#### Abstract

A conformational analytical study of a series of trimethylsilyloxy- (TMSO) and tert-butoxy- (TBO) substituted 1,4-dioxanes was performed using NMR techniques. It was found that the TMSO and TBO groups (in contrast to MeO, AcO , and PhO substituents ${ }^{2}$ ) alleviate the anomeric effect. Arguments based on molecular mechanics (MM2-parametrized for the anomeric effect) and MO ab initio calculations of $\operatorname{ROCOR}^{\prime}\left(\mathrm{R}=\mathrm{CH}_{3}, \mathrm{H} ; \mathrm{R}^{\prime}=\mathrm{SiH}_{3}\right)$ at various levels help rationalize this behavior, by isolating and identifying steric and electronic contributions. The electronic factors are (i) strong attractive nonbonded $\mathrm{OSi} \cdots \mathrm{O}$ interactions within the $\mathrm{R}-\mathrm{O}-\mathrm{C}-\mathrm{O}-\mathrm{Si}$ system, which reduce considerably the $\mathrm{O}-\mathrm{C}-\mathrm{O}-\mathrm{Si}$ dihedral angle (down to $0^{\circ}$ ) and the energy of the "ag" (equatorial) form vs. the " $g^{+} g^{+"}$ one and (ii) inductive electron donation by $\mathrm{SiMe}_{3}$ (or $\mathrm{CMe}_{3}$ ) which lowers the electronegativity of TMSO (or TBO). Steric factors and ( $\mathrm{p} \rightarrow \mathrm{d}$ ) $\pi$ bonding are negligible. A single-crystal X-ray analysis of 2,5 -di-tert-butoxy-1,4-dioxane revealed structural data in line with all the above.

The anomeric effect is recently an intensively studied and increasingly documented topic. ${ }^{1-5.9-11}$ Phenomenologically, it consists of the tendency of a $\mathrm{R}-\mathrm{X}-\mathrm{C}-\mathrm{Y}-\mathrm{R}^{\prime}$ moiety to assume "gauche" conformations about the $\mathrm{X}-\mathrm{C}-\mathrm{Y}$ bonds or, e.g., of a 2-(R) oxytetrahydropyran-type molecule (as in the ubiquitous carbohydrate-pyranoside system) to prefer the axial form over the equatorial one (cf. 1 vs. 2). Theoretically, it was first in-

1

3

2

4
terpreted in terms of electrostatic interactions (e.g., destabilization of $\mathbf{2}$ by repulsive, parallel dipoles) and later in molecular orbital terms of delocalization of an $n_{p}$ lone pair of one O into the $\sigma^{*}$ orbital of the adjacent $\mathrm{C}-\mathrm{O}$ bond as in $3^{5 \mathrm{C}}$ or in valence bond terms of double-bond - no-bond resonance $(3 \leftrightarrow 4)^{5 c . d . h}$ or hyperconjugation. ${ }^{11,12}$ It was additionally suggested to be a result of interaction between bonded electron pairs (of $\mathrm{R}-\mathrm{X}$ and $\mathrm{Y}-\mathrm{R}$ ). ${ }^{\text {. }}$. The phenomenon, while well perceived, seems far from being straightforwardly interpreted.

The existence of an anomeric effect in a system is eminently manifest in its properties, ${ }^{4}$ as follows: (i) structure, e.g., shorter and/or longer anomeric C-O bonds; (ii) energy, i.e., greater stability of gauche (axial) forms (1) over anti (equatorial) ones (2); (iii) reactivity, i.e., variation of rates of attack at or around the anomeric center, all those as a function of geometry.

We have recently started to probe the anomeric effect in some of its manifestations. Thus the first, structural criterion was delineated ${ }^{1}$ and is being currently examined in more detail, while the energy criterion was examined in di(R)oxy-1,4-dioxanes, ${ }^{2}$ e.g., $\mathrm{R}=\mathrm{Me}$ (5t). These, similarly to the earlier studied dihalogeno derivatives, ${ }^{\text {sc }}$ exhibit an overwhelming prevalence of diaxial conformations in trans 2,3- and 2,5-disubstituted derivatives, with $\Delta G($ diax - dieq $)>2 \mathrm{kcal} / \mathrm{mol}$. The principal conclusions were

[^0]that the energetics of 1,4-dioxanes bearing polar substituents are determined by a combination of anomeric, steric, and gauche

${ }^{a}$ Chemical shifts in ppm, coupling constants in Hz (obtained at 90 or 360 MHz on ca. $5 \% \mathrm{CDCl}_{3}$ solutions). The $\mathrm{AA}^{\prime} \mathrm{BB}^{\prime}$ spectra 6 and 7 were analyzed using simulation techniques; with 9,10 , and 12 the data were obtained by direct analysis. ${ }^{b}$ Data cited from ref 3 for ready comparison. ${ }^{c}$ Cf. Figure 1 for visualization of the two various conformations and notations. ${ }^{d} J_{\mathrm{AA}^{\prime}}$ in 6 and $7: J_{\mathrm{BX}}$ in 9,10 , and $\mathbf{1 2}$. ${ }^{e} J_{\mathrm{BB}}$, in $\mathbf{6}$ and 7 . In the cis-2,3 substituted compounds, rapid ring inversion averages the coupling constants to give ${ }^{1} / 2\left(J_{\mathrm{AA}^{\prime}}+J_{\mathrm{BB}^{\prime}}\right)$. $J_{\mathrm{AB}^{\prime}}=J_{\mathrm{A}^{\prime} \mathrm{B}}$ in $\mathbf{6}$ and $\mathbf{7} ; J_{\mathrm{AX}}$ in 9,10 , and $\mathbf{1 2}$. ${ }^{8}$ The magnitude of the couplings between the methinic protons ( ${ }^{3} J_{2,3}$ ) were evaluated from ${ }^{13} \mathrm{C}$ satellite spectra. The half-width ( $W_{1 / 2}$ ) of the singlet was taken from the regular spectrum after optimizing the natural bandwidth ( $W_{1 / 2}$ of $\mathrm{CHCl}_{3}-0.35 \mathrm{~Hz}$ ). In the cases where the satellites were poorly resolved we chose to quote upper limits for ${ }^{3} J_{2.3} .{ }^{h} R=J_{\mathrm{t}} / J_{\mathrm{c}}=1 / 2\left(J_{\mathrm{aa}}+J_{\mathrm{ee}}\right) / 1 / 2\left(J_{\mathrm{ae}}+J_{\mathrm{ea}}\right) ; \psi_{\text {deg }}=\operatorname{arc} \cos [3 /(2+4 R)]^{1 / 2.37}$ i Evaluated from the relationship $J_{\text {obsd }}=X_{a a} J_{a a}+\left(1-X_{a a}\right) J_{e e}$ where $J_{\text {obsd }}$ is $J_{\text {trans }}, X_{a a}$ the molar ratio of the diaxial (or axial) conformer and $J_{\text {aa }}$ and $J_{\text {ee }}$ are, respectively, the limiting vicinal diaxial and diequatorial coupling constants for the $\mathrm{AA}^{\prime} \mathrm{BB}^{\prime}$ spectra (of 6 and 7) or for the ABX spectra (of 9 and 10) as taken from ref 3 (cf. also compd 5t): $J_{a a}=11.3$ and $J_{e e}=1.47 \mathrm{~Hz}$ for $\mathrm{AA}^{\prime} \mathrm{BB}^{\prime} ; J_{a a}=7.7$ and $J_{e e}=1.2 \mathrm{~Hz}$ for ABX. It is assumed that these values are solvent and temperature invariant. ${ }^{j}$ This value is to be compared with available literature values for 2 -methoxy-1,4-dioxane (11), viz. $70 \%$ axial in $\mathrm{CDCl}_{3}{ }^{3 \mathrm{f}}$ and $\mathrm{MeCN}-d_{3}{ }^{30 \mathrm{~b}}$ and for 2-tert-butoxy-1,4-dioxane (13) viz. $50 \%$ diaxial in $\mathrm{MeCN}-d_{3} .{ }^{30 b}$
effects, with the first being the most important factor in this interplay.

## Synthesis and Conformational Analysis

We wish now to elaborate on a rather peculiar phenomenon that we came across in our study of such systems. First, we found that trans-2,3- and -2,5-di(trimethylsilyloxy)-1,4-dioxanes consistently exhibit relatively weak anomeric effects. ${ }^{2 a}$ This was assessed in an NMR study, using various techniques as a diagnostic tool. Thus (Table I), one can readily see that the trans-2,3- (6t)

and the trans-2,5-di(trimethylsilyloxy) (9t) derivatives as well as 2 -trimethylsilyloxy-1,4-dioxane (12) show spectra which can be only understood if one assumes almost equimolar dynamic mixtures of axial-equatorial conformations (see Figure 1). This is especially borne out by the $\mathrm{AA}^{\prime} \mathrm{BB}^{\prime}$ spectra of $\mathbf{6 t}, \mathbf{9 t}$, and $\mathbf{1 2}$ in which values of ${ }^{3} J_{\text {Irans }}$ and ${ }^{3} J_{\text {Irans }}$ are all quite similar and around 6 Hz in contrast to the situation in well-defined systems like the dimethoxy derivative (5t) (Table I) in which ${ }^{3} J_{1 \text { rans }}$ is 11.30 Hz (i.e., diaxial) and ${ }^{3} J_{\text {Irans }}$ is 1.47 Hz (i.e., diequatorial) because of its well-defined conformation with better than $96 \%$ diaxial methoxy ( MeO ) groups. This is also confirmed by additional criteria which we used to probe the conformations of the TMSO derivatives, namely, ${ }^{3} J_{2.3}$ and ${ }^{13} \mathrm{C}$ data (Table I) (as well as by comparison with fixed analogous systems). ${ }^{25}$

These results suggested that one deals with an apparent alleviation of the anomeric effect in mono- and di(R)oxy-1,4-dioxanes in which $\mathrm{R}=\mathrm{SiMe}_{3}$. To gain a better understanding of the origin of this behavior, it was considered desirable to look also into the behavior of the analogous tert-butoxy (TBO) substituted derivatives. It should be mentioned that the 2,3 -di-TBO derivatives have been independently and contemporaneously prepared by Bou et al. ${ }^{6 \mathrm{a}}$ and discussed ${ }^{\text {bb }}$ (see, however, Discussion below). While the 2,3 -di(TMSO) derivatives ( $\mathbf{6 t}$ and $\mathbf{6 c}$ ) had been prepared earlier ${ }^{7 \text { a }}$ from the corresponding 2,3 -dihydroxy-1,4-dioxanes and the $2,5-\mathrm{di}(\mathrm{TMSO}$ ) derivative ( 9 t ) from trans-2,5-dihydroxy-1,4dioxane, ${ }^{7 \mathrm{~b}}$ the analogous tert-butoxy derivatives were obtained from the isomeric 2,3 - and 2,5 -dichloro- 1,4 -dioxanes ${ }^{8}$ with tertbutyl alcohol.

We decided to study both the 2,3- and 2,5-di-tert-butoxy-1,4dioxanes using NMR techniques similar to those for the TMSO derivatives. Significantly, the results (Table I) are also very similar to those from the TMS series, implying that trans-2,3- and trans-2,5-di-tert-butoxy-1,4-dioxane ( $\mathbf{7 t}$ and $\mathbf{1 0 t}$, respectively) also

I II

(a)

(b)

Figure 1. Conformational equilibria in disubstituted 1,4-dioxanes: (a) 2,3-di(R)oxy-1,4-dioxane and (b) 2,5-di(R)oxy-1,4-dioxane [trans (I, II, V , and VI) and cis (III, IV, VII, and VIII)]. The ring protons are labeled for the purpose of NMR analysis (cf. Table I).
occur as diaxial-diequatorial dynamic equilibrium mixtures (Figure I: I $\rightleftharpoons \mathrm{II} ; \mathrm{V} \rightleftharpoons \mathrm{VI}$ ).

In addition to that, we analyzed both the static and dynamic NMR spectra of the cis-2,3- and cis-2,5-disubstituted 1,4-dioxanes $\mathbf{6 c}, \mathbf{7 c}$, and $\mathbf{1 0 c}$. The data (Table I) fully substantiate the configurational (cis) and conformational ( $\mathrm{ae} \rightleftharpoons \mathrm{ea}$ ) assignments. The dynamic, variable-temperature NMR study of 7 c down to -100 ${ }^{\circ} \mathrm{C}\left(\Delta \nu_{\mathrm{Me}}=49.5 \mathrm{~Hz}\right.$ at 360 MHz$)$ showed coalescence at -83 ${ }^{\circ} \mathrm{C}$. Using the expression for noninteracting two sites ( $K_{\mathrm{c}}=$ $\pi \Delta \nu / \sqrt{ } 2)$ and the Eyring equation, one obtains $\Delta G_{190}=4.56 T$. $(10.32+\log T / k)=9.15 \mathrm{kcal} / \mathrm{mol}$ for the barrier to ring inversion (Figure la, III $\rightleftharpoons$ IV).

To quantify the information obtained on the trans-2,3 derivatives, we evaluated the conformational composition of the equilibrium mixtures (Table I) by using the relationship $J_{\text {obsd }}=X J_{\text {aa }}$ $+(1-X) J_{\mathrm{ee}}$ and taking $J_{\mathrm{aa}}=11.3 \mathrm{~Hz}$ and $J_{\mathrm{ee}}=1.47 \mathrm{~Hz}$ from the 2,3 -dimethoxy derivative ( $\mathbf{5 t}$ ) which has been shown to be a conformationally all but homogeneous system existing in better than $96 \%$ diaxial conformation, hence a diaxial $\rightleftharpoons$ diequatorial free-energy difference of or over $\mathrm{ca} .2 \mathrm{kcal} / \mathrm{mol}$, with very little, if any, temperature and solvent dependence. ${ }^{2}$

As for the mono- and trans-2,5-disubstituted TMSO and TBO derivatives, the limiting $J_{\mathrm{aa}}$ and $J_{\mathrm{ee}}$ values in the ABX spectra were taken from previous work ${ }^{3}$ as 7.7 and 1.2 Hz , respectively. This led to even more striking results (Table I) i.e., predominant contribution of equatorial forms in the conformational equilibria in chloroform.

## Ab Initio MO Calculations

The initial theoretical postulates, which were meant to rationalize the anomeric and related effects in MO terms, ${ }^{5 c, 10}$ were followed by a decade of increasingly elaborate efforts from various quarters of theoretical chemistry. ${ }^{9-12}$ The goal was to duplicate the experimental results, in particular concerning energies and structural features, and to provide thereby a better understanding of the stereoelectronics of this, both ubiquitous and sophisticated, phenomenon. Gradually, it became clear that quantum chemical (MO) ab initio calculations provide results of (varyingly) good reliability, ${ }^{9}$ while early attempts of calculations using semiempirical (MO) methods were largely unsuccessful in tackling the anomeric effect. Recently, however, significant progress was made, indi-
cating an eventual breakthrough in handling larger molecules of this kind by semiempirical $\mathrm{MO}^{13.14}$ methods.

At this time, ab initio calculations could be performed only on relatively small molecular species, ${ }^{9}$ and dimethoxymethane is, understandably, the most studied model for oxygen-containing molecules exhibiting anomeric effects. ${ }^{\text {gd.e. } .1-15}$ Hence, it is clear why we decided to use this as a reference species in order to probe theoretically the problem of alleviation of the anomeric effect by the silyl substituent. We calculated, therefore, the two lowest conformations, viz. " $g^{+} g^{+"}$ (related to 1 ) and " $a g^{+"}$ (related to 2) of dimethoxymethane (DMM) and methoxymethanol (MMO) along with the simplest possible models for our Si-containing systems, namely, methoxysilyloxymethane (MSM) and silyloxymethanol (SMO). This was done using Gaussian $80^{16 a}$ with the STO-3G, ${ }^{16 \mathrm{~b}} 3-21 \mathrm{G},{ }^{17 \mathrm{ab}}$ 3-21G, ${ }^{* 17 \mathrm{c}}$ and 4-21G**18 $\left(3-3-21 \mathrm{G}^{*}\right.$ for $\mathrm{Si}^{18 \mathrm{~b} . \mathrm{c}}$ ) basis sets. The latter two include polarization functions for assessing the role of d orbitals in the stereoelectronic interplay. The $3-21 G^{*}$ is a fully polarized basis set, constructed directly from the $3-21 \mathrm{G}$ representations ${ }^{17 \mathrm{ar}}$ (following essentially the guidelines of Pietro et al. for $3-21 \mathrm{G}^{(*) 17 c}$ ) and augmented by a complete set of six d-type functions on all heavy atoms, identical with the set used in the larger 6-31G* basis set (the 3-21G* basis set was recently used also by Bachrach and Streitwieser ${ }^{19 \mathrm{a}}$ ). Similarly, $4-21 G^{* *}$ was constructed from the $4-21 G$ basis set, ${ }^{18 a}$ using a 3-3-21 basis set for silicon ${ }^{18 \mathrm{~b}}$ and adding a set of d functions on all heavy atoms ${ }^{18 \mathrm{c}}$ as well as a set of p functions on hydrogens (following the procedure of Hariharan and Pople for the 6-31G** basis set ${ }^{17 \mathrm{~d}}$ ).

The calculated relative energies are assembled in Table II and the relevant structural parameters, i.e., the $\mathrm{R}-\mathrm{O}-\mathrm{C}-\mathrm{O}-\mathrm{R}^{\prime}$ bond lengths and angles and $\mathrm{O}-\mathrm{C}-\mathrm{O}-\mathrm{R}$ dihedral angles, in Table III. It should be stressed that these structural features are very sensitive probes of the anomeric effect, ${ }^{1,40.5 c .9}$ and, therefore, the calculations were performed at several levels of geometry optimization. First we optimized the relevant bond lengths, bond angles, and torsional angles, and eventually complete optimization was carried out (cf. Table II, items 2 and 3). Some single point calculations of certain significant conformations were also performed at relatively high levels of theory (items $3-5$; e.g., 3-21G*//3-21G denotes a single point $3-21 \mathrm{G}^{*}$ calculation at the fully optimized $3-21 \mathrm{G}$ geometry).
It is worth mentioning that polarization functions are essential for calculating reasonably accurate $\mathrm{Si}-\mathrm{O}$ bond lengths and $\mathrm{Si}-\mathrm{O}-\mathrm{C}$ bond angles ${ }^{18.19 \mathrm{~b}}$ (here polarization functions on hydrogen may also be important) which otherwise are both too large. ${ }^{18 b, 196}$ This is well illustrated in Table III for SMO where both the $\mathrm{Si}-\mathrm{O}$ bond length and the Si-O-C bond angle are larger by ca. $0.03 \AA$ and ca. $10^{\circ}$, respectively, in the $3-21 \mathrm{G}$ structure than in the $4-21 \mathrm{G}^{* *}$ one; a similar correction would then apply for MSM (for similar findings in other silyloxy systems (cf. ref 18 and 19b). It may also be noted that in both respects, energy and structure, the STO-3G calculation indicates only trends and no quantitative validity.

Table II. Relative Energies as Calculated ab Initio of Dimethoxymethane (DMM), Methoxysilyloxymethane (MSM), Methoxymethanol (MMO), and Silyloxymethanol (SMO) in Their Lowest Conformations: ${ }^{a} g^{+} g^{+}$vs $a g^{+}$(as)

${ }^{a}$ The values are $\Delta E=E_{a g}-E_{g g}$ and $\Delta \Delta E=\Delta E_{\mathrm{Me}}-\Delta E_{\mathrm{Si}}$ in $\mathrm{kcal} / \mathrm{mol}$; the relevant, lowest geometries are shown for easy reference; cf. also Table III. ${ }^{b} \mathrm{~d}$ functions on all heavy atoms and p functions on hydrogen. ${ }^{c}$ Calculated at $3-21 \mathrm{G}$ geometries. ${ }^{d} \mathrm{~d}$ functions on all heavy atoms. ${ }^{e} \mathrm{~d}$ functions only on Si. ${ }^{17 \mathrm{~d}}$ f Partly optimized structures (dihedral angles were kept at $180^{\circ}(a)$ and $60^{\circ}(g)$ ). ${ }^{8}$ Literature data for comparison.

The best theoretical results in both tables, i.e., from the most sophisticated calculations of known systems, are in good agreement with literature data for the anomeric effect: the energy difference $\Delta E=E_{g g}-E_{a g}$ of ca. $4 \mathrm{kcal} / \mathrm{mol}$ (e.g., in dimethoxymethane) is invariably accompanied by relative $\mathrm{C}-\mathrm{O}$ bond-length shortening and COR bond-angle opening in the gauche (g) part of the (ag) conformations, as indeed expected from the MO representation of the anomeric effect and well-documented both experimentally ${ }^{1.4 a .5 c}$ and theoretically. ${ }^{9}$

The next task was to attempt to assess the contributions of electronic and steric effects in the described alleviation of the anomeric effect, and it was thought that this could be achieved by judicious combination of the above results with those from molecular mechanics calculations.

## Molecular Mechanics Calculations

Calculations of molecular structures and energies using empirical force fields or the so-called molecular mechanics method ${ }^{20}$ are becoming increasingly vital in organic-chemical research for both verificative and predictive purposes. One of the currently most popular and useful force fields is undoubtedly Allinger's MM2 program ${ }^{21}$ which we also use in this work, with a ppropriate modifications as discussed below.

It has long been recognized that the incorporation of geminal and vicinal heteroatoms in organic molecules is bound to cause considerable difficulties in force field parametrization because of the strong induced (through-bond and through-space) interactions. ${ }^{201,22,25}$ The anomeric effect is a typical such example and its ubiquity ${ }^{4,5}$ was compelling in seeking a proper solution to the

[^1]problem. The original MM2 program ${ }^{22 a}$ has been improved for dealing with alcohols and ethers ${ }^{21,22 \mathrm{~b}}$ and further parametrized in the torsional terms and in dipole-dipole interactions, enough to lead to reasonable energies in compounds containing also $\mathrm{R}-\mathrm{O}-\mathrm{C}-\mathrm{O}-\mathrm{R}$ moieties and, hence, anomeric effects. Another such effort had been made by Burkert ${ }^{2 b, 23}$ with similar results. In the meantime, however, it became clear ${ }^{4.5}$ that the anomeric effect has far-reaching implications (vide supra) not only concerning relative energies of anomeric isomers but also their structural features. ${ }^{1}$ These, viz. bond angles and bond lengths and, in particular, the latter, were inadequately accounted for in the described force fields. Efforts to remedy this situation were made by Jeffrey et al. ${ }^{24}$ and most recently by Allinger himself ${ }^{25}$ who provided a general scheme of parametrization involving a redetermination of $l_{0}$ for the $\mathrm{O}-\mathrm{C}-\mathrm{O}$ bonds as a function of the torsional angles around them. ${ }^{262}$ In the original MM2, ${ }^{22} l_{0}$ had a fixed value and nothing for torsion-stretch interactions, and the latter were, in fact, simulated by the above-mentioned procedure. It should be noted that a stretch-bend term has been included in MM2, and this, after slight reparametrization, took care of the changes in bond angles in the $\mathrm{O}-\mathrm{R}-\mathrm{C}-\mathrm{O}-\mathrm{R}$ moiety as the $\mathrm{C}-\mathrm{O}$ bond lengths are shortened or lengthened.

An impressive list of molecular structures was compiled ${ }^{25}$ to test and exemplify the described procedure by comparison of the data from calculated structures with those from experimentally determined ones (by neutron or high-precision X-ray diffraction methods). Indeed, the calculated $\mathrm{O}-\mathrm{C}-\mathrm{O}$ bond lengths matched well the experimental ones-not so, however, the terminal R-O bonds, the calculated lengths of which were systematically shorter than in reality (by more than $0.01 \AA$ ).

All available structural data of systems exhibiting $\mathrm{R}-\mathrm{O}-\mathrm{C}-\mathrm{O}-$ $\mathrm{R}^{\prime}$ moieties, stemming from experimental ${ }^{1,4 a, b, 5 c}$ or theoretical ( $a b$ initio) ${ }^{9}$ studies (see also Table III in this work), show what may be called a first-order effect of $\mathrm{O}-\mathrm{C}-\mathrm{O}$ bond lengths and $\angle \mathrm{ROC}$ bond angle variations with $\mathrm{RO}-\mathrm{CO}$ torsion angles. These are readily understood from the structures 3 and 4: an RO-CO gauche conformation causes a shortening of the $\mathrm{O}-\mathrm{C}$ bond and a lengthening of the adjacent ( $\mathrm{C}-\mathrm{O}$ ) one as well as an increase in the $\angle R O C$ bond angle; an anti conformation is apparently not

${ }^{a}$ See footnote $a$ and geometries depicted in Table II: $g=$ gauche ${ }^{+}, a=$ anti, $s=\operatorname{syn} ; \omega, \omega^{\prime}=$ dihedral angles RO-CO and OC-OR' respectively. ${ }^{b}$ This work: (I) STO-3G//STO-3G; (II) 3-2IG//3-21G; (III) 3-21G(*)//3-2IG; (IV) 3-21G*//3-21G; (V) 4-21G**//4-21G**. ${ }^{c}$ Literature data; (I) $4-21 \mathrm{G} / / 4-21 \mathrm{G} ;{ }^{9 i}$ (II) $4-31 \mathrm{G} .{ }^{9 \mathrm{c}}$ d Electron diffraction data.
affecting these parameters. All this is superimposed upon a basic bond shortening occurring in any geminal $\mathrm{CX}_{2}$ unit ( $\mathrm{X}=$ electronegative atom). ${ }^{1}$

There is, however, an additional structural feature, namely, an increase in the outer $\mathrm{R}-\mathrm{O}$ bond length in any gauche ( $\mathrm{RO}-\mathrm{CO}$ ) segment which may possibly be rationalized as a hybridization phenomenon connected to the above-mentioned $\mathrm{C}-\mathrm{O}$ bond shortening. While this may be seen as a second-order effect, it is real, general, and by no means negligible.

We have decided therefore to incorporate this feature in a parametrization of MM2(80) ${ }^{21 a}$ for the anomeric effect. This was done essentially along the lines set by Nørskov-Lauritsen and Allinger ${ }^{25}$ but redefining $l_{0}$ also for the terminal $\mathrm{R}-\mathrm{O}$ bonds ${ }^{26}$ as an empirical function of the adjacent $\mathrm{O}-\mathrm{C}$ bond:

$$
l_{0}^{\prime}(\mathrm{OR})=l_{0}+\Delta
$$

where

$$
\Delta=a X_{(\mathrm{OC})}+b
$$

and

$$
x_{\mathrm{OC}}=l_{0^{\prime}(\mathrm{OC})}-l_{0}
$$

The results are given in Table IV for six structures (14-19) taken from ref 25 , representing all ( $g^{+} g^{+}, g^{+} g^{-}$, and $a g^{ \pm}$) conformations. While the fit with the experimental data is still not perfect and further work should be done for improving it, the problem of the outer ( $\mathrm{R}-\mathrm{O}$ ) bonds is largely rectified. We take it, hence, as good enough for probing the subject of our immediate interest.
We calculated, using MM2 (parametrized as above), the mono-, 2,3 -di-, and 2,5 -di-tert-butoxy-1,4-dioxanes as well as the analogous methoxy derivatives for comparison (Figure 2i-iii). The relevant data for the two lowest (axial/diaxial and equatorial/ diequatorial) conformations in each series are given, namely, the relative energies and dihedral angles as calculated by MM2 along with the recognized steric and electronic interactions operating in such systems, which can be regarded as six-membered rings made up of (dialkoxymethane) COCOC and (dialkoxyethane) COCCOC fragments. ${ }^{2 b}$ It is worth recalling the interactions inherent in such moieties. (i) COCOC is the basic grouping subject to anomeric effects (vide supra) and preferring the $g^{ \pm} g^{ \pm}$ form, where two anomeric effects obtain. In dimethoxymethane itself, these are degenerate by virtue of $C_{2}$ symmetry, which is

14

16

18
destroyed in such compounds as 2 -methoxytetrahydropyran or $-1,4$-dioxane (Figure 2i). (ii) COCCOC is the basic grouping subject to gauche effects ${ }^{27}$ and preferring the aaa and $a g^{ \pm} a$ forms almost equally well (by more than $85 \%$ ) over all the other forms. ${ }^{28}$

As a further test of the reliability of our approach as well as of the modified MM2 force field we are using, we calculated (Table V) these basic moieties including terminal tert-butyl; i.e., in the ROCOR ' series (with $\mathrm{R}, \mathrm{R}^{\prime}=$ methyl and/or tert-butyl), dimethoxymethane (DMM), tert-butoxymethoxymethane (TBMM), and di(tert-butoxy)methane (DTBM); and in the ROCCOR' series, 1,2-dimethoxyethane (DME), 2-tert-butoxymethoxyethane (TBME), and 1,2-di(tert-butoxy)ethane (DTBE). The results, viz. relative energies vs. dihedral angles (Table V), are very interesting, in that the relative energies show little change in each series notwithstanding tert-butyl substitution, the molecular relaxation taking place mainly by increasing bond angles and dihedral angles.

## Discussion

Before going into a thorough analysis of our results and for the sake of clarity it is deemed useful to stress certain significant principles and implications of the (generalized ${ }^{5 \text { 5.h }}$ ) anomeric effect.

To start with, its quantification turned out to be not at all a straightforward matter. Since the anomeric effect had been defined as the preference of an electronegative substituent at the anomeric center of pyranoside derivatives for the axial conformation, ${ }^{4,5}$ its magnitude has been taken ${ }^{29.30}$ as the sum of the free-energy difference for the axial-equatorial equilibria in a 2 -substituted tetrahydropyran (e.g., $\Delta G^{\circ}{ }_{1 \rightarrow 2}$ ) and the corresponding " $A$ value" in an appropriate cyclohexyl derivative. In time, this procedure was critically discussed ${ }^{30.31}$ and adjusted ${ }^{31}$ so that the anomeric effect for, e.g., an alkoxy group was evaluated at ca. $2.1 \mathrm{kcal} / \mathrm{mol}$. To be sure, this is a $\Delta \Delta G^{\circ}$ value and includes a medium- and temperature-dependent $\Delta \Delta S$ term, whereas the anomeric effect is of enthalpic nature. ${ }^{1 \mathrm{~b}, 32}$. In this context, some $\Delta \Delta H$ data have been most recently reported ${ }^{32}$ and smaller values were obtained, but further elaboration and a larger data base is needed before passing final judgment. As to the theoretically (ab initio) calculated values, they are consistently higher, viz., 2.7-4.5 $\mathrm{kcal} / \mathrm{mol}$ (cf. Table II and ref 9) for an "anomeric effect" in a basic $\mathrm{R}-\mathrm{O}-\mathrm{C}-\mathrm{O}-\mathrm{Me}$ unit, which in this case is the energy difference between its "ag" and " $g^{+} g^{+"}$ conformations.

[^3]At this point one should recall that any $\mathrm{R}-\mathrm{O}-\mathrm{C}-\mathrm{O}-\mathrm{R}^{\prime}$ unit has two halves, each capable of exhibiting such an anomeric effect. In cyclic systems (e.g., of the pyranoside type) this is well-perceived: while the anomeric effect represents the prevalence of the axial (1) over the equatorial (2) form, both show a clear preference of the glycosidic substituent for the "gauche" (over the "anti") form, and this is known as the exo-anomeric effect. ${ }^{33 a}$ The latter is, in fact, competitively stronger than the anomeric effect, ${ }^{33 \mathrm{a}, 1 \mathrm{lb}, 32}$ apparently because of the rotational freedom of the glycosidic substituent to attain the optimal geometry in each case.

In this work, the experimentally studied cyclic systems exhibit, of course, both the anomeric effect and its exo counterpart, but in our measurements we can assess only the first since the second is operating in both axial and equatorial conformations. ${ }^{1,33}$ In the theoretical ab initio calculations of ROCOR' systems (Table II), this is evaluated by the magnitude of $\Delta E$, i.e., the energy difference between the two lowest " $g^{+} g^{+ \text {" }}$ and " $g^{+} a$ " conformations. For $\mathrm{R} \neq \mathrm{R}^{\prime}$ there are two such values (Table II), with $\Delta \Delta E$ measuring the substituent effect, i.e., when H or Me is replaced by $\mathrm{SiH}_{3}$.
It may be useful to note that in MO terms ${ }^{11,12}$ the $\Delta E$ values can be considered as representing mainly the acceptor properties of the $\sigma^{*}\left(\mathrm{C}-\mathrm{OR}^{\prime}\right)$ relative to the $\sigma^{*}(\mathrm{C}-\mathrm{H})$ orbitals (i.e., in the " $g^{+} g^{+}$" vs. the " $g^{+} a$ " conformations) ${ }^{33 b}$ along with the donor properties of the $\mathrm{n}_{\mathrm{p}}(\mathrm{RO}-\mathrm{C})$ lone pair. Following the superjacent orbital control theory, ${ }^{9, \mathrm{~b}, \mathrm{~b} 3 \mathrm{~b}}$ the lower the $\sigma^{*}\left(\mathrm{C}-\mathrm{OR}^{\prime}\right)$ orbital and the higher the level of the $n_{p}(\mathrm{RO}-\mathrm{C})$ lone pair, we should expect enhancement of the anomeric effect (i.e., higher $\Delta E$ ) and vice versa. Furthermore, the more electronegative an $X$ substituent is, the lower is the corresponding $\sigma^{*}(\mathrm{C}-\mathrm{X})$ orbital. ${ }^{12}$ At the same time, the less electronegative an R substituent on Y is, the more available a lone pair in $\mathrm{R} \ddot{Y}$ is bound to be (a useful criterion for this property is the ionization potential of molecules containing RY units) with corresponding enhancement of the anomeric effect. For a more detailed and historical recent account on the origins of the anomeric effect and its interpretations, of. ref 9 f as well as ref $4 \mathrm{a}, \mathrm{b}$.
Turning back to our own work, the NMR results (Table I) unequivocally indicate a considerable increase in the population of equatorial conformations of trimethylsilyloxy- (TMSO) and tert-butoxy- (TBO) substituted 1,4-dioxanes as compared with corresponding alkoxy (e.g., MeO) derivatives. ${ }^{2}$ The latter, one may recall, as well as the phenoxy-, ${ }^{2}$ acetoxy-, ${ }^{2}$ or halogenosubstituted ${ }^{2 \text { 2.5c }} 1,4$-dioxanes (in 2 and/or 3 position) overwhelmingly prefer (di)axial conformations over (di)equatorial ones as a consequence of the anomeric effect. ${ }^{4}$ While our main concern is the origin of the above alleviation of the anomeric effect by TMSO and TBO, the results and the techniques we used to obtain them carried us far beyond that.

A careful literature search revealed some early, albeit sporadic reports showing increased populations of the equatorial conformation of trimethylsilyloxy. ${ }^{34}$ and tert-butoxy-substituted ${ }^{35} 1,4$ dioxanes and 2-tert-butoxytetrahydropyran; ${ }^{30.36}$ the latter cases were taken to indicate a weaker than usual anomeric effect but were not further investigated. Also, before going into a more elaborate discussion, we had to make sure that we did not deal with spurious effects involving nonchair conformations; this was taken care of by applying the R-value criterion ${ }^{37}$ (Table I), which indicated that ours are veritable chair structures.

A first attractive and obvious factor to invoke in the explanation of the phenomenon we deal with was the classic steric effect, viz., an apparent weakening of the anomeric effect by the possible preference of the bulky TMSO or TBO groups for the equatorial

Figure 2. Two (one axial/diaxial and one equatorial/diequatorial) most stable conformations of (i) 2-methoxy-and 2-tert-butoxy-1,4-dioxane (11 and 13), (ii) trans-2,3-dimethoxy-and di(tert-butoxy)-1,4-dioxane (5t and 7t), and (iii) trans-2,5-dimethoxy-and di(tert-butoxy)-1,4-dioxane (8t and $10 t$ ) with the steric and electronic interactions within and energies of the optimized geometries (cf. dihedral angles $\omega$ ) as calculated by MM2 (parametrized for the anomeric effect). The notation for the (dimethoxymethane) COCOC fragments defines the two $\mathrm{O}-\mathrm{C}-\mathrm{O}$ dihedral angles and that in the (diethoxyethane) $C O C C O C$ fragments defines the three $O-C-C-O$ dihedral angles: $a x=a x i a l, ~ e q=e q u a t o r i a l, a=a n t i, g=$ gauche, $\mathrm{AE}=\mathrm{anomeric}$ effect, eAE $=$ exo-anomeric effect, $E=$ energy, $E_{\text {rel }}=$ relative energy with the lowest form taken as zero in each case.
conformation. A first, admittedly circumstantial indication that this is not so was the fact that the conformational (axial-equatorial) free-energy difference $-\Delta G_{\text {conf }}=A$ for the $-\mathrm{OSiMe}_{3}$ group (in cyclohexane derivatives) was reported to be a mere 0.75 $\mathrm{kcal} / \mathrm{mol}^{38}$ which is in between the OH and OMe groups (surprisingly, the $A$ value of the $-\mathrm{OCMe}_{3}$ group is not known and we hope to remedy this situation soon). A recent paper, ${ }^{6 \mathrm{~b}}$ however,

[^5]raised some rather tenuous arguments in favor of a steric origin to the above-mentioned alleviation, by inferring from an MNDO calculation of the geometry of 2-methoxy-1,4-dioxane (11) in its axial form (showing a $87^{\circ}$ dihedral angle in the anomeric OC$\mathrm{OCH}_{3}$ fragment) that a similar tert-butoxy derivative would exhibit so much steric interference with the axial ring hydrogens on $\mathrm{C}_{6}$ as to distort even more the $\mathrm{OC}-\mathrm{O}-t$ - Bu dihedral angle; it was speculated that this may prevent the exo-anomeric effect from operating in the axial form, destabilizing it in favor of the
equatorial one. We were not convinced by both the inference and the speculation, but it was clear that a thorough investigation is needed, leading to a separation of electronic from steric effects in order to assess their respective contribution to the origin of the described phenomenon.

Another electronic effect we had to reckon with was the possibility of $(\mathrm{p} \rightarrow \mathrm{d}) \pi$ bonding in $\mathrm{Si}-\mathrm{O}$. This was given, however, very little importance as soon as we found that corresponding TMSO and TBO derivatives show very similar behavior concerning the weakening of the anomeric effect and as we learned that recent ab initio calculations ${ }^{18 c .19 b}$ showed ( $p \rightarrow d$ ) $\pi$ bonding to be a minor factor in the $\mathrm{Si}-\mathrm{O}$ bond. Moreover, even the involvement of dipole-dipole interactions were considered of little importance in this context, after a cursory search, ${ }^{39}$ which revealed that MeOH and $t-\mathrm{BuOH}$ have practically the same dipole moments ( 1.70 and 1.67 D , respectively) and that of $\mathrm{Me}_{3} \mathrm{SiOH}$ is not too different ( 1.53 D ).

We start the analysis of our theoretical results with a scrutiny of Table II, i.e., the relative energies of the two lowest conformations in ROCOR' groupings: " $g^{+} g^{+"}$ vs. " $a g^{+"}$ (" $g$ " = gauche, " $a$ " $=$ anti), as calculated ab initio. Items 2 and 3 represent the best calculations, both fully optimized; item 2 is the most complete set, i.e., for dimethoxymethane (DMM), methoxysilyloxymethane (MSM), methoxymethanol (MMO), and silyloxymethanol (SMO) at $3-21 \mathrm{G} / / 3-21 \mathrm{G}$; and item 3 is the highest level $\left(4-21 \mathrm{G}^{* *} / / 4\right.$ $21 \mathrm{G}^{* *}$ ) calculation of MMO and SMO. In both, the $\Delta E$ values (which are a measure of the anomeric effect) of DMM and MMO are around $4 \mathrm{kcal} / \mathrm{mol}$ in accord with the best available literature values (items 7 and 9). ${ }^{9 c \cdot i}$ Substitution of $\mathrm{R}^{\prime}=\mathrm{CH}_{3}$ by $\mathrm{SiH}_{3}$, which is taken to model the problem we are facing (by representing closely the relationship between, say, 11 and 12) brings about a dramatic decrease of $\Delta E$. At $3-2 \mathrm{lG} / / 3-2 \mathrm{lG}$ (item 2 ), $\Delta E$ is nearly zero in MSM and $1.9 \mathrm{kcal} / \mathrm{mol}$ in SMO. Hence, $\Delta \Delta E$ values are 4.0 and 2.4 for the pairs DMM-MSM and MMOSMO, respectively; at higher level (items 3 and 4), $\Delta \Delta E$ 's for the latter (MMO-SMO) pair are smaller ( 1.4 and 1.0 ) but trendpreserving. These results amount to a considerable alleviation of the anomeric effect, as experimentally observed.

At the same time, however, we examined the behavior of R -$\mathrm{O}-\mathrm{C}-\mathrm{O}-\mathrm{R}^{\prime}$ with $\mathrm{R}=\mathrm{SiH}_{3}$ vs. $\mathrm{CH}_{3}$ in order to assess the donor properties of the $\mathrm{OSiH}_{3}$ substituent in such systems. Notably, the $\Delta E$ values are all high and (in the best calculations, especially those including polarization functions; cf. items 2-5 in Table II) the $\Delta \Delta E$ values diminish appreciably, down to negative values in the last column. Thus, when $\mathrm{R}=$ methyl is substituted by silyl, $\Delta \Delta E=0.6$ for MSM ( $\mathrm{R}=\mathrm{SiH}_{3}, \mathrm{R}^{\prime}=\mathrm{CH}_{3}$; item 2) and -0.6 , $-1.1,-1.4$, and -1.0 for $\mathrm{SMO}\left(\mathrm{R}=\mathrm{SiH}_{3}, \mathrm{R}^{\prime}=\mathrm{H}\right.$; items 2,3 , 4 , and 5 , respectively). This is, in fact, tantamount to an enhancement of the anomeric effect, which is actually related to the so-called exo-anomeric effect in ring systems ${ }^{33}$ (such as $\mathbf{1}$ or $\mathbf{2}$ with $\mathrm{R}^{\prime}=\mathrm{SiH}_{3}$ ).

The rationalization of these results is, prima facie, straightforward. The alleviation of the anomeric effect in the silyloxysubstituted systems can be taken as a manifestation of $\mathrm{SiO}-\mathrm{C}$ being a poorer $\sigma^{*}$ acceptor relative to $\sigma^{*}(\mathrm{CO}-\mathrm{C})$, because of the inductive electron-donating effect of silicon. Thus, the electronegativity of $\mathrm{R}^{\prime} \mathrm{O}$ is lowered (when $\mathrm{R}^{\prime}=\mathrm{SiH}_{3}$ as compared to $\mathrm{CH}_{3}$ ), raising the energy of the $\sigma^{*}(\mathrm{SiO}-\mathrm{C})$ level and, implicitly, the $n_{p}-\sigma^{*}$ energy gap. ${ }^{9, b, b, 19 c}$ It appears, furthermore, that the enhancement of the exo-anomeric effect is equally consistent with the above rationale since by virtue of the same inductive effect Si-O may be a better $n_{p}$ donor, raising the $n_{p}$ level by increasing the electron density on oxygen. All this is in line with the theory ${ }^{5 c, 9 a, b, f, 10-12}$ of (hyperconjugative) $O$ lone-pair electrons delocalization into the adjacent $\mathrm{C}-\mathrm{O} \sigma^{*}$ orbital. ${ }^{19 \mathrm{c}}$

At this point, however, a closer examination of Table II along with a careful perusal of the geometrical parameters in Table III reveal some surprising features and a caveat. Geometry optimization (at any level) of methoxymethanol (MMO) and di-

[^6]methoxymethane (DMM) shows that the " $g^{+} g^{+}$", " $a g^{\prime}$ ", and " $g a$ " conformations (with $g=60 \pm 8^{\circ}$ ) are local minima on the rotational potential surface; not so the corresponding silyloxymethanol (SMO) and methoxysilyloxymethane (MSM) in which geometry optimizations reveal extensive distortion of the gauche $\mathrm{O}-\mathrm{C}-\mathrm{O}-\mathrm{Si}$ dihedral angle ( $\omega^{\prime}$ ) toward a syn conformation. At $3-21 \mathrm{G}$, this reaches, in fact, $0^{\circ}$, i.e., full eclipsing, turning the " $a g$ " geometries of MSM and SMO into actual "as" (" $s$ " stands for syn) geometries, but this phenomenon is less drastic at higher level (e.g., $4-21 G^{* *}$ ) and in the " $g^{+} g^{+"}$ forms.

An attractive explanation of this behavior is the existence of a relatively strong bonding interaction between Si and the nonbonded $\gamma$-O (while we are not aware of other instances where such behavior in $\mathrm{Si}-\mathrm{O}-\mathrm{C}-\mathrm{O}$ systems was reported it finds some analogy in the preferred syn conformation calculated for $\mathrm{Li}-\mathrm{CH}_{2}-$ $\mathrm{CH}_{2}-\mathrm{F}^{40}$ ). The above suggestion is supported by the calculated overlap populations; e.g., in SMO the interatomic distances OSi---O are $3.27 \AA$ in " $g^{+} g^{+"}$ ( Table II, item 6), $2.97 \AA$ in " $g^{+} g^{+"}$, and $2.79 \AA$ in "as" (Table II, item 2). The corresponding overlap populations are $0.01,0.04$, and 0.05 , respectively (for comparison, the overlap population of the covalently bonded $\mathrm{O}-\mathrm{Si}$ atoms is ca. 0.26). It appears, therefore, that the geometry of minimum energy is imposed by an interplay of $\mathrm{OSi} \cdots \mathrm{O}$ attractive forces, anomeric effects, as well as a certain steric effect. An estimation of the relative importance of these factors can be obtained from item 6 in Table II (see also footnote $f$ there). In these 3-21G calculations the $\mathrm{O}-\mathrm{SiH}_{3}$ group is held in the gauche $\left(60^{\circ}\right)$ conformation where OSi- - O interactions are bound to be relatively small owing to the relatively large separation. With these constraints the calculated $\Delta E$ value for $\mathrm{R}^{\prime}=\mathrm{SiH}_{3}$ in MSM is 3.16 $\mathrm{kcal} / \mathrm{mol}$, only $\Delta \Delta E=0.44 \mathrm{kcal} / \mathrm{mol}$ lower than for $\mathrm{R}^{\prime}=\mathrm{CH}_{3}$ in DMM; similarly, $\Delta \Delta E=0.14 \mathrm{kcal} / \mathrm{mol}$ for the MMO-SMO pair. We cannot but conclude that much of the anomeric effect alleviation in $\mathrm{R}-\mathrm{O}-\mathrm{C}-\mathrm{O}-\mathrm{Si}$-type molecules (manifested by the large $\Delta \Delta E$ values for MSM and SMO in the fully optimized structure) originates in the OSi---O attractive forces which result in a propensity for $\mathrm{O}-\mathrm{C}-\mathrm{O}-\mathrm{Si}$ eclipsing and lower the energy of the "ag" (or equatorial, e.g., 2) forms appreciably more than that of the " $\mathrm{g}^{+} \mathrm{g}^{+}$" (or axial, e.g., 1) forms. The latter's smaller tendency for eclipsing and higher energy may be due to a lower negative charge on the $\gamma$-oxygen and to steric interference of the two termini in $\mathrm{R}-\mathrm{O}-\mathrm{C}-\mathrm{O}-\mathrm{Si}$ as $\mathrm{O}-\mathrm{C}-\mathrm{O}-\mathrm{Si}$ eclipsing is approached. Since the experimental data are on trimethylsilyloxy(TMSO) (and not $\mathrm{H}_{3} \mathrm{SiO}$-) substituted systems, the bulky terminus in such real systems is bound to exert considerable steric hindrance to eclipsing in both " $a g$ " and " $g^{+} g^{+ \text {" }}$ forms (perhaps still more in the latter). This should restore the $\mathrm{O}-\mathrm{C}-\mathrm{O}-\mathrm{SiMe}_{3}$ dihedral angle to a more conventional value and diminish the $\mathrm{OSi}-\cdots \mathrm{O}$ attractive contribution to the molecular energy. This may also contribute to the similar behavior of TMSO and TBO groups in alleviating the anomeric effect (vide infra).

The above argument is well-supported by the structural data in Table III. Thus, focusing on MSM as calculated with the 3-21G//3-21G basis set (no. II there), the "ag" ("as") form has $\omega=180^{\circ}, \omega^{\prime}=0^{\circ}$, and $\mathrm{MeO}-\mathrm{C}-\mathrm{OSi}$ bond lengths, of 1.431 and $1.398 \AA$, respectively, indicating a strong "exo"-anomeric interaction. ${ }^{\text {b }}$ In contrast, the " $g^{+} g^{+"}$ " form exhibits $\omega=82^{\circ}, \omega^{\prime}=33^{\circ}$, and $\mathrm{MeO}-\mathrm{C}-\mathrm{OSi}$ bond lengths of 1.420 and $1.413 \AA$, respectively. Turning to SMO as calculated at the highest level, viz. 4 $21 \mathrm{G}^{* *} / / 4-21 \mathrm{G}^{* *}$ (Table III, no. V), the "ag" ("as") form exhibits $\omega=220^{\circ}, \omega^{\prime}=30^{\circ}$, and HO-C-OSi bond lengths of 1.40 and $1.38 \AA$, respectively, whereas the " $g^{+} g^{+ \text {" }}$ form has $\omega=65^{\circ}, \omega^{\prime}$ $=49^{\circ}$, and $\mathrm{HO}-\mathrm{C}-\mathrm{OSi}$ bond lengths of 1.393 and $1.396 \AA$, respectively. In the latter case, the " $g a$ " conformation features normal dihedral angles and the bond lengths are characteristic of a strong "exo"-anomeric effect.

Our next worry was how to isolate the overall steric effect in order to assess if, how, and to what extent it contributes to the observed behavior. It is to this end that we undertook to improve

the parametrization of MM2 (as described above) for optimal accuracy in geometry calculations of the molecules under scrutiny. The leading thought was that, having a force field accurately parametrized for the anomeric effect but not for electronic inductive effects of, say, tert-butyl, we would take advantage, in fact, of what it cannot do. The calculated tert-butoxy (TBO) substituted systems and the relevant results are depicted in Figure 2 and are taken to indicate that steric effects play no significant role in the observed alleviation of the anomeric effect.

Indeed, the molecular mechanics calculations (Figure 2 i -iii) give $\Delta E=1.5 \mathrm{kcal} / \mathrm{mol}$ in favor of the axial form of 2 -meth-oxy-1,4-dioxane and nicely double this value for both trans-2,3and 2,5 -dimethoxy-1,4-dioxane, in good agreement with experimental observations. ${ }^{2 b, 5 f}$ Similar calculations of the corresponding tert-butoxy derivatives leave these energy differences almost unchanged (the only exception, viz., $2.2 \mathrm{kcal} / \mathrm{mol}$ for trans-2,3-di(tert-butoxy)-1,4-dioxane still means net preference for the diaxial form and is partially accounted for below), in flagrant conflict with the experimental results (vide supra and Table I). For the record, in each case of the three in Figure 2 the entire potential surface was calculated, but all other conformations were deleted for being more than $4 \mathrm{kcal} / \mathrm{mol}$ above the ground state; hence, only the two lowest forms in each case were given. The most stable is always the axial or diaxial where both the anomeric effect and an exo-anomeric effect operate, and the next one is the equatorial or diequatorial form with no anomeric but with an exo-anomeric effect; all other rotamers are much less stable. Interestingly, the same energetic trends are preserved in calculations using MM2(80). We take the above results to suggest that steric effects per se do not account for the observed alleviation of the anomeric effect.
For additional evidence, the basic fragments ROCOR' and ROCCOR' were calculated with the same force field (Table V); tert-butyl vs. methyl substitution for $\mathrm{R}\left(\mathrm{R}^{\prime}\right)$ does not affect the energy differences in ROCOR' ( $E_{\mathrm{ga}}-E_{\mathrm{gg}}$ ) but shows some decrease for ROCCOR' ( $E_{\text {aga }}-E_{\text {aaa }}$ ) in the same direction as that observed in Figure 2ii.

Furthermore, the torsional angles $\omega$ increase in all cases where tert-butyl takes the place of methyl both in axial and (even more so) in equatorial conformations, without altering the energetic order. Hence, this relaxation process cannot account for the observed weakening of the anomeric effect, as inferred by Giralt et al. ${ }^{6 \mathrm{~b}}$ Furthermore, the details of our calculation of the trans-2,3-di(R)oxy derivatives (Figure 2ii) show that, contrary to the assumption of Giralt et al., ${ }^{6 \mathrm{~b}}$ the axial OR substituents experience no repulsive interaction with the axial hydrogens on $\mathrm{C}_{5}$ or $\mathrm{C}_{6}$, the closest interatomic distance $(\mathrm{H} \cdots \mathrm{H})$ being $3 \AA$.

The slight deviation from the trend observed in the 2,3 -di-tert-butoxy derivative in Figure 2ii is, therefore, attributed to a balance of steric interactions, including the one (Table V) which causes a decrease of the energy difference $E_{a g a}-E_{a a a}$ for 1,2-di(tert-butoxy)ethane (DTBE) as compared with 1,2 -dimethoxyethane (DME).

At this point, we present and discuss the structural data of trans-2,5-di-tert-butoxy-1,4-dioxane (10t) since (while this paper was being written up) we succeeded in growing a single crystal of $\mathbf{1 0 t}$ and subjecting it to X-ray diffraction analysis. The results are rather interesting and gratifying.

As evident from the data in Tables VI and VII and from the ORTEP drawing (Figure 3) of the molecule (10t), the latter exists in the crystal in the diaxial form, which in $\mathrm{CDCl}_{3}$ solution at room

Table VII. Geometrical Parameters of trans-2,5-Di-tert-butoxy-1,4-dioxane (10t) (Crystallographic Inversion at $0,0,1 / 2$ )

Figure 3. X-ray (ORTEP) structure of trans-2,5-di-tert-butoxy-1,4-dioxane ( $\mathbf{1 0 t}$ ).
temperature contributes only $23 \%$ to the equilibrium mixture. While this may well be due to favorable packing forces, it is of interest to examine the relevant structural parameters in comparison with known literature values, e.g., in analogous carbohydrates, viz. $\alpha$-glycosides. ${ }^{1,41}$ The latter exhibit characteristic (average) bond lengths of $\mathrm{C}_{6}-\mathrm{O}_{1} 1.437, \mathrm{O}_{1}-\mathrm{C}_{2} 1.415$, and (exo) $\mathrm{C}_{2}-\mathrm{O}_{7} 1.403 \AA$, and bond angles of (endo) $\mathrm{C}_{2}-\mathrm{O}_{1}-\mathrm{C}_{6} \simeq$ (exo) $\mathrm{C}_{2}-\mathrm{O}_{7}-\mathrm{C}_{8}=113.5^{\circ}$ (cf. Figure 3 for atom numbering, which differs from the usual carbohydrate numbering, for better convenience).
The corresponding values observed in $10 t$ are $\mathrm{C}_{6}-\mathrm{O}_{1} 1.427$, $\mathrm{C}_{2}-\mathrm{O}_{1} 1.424, \mathrm{C}_{2}-\mathrm{O}_{7} 1.400 \AA \mathrm{C}_{2}-\mathrm{O}_{1}-\mathrm{C}_{6}=111.9^{\circ}, \mathrm{C}_{2}-\mathrm{O}_{7}-\mathrm{C}_{8}=$

[^8]$118.4^{\circ}, \mathrm{C}_{6}-\mathrm{O}_{1}-\mathrm{C}_{2}-\mathrm{O}_{7}=65.6^{\circ}$, and $\mathrm{O}_{1}-\mathrm{C}_{2}-\mathrm{O}_{7}-\mathrm{C}_{8}=84.1^{\circ}$. The relatively long $\mathrm{C}_{2}-\mathrm{O}_{1}$ bond and small $\mathrm{C}_{2}-\mathrm{O}_{1}-\mathrm{C}_{6}$ angle indicate an alleviated anomeric effect, but with a strong exo-anomeric effect, as expected. ${ }^{16}$ We proceed now to compare these with the corresponding calculated data (by MM2, parametrized for the a nomeric effect) in 10t (cf. Figure 2iii): $\mathrm{C}_{6}-\mathrm{O}_{1} 1.443, \mathrm{O}_{1}-\mathrm{C}_{2}$ $1.411, \mathrm{C}_{2}-\mathrm{O}_{7} 1.409 \AA ; \mathrm{C}_{6}-\mathrm{O}_{1}-\mathrm{C}_{2}=112.4^{\circ}, \mathrm{C}_{2}-\mathrm{O}_{7}-\mathrm{C}_{8}=116.9^{\circ}$, $\mathrm{C}_{6}-\mathrm{O}_{1}-\mathrm{C}_{2}-\mathrm{O}_{7}=66.8^{\circ}$, and $\mathrm{O}_{1}-\mathrm{C}_{2}-\mathrm{O}_{7}-\mathrm{C}_{8}=88.6^{\circ}$. These results are, in our opinion, significant in that indeed they did not succeed to duplicate the experimental bond lengths, and are logically attributed to the above-stressed fact that MM2 accounts for steric and anomeric effects but not for the electronic inductive effect of tert-butyl. Therefore, no intrinsic steric effect is at the roots of the observed alleviation of the anomeric effect, since otherwise our MM2 calculations would have reflected it.

It is novel and revealing that by also applying the structural criterion ${ }^{16}$ one can observe that tert-butoxy (TBO) anomeric substitution weakens the anomeric effect. This, in fact, strengthens the argument that we deal with an electron-donating inductive effect of tert-butyl which lowers the electronegativity of TBO, but an electrostatic attraction between the positively charged quaternary carbon in $\mathrm{OCMe}_{3}$ and the $\gamma$-oxygen could still operate and be stronger in equatorial than in axial form. In fact, our above-presented findings and arguments may well make it worth reevaluating the role of electrostatic attraction between a terminal (carbon, silicon) atom in a $\mathrm{R}-\mathrm{O}-\mathrm{C}-\mathrm{X}-\mathrm{R}^{\prime}$ moiety and the $\gamma-$ heteroatom, i.e., $\mathrm{RO}^{\delta} \ldots .^{\delta+} \mathrm{R}^{\prime} \mathrm{X}$ or $\mathrm{OR}^{\delta+} \ldots \mathrm{A}^{\delta-} \mathrm{XR}^{\prime}$, in the framework of the anomeric effect. ${ }^{36.47}$ We believe that taking into account such a contribution may help rationalize some features of the anomeric effect, which are still unaccounted for, such as the elongation of the terminal ( $\mathrm{O}-\mathrm{R}$ ) bond lengths ( cf . section on molecular mechanics calculations). This aspect is being looked into presently and will be reported in due time.

In conclusion, we have shown experimentally that tert-butoxyand trimethylsilyloxy derivatives of 1,4 -dioxane exhibit weaker than usual anomeric effects. We have improved the parametrization of MM2 for the anomeric effect and used it in conjunction with ab initio MO calculations to show that no steric effects but rather electronic factors cause this phenomenon. These electronic factors involve an inductive electron donation by TBU or TMS and also a peculiar $\gamma-\mathrm{O}-\mathrm{SiO}_{\text {attractive interaction for the latter }}$ case (entropy could have some significance in this picture, but we have no information, as yet, what role it plays, if at all; we plan to deal with this problem presently). Finally, we secured corroborative X-ray structural data (for 10).

One may well expect the described phenomenon to become useful for directing both conformational behavior and, even more significantly, reactivity by judicious introduction of trimethylsilyl or tert-butyl in anomeric positions.

## Experimental Section

NMR spectra were measured on Bruker WH-90 and AM-360 WB instruments. Theoretical spectra were calculated using either the original LAOCON 3 simulation program ${ }^{42}$ or its PANIC (Bruker-ASPECT 2000) version and tested for reliability at various field strengths. Mass spectra were taken on a DuPont 21-491 B mass spectrometer. Gas chromatography was performed on a Packard-427 instrument using a Carbowax capillary colunn and a Spectrophysics System I electronic integrator. The NMR data are assembled in Table I.

Preparative Work. The diastereoisomeric 2,3 -di(trimethylsilyloxy)-1,4-dioxanes ( $\mathbf{6 t}, \mathbf{6 c}$ ) were prepared according to a published procedure. ${ }^{7 a}$
trans-2,5-Di(trimethylsilyloxy)-1,4-dioxane (9t) was prepared by trimethylsilylation of the 2,5 -dihydroxy derivative made by dimerization of glycolaldehyde. ${ }^{43}$ It was isolated from the isomeric mixture by preparative GLPC ( $R_{T}=25 \mathrm{~min}$ on a $20 \%$ Carbowax- $20 \mathrm{M} /$ Chromosorb W column at $125^{\circ} \mathrm{C}$ and $100 \mathrm{~mL} / \mathrm{min}$ carrier flow) and exhibited largely the reported properties. ${ }^{34}$

2-Trimethylsilyloxy-1,4-dioxane (12) was prepared by trimethylsilylation ( 1.9 g of TMSCl +1.4 g of pyridine) of 2-hydroxy-1,4-dioxane ${ }^{44}(3.9 \mathrm{~g}$ in 20 mL of benzene). The crude product ( 1.1 g ) was

[^9]distilled in vacuo ( $130-150^{\circ} \mathrm{C}(25$ torr) ) and purified by preparative chromatography as above ( $R_{T}=8 \mathrm{~min}$ ) to give $0.7 \mathrm{~g}(16 \%)$ of product (9) as a colorless oil: MS $m / z 176\left(5, \mathrm{M}^{+}\right)$; IR $\nu_{\text {max }}$ (neat) 1270,1255 $\mathrm{cm}^{-1}$.
The diastereoisomeric 2,3 -di(tert-butoxy)-1,4-dioxanes ( $7 \mathrm{t}, 7 \mathrm{c}$ ) were prepared using a recently published procedure. ${ }^{\text {6a }}$ Earlier we had used a somewhat less efficient procedure. A mixture of absolute tert-butyl alcohol ( 400 mL ), trans-2,3-dichlorodioxane ${ }^{8 \mathrm{Aa}}(12.85 \mathrm{~g}$ ), and pyridine ( 13 g) was stirred under nitrogen at $50^{\circ} \mathrm{C}$ for 20 h . Most of the tert-butyl alcohol was evaporated in vacuo and the residue taken up in $\mathrm{CH}_{2} \mathrm{Cl}_{2}$. This solution was washed with water (three times) and dried over anhydrous $\mathrm{K}_{2} \mathrm{CO}_{3}$. After filtration, the organic solvents were removed to leave a crude residue of $14.6 \mathrm{~g}(92 \%)$ consisting of a roughly $2: 1$ mixture of trans- and cis-2,3-di(tert-butoxy)-1,4-dioxane ( $7 \mathbf{t}$ and $7 \mathbf{c}$, respectively). These were resolved by HPLC (SI-1000, $8 \%$ ethyl acetate in cyclohexane); $\mathbf{7 t}$ was recrystallized from petroleum ether, $\mathrm{mp} 60-62^{\circ} \mathrm{C}$ and 7 c remained a colorless oil, properties as given ${ }^{6 a}$ (Table I).

The diastereoisomeric 2,5 -di (tert-butoxy)-1,4-dioxanes (10t, 10c) were prepared by adding 2,5 -dichloro-1,4-dioxane ${ }^{8 \mathrm{~b}}(5.5 \mathrm{~g})$ to a solution of dry pyridine ( 5.7 g ) in dry tert-butyl alcohol ( 150 ml ). The mixture was stirred under nitrogen at $30^{\circ} \mathrm{C}$ for 24 h after which the tert-butyl alcohol was evaporated; the residue was taken up in methylene chloride. The resulting solution was washed with $0.5 \% \mathrm{HCl}$ and water, dried, and evaporated to dryness. The crude mixture of diastereoisomers ( 4.2 g , $50 \%$ ) consisting of $65 \%$ cis ( $\mathbf{1 0 c}$ ) and $35 \%$ trans ( $\mathbf{1 0 t}$ ) (by NMR) was resolved by fractional crystallization from hexane. The trans isomer (10t) crystallized first: $\mathrm{mp} 110^{\circ} \mathrm{C} ; \mathrm{m} / \mathrm{z} 232\left(\mathrm{M}^{+} 12 \%\right), 57\left(\mathrm{C}_{4} \mathrm{H}_{9}{ }^{+}, 100 \%\right)$; ${ }^{1} \mathrm{H}$ and ${ }^{13} \mathrm{C}$ NMR in Table I. The pure cis isomer (10c) was obtained free of trans contamination after repeated recrystallizations: $\mathrm{mp} 70^{\circ} \mathrm{C}$; $\mathrm{m} / \mathrm{z} 232\left(\mathrm{M}^{+}, 8 \%\right), 57\left(\mathrm{C}_{4} \mathrm{H}_{9}{ }^{+}, 100 \%\right)$; ${ }^{1} \mathrm{H}$ and ${ }^{13} \mathrm{C}$ NMR in Table I .
X-ray Diffractlon Work. Intensity data were collected at ca. 291 K on an Enraf-Nonius CAD-4 diffractometer, using monochromatized Mo $\mathrm{K} \alpha$ radiation ( $0.7107 \AA$ ) in the $\omega-2 \theta$ mode with a scan width $1.25+0.3$ $\tan \theta$ out to $2 \theta=54^{\circ}$.

The structure was solved by direct methods (MULTAN 80) ${ }^{46}$ and refinement of the asymmetric unit (one-half of the molecule which is located on a crystallographic center of inversion) was performed by full-matrix least-squares calculations. ${ }^{47}$ All hydrogens were located directly on the difference maps; the methyls were refined as geometrically rigid groups.
Crystal data for $10 \mathrm{t}\left(\mathrm{C}_{12} \mathrm{H}_{24} \mathrm{H}_{4}\right): M=232$, monoclinic, space group $P 2_{1} / c ; a=6.148$ (4),$b=5.632$ (1), $c=19.270$ (3) $\AA ; \beta=91.67$ (3) ${ }^{\circ}$; $Z=2 ; V=667.0(5) \AA^{3} ; D_{x}=1.157 \mathrm{~g} \mathrm{~cm}^{-3}$. Of 1731 measured reflections, 1111 were unique ( $R_{\text {int }}=0.333$ ); $F(000)=256, R=0.042$, $R_{w}=0.044$ for 621 observations with $I>3 \sigma(I)$. Final atomic coordinates and thermal parameters are given in Table VI and relevant bond lengths, bond angles, and torsion angles are given in Table VII. The average esd's are $0.004 \AA, 0.2^{\circ}$, and $0.3^{\circ}$ for bond lengths, bond angles, and torsion angles, respectively. The full list along with the structure tables are deposited as supplementary material.

Acknowledgment. The computations were performed at the Tel-Aviv University Computational Center on IBM-4381 and CYBER-855 computers and at the Technion Computer Center on an IBM-3081 computer. We are grateful to Dr. Drora Cohen, Bar-Ilan University, for her gracious and helpful assistance with some of the (MO) calculations.
