$$
\begin{aligned}
& T \Delta S(1, \text { classical })=13.3 \pm 0.4 \\
& T \Delta S(2, \text { quantum })=11.3 \pm 0.4 \\
& T \Delta S(2, \text { classical })=12.4 \pm 0.4
\end{aligned}
$$

where 1 and 2 denote peptides 1 and 2 , respectively, and $T=307.9$ K ; the quantum and classical refer to results obtained by eqs 48 and 49 , respectively. These results show a difference of $\sim 1$ $\mathrm{kcal} / \mathrm{mol}$ between the corresponding results for peptides 1 and 2. The values of $\Delta \boldsymbol{S}$ (classical) are always larger by $\sim 1 \mathrm{kcal} / \mathrm{mol}$ than the corresponding quantum mechanical values. The above results, as a whole, are $2-4 \mathrm{kcal} / \mathrm{mol}$ larger than the value of 9.4 obtained by the local states method. It should be pointed out again that our elimination of the contribution of only six frequencies for the peptides in the crystal is somewhat arbitrary since nonzero components of translation and rotation were found to exist for other frequencies as well (notice that elimination of additional frequencies would lower the values of $\Delta S$ ).

For the peptide in vacuum we have calculated the entropy for several other minimum energy conformations accessible to the molecule. The difference between the maximum and minimum values found for the quantum mechanical entropy ( $T S$, eq 48) was $1.5 \mathrm{kcal} / \mathrm{mol}$. Also, in the calculations described above of $S_{\mathrm{p}}{ }^{\mathrm{A}}$ (cell) for the peptide in the crystal, the data from both peptides were used together to obtain a single value of the entropy (Table IV). We have calculated tables similar to Tables I and IV for the peptides 1 and 2 separately. The corresponding values of $\Delta \alpha_{k}$ are obviously smaller than those based on the two peptides together, and thus the values of $T \Delta S^{\mathrm{A}}$ are up to $1 \mathrm{kcal} / \mathrm{mol}$ larger than those of Table IV, but they are still smaller than those obtained with the harmonic approximations.

## IV. Summary

The LS method is general in the sense that it is not limited to handling the entropy of harmonic or quasiharmonic conformational changes but can be applied to any chain flexibility (see ref 37). The method provides approximations for the entropy which can be systematiclly improved by increasing the correlation and discretization parameters, $b$ and $l$, respectively.

Here the LS method was applied to samples obtained from molecular dynamics simulations of cyclo-(Ala-Pro-D-Phe) ${ }_{2}$ in vacuum and in the crystal. The free energy functionals $F^{B}$ (eq 21) and $F^{\mathrm{A}}$ (eq 18) and the fluctuation $\sigma_{F}^{A}$ (eq 29) of the latter were calculated ( $F^{B}$ was only calculated for the peptide in vacuum)
and shown to satisfy certain theoretical relations, which suggests that the method is reliable. In the usual application of the LS method to a chain in vacuum, one would seek to estimate $F^{\mathrm{M}}=$ $\left(F^{\mathrm{A}}+F^{\mathrm{B}}\right) / 2$, which is expected to provide the best approximation for the correct free energy, $F$. However, this might require generating relatively large samples in order to adequately estimate $F^{\mathrm{B}}$. Also, for a peptide in solvent or in the crystal, $F^{\mathrm{B}}$ for the peptide chain is not well defined. Therefore, in such cases one can only calculate $S^{\mathrm{A}}$ (or some approximations $F^{\mathrm{A}}$ ) and the difference $\Delta S^{\mathrm{A}}\left(\Delta F^{\mathrm{A}}\right)$ between the $S^{\mathrm{A}}\left(F^{\mathrm{A}}\right)$ values of two different conformational states. An important conclusion is that in certain cases the results for $\Delta F^{\mathrm{A}}(b, l)$ and $\Delta S^{\mathrm{A}}(b, l)$ converge rapidly at small values of $b$ and $l$, which suggests that these functionals provide very good approximations for the correct $\Delta F$ and $\Delta S$, respectively. The computational advantage of using $F^{\mathrm{A}}$ and $S^{\mathrm{A}}$ rather than $F^{\text {B }}$ lies in the fact that they can be estimated efficiently from relatively small samples. Furthermore, if the ranges of the angle-angle correlations (measured by $b$ ) of two states are comparable and the corresponding values of $\Delta \alpha_{k}$ are not extremely different, the worst approximation, which ignores correlations and assumes homogeneous distribution of angles ( $b=0, l=1$ ), provides a reasonable estimate of the correct $\Delta F$ (and $\Delta S$ ). This is also important since the above approximation requires the minimal number of local states $K^{\prime}$ (i.e., the total number of angles), and therefore relatively small samples and very little computer memory are needed; thus, it can be applied efficiently to proteins of any size.

The LS method could be used (together with the appropriate energy contributions) to compare approximately the free energy of binding of various ligands to a protein, where at this stage the contribution of solvent entropy is ignored. ${ }^{3}$ However, in principle, the entropy of diffusive systems such as a fluid can also be calculated with the LS method, since it was originally developed for Ising and lattice gas models. ${ }^{31-33}$ This is planned for future work.

# Ab Initio Studies of Fundamental Cluster Rearrangement Mechanisms 

David J. Wales* and Richard G. A. Bone<br>Contribution from the University Chemical Laboratories, Lensfield Road, Cambridge CB2 1EW, UK. Received December 16, 1991

#### Abstract

Two fundamental cluster rearrangement mechanisms are investigated by ab initio calculations, namely the single diamond-square-diamond (DSD) process in $\mathrm{B}_{8} \mathrm{H}_{8}{ }^{2-}$ and the square-diamond-diamond-square (SDDS) process in $\mathrm{C}_{5} \mathrm{H}_{5}{ }^{+}$. Geometry optimizations and frequencies are compared for the SCF and second-order Moller-Plesset (MP2) approximations with basis sets ranging in size from STO-3G to double- $\zeta$ plus polarization (DZP). The results are in good agreement with expectations, especially orbital symmetry selection rules, and enable us to compare the effects of electron correlation and polarization functions upon the energy and the character of the stationary points. The topology of the potential energy surface of $\mathrm{C}_{9} \mathrm{H}_{g}{ }^{+}$is studied in detail, demonstrating that the SDDS mechanism allows all versions of the structure to be accessed.

## I. Introduction

In 1966 Lipscomb first proposed the diamond-square-diamond (DSD) process to account for rearrangements in boranes and carboranes. ${ }^{1}$ This mechanism is a cornerstone of recent theoretical

[^0]developments based upon Stone's Tensor Surface Harmonic (TSH) theory which have provided powerful general orbital symmetry selection rules for such processes. ${ }^{2-5}$ These theories

[^1]

Figure 1. Scheme showing the diamond-square-diamond (DSD) process.
have now been extended to transition-metal and nido clusters, ${ }^{3.5}$ where new skeletal rearrangement mechanisms must also be considered, such as the square-diamond-diamond-square (SDDS) process. The DSD and SDDS processes will be described in detail in the next section.

The TSH theory approach enables cluster rearrangement processes that are "forbidden" in the Woodward-Hoffmann sense ${ }^{6}$ due to orbital crossings to be identified very easily, usually by inspection. The first application of the method to closo-boranes and carboranes enabled all the existing experimental data for cage fluxionalities to be understood, ${ }^{2}$ and the subsequent applications to more exotic systems led to a number of predictions, some of which are still to be tested by experiment. For example, the SDDS mechanism is expected to be the most favorable rearrangement pathway in systems such as $\mathrm{C}_{5} \mathrm{H}_{5}{ }^{+}$. However, ab initio calculations including the effects of electron correlation and polarization basis functions have yet to be reported for either of the DSD or SDDS mechanisms. This is the principal aim of the present paper, where we characterize the archetypal symmetry-allowed DSD and SDDS rearrangements in $\mathrm{B}_{8} \mathrm{H}_{8}{ }^{2-}$ and $\mathrm{C}_{5} \mathrm{H}_{5}{ }^{+}$, respectively.

Lipscomb and co-workers have previously reported a number of studies of the effects of electron correlation and polarization functions in borohydride compounds, ${ }^{7-12}$ especially in connection with pyrolysis reaction pathways. For example, the ground-state structure of triborane, $\mathrm{B}_{3} \mathrm{H}_{9}$, which is probably an important intermediate in the pyrolysis of diborane, is very sensitive to correlation. ${ }^{12}$ The electronic contribution to the dissociation energy of diborane is also rather different at the SCF and correlated levels of theory, ${ }^{10}$ and both correlation and the inclusion of polarization basis functions change the relative stabilities of various $\mathrm{B}_{4} \mathrm{H}_{10}$ structures. ${ }^{8}$ Results for $\mathrm{B}_{2} \mathrm{H}_{4}$ and $\mathrm{BH}_{5}$ indicate that the relative effects of polarization functions and correlation corrections are additive to a good approximation. ${ }^{9}$ However, although certain high energy double DSD processes have been studied in carboranes, ${ }^{13}$ the fundamental low energy DSD and SDDS processes have not been accurately characterized before in terms of tran-sition-state calculations. Neither species has any bridging hydrogen atoms, and, of course, the rearrangements considered are nondissociative, so our results provide some interesting comparisons with the previous calculations. In particular, we anticipate that polarization functions may be especially important for $\mathrm{B}_{8} \mathrm{H}_{8}{ }^{2-}$ with a double negative charge. In the next section we review the DSD and SDDS mechanisms and explain why they are of such importance in cluster chemistry.

## II. DSD and SDDS Mechanisms

The DSD Process. In the DSD process (Figure 1) an edge common to two triangular faces of a cluster skeleton breaks and

[^2]
(a)

(b)

Figure 2. Scheme showing the square $\rightarrow$ diamond, diamond $\rightarrow$ square (SDDS) mechanism for a square-based pyramid (a) and a capped square antiprism (b).
a new edge is formed perpendicular to it. DSD rearrangements, or combinations of several concerted DSD processes, have been proposed to rationalize fluxional processes and isomerizations of boranes, carboranes, and metalloboranes. ${ }^{14,15}$ King ${ }^{16}$ used topological considerations to distinguish between inherently rigid clusters (which contain no degenerate edges) and molecules for which one or more DSD processes are geometrically possible. An edge is said to be degenerate if a DSD rearrangement in which it is broken leads back to the same cluster skeleton, where atoms of the same element are not distinguished. For example, the three equatorial edges of trigonal-bipyramidal $\mathrm{B}_{5} \mathrm{H}_{5}{ }^{2-}$ are degenerate and the others are not. For a degenerative DSD rearrangement to be geometrically possible the connectivities of the new cluster vertices must match those of the original skeleton; in the closoborane series only $\mathrm{B}_{5} \mathrm{H}_{5}{ }^{2-}, \mathrm{B}_{8} \mathrm{H}_{8}{ }^{2-}, \mathrm{B}_{9} \mathrm{H}_{9}{ }^{2-}$, and $\mathrm{B}_{11} \mathrm{H}_{11}{ }^{2-}$ satisfy these requirements. King's approach was partially successful in that all the structures he predicted to be rigid are found experimentally to be nonfluxional. However, some of the above molecules in the $\mathrm{B}_{n} \mathrm{H}_{n}{ }^{2-}$ series with topologically possible single DSD rearrangements are not fluxional on the NMR time scale. They are the ones that have $4 p+1$ vertex atoms.
Stone's TSH theory ${ }^{5,17}$ enables us to explain why the DSD process is so favorable and provides a framework for the derivation of some powerful orbital symmetry selection rules. For example, we can show that transition states for closo-boranes or carboranes with a single atom on a principal rotation axis of order $\geq 3$ generally have an orbital crossing. ${ }^{2}$ These results may be extended to show that an orbital crossing will generally result if a mirror plane through the critical face is retained throughout the process. ${ }^{3}$ If a $C_{2}$ axis is retained, however, then there is an avoided crossing and the process is "allowed". Using the above rules, and the additional criterion that multiple DSD processes are likely to be less favorable than the single DSD process, it is possible to rationalize the whole range of rearrangement rates of the closoboranes and carboranes. ${ }^{2}$ We have also discussed the application of the rules to rearrangements of transition-metal clusters and suggested some new mechanisms for these species. ${ }^{3}$ Second-order Jahn-Teller analysis supports the selection rules deduced from TSH theory. ${ }^{4}$ Previous calculations on $\mathrm{B}_{8} \mathrm{H}_{8}{ }^{2-}$ using the MNDO ${ }^{18}$

[^3]and PRDDO ${ }^{19}$ methods support the theoretical analysis and suggest that there is a bicapped trigonal prismatic transition state of $C_{w}$ symmetry. A qualitative analysis by Fuller and Kepert leads to the same conclusion. ${ }^{20}$

It is also of interest to note that numerous DSD processes, and combinations thereof, have been identified as true transition states in model inert gas and trapped ion clusters. ${ }^{21}$ In such species the cohesive forces that bind the cluster are much easier to describe, and there are no orbital symmetry "forbidden" processes. Hence, King's topological analysis may be applied directly to rationalize the relative fluxionalities of small inert gas and trapped ion clusters. This result has far-reaching implications for the dynamical behavior of such systems, especially for the theory of solid-like/liquid-like coexistence, as we have explained elsewhere. ${ }^{22}$

The SDDS Process. The presence of a single square face in an otherwise deltahedral cluster introduces the possibility of a new low energy rearrangement mechanism. Such a process may be written as a square $\rightarrow$ diamond, diamond $\rightarrow$ square or SDDS mechanism. This concerted process is illustrated for the square-based pyramid and the capped square antiprism in Figure 2; we see that there are two critical edges-one is broken and one is made. If a mirror plane which contains one of these edges and is perpendicular to the other is retained throughout, then this mechanism involves two orbital crossings. ${ }^{3}$ If the edges are parallel (Figure 2) then there are two avoided crossings and the process is orbital symmetry allowed. There is no TSH symmetry-forced crossing, since the starting and finishing molecules both have a single atom on the 4 -fold principal axis. Hence this may be a favorable process for nido clusters. For nido-boranes, however, the presence of bridging hydrogen atoms around the open face means that this mechanism is not likely to occur. It could, however, be significant in accounting for the behavior of $\mathrm{B}_{8} \mathrm{H}_{8}{ }^{2-}$ in solution ${ }^{23}$ where a fluxional bicapped trigonal prismatic geometry may be present. The SDDS mechanism is allowed by orbital symmetry for the latter species and may account for its non-rigidity.
Probably the simplest molecule for which we predict the SDDS process to be favorable is $\mathrm{C}_{5} \mathrm{H}_{5}{ }^{+}$, which is expected to exhibit a local energy minimum for the nido square-based pyramid. The latter structure and our suggested $C_{20}$ transition state (Figure 3) were considered by Stohrer and Hoffmann in a study of tricyclopentanes. ${ }^{24}$ These early semiempirical calculations suggested that the $C_{2 v}$ structure is higher in energy than the $C_{4 v}$ square-based pyramid, in line with our theoretical expectations. A subsequent study by Bouman et al. ${ }^{25}$ coupled permutation-inversion symmetry ${ }^{26}$ and group theory with CNDO calculations of energies and derivatives and concluded that the $C_{2 v}$ structure is a saddle point of index 3, i.e. not a true transition state. ${ }^{27}$ From group theoretical arguments the latter authors also concluded that even if the $C_{2 v}$ structure were a transition state, it could not lead to all possible permutational exchanges of vertices. This again contradicts the conclusions of Stohrer and Hoffmann. However, the present work shows that the $C_{2 v}$ structure is indeed a true transition state, that the SDDS mechanism for the square-based pyramid is correct, and that if this mechanism is feasible ${ }^{26}$ then the effective molecular symmetry group is the complete nuclear permutation-inversion group.

[^4]

Figure 3. Mechanism of the SDDS process in $\mathrm{C}_{5} \mathrm{H}_{5}{ }^{+}$. The transition vector corresponding to the normal mode with the imaginary frequency has been sketched for the transition state, and the square faces are highlighted. The labeling is consistent with that shown in Figure 2. The permutation-inversion symmetry operations are listed below each structure. Note that the operation (bc)* (corresponding to the operation of reflection in the plane containing atoms a, e, and d) is conserved throughout.

## III. Results and Discussion

We performed symmetry-constrained geometry optimizations in internal coordinates for both $\mathrm{B}_{8} \mathrm{H}_{8}{ }^{2-}$ and $\mathrm{C}_{5} \mathrm{H}_{5}{ }^{+}$at each level of theory using the CADPAC suite of programs. ${ }^{28}$ At the SCF level we were able to use the full point group symmetry. However, at the MP2 level we could only employ the subgroup $C_{2 v}$ for both $C_{4 v}$ square-pyramidal $\mathrm{C}_{5} \mathrm{H}_{5}{ }^{+}$and the $D_{2 d} \mathrm{~B}_{8} \mathrm{H}_{8}{ }^{2-}$ dodecadeltahedron. The magnitude of the maximum component of the Cartesian gradient was reduced to $10^{-5}$ hartree bohr ${ }^{-1}$, except in the case of $D_{2 d} \mathrm{~B}_{8} \mathrm{H}_{8}{ }^{2-}$ at the MP2/DZ level, for which the surface was found to be very flat and a tolerance of $10^{-4}$ was used. Analytic force constant matrices obtained from a lower level of theory were used to ensure rapid convergence. Three basis sets were considered: minimal STO-3G for preliminary investigations, double- $\zeta$, ${ }^{29}$ and double- $\zeta$ plus polarization (DZP) with a single set of p -functions on the hydrogen atoms (exponent 1.0 ) and a single set of d-functions on the boron and carbon atoms (exponents 0.7 and 0.8 , respectively). The DZP basis therefore comprised 105 basis functions for $\mathrm{C}_{5} \mathrm{H}_{5}{ }^{+}$and 168 for $\mathrm{B}_{8} \mathrm{H}_{8}{ }^{2-}$, the largest that could reasonably be employed with current resources.

We expect that polarization functions are likely to be very important for a good description of the $\mathrm{B}_{8} \mathrm{H}_{8}{ }^{2-}$ dianions. In addition, realization is growing that polarization functions with medium size exponents are important in a correlated calculation to account for correlation corrections from the valence electrons. The MP2 method is the least computationally expensive way of introducing the correlation energy available today. ${ }^{30}$ We are justified in using it for the present systems because at each geometry in question a single reference configuration is dominant. Hence, a method which models dynamic electron correlation is appropriate. For highly accurate calculations it is now accepted that large basis sets are required, but a practical compromise must be made because at present disc-space requirements are prohibitive for MP2 gradient and analytic force constant calculations unless there is high symmetry. Our physical interest is in surface topology, and for these 10 - and 16 -atom clusters frequencies must be calculated by analytic methods. Currently it is not practical to obtain these in calculations with more than about 120 basis functions. Hence we were not able to check the frequencies of the two $\mathrm{B}_{8} \mathrm{H}_{8}{ }^{2-}$ structures at the MP2/DZP level or $D_{2 d} \mathrm{~B}_{8} \mathrm{H}_{8}{ }^{2-}$ at the MP2/DZ level; however, the advent of fully direct algorithms in the future will help to alleviate such difficulties. For $\mathrm{B}_{8} \mathrm{H}_{8}{ }^{2-}$ at the MP2 level we hope that the surface topology will not change with the inclusion of polarization functions; the change in the barrier height will be discussed.

The energies, rearrangement barriers, and Hessian indices of the four geometries, two for each of the $\mathrm{B}_{8} \mathrm{H}_{8}{ }^{2-}$ and $\mathrm{C}_{5} \mathrm{H}_{5}{ }^{+}$, are

reported in Table I. The zero-point-energy corrections to the barriers neglect all imaginary frequencies. The MP2 contributions to the energies and barriers are given in Table II, all the frequencies are collected for $\mathrm{B}_{8} \mathrm{H}_{8}{ }^{2-}$ in Table III and for $\mathrm{C}_{5} \mathrm{H}_{5}{ }^{+}$in Table IV, and some geometrical parameters are compared with experiment in Table V for $\mathrm{B}_{8} \mathrm{H}_{8}{ }^{2-}$. For both molecules the proposed structures are indeed transition states, except for $\mathrm{C}_{5} \mathrm{H}_{5}{ }^{+}$ at the MP2/DZ level, where the $C_{2 v}$ geometry has Hessian index 2, and $\mathrm{B}_{8} \mathrm{H}_{8}{ }^{2-}$ at the SCF/DZ level, where the $C_{2 v}$ structure is a minimum. The mechanisms are illustrated in Figures 3-5.

The SDDS process (Figures 3 and 4) is equivalent to the rearrangement first proposed by Stohrer and Hoffmann. ${ }^{24}$ Bouman et al. identify what appears to be the same motion as the one associated with the imaginary frequency of greatest magnitude in their calculations, but they interpret it as a Berry pseudorotation ${ }^{32}$ which involves a quite different permutation of the vertices. The pseudorotation mechanism would correspond to a transition vector of $A_{2}$ symmetry, with no component on the edge-bridging carbon atom. In fact this mode represents the motion with the smallest real frequency for the $C_{2 v}$ structure in both the MP2/DZP and MP2/DZ calculations. We conjecture that Bouman et al. have plotted the normal mode corresponding to the SDDS process in their Figure 4c. Furthermore, the softest $E$ mode of the $C_{4 v}$ minimum ranges between 342 and $546 \mathrm{~cm}^{-1}$ in frequency, and we see no evidence of the "large number of force constants near zero" reported by these authors. The normal mode associated with the other imaginary frequency for MP2/DZ $\mathrm{C}_{2 v} \mathrm{C}_{5} \mathrm{H}_{5}{ }^{+}$is sketched in Figure 6. It is significant that it does not correspond to either a pseudorotation or a "direct collapse" mechanism. ${ }^{25}$

It is clear from Table I that at both the SCF and MP2 levels of theory the effect of the polarization functions is to nearly double the barrier for the DSD process in $\mathrm{B}_{8} \mathrm{H}_{8}{ }^{2-}$; this is also true when the zero-point correction is included. For the SDDS mechanism in $\mathrm{C}_{5} \mathrm{H}_{5}{ }^{+}$the effect is not as dramatic, but it is nevertheless apparent. The STO-3G results are inconsistent with this trend, presumably due to the inadequacies of this minimal basis. The MP2 corrections in $\mathrm{B}_{8} \mathrm{H}_{8}{ }^{2-}$ show that polarization functions have a similar influence when electron correlation is included, whereas the contribution to the barrier in $\mathrm{C}_{5} \mathrm{H}_{5}{ }^{+}$is insignificant. This presumably reflects the importance of polarization functions for the anionic species.

The effect of the polarization functions upon the surface topology is a little disturbing. The $\mathrm{B}_{8} \mathrm{H}_{8}{ }^{2-} D_{2 d}$ structure is a min-

[^6]

Figure 4. An alternative representation of the SDDS process in $\mathrm{C}_{5} \mathrm{H}_{5}{ }^{+}$. The transition state is in the center, and the transition vector from the MP2/DZP calculations is plotted on the right. The geometries above and below the transition state were generated by adding (bottom) and subtracting (top) a suitable multiple of the transition vector to the transi-tion-state geometry. ${ }^{31}$
imum at each level of theory, but the $C_{2 v}$ structure is actually a minimum at the SCF DZ level. This is reversed again at the SCF/DZP level. Table V shows that the SCF/DZ geometry is significantly different from all the other levels of theory, although the ratio of the boron distances from the center of mass is actually closest to that reported experimentally.

For $\mathrm{C}_{5} \mathrm{H}_{5}{ }^{+}$the $\mathrm{C}_{2 v}$ structure is a transition state at every level of theory except MP2/DZ, where its Hessian index is 2, i.e. there are two negative Hessian eigenvalues in addition to the six zeros. Although the second imaginary frequency is small in magnitude, it cannot be ignored, and it may be regarded as an artefact of a substantially incomplete basis. There is probably a second type of minimum at this level of theory.

The effect of electron correlation is greater for $\mathrm{B}_{8} \mathrm{H}_{8}{ }^{2-}$ than for $\mathrm{C}_{5} \mathrm{H}_{5}{ }^{+}$. For any given basis set the barrier to the DSD or SDDS process is approximately doubled in the former and increases only some $20-30 \%$ for the latter. The effect on the surface topology, however, is less dramatic than the effect of the polarization functions, so we can be fairly certain that dynamic correlation plays a less important role in an accurate description of these systems. Certainly the $\mathrm{B}_{8} \mathrm{H}_{8}{ }^{2-}$ potential energy surface remains flatter in the region of the stationary points than that of $\mathrm{C}_{5} \mathrm{H}_{5}{ }^{+}$ at both the SCF and MP2 levels, and the curvature increases when electron correlation is included in both cases. This is in line with the associated increase in the barrier heights. Finally, we note that the correlation energy itself increases by some 40-50\% from the DZ to the DZP level in each system.

## IV. Group Theory

In this section we briefly analyze the permutational symmetry of the SDDS mechanism. (The implications of the DSD mechanism for $\mathrm{B}_{8} \mathrm{H}_{8}{ }^{2-}$ have been largely worked out before. ${ }^{33}$ ) We shall use a terminology recently described elsewhere ${ }^{34}$ in which

a structure specifies a particular geometry and has a number of versions distinguished from one another by the arrangement of atom labels. The correct symmetry group to use to describe isomerization reactions is the Molecular Symmetry (MS) group of Longuet-Higgins ${ }^{26}$ and Bunker. ${ }^{35}$ Boumann et al. were probably the first to use this group outside the field of spectroscopy,

[^7]but, as we will explain, they have arrived at some incorrect conclusions concerning this reaction. The issue is to determine whether all the versions of the square-based pyramid may be accessed through the SDDS mechanism, and to demonstrate that the $C_{2 v}$ transition state is consistent with a group theoretical description of this rearrangement.

Bouman et al. state that the Stohrer-Hoffmann (SDDS) mechanism cannot lead to all five carbon atoms becoming equivalent. Again this contradicts Stohrer and Hoffmann, ${ }^{24}$ who claim to have produced a complete, closed reaction graph for the 30 versions of the $C_{4 c}$ square-based pyramid. Here again we find in favor of Stohrer and Hoffmann's original conclusions. The problem arises because Bouman et al. classify the SDDS mechanism as a permutation corresponding to (aed) in our Figure 2. This permutation belongs to the class $\left(1^{2}, 3\right)$ in $£_{5}$, the permutation group of five objects. Because the character of operations in the class $\left(1^{2}, 3\right)$ for the totally antisymmetric irreducible representation of this group is not minus one, they conclude that this mechanism could not lead to all five vertices becoming equivalent. The error in this analysis comes from the choice of the permutation (aed) to represent the SDDS mechanism. As we have explained elsewhere, ${ }^{34}$ this choice involves ambiguity because one may combine the (aed) permutation with symmetry operations of the squarebased pyramid such as (abec) (Figure 2). In fact, ${ }^{34}$ the correct generating operation must be self-inverse so that it is a symmetry operation of the transition state. Consequently the operation can contain no permutations of cycle 3 or more, but it may contain the inversion of all particle coordinates, $E^{*}$. As we can see from Figure 3, which shows the same versions as Figure 2, in this case we may choose either (de)* or (de)(bc). The transition vector at the transition state is, of course, antisymmetric with respect to these two operations, corresponding to motions that interchange reactants and products, as required by the McIver-Stanton rules. ${ }^{36}$

We have verified that the reaction graph for the 30 versions of the $C_{40}$ structure is indeed closed for this mechanism. This means that if the SDDS mechanism is feasible ${ }^{26}$ then the effective molecular symmetry group is the complete nuclear permuta-

${ }^{a}$ Degenerate pairs in boldface.
tion-inversion (CNPI) group. To prove this concisely we need only give the sequence of operations that results in pairwise exchange of two equatorial atoms and an equatorial atom with the axial atom for the square-based pyramid. The motion between two adjacent versions on the reaction graph interchanges the apical atom with one at the base; exchange of two neighboring basal atoms may be achieved in three steps, e.g. $(\mathrm{bd})=(\mathrm{ec})^{*}(\mathrm{ca})^{*}(\mathrm{ae})^{*}$, where ( ae$)^{*}$ is the first operation and (ec)* is the last and our labels are for the "reactant" square-based pyramid in Figure 2. The exchange of an atom in the equator with that at the apex may be achieved in four steps, e.g. $(\mathrm{ae})=(\mathrm{ac})^{*}(\mathrm{~cd})^{*}(\mathrm{db})^{*}(\mathrm{be})^{*}$. We also agree with Stohrer and Hoffmann that five steps are needed to interconvert enantiomers, which are those versions related by the $E^{*}$ inversion operation. ${ }^{34}$ Clearly, when using generators of the type (de)*, an odd number of steps are required to leave us with an overall inversion; enantiomers are in fact related by the interchange of opposite equatorial vertices. This class of generator cannot effect such a swap in three steps; however, the sequence $(\mathrm{bc})=(\mathrm{ec})^{*}(\mathrm{ca})^{*}(\mathrm{ab})^{*}(\mathrm{bd})^{*}(\mathrm{de})^{*}$ does the trick.

It has also been shown ${ }^{34}$ that the collection of operations comprising an MS group relates not only the versions of the equilibrium structure to one another but also those of any structure on the paths which connect them. Consequently if the order of the point group of any structure is $h$, and there are $n$ distinct versions of that structure (connected by surmountable barriers), then the order of the MS group is $n h$. The order of the point group

Figure 7. Geometrical interpretation of the tunnelling states for the rearrangement of $C_{4 v} \mathrm{C}_{5} \mathrm{H}_{5}{ }^{+}$by the SDDS mechanism. ${ }^{31}$ Top: Two views of the icosidodecahedron superimposed on an icosahedron, of which it is the edge dual. The black vertices represent distinct versions of the square-based pyramid, but the edges between them do NOT represent the transition states. Bottom: Two views of the truncated icosahedron superimposed on an icosahedron. Here, the black vertices represent distinct versions of the $C_{2 v}$ transition state. The edges are not physically meaningful in this context.
$C_{4 v}$ is 8 and that of $C_{2 v}$ is 4 , so there must be $(8 \times 30) / 4=60$ versions of the transition state involved. This is consistent with Stohrer and Hoffmann's discussion ${ }^{24}$ and also the reaction graph we have derived.

Following the methods outlined by Bunker ${ }^{35}$ we may correlate the ground vibrational state in one version of the minimum with the levels of the wave functions spanned by the 30 minima. We label the irreducible representations of the CNPI group $\mathcal{\delta}_{5}{ }^{*}=$ $\left(E, E^{*}\right) \otimes \mathcal{S}_{5}$ as $\Gamma_{1-7}$ according to those of $\delta_{5}$ following Hamermesh, ${ }^{37}$ with an additional superscript $\pm$ to denote the parity under $E^{*}$. Using "upward-correlation" ${ }^{38}$ we obtain the symmetries of the levels. The wave functions spanning the 30 minima may be found directly by diagonalizing the adjacency matrix of the reaction graph. ${ }^{39}$ If $x$ is the value of the matrix element which couples two versions of the square-based pyramid that are connected by a single step (and the other elements are assumed to be zero), we find the following states and energies (with degeneracies in parentheses):

$$
\begin{array}{ccccccc}
\Gamma_{1}^{+}(1) & \Gamma_{4}^{-}(4) & \Gamma_{5}^{+}(5) & \Gamma_{6}{ }^{-}(5) & \Gamma_{3}^{+}(4) & \Gamma_{6}^{+}(5) & \Gamma_{7}^{-}(6) \\
4 x & 3 x & 2 x & 0 & -x & -2 x & -2 x
\end{array}
$$

In fact, it is not possible to determine which of the five-degenerate irreducible representations at energies of $-2 x$ and $2 x$ is $\Gamma_{5}$ and which is $\Gamma_{6}$. The accidental degeneracy observed at $-2 x$ is typical of highly symmetrical simpel "Hückel" problems. The eigenvalue of $4 x$ simply reflects the connectivity of the reaction graph ${ }^{5}$-it corresponds to the totally in-phase linear combination.

The structure of the CNPI group $\delta_{5}{ }^{*}$ contains a hidden symmetry which may be used to provide a geometrical interpretation of the potential surface. First we note that the alternating group of order $5, \mathcal{A}_{5}$, is a subgroup of $\delta_{5}$ and is isomorphic to the point group $I$. Similarly, $I_{h}$ is isomorphic to $\mathcal{A}_{5}{ }^{*}=\left(E, E^{*}\right) \otimes \mathcal{A}_{5}$ which is a subgroup of $\mathscr{\delta}_{5}{ }^{*}$, where the $g / u$ parity in $I_{h}$ correlates with the parity under $E^{*}$ in $\mathcal{A}_{5}{ }^{*}$ and $\AA_{5}{ }^{*}$. This means that the tunnelling states of the minima span a 30 -dimensional representation of $I_{h}$, and the tunnelling states of the transition states span a

60-dimensional representation. In fact, the above representations are simply those spanned by the 30 and 60 orbits of $I_{h}$ which correspond to the vertices of an icosidodecahedron and of a truncated icosahedron, respectively. (An orbit of a point group is a complete set of symmetry equivalent points. ${ }^{40}$ ) These structures are shown in Figure 7; the icosidodecahedron is the face dual of the icosahedron and of the dodecahedron-the truncated icosahedron has recently become ubiquitous in the chemical literature. ${ }^{41}$ The two representations are easily formed and reduced:

$$
\begin{array}{r}
\Gamma_{30} \cong A_{g} \oplus G_{g} \oplus G_{u} \oplus 2 H_{g} \oplus H_{u} \oplus T_{1 u} \oplus T_{2 u} \\
\Gamma_{60} \cong A_{g} \oplus T_{1 g} \oplus T_{2 g} \oplus 2 G_{g} \oplus 3 H_{g} \oplus 2 T_{1 u} \oplus 2 T_{2 u} \oplus \\
2 G_{u} \oplus 2 H_{u}(1
\end{array}
$$

Descent-in-symmetry from $\delta_{5}{ }^{*}$ now enables us to deduce the tunnelling energy levels. We gave the result for $\Gamma_{30}$ above (note that $T_{1 u} \oplus T_{2 u}$ correlates with the 6 -fold degenerate irreducible representation $\Gamma_{7}^{-}$); for $\Gamma_{60}$ we obtain

$$
\begin{align*}
\Gamma_{60} \cong \Gamma_{1}^{+}(1) \oplus \Gamma_{7}^{+}(6) \oplus & 2 \Gamma_{3 / 4}{ }^{+}(4) \oplus 3 \Gamma_{5 / 6}{ }^{+}(5) \oplus \\
& 2 \Gamma_{7}^{-}(6) \oplus 2 \Gamma_{3 / 4}(4) \oplus 2 \Gamma_{5 / 6}^{-}(5) \tag{2}
\end{align*}
$$

We have labeled these $\delta_{5} *$ irreducible representations as before; however, the parity under an operation in the class ( $2,1^{3}$ ), such

[^9]as (ab), is not known because we have used descent-in-symmetry rather than Watson's "upwards correlation". Hence we cannot distinguish between e.g. $\Gamma_{3}$ and $\Gamma_{4}$ both of which are 4 -fold degenerate, without further calculation. However, the descent-insymmetry approach is much faster and gives the correct pattern of degeneracies.

Therefore, although it is tempting to identify the 60 edges of the icosidodecahedron (Figure 7) with the 60 transition states, the connectivity of the reaction graph is actually much more complicated than this. Although both the minima and transition states may be represented separately as orbits of $I_{h}$, it is not possible to represent them simultaneously in this way. The complexity is apparent if we consider the 60 transition states, each of which must be linked to 6 others by 2 distinct minima. If the edges of the icosidodecahedron really reflected the connectivity of the reaction graph then we would be able to construct an approximate level diagram merely by node-counting ${ }^{5}$ for the appropriate spherical harmonics with $L=0,1,2$, etc. By descent-in-symmetry $L=0$ corresponds to the $A_{g}$ state in $I_{h}$ with no nodes, $L=1$ corresponds to $T_{1 u}$ with one nodal plane, $L=2$ corresponds to $H_{g}$ with two nodes, and so forth. However, the $T_{1 u}$ states actually lie at the opposite end of the spectrum from the $A_{g}$, indicating that the connectivity is much more complicated than this. The complete graph is available on request from the authors.

## V. Conclusions

We have characterized the DSD mechanism for $\mathrm{B}_{8} \mathrm{H}_{8}{ }^{2-}$ and the SDDS mechanism for $\mathrm{C}_{5} \mathrm{H}_{5}{ }^{+}$by ab initio calculations including polarization functions and correlation energy corrections at the MP2 level. In both cases we are able to confirm that the expected structures are indeed true transition states at most levels of theory, including the highest. Although the topologies of the potential energy surfaces are relatively insensitive to the basis set and electron correlation, the rearrangement barriers may change by up to a factor of 2 . We have also deduced the effective molecular symmetry group for $\mathrm{C}_{5} \mathrm{H}_{5}{ }^{+}$when the SDDS mechanism is feasible. We conclude that this group is in fact the complete nuclear permutation-inversion (CNPI) group, in agreement with the original analysis of Stohrer and Hoffmann.
We also note that for both mechanisms studied in this paper the motion can be thought of as an initial perturbation along one component of a doubly degenerate vibrational mode. This leads to the required lowering of symmetry and also allows the connectivity of the reaction graph to be four at each minimum. If
the mode in question were nondegenerate then it would have to transform into plus or minus itself under any point group symmetry operation. Hence there could not be more than two versions of the transition state connected to any given minimum.

# Theoretical Studies of Spin-Forbidden Radiationless Decay in Polyatomic Systems: Insights from Recently Developed Computational Methods 

David R. Yarkony<br>Contribution from the Department of Chemistry, The Johns Hopkins University, Baltimore, Maryland 21218. Received January 2, 1992

#### Abstract

We consider spin-forbidden radiationless decay of a bound electronic state which is metastable owing to a crossing with a dissociative potential energy surface of different spin-multiplicity. The minimum energy point on the spin-allowed surface of intersection of the bound and dissociative potential energy surfaces (the minimum energy crossing point) represents a key bottleneck along the minimum energy dissociation path, and frequently represents the transition state for this process. Thus the characterization of the minimum energy crossing point yields valuable mechanistic insights into this class of reactions, providing information concerning the feasibility of radiationless decay and the likely decomposition products. Traditional approaches for determining this point using multireference CI wave functions are computationally costly. However, a recently introduced algorithm, which uses analytic energy gradients and determines this point directly, that is without prior characterization of the surface of intersection, has reduced considerably the requisite computational effort. This algorithm is used to consider postulated spin-forbidden radiationless decay channels in tetrahedral $\mathrm{N}_{4}, \mathrm{~N}_{4}\left({ }^{1} \mathrm{~A}_{1}\right) \rightarrow \mathrm{N}_{4}\left({ }^{3} \mathrm{~A}^{\prime \prime}\right) \rightarrow \mathrm{N}_{2}\left(\mathrm{X}^{1} \Sigma_{\mathrm{g}}{ }^{+}\right)+\mathrm{N}_{2}\left(\mathrm{~A}^{3} \Sigma_{\mathrm{u}}{ }^{-}\right)$ and in the methoxy cation, $\mathrm{CH}_{3} \mathrm{O}^{+}\left({ }^{3} \mathrm{~A}_{2}\right) \rightarrow \mathrm{CH}_{3} \mathrm{O}^{+}\left({ }^{1} \mathrm{~A}^{\prime}\right) \rightarrow \mathrm{HCO}^{+}\left(\mathrm{X}^{2} \Sigma^{+}\right)+\mathrm{H}_{2}\left(\mathrm{X}^{1} \Sigma_{8}{ }^{+}\right)$. For the methoxy cation it is shown, using CI expansions as large as 2.5 million configuration state functions, that $\Delta E=15.4 \mathrm{kcal} / \mathrm{mol}$, where $\Delta E$ is defined as the difference between the energy at minimum energy crossing structure and the energy at the minimum on the bound state potential energy surface. Thus the indicated reaction provides a low energy decomposition pathway. For tetrahedral $\mathrm{N}_{4}, \Delta E$ for the indicated process is $28.2 \mathrm{kcal} / \mathrm{mol}$ which is half the barrier for the spin-allowed decay channel.

## I. Introduction

In this work we consider systems in which the vibrational levels of a bound potential energy surface are rendered metastable by the spin-orbit induced coupling to a dissociative state of different spin-multiplicity. In a phenomenological sense, this process, spin-forbidden predissociation or spin-forbidden radiationless decay, is well understood. However, the computational treatment of this problem in polyatomic systems is particularly challenging. The first task is to establish the dissociation pathway (or pathways) which is (are) energetically accessible to the quasibound molecule. The minimum energy point on the spin-allowed surface of intersection of the two surfaces in question, the minimum energy crossing point, represents a key bottleneck along the minimum energy path ${ }^{1}$ and is frequently the transition state for this pathway. Thus the determination of this point (i) provides the barrier for the decomposition pathway, or at least a lower bound if the true transition state lies elsewhere on the bound state surface, and (ii) can, particularly for a late or product channel minimum energy crossing point, establish the products of the radiationless decay process. Clearly then, the determination of this point provides essential information concerning the mechanism and feasibility of spin-forbidden radiationless decay and is a logical starting point for any treatment of this process.

The straightforward procedure that has been used in the past to locate the minimum energy point, ${ }^{2}$ the indirect determination

[^10]of this point, initially determines the crossing surface and then characterizes its minimum. This procedure is computationally costly since for a system with $N$ internal degrees of freedom a crossing surface, or seam, of dimension $N-1$ must be determined and analyzed. Thus the determination of this point represents a computational bottleneck in the study of this class of processes. However, this bottleneck can be avoided. Fletcher ${ }^{3}$ has shown that the minimum energy crossing point can be determined by a Lagrange multiplier constrained minimization procedure which determines this point directly, that is, without prior determination of the crossing surface itself. Implementations of this algorithm have been reported initially by Koga and Morokuma ${ }^{4}$ based on SCF wave functions and more recently by the present author ${ }^{5}$ using MCSCF/CI wave functions.

This work focuses on the use of this methodology to determine the feasibility of proposed spin-forbidden radiationless decay processes. This is the essential first step in a quantitative characterization of a predissociation or radiationless decay rate. The complete description, which is beyond the scope of the present work, requires (i) a more complete knowledge of the relevant potential energy surfaces, (ii) the spin-orbit induced coupling between these potential energy surfaces, and (iii) the solution of
