Table I. EPR Parameters of the Products from Reaction of Al Atoms with $\mathrm{NH}_{3}$ in Adamantane at $77 \mathrm{~K}^{a}$

| species | $a_{\\|}(\mathrm{Al})$ | $a_{\perp}(\mathrm{Al})$ | $a_{\mathrm{H}}$ | $a_{\mathrm{N}}$ | $g_{\\|}$ | $g_{\perp}$ |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
| $\mathrm{Al}\left(\mathrm{NH}_{3}\right)_{4}(\mathrm{~A})$ | 786.3 | 786.3 |  | 23.0 | 1.9997 | 1.9997 |
| HAlNH | $(\mathrm{B})$ | 922.5 | 922.5 | 228.7 | 27 | 2.0003 |
|  |  |  | $27^{b}$ |  |  |  |
|  |  |  |  |  |  |  |
| $\mathrm{Al}\left(\mathrm{NH}_{3}\right)_{2}(\mathrm{C})$ | 131.5 | ca. 20 |  |  | 1.9990 | 1.9990 |
| $\mathrm{HAlOH}(\mathrm{D})$ | 911.3 | 911.3 | 286.4 |  | 1.9998 | 1.9998 |

${ }^{a}$ Hyperfine interactions in $\mathrm{MHz} .{ }^{b} \mathrm{Hfi}$ of one of the amino hydrogens.
readily seen overlapping the $M_{1}= \pm 3 / 2$ lines of B. An exact solution of the Breit-Rabi equation for D gave $a_{A 1}=911.3 \pm 1.06$ $\mathrm{MHz}, a_{\mathrm{H}}=286.4 \pm 3.7 \mathrm{MHz}$, and $g=1.9998 \pm 0.0004$. These parameters are close enough to those of $\mathrm{HAlOH}\left(\left\langle a_{\mathrm{A} 1}\right\rangle=921\right.$ $\mathrm{MHz}, a_{\mathrm{H}}=282 \mathrm{MHz}$, and $\langle\mathrm{g}\rangle=2.0007$ ) that we can assign spectrum D to this species. Knight and co-workers ${ }^{25}$ have suggested that HAlOH has a charge distribution and electronic structure that can be described as $\mathrm{AlH}^{+} \mathrm{OH}^{-}$with $90 \%$ of the unpaired electron on the $\mathrm{AlH}^{+}$fragment. HAlOH must be formed by reaction of Al atoms with adventitious $\mathrm{H}_{2} \mathrm{O},{ }^{8,25}$
Further evidence for the identity of D was obtained from the reaction of ground-state Al atoms with $\mathrm{D}_{2} \mathrm{O}$ in adamantane at 77 K which resulted in the formation of DAIOD with the pa-
rameters $a_{\mathrm{Al}}=907.8 \pm 0.78 \mathrm{MHz}, a_{\mathrm{D}}(1)=44.8 \pm 2.3 \mathrm{MHz}$, and $g=1.9990 \pm 0.0004$.

Annealing Experiments: $\mathrm{Al}\left(\mathrm{NH}_{3}\right)_{2}, \mathrm{HAlNH}_{2}$, and $\mathrm{Al}\left(\mathrm{NH}_{3}\right)_{4}$ in adamantane disappeared rapidly when samples were warmed above 150 K , but we were not able to determine the relative stabilities from these experiments because the spectrum of Al $\left(\mathrm{NH}_{3}\right)_{2}$ was much more intense than those of $\mathrm{HAlNH}_{2}$ and $\mathrm{Al}\left(\mathrm{NH}_{3}\right)_{4}$. A narrow line $\left(\Delta H_{\mathrm{pp}}=13.5 \mathrm{G}\right)$ centered at $g=1.9998$ was the only signal that remained above this temperature. This line was much broader than the single line ( $\Delta H_{\mathrm{pp}}=1.6 \mathrm{G}$ ) that was obtained when samples of Al and $\mathrm{ND}_{3}$ in adamantane were warmed above 150 K . These line widths are consistent with a trapped electron interacting with ammonia although the $g$ factor seems low. ${ }^{16}$

Conclusions, Reaction of ground-state Al atoms with $\mathrm{NH}_{3}$ in adamantane at 77 K gives at least three transient mononuclear $\mathrm{Al}(0)$ paramagnetic products, $\mathrm{Al}\left(\mathrm{NH}_{3}\right)_{4}, \mathrm{HAlNH}_{2}$, and $\mathrm{Al}\left(\mathrm{NH}_{3}\right)_{2}$. These are probably the initial products in the production of amide and hydrogen from Al atoms and $\mathrm{NH}_{3}$.

# Application and Evaluation of ab Initio Chemical Shift Calculations for Boranes and Carboranes. How Reliable Are "Accurate" Experimental Structures? ${ }^{\dagger}$ 

Michael Bühl and Paul von Raguê Schleyer*<br>Contribution from the Institut für Organische Chemie, Universität Erlangen-Nürnberg, Henkestrasse 42, D-8520 Erlangen, Germany. Received January 14, 1991

#### Abstract

The ${ }^{11} \mathrm{~B}$ chemical shifts of the boranes $\mathrm{B}_{2} \mathrm{H}_{6}, \mathrm{~B}_{4} \mathrm{H}_{10}, \mathrm{~B}_{5} \mathrm{H}_{9}, \mathrm{~B}_{5} \mathrm{H}_{11}, \mathrm{~B}_{6} \mathrm{H}_{10}, \mathrm{~B}_{6} \mathrm{H}_{12}$, the borane anions $\mathrm{B}_{2} \mathrm{H}_{7}{ }^{-}, \mathrm{B}_{3} \mathrm{H}_{8}{ }^{-}$, $\mathrm{B}_{4} \mathrm{H}_{9}{ }^{-}$, and the carboranes 1,3- $\mathrm{C}_{2} \mathrm{~B}_{2} \mathrm{H}_{4}, 1,5-\mathrm{C}_{2} \mathrm{~B}_{3} \mathrm{H}_{5}, 1-\mathrm{CB}_{5} \mathrm{H}_{7}, 1,6-\mathrm{C}_{2} \mathrm{~B}_{4} \mathrm{H}_{6}, 1,2-\mathrm{C}_{2} \mathrm{~B}_{4} \mathrm{H}_{6}, 2,4-\mathrm{C}_{2} \mathrm{~B}_{5} \mathrm{H}_{7}, 1,2-\mathrm{C}_{2} \mathrm{~B}_{3} \mathrm{H}_{7}, 2-\mathrm{CB}_{5} \mathrm{H}_{9}$, 2,3- $\mathrm{C}_{2} \mathrm{~B}_{4} \mathrm{H}_{8}, 2,3,4-\mathrm{C}_{3} \mathrm{~B}_{3} \mathrm{H}_{7}$, and 2,3,4,5-C4 $\mathrm{B}_{2} \mathrm{H}_{6}$ have been calculated using the IGLO (individual gauge for localized orbitals) method. Three sets of ab initio geometries have been employed, $3-21 \mathrm{G}, 6-31 \mathrm{G}^{*}$, and MP2/6-31 $\mathrm{G}^{*}$. For the geometries optimized ab initio at a correlated level (MP2/6-31G*), the agreement with the experimental values is excellent in the case of the binary boron hydrides (standard deviation 1.4 ppm ) and acceptable in the case of the carboranes (standard deviation 3.3 ppm ). The IGLO chemical shifts, calculated using the experimental geometries recommended in Beaudet's recent compilation, gave significantly poorer results than the MP2/6-31G* geometries. For $\mathrm{B}_{8} \mathrm{H}_{12}$, an alternative assignment of the observed boron resonances is supported by the IGLO calculations. The effect of counterions on geometry and chemical shifts of $\mathrm{B}_{3} \mathrm{H}_{8}{ }^{-}$is shown to be very small. No relationship between ${ }^{11}$ B chemical shifts and calculated atomic charges is apparent.

## Introduction

The structures of polyhedral boranes challenged the chemists for many years, until the Lipscomb group solved the essential nature of these species. ${ }^{1}$ In his recent critical review, "The Molecular Structures of Boranes and Carboranes", ${ }^{2}$ R. A. Beaudet summarized the best currently available structural data for these compounds, based on X-ray structure analysis, gas-phase electron diffraction, and microwave spectroscopy. He presented recommended sets of cartesian coordinates for 31 molecules, including the principal boranes and carboranes, and pointed out that accurate structural data are essential for a refined knowledge of the bonding in electron-deficient molecules. I. and M. Hargittai also recently emphasized "The Importance of Small Structural Differences", ${ }^{3}$

[^0]and included quantum chemical calculations as an additional source of structural information. Indeed, ab initio molecular orbital theory has become increasingly successful in predicting molecular structures and establishing their accuracy. 4,5 E.g., we have been using IGLO (individual gauge for localized orbitals) ${ }^{6}$

[^1]chemical shift calculations to distinguish among structural alternatives for numerous carbocations. ${ }^{7}$ Since the computed ${ }^{13} \mathrm{C}$ chemical shifts often are very sensitive to small geometric changes, the combined ab initio/IGLO/NMR method affords a valuable tool for structural investigations.

We have reported similar applications to boron compounds in preliminary communications. A $\mathrm{C}_{1}$ form of $\mathrm{B}_{5} \mathrm{H}_{11}$ was favored over the $C_{s}$ geometry. ${ }^{8}$ The deficiencies of the electron diffraction structure of $\mathrm{B}_{6} \mathrm{H}_{12}$ were shown on the basis of the IGLO calculations. ${ }^{9}$ We now examine a wider scope of polyhedral boron compounds ${ }^{10}$ in order to test and to demonstrate the reliability of this approach.

As NMR spectroscopy is particularly useful in boron chemistry, much $\delta{ }^{11} \mathrm{~B}$ NMR data are available. ${ }^{11}$ Theoretical calculations of boron chemical shifts have been reported, both at semiempirical ${ }^{12}$ and at SCF levels. ${ }^{13}$ The evaluation of the paramagnetic contributions usually is the critical problem. Recently, several ab initio methods for the calculation of NMR shifts have been developed ${ }^{14}$ which are based on the coupled Hartree-Fock (CHF) theory. We have now applied the IGLO method to assess the quality of four different sets of borane and carborane geometries (experimental and ab initio at various theoretical levels). In the present systematic study we will show that ab initio calculated molecular structures are at least as accurate as those derived by experimental techniques.

## Methods, Basis Sets and Geometries

The chemical shifts were calculated using the IGLO method. ${ }^{6}$ Huzinaga ${ }^{15}$ basis sets, recommended by the Bochum group, ${ }^{6 b}$ were employed which were contracted as follows:

| Basis DZ | C,B <br> H | 7s3p <br> 3 s | contracted to $[4111,21]$ <br> contracted to $[21]$ |
| :--- | :--- | :--- | :--- |
| Basis $\mathrm{II}^{\prime}$ | C | 9s5pld | contracted to $[51111,2111,1]$ <br> p-coefficient 1.0 |
|  | B | 9s5pld | contracted to $[51111,2111,1]$ <br> p-coefficient 0.5 <br> same as DZ |

$\mathrm{B}_{2} \mathrm{H}_{6}$ was used as the primary reference, and the $\delta$ values were converted to the $\mathrm{BF}_{3}, \mathrm{OEt}_{2}$ scale using the experimental value of $\delta\left(\mathrm{B}_{2} \mathrm{H}_{6}\right)=16.6$ ppm. ${ }^{16}$

The geometries were optimized $a b$ initio at the restricted HartreeFock (RHF) level using the GAUSSIAN 82, ${ }^{17}$ GAUSSIAN $86,{ }^{18}$ and CADPAC ${ }^{19}$

programs with standard basis sets ${ }^{4.20} 3-21 G, 6-31 G^{*}$, and in one case 6-31G**. Electron correlation was included in terms of Møller-Plesset second-order perturbation theory. ${ }^{21}$ CADPAC was employed for most of the MP2/6-31G* optimizations using analytical gradients.

The most of the experimental geometries that were employed for IGLO calculations were taken from the compilation by Beaudet. ${ }^{2}$ These are a composite of the "best available structural data" and were provided conveniently in cartesian coordinate format. Beaudet also presented a comprehensive and critical evaluation of the experimental geometries. One should bear in mind that the different techniques (electron/X-ray diffraction, microwave spectroscopy, theoretical calculations) yield different structural parameters ( $r_{\mathrm{g}}, r_{\mathrm{s}}, r_{\mathrm{e}}$ values, respectively). Hence, direct comparisons should always be made with caution. ${ }^{22}$ The differences between these parameters, estimated by Beaudet to be less than ca. $\pm 0.01$ $\AA,{ }^{2}$ are often smaller than the discrepancies reported here. One referee has suggested that we take experimental errors into consideration and provide "a detailed examination of the experimental information". This has already been undertaken by Beaudet, and we refer readers to his review. ${ }^{2}$

## Results

General Performance of IGLO Calculations, The structural parameters for 1-21 are summarized in Table I (for numbering see Figures 1 and 2) and are compared with the experimental geometries, if available. The IGLO calculated ${ }^{11} \mathrm{~B}$ chemical shifts are presented in Table II together with the experimental NMR data. Figures $3 a-f$ shows plots of the calculated vs the experimental ${ }^{11} \mathrm{~B}$ chemical shifts; the results of statistical analysis are presented in Table III.

In Figure 3a, the IGLO values are calculated employing the experimental geometries. The agreement between calculated and experimental ${ }^{11} \mathrm{~B}$ chemical shifts is only modest. For some compounds ( $\mathrm{B}_{6} \mathrm{H}_{12}, 1,2-\mathrm{C}_{2} \mathrm{~B}_{3} \mathrm{H}_{7}, 1-\mathrm{CB}_{5} \mathrm{H}_{9}$ ), exceptionally large deviations of ca. $15-19 \mathrm{ppm}$ are noted.

The computed energy of a structure might be an additional criterion for its accuracy. In Table IV, single point calculations at the MP2(full)/6-31G* level for the experimental geometries are compared to the $a b$ initio optimized energies at the same level. While most of the gas-phase determined structures are only a few $\mathrm{kcal} / \mathrm{mol}$ higher in energy as compared to the ab initio geometries, the $X$-ray derived geometries of $\mathrm{B}_{6} \mathrm{H}_{10}$ and $\mathrm{B}_{8} \mathrm{H}_{12}$ perform somewhat more poorly (ca. $28 \mathrm{kcal} / \mathrm{mol}$ less stable than the optimized structures). Exceptionally high relative energies ( $30-60$ $\mathrm{kcal} / \mathrm{mol}$ ) are computed for the experimental structures of $\mathrm{B}_{6} \mathrm{H}_{12}$, $\mathrm{C}_{2} \mathrm{~B}_{3} \mathrm{H}_{7}$, and $\mathrm{CB}_{5} \mathrm{H}_{9}$. As pointed out above, these also show the largest deviations of IGLO vs experimental chemical shifts. The apparent imperfections of these geometries will be discussed later.

In Figure 3b,c, the geometries employed in the IGLO calculations were optimized ab initio at Hartree-Fock levels, using 3-21G and $6-31 \mathrm{G}^{*}$ basis sets, respectively. The overall performance is comparable to that of the experimental geometries in Figure 3a. Many of the computed $\delta$ values are shifted more or less pronounced to higher field. Relatively large deviations are found for $1,5-\mathrm{C}_{2} \mathrm{~B}_{3} \mathrm{H}_{5}$ and $1-\mathrm{CB}_{5} \mathrm{H}_{7}$ (see below).

Figure 3d,e shows the same plots for MP2/6-31G* optimized geometries, using DZ and II' basis sets, respectively, in the IGLO calculations. Here, the agreement is quite good (standard deviation for all points ca. 3 ppm , correlation coefficient over 0.99). At the highest theoretic level employed, $\mathrm{II}^{\prime} / / \mathrm{MP} 2 / 6-31 \mathrm{G}^{*}$, only the

values computed for the two carboranes $1,5-\mathrm{C}_{2} \mathrm{~B}_{3} \mathrm{H}_{5}$ and $1,2-$ $\mathrm{C}_{2} \mathrm{~B}_{3} \mathrm{H}_{7}$ show large deviations from experiment (ca. 10 ppm , see below). If these compounds are excluded from the least-squares fit, the correlation is excellent: the slope is with 1.02 close to the ideal value, the correlation coefficient is 0.999 , and the maximum and standard deviations are only 3.1 and 1.3 ppm , respectively.

As can be seen from the data in Table III, the performance of binary boron hydrides and carboranes is different: For the former, even geometries optimized at HF level give acceptable IGLO results, and the chemical shifts computed at the DZ// MP2/6-31* level without exception are in excellent accord with the experimental data (e.g., largest deviation 1.2 ppm ). ${ }^{10}$ For the carboranes, the degree of agreement is less convincing. It appears that-in order to obtain results comparable in quality to the boron hydrides-a somewhat higher level of theory is required. E.g., the performance of the 3-21G geometries is relatively poor (Figure 3b) with many of the chemical shifts being calculated at a field far too low. Also, the effect of employing a larger basis set in the IGLO calculations, which is less pronounced for the boron hydrides, seems more important in the case of the carboranes (Figure 3e,f, Table II). However, at the highest level of theory employed, $\mathrm{II}^{\prime} / / \mathrm{MP} 2 / 6-31 \mathrm{G}^{*}$, the agreement of computed and measured ${ }^{11} \mathrm{~B}$ chemical shifts is excellent for all compounds of this study except for the two carboranes $1,5-\mathrm{C}_{2} \mathrm{~B}_{3} \mathrm{H}_{5}$ and $1,2-$ $\mathrm{C}_{2} \mathrm{~B}_{3} \mathrm{H}_{7}$.

In the following, the results for individual molecules are discussed in more detail.

## Neutral Boranes 1-8

$\mathrm{B}_{2} \mathbf{H}_{6}$ (1), Diborane(6), certainly the most important of all boron hydrides, served as the primary reference in the IGLO chemical shift calculations: the experimental structure ${ }^{23}$ was taken as the standard. The IGLO ${ }^{11} \mathrm{~B}$ chemical shifts for the various theoretical structures are in close agreement with experiment. ${ }^{24}$ No pronounced dependence on the optimization level (Table II) is apparent. Hence, diborane is well suited to be used as the "theoretical reference". The IGLO results for $\mathrm{B}_{2} \mathrm{H}_{6}$ have been analyzed more detailed in terms of localized orbital contributions. ${ }^{6 b}$
$\mathbf{B}_{4} \mathbf{H}_{10}$ (2), It is known from experiment ${ }^{25}$ that $\mathrm{B}_{4} \mathrm{H}_{10}$ adopts a "butterfly" structure with overall $C_{2}$ symmetry. The geometrical parameters of the boron framework calculated at the MP2 level are in close agreement to those obtained from microwave spectroscopy (MW) ${ }^{25 \mathrm{a}}$ and gas-phase electron diffraction (GED). ${ }^{25 b}$

[^3]However, there is some disagreement concerning the positions of the bridging hydrogens. In the ab initio structures, the $\mathrm{B}-\mathrm{H}-\mathrm{B}$ bridges are rather unsymmetric with close contacts to B1 and B3 (closer than measured in the GED study). In the MW investigation, one bridge-H coordinate could not be obtained. ${ }^{25 \mathrm{a}}$ A more asymmetric $\mathrm{B}-\mathrm{H}-\mathrm{B}$ bridge would also fit the data, but the theoretical values still do not fall within the reported experimental error (ca. $0.02 \AA$ for $\mathrm{B}-\mathrm{Hb}$ lengths). While the IGLO $\delta^{11} \mathrm{~B}$ values for all structures are in reasonable accord with experiment, the best fit is found for the structures optimized at MP2 level.
For this relatively small and symmetric molecule we probed the effect of employing a larger basis set in the optimization ( $6-31 \mathrm{G}^{* *}$ which includes polarization functions on hydrogen). The MP2/6-31G* and MP2/6-31G** optimizd geometrical parameters do not show significant differences. Consequently, the chemical shifts calculated for these geometries are nearly identical. In contrast to many carbocation structures, ${ }^{7}$ no polarization functions on hydrogen need to be used in the optimizations of boron hydrides. ${ }^{26}$
$\mathrm{B}_{5} \mathrm{H}_{9}$ (3), The calculated geometrical parameters and the chemical shifts of $\mathrm{B}_{5} \mathrm{H}_{9}$ do not show a pronounced dependence on the optimization level. The experimental geometry recommended by Beaudet (MW) ${ }^{27}$ as well as the best theoretical structure (MP2/6-31G*) perform nearly equally well: both are comparable in energy (Table IV) and have similar IGLO chemical shifts (Table II).
$\mathrm{B}_{5} \mathrm{H}_{11}$ (4), It is known both from experimental ${ }^{28}$ and theoretical ${ }^{8.29}$ investigations, that the unique bridging hydrogen in $\mathrm{B}_{5} \mathrm{H}_{11}$ prefers an unsymmetric location, resulting in overall $C_{1}$ symmetry. The best theoretical structure for 4-optimized at the MP2/6-31G* level-shows the critical hydrogen $\mathrm{H}_{\mathrm{b}}$ to be involved in a perfectly normal, unsymmetrical $\mathrm{B}-\mathrm{H}-\mathrm{B}$ bond. Hence, the "styx" formulation ${ }^{1}$ of $\mathrm{B}_{5} \mathrm{H}_{11}$ should be 4112 rather than 3203. The barrier for the tautomerization of this unique hydrogen, proceeding through a transition state of $C_{s}$ symmetry, was calculated to very low (about $1 \mathrm{kcal} / \mathrm{mol}$ at MP4sdtq $/ 6-31 \mathrm{G}^{*} / / 6$ $31 \mathrm{G}^{*}+$ ZPE). The IGLO values computed for this transitionstate geometry, however, showed pronounced deviations from experiment (up to ca. 8 ppm at $\mathrm{DZ} / / \mathrm{MP} 2 / 6-21 \mathrm{G}^{*}$ ).

The IGLO $\delta{ }^{11} \mathrm{~B}$ values calculated for the ab initio structures of 4 are very sensitive to the "quality" of the geometry. With increasing level of theory employed in the optimization, the

chemical shifts steadily approach the experimental values. Those for the MP2/6-31G* geometry are in excellent agreement with experiment.

The individual chemical shifts of B3 and B4 in 4 are calculated to be very different ( -13.5 and +10.3 ppm ), even though these atoms are not directly associated with the "critical" hydrogen (cf. $\mathrm{B}_{8} \mathrm{H}_{12}$ below). This emphasizes the general importance of the exact positions of bridging hydrogens. The pronounced chemical shift difference between B3 and B4 to a large extent is due to the unsymmetric location of $\mathrm{H}_{\mathrm{b}}$ : in the refinement of the experimental

GED structure, the whole molecule with the exception of $\mathrm{H}_{\mathrm{b}}$ was constrained to have $C_{s}$ symmetry (cf. Table I). Despite a smaller "displacement" of $\mathrm{H}_{\mathrm{b}}$ from the symmetric position (as compared to the theoretical structures), the calculated $\delta$ values of B3 and B4 also show a pronounced difference ( -7.5 and +1.4 ppm ).
$\mathbf{B}_{6} \mathbf{H}_{10}$ (5), At room temperature, the molecule is fluxional due to a rapid tautomerization of the bridging hydrogens. ${ }^{30}$ Thus,

${ }^{a}$ Results of a least-squares analysis, IGLO vs experimental ${ }^{11} \mathrm{~B}$ chemical shifts. ${ }^{b}$ In ppm.
the five basal boron atoms, $B(2-6)$, are equivalent on the NMR time scale. At lower temperature, the single peak observed for $\mathbf{B}(2-6)$ is split into two resonances, which have been assigned to the static $C_{s}$ structure 5 that is found in the solid state ${ }^{31}$ and in the gas phase. ${ }^{32}$ In this symmetry, three basal boron atoms are nonequivalent. Hence, two of these [(B3,6) and $B(4,5)$ ] must have nearly identical $\delta{ }^{11} \mathrm{~B}$ values. The IGLO chemical shifts for the ab initio geometries are in excellent accord with experiment, and $B(3,6)$ and $B(4,5)$ indeed have very similar $\delta{ }^{11} B$ values. In contrast to earlier predictions, ${ }^{33}$ the substantial difference in the chemical shifts between these four borons and the other basal boron B 2 is reproduced well by the IGLO calculations.
$\mathrm{B}_{6} \mathrm{H}_{12}$ (6), A gas-phase electron diffraction (GED) study for this molecule has been reported recently which established the molecular $C_{2}$ symmetry. ${ }^{34}$ However, on the basis of structural, energetic, and NMR criteria, the accuracy of the molecular dimensions derived by GED has been questioned. ${ }^{9}$ As can be seen

${ }^{\text {a }}$ MP2(full)/6-31G* optimized energies. ${ }^{b}$ MP2(full)/6-31G* single point energies employing the experimental structures; unless otherwise noted, these were taken from ref 2 . ${ }^{\text {' Relative energy ( } \mathrm{kcal} / \mathrm{mol} \text { ) of the }}$ experimental geometries with respect to the ab initio structures. ${ }^{d}$ Reference 27. ${ }^{e}$ Reference 34. ${ }^{\delta}$ Reference 41 (neutron-diffraction). ${ }^{g}$ Experimental structure based on X-ray analysis. ${ }^{h}$ "Preliminary" experimental structure from ref 2 (see text). ${ }^{i}$ No carbon positions refined experimentally (see text).
from the data in Table II, the IGLO $\delta{ }^{11} \mathrm{~B}$ values computed for the GED geometry do not agree at all with the experimental chemical shifts. The theoretical calculations are complicated somewhat by the existence of a high-lying "false" minimum at lower levels of theory. ${ }^{9}$ However, the IGLO chemical shifts computed for the MP2/6-31G* geometry of 6 , the only minimum found at that level, are in excellent agreement with experiment. Hence, the geometric parameters calculated at the MP2/6-31G* level are probably more accurate than those derived by GED.
$\mathrm{B}_{8} \mathrm{H}_{12}$ (7), On the NMR time scale, $\mathrm{B}_{8} \mathrm{H}_{12}$ shows $C_{2 v}$ symmetry, ${ }^{35}$ whereas this is reduced to $C_{s}$ in the solid state (cf. $7 \mathbf{b}$ ). ${ }^{36}$ Fluxional behavior in solution was considered involving two equivalent $C_{s}$ structures. Beaudet suggested a gas-phase structure determination in order to confirm structural details of the "unaesthetic" $C_{s}$ form. ${ }^{2}$ Theoretical calculations by McKee reproduced the solid-state geometry quite well (3-21G basis set, see Table I) and predicted a very low barrier for the scrambling of the bridging hydrogens ( $C_{2 v}$ transition state, cf. 7a). ${ }^{37}$ Our calculations, performed at a somewhat higher level of theory, reach the same conclusions: The MP2/6-31G* geometry of the $C_{s}$ form 7b is in good agreement with the X-ray structure. The

${ }^{a}$ Calculated with 6-31G* basis set for MP2/6-31G* geometries.
"asymmetry" of the bridging hydrogens H 45 and H 67 with respect to the borons B3,5 and B6,8, respectively, is even larger in the MP2 geometry (1.391, $2.116 \AA$; X-ray: 1.469, $2.021 \AA$ ). Also, the H -bridged B 3 B 8 bond $(1.647 \AA$ ) is nearly as short as the unbridged B4B5 bond in $\mathrm{B}_{6} \mathrm{H}_{10}(5,1.638 \AA$, see Table I).

The $C_{2 v}$ form 7 a is only $3.0 \mathrm{kcal} / \mathrm{mol}$ higher in energy at MP2/6-31G*//MP2/6-31G*. This very low barrier is in accord with fluxionality on the NMR time scale.
The IGLO $\delta{ }^{11} \mathrm{~B}$ values for 7 a and 7 b in Table IV are most revealing: The chemical shifts computed employing the X -ray structure do not agree very well with experiment (ca. 10 ppm deviation). Also, the $C_{2 v}$ ab initio geometries do not perform satisfactory ( 20 ppm deviation at DZ//MP2/6-31G*).

The averaged IGLO values for the MP2/6-31G* geometry of 7b give rise to the question whether the original assignment of the $\mathrm{B}(1,2)$ and $\mathrm{B}(4,7)$ resonances is correct. From the published data this assignment seems a little tentative. If the assignment for $\mathrm{B}(1,2)$ and $\mathrm{B}(4,7)$ is reversed, then the IGLO $\delta^{11} \mathrm{~B}$ chemical shifts at the DZ//MP2/6-31G* level are in excellent agreement with the experimental values (in parentheses): -22.4 (-22.0), -18.2 (-19.4), and 8.2 (7.5) ppm. Since more experimental information appears to be needed in order to ascertain the assignments, the IGLO values for $7 \mathbf{b}$ have not been included in the correlation of Figure 3 and Table III.
Interestingly, the computed individual chemical shifts for B1 and B 2 in the static $C_{s}$ form 7 b show large differences ( 7.9 and $-44.3 \mathrm{ppm}, \mathrm{DZ} / / \mathrm{MP} 2 / 6-31 \mathrm{G}^{*}$ level). The same has been found for B 3 and B 4 in $\mathrm{B}_{5} \mathrm{H}_{11}$ (see above). These theoretical values are in line with the observing, that a boron nucleus "opposite" to a $\mathrm{B}-\mathrm{H}-\mathrm{B}$ arrangement resonates at higher field than one "opposite" to unbridged $B-B$ edge. ${ }^{38}$ In the cases of $\mathrm{B}_{5} \mathrm{H}_{11}$ and $\mathrm{B}_{8} \mathrm{H}_{12}$, however, the low scrambling barriers are likely to preclude the experimental confirmation of the predicted individual chemical shifts.

## Borane Anions 8-10

$\mathrm{B}_{2} \mathrm{H}_{7}$ (8), An earlier ab initio study (including MP2/6-31G* geometry optimizations) ${ }^{39}$ showed the $\mathrm{B}_{2} \mathrm{H}_{7}{ }^{-}$anion to be strongly
(38) Her̄mänek, S.; Jelīnek, T.; Ples̄ek, J.; S̄tībr, B.; Fusek, J.; Mares̄, F. In Boron Chemistry, Proceedings of the 6th IMEBORON; Her̈mänek, S., Ed.; World Scientific: Singapore, 1987; pp 26-73.
bent as has been found in the solid state. ${ }^{40,41}$ The symmetrical $C_{2}$ form 8 c turned out to be the minimum, whereas the slightly unsymmetrical $C_{s}$ form $\mathbf{8 b}$ has one imaginary frequency and therefore should be a transition state (the linear $D_{3 d}$ structure has two imaginary frequencies denoting a "hilltop"). As in the case of $\mathrm{B}_{4} \mathrm{H}_{10}$ (see above), optimization of $\mathbf{8 a}$ and $\mathbf{8 b}$ at the MP2/6$31 \mathrm{G}^{* *}$ level does not affect structure and nature of these forms significantly.

In the solid state, however, $C_{s}$ symmetry with an unsymmetrical $\mathrm{B}-\mathrm{H}-\mathrm{B}$ bridge is found. ${ }^{40,41}$ According to the calculations, the potential energy surface is very flat; e.g., the $\mathrm{BH}_{3}$ groups can rotate nearly without a barrier. Hence, crystal packing forces may well dominate the actual geometry in the solid state. In the gas phase or in solution more symmetric forms are to be expected.

The crucial geometric parameter that governs the chemical shifts of $\mathrm{B}_{2} \mathrm{H}_{7}^{-}$seems to be the $\mathrm{B}-\mathrm{H}-\mathrm{B}$ angle. The level of theory employed in the optimization strongly affects the value of this angle; the inclusion of electron correlation is especially important ${ }^{39}$ (e.g., for 8 c the $\mathrm{B}-\mathrm{H}-\mathrm{B}$ angle is $140.8^{\circ}$ at $6-31 \mathrm{G}^{*}$ and $126.4^{\circ}$ at MP2/6-31 $\mathrm{G}^{*}$ ). The significant ${ }^{11} \mathrm{~B}$ chemical shift differences between the $6-31 \mathrm{G}^{*}$ and the MP2/6-31 G* geometries for $\mathbf{8 b}$ and 8 c show optimizations with correlation to be essential here. The IGLO ${ }^{11} \mathrm{~B}$ chemical shifts of the bent forms 8 b and $8 \mathrm{c},-22.9$ and -23.1 ppm , respectively, are in close agreement with the experimental value $(-24.6 \mathrm{ppm}) .{ }^{42}$ Since linear 8 a shows a significant deviation ( -14.7 ppm ), the bent $\mathrm{B}-\mathrm{H}-\mathrm{B}$ moiety found in the solid state obviously is retained in solution. However, since the chemical shifts of 8 b and 8 c are nearly identical, no distinction between these two forms can be made on this basis.

The imperfections of the X-ray structure with respect to the hydrogen locations are shown by an IGLO calculation employing this geometry, which results in poor agreement with the experimental chemical shifts (Table II). On the other hand, the IGLO values based on the structure derived by neutron diffraction are

[^7]
$9 C_{2 v}$

$\delta{ }^{11} B \quad-32.0$

-30.4

Figure 4. Comparison of geometries (MP2/6-31G* optimized) and averaged ${ }^{11} \mathrm{~B}$ chemical shifts (IGLO II'//MP2/6-31G*) for $\mathrm{B}_{3} \mathrm{H}_{8}{ }^{-}(9 b), \mathrm{B}_{3} \mathrm{H}_{8} \mathrm{Li}$, and $\mathrm{B}_{3} \mathrm{H}_{8} \mathrm{Na}$.
in good accord with experiment.
$\mathrm{B}_{3} \mathrm{H}_{8}{ }^{-}$(9), Of the two structural alternatives considered, 9a with $C_{s}$ with 9 b with $C_{2 v}$ symmetry, the latter has been found in crystal structures. ${ }^{43}$ McKee and Lipscomb ${ }^{44}$ have examined the relative energies of 9 a and 9 b at various levels of theory, but only with 3-21G optimized geometries. Reoptimization at 6-31G* and MP2/6-31G* affords somewhat shorter bond distances. The MP2 geometry is in good agreement with the X-ray structures.

The nature of the two stationary points depends on the level of theory employed: At Hartree-Fock levels (3-21G, 6-31G*), 9 a is a minimum and is lower in energy than 9 b (transition state), whereas this is reversed at MP2/6-31G*: at this correlated level, 9 b is a minimum and 9 a a transition state. The very low scrambling barrier, ca. $0.9 \mathrm{kcal} / \mathrm{mol},{ }^{10,44}$ is consistent with the fluxional character of the molecule.

The averaged IGLO chemical shifts (DZ//MP2/6-31G*) are in good accord with experiment for 9 b ( -31.6 ppm , exptl: -29.8 ) but show a significant deviation for $9 \mathrm{a}(-21.1 \mathrm{ppm})$. This indicates the $C_{2 v}$ form of the solid state to be present in solution as well. The individual chemical shifts of the static form $9 \mathrm{a}(-50.6,-7.5$ ppm , basis $\mathrm{II}^{\prime}$ ) are comparable to those found experimentally for $\mathrm{B}_{3} \mathrm{H}_{3} \mathrm{~L}$ Lewis base adducts which possess $C_{s}$ symmetry (e.g., -52.6 , -6.4 ppm for $\mathrm{L}=\mathrm{CO}{ }^{47}-51.6,-11.2 \mathrm{ppm}$ for $\mathrm{L}=\mathrm{PH}_{3}{ }^{48}$ ).

The rather good agreement of chemical shifts computed for isolated neutral boranes with measured values for the species in solution (see Table II) suggests that solvent effects on the chemical shift usually play only a minor role. But is this also true for the effects of counterions in the case of the anionic boron hydrides? To clarify this point, we studied the complexes of 9 with $\mathrm{Li}^{+}$and $\mathrm{Na}^{+}$. The MP2/6-31G* optimized geometries in Figure 4 demonstrate that the key geometric parameters of 9 remain practically unchanged. Although the overall molecular symmetry is reduced to $C_{s}$ in the complexes, the bridging hydrogens remain in the BBB plane. As it is the case with the geometries, the calculated (averaged) chemical shifts of $9,9 \cdot \mathrm{Li}^{+}$, and $9 \cdot \mathrm{Na}^{+}$show only minor differences. This is also found experimentally for many different counterions. ${ }^{49}$ Hence, the chemical shifts of anionic boron hy-

[^8]drides should be described reasonably well by regarding the "naked" anions.
$\mathrm{B}_{4} \mathbf{H}_{9}^{-}$(10), No X-ray structure is known for a $\mathrm{B}_{4} \mathrm{H}_{9}{ }^{-}$salt. On the basis of the NMR spectrum, ${ }^{50}$ a $C_{s}$ symmetric structure (10) with "fractional three-center BBB bonds" ${ }^{11}$ has been proposed.

We carried out geometry optimizations in $C_{s}$ symmetry including polarization functions and electron correlation; a frequency calculation showed this structure to be a minimum at the 6-31G* level. As pointed out above, the structural parameters for $\mathrm{B}_{4} \mathrm{H}_{9}{ }^{-}$ optimized at the MP2/6-31G* level should be reliable. This is confirmed by the IGLO results for $\mathbf{1 0}$ which are in excellent agreement with the experimental chemical shifts.

## Carboranes 11-21

1,3- $\mathrm{C}_{2} \mathrm{~B}_{2} \mathrm{H}_{4}$ (11), Although a search for this smallest conceivable closo-carborane has been undertaken by a number of chemists, the parent compound is still unknown. A rather open, puckered four-membered ring structure rather than a closo-type "tetrahedron" has been predicted. ${ }^{52}$ A number of substituted derivatives has been synthesized, and some of them characterized by X-ray structure analysis. For these, the puckered $\mathrm{C}_{2} \mathrm{~B}_{2}$ unit has been confirmed. ${ }^{53,54}$

More refined geometric parameters and the predicted chemical shifts for the parent compound 11 are included in Tables I and II. A discussion of substituent effects on $\delta{ }^{13} \mathrm{C}$ in this system will be published elsewhere. ${ }^{54}$
$\mathbf{1 , 5}-\mathrm{C}_{2} \mathrm{~B}_{3} \mathrm{H}_{5}(\mathbf{1 2 )}$, The structure of this smallest known clo-so-carborane has been determined by electron diffraction. ${ }^{55}$ The MP2/6-31G* optimized geometric parameters for 12 ( $D_{3 h}$ symmetry) are in good agreement with the experimental results (Table I). A frequency calculation at the correlated MP2/6-31G* level confirmed this $D_{3 h}$ form to be a minimum.

As mentioned above, the IGLO $\delta^{11} \mathrm{~B}$ chemical shifts for 12 give only poor accord with experiment (Table II). Employing the

GED structure results in a deviation of ca. 12 ppm . The 3-21G and 6-31G* geometries perform even worse ( 19 and 15 ppm deviation, respectively), and at the highest level of theory, $\mathrm{II}^{\prime} / /$ MP2/6-31 $\mathrm{G}^{*}$, the boron is computed too strongly deshielded by 10 ppm . A GIAO calculation ( $6-31 \mathrm{G}^{*}$ basis set) employing the MP2/6-31G* geometry gives essentially the same result. ${ }^{56}$ This suggests that the basic theoretical procedure underlying the chemical shift calculations (which remains at Hartree-Fock level, i.e., without treatment of electron correlation) may not be sufficient in this case.

The dependence of the calculated chemical shifts on the geometric parameters is not very pronounced: if one artificially reduces the BB distance in the MP2/6-31G* geometry of $\mathbf{1 2}$ from 1.853 to 1.750 (leaving the BC distance constant), then the computed $\delta^{" 1} \mathrm{~B}$ value of 5.3 ppm is closer to the experimental value ( 1.4 ppm ). However, this geometry is not realistic: the distortion "costs" $14 \mathrm{kcal} / \mathrm{mol}$. The reason for the discrepancy between theoretic and experimental chemical shifts in this case is not known. Perhaps a correlated wave function is needed for the chemical shift calculation.
1,2- $\mathrm{C}_{2} \mathrm{~B}_{3} \mathrm{H}_{7}$ (13), This relatively unstable nido-carboranewhich instantaneously polymerizes in the liquid state-is isoelectronic with $\mathrm{B}_{5} \mathrm{H}_{9}$ (3). Since three-center $\mathrm{C}-\mathrm{H}-\mathrm{B}$ bridges usually are avoided, one carbon atom assumes an apical position to accomodate the two bridging hydrogens. A previously unpublished, "preliminary" microwave structure has been reported by Beaudet in his review. ${ }^{2}$ However, the geometric parameters given there show pronounced differences from those obtained by ab initio optimizations (Table I). The computed and the experimental bond distances differ by up to $0.19 \AA$. E.g., the reported short CC distance of $1.453 \AA$ is not reproduced by the calculations (MP2/6-31 G*: $1.604 \AA$ ).
As mentioned above, the IGLO ${ }^{11} \mathrm{~B}$ chemical shifts for 13 do not agree with the experimental values. The maximum deviation is ca .19 ppm for the microwave structure and ca .9 ppm for the MP2/6-31G* geometry (DZ basis). Even at the highest theoretical level employed, $\mathrm{II}^{\prime} / / \mathrm{MP} 2 / 6-31 \mathrm{G}^{*}$, computed and experimental chemical shifts differ by ca. 8 ppm (Table II). Together with $\delta{ }^{11} \mathrm{~B}$ of $1,5-\mathrm{C}_{2} \mathrm{~B}_{3} \mathrm{H}_{5}$ (12), these deviations are considerably larger than found for the other molecules of this study (cf. Table III). Evidently, small strained carboranes 12 and 13 require even higher (e.g., correlated) levels of theory for a correct description of geometries and chemical shifts.
The computed large upfield shift for the apical carbon Cl in 13 ( -34.8 ppm at the $\mathrm{II}^{\prime} / / \mathrm{MP} 2 / 6-31 \mathrm{G}^{*}$ level) compares rather well to the value of -23.0 ppm reported for Cl in Masamunes's cation, a substituted derivative of the isoelectronic $(\mathrm{CH})_{5}{ }^{+} .{ }^{57}$

The $\delta{ }^{13} \mathrm{C}$ chemical shifts computed for $\mathbf{1 3}$ are strongly dependent on the basis set used in the IGLO calculation (Table II). Unfortunately, no experimental data are known for comparison.

We also considered a cyclic isomer of 13 ( $C_{s}$ symmetry), which-in reduced form-can act as a ligand in transition-metal complexes. ${ }^{58}$ However, at the MP2/6-31G*//MP2/6-31G* + ZPE (6-31G*) level this isomer is less stable than 13 by 16.6 $\mathrm{kcal} / \mathrm{mol}$.

[^9]$1-\mathrm{CB}_{5} \mathrm{H}_{7}$ (14), The molecular structure of $\mathrm{CB}_{5} \mathrm{H}_{7}(14)$ has been the topic of several experimental ${ }^{59}$ and theoretical ${ }^{29}$ studies. While there is general agreement that the carborane cage consists of a distorted octahedron, the exact position of the "extra" hydrogen has been the matter of some debate. In the GED study, ${ }^{59 \mathrm{a}}$ this hydrogen was reported to bridge the $\mathrm{B}(2) \mathrm{B}(3) \mathrm{B}(6)$ face; however, the electron diffraction technique is less reliable when two or more bond distances of the same magnitude are involved. In the MW study, ${ }^{596}$ no hydrogens were refined at all. The three somewhat elongated B-B distances on one of the cage faces strongly favored the triply bridging arrangement. In the Beaudet's recommended structure, a position for the critical H with three nearly identical B-H lengths was assumed. In contrast, ab initio calculations at the $3-21 \mathrm{G}$ level showed a very unsymmetric arrangement (with respect to the triangular face), the three $\mathrm{B}-\mathrm{H}$ distances being 1.353, 1.353, and 1.857 (!) $\AA$, respectively (Table I). ${ }^{29}$ At the highest level employed, MP2/6-31G*, the calculated dimensions of the carborane cage agree well with those inferred from experiment. The critical hydrogen exhibits the most dramatic sensitivity toward the theoretical level: the nature of this bridge changes from an essentially three-center bond at 3-21G to a nearly pure four-center bond at MP2/6-31G* (B-H distances 1.389, $1.389,1.475 \AA$ ). The $6-31 \mathrm{G}^{*}$ geometry is intermediate between these two. This sensitivity toward the computational level is indicative of a very flat potential energy surface for the motion of the critical hydrogen.

The IGLO results for $\mathrm{CB}_{5} \mathrm{H}_{7}$ (Table II) show a pronounced dependence on the various geometries employed. The most sensitive atom, B 6 , is involved in the critical hydrogen bridge. As the $\mathrm{B} 6-\mathrm{Hb}$ distance decreases in going from the $3-21 \mathrm{G}$ to the MP2/6-31G* geometry this boron is increasingly shielded. At the highest theoretical level employed ( $\mathrm{II}^{\prime} / / \mathrm{MP} 2 / 6-31 \mathrm{G}^{*}$ ), the agreement between theoretical and experimental $\delta{ }^{4} \mathrm{~B}$ values is excellent.

More refined calculations on the transition structure and the barrier for hydrogen scrambling in $\mathrm{CB}_{5} \mathrm{H}_{7}$ will be reported elsewhere. ${ }^{60}$

1,2- $\mathrm{C}_{2} \mathrm{~B}_{4} \mathrm{H}_{6}$ (15) and $1,6-\mathrm{C}_{2} \mathrm{~B}_{4} \mathrm{H}_{6}(16)$, There is no unusual dependence of computed geometries and chemical shifts on the level of theory for these two closo-carborane isomers. The 1,6isomer, 16 , is more stable than 15 by $9.7 \mathrm{kcal} / \mathrm{mol}$ at MP2/6$31 \mathrm{G}^{*} / / \mathrm{MP}^{2} / 6-31 \mathrm{G}^{*}+\mathrm{ZPE}\left(6-31 \mathrm{G}^{*}\right)$. This value is in agreement with calculations reported by McKee (employing 3-21G geometries) ${ }^{61}$ who also investigated the reaction path interconverting the two isomers. Electron-releasing amino substituents on boron favor a bicyclic, "classical" isomer. ${ }^{62}$

2-CB $\mathrm{CB}_{5} \mathrm{H}_{9}$ (17), 2,3- $\mathrm{C}_{2} \mathrm{~B}_{4} \mathrm{H}_{8}$ (18), 2,3,4- $\mathrm{C}_{3} \mathrm{~B}_{3} \mathrm{H}_{7}$ (19), and 2,3,4,5-C $\mathrm{C}_{4} \mathrm{~B}_{2} \mathrm{H}_{6}(20)$, These four nido-carboranes are structurally related to $\mathrm{B}_{6} \mathrm{H}_{10}$; they are derived formally by successive replacement of one boron and one bridging hydrogen by a carbon. All have the same basic pentagonal-pyramidal structure (Figure 2).

For $2-\mathrm{CB}_{5} \mathrm{H}_{9}$ (17), a partial microwave structure was published, ${ }^{63}$ without refinement of carbon and hydrogen positions. The reported B-B distances are in good agreement with the computed values (Table I). Beaudet tabulated coordinates for all atoms in his review, probably based on reasonable assumptions. The IGLO ${ }^{11} \mathrm{~B}$ chemical shifts for his recommended structure, however, show a large deviation for B1 ( -38.7 ppm , exptl: -51.9 , Table II). The IGLO values computed for the ab initio geometries are in good accord with experiment, without even showing large dependence on the level of theory. The same is found for 2,3$\mathrm{C}_{2} \mathrm{~B}_{4} \mathrm{H}_{8}$ (18).

For $2,3,4-\mathrm{C}_{3} \mathrm{~B}_{3} \mathrm{H}_{7}$ (19), neither an accurate structure nor chemical shifts are known experimentally. Substituted derivatives

[^10]

Figure 5. Correlation of ${ }^{11} B$ chemical shifts with atomic charges obtained (a) from Mulliken and (b) from natural population analysis (NPA): circles, neutral boranes 1-7; triangles; borane anions 8-10; squares, carboranes 11-21.
have been prepared. The chemical shift of Bl measured for 2,4-dimethyl-2,3,4- $\mathrm{C}_{3} \mathrm{~B}_{3} \mathrm{H}_{5},-51.6 \mathrm{ppm}$, ${ }^{64}$ differs somewhat from that computed for the parent compound $19,-57.9 \mathrm{ppm}$. The latter value, however, is in line with the trend observed in 17-20: an increasing number of basal carbon atoms is paralleled by a high field shift of $B(1):-51.9,-53.3,-57.9$ (IGLO) and -60.8 ppm for $17,18,19$, and 20, respectively (see Table II).

The MP2/6-31G* optimized geometrical parameters of $2,3,4,5-\mathrm{C}_{4} \mathrm{~B}_{2} \mathrm{H}_{6}(20)$ are very similar to the reported $6-31 \mathrm{G}^{*}$ values ${ }^{65}$ and are in good accord with the microwave data. The IGLO "B chemical shifts also agree well with experiment.
$\mathbf{2 , 4}-\mathrm{C}_{2} \mathrm{~B}_{5} \mathrm{H}_{7}$ (21), The structure of 21, the largest carborane included in this study, has been determined by $\mathrm{MW}^{66}$ and by GED, ${ }^{67}$ where the molecular $C_{2 v}$ symmetry was established. Although the computed structural parameters depend somewhat on the level of theory (Table I), the ${ }^{11}$ B IGLO DZ chemical shifts show only minor differences for the various ab initio geometries (ca. 2 ppm , Table II). The effect of the larger II' basis set with respect to the DZ basis is more pronounced: the computed $\delta{ }^{11} \mathrm{~B}$ values differ up to ca. 4 ppm (compare DZ//MP2/6-31G* and $\mathrm{II}^{\prime} / / \mathrm{MP} 2 / 6-31 \mathrm{G}^{*}$ values in Table II). However, the ${ }^{11} \mathrm{~B}$ chemical shifts calculated at the highest level ( $\mathrm{II}^{\prime} / / \mathrm{MP2} / 6-31 \mathrm{G}^{*}$ ) agree rather well with the experimental values (maximum deviation ca. 3 ppm ).
${ }^{13} \mathrm{C}$ Chemical Shifts, Experimental ${ }^{13} \mathrm{C}$ data for the unsubstituted small carboranes are very sparse. ${ }^{68}$ Among the compounds of this study, only $\delta{ }^{13} \mathrm{C}$ values for $1,3-\mathrm{C}_{2} \mathrm{~B}_{3} \mathrm{H}_{5}$ (12), $1,6-\mathrm{C}_{2} \mathrm{~B}_{4} \mathrm{H}_{6}(\mathbf{1 6}), 2,3-\mathrm{C}_{2} \mathrm{~B}_{4} \mathrm{H}_{8}$ (18), and $2,4-\mathrm{C}_{2} \mathrm{~B}_{5} \mathrm{H}_{7}(\mathbf{2 1})$ have been published. ${ }^{68}$ The IGLO chemical shifts of these four compounds (II'//MP2/6-31G* level, Table II) are in moderately good agreement with the literature data; the largest deviation is ca. 7 ppm for 16.

Two general characteristics are observed for the computed $\delta$ ${ }^{13} \mathrm{C}$ values: First, the IGLO ${ }^{13} \mathrm{C}$ chemical shifts usually are not
(64) Howard, J. W.; Grimes, R. N. Inorg. Chem. 1971, 10, 2770.
(65) Budzelaar, P. H. M.; v. d. Kerk, S. M.; Krogh-Jespersen, K.; Schleyer, P. v. R. J. Am. Chem. Soc. 1986, 108, 3960.

(68) (a) Todd, L. J. Pure Appl. Chem. 1972, 30, 587. (b) Olah, G. A.; Prakash, G. K. S.; Liang, G.; Henold, K. L.; Haigh, G. B. Proc. Natl. Acad. Sci. U.S.A. 1977, 74, 5217.
very sensitive to small geometric changes ( DZ values, Table II). In many cases, the variation in $\delta{ }^{11} \mathrm{~B}$ is larger. Second, larger IGLO basis sets sometimes strongly affect the computed $\delta^{13} \mathrm{C}$ values (compare DZ//MP2/6-31G* and $\mathrm{II}^{\prime} / / \mathrm{MP}^{2} / 6-31 \mathrm{G}^{*}$ values in Table II). In some systems, the DZ - II' difference can be rather large (e.g., up to 15 ppm in 13). The $I I^{\prime} \delta{ }^{13} \mathrm{C}$ values usually are shifted upfield with respect to the DZ results (except 12 and 21). Interestingly, the IGLO $\delta{ }^{13} \mathrm{C}$ values are too far upfield with respect to available experimental data. A critical evaluation of these deviations, however, must await more experimental determinations. Consequently, only qualitative trends can be discussed. Most of the ${ }^{13} \mathrm{C}$ chemical shifts calculated for 12-21 are in the range between ca. 80 and 120 ppm . Interesting exceptions are the resonances at higher field predicted for $1-\mathrm{CB}_{5} \mathrm{H}_{7}$ and $1,2-\mathrm{C}_{2} \mathrm{~B}_{4} \mathrm{H}_{6}$ (around ca. 45 ppm ) and, as mentioned above, Cl of $1,2-\mathrm{C}_{2} \mathrm{~B}_{3} \mathrm{H}_{7}$ (ca. -30 ppm ).

## Discussion

The most obvious property with which the chemical shift might be correlated is the atomic charge. Several correlations of $\delta^{11} B$ with total or $\pi$ charge densities have been reported. ${ }^{69,70}$ The atomic charges-which are not observable properties-mostly were calculated at semiempirical levels employing Mulliken population analysis (MPA).
We employed another method, natural population analysis (NPA) ${ }^{71}$ which generally has the advantage of showing little basis set dependence. The results of these two methods $\left(6-31 \mathrm{G}^{*}\right.$ basis set for MP2/6-31G* geometries) are compared in Table $V$ and are correlated with the experimental chemical shifts ${ }^{72}$ in Figure 5.

The NPA charges span a considerably wider range than those obtained from Mulliken analysis, and it may seem to be unusual

[^11]for a boron to bear nearly half a negative ( B 1 in $\mathrm{B}_{4} \mathrm{H}_{9}{ }^{-}, 10$ ) or half a positive charge (in $1,5-\mathrm{C}_{2} \mathrm{~B}_{3} \mathrm{H}_{5}, 12$ ). The plots in Figure 5 illustrate that there is no general relationship between ${ }^{11} \mathrm{~B}$ chemical shifts and total atomic charges. While one might perceive a trend for the binary boron hydrides in the plot vs NPA charges ( 0 and $\Delta$ in Figure 5 b ), this is not found at all for the carboranes (D). Boron atoms attached to the more electronegative carbon appear to be more positively charged. However, this is not reflected in the ${ }^{11} \mathrm{~B}$ chemical shifts.

The apical borons B 1 in the series of pentagonal pyramids 17-20 (the $\square$ in lower half of Figure 5 b ) are unique in showing exceptionally strong upfield shifts with respect to the computed charges. This might support the ring current models that have been proposed to explain proton NMR chemical shifts of substituted compounds. ${ }^{73}$

## Conclusions

The ${ }^{11} \mathrm{~B}$ chemical shifts of several boron hydrides and carboranes have been calculated ab initio using the IGLO method. Except for the two smallest carboranes, the agreement between theoretical and experimental values is excellent provided accurate geometries are employed (e.g., optimized ab initio with inclusion of electron correlation). A correct description of $\delta{ }^{11} \mathrm{~B}$ chemical shifts in carboranes is somewhat more demanding with respect to the level of theory employed: in many cases, the larger TZP type basis II' is needed in order to reproduce the experimental results. The accuracy that can be achieved is remarkable: although two of the observed boron resonances of $\mathrm{B}_{8} \mathrm{H}_{12}$ differ by merely 2 ppm , an alternative assignment is suggested by the IGLO calculations.

The effect of counterions on geometry and chemical shifts is shown to be very small in the case of $\mathrm{B}_{3} \mathrm{H}_{8}{ }^{-}$. Hence, even the treatment of anions as isolated molecules seems justified, and no inherent errors are apparent.
A pessimistic opinion states only two years ago, "...theoretical calculations of these NMR characteristics are of little importance because they cannot be performed as accurately as necessary for the structural elucidation of boron compounds ${ }^{38}$ no longer is valid. A certain limitation, however, is that this accuracy-at least in the case of polyhedral boranes-can only be achieved for geometries optimized at a correlated level (these optimizations can be rather expensive, e.g., 50000 CPU s for the MP2/6-31G* optimization of $\mathrm{B}_{6} \mathrm{H}_{12}$ on a CRAY-YMP).

#### Abstract

The geometries of a series of monomeric alkaline earth $\mathrm{MX}_{2}$ compounds ( $\mathrm{M}=\mathrm{Ca}, \mathrm{Sr}, \mathrm{Ba} ; \mathbf{X}=\mathrm{Li}, \mathrm{BeH}, \mathrm{BH}_{2}$, $\mathrm{CH}_{3}, \mathrm{NH}_{2}, \mathrm{OH}, \mathrm{F}$ ) have been calculated at the Hartree-Fock level, using quasirelativistic pseudopotentials for $\mathrm{Ca}, \mathrm{Sr}$, and Ba . The energies of fully optimized structures are compared with those of linear X-M-X geometries. Most barium compounds studied (except $\mathrm{BaLi}_{2}$ ) are bent with angles between 115 and $130^{\circ}$ and linearization energies up to ca. $8 \mathrm{kcal} / \mathrm{mol}\left(\right.$ for $\left.\mathrm{Ba}\left(\mathrm{CH}_{3}\right)_{2}\right)$. The degree of bending for $\mathrm{M}=\mathrm{Sr}$ is smaller but is still significant (except for $\mathrm{X}=\mathrm{Li}, \mathrm{BeH}$ ). However, most of the Ca compounds may be termed quasilinear, i.e., they either are linear or nearly so and bend easily. The XMX bond angles for $\mathrm{M}=\mathrm{Sr}, \mathrm{Ba}$ do not decrease monotonously along the series $\mathrm{X}=\mathrm{Li}, \mathrm{BeH}, \mathrm{BH}_{2}, \mathrm{CH}_{3}, \mathrm{NH}_{2}, \mathrm{OH}, \mathrm{F}$ but show a minimum for $\mathrm{X}=\mathrm{CH}_{3}$ ! Natural atomic orbital population analyses indicate the larger angles with $\mathrm{O}, \mathrm{N}$, and F to be due to $\pi$-type interactions of lone pairs with empty metal d-orbitals. These $\mathrm{p}_{\mathrm{x}} \rightarrow \mathrm{d}_{\mathrm{\pi}}$ interactions tend to favor linear structures. For the diamides ( $\mathrm{X}=$ $\mathrm{NH}_{2}$ ), significant $\pi$-bonding contributions lead to a preference for $C_{2 v}$ structures with the hydrogen atoms in the $\mathrm{N}-\mathrm{M}-\mathrm{N}$ plane over $C_{s}$ or out-of-plane $C_{2 v}$ geometries. The barriers to rotation around the $\mathrm{M}-\mathrm{N}$ bonds are significant. For $\mathrm{X}=\mathrm{BH}_{2}$, $C_{s}$ and out-of-plane $C_{2 v}$ arrangements are slightly more favorable than an in-plane $C_{2 v}$ geometry. The dimethyl compounds generally exhibit almost free $\mathrm{MCH}_{3}$ rotation.

## Introduction

Inorganic chemistry textbooks usually treat the chemistry of $\mathrm{Ca}, \mathrm{Sr}$, and Ba (e.g., the bioinorganic chemistry of Ca ) as that of completely ionic systems, neglecting covalent bonding contributions or even any deviations from a rigid spherical dication model. These assumptions may well be justified in some respects. However, the bent structures of some monomeric dihalides of the heavier group 2 elements are major exceptions to the valence shell electron pair repulsion (VSEPR) model. ${ }^{1}$ This is also true for
all other common structural models for main group chemistry, ${ }^{2}$ including those based only on coulombic forces, assuming completely ionic bonding. There is continuing experimental and
