Tolbert ${ }^{1 \mathrm{c}}$<br>Contribution from the Departments of Chemistry, University of California, Berkeley, California 94720, and Georgia Institute of Technology, Atlanta, Georgia 30332. Received May 22, 1986

#### Abstract

Two local minima and one transition structure have been found in the potential energy surface for 2,3-dilithiopropene with use of the RHF/3-21G level of theory. The relative energies and vibrational harmonic frequency calculations indicate a highly fluxional molecule in which the bonding to lithium is essentially ionic.

Ab initio studies of various di- and polylithiated organic compounds have revealed a plethora of unusual geometries at the stationary points within symmetry constraints at potential energy surfaces. ${ }^{2}$ One example is the "planar tetracoordinate carbon" structure for certain dilithiocarbons. ${ }^{3}$ 2,3-Dilithiopropene is of interest in connection with recent NMR studies of dilithium tetraphenylallenide. ${ }^{4.5}$ These experiments have suggested an allyl-like hydrocarbon framework with two lithiums that are equivalent on the NMR time scale and coupled exclusively to the central carbon. This finding has raised the possibility of a planar tetracoordinate structure as the observed species. ${ }^{5 \mathrm{a}}$
A previous ab initio study of 2,3-dilithiopropene has been limited to structures with lithiums at the $C_{s}$ plane of symmetry. ${ }^{6}$ We now report the ab initio exploration of the potential energy surface for 2,3-dilithiopropene, including harmonic vibrational frequency calculations at the stationary points.

## Computational Details

Geometries corresponding to the stationary points on the potential energy surface were located by spin-restricted Hartree-Fock (RHF) calculations with use of the 3-21G basis set ${ }^{7}$ in conjunction with the analytical gradients method of Gaussian $82 .{ }^{8}$ Previous calculations on closed-shell lithiocarbons have demonstrated that this level of theory gives adequate geometries. ${ }^{9}$ Relative energies are also tolerable, but inclusion of polarization and diffuse functions at the anionic centers improves them somewhat, partially because of reduction in the basis set superposition error, ${ }^{10}$ geometry reoptimization with these larger basis sets have been shown to give no or very little improvement. ${ }^{9 a}$ Accordingly, single-point

[^1]calculations at the 3-21G geometries were performed by employing the $6-31+\mathrm{G}^{*}$ basis set ${ }^{7}$ with sp-diffuse and d-functions on carbons. The predominantly ionic character of the carbon-lithium bond makes the relative correlation energy corrections for the structures with different disposition of lithiums very similar. ${ }^{9.11}$ Harmonic vibrational frequencies, which were used to characterize saddle points and minima, were evaluated from second derivatives obtained by the finite difference method from the analytical first derivatives. ${ }^{8}$ Because vibrational frequencies at the HF/3-21G level are generally overestimated by about $10 \%$, ${ }^{12}$ the calculated frequencies of Table III and zero-point vibrational energies (ZPVEs) of Table II are scaled by 0.9 .

## Results and Discussion

Geometries of 2,3-dilithiopropenes were optimized at the ab initio HF/3-21G level. The lowest stationary point determined in this work, 1, which is similar to one found previously, ${ }^{6}$ possesses a 2-lithioallyllithium structure; i.e., both lithiums lie on the $C_{s}$ plane with one ( $\mathrm{Li}(1)$ ) bridging the terminal carbons ( $130.3^{\circ}$ below the CCC plane) while the other $(\mathrm{Li}(2))$ is in the proximity of the central carbon ( $3.0^{\circ}$ above the CCC plane). The hydrogens are bent outward from $\mathrm{Li}(1)$; i.e., endo $\mathrm{H}^{\prime}$ s are $27^{\circ}$ and exo are $0.6^{\circ}$ above the CCC plane. The large bending of the endo hydrogens is reminiscent of allyllithium. ${ }^{10}$ Placing $\operatorname{Li}(2)$ exactly in the CCC plane and reoptimizing the structure raises the energy by only

${ }^{a} \mathrm{In} \mathrm{cm}^{-1}$; scaled by 0.9 .
$24 \mathrm{cal} \mathrm{mol}^{-1}$, which may reflect increased $\mathrm{Li}-\mathrm{Li}$ electrostatic repulsion.

The frequency calculations reveal that structure $\mathbf{1}$ is in fact a transition structure (one imaginary frequency, $37.61 \mathrm{~cm}^{-1}$, Table III). The low magnitude of this frequency indicates an extremely flat potential energy surface in the neighborhood of the point corresponding to 1 . Indeed, reoptimization with the hydrocarbon framework constrained to the geometry of $\mathbf{1}$ and with the lithiums allowed to move freely on the potential energy surface lowers the energy by only $0.3 \mathrm{cal} \mathrm{mol}^{-1}$ relative to $1 . \operatorname{Li}(2)$ moves by $3^{\circ}$ off the $C_{s}$ plane (plane of symmetry for the hydrocarbon framework) toward one of the terminal carbons while $\operatorname{Li}(1)$ remains at the $C_{s}$ plane (within $0.001^{\circ}$ ). The $\mathrm{C}(2)-\mathrm{Li}$ distances increase slightly (less than $0.001 \AA$ ), but the LiLi separation is not increased compared to that of 1 . The resulting structure is not strictly a global minimum because the hydrocarbon framework was fixed as that of $\mathbf{1}$. Nevertheless, the minute energy changes involved indicate that the global minimum has an energy hardly less than that of 1 and a structure that cannot be much different. Because the potential energy surface is so flat in this region, it made little sense to determine the true global minimum. The use of a different basis set could change the lithium positions somewhat, but undoubtedly without significant change in relative energy. This nondirectional character of the $\mathrm{C}-\mathrm{Li}$ bonds suggests high ionic character. Indeed, when the 3-21G lithiums (that includes 2 s and 2 p functions) are replaced by lithium cations ${ }^{13,14}$ (effectively no 2 sp shell) the resulting structure is virtually the same. That is, optimization with the hydrocarbon framework fixed at the geometry of 1 locates $\operatorname{Li}(2) 3^{\circ}$ off the $C_{s}$ plane and $\mathrm{Li}(1)$ at the $C_{s}$ plane (within $0.003^{\circ}$ ), an arrangement very close to that with standard 3-21G lithiums.

Two additional structures, $\mathbf{2}$ and $\mathbf{3}$, were located as well (Tables I and II). The harmonic frequency calculations determine them to be local minima on the potential energy surface. The existence of normal modes with very low frequencies points again to the flatness of the potential energy surface (Table III). The $C_{2 c^{-}}{ }^{-}$ symmetric structure 2 is $2.47 \mathrm{kcal} \mathrm{mol}^{-1}$ above 1 . The $C_{2}$-symmetric structure $3\left(6.08 \mathrm{kcal} \mathrm{mol}^{-1}\right.$ above 1$)$ is obtained upon reoptimization of the $C_{2 v}$-symmetric "planar tetracoordinate carbon" structure 4 ( $19.77 \mathrm{kcal} \mathrm{mol}^{-1}$ above 1). The terminal methylenes in $\mathbf{1}$ and $\mathbf{3}$ are somewhat pyramidal ( $5.4^{\circ}$ and $4.3^{\circ}$, respectively). ${ }^{6.15}$

[^3]

Figure 1. Structures of 2,3-dilithiopropene.
A 1,1-dilithiocyclopropane structure with planar tetracoordinate $\mathrm{C}(1)$, which was optimized within the $C_{24}$-symmetry constraint, is $49.17 \mathrm{kcal} \mathrm{mol}^{-1}$ above 1 . Note that this is even above 4. Previous optimizations at the HF/STO-3G level have shown that the tetrahedral $\mathrm{C}(1)$ structure for 1,1 -dilithiocyclopropane is 7.15 $\mathrm{kcal} \mathrm{mol}{ }^{-1}$ above the planar one. ${ }^{36}$ Thus, we conclude that $1,1-$ dilithiocyclopropane is thermodynamically unstable with respect to the cyclopropane ring opening leading to 2,3 -dilithiopropenes.

The potential energy surface for lithium shifts in the $C_{s}$ plane (structure 1) is also rather flat. For example, when the $\mathrm{Li}(2)-$ central carbon bond axis is fixed at $45^{\circ}$ or $70^{\circ}$ above the CCC plane and the structures are fully optimized within the $C_{s}$ symmetry constraint, the relative energies are 2.24 and $2.74 \mathrm{kcal} \mathrm{mol}^{-1}$, respectively. The other $\operatorname{Li}(1)$-carbon axis is $122.9^{\circ}$ and $119.0^{\circ}$, respectively, below the CCC plane. Therefore, one may anticipate a low barrier (about $3 \mathrm{kcal} \mathrm{mol}^{-1}$ at $3-21 \mathrm{G}$ ) for intramolecular lithium exchange in structure 1, possibly via structure 2 (lithiums $107.6^{\circ}$ above and below the CCC plane). Zero-point vibrational energies are about $34 \mathrm{kcal} \mathrm{mol}^{-1}$ for all structures 1, 2, and 3. Single-point calculations with the $6-31+G^{*}$ basis set using $3-21 G$ geometries increase the relative energy of structure 2 to 4.14 kcal $\mathrm{mol}^{-1}$ after zero-point energy correction (Table II). This result suggests that the barrier for Li exchange in 1 within the $C_{s}$ plane may be somewhat higher, perhaps about $5 \mathrm{kcal} \mathrm{mol}^{-1}$.

The nature of the barrier-to-lithium exchange is clearly indicated by the electrostatic map for the $\mathrm{CH}_{2} \mathrm{CCH}_{2}$ dianion (RHF/3-21G at the geometry of 2) calculated for the plane containing the $\mathrm{C}(2)$ and orthogonal to the CCC plane (Figure 2). This map gives the electrostaic potential for the dianion with correction for the polarization by a single cation. ${ }^{16}$ Figure 2 includes a circle of radius $2.0 \AA$ centered at $\mathrm{C}(2)$; the normal $\mathrm{C}-\mathrm{Li}$ bond distance is $2.0 \AA$ (Table I), and the circumference of this circle indicates the closest normal approach of Li to C . Within these constraints the maximum electrostatic potential is that at the point marked by " M ". Neither lithium, however, can occupy this site because it is too close to two of the methylenic hydrogens. In the lowest energy structure 1 one lithium moves above the CCC plane to the position marked " 1 ". Putting the second lithium at the equivalent $C_{2}$. position, however, apparently involves too much

[^4]

Figure 2. Electrostatic map for $\mathrm{CH}_{2} \mathrm{CCH}_{2}$ dianion calculated at the RHF/3-21G level at the geometry of $\mathbf{2}$ and with polarization correction for a single positive charge. The plane of the plot is orthogonal to the CCC plane and contains the $\mathrm{C}(2)$. This is the plane where the lithiums in structures 1 and 2 are located. The $\mathrm{C}(2)$ is indicated by " C " and the full line is a circle of radius $2.0 \AA$ centered at this atom. Because the $\mathrm{C}(2)$-Li distances in 1 and 2 are about $2 \AA$ the electrostatic potential at this circumference circle is a guide to the disposition of the lithiums within the plane of the plot. The contours are ploted from -0.74 to -0.41 by 0.03 hartree.
$\mathrm{Li}-\mathrm{Li}$ repulsion. The positions marked " 2 ", where the lower electrostatic potential is offset by reduced $\mathrm{Li}-\mathrm{Li}$ repulsion, correspond to the actual location of the lithiums in structure 2. Alternatively, in structure 1 one lithium remains at the position " 1 " close to the electrostatic potential maximum and the second lithium locates at the carbon lone pair position " 1 " far from the first lithium and yet at an electrostatic potential equivalent to position " 2 ". These two factors show why structure $\mathbf{2}$ is of higher energy than 1. Of course, additional variations are to be expected from the perturbation of the electrostatic potential caused by polarization by the second lithium. The electrostatic potential map for the dianion itself, however, is qualitatively similar to that corrected for a single positive charge in Figure 2; hence, the polarization correction for a second positive charge is expected to have no significant effect on the conclusions. The important point is that the essential features of the structures are excellently represented by the simplest type of electrostatic energy analysis. This result is in line with a recent study of methyl lithiomethyl sulfone ${ }^{17}$ in which structures were also well understood in terms of simple electrostatic considerations. Finally, moving Li from position "1" to position "2" in Figure 2 requires traversing a barrier of reduced electrostatic potential-the obvious source of the barrier for lithium exchange.

Although the above discussion documents the high ionic character of the carbon-lithium bonds, we cite further aspects of the electronic structure of 2,3 -dilithiopropene. Orbital interactions for structures 1, 2, and $\mathbf{3}$ between the lithiums and the hydrocarbon framework are essentially unimportant because all occupied MOs are overwhelmingly localized on the carbons and hydrogens and only lower virtual valence orbitals are on the lithiums. This trivial manifestation of the predominantly ionic

character of the CLi bond is confirmed by the Natural Population (NP) procedure of Reed and Weinhold ${ }^{18}$ (Table IV). Calculated total NPs for the lithiums are between 2.13 and 2.20 electrons, in essential agreement with both NPs and integrated spatial electron populations for other organolithium compounds. ${ }^{3 \mathrm{a}, 10,19,20}$ The lithiums or, approximately, the lithium cations exert a small influence on the charge distribution within the hydrocarbon framework; for example, increased lithium coordination of the $C(2)$ as in structures $\mathbf{2}, \mathbf{1}$, and $\mathbf{3}$ leads to larger negative charge associated with this carbon. Incidentally, the energy of the subjacent HOMO, which is predominantly the free-electron pair at $\mathrm{C}(2)$, is lowered in the same order. The other two occupied neighboring MOs (HOMO and SSHOMO) correspond virtually to the nonbonding and bonding allylic $\pi$-MOs, respectively. The energetics of these three highest occupied MOs does not reflect trends in the total energies for $\mathbf{1}, \mathbf{2}$, and 3. The $\mathrm{C}(2)$ atom, which formally bears the free electron pair, has less negative charge than the terminal carbons, thus indicating an important polarization of the $\pi$-electron density within the allylic framework, reminiscent of vinyl anion. ${ }^{21}$

## Conclusion

The symmetry-breaking lithium shift in the 2 -lithioallyllithium $C_{s}$-symmetric structure 1 , which occurs at an extremely flat fragment of the potential energy surface, exemplifies once again an effect originating in the ionicity of the carbon-lithium bond. ${ }^{2 a}$ The $\eta^{3}$-bridging lithium has a tendency to remain close to the $C_{s}$ plane of symmetry in clear analogy with the $C_{s}$-symmetric structure for allyllithium.

The two local minima on the potential energy surface considered above are characterized by exceedingly small curvatures; some of the vibrational normal modes involving displacements of lithiums possess underlying frequencies on the order of only $100 \mathrm{~cm}^{-1}$.

The barrier for lithium shifts leading to the exchange of the lithiums is estimated as no more than about $5 \mathrm{kcal} \mathrm{mol}^{-1}$. The calculations apply to unsolvated lithiums; however, because of high ionic character of bonds to lithium the barrier should be lower for solvated lithium cations. Indeed, this result is in qualitative agreement with a recent low-temperature ${ }^{7} \mathrm{Li}$ and ${ }^{6} \mathrm{Li}$ NMR study of the tetraphenyl derivative. ${ }^{56}$

The planar tetracoordinate carbon structure is about 13 kcal $\mathrm{mol}^{-1}$ above the local minimum corresponding to "tetrahedral carbon" and about $19 \mathrm{kcal} \mathrm{mol}^{-1}$ above the global minimum structure of 2-lithioallyllithium.
