# Electronic Structure of Borabenzene and Its Adducts with Carbon Monoxide and Nitrogen 

J. Cioslowski* and P. J. Hay<br>Contribution from Los Alamos National Laboratory, Theoretical Division, Group T-12, MS-J569, Los Alamos, New Mexico 87545. Received April 10, 1989

#### Abstract

Electronic structures of borabenzene and its adducts with carbon monoxide and nitrogen have been studied with HF/6-31G* and MP2/6-31G* molecular orbital calculations. All three molecules are predicted to be stable and possess a planar geometry. At the highest level of theory used (MP2/6-31 $\mathrm{G}^{*}$ ) the calculated heats of formation (relative to the isolated molecules) are -39.4 and $-19.2 \mathrm{kcal} / \mathrm{mol}$ for the carbon monoxide and the nitrogen adducts, respectively. The bonding between borabenzene and CO or $\mathrm{N}_{2}$ involves a $\sigma$ donation to the borabenzene molecule and a $\pi$ back-donation to the CO or $\mathrm{N}_{2}$ molecule. The sources of overestimation of the latter and underestimation of the former interactions within the Bader population analysis are discussed.

Although several complexes of borabenzene (borinine) (1) have been characterized ${ }^{1}$ and some of its adducts have been synthesized, ${ }^{2}$ the very existence of a free molecule has not been proven until very recently. ${ }^{3}$ Flash thermolysis of a borahexadiene precursor yielded the borabenzene-nitrogen adduct (3) when nitrogen was used as the carrier gas. Similarly, formation of the carbon monoxide adduct (2) was also observed.

Borabenzene is a remarkable molecule. According to both semiempirical MNDO ${ }^{4}$ and ab initio STO-3G and $4-31 \mathrm{G}^{5}$ calculations 1 is planar and the $\pi$-electrons of the boron-carbon backbone are highly delocalized. Therefore $\mathbf{1}$ can be regarded as an aromatic system. However, the presence of an electron hole at the boron atom leads to a substantial distortion of the predicted geometry from that a regular hexagon. The resulting strain lowers the stabilization energy by ca. $30 \mathrm{kcal} / \mathrm{mol}$ as compared to benzene. ${ }^{5}$ Another consequence of the boron substitution is the presence of a low-lying $\sigma^{*}$ orbital that is responsible for a pronounced Lewis acidity and a high reactivity of borabenzene.

Since theoretical studies on 1 are scarce ${ }^{4-6}$ and, to our knowledge, no calculations on either $\mathbf{2}$ or $\mathbf{3}$ have been reported, we decided to optimize the geometries and investigate the electronic structure of 1,2 , and 3 at the $\mathrm{HF} / 6-31 \mathrm{G}^{*}$ level. ${ }^{7}$ The single-point energies at the MP2/6-31G* also have been computed together with the HF/6-31G* vibrational frequencies.

## Details of Calculations

The SCF and MP2 calculations have been performed with a vectorized version of the GAUSSIAN-82 package. ${ }^{8}$ The geometry optimization required ca. 20 h of combined CPU and IO times (CRAY X-MP48) per molecule. The CPU/IO time for the vibrational frequencies was ca. 5 h. The electron density has been analyzed with programs EXTREME and PROAIM developed by Bader et al. ${ }^{9}$ The effective atomic charges have been calculated with the recently developed GAPT partitioning. ${ }^{10}$ In this approach the atomic charge of atom A is given as an isotropically averaged atomic polar tensor ${ }^{11}$

$$
\begin{equation*}
Q\left(X_{X P T}=(1 / 3)\left[\frac{\partial \mu_{x}}{\partial x_{\mathrm{A}}}+\frac{\partial \mu_{y}}{\partial y_{\mathrm{A}}}+\frac{\partial \mu_{z}}{\partial z_{\mathrm{A}}}\right]\right. \tag{1}
\end{equation*}
$$

where $\mu_{\mathrm{r}}$ and $r_{\mathrm{A}}(r=x, y, z)$ denote the components of the dipole moment and the position vector of the nucleus A, respectively. The GAPT charges are byproducts of the computation of the IR intensities and therefore are easily available.

## Results and Discussion

Both borabenzene (1) and its adducts ( 2 and 3 ) are predicted to be minima on the potential energy hypersurface. All the molecules are planar. The optimized geometry of 1 is similar to that obtained in previous $4-31 \mathrm{G}$ calculations, ${ }^{5}$ but the distortion of molecule from the shape of a regular hexagon is slightly larger.

[^0]The geometries of adducts $\mathbf{2}$ and $\mathbf{3}$ show several interesting features (Figure 1). First of all, the deviations of bond angles from the value of $120^{\circ}$ are much smaller than in 1 . This is accompanied by a substantial lengthening of the $\mathrm{B}-\mathrm{C}_{1}$ bonds. Both effects are more pronounced in the CO adduct than in the $\mathrm{N}_{2}$ one. There is a remarkable insensitivity of the geometry of the CO and $\mathrm{N}_{2}$ parts to formation of the adducts. The respective bond lengths are within less than $0.001 \AA$ of those in free molecules. The boron-ligand bond lengths are comparable to but shorter than the B-C bond length (HF/6-31G*:1.627 $\AA$ ) in the $\mathrm{BH}_{3} \cdot \mathrm{CO}$ complex. This reflects the greater stability of the borabenzene adducts.

At the HF level, the stability ( $\Delta H_{\mathrm{HF}}$ in Table I) of $\mathbf{2}$ is much higher than that of 3 . When the zero-point vibrational energies (as calculated from the $\mathrm{HF} / 6-31 \mathrm{G}^{*}$ vibrational frequencies) are taken into account, the energy ( $\Delta H_{\mathrm{HF}}$ in parentheses, Table I) of the $\mathrm{N}_{2}$ adduct is only ca. $-3 \mathrm{kcal} / \mathrm{mol}$ lower than the sum of the energies of free molecules. Upon inclusion of the electron correlation at the MP2 level, the stability of both $\mathbf{2}$ and $\mathbf{3}$ increases by about $15 \mathrm{kcal} / \mathrm{mol}\left(\Delta H_{\mathrm{MP2}}\right.$, Table I). The MP2/6-31G* dissociation energy of the $\mathrm{B}-\mathrm{C}_{4}$ bond in 2 amounts to ca. $40 \%$ of the dissociation energy of a typical single $\mathrm{C}-\mathrm{C}$ bond. The HF and MP2 stabilities of $\mathbf{2}$ and $\mathbf{3}$ can be compared to the values of $-9.1 \mathrm{kcal} / \mathrm{mol}\left(\mathrm{HF} / 6-31 \mathrm{G}^{*}\right)$ and $-24.6 \mathrm{kcal} / \mathrm{mol}$ (MP2/6-31G*) for the $\mathrm{BH}_{3} \cdot \mathrm{CO}$ complex.

The possible orbital interactions that lead to the borabenz-ene-ligand bonding are conveniently classified according to their symmetries. They are as follows: the $\sigma$ donation from the nonbonding $\sigma$ orbitals of CO or $\mathrm{N}_{2}$ to the low-lying antibonding $\sigma^{*}$ of borabenzene $\left(a_{1}\right)$, the $\pi$ back-donation from the $\pi$ orbitals of borabenzene to the vacant $\pi^{*}$ orbitals of CO or $\mathrm{N}_{2}\left(\mathrm{~b}_{1}\right)$, and the back-donation of the antisymmetrical $\sigma$ orbitals of borabenzene to the vacant "in-plane" $\pi^{*}$ orbital of CO or $\mathrm{N}_{2}\left(\mathrm{~b}_{2}\right)$. The an-

tisymmetrical $\pi$ orbital of borabenzene ( $a_{2}$ ) has neither CO nor $\mathrm{N}_{2}$ counterparts.
The features of the bonds within the CO and $\mathrm{N}_{2}$ ligands are largely preserved in adducts 2 and 3. This is reflected in the aforementioned bond lengths (Figure 1) and force constants for the bond stretching (Table II). The topological characteristics of the bonds, ${ }^{12}$ such as the position of the critical point ( $r_{\mathrm{C} 4-\mathrm{Crit}}$ and $r_{\mathrm{Nl-Crit}}$ ), the electron density at the critical point ( $\rho_{\text {Crit }}$ ), and the Laplacian at the critical point ( $\nabla^{2} \rho_{\text {crit }}$ ) also change only a little (Table III). Any substantial $\pi$ back-donation would result in lengthening of the CO and $\mathrm{N}_{2}$ bonds and decrease in the respective force constants. The bonding situation in the $\mathrm{Ni}(\mathrm{CO})_{4}$ molecule can serve as a typical example. ${ }^{13}$ Therefore we conclude that the borabenzene-ligand bonding arises primarily from the $\sigma$ donation to the vacant $\sigma^{*}$ orbital that is mostly localized at the boron atom ${ }^{4}$ (see also discussion below).

Bader's quantum theory of atoms in molecules provides the necessary formalism for assigning the effective charges to atoms. ${ }^{12}$ These charges can be further broken down into contributions from the individual orbitals by considering the relevant atomic orbital overlap matrices. ${ }^{\text {. }}$ We have performed such a population analysis for adducts 2 and 3 in order to further elucidate the role of $a_{1}$ ( $\sigma \rightarrow \sigma^{*}$ donation), $\mathrm{b}_{1}$ ( $\pi \rightarrow \pi^{*}$ back-donation), and $\mathrm{b}_{2}\left(\sigma \rightarrow \pi^{*}\right.$ back-donation) interactions in forming the borabenzene-ligand bonds. The results are presented in Table IV.

[^3]Figure 2. Schematic correlation diagram for the occupied $\pi$-orbitals in borabenzene and its adducts. Orbital energies are given in atomic units.

As expected, there is no significant $a_{2}$ interaction. However, the data in Table IV reveal a large $b_{1}(\pi)$ back-donation. In fact, the $\pi$-electron charge transfer has a greater magnitude than the $\sigma$-electron ( $\mathrm{a}_{1}$ ) one. This results in a net electron transfer from the borabenzene molecule to the CO or $\mathrm{N}_{2}$ ligand. The $\mathrm{b}_{2}$ back-donation is also pronounced, although its magnitude amounts to ca. $\mathbf{3 0 \%}$ of the $\mathrm{b}_{1}$ one. The results of Bader population analysis are quite unexpected, taking into account the presumed lack of $\pi$-electron back-donation as discussed above. The large $\pi$-electron charge transfer (as compared to the $\sigma$-electron one) is also at variance with the presence of a low-lying, strongly localized $\sigma^{*}$ orbital of borabenzene (the orbital energy: $\epsilon=0.10083 \mathrm{au}$ ) and the higher energy of the $\pi^{*}$ orbitals of the $\mathrm{CO}(\epsilon=0.16795 \mathrm{au})$ and $\mathrm{N}_{2}(\epsilon=0.18096 \mathrm{au})$ molecules that are highly delocalized. Also, if one uses the differences of the orbital energies as a rough measure of the stabilization/destabilization effects, the combined $a_{2}$ and $b_{1}$ interactions destabilize the CO adduct by about 3 $\mathrm{kcal} / \mathrm{mol}$ and stabilize the $\mathrm{N}_{2}$ adduct by about $10 \mathrm{kcal} / \mathrm{mol}$

${ }^{a}$ A plus sign corresponds to the charge transfer from the borabenzene moiety.
(Figure 2). This means that, at least in 2, the $\pi$ interactions play only a secondary role.

There is a plausible explanation of this underestimation of the $\sigma$ donation and exaggeration of the $\pi$ back-donation within the Bader analysis. The calculated charge transfer for the $\mathrm{N}_{1}$ atom in 3 provides the first clue (Table IV). There is a small $\sigma$-electron charge transfer from the borabenzene molecule! The gradient maps (Figure 3) are also helpful. Two characteristic features are present: First, the atomic basin of the boron atom in 1 has a very narrow opening angle. Second, the critical points in 2 and 3 (and the positions of the atomic boundaries) are very close to the boron atom. As revealed in Table IV, the boron atom-critical point distance ( $r_{\mathrm{B}}$-Crit ) constitutes only about $30 \%$ of the bond length.

When a new bond is formed three distinct phenomena occur: There is a charge transfer from one fragment to the other. There is a polarization of the fragments which results in induction of dipole moments. The third effect, which is inherent to the quantum theory of atoms in molecules, is a formation of a new atomic boundary. The changes in atomic populations arise from both charge transfer and the altered shapes of atomic basins as the integration domains for the individual atoms change. It is usually presumed that these two contributions are somehow proportional. In 2 and 3, however, the atomic basin of the boron atom shrinks dramatically upon formation of the adducts. The net effect is a formal additional acquisition of the negative electric charge by the atoms $C_{4}$ in 2 and $N_{1}$ in 3 . This translates into

${ }^{a}$ A plus sign corresponds to the charge transfer from the borabenzene moiety.
the calculated smaller $\sigma$ donation to and larger $\pi$ back-donation from the borabenzene molecule than it would be if only the genuine charge-transfer effects were considered.

Another formal look at the electron distribution in 1, 2, and 3 is provided by the GAPT atomic charges. ${ }^{10}$ The results are given in Table V. In the borabenzene molecule the GAPT analysis results in a pattern of alternating positive and negative charges. This is a nice illustration of a general rule which says that upon a single-site perturbation of a carbon backbone each second atom acquires a charge of the same sign. ${ }^{14}$ As expected, the boron atom in 1 bears a positive charge. According to the GAPT analysis, upon formation of both 2 and 3 a net electron transfer ( $\Delta Q$ in Table V ) to the borabenzene moiety occurs. The magnitude of this transfer in 2 is roughly twice as much as in 3 , which is in agreement with the relative stabilities and respective force constants for the $\mathrm{B}-\mathrm{C}_{4}$ and $\mathrm{B}-\mathrm{N}_{1}$ bonds (Table II). In the CO adduct, the major part of the electric charge is localized within the $\mathrm{B}-\mathrm{C}_{4}-\mathrm{O}$ moiety. For the sake of comparison we also list here the Bader and GAPT magnitudes of charge transfer for the $\mathrm{BH}_{3} \cdot \mathrm{CO}$ complex. They are -0.083 and 0.2522 , respectively.

Although we have not calculated either Bader or GAPT atomic charges for the MP2 wave function, we anticipate that inclusion of electron correlation would result in reduction of the magnitudes of the calculated charges. This prediction stems from the general observations already published in chemical literature. ${ }^{10,15,16}$

[^4]Final comment should be devoted to the calculated vibrational frequencies. At the HF/6-31G* level, the shift in the frequency of the $\mathrm{N}-\mathrm{N}$ stretching in 3 is $\Delta \nu=-51 \mathrm{~cm}^{-1}$ compared to the $\mathrm{N}_{2}$ molecule. The reported experimental value is $\Delta \nu=-133 \mathrm{~cm}^{-1}$. ${ }^{3}$ We believe that inclusion of the electron correlation is necessary to obtain a reasonable agreement for $\Delta \nu$. For the CO adduct, the calculations yield $\Delta \nu=-42 \mathrm{~cm}^{-1}$.

## Conclusions

The results of HF/6-31G* and MP2/6-31G* calculations demonstrate high reactivity of the borabenzene molecule toward carbon monoxide and nitrogen. The adduct formed between
borabenzene and carbon monoxide exhibits a remarkable stability. The nitrogen adduct, though less stable, should be isolable. The reactivity of borabenzene can be attributed to a donation from the nonbonding $\sigma^{0}$ orbital of either CO or $\mathrm{N}_{2}$ to the low-lying vacant $\sigma^{*}$ orbital of borabenzene. Relief of the strain within the borabenzene ring can further contribute to the exothermicity of the addition reactions. The charge distribution in both free borabenzene and its adducts seems to be better rationalized within the GAPT population analysis than the Bader one.

# Ab Initio SCF MO and Natural Bond Orbital Studies of 7-Silanorbornadiene and 7,7-Dimethyl-7-silanorbornadiene. Two Molecules Possessing an Inverted Sequence of $\pi$ Orbitals 

Michael N. Paddon-Row, ${ }^{*, \dagger}$ Stephen S. Wong, ${ }^{\dagger}$ and Kenneth D. Jordan*, ${ }^{\dagger}$<br>Contribution from the School of Chemistry, University of New South Wales, P.O. Box 1, Kensington, New South Wales 2033, Australia, and Department of Chemistry, University of Pittsburgh, Pittsburgh, Pennsylvania 15260. Received January 17, 1989

#### Abstract

The geometries of norbornadiene, 1, 7-sila norbornadiene, 2, and 7,7-dimethyl-7-silanorbornadiene, 3, have been optimized at the HF/STO-3G and HF/3-21G levels (within $C_{2 v}$ symmetry constraint). In addition, 2 has also been optimized by using the $3-21 \mathrm{G}\left({ }^{*}\right)$ basis set which contains a set of polarization functions on Si . It was found that, although the $\pi$ canonical MOs (CMOs) of 1 followed the natural sequence, i.e., $\pi_{+}\left(a_{1}\right)$ below $\pi_{-}\left(b_{1}\right)$, the inverted sequence is observed (i.e., $\pi_{+}$above $\pi_{-}$) for both 2 and 3. Through-bond (TB) orbital interactions are therefore more important than through-space (TS) orbital interactions in $\mathbf{2}$ and 3. The $\pi^{*} \mathrm{CMOs}$, on the other hand, followed the natural sequence in all three molecules. Orbital interactions in 1 and 2 were dissected into TS and TB components by using the Weinhold natural bond orbital (NBO) localization procedure. It is found that TS interactions are weaker in 2 than in $\mathbf{1}$, owing to the former molecule having a larger dihedral angle $\left(120^{\circ}\right)$ for the six-membered ring compared to $\mathbf{1}\left(114^{\circ}\right)$. In addition, TB coupling to the $\pi_{+}$orbital (which raises that level) is substantially larger in 2 than in 1 , an effect that is attributed to the more electropositive nature of silicon compared to carbon. The combination of weakened TS interactions and strengthened TB interactions is sufficient to cause the inverted sequence of $\pi$ levels in 2 (and in 3). TB and TS effects are found to reinforce each other in the $\pi^{*}$ manifolds of both 1 and 2 ; consequently, an inverted sequence of $\pi^{*}$ levels is unlikely to be found in any type of simple norbornadiene molecule. The NBO analysis of interactions in the $\pi$ manifold showed that $\sigma / \pi$ interactions dominate over $\sigma^{*} / \pi$ interactions. However, both $\sigma^{*} / \pi^{*}$ and $\sigma / \pi^{*}$ interactions should be considered in the analysis of TB coupling in the $\pi^{*}$ manifold, with the former being slightly larger than the latter.

Recent experimental studies ${ }^{1}$ have demonstrated the occurrence of unusually rapid intramolecular electron transfer between donor and acceptor groups fixed at predetermined distances, by rigid polynorbornyl spacers. Such rapid rates were attributed to a strong through-bond coupling mechanism between the donor and acceptor orbitals with those of the polynorbornyl framework. ${ }^{\text {1e }}$ In order to obtain a more detailed understanding of the coupling factor which is responsible for these large rates, we have undertaken both experimental and theoretical investigations of a series of model dienes with the two double bonds separated by norbornylogous spacer groups. Particular emphasis has been placed on the splittings between the $\pi$ cation and between the $\pi^{*}$ anion states of these compounds. These splittings, which provide a measure of the electronic coupling between the donor and acceptor groups (both ethylenic in the model compounds), figure prominently in the theory of electron transfer. In the present work, we examine in detail the simplest member of this series of model compounds, norbornadiene, 1 , and consider as well 7 -silanorbornadiene, 2 , and 7,7-dimethyl-7-silanorbornadiene, 3. Specifically, we explore the utility of localized orbital methods for analyzing the contributions of through-bond (TB) and through-space (TS) interactions to the

[^5]splittings between the $\pi$ cation and between the $\pi^{*}$ anion states. ${ }^{2}$
Norbornadiene 1 has become a paradigm for a molecule that exhibits dominant through-space (TS) orbital interactions within both $\pi$ and $\pi^{*}$ manifolds. ${ }^{2-8} \quad$ This is a consequence of the structurally enforced propinquity of the double bonds in 1 (they
