#### Abstract

A b\) initio quantum mechanical methods, as well as molecular mechanics (MM2 and MM3) and semiempirical theoretical methods (AM1), have been used to predict the molecular structures and energetics of the plausible isomers of [10]annulene. Standard double- $\zeta$ (DZ) and double- $\zeta$ plus polarization (DZP) basis sets have been used for the $a b$ initio self-consistent-field (SCF) studies. Full geometry optimizations have been carried out by these different methods. The harmonic vibrational frequencies and their infrared intensities are also predicted for all these isomers. The most likely observable isomers are the two structures with $C_{2}$ symmetry, one of which could be called naphthalene-like and the other twisted. Isomers with $C_{s}$ (including a low-lying boat-like structure) and $C_{1}$ (including a low-lying azulene-like structure) symmetries are also discussed. The aromatic character for the planar isomers, which are not local minima, has been studied using second-order perturbation theory. A random conformational searching procedure based on the MM3 method was also carried out to avoid losing any possible energetically low-lying conformations. The latter procedure uncovered one low-lying structure that had never been suggested previously. A comparison with the experimental conclusions of Masamune and co-workers is made.

## Introduction

Since the structure of benzene (or [6] annulene) was determined in 1865, aromatic compounds have been a very important part of organic chemistry. And so the attempt to find other cyclic, conjugated polyenes has become a popular subject. Disappointing to many, the properties of the next closed-shell candidate, cyclooctatetraene ([8]annulene)-which was prepared in 1911-are quite different from those of aromatic compounds. After Huckel's $4 n+2$ rule had been put forward in 1932, [10]annulene was expected to be the next homolog of benzene. However, the latter was not synthesized until 8 years after [18]annulene was reported by Sondheimer ${ }^{1}$ in 1959. The transient existence of cyclodecapentaene ( $[10]$ annulene) was first reported by van Tamelen and Burkoth in 1967. ${ }^{2}$ In 1969, Masamune and co-workers ${ }^{3-5}$ reported that they isolated two isomers of [10]annulenes in crystalline form, and they qualitatively assigned the geometries of these structures on the basis of the NMR and UV spectra. They concluded that the [10]annulenes are not planar in structure, and accordingly have no aromatic character.

In the 1970s several empirical and semiempirical theoretical studies on [10]annulenes were published. ${ }^{6.7}$ The first systematic ab initio study on plausible structures of [10]annulenes was made by Farnell, Kao, Radom, and Schaefer ${ }^{8}$ in 1981. They optimized (but kept all C-H bond lengths fixed at $1.09 \AA$ ) six structurse of isomeric [10]annulenes at the STO-2G and STO-3G SCF levels of theory and predicted the relative stabilities of these isomers. However, with a decade's hindsight, the minimum basis sets may be seen to be inadequate, and so full geometry optimizations at a higher level of theory are certainly in order.

[^0]Moreover, the vibrational character of the lower symmetry $\mathrm{C}_{10} \mathrm{H}_{10}$ stationary points has never been established. Although Haddon and Raghavachari carried out much improved ab initio calculations with split valence basis sets, ${ }^{9.10}$ their work was limited to the planar structures, which we will demonstrate are not local minima on the potential surface. The present paper will study both the planar structures of [10]annulene with their aromatic purported character and the other energetically lower-lying structures which might be observable in the laboratory.

## Theoretical Approach

In this research, full geometry optimizations and harmonic vibrational frequency analyses were carried out by the self-consistent-field (SCF) method in conjunction with two basis sets for eight possible isomers of [10]annulenes. The first basis was the double- $\zeta$ (DZ) set of Huzinaga ${ }^{11}$ and Dunning, ${ }^{12}$ which may be designated as $\mathrm{C}(9 \mathrm{~s} 5 \mathrm{p} / 4 \mathrm{~s} 2 \mathrm{p})$ and $\mathrm{H}(4 \mathrm{~s} /$ 2s). The second basis was the DZ set appended with pure angular momentum (i.e., five functions for the d shell) polarization functions (DZP) with $\alpha_{d}(C)=0.75$ and $\alpha_{p}(H)=0.75$. Single-point energies were also evaluated by using second-order Moller-Plesset perturbation theory (MP2) to study the effects of electron correlation. The ab initio research reported here was carried out by using the programs TURBOMOLE (the direct SCF approach of Ahlrichs and co-workers ${ }^{13}$ ), PSI, developed in our research group, ${ }^{14}$ and Gaussian $92 .{ }^{15}$

In addition, two kinds of empirical molecular mechanics ${ }^{16}$ (MM2 and MM3) methods and one semiempirical (AM1 ${ }^{17}$ ) method were employed

## Results and Discussion

Planar Structures. The planar all-cis structures 1 ( $D_{10 h}$ ) and $2\left(D_{s h}\right)$ have drawn the most attention from previous theoretical researchers. ${ }^{9,10}$ While benzene is the first stable aromatic species ( $n=1$ from Huckel's $4 n+2$ rule), the planar [10]annulene should be the next one ( $n=2$ ). The optimized geometrical parameters of structures $\mathbf{1}$ and $\mathbf{2}$ at various levels of theory are shown in Charts 1 and 2, while their vibrational frequencies are given in Tables A and B (supplementary material), and energies in Table 4. Due to the $D_{10 h}$ symmetry constraint, the ring structure of 1 has identical $C-C$ bond lengths. The theoretical results are qualitively in agreement among the different methods, and are encouragingly close to those of benzene. Electron correlation effects increase the C-C bond length from 1.400 (DZ SCF) to $1.430 \AA$ ( DZ MP2), the latter value being artificially long due to the incompleteness of the DZ basis set. The addition of polarization functions has little effect on the ab initio SCF structures. However, polarization functions make a significant change for the MP2 structure, decreasing the $\mathrm{C}-\mathrm{C}$ bond length to $1.411 \AA$ (DZP MP2). The empirical MM2 and MM3 results

[^1]( 1.396 and $1.389 \AA$ ) are basically in agreement with the $a b$ initio predictions, while the AM1 C-C bond length ( $1.377 \AA$ ) is slightly shorter. The stationary point geometry for structure $2\left(D_{5 h}\right)$ has alternating single $\mathrm{C}-\mathrm{C}$ and double bonds at the SCF level of theory, although the extent of bond alternation is much less than one might expect from standard single and double bond distances $(1.35,1.54 \AA)$. These bond lengths are close to those in cyclobutadiene and cyclooctatetraene. Similar to the results of ref 9 , our work shows that the SCF treatment favors the bond alternating structure 2, but the energy difference between 1 and 2 is very small ( $<1 \mathrm{kcal} / \mathrm{mol}$; see Table 4). Using the empirical and semiempirical methods, the $D_{5 h}$ structure also has a slightly lower energy than the $D_{10 h}$. Accordingly, structure $1\left(D_{10 h}\right)$-in addition to the degenerate imaginary frequency related to the ring puckering modes for structure 2 ( $D_{5 h}$ )-has one more imaginary vibrational frequency related to the $\mathrm{C}-\mathrm{C}$ stretch mode. Rather surprisingly, the $C-C$ stretching fundamental of $b_{2 u}$ symmetry for the $D_{10 h}$ structure ( $1953 \mathrm{~cm}^{-1}$ ) is not predicted to be imaginary with the MM3 method, while its total energy is still higher than that of the $D_{5 h}$ structure. Since the energy differences between 1 and 2 are very small-i.e., only 2.18 (MM2), 1.18 (MM3), 0.67 (AM1), 0.02 (DZ SCF), and 0.66 (DZP SCF) $\mathrm{kcal} / \mathrm{mol}$, respectively-it is possible that the order of energy might be reversed at higher levels of theory.
As a matter of fact, the MP2 single point energies at the DZ and DZP SCF stationary point geometries for the $D_{10 n}$ structure are lower than those of the $D_{5 h}$ structure ( $0.89 \mathrm{kcal} / \mathrm{mol}$ with the DZ basis set, and $6.89 \mathrm{kcal} / \mathrm{mol}$ with the DZP basis set). When we optimize the geometries at the DZ MP2 and DZP MP2 levels, the $D_{5 h}$ structure is no longer a stationary point; it collapses to the same $D_{10 h}$ structure with longer C-C ( $1.430 \AA$ ) and C-H ( $1.101 \AA$ ) bond lengths. If the MP2 results are correct, then the MM2, MM3, AM1, and SCF methods all inproperly characterize this $D_{5 h}$ feature of the $\mathrm{C}_{10} \mathrm{H}_{10}$ potential energy hypersurface. This is consistent with the statement made in refs 7 and 10 that SCF and semiempirical methods prefer the localized $\pi$ bonding structure, while electron correlation favors the delocalized one. Unfortunately, although these two planar structures are favorable for $\pi$ electron occupation (predicted aromatic by Huckel's $4 n+$ 2 rule), their $\sigma$ skeletons exhibit such severe angle strain that the ring structures tend to twist or pucker. That is whay our theoretical study gives two imaginary vibrational frequencies (see Tables A and B in the supplementary material) and quite high relative energies (see Table 4). Therefore, these very high symmetry structures will not be observable in the laboratory.

We emphasize that in going from the DZ to the DZP basis set, the $D_{10 h} \mathrm{C}-\mathrm{C}$ bond distance at the MP2 level decreases from an unreasonably long $1.430 \AA$ to $1.411 \AA$. Thus the predicted carboncarbon distances for other [10]annulene DZ MP2 structures should reasonably be reduced by $\sim 0.02 \AA$ if comparison with experimental structures becomes possible in the future.
$C_{2}$ Symmetry Structures. Following the previous lower-level theoretical results of ref 8, we have obtained two energetically favorable structures with $C_{2}$ symmetry ( 4 and 5 ). Structure 4 (TCCCC) may be called twisted or propeller-shaped and structure 5 (TCTCC) naphthalene-like. Charts 4 and 5 show that both optimized geometries, with all methods we used, exhibit alternating single and double bonds. An inset to structure 5 demonstrates that the naphthalene-like structure is also chair-like. The geometrical parameters optimized at different theoretical levels are in reasonable agreement. Since correlation effects would probably favor the delocalized $\pi$ bonding structure, ${ }^{6.7}$ as in the comparison between structures 1 and 2 , the alternating $\mathrm{C}-\mathrm{C}$ single and double bonds in structures 4 and 5 should more closely approach parity when correlation is properly taken into account. However, such an effect should not be as strong as for the planar structures, so this remains a question to be resolved by further study with high-level theoretical treatments. The probable

Chart 4

unimportance of such higher order effects is indicated by the fact that the MM2 and MM3 methods predict longer C-C double bonds and shorter single bonds than those predicted by ab initio methods. Table 4 shows that structures $\mathbf{4}$ and $\mathbf{5}$ have lower energy than the other $\mathrm{C}_{10} \mathrm{H}_{10}$ structures, with a very small difference between the two.

To consider the point raised in the previous paragraph, structures 4 and 5 were reoptimized at the DZ MP2 level of theory. As speculated above, there is some decrease in the extent of bond alternation. As expected, all $\mathrm{C}-\mathrm{C}$ bond distances increase in going from DZ SCF to DZ MP2. However the $\mathrm{C}=\mathrm{C}$ double bond distances increase by about $0.040 \AA$, while the $C-C$ single bond distances increase by about $0.015 \AA$. Thus the extent of bond alternation is decreased by about $0.025 \AA$. Nevertheless, the extent of bond distance alternation remains substantial, in the range $0.11-0.14 \AA$.

## Chart 5

Empirical and semiempirical methods predict that the energy of the naphthalene-like 5 is lower than that of the twisted 4, i.e., by 3.62 (MM2), 4.82 (MM3), and 0.68 (AM1) $\mathrm{kcal} / \mathrm{mol}$, respectively. The $a b$ initio SCF results, in contrast, show that structure 4 has the lower energy. But the MP2 single-point energies significantly reduce the difference (from 2.96 to 1.94 $\mathrm{kcal} / \mathrm{mol}$ with the DZ basis set, and from 2.91 to $0.51 \mathrm{kcal} / \mathrm{mol}$ with the DZP basis set). It would not be surprising if higher levels of theory (larger basis sets and more complete descriptions of electron correlation) reverse the energetic order of these two structures. In any case, both species are likely to be observable.

The theoretical harmonic vibrational frequencies and their infrared intensities are shown in Tables 1 and 2. The assignments in these tables are based on the potential energy distributions (PED) from the SCF results. The fact that all the vibrational frequencies are real numbers indicates that both structures 4 and 5 are genuine minima. The results are in qualitive agreement among the different theoretical methods, but the MM3 and AM1 frequencies are slightly lower. It is known that DZP SCF frequencies are about $10 \%$ higher than the experimental fundamentals, while the empirical and semiempirical results (with parameters obtained by fitting to the experimental data) are generally closer in absolute value to the observed fundamentals. Since structures $\mathbf{4}$ and 5 are genuine minima with low energies, they are most likely to be observed. The twisted structure 4 has some strong infrared absorption bands (with IR intensities about $40-70 \mathrm{~km} / \mathrm{mole}$ ) around $3100 \mathrm{~cm}^{-1}$ related to $\mathrm{C}-\mathrm{H}$ stretching modes, some bands (with IR intensities about $30-60 \mathrm{~km} / \mathrm{mole}$ ) around $700-800 \mathrm{~cm}^{-1}$ related to the $\mathrm{C}-\mathrm{H}$ wagging and ring deformation modes, and also a weaker band representing a $\mathrm{C}=\mathrm{C}$ stretching mode at about $1700 \mathrm{~cm}^{-1}$ (with IR intensity 28 km / mol ). The naphthalene-like structure 5 has a very strong infrared absorption band (with IR intensity more than $100 \mathrm{~km} / \mathrm{mol}$ ) around $700-800 \mathrm{~cm}^{-1}$ related to the $\mathrm{C}-\mathrm{H}$ wagging mode, and then some intense IR bands around $3100 \mathrm{~cm}^{-1}$ corresponding to $\mathrm{C}-\mathrm{H}$ stretching modes.
$C_{s}$ Symmetry Structures. Structures 3 (CCCCC) and 6 (CTCTC) are predicted to have energies slightly higher than those of structures $\mathbf{4}$ or 5 . At the SCF level of theory the energy of the boat-like structure 3 is even lower than that of structure

5 (see Table 4), which supports the explanation of the NMR measurements. ${ }^{3,4}$ However, the MP2 method raises the boatlike structure 3 significantly above the naphthalene-like structure 5 in energy. Molecular mechanics methods and AM1 also show that structure 3 is of higher relative energy. The energy of structure 6 is even higher (MM2 failed to optimize the $C_{s}$ geometry of structure 6, diverting instead of structure 8). Both structures 3 and 6, like structures 4 and 5 , involve alternating single and double bonds. The bond lengths are basically similar to those of structures 4 or 5 at all levels of theory. Similar to structures 4 and 5, the MM2 and MM3 methods predict longer C-C double bonds and shorter single bonds than those predicted by ab initio methods. However, both structures $\mathbf{3}$ and $\mathbf{6}$ are transition states with the imaginary vibrational frequency related to the ring deformation mode (except for the AM1 method, which predicts that 6 is a minimum; see Tables $C$ and $D$ in the supplementary material). This seems contrary to the experimental reports ${ }^{3-5}$

concerning the observation of the boat-like structure 3. However, since the magnitudes of the imaginary vibrational frequencies are quite small (only $20-30 \mathrm{icm}^{-1}$ for structures 3 ; slightly larger for structures 6, but real for AM1), the imaginary frequencies might conceivably become real at higher theoretical levels. In addition, the energies of structures 3 and 6 are only about 10 $\mathrm{kcal} / \mathrm{mol}$ above those of structures 4 and 5, so we cannot absolutely exclude the possibility of their observation (especially structure 3) by experiment.

In light of the visual similarity of the boat-like structure 3 to cyclooctatetraene (COT), some comparison is in order. In fact,

## Chart 6

Chart 7
Structure 7 ( $\mathrm{D}_{5 \mathrm{~d}}$ for MM2, MM3 and DZ SCF) ( $D_{5}$ for AM1) ( $\mathrm{C}_{5 \mathrm{~V}}$ for DZP SCF)

| Dihedral Angles: |  |
| :--- | ---: |
| $\boldsymbol{\tau}_{1.9 .2 \cdot 10}$ | $\tau_{8 \cdot 1 \cdot 9.2}$ |
| $110.3^{\circ}$ | $-110.3^{\circ}$ |
| $108.9^{\circ}$ | $-108.9^{\circ}$ |
| $110.7^{\circ}$ | $-109.9^{\circ}$ |
| $109.6^{\circ}$ | $-109.6^{\circ}$ |
| $110.2^{\circ}$ | $-110.2^{\circ}$ |

the extent of bond distance alternation is quite similar. With the DZP SCF method, the COT bond distances are 1.329 and 1.481 $\AA$. For our boat-like $\mathrm{C}_{10} \mathrm{H}_{10}$ structure 3 the $\mathrm{C}=\mathrm{C}$ double bond distances (DZP SCF) are 1.325-1.335 $\AA$, while the C-C single bond distances are 1.481-1.488 $\AA$. By this criterion, [10]annulene is no more "aromatic" than cyclooctatetraene. Another appropriate comparison is with the prototypical linear polyene hexatriene. For hexatriene the DZP SCF C=C double bond distances are 1.329 and $1.334 \AA$, while the $\mathrm{C}-\mathrm{C}$ single bond distance is $1.466 \AA$. Thus the prototypical linear polyene shows somewhat less bond alternation than [10]annulene.

A Structure with a $C_{5}$ Axis of Symmetry. The optimization of structure 7 began with the $C_{5}$ structure in ref 8 (number 12 in ref 8 ). Our result showed that the final structure differs greatly

from the initial one. With all the different computational methods used in this research, this structure is crown-shaped with $\mathrm{C}-\mathrm{H}$ bonds in the axial positions. The symmetry of this structure depends strongly on the theoretical method employed (see Chart 7). Only AM1 gave the structure with alternant $\mathrm{C}-\mathrm{C}$ single and double bonds ( $D_{5}$ symmetry), while the other methods (empirical and $a b$ initio studies) gave equivalent $\mathrm{C}-\mathrm{C}$ bond structures ( $D_{5 d}$ symmetry for the MM2, MM3, and DZ SCF methods; $C_{5 v}$ for the DZP SCF method). Although all the vibrational frequencies of this interesting structure 7 (Table E in the supplementary material) are real for all theoretical methods, its energies are so high ( $\geq 47 \mathrm{kcal} / \mathrm{mol}$; see Table 4) that it is unlikely to be observed by experiment.

The MM3 Searching Method and New Structures. Finally, a stochastic conformational searching ${ }^{17}$ has been used in an attempt to locate any previously undetected conformations. This searching method of Saunders, available in MM3 ( 92 version), ${ }^{18}$ samples conformation space by randomly pushing atoms in the molecule and then minimizing the structure through the MM3 force field.

Structure 6 was used here as the starting structure. From this structure, the next structure has been created by randomly pushing all 20 atoms (moving the positions of atoms and checking the validation of the bond length) in the molecule within a certain range. Then this structure is energy optimized. If the resulting structure has not been found before, it will be considered as a new conformation. For the next iteration, the computer randomly selects the starting geometry from either the original starting geometry or the last geometry that was found.

Because all possible conformations will eventually be randomly chosen as the starting structure, the selection of the first one will not affect the total number of conformations that could be found if the total number of structure perturbations is large enough. The moments of inertia and the total energy are used as the criteria to detect a new conformation. A new structure that has different moments of inertia or different total energy from the structures that have been found previously will be treated as a new conformation. If the newly optimized structure has the same moments of inertia and the same total energy as one of the conformations previously determined, this structure will be considered as identical with the old one and discarded. In order
to eliminate transition-state structures the MM3 block-diagonal and subsequent full-matrix optimization (option 8 in the MM3 program ' 92 version) has been used to minimize the molecular structures. With this option the nonconjugated system with the same conformation can be guaranteed to have exactly the same moments of inertia and total energy. Since the valence electronic self-consistent-field (VESCF) method has been applied prior to geometry optimization and will not be repeated, unless the geometry has been improved significantly, the conjugated system with the same conformation may have slightly different moments of inertia and total energy and be considered as a different conformation. Thus, reoptimization is necessary to force MM3 to recalculate the VESCF and to group them together.

After 2000 iterations of random searching and 12-20 cycles of reoptimization for each conformation (the optimization for each of those conformations has been retained until there is no further change in the total energy), a total of 16 minima were found. Besides the three minima which had been found by $a b$ initio methods, 13 new minima were revealed to have heats of formation below the highest $\Delta H_{\mathrm{f}}{ }^{\circ}$ that was previously found (i.e. structure 7).

In order to confirm the result of the MM3 search method, we chose the new conformation with the lowest energy (the azulenelike structure 8 , which actually bears more resemblance to homoazulene, synthesizd by $\operatorname{Scott}^{20}$ in 1981) as a starting point to carry out geometry optimizations using the AM1 and SCF methods. While the result of the AM1 optimization collapsed to structure 6 (note that structure 6 is found as a minimum only by the AM1 method), the ab initio results with the DZ and DZP SCF basis sets have qualitively the same geometries as MM3 with an energy even lower than that of structure 6. The geometrical parameters of the azulene-like structure 8 are shown in Chart 8. This is a $C_{1}$ symmetry ten-membered ring with alternating single and double $\mathrm{C}-\mathrm{C}$ bonds. Its relative energy and harmonic vibrational frequencies are shown in Tables 3 and 4. The energy of 8 is $8.14 \mathrm{kcal} / \mathrm{mol}$ higher than that of the twisted structure 4 at the DZP SCF level. It is very close energetically to structure 6. An interesting result is that at the DZP SCF/ MP2 level, the relative energy of the azulene-like structure 8 is $5.25 \mathrm{kcal} / \mathrm{mol}$ lower than that of structure 6. After ZPVE correction, the relative energy of structure 8 is still $4.85 \mathrm{kcal} / \mathrm{mol}$ lower than that of structure 6 , and even $0.91 \mathrm{kcal} / \mathrm{mol}$ below that of structure 3. It is a genuine minimum with $136 \mathrm{~cm}^{-1}$ as its smallest harmonic vibrational frequency at the DZP SCF level. The discovery of the azulene-like structure 8 is an encouraging example of finding a new conformation independently via the molecular mechanics searching program. This method is, no doubt, a very helpful means for locating new minima on complicated potential energy hypersurfaces, and it is especially useful for larger molecular systems.

All of the other 12 structures located also have $C_{1}$ symmetry. Their geometrical shapes, heats of formation, and energies relative to the twisted structure 4 with the MM3 method are shown in Chart 9. Since all of them have higher energies than the azulenelike structure 8 , it is not of comparable importance to investigate them with the AMl or $a b$ initio methods.

## Concluding Remarks

(1) The planar structures ( $D_{10 h}$ and $D_{5 h}$ symmetry) of [10]annulene are the logical next candidates after benzene following Huckel's rule. They are suitable examples for studying conjugation effects and resonance energies theoretically, even though both are transition states with relatively high energies and therefore not observable. While the SCF studies show that the

${ }^{a}$ AM1: collapses to structure 6.
$D_{5 h}$ (with C-C bond length alternation) structure has a slightly lower energy than the $D_{10 h}$ (with equal bond lengths) structure, the MP2 methods favor the $D_{10 h}$ structure, which implies that conjugation effects are still favorable in planar 10 -membered ring polyenes. It is noteworthy that single-point $6-31 G^{*}$ MP2 calculations on [18]annulene also reverse the order of the structures, making the $D_{6 h}$ form the more stable. ${ }^{21}$
(2) Table 4 shows the relative energies for the structures considered with all methods. The zero-point vibrational energy correction does not change the relative energies significantly. The two structures with $C_{2}$ symmetry [structures 4 (twisted) and

${ }^{a}$ Total energies (for $a b$ initio results, in hartrees) or heats of formation (for MM2, MM3, and AM1, in kcal/mol) are given in parentheses. ${ }^{b}$ The symmetry for structure 7 varies at different levels (see text). ${ }^{〔}$ SCF/MP2 indicates the full (i.e. no frozen core) MP2 single-point energies at appropriate SCF geometries. ${ }^{d}$ Ten cores and ten counterpart virtual orbitals were frozen for the DZ MP2 optimization. ${ }^{\text {e }}$ The energy at the DZP SCF/MP2 level corrected by the zero-point vibrational energies at the DZP SCF level.

## Chart 9

structure 9 $108.0 \mathrm{kcal} / \mathrm{mol}$ ( $12.5 \mathrm{kcal} / \mathrm{mol}$ )

structure 10
$116.5 \mathrm{kcal} / \mathrm{mol}$ $(21.0 \mathrm{kcal} / \mathrm{mol})$

structure 13
$123.8 \mathrm{kcal} / \mathrm{mol}$ ( $28.4 \mathrm{kcal} / \mathrm{mol}$ )

structure 14 $124.5 \mathrm{kcal} / \mathrm{mol}$ ( $29.0 \mathrm{kcal} / \mathrm{mol}$ )

structure 15

( $30.4 \mathrm{kcal} / \mathrm{mol}$ )

structure 16
$126.8 \mathrm{kcal} / \mathrm{mol}$
( $31.3 \mathrm{kcal} / \mathrm{mol}$ )

structure 17
$133.4 \mathrm{kcal} / \mathrm{mol}$ ( $37.9 \mathrm{kcal} / \mathrm{mol}$ )

structure 18
$137.1 \mathrm{kcal} / \mathrm{mol}$ ( $41.6 \mathrm{kcal} / \mathrm{mol}$ )

structure 19 $150.7 \mathrm{kcal} / \mathrm{mol}$ ( $55.2 \mathrm{kcal} / \mathrm{mol}$ )

structure 20
$158.9 \mathrm{kcal} / \mathrm{mol}$ ( $63.5 \mathrm{kcal} / \mathrm{mol}$ )

5 (naphthalene-like)] are the genuine minima with the lowest relative energies among the stationary points. Both are $\mathrm{C}-\mathrm{C}$ bond-length alternating; the energetic order between them varies somewhat with different computational methods. They are the most likely to be observable of the [10]annulene structures. The $C_{s}$ symmetry structures appear to be transition states. This is contrary to previous experimental assignments. ${ }^{5}$ However, in light of the small values of the imaginary vibrational frequencies, and the slightly higher relative energies than structures 4 (twisted) and 5 (naphthalene-like), the possibility of observation (especially the boat-like structure 3) cannot be absolutely ruled out. An
isomer with $C_{1}$ symmetry (the azulene-like structure 8) is also a minimum with energy very close to that of boat structure 3 . The crown-shaped structure (structure 7) is another minimum on the potential hypersurface, but with significantly higher energy.
(3) In most cases, the MM3 method gives similar results for the geometries, relative energies, and vibrational frequencies. An exception is the relative energy of the $D_{10 \text { h }}$ structure 1 , which appears to be artificially high with the MM3 method. Comparing the relative energies between MM3 and ab initio methods in Table 4, it is noteworthy that for the larger basis sets the relative energy difference becomes smaller. According to MM3, the ground state of [10]annulene should be the naphthalene-like structure 5. In contrast to this, the different $a b$ initio methods all give the twisted structure 4 as the [10]annulene global minimum, but the energy difference is decreased when higher levels of theory are used.
(4) Random conformation searching via MM3 is a useful tool for finding other possible comformations in addition to those readily imagined. For [10]annulene, Saunders' MM3 searching method located several new conformations within the given energy range. Some of them (e.g. structures 8 and 9) have heats of formation not far from the [10]annulene minimum (i.e., 5 and $13 \mathrm{kcal} / \mathrm{mol}$, respectively, above the twisted structure 4).
(5) Masamune and Darby ${ }^{5}$ have assigned their two observed [10] annulene moieties to the structures we have labeled boat-like (3) and twisted (4). They designate our boat-like structure 3 as cis ${ }^{5}$-[10]annulene and our twisted structure 4 was trans-cis ${ }^{4}$ [10] annulene. The match with the present theoretical predictions is good in that the highest level $a b$ initio method predicts the twisted structure 4 to be the global minimum among [10]annulene structures. However, the agreement is less satisfactory in that theory predicts the boat-like structure 3 to be a transition state. Structure 3 is, however, predicted to be only $6.1 \mathrm{kcal} / \mathrm{mol}$ above the global minimum. Also somewhat puzzling is Masamune's suggested exclusion of our naphthalene-like chair structure 5 as one of the two observed [10]annulene structures. Masamune considered 5 to be "unlikely" due to the apparent absence of a low-energy process to make all like nuclei equivalent. We hope that the present fairly exhaustive theoretical study of [10] annulene structures will stimulate new experiments on this fascinating and important molecular system.
(6) Experimental infrared spectra of the two observed [10]annulene structures might be highly informative in light of the theoretical infrared intensities reported here. For example, the naphthalene-like structure 5 (labeled "unlikely" by Masamune) has no significant predicted IR features in the range 400-630 $\mathrm{cm}^{-1}$, while both the twisted structure 4 and the boat-like structure

3 (predicted by us to be a transition state but identified in the laboratory by Masamune) have fundamentals with substantial IR intensity in this range. Similarly, our structure 5 has features with large IR intensity at $1030(61 \mathrm{~km} / \mathrm{mol})$ and $984 \mathrm{~cm}^{-1}(27$ $\mathrm{km} / \mathrm{mol}$ ), while Masamune's structure 3 has no IR intensities above $1 \mathrm{~km} / \mathrm{mol}$ in this range. Should the homoazulene-like structure 8 prove observable, its IR spectrum would be identifiable due to the $\mathrm{C}-\mathrm{H}$ wag mode at $742 \mathrm{~cm}^{-1}$, which has the strongest IR intensity ( $114 \mathrm{~km} / \mathrm{mol}$ ). Also, there are three $\mathrm{C}-\mathrm{H}$ stretches at 3022,3013 , and $2999 \mathrm{~cm}^{-1}$ with modest IR intensities ( 38,45 , and $53 \mathrm{~km} / \mathrm{mol}$, respectively). All of the above vibrational frequencies have been reduced by $10 \%$ from the DZP SCF values to account for the limitations of the basis set, as well as for the effects of correlation and anharmonicity.

Acknowledgment. This research was supported by the U.S. Department of Energy, Office of Basic Energy Sciences, Division of Chemical Sciences Fundamental Interactions Branch, Grant No. DE-FG09-87ER 13811. Some of the computations reported here were performed using the IBM RS/6000s at the Cornell National Supercomputer Facility. Y.X. thanks Dr. Cynthia Meredith for helpful discussions.

Supplementary Material Available: Tables of harmonic vibrational frequencies and infrared intensities for $\mathbf{1 , 2 , 3}, \mathbf{6}$, and 7 ( 5 pages). This material is contained in many libraries on microfiche, immediately follows this article in the microfilm version of the journal, and can be ordered from the ACS; see any current masthead page for ordering information.
