polarizability derivatives are available from the authors upon request. ${ }^{\text {Ss }}$ The modes presented in Table $V$ can be used in the analytical identification of various tautomeric forms by IR/Raman spectroscopy. The overall agreement with the matrix isolation data is reasonable. Following the data presented in Table V, the S-H mode intensity in the IR spectra should be almost two orders of magnitude smaller than that of the Raman intensity, which may suggest that the $\mathrm{S}-\mathrm{H}$ mode can hardly be visible in IR but should be active in Raman. In order to understand the $\mathrm{S}-\mathrm{H}$ vibrations and their activities, we performed benchmark SCF/ 3-21G*, SCF/6-31G**, and MP2/6-31G** calculations for the
symmetric stretching S-H mode in $\mathrm{H}_{2} \mathrm{~S}$ (Table VI). Upon examining the results, one sees that regardless of the method the IR intensities for the symmetric vibrational mode remain small. This seems to suggest that the low IR intensity of the S-H stretching in thiouracils is not an artifact of the SCF/3-21G* approximation. This would also mean that Raman will be more suitable than IR for an identification of mercapto tautomeric forms. On the other hand (somewhat surprising in view of the present study), in the low-temperature ( $T=10-14 \mathrm{~K}$ ) matrixisolation IR spectra for the 4 -neopentoxy-2-thiouracil, a strong single peak in the $2700-2500 \mathrm{~cm}^{-1}$ region has been observed and interpreted as the $\mathrm{S}-\mathrm{H}$ stretching. ${ }^{27}$

Szczepaniak for reading the manuscript and notifying us of her latest experimental IR matrix isolation studies on thiouracils.

# Butadiene. 1. A Normal Coordinate Analysis and Infrared Intensities. Structure of the Second Rotamer 

Kenneth B. Wiberg* and Robert E. Rosenberg<br>Contribution from the Department of Chemistry, Yale University, New Haven, Connecticut 06511. Received July 24, 1989

#### Abstract

The question of the structure of the second stable conformer of butadiene (cis or gauche) has been reexamined by using a combination of theoretical and experimental methods. High level MP3/6-311+G**//MP2/6-31G* ab initio calculations predicted the gauche conformer to be energetically preferred by $0.98 \mathrm{kcal} / \mathrm{mol}(0.85 \mathrm{kcal} / \mathrm{mol}$ after correction for zero-point energies) over the cis conformer. Experimental data were reexamined as follows. An ab initio derived force field for $s$-trans-butadiene was fit to the observed gas-phase infrared and Raman spectra. Infrared intensities for $s$-trans-butadiene were measured and converted to dipole moment derivatives with respect to the internal coordinates, and the derivatives were compared to those obtained theoretically. The intensity data proved useful in determining the form of the normal coordinates for the out-of-plane bending modes. These data should prove useful in comparisons with force fields and dipole moment derivatives for other alkenes. The scaling factors obtained in the normal coordinate analysis were transferred to the calculated force fields for the cis and gauche forms, and the vibrational spectra were derived from these data. The ratios of dipole moment derivatives between experiment and theory, along with the calculated derivatives for the other rotamers, were used to predict intensities for both cis- and gauche-butadiene. The constructed spectra for the minor rotamers were compared to the experimental spectra. gauche-Butadiene was found to fit the data better than the cis conformer, in agreement with ab initio calculations. Vertical transition energies for the $\pi$ to $\pi^{*}\left(\mathrm{~A}_{8} \rightarrow \mathrm{~B}_{4}\right)$ transition for cis, gauche, and trans rotamers were calculated. While absolute transition energies were $5-10 \%$ too large, relative energies (with an origin corrected to trans-butadiene) supported a gauche conformer -5 to +10 nm to the red of the trans form and a cis form nearly 30 nm to the red. Although the second conformer was previously reported to be 14 nm to the red of the trans form, new experimental data suggested this gap may be only 3 nm . Significantly, both assignments of $\lambda_{\max }$ were in agreement with a twist angle near $25-35^{\circ}$. This correlation of $\lambda_{\max }$ to twist angle was supported empirically with the known data for cycloheptadiene and cyclooctadiene.

## 1. Introduction

As one of the simplest of the $\pi$-conjugated systems, butadiene has received extensive study both experimentally and theoretically. Despite these studies, some important questions remain unresolved: (1) What is the structure of the second rotamer? (2) What is the origin of the $3.5 \mathrm{kcal} / \mathrm{mol}$ stabilization of butadiene which is found in hydrogenation studies? ${ }^{1}$ (3) What is the origin of the $4-5 \mathrm{kcal} / \mathrm{mol}$ rotational barrier? ${ }^{2}$ We shall attempt to answer
the first question herein, and we shall consider the other two related questions subsequently.

It has long been recognized that butadiene exists primarily in the $s$-trans form, and it has been believed that a second rotamer also exists. The question of the structure of the less stable isomer of butadiene is still in doubt. Is it $s$-cis or $s$-gauche? The structural question has been the subject of numerous experimental ${ }^{3-6}$ and

theoretical studies. ${ }^{7-9}$ Experimental resolution of this question is not straightforward as the energy difference between the two forms is $2.5-3.1 \mathrm{kcal} / \mathrm{mol}$, which means that at room temperature only about $1 \%$ of the less stable conformer will be present. This problem was first circumvented by Huber-Wälchli and Günthard ${ }^{10}$ who heated butadiene up to 800 K , giving a significant Boltzmann population of the less stable form ( $\sim 15 \%$ ). The mixture was then quickly cooled below 20 K which trapped the high-temperature distribution, without allowing the mixture to reequilibrate (the activation barrier for this is about $4 \mathrm{kcal} / \mathrm{mol}$ ). This method allowed Squillacote, Sheridan, Chapman, and Anet (SSCA) ${ }^{4 \mathrm{a}}$ to record the infrared and ultraviolet spectrum of the minor conformer. The $\lambda_{\max }$ of the second conformer was found to be 14 nm to the red of the trans. Pariser-Parr calculations suggested a blue shift for the gauche rotamer, and therefore the minor rotamer was assigned the cis conformation. Later, Furakawa et al. ${ }^{3}$ carried out a detailed normal coordinate analysis with the $d_{0}$, $d_{4}$, and $d_{6}$ butadiene minor conformers which suggested the gauche form. Subsequently, Squillacote, Semple, and Mui ${ }^{4 b}$ argued for a cis form on the basis of more UV data concerning dimethylbutadienes, and their conclusions were supported by Fisher and Michl's elegant polarization study. ${ }^{5}$

Many theoretical studies have been carried out. Two recent studies led to different conclusions. One found the gauche form to be $0.7 \mathrm{kcal} / \mathrm{mol}$ more stable than cis,? and the other concluded that theory could not distinguish unambiguously between the two forms. ${ }^{8}$ We felt that by extending the theory and reexamining the experimental data, we might arrive at a consistent prediction for the torsional angle between the two double bonds in the minor form of butadiene.

We have calculated the structures and energies of butadiene rotamers including electron correlation. We have reexamined the vibrational force field of the trans form making use of new experimental data combined with a theoretically determined force field. Dipole moment derivatives have been obtained from measured infrared intensities. They have been used to calculate atomic polar tensors, which are helpful in comparing intensity data between similar molecules. The infrared spectra of gauche- and

cis-butadienes were calculated theoretically and scaled to form an experimental spectrum by using the scaling factors derived from the fitting of trans-butadiene with use of both line transitions and intensities. The simulated spectra have been compared with the available experimental data. Electronic absorption vertical transitions for the various conformers of butadiene were calculated and compared to experiment. The predicted spectra are discussed within the context of the known $\lambda_{\text {max }}$ of cycloheptadiene and cyclooctadiene.

## 2. Theoretical Studies

The most recent ab initio studies have reached different conclusions. The first, reported by Breulet, Lee, and Schaefer ${ }^{7}$ used a double- $\zeta$ plus polarization ( $\mathrm{DZ}+\mathrm{P}$ ) fully optimized geometry and included configuration interaction using all single and double excitations at the DZ + P geometry (SD-CI). They found that gauche-butadiene was energetically preferable to the cis form by $0.7 \mathrm{kcal} / \mathrm{mol}$. Davidson and Feller, ${ }^{8} 2$ years later, reported optimized MCSCF energies with use of the Dunning-Hay SV basis set and found that the cis form was $120 \mathrm{cal} /$ mol more stable than the gauche. However, this conclusion is tempered by the fact that the inclusion of polarization functions in going from $\mathrm{DZ}+\mathrm{DZ}+\mathrm{P}$ at the DZ optimized geometries resulted in a $420 \mathrm{cal} / \mathrm{mol}$ bias favoring the gauche compound. The authors noted that inclusion of polarization functions to give MCSCF DZ + P optimized structures may favor the gauche form. They said that any predictions made by using such small energy differences "should be viewed with a certain amount of skepticism". Thus current theory leans toward the gauche form but not unambiguously.

We sought to clarify the problem by trying to include in our computational methods tools that would accurately reproduce factors of import to this question. Presumably, the energetic preference for gauche-versus cis-butadiene is due to the severe steric interactions between the inner hydrogens on Cl and C 4 as can be seen from a comparison of the bond angles in the cis and trans forms (Table I). Bond lengths at the 6-31G* level of theory are known to be about $1 \%$ too short. ${ }^{11}$ This bond compression would heighten the steric problems in the cis form. Correction for electron correlation using the Moller-Plesset perturbation theory through the second-order (MP2) ${ }^{12}$ is known to reproduce

Figure 1. Energies of butadiene rotamers as a function of the $\mathrm{C}-\mathrm{C}-\mathrm{C}-\mathrm{C}$ torsional angle. The solid line gives the $\mathrm{HF} / 6-31 \mathrm{G}^{*}$ energy changes, and the dashed line gives the MP2/6-31G* energies.
experimental bond lengths quite well, ${ }^{13}$ possibly alleviating some of the steric problems. After this work was completed, Bock and Panchenko ${ }^{14}$ reported the MP2/6-31G* structures and energies for cis- and gauche-butadiene, leading to results and conclusions which are in complete agreement with the following.

The MP2/6-31G* calculated structure for trans-butadiene is compared with the experimental structure ${ }^{15}$ in Table II, and a good agreement is found. As can be seen from Tables I and II and Figure 1; the MP2/6-31G* torsional potential appears nearly identical with the $6-31 \mathrm{G}^{*}$ potential and was in favor of the gauche form ( $\Delta E=0.75 \mathrm{kcal} / \mathrm{mol}$ ). More extensive correction for electron correlation and the use of larger basis sets would probably have only a small effect on geometries (most of this having been taken into account in the MP2 optimizations) but may favor one form or the other energetically. Thus the basis set was expanded to triple- $\zeta$ quality with diffuse functions on carbon and polarization functions on all atoms $-6-311+G^{* *}$. The stabilizing interaction of coplanar double bonds in $s$-cis-butadiene, to be discussed more fully in a subsequent publication, would almost surely benefit from this larger basis set, while a smaller effect was expected for the $s$-gauche structure. Nonetheless, the MP3/6-311+G**// MP2/6-31G* energies favored the gauche form over cis by 0.98 $\mathrm{kcal} / \mathrm{mol}$. Correction for the differences in zero-point energies with use of the data presented below gave a barrier of 0.85

[^2]$\mathrm{kcal} / \mathrm{mol}$. Interestingly, as electron correlation was added, and then the basis set enlarged, the torsional potential remained surprisingly the same. We thus conclude that theory predicts gauche to be the second stable form of butadiene and furthermore that higher levels of theory will not reverse this ordering. Due to numerous past successes with theory in this type of problem, ${ }^{16}$ it seems unlikely that theory would be wrong in this case. Can the experimental data be interpreted as consistent with the theory?

## 3. Vibrational Spectra

The spectra of the second stable form of butadiene have been examined by several groups, who came to different conclusions. Furakawa et al. favored a gauche form based on the infrared spectrum but suggested that the cis form is an adequate model, ${ }^{3}$ while SSCA used ultraviolet absorption studies to support a cisoid structure. ${ }^{42}$
The vibrational spectrum of s-trans-butadiene has been studied many times, and several normal coordinate analyses have been reported. ${ }^{17}$ However, the interpretation of the spectrum has been difficult because of the well-known problem of determining a unique force field for polyatomic molecules of more than four or five atoms. Only $3 N-6$ pieces of data come from each isotopomer, while $(N)(N+1) / 2$ pieces of data are needed to uniquely define the force field. Furthermore, reducing the potential energy $F$ matrix by employing symmetry and obtaining additional data through the use of isotopomers, methods used for small molecules, does not yield enough data for a unique force field determination. While it may appear that generating enough isotopomers would eventually clarify the force field, product rules relating isotopomers reduce the number of unique data available from each species. We have therefore employed theoretical calculations as a starting point for a normal coordinate analysis.

There is a clear consensus as to the vibrational assignment for butadiene. ${ }^{17}$ However, the previous work was unsatisfactory for our purposes because most of the Raman data were obtained in the liquid phase, and it is known that there are shifts in band positions on going from the liquid to the gas phase. In order to have a consistent set of data, all obtained in the gas phase, we have redetermined the band positions. Butadiene- $d_{0},-2,3-d_{2}$, $-1,1,4,4-d_{4}$, and $-d_{6}$ isomers were thus reexamined. Their synthesis followed literature procedures, ${ }^{18}$ and purity was determined by

both NMR and IR. The infrared spectra were obtained with a Nicolet 7199 spectrometer at $0.25-\mathrm{cm}^{-1}$ resolution by using a 7.25 cm gas cell. The Raman spectra were measured in the gas phase with $2-\mathrm{cm}^{-1}$ resolution by using a Spex 1403 Ramalog.

As would be expected most vibrational frequencies were in accord with literature values. Only one significant change was made: $\nu_{18}$ of the light compound was assigned to $2984 \mathrm{~cm}^{-1}$ by Panchenko ${ }^{17 \mathrm{~d}, \mathrm{e}}$ and $3031 \mathrm{~cm}^{-1}$ by us. Both bands appeared in the $d_{1}$ and $d_{2}$ species. The higher energy band was assigned to $\nu_{18}$ because it fits both the force field for butadiene and was consistent with the intensity data, vide infra. We note that $\nu_{17}$ of the $d_{4}$ compound was at $3020 \mathrm{~cm}^{-1}$, which is the exact midpoint of $\nu_{18}$ and $\nu_{19}$ in the parent. One possibility is that these two bands interact in a first order sense in the parent and that when this interaction is removed by deuteration in the $d_{2}$ case the band shifts to higher energy. We assigned the $2984-\mathrm{cm}^{-1}$ band to the $8 \%$ residual $d_{1}$ in the $d_{2}$ compound (present in both laboratories, since the method of preparation was the same). Additionally, $\nu_{17}$ of the $d_{4}$ compound was reported at 3037 and $3041 \mathrm{~cm}^{-1}$, while we found it at $3020 \mathrm{~cm}^{-1}$. As this band was quite strong and the only band present, we attribute this to a poor choice of band origin in the lower resolution spectra. It should be noted that these two discrepancies do not significantly change the fit force field, due to the identical assignments on the more than 80 other bands.

A harmonic force field was calculated by using ab initio methods at the $6-31 \mathrm{G}^{*}$ level of theory. ${ }^{19}$ Due to bond shortness, leading to higher force constants, the problem of anharmonicity, and the limitations of ab initio methods (basis set incompleteness, lack of electron correlation), the frequencies calculated are generally found to be about $10 \%$ higher than the observed anharmonic frequencies. The calculated spectra for the four isotopomers are compared with the experimental data in Table III. We have found that a simple scaling scheme ( 0.91 for CH stretches, 0.88 for all other frequencies) normally results in an RMS error of less than $25 \mathrm{~cm}^{-1} .{ }^{20}$ This was also found to be the case with butadiene.

[^3]Table IV. Symmetry Coordinates for Butadiene ${ }^{a}$

${ }^{a}$ The $\gamma$ 's are HCCC torisional angles, and the $\epsilon$ 's are CH out-ofplane bending coordinates.

The calculated force constants were then adjusted to give a "best fit" to the observed spectrum based on the symmetry coordinates given in Table IV and the experimental geometry. The fitting procedure used one scaling factor for each diagonal $\mathbf{F}$ matrix element and one for all the off-diagonal elements in a given symmetry block for 28 in all. This reduced the rms error to only $10 \mathrm{~cm}^{-1}$ with much of the error coming from the highly anharmonic CH stretches (Table V). In fact, without the CH stretches the rms error of the fit was less than $3 \mathrm{~cm}^{-1}$. The scaling factors and force constants are summarized in Table VI. It should be noted that scaling factors (ratio of fit to calculated) were almost uniformly near 0.8 (mean $=0.8304, s=0.080$ ). The narrowness of their spread is necessary though not sufficient to show that the calculation is qualitatively correct and that the data is not fit from just a random force field.

The force constants reported by Furakawa et al. ${ }^{3}$ are also given in Table VI. There are significant differences between their values and those obtained in this investigation. This resulted in large measure from the necessity in the previous work of setting many

of the off-diagonal terms to zero. The present results show that in many cases this assumption was not satisfactory.

## 4. Intensity Data

Information on the infrared band intensities was desired for two reasons. First, they are of value in testing vibrational force fields and give information on charge distributions in molecules. ${ }^{21}$ Second, in the present case, they would be useful in predicting the band intensities of the cis and gauche forms of butadiene. Empirically, ab initio intensities frequently have errors of $\pm 20-50 \%$ as compared to the actual intensities and are only a rough guide as to actual observed intensities. ${ }^{22}$ We hoped to reduce some of this uncertainty by scaling the calculated intensities for the trans compound to the actual observed intensities and by using these scaling factors to better predict intensities for the cis and gauche form from the calculated data. While we hope to predict intensities as accurately as possible, it is also important to see how well intensity data from one molecule (trans-butadiene) transfers to similar molecules (cis- and gauche-butadiene). In the past, force field data has been transferred from one molecule to another successfully, ${ }^{23}$ and we hoped intensity data would behave similarly.

Unfortunately, infrared intensity data are quite scarce, due in no small part to the experimental difficulties. We have measured for the first time the absolute infrared intensities of the four isotopic butadienes in the gas phase at $0.25-\mathrm{cm}^{-1}$ resolution following the Wilson-Wells-Penner procedure. ${ }^{24}$ A brass highpressure cell similar to that described by Dickson et al. ${ }^{25}$ with a path length of 72.5 mm was used for all measurements. The spectra were obtained at a pressure of 300 psi of nitrogen in order to broaden the rotational lines and were obtained for a range of butadiene partial pressures. Care was taken such that at least five pressures were available for all bands (strong bands saturate the signal and must be measured at lower pressures, while weak

[^4]

Figure 2. Beer's law plots of $\mathrm{Apl}(\mathrm{km}-\mathrm{atm} / \mathrm{mol}-\mathrm{cm}$ ) against pl (atm- cm ) for butadiene- $d_{0}$. The integration regions were as follows: $\mathrm{A}, 800-967$ $\mathrm{cm}^{-1}$; B, 2850-3225 cm ${ }^{-1} ; \mathrm{C}, 967-1125 \mathrm{~cm}^{-1} ; \mathrm{D}, 1525-1650 \mathrm{~cm}^{-1} ; \mathrm{E}$, $1337-1408 \mathrm{~cm}^{-1}$; and $\mathrm{F}, 1200-1337 \mathrm{~cm}^{-1}$.
bands need higher pressures for adequate signal to noise). In each case, Beer's law plots were linear (Figure 2). The intensity data are given in Table VII.

As is frequently observed, some of the infrared bands overlap, and it was necessary to find a way in which to obtain the individual band contributions. Three methods were employed to solve this problem. A cut and weigh method, which is clearly a subjective determination, was used to deconvolute intensity in all cases. In some cases, the ratio of the bands could be obtained from solu-tion-phase spectra where the bands were relatively narrow because the rotational structure has been eliminated. This was effective for only those bands without severe overlap problems and gave results which agreed well with the cut and weigh method above.

| 23 |  |  |  |  | 0.02 |  |  | parentheses. All of the others were previously assigned as zero.

As shown in Table VIII, the ratio of intensity as calculated ab initio was close to the subjective method above, and, in the absence of other data, the ratio of calculated intensities were used to separate the components of severely overlapped bands.

It should be noted that for each intensity datum, there are two choices of sign for $\mathrm{d} \mu / \mathrm{d} Q$ since the intensity is proportional to the square of this quantity. Moreover, if polarization is not along a unique axis, as is the case with butadiene, it is impossible to partition intensity between the unique directions. This problem

has not been solved in general for polyatomics in the past, and only recently with ab initio methods has it been possible to use intensity data from a molecule as large as butadiene. The procedure of Person and Newton was followed, ${ }^{26}$ by using a set of programs written by Dempsey. ${ }^{27}$ The ab initio atomic polar tensors ( $P_{\mathbf{X}}$, APT's) were transformed to normal coordinates

$$
P_{\mathrm{Q}}=P_{\mathrm{X}} \times \mathbf{L}
$$

where $L$ is the matrix of normal coordinate vectors derived by diagonalizing FG. The calculated signs and partitioning of intensity between various directions were transferred to the experimental data in order to obtain the experimental $P_{\mathrm{Q}}(\partial \mu / \partial Q)$. While absolute intensities are not reproduced well by ab initio methods, the sign of the transition moment is usually correct in all cases with a significant moment. The experimental APT's were then obtained by using the reverse of the above transformation (Table IX). The correctness in this approach is evidenced in the good agreement between the APT's of the four isotopomers of butadiene examined. If a sign of polarization error was made it would affect the results adversely. Finally, the APT's were transformed to the dipole moment derivatives with respect to the symmetry coordinates (PS) by

$$
P_{\mathrm{S}}=P_{\mathrm{X}} \times \mathbf{B}^{-1}
$$

where $\mathbf{B}^{-1}$ is the inverse of the full $3 n \times 3 n \mathbf{B}$ matrix. Here, the common $3 n-6 \times 3 n$ symmetrized $\mathbf{B}$ matrix has been augmented to include the Eckart conditions which preserve the center of mass and the angular momentum during vibrations.

The consistency of the intensity data was very good except for the $A_{u}$ block ( $y^{2}$, Table IX). The $d_{0}$ and $d_{4}$ compounds showed

[^5]one trend, and $d_{2}$ showed another. This was probably due to the proximity of $\nu_{10}$ and $\nu_{11}$ in the $d_{2}$ compound which causes greater mixing of the symmetry coordinates. This results in nearly degenerate eigenvalues leading to an infinite number of acceptable normal coordinate vectors, which determine intensity. In order to find a consistent set of eigenvectors (i.e., that gives consistent intensity data for all molecules) we used a steepest descent algorithm. This program used the scaled $\mathbf{F}$ matrix and the average $P_{S}$ tensor as input and calculated the frequencies and intensities. All of the independent variables were adjusted to fit the experimental data. Due to the limited data for the $d_{6}$ molecule, it was not included. Thus 14 scale factors were used to fit 24 data points. It was necessary to choose an arbitrary weighting of the errors in frequency and in intensity in giving the overall error used to determine the steepest descent vector. The errors in frequency (in $\mathrm{cm}^{-1}$ ) were given a weighting factor of 1 , and the errors in intensity (in $\mathrm{km} / \mathrm{mol}$ ) were given a weighting factor of 3 . A total of 20000 steps at a maximum increment of $10^{-5}$ was followed by 40000 at $2.5 \times 10^{-6}$, whereupon no further improvement was found. The results of this calculation are given in Tables $X$ and XI. It is interesting to note that the $\mathbf{F}$ submatrix is little changed by program, except for the 10,13 element, and that the frequency fit is only slightly worse than before the changes, while the intensity data is much better. This points out a common problem in normal coordinate analyses. The form of the normal coordinate vector may not be well-defined when two vibrational modes in a given symmetry block have similar frequencies. Here, a study of the intensities of the bands provides important additional information for the relative intensities of the two bands will often be strongly dependent on the form of the normal coordinate vectors.

The dipole moment derivatives in symmetry coordinates are given in Table XII. The largest values were found with the $\mathrm{C}-\mathrm{H}$ out-of-plane bending modes, $S_{10}$ and $S_{13}$ and with angle deformation mode, $\mathrm{S}_{24}$. The out-of-plane bending modes frequently give large dipole moment derivatives with alkenes. The difference in sign between $\partial \mu / \partial S_{10}$ and $\partial \mu / \partial S_{13}$ is due to the difference in the way in which they were defined. In both cases, a hydrogen moving in the positive coordinate direction leads to an induced dipole with a positive sign. Although this suggests a $\mathrm{C}-\mathrm{H}$ bond dipole in the sense $\mathrm{C}^{-}-\mathrm{H}^{+}$, we have shown that it actually arises from limited orbital following with the proton moving ahead of the charge density in the overlap region. ${ }^{21}$ The $\mathrm{C}-\mathrm{H}$ stretching modes have dipole moment derivatives which correspond to a bond dipole in the sense $\mathrm{C}^{+}-\mathrm{H}^{-}$, which has been found for all alkanes and alkenes. The alkynes are an exception, with a reversed sense of the dipole moment derivative for the $\mathrm{C}-\mathrm{H}$ stretching modes, corresponding to the calculated reversed sign of the bond dipole. ${ }^{21}$

The reason for the large dipole moment derivative for $S_{24}$ is not so clear and will be the subject of further study.

## 5. Spectra of Cis and Gauche Forms of Butadiene

The infrared spectra for the cis and gauche forms were calculated by using the $6-31 \mathrm{G}^{*}$ basis set. Since they have a lower symmetry than trans-butadiene, the force constants for the latter were obtained with respect to the internal coordinates, and the dipole moment derivatives also were obtained for these coordinates. ${ }^{28}$ Here, the diagonal terms of $\mathbf{F}$ matrix were given independent scaling factors, and the off-diagonal elements were scaled by the geometric mean of the factors for the corresponding diagonal terms. ${ }^{18 a}$ The scaling factors for trans-butadiene were transferred to the calculated force constants for cis and gauche, and the vibrational frequencies were calculated giving the predicted spectra presented in Tables XIII and XIV.

The intensities were treated in a similar fashion. The theoretical $\mathrm{d} \mu / \mathrm{d} R$ obtained for the cis and gauche forms were scaled by the ratio of calculated to observed derivatives found for trans-butadiene. The predicted line intensities for the cis and gauche form also are presented in Tables XIII and XIV.

By using the data from Tables XIII and XIV, we now may construct spectra for the cis and gauche form (Figure 3). Not
(28) These data are available as Supplementary Material.

${ }^{a}$ The values for the Au block are those obtained after fitting frequencies and intensities simultaneously (Table X).
surprisingly the two spectra are similar overall. Minor alterations in intensity and line positions must be ignored as experimental data were obtained in a matrix, while our predictions are for the gas phase. However, one region stands out. A predicted line at $733 \mathrm{~cm}^{-1}\left(\nu_{11}\right)$ of moderate intensity for the gauche compound is apparent in the actual experimental spectra. The closest lines for the cis compound are over $100 \mathrm{~cm}^{-1}$ away. The only line that accounts for this is the forbidden $\mathrm{A}_{2}$ transition ( $\nu_{12}$ ) of the cis compound, which, of course, becomes allowed as the symmetry is lowered in the gauche compound. Moreover, in the $d_{4}$ and $d_{6}$ compounds this transition exists near $600 \mathrm{~cm}^{-1}$ ( 594 and $585 \mathrm{~cm}^{-1}$

Figure 3. Spectra for butadiene rotamers. The upper plot (A) is the observed matrix isolated spectrum of the second rotamer of butadiene (ref 4). The center plot (B) is that calculated for the gauche rotamer, and the lower plot $(\mathrm{C})$ is that for the cis rotamer.
predicted; 592 and 583 obs) corresponding again to the gauche species with no nearby cis transition. The fact that the weak band at $733 \mathrm{~cm}^{-1}$ is shifted to $\sim 600 \mathrm{~cm}^{-1}$ in the $d_{4}$ and $d_{6}$ compounds supports the assignment of this band as $\nu_{11}$ and not some impurity.

While ab initio frequencies can be off by as much as $30 \mathrm{~cm}^{-1}$, the much larger discrepancy assuming a cis form is unreasonable. We are forced to conclude that the minor rotamer of butadiene is not planar, though it need not be significantly nonplanar to fit the above data. Other data interpretations are possible. First, the crucial band may not belong to the gauche butadiene at all. However, several laboratories have assigned this band to the minor rotamer. ${ }^{3,4 \mathrm{a}, 5,6}$ More importantly, the bands in question could be the result of a combination band. Specifically, only one combination, between $\nu_{13}$ (assuming a real vibration) and $\nu_{24}$, would produce the appropriate frequency. This combination band does not fit our predictions nearly as well as the fundamental. Moreover, though a weak band, this band would be quite strong for a combination band.

We should note that Furakawa ${ }^{3}$ came to this same conclusion by using just an experimentally derived force field.

## 6. Ultraviolet Absorption Data

While the infrared data clearly indicates that the second stable conformer of butadiene is gauche, the electronic absorption data

are more ambiguous. A mixture of the two forms of butadiene enriched in the minor isomer was matrix isolated, and an ultraviolet absorption spectrum of this mixture was taken by SSCA. ${ }^{4 a}$ The absorption curve for the minor isomer was identified by photolysis at 214 nm which led to the disappearance of the trans form. Assuming that only the trans isomer absorbs at this wavelength, the minor isomer was characterized by a $\lambda_{\max }$ of 226 nm , comıpared to the $212 \mathrm{~nm} \lambda_{\max }$ of the trans form. On the basis of these data and some early Pariser-Parr type calculations, ${ }^{29}$ SSCA assigned the minor isomer to the cis form. Ten years later, Saltiel et al. used their principle component analysis-self modeling method to

[^6]determine that in the gas phase the $\lambda_{\text {max }}$ of the second form was 212 nm , the $\lambda_{\max }$ of the trans form occurring at $209 \mathrm{~nm} .^{30}$ The same arguments used by SSCA and applied to Saltiel's data would assign the minor isomer to a gauche structure with a significant twist angle. We used two methods to determine the $\mathrm{C}-\mathrm{C}-\mathrm{C}-\mathrm{C}$ torsion angle as a function of $\lambda_{\text {max }}$ and applied the results to both sets of data above.

Cave and Davidson have shown via calculations that the lowest excited singlet state of 1,3 -butadiene is a $\pi-10-\pi^{*}\left(\mathrm{~A}_{\mathrm{g}} \rightarrow \mathrm{B}_{\mathrm{u}}\right)$ transition. ${ }^{31}$ We calculated the vertical transition energy, i.e.,

Figure 4. Calculated ( $\mathrm{ClS} / 6-311+\mathrm{G}^{*}$ ) spectral shifts for butadiene rotamers.
$\lambda_{\text {max }}$, for butadiene at four different torsional angles. We employed two basis sets and two kinds of configuration interaction (CI) as shown in Table XV. The larger $6-311+G^{*}$ basis set is better than the smaller $6-31 \mathrm{G}^{*}$ basis set for two reasons. First, the diffuse functions on the larger basis set allow a better description of Rydberg character of the excited state. Cave and Davidson found a significant amount of Rydberg character in the lowest excited singlet state of butadiene. Second, the triple- $\zeta$ basis allows a better description of the virtual orbitals. The CI singles (CI-S) value is probably more reliable than the CI single and doubles (CI-SD), since the large size of the latter calculation necessitated truncation of the CI expansion beyond the 18th virtual orbital. Such truncation leads to unpredictable effects for the different rotamers studied. The important observation was that the spectral shifts obtained via the two CI methods with either basis set were comparable.

A simple interpolated three-point plot of torsion angle versus $\Delta \lambda$ for the $6-311+G^{*}$ CIS values illustrates the major findings (Figure 4). The $\lambda_{\max }$ of butadiene falls off slowly from a maximum value at $0^{\circ}$ between $0^{\circ}$ and $18^{\circ}$ and then falls off more rapidly between $18^{\circ}$ and $40^{\circ}$. With use of SSCA's value of 226 nm for the $\lambda_{\text {max }}$ of the minor isomer and 212 nm for the $\lambda_{\text {max }}$ of the major isomer, Figure 4 predicts a twist angle of $25^{\circ}$. With use of Saltiel's data, a twist angle of $33^{\circ}$ is predicted. As the torsion angle changes very slowly with energy, we feel that a twist angle between $25^{\circ}$ and $33^{\circ}$ is close to the true torsion angle of gauche-butadiene.

The cisoid dienes 1,3-cycloheptadiene and 1,3-cyclooctadiene were selected as model unstrained dienes which would provide experimental backing for the above conclusions. The cycloheptadiene geometry is not known but was found by ab initio 3-21G optimizations to have nearly a $0^{\circ}$ dihedral angle between the cis double bonds. The cyclooctadiene geometry, obtained in

Figure 5. Ultraviolet spectra (gas phase) of trans,trans-2,4-hexadiene (A), 1,3-cyclooctadiene (B), and 1,3-cycloheptadiene (C). The absorbance scale is arbitrary.
a similar way, had a $57^{\circ}$ dihedral angle, a value predicted by previous MM2 calculations. ${ }^{32}$ The measured gas-phase $\lambda_{\text {max }}$ of cycloheptadiene was 242 nm ( 248 nm in isooctane) ${ }^{33}$ and of cyclooctadiene 221 nm ( 228 nm in cyclohexane). ${ }^{21 \mathrm{~b}}$ A similarly substituted open chain diene, trans, trans-2,4-hexadiene, had $\lambda_{\text {max }}$ at 214 nm (Figure 5). These data place a gauche form 7 nm to the red of trans and a cis form 28 nm to the red, which is consistent with the calculations shown in Figure 4. Again, they indicate that the second rotamer of butadiene should be gauche with a torsional angle on the order of $30^{\circ}$.

## 7. Conclusions

We have shown that ab initio predictions, vibrational data, and electronic absorption data all consistently predict a gauche structure for the second conformer of butadiene. The higher the level of the ab initio calculations, $6-31 \mathrm{G}^{*}$ to MP2/6-31G* to MP3/6-311+G**//MP2/6-31G*, the deeper the well separating the minimal gauche conformer from the transition-state cis conformer. Bands in the infrared spectra for three isotopomers of the second rotamer correspond well to predicted values for a gauche structure only. The $\lambda_{\text {max }}$ of electronic absorption spectra of the second rotamer, though somewhat controversial, was calculated to be consistent with a gauche structure with a significant twist angle and not a cis structure. These calculations are supported by the observed $\lambda_{\text {max }}$ of cycloheptadiene and cyclooctadiene, the former a nearly cisoid diene and the latter a fair model of a gauche structure. Though each method has minor objections, taken together all the evidence points toward a gauche structure with a significant dihedral angle between the two double bonds. The one experimental datum which is not compatible with a gauche structure is the polarization study of Michl et al. ${ }^{5}$ Bock and Panchenk $0^{14}$ have presented a detailed analysis of this experiment and have concluded that it is not able to give an unambiguous answer. In addition, since it was carried out in a matrix, it is possible that interactions with the matrix leads to a bias toward the cis form.

It would be very helpful to have experimental data for the second rotamer in the gas phase. It should be possible to obtain such data via supersonic jet expansion from a heated nozzle and examine the spectrum as a function of the nozzle temperature. This experiment would freeze the high-temperature rotamer population as rotationally and vibrationally cooled molecules. Although the number density of molecules in the jet would be low,

[^8]the UV cross section is sufficiently large that it should be possible to observe the change in electronic spectrum with temperature. The infrared spectrum presents more of a problem since the cross section for the bands of interest is relatively low, and since the minor rotamer will only be $\sim 10 \%$ of the mixture. Nevertheless, the greatly increased sensitivity afforded by infrared diode lasers should permit the spectrum to be observed. Experiments of these types are planned.

## 8. Calculations

The ab initio calculations were carried out by using GAUSSIAN-86 ${ }^{34}$ along with standard basis sets. The calculations for the electronically excited states were carried out using the meld package. ${ }^{35}$

#### Abstract

In an approach to the synthesis of ligands specific for $\mathrm{Pb}^{2+}$, lead complexes with mono- and bis(thiohydroxamic acids) have been prepared and characterized on the basis of their elemental analyses and their infrared, NMR, and UV spectra. The structures of the two compounds bis( $N$-methylthiobenzohydroxamato)lead(II) (2) and bis( $N$-methylthioacetohydroxamato)lead(II) (5) have been determined by single-crystal X-ray diffraction using automated counter methods. The structure of $\mathbf{2}$ is based on a five-coordinate geometry in which the sulfur atoms and the stereochemically active electron lone pair on $\mathrm{Pb}^{2+}$ occupy the equatorial positions of a trigonal bipyramid. The axial positions are occupied by the oxygen atoms and weak, outer-sphere coordination occurs from ligation by the thiohydroxamate oxygen atoms of adjacent molecules. Compound 5 exists in a similar pseudotrigonal-bipyramidal geometry in the solid state, but the equatorial positions are occupied by the lone electron pair on lead, one oxygen atom, and one sulfur atom. Additional weak coordination is formed by two oxygen atoms and one sulfur atom from neighboring molecules. Bis( $N$-methylthiobenzohydroxamato)lead(II) (2) crystallizes in space group $C 2 / c$ with $Z=4, a=18.067$ (2) $\AA, b=12.518$ (2) $\AA, c=8.103$ (1) $\AA$ and $\beta=101.93$ (1) ${ }^{\circ}$. Full-matrix least-squares refinement using 1805 reflections with $F_{0}^{2}>3 \sigma\left(F_{0}\right)^{2}$, with all non-hydrogen atoms given anisotropic temperature factors, converged to unweighted and weighted $R$ factors of 1.7 and $1.9 \%$, respectively. Bis(acetothiohydroxamato)lead(II) (5) crystallizes in space group $P 2_{1} / n$ with $Z=4, a=7.958$ (2) $\AA, b=7.445$ (1) $\AA, c=19.007$ (3) $\AA$, and $\beta=98.74$ (2) ${ }^{\circ}$. Full-matrix least-squares refinement using 1924 reflections with $F_{0}^{2}>3 \sigma\left(F_{0}\right)^{2}$, with all non-hydrogen atoms given anisotropic temperature factors, converged to unweighted and unweighted $R$ factors of 4.1 and $5.1 \%$, respectively.

This paper is the first of a planned series for a research program with the goal of developing specific complexing agents for lead. To that end we will present here the background to the problems posed by lead intoxication and the chemical and biological parameters that form the boundary conditions for our ligand design.
Due to the increasing industrial uses of lead, huge amounts of lead and its compounds enter the environment each year. ${ }^{1,2}$ It is estimated that $\sim 3.5 \times 10^{9} \mathrm{~kg}$ of lead ores were mined in 1974 . $^{3}$ Industrial uses of lead include storage batteries, alkyllead production, cable sheathing, pigments, and lead alloys. ${ }^{24}$ Thus, even with precautions being taken, plants, animals, and humans are exposed to, and are contaminated with, lead.

Lead uptake by humans occurs through absorption of lead compounds or lead-contaminated food or drink from the gastrointestinal tract, through absorption of airborne particles through the lungs, and through absorption of lead through the skin. ${ }^{5-7}$ Most lead compounds are insoluble in vivo, so only small amounts

[^9]of lead are absorbed from the gastrointestinal tract. However, since it is slowly eliminated, lead accumulates in liver, kidneys, bones, and other parts of the body. ${ }^{8}$ The inhalation of lead compounds as lead carbonate and lead sulfate dust results in the
