  of 0.026 is close to those normally found (0.03–0.04) in non-rotating  $\text{CH}_3$  groups.<sup>33</sup> The values of  $\nu_s(\text{CH}_3)$  and  $\nu_{\text{as}}^{\text{av}}(\text{CD}_3)$  are very close to those estimated or observed (2898 and 2235  $\text{cm}^{-1}$ , respectively). In the case of the Re compound, however, the value of  $f'$  of 0.007 is anomalously low, and the prediction of  $\nu_s^0(\text{CH}_3)$  and  $\nu_{\text{as}}(\text{CD}_3)$  distinctly poorer (these should be 2879 and 2217  $\text{cm}^{-1}$ , respectively). A possible factor contributing to the latter might be that the midpoint of the  $\nu_{\text{as}}(\text{CH}_3)$  doublets should be equated to  $\nu_{\text{vib}}^0 + A(1 - 2\zeta)$ , rather than  $\nu_{\text{vib}}^0$ . When a  $\zeta$  value of 0.065 from  $\text{CH}_3\text{Cl}$  is borrowed,  $\nu_{\text{as}}^0(\text{CH}_3)$  is found to be 2975.4 (Mn) and 2958.1 (Re)  $\text{cm}^{-1}$ , respectively. These then give the calculated quantities listed under (2) in Table IV. The prediction of  $\nu_s^0(\text{CH}_3)$  and  $\nu_{\text{as}}^{\text{av}}(\text{CD}_3)$  for the Re compound then becomes very good, with  $f'$  satisfactory, whereas the agreement for the Mn compound is poorer than before. While part of the discrepancies involved may arise from errors in the Fermi resonance corrections on  $\nu_s(\text{CH}_3)$ , there does appear to be a real difference in the value of  $f'$  for the Mn and Re compounds.

The calculations also give some guidance as to the assignment of other bands in the spectra. Thus the prediction of  $\nu_s^0(\text{CD}_3)$ (Mn) in the range 2104–2111  $\text{cm}^{-1}$  means that the band observed at 2071  $\text{cm}^{-1}$  with pronounced <sup>13</sup>C shift must be at best a Fermi resonating component, the other component underlying the  $A_1$   $\nu(\text{CO})$  band near 2120  $\text{cm}^{-1}$ . The strong band with PQR-type contour at 2147.5  $\text{cm}^{-1}$  in the  $\text{CHD}_2\text{Mn}$  compound is, however, at an appropriate frequency for  $\nu_3$  of the  $\text{CHD}_2$  group, although its coincidence with a  $\nu(\text{CO})$  combination band in the  $\text{CH}_3\text{Mn}$  spectrum may indicate another origin, as discussed earlier.  $\nu_2$  for the  $\text{CHD}_2\text{Mn}$  group, predicted in the range 2231–2234  $\text{cm}^{-1}$ , lies slightly above the mean of the observed  $\text{CHD}_2$  doublet ( $\sim 2228 \text{ cm}^{-1}$ ) although the lower component of the doublet is very poorly defined due to overlap with another  $\nu(\text{CO})$  combination.  $\nu_1$  for the  $\text{CH}_2\text{D}$  group is calculated in the range 2975–2980  $\text{cm}^{-1}$  which encompasses that of a broad observed maximum at 2977  $\text{cm}^{-1}$ , while  $\nu_2$  for the same group, calculated in the range 2928–2932  $\text{cm}^{-1}$ , can just be reconciled with the observed band at 2940.6  $\text{cm}^{-1}$  if a Fermi resonance correction of the order of 10  $\text{cm}^{-1}$  be applied to the latter.<sup>34</sup>

A final comment on this aspect of the calculations is that the central maximum observed at 2967  $\text{cm}^{-1}$  in the  $\nu_{\text{as}}(\text{CH}_3\text{Re})$  band

(33) McKean, D. C.; Torto, I. *J. Mol. Struct.* **1982**, *81*, 51.

(34)  $\delta_s(\text{CH}_2)$  in  $\text{CH}_2\text{DMn}(\text{CO})_5$  is seen at 1409  $\text{cm}^{-1}$ . Allowing 10  $\text{cm}^{-1}$  for a normal anharmonicity deficit,  $2\delta_s(\text{CH}_2)$  might be expected at 2808  $\text{cm}^{-1}$ , whereas it is observed at 2800  $\text{cm}^{-1}$ .

Table VI. Predictions of Methyl Group Geometries and Other Parameters for MeM(CO)<sub>5</sub>

M =	$r_0(\text{CH})$ , <sup>a</sup> Å	$\angle\text{HCH}$ , <sup>b</sup> deg	$A_0$ , <sup>c</sup> cm <sup>-1</sup>				$D_0^{298}(\text{CH})$ , <sup>d</sup> kcal mol <sup>-1</sup>
			CH <sub>3</sub>	CH <sub>2</sub> D	CHD <sub>2</sub>	CD <sub>3</sub>	
Mn	1.095 <sub>9</sub>	108.0 <sub>3</sub>	5.320	3.997	3.203	2.672	100.0
Re	1.098 <sub>0</sub>	107.0 <sub>7</sub>	5.363	4.031	3.229	2.693	98.3

<sup>a</sup> From  $r_0(\text{CH}) = 1.3982 - 0.0001023\nu^{\text{is}}(\text{CH})$ .<sup>9</sup> <sup>b</sup> From  $\angle\text{HCH} = 0.04709\nu^{\text{is}}(\text{CH}) - 31.12$ .<sup>9</sup> <sup>c</sup> Assuming  $\delta r_0(\text{CH-CD}) = 0.002$  Å. <sup>d</sup> From  $D_0^{298}(\text{CH}) = 0.08616\nu^{\text{is}}(\text{CH}) - 154.6$ .<sup>9</sup>

is significantly higher than the higher of the two average values chosen in Table IV and cannot easily be reconciled with  $\nu_{\text{as}}^{\text{av}}(\text{CH}_3)$ , particularly if the  $A(1 - 2\zeta)$  connection is applied to the latter without a smaller value of  $f'$ .

While these results must be considered not unsatisfactory, immediate difficulties arise if one attempts to reconcile the  $\nu_{\text{as}}^{\text{av}}(\text{CH}_3)$  and  $\nu(\text{CHD}_2)$  splittings on a purely vibrational basis. Table V shows the variety of  $\nu_{\text{as}}(\text{CH}_3)$ ,  $\nu_{\text{as}}(\text{CD}_3)$ , and  $\nu(\text{CHD}_2)$  splittings found previously for molecules *with* free internal rotation and *without* it, the latter being chosen from cases where the methyl group retains a local plane of symmetry. It is apparently normal for the CHD<sub>2</sub> splitting to be greater than the CH<sub>3</sub> one, exceptions being the cases of (MeBO)<sub>3</sub> and CH<sub>3</sub>COCl.

The data for  $\Delta\nu(\text{CHD}_2)$  for the current Mn and Re compounds are based on the observed wing maxima, which must surely represent the maximum variation in  $\nu(\text{CH})$  possible. It is seen that the pentacarbonyl splittings parallel those for (MeBO)<sub>3</sub>, with  $\Delta\nu_{\text{as}}(\text{CH}_3)$  appreciably larger than  $\Delta\nu(\text{CHD}_2)$ , and a big difference between  $\Delta\nu_{\text{as}}(\text{CH}_3)$  and  $\Delta\nu_{\text{as}}(\text{CD}_3)$ . It follows that on a vibrational basis they could only be explained by a large and implausible variation with angle of the interaction constant, as for (MeBO)<sub>3</sub>.<sup>12</sup> What happens to the vibration frequencies for a constant interaction force constant is illustrated in Table I and Figure 3 where the three frequencies for each of the CH<sub>3</sub>, CD<sub>3</sub>, CH<sub>2</sub>D, and CHD<sub>2</sub> groups are shown as a function of angle  $\phi$ , over half a cycle in  $\phi$ , on the assumption that each individual stretching force constant varies according to

$$f_i = f_0 + f_4 \cos 4(\phi + \delta) + f_8 \cos 8(\phi + \delta)$$

where  $\delta = 0, 120, \text{ and } 240^\circ$  for the three H atoms, respectively. The values of  $f_0$  and  $f_4$  were chosen so as to yield  $\nu_1(\text{CHD}_2)$  frequencies agreeing closely with the wing maxima and central band frequencies of that group. Calculations were made for two cases: (1) for  $f_8 = 0$  and (2) for a value of  $f_8 = 0.3 f_4$ , analogous to the  $f_4 = 0.3 f_2$  relationship found in nitromethane.<sup>11</sup> In case 1, the 54-cm<sup>-1</sup> variation in  $\nu_1(\text{CHD}_2)$  is accompanied by a  $\nu_{\text{as}}(\text{CH}_3)$  ( $\nu_1 - \nu_2$ ) splitting varying from 30.9 to 22.6 cm<sup>-1</sup>, with an average value of 26.8 cm<sup>-1</sup>. The  $\nu_{\text{as}}(\text{CD}_3)$  splitting similarly varies from 21.8 to 19.0 cm<sup>-1</sup> with an average value of 20.4 cm<sup>-1</sup>. These calculated splittings are therefore less than half of the observed ones. In case 2 the variations with  $\phi$  in both  $\nu_1$  and  $\nu_2$  are somewhat greater than the above.

The situation in fact may be rather worse than this. The CHD<sub>2</sub> wings on our interpretation are due to barriers in the *upper*  $\nu(\text{CH})$  vibrational state, where the energy is  $\frac{3}{2}(\nu_{\text{vib}} \pm \frac{1}{2}\Delta\nu)$ . A barrier of about 60 cm<sup>-1</sup> here therefore implies a  $\Delta\nu(\text{CH})$  of about 40 cm<sup>-1</sup>, not 54 cm<sup>-1</sup> as in the above simple calculation.

Another feature of the calculations is a pronounced, non-sinusoidal variation in both  $\nu_1$  and  $\nu_2$  of the CH<sub>2</sub>D group (and similarly for  $\nu_2$  and  $\nu_3$  of CHD<sub>2</sub>). This gives rise to what is basically a  $V_4$  barrier of about 7 cm<sup>-1</sup> in the ground vibrational state (see  $G_{000}$  in Table I) but about 35 or 44 cm<sup>-1</sup> in the 100 state depending on whether an  $f_8$  contribution is included or not. This then leads to a possible interpretation of the  $\nu(\text{CH})$  region of the CH<sub>2</sub>D group in the Mn compound. The band at 2977 cm<sup>-1</sup> could arise from a parallel component of the dipole derivative associated with  $\nu_1$ , or to transitions between states essentially torsional in character, also associated with  $\nu_1$ , while the maximum at 3006 cm<sup>-1</sup> could be a wing of the perpendicular type band associated with  $\nu_1$ , whose inner parts are missing, as in the  $\nu(\text{CH})$  band of the CHD<sub>2</sub> group. The other wing would be concealed by the 2940.6-cm<sup>-1</sup> band whose incipient PQR contour identifies it as the parallel band arising from the essentially symmetric stretching

mode  $\nu_2$ , itself an "average" frequency, like the  $\nu(\text{CH})$  CHD<sub>2</sub> parallel band. The difficulty with this interpretation is that the wing spacing would then be about 58 cm<sup>-1</sup> [=2(3006 - 2977)] which is larger than that observed for the CHD<sub>2</sub> group (55 cm<sup>-1</sup>), whereas the model predicts a significantly smaller barrier. There has of course been no attempt here to consider the possibility of perturbations between  $K$  levels of the  $\nu_1$  and  $\nu_2$  vibrations of the CH<sub>2</sub>D group which might be analogous to those which lead to the observed wings in  $\nu_{\text{as}}(\text{CH}_3)$  in the CH<sub>3</sub> group.

Perhaps the strongest evidence for a combination of variation of  $\nu^{\text{is}}(\text{CH})$  with orientation, together with free internal rotation of the methyl group, in these molecules, is just the difficulty experienced here in applying the "3 × 3" refinement which accounts so well for the CH<sub>3</sub> and CD<sub>3</sub> spectra of non-rotating methyl groups.

It remains to list the main features that a comprehensive treatment of the energy levels and transitions of these systems should embody, even within the confines of an energy-factored force field. Variations with internal rotation angle must be considered in (1) the individual CH stretching force constants, (2) the stretch-stretch interaction force constants, (3) the direction and magnitude of the dipole derivatives, and (4) the CH bond lengths and HCH angles. These variations should include the possibility of both  $V_4$  and  $V_8$  terms. For the pentacarbonyl molecules, and for the earlier CH<sub>3</sub>XY<sub>2</sub> ones, the calculations will need to include the overall rotation of the molecule as well as the internal rotation, in order to predict the observed spectra satisfactorily.

**Geometry of the Methyl Group and Chemical Significance.** The average frequencies of the CHD<sub>2</sub> groups, in conjunction with established correlations between  $\nu^{\text{is}}(\text{CH})$  and  $r_0(\text{CH})$ ,  $\alpha\text{HCH}$ , and  $D_0^{298}(\text{C-H})$ ,<sup>9a</sup> yield the values listed in Table VI.

The first point to make is that these CH bonds are of normal strength and length.<sup>35</sup> That in CH<sub>3</sub>Mn(CO)<sub>5</sub> (2955 cm<sup>-1</sup>) is comparable with that in (CH<sub>3</sub>)<sub>2</sub>Hg (2953.8 cm<sup>-1</sup>)<sup>20</sup> or (CH<sub>3</sub>)<sub>4</sub>Ge (2954 cm<sup>-1</sup>)<sup>36</sup> and slightly stronger than that in ethane (2950 cm<sup>-1</sup>)<sup>9a</sup>. The CH bond in CH<sub>3</sub>Re(CO)<sub>5</sub> (2934.6 cm<sup>-1</sup>) is similar to those in (CH<sub>3</sub>)<sub>2</sub>Zn (2935.0 cm<sup>-1</sup>)<sup>20</sup> and neopentane (2934 cm<sup>-1</sup>)<sup>9a</sup> and marginally weaker than that in (CH<sub>3</sub>)<sub>4</sub>Si (2939 cm<sup>-1</sup>)<sup>36</sup>.

Secondly, the range of frequency from Mn to Re (20 cm<sup>-1</sup>) is similar but in the opposite direction to that from Me<sub>2</sub>Zn to Me<sub>2</sub>Hg or Me<sub>4</sub>Si to Me<sub>4</sub>Sn (2960 cm<sup>-1</sup>).<sup>35</sup> In all three groups, however,  $\nu^{\text{is}}(\text{CH})$  exhibits an inverse relationship to  $D_0(\text{M-CH}_3)$ .<sup>20</sup> Thus  $D_0(\text{Re-CH}_3) - D_0(\text{Mn-CH}_3) = 25.3$  or 22.3 kcal mol<sup>-1</sup>.<sup>37</sup> The possibilities for predicting  $D_0(\text{M-CH}_3)$  values from  $\nu^{\text{is}}(\text{CH})$  are thereby increased. More usefully, perhaps, data for groups 2B, 4A, and 7B indicate that differences of 1 cm<sup>-1</sup> in  $\nu^{\text{is}}(\text{CH})$  in structurally related molecules imply differences of the order of 0.7–1.3 kcal mol<sup>-1</sup> in  $D_0(\text{M-CH}_3)$ .

(35) The conclusion of Andrews et al.<sup>4</sup> that these bonds are anomalously weak apparently rests on the extrapolation to MeM compounds of a correlation between  $\nu(\text{CH})$  values in CH<sub>3</sub>X (X = F, Cl, Br, I) and  $\nu(\text{HX})$  ones. In view of the numerous specific effects *not* associated with electronegativity which  $\nu^{\text{is}}(\text{CH})$  values exhibit (including one in CH<sub>3</sub>F), we feel that this approach is unfruitful. Speculation about the specific effects of metal d orbitals on antisymmetric and symmetric CH<sub>3</sub> stretching frequencies is also likely to be unhelpful. The primary concern must be to identify effects on the individual CH stretching force constant. This achieved, examination of stretch-stretch interaction constants, which determine the  $\nu_{\text{as}}/\nu_{\text{s}}$  separation, might follow.

(36) Burger, H.; Biedermann, S. *Spectrochim. Acta, Part A* **1972**, *28A*, 2283.

(37) Lalage, D.; Brown, S.; Connor, J. A.; Skinner, H. A. *J. Organomet. Chem.* **1974**, *81*, 403.

Thirdly, we predict a variation in  $r_0(\text{CH})$  with internal rotation angle of the order of 0.004–0.006 Å, in both compounds. While the absence of a fully quantitative treatment of the potential function precludes an exact prediction, the general resemblance of the  $\nu_{\text{as}}(\text{CH}_3)$  and  $\nu(\text{CHD}_2)$  splittings to those in  $(\text{MeBO})_3$ , where a variation of the above order is confirmed by ab initio calculations,<sup>38</sup> provides additional support for the proposed bond length fluctuation in the  $\text{MeMn}(\text{CO})_5$  and  $\text{MeRe}(\text{CO})_5$  compounds.

### Conclusions

1. The infrared spectra of  $\text{MeMn}(\text{CO})_5$  and  $\text{MeRe}(\text{CO})_5$  species in the CH and CD stretching regions can be qualitatively interpreted in terms of a CH stretching force constant which varies with internal rotation angle of an essentially freely rotating methyl group.

(38) Although described earlier as 4-31G calculations,<sup>12</sup> these were in fact STO-3G ones, scaled up according to STO-3G/4-31G differences in  $\text{MeNO}_2$  and  $\text{MeBF}_2$  (P. D. Mallinson, private communication).

2. The ground-state barrier to internal rotation is probably of  $V_{12}$  origin and very low,  $<10 \text{ cm}^{-1}$ .

3. Mean CH bond lengths of 1.095<sub>9</sub> and 1.098<sub>0</sub> are predicted for the Mn and Re compounds, respectively, with variations of the order of 0.004–0.006 Å during internal rotation.

4. The CH bonds are of average strength, that in the Re compound being slightly the weaker, and bear an inverse relationship to  $D_0(\text{M}-\text{CH}_3)$ , as in other MeM compounds.

5. Further development of theory is needed for a quantitative interpretation of the spectra, especially the  $\nu_{\text{as}}(\text{CH}_3)$  and  $\nu_{\text{as}}(\text{CD}_3)$  splittings.

## Molecular Structure of *s-cis*- and *s-trans*-Acrolein Determined by Microwave Spectroscopy

C. E. Blom,<sup>†</sup> G. Grassi, and A. Bauder\*

Contribution from the Laboratorium für Physikalische Chemie, Eidgenössische Technische Hochschule, CH-8092 Zürich, Switzerland. Received December 21, 1983

**Abstract:** The rotational spectra of highly enriched single D-, <sup>13</sup>C-, and <sup>18</sup>O-substituted species of acrolein have been measured and analyzed over 12–58 GHz. The complete substitution structure has been determined for the less abundant *s-cis* conformer from the ground-state rotational constants. In addition newly assigned  $\mu_b$ -type transitions for all isotopic species of the more abundant *s-trans*-acrolein have improved the structure of this conformer. Careful measurements of the Stark effect have resulted in an accurate determination of the electric dipole moment of the *s-trans* conformer. A comparison of the molecular structures of the two conformers has revealed significant differences in the central C–C bonds.

Among the simplest 1,3-conjugated double-bond systems butadiene ( $\text{CH}_2=\text{CH}-\text{CH}=\text{CH}_2$ ), acrolein ( $\text{CH}_2=\text{CH}-\text{CH}=\text{O}$ ), and glyoxal ( $\text{O}=\text{CH}-\text{CH}=\text{O}$ ) only acrolein possesses a non-vanishing electric dipole moment in the most abundant *s-trans* conformer.<sup>1</sup> Acrolein represents a crucial system for studying the effect of the change of conformation on the structure in a 1,3-conjugated double-bond system by the microwave method. Several investigations of the rotational spectra of *s-trans*-acrolein have been reported.<sup>2–5</sup> They include the assignment of  $\mu_a$ -type transitions of isotopically substituted species measured in natural abundance except for the deuterated species.<sup>3</sup> Their analysis allowed the determination of a substitution structure of the planar *s-trans* conformer. Only recently the rotational spectrum of the less abundant *s-cis*-acrolein has been assigned.<sup>6</sup> Its analysis established that this conformer is likewise a planar molecule.

The present contribution continues our earlier work on *s-cis*-acrolein,<sup>6</sup> providing now the complete substitution structure of this conformer. Highly enriched isotopically substituted species of acrolein had to be prepared since the intensities of the rotational transitions of the *s-cis* conformer were only 2% of those of the *s-trans* conformer. In the course of this study it became clear that more accurate data for the isotopic species of *s-trans*-acrolein were needed in order to make a comparison of the structural parameters of *s-cis* and *s-trans* conformers possible. Therefore we have re-measured the rotational spectra of D-, <sup>13</sup>C-, and <sup>18</sup>O-substituted

species of *s-trans*-acrolein and have also assigned  $\mu_b$ -type transitions. With the help of the newly measured transition frequencies three rotational and five quartic centrifugal distortion constants could be determined for all isotopic species, improving the previous analysis.<sup>3</sup> In addition accurate measurements of the Stark splittings of optimally selected transitions have allowed a better determination of the electric dipole moment, especially of the  $\mu_b$  component.

### Experimental Details

**Chemicals.** Five isotopic species of acrolein were prepared by an aldol condensation from appropriate isotopic species of formaldehyde and acetaldehyde.<sup>7</sup> The reactions were carried out in the gas phase at 280 °C in a reactor filled with an alkaline catalyst following the modifications by Renaud and Stephens.<sup>8</sup> The catalyst was composed of silica gel 40 (70–230 mesh, Fluka AG) treated with a 10% sodium carbonate solution.<sup>7</sup> The crude products from the aldol condensation were purified by gas chromatography (Perkin-Elmer F-21, 4.5-m packed column with 15% QF-1 on Chromosorb W, 40 °C).

(1) *s-trans* refers to the trans orientation of the conjugated double bonds about the C–C single bond, *s-cis* to the cis orientation.
