The analysis has shown that the small differences between the stabilization energies along a column arise from large cancellations of effects of similar order of magnitude. We should also point out that the values of the various components depend critically on the geometry of the cation. Solvation will certainly change the geometry of the cation, and thus also the values of the various components, so that also the overall preference might change.

Thus it can be expected that solvation might change the trend of the SE values along a column, while along a row the change is less likely.

#### Abstract

High level MP4/6-311G(d,p)//6-31G(d)+ZPVE ab initio MO calculations predict two stable $\mathrm{CH}_{3} \mathrm{~N}^{2+}$ isomers; the global minimum corresponds to the aminomethylene dication, $\mathrm{H}_{2} \mathrm{NCH}^{2+}(5)$, which at the highest level of theory is predicted to be $49 \mathrm{kcal} / \mathrm{mol}$ more stable than $\mathrm{H}_{3} \mathrm{NC}^{2+}(6)$, which can be viewed as a donor/acceptor molecule. Both isomerization and dissociation pathways were studied, and the two isomers are prevented by significant barriers from isomerization as well as dissociation (charge separation). Vertical and adiabatic ionization energies for removing an electron from the corresponding, as yet unknown, monocations are estimated as are the heats of formation of the resulting dictations. For $5, \Delta H_{\mathrm{f}}^{\circ}$ is estimated to $644 \mathrm{kcal} / \mathrm{mol}$, and for 6 a value of $700 \mathrm{kcal} / \mathrm{mol}$ has been obtained.

The remarkable chemistry and physics of multiply charged, gaseous cations is of considerable interest to both experimentalists and theoreticians. ${ }^{1}$ Salient features of the dications which can be conveniently generated from monocations in the gas phase by charge stripping (CS) mass spectrometry ${ }^{2}$ are the following ones: (1) reversal of stability order of dicationic isomers when compared with their mono-charged or neutral counterparts; (ii) significant structural changes which often favor anti-van't Hoff geometries for the dications; ${ }^{3}$ and (iii) highly exothermic charge separation reactions which in the gas phase, however, are prevented by significant barriers to occur spontaneously. Thus, observation of the intrinsically thermochemically unstable dications is feasible, while in solution proton transfer to the solvent shell or transfer of negatively charged species to the dication will take place with avidity thus making it unlikely to generate under these conditions small organic dications as viable species. Larger organic dications or species which are stabilized intramolecularly can, of course, be generated as stable systems in solution. ${ }^{4}$

High-level ab initio molecular orbital (MO) calculations play a decisive role in the description and characterization of the species of interest in that they not only allow comparison of theoretically predicted and experimentally evaluated ionization energies but also provide information on the energetics of the ions, their electronic structures and their isomerization/dissociation characteristics.

While the potential energy surface of the $\mathrm{CH}_{3} \mathrm{~N}^{++}$system, which is believed to play an important role in the interstellar production of organic molecules, ${ }^{5}$ is now quite well understood, ${ }^{6}$ to the best of our knowledge no high-level ab initio MO calculations have been reported on the corresponding dicationic $\mathrm{CH}_{3} \mathrm{~N}^{2+}$ system, which is the subject of the present paper. For the monocations the aminomethylene cation (2) is predicted to be $8.8 \mathrm{kcal} / \mathrm{mol}$ (MP2/6-31G(d)//4-31G) more stable than the methyleneimine radical cation (1) (Chart I). A high-energy barrier ( $57 \mathrm{kcal} / \mathrm{mol}$ (MP2/6-31G(d)//4-31G)) for the reaction $\mathbf{1} \rightarrow 2$ largely prevents the two ions from isomerizing prior to the microsecond frag-

(d,p)//6-31G(d)) above 2. What the situation looks like, when an additional electron is removed from $\mathbf{1}$ and 2 , has been evaluated by high-level ab initio MO calculations, and likely features of CS experiments are predicted.

## Method

Standard ab initio MO calculations were carried out with use of the CRAY version of the gaUSSIAN 82 series of programmes. ${ }^{7}$ Optimized geometries, harmonic frequencies, and zero-point vibrational energies were calculated with the $6-31 \mathrm{G}(\mathrm{d})$ basis set, ${ }^{8}$ whereas single-point calculations on the optimized geometries were performed with the d,p-polarized $6-311 \mathrm{G}(\mathrm{d}, \mathrm{p})$ basis set ${ }^{9}$ which is of triple valence quality. Openshell systems were treated with the unrestricted HF (UHF) formalism. ${ }^{10}$ Effects of valence electron correlation were incorporated by means of Moller-Plesset perturbation theory up to full fourth order. ${ }^{11}$ This level of theory, which is used throughout in the paper if not stated otherwise, will be referred to as MP4/6-311G(d,p)//6-31G(d).

## Results and Discussion

Optimized 6-31G(d) structures (bond length in $\AA$, bond angle in deg) are displayed in Chart II; charges, which were obtained at the $6-311 \mathrm{G}(\mathrm{d}, \mathrm{p})$ level by means of Mulliken population analysis, are given in parentheses. Energies (total energies in hartrees, relative energies, $E_{\text {rel }}$, and zero-point vibrational energy (ZPVE), scaled by a factor of 0.9 to account for the overestimation of harmonic frequencies at that level of theory, ${ }^{12}$ are given in $\mathrm{kcal} / \mathrm{mol}$ ) obtained at the various levels of theory are given in Table I. Energies discussed in the text refer to the MP4/6-

[^2] J. Quantum Chem. Symp. 1981, 15, 269.

$31 \mathrm{G}(\mathrm{d}, \mathrm{p}) / / 6-31(\mathrm{~d})+$ ZPVE and structural parameters to the 6-31G(d) values. In Table I we also include some data of mono-charged $\mathrm{CH}_{3} \mathrm{~N}^{++}$isomers pertinent to the discussion of vertical and adiabatic energies for the respective mono-cations. Also included in Table I are energies of transition states for both isomerization and dissociation processes of $\mathrm{CH}_{3} \mathrm{~N}^{2+}$ together with data for the relevant products.

Among the four possible isomers of $\mathrm{CH}_{3} \mathrm{~N}^{2+}$, we have located species 4,5 , and 6 as minima. The fourth isomer, $\mathrm{CH}_{3} \mathrm{~N}^{2+}(7)$, does not correspond to a minimum; upon geometry optimization 7 falls apart into $\mathrm{H}_{2}$ and $\mathrm{HCN}^{2+}$. The global minimum on the potential energy surface corresponds to the aminoethylene dication (5), which at the highest level of theory is found to be 45.8 $\mathrm{kcal} / \mathrm{mol}$ more stable than the conventional methyleneimine dication (4). Thus, in the case of the $\mathrm{CH}_{3} \mathrm{~N}^{++} / \mathrm{CH}_{3} \mathrm{~N}^{2+}$ systems removal of an electron does not result in a reversal of stability order but rather increases the difference (compare the 8.3$\mathrm{kcal} / \mathrm{mol}$ difference for the $1-2$ pair with $45.8 \mathrm{kcal} / \mathrm{mol}$ for the dicationic 4-5 system). One possible reason for the increased stability of 5 over 4 may be found in the charge distribution of the dications. While most of the charge in all small dications is, for electrostatic reasons, invariably deflected to the hydrogen periphery, $\mathbf{5}$ is additionally stabilized over $\mathbf{4}$ by Coulomb attraction

## Chart III

Table II. Calculated Vertical and Adiabatic Ionization Energies (in eV ) of $\mathrm{CH}_{3} \mathrm{~N}^{++}$Isomers

| $\mathrm{CH}_{3} \mathrm{~N}^{\bullet+}$ isomers | $\mathrm{IE}_{\mathrm{v}}$ | $\mathrm{IE}_{\text {ad }}$ |
| :---: | :---: | :---: |
| $\mathrm{CH}_{2} \mathrm{NH}^{\bullet+}(\mathbf{1})$ | 20.2 |  |

| $\mathrm{CNH}_{3}{ }^{+}(3)$ | 17.0 | 16.8 |

between the HNC unit due to charge alternation; 4, however, lacks this special stabilization. Common to both dications is the surprisingly short $\mathrm{C}-\mathrm{N}$ bond length ( $1.194 \AA$ for 4 and $1.191 \AA$ for 5) which is significantly shorter than that for the respective mono-charged radical ions 1 and 2 (1, $1.243 \AA ; 2,1.251 \AA$ ). In terms of valence bond structures, the bond shortening could be due to structures like $\mathrm{H}_{2} \mathrm{C}=\mathrm{N}^{2+} \mathrm{H}$ (for 4) and $\mathrm{H}_{2} \mathrm{~N}^{+}=\mathrm{C}^{+} \mathrm{H}$ (5) which, again, would energetically favor 5 over 4 . Only 3.2 $\mathrm{kcal} / \mathrm{mol}$ less stable than 4 is the dication 6 which can be viewed as a donor/acceptor molecule between $\mathrm{NH}_{3}$ and $\mathrm{C}^{2+}\left({ }^{1} \mathrm{~S}\right)$ (Chart III).

Quite surprisingly, the $\mathrm{NH}_{3}$ fragment of 6 has retained several structural features of the uncomplexed $\mathrm{NH}_{3}$. For example, the overall symmetry is unchanged whereas the XNH angle is only slightly changed $\left(\mathrm{NH}_{3} ; \angle \mathrm{XNH}=111.6^{\circ} ; 6,117.7^{\circ}\right)$, and the NH distance of free $\mathrm{NH}_{3}\left(d_{\mathrm{NH}}=1.002 \AA\right)$ is elongated to $1.062 \AA$ in 6 . The charge distribution of 6 points to a formal charge transfer of 1.05 electrons from the lone pair of $\mathrm{NH}_{3}$ to the empty $\mathrm{p}_{z}$ orbital of $\mathrm{C}^{2+}$, resulting in a CN bond the bond length of which is $1.375 \AA$, in between a CN single (ca. $1.47 \AA$ ) and CN double bond (ca. $1.30 \AA$ ). Again, one reason for the short CN bond of 6 may be found in the Coulomb attraction between the two heavy atoms.

The instability of $\mathbf{7}$ can be explained by comparing the relevant VB structures of 6 and 7. While in 6 the two positive charges are located on two different centers, i.e., $\mathrm{H}_{3} \mathrm{~N}^{+}-\mathrm{C}^{+}$, this is not possible in 7, i.e., $\mathrm{H}_{3} \mathrm{C}-\mathrm{N}^{2+}$. As a consequence, the extremely electron deficient nitrogen in 7 will attract electron density from the $\mathrm{CH}_{3}$ bonding orbitals, resulting in a weakening of these bonds, which finally leads to dissociation. Geometry optimization of 7 under the constraint of $C_{3 v}$ symmetry (to prevent dissociation) leads to a structure (which is, of course, artificial and without any chemical relevance) which is $134 \mathrm{kcal} / \mathrm{mol}$ less stable than 5 ( $6-31 \mathrm{G}(\mathrm{d})$ ). This result also points to the extreme thermodynamic instability of this structural arrangement.

From the data presented in Table I both the vertical (IE $\mathrm{F}_{\mathrm{v}}$ ) and adiabatic ionization energies ( $I E_{a d}$ ) for removing an electron from $\mathbf{1 , 2}$, and 3 can be evaluated. The data are given in Table II and should guide experimentalists to perform charge stripping experiments. As both ions 5 and 6-but not 7, as shown belowreside in deep potential wells, these novel dications should, in principle, be accessible in gas-phase experiments by using CS. 4, however, if generated via vertical electron loss from 1 , is predicted to rearrange spontaneously to 5 .

For further characterization of the $\mathrm{CH}_{3} \mathrm{~N}^{2+}$ potential energy surface we have performed various calculations for both isomerization and dissociation processes. For the isomerization $5 \rightarrow$ 6, via transition state TS8, we obtain a barrier of $74.3 \mathrm{kcal} / \mathrm{mol}$ which leaves no doubt that both isomers once generated will not

## Chart IV

TS9

TS11

TS12

TS13

TS14
spontaneously interconvert. The location of the transition state connecting 5 with 4, via TS9, caused some problems. At the $6-31 \mathrm{G}(\mathrm{d})$ level TS 9 was found to be only $0.1 \mathrm{kcal} / \mathrm{mol}$ less stable than 4. If one includes the effects of correlation energy and ZPVE, the $0.1-\mathrm{kcal} / \mathrm{mol}$ barrier for the reaction $4 \rightarrow 5$ disappears, in other words, at the highest level of theory $\mathrm{CH}_{2} \mathrm{NH}^{2+}$ (4) cannot be regarded as a stable species but rather rearranges to $\mathrm{CHNH}_{2}{ }^{2+}$ (5). This behavior is somewhat reminiscent of that for the $\mathrm{C}_{2} \mathrm{H}_{3}{ }^{+}$ system, which is isoelectronic with $\mathrm{CH}_{3} \mathrm{~N}^{2+}$, and for which it was observed that the barrier for the degenerate 1,2 -hydrogen migration completely disappears at a higher level of theory thus leaving the bridged $\mathrm{C}_{2} \mathrm{H}_{3}{ }^{+}$as the only minimum. ${ }^{13}$

For the remaining $\mathrm{CH}_{3} \mathrm{~N}^{2+}$ isomers 5 and 6 we have investigated several charge separation processes (eq 1-5) involving the transition states TS $10-\mathrm{TS} 14$. Although most of these charge separation processes are (not unexpected) exothermic, they are nevertheless characterized by substantial barriers thus preventing spontaneous dissociation to mono-charged species. While the

| $\Delta H^{\circ}$ |  |  |
| :---: | ---: | ---: |
| $(\mathrm{kcal} / \mathrm{mol})$ | $E_{\mathrm{a}}$ |  |

calculated barriers for processes 1-4 are likely to be correct, this must not be the case for reaction 5 which is associated with a

[^3]

Figure 1. Potential energy diagramme for $\mathrm{CH}_{3} \mathrm{~N}^{2+}$ isomers. Relative energies (referred to the energy of $\mathrm{H}_{2} \mathrm{NCH}^{2+}(5)$ ) are given in $\mathrm{kcal} / \mathrm{mol}$. The reaction co-ordinate is a complex co-ordinate.
transition state of singlet diradicaloid character. As the UHF method (which has been used to localize this saddle point) is known for its poor description of singlet diradicals, the energy of TS14 is likely to be too high. But, ion 6 also seems to be prevented by
significant barriers from spontaneous dissociation. In Figure 1 the various isomerization/dissociation processes are given in a simplified two-dimensional potential energy surface.

Heats of formation $\Delta H_{\mathrm{f}}{ }^{\circ}$, of 5 and 6 can be estimated from combining the $\Delta H^{\circ}$, of reactions $1-5$ with the experimentally determined heats of formation of the various mono-cations; ${ }^{14}$ by doing this, for $\mathrm{H}_{2} \mathrm{NCH}^{2+}(5)$ an averaged value of $\Delta H_{f}^{\circ}=644$ $\mathrm{kcal} / \mathrm{mol}$ and for $\mathrm{H}_{3} \mathrm{NC}^{2+}(6)$ of $\Delta H_{\mathrm{f}}^{\circ}=700 \mathrm{kcal} / \mathrm{mol}$ is obtained. Both numbers indicate the extreme thermodynamic instability of the two dications, and it is highly unlikely to ever generate a stable $\mathrm{CH}_{3} \mathrm{~N}^{2+}$ species in solution. Proton transfer to the solvent shell or capture of negatively charged species from it will occur with avidity.

# Nonempirical Valence Bond Studies of the Origin of the Antiferromagnetism of Copper(II) Carboxylate Dimers 

Richard D. Harcourt, ${ }^{* \dagger}$ Frances L. Skrezenek, ${ }^{\dagger}$ and Robert G. A. R. Maclagan ${ }^{\star}$<br>Contribution from the Department of Physical Chemistry, University of Melbourne, Parkville, Victoria 3052, Australia, and the Department of Chemistry, University of Canterbury, Christchurch 1, New Zealand. Received February 18, 1986

#### Abstract

The origin of the antiferromagnetism of copper(II) carboxylate dimers is examined by using nonempirical valence bond procedures to calculate values for $-2 J=E_{\text {triplet }}-E_{\text {singlet }}$, in which $J$ is the magnetic exchange parameter. Ten electrons and six atomic orbitals are explicitly included in the calculations. The orbitals consist of the copper $d_{x^{2}-y^{2}}$ and a lone-pair $2 \mathrm{p} \tilde{\pi}$ orbital on each oxygen atom of two carboxylate ligands. The nearest-neighbor $\mathrm{Cu}-\mathrm{O}$ overlap is essentially $\sigma$ in character. The results of the calculations support a conclusion obtained from an earlier semiempirical study, namely that O - O overlap within each of the carboxylate ligands is primarily responsible for the antiferromagnetism. The $\mathrm{O}-\mathrm{O}$ overlap becomes effective when the oxygen lone-pair electrons delocalize into the singly occupied $d_{x^{2}-y^{2}}$ orbitals and leads to appreciable stabilization of the $S=0$ state via covalent-ionic resonance. For $-2 J \simeq 300 \mathrm{~cm}^{-1}$, the primary covalent and ionic structures for this purpose involve three $2 p \tilde{\pi}$-electrons within either or both carboxylate ligands. The resulting covalent-ionic resonance leads to the development of a Pauling "3-electron bond", $\mathrm{O} \cdots \mathrm{O}(\equiv \mathrm{O}: \mathrm{O} \leftrightarrow \mathrm{O} \cdot \mathrm{O})$ within a carboxylate ligand.

The copper acetate monohydrate dimer is perhaps the bestknown member of a large class of similarly structured Cu (II) carboxylate dimers with the general formula $\mathrm{Cu}_{2}\left(\mathrm{RCO}_{2}\right)_{4}, \mathrm{~L}_{n}$, where $n=0$ or 2. Each of these dimers involves two $\mathrm{Cu}^{2+}$ ions which are bridged symmetrically by four carboxylate ligands. It is well-known that this type of dimer involves an $S=0$ ground state, i.e., the spins of the two magnetic electrons which originate from the ( 3 d ) ${ }^{9}$ configurations of the two $\mathrm{Cu}^{2+}$ ions are antiparallel, and a thermally accessible $S=1$ excited state. As a result, antiferromagnetism is observed. A singlet-triplet energy separation ( ${ }^{3} E-{ }^{1} E=-2 J$ ) of $286 \mathrm{~cm}^{-1}$ has been reported ${ }^{1.2}$ for $\mathrm{Cu}_{2}\left(\mathrm{CH}_{3} \mathrm{CO}_{2}\right)_{4}, 2 \mathrm{H}_{2} \mathrm{O}$, and other copper(II) carboxylate dimers have $-2 J$ values of $100-550 \mathrm{~cm}^{-1} .^{3-7}$

To account for the antiferromagnetism of copper acetate, Figgis and Martin ${ }^{1.2}$ suggested that for the $S=0$ ground state, a weak
