Received October 6, 2003; E-mail: ajcoluss@caltech.edu

Abstract: Hydrogen peroxide exalts the reactivity of aqueous ozone by reasons that remain obscure. Should H₂O₂ enhance free radical production, as it is generally believed, a chain mechanism propagated by $(\cdot OH/\cdot O_2^{-})$ species would account for O₃ decomposition rates in neat H₂O, ^HR_{-O₃}, and in peroxone (O₃ + H_2O_2) solutions, $H^pR_{-O_3}$. We found, however, that: (1) the radical mechanism correctly predicts $H_{R_{-O_3}}$ but vastly overestimates $^{HP}R_{-Q_3}$, (2) solvent deuteration experiments preclude radical products from the (O_3 + HO_2^{-}) reaction. The modest kinetic isotope effect (KIE) we measure in H_2O/D_2O : ${}^{H}R_{-O_3}{}^{D}R_{-O_3} = 1.5 \pm$ 0.3, is compatible with a chain process driven by electron- and/or O-atom transfer processes. But the large KIE found in peroxone: ${}^{HP}R_{-O_3}/{}^{DP}R_{-O_3} = 19.6 \pm 4.0$, is due to an *elementary* (O₃ + HO₂⁻) reaction involving $H-O_2^-$ bond cleavage. Since the KIE for the hypothetical H-atom transfer: $O_3 + HO_2^- \xrightarrow{2b} HO_3^+$ + •O2⁻, would emerge as a KIE^{1/2} factor in the rates of the ensuing radical chain, the magnitude of the observed KIE must be associated with the hydride transfer reaction that yields a diamagnetic species: O₃ + HO₂^{- $\frac{2a}{\longrightarrow}$} HO₃⁻ + O₂. HO₃⁻/H₂O₃ may be the bactericidal trioxide recently identified in the antibodycatalyzed addition of $O_2(^1\Delta_q)$ to H_2O .

Introduction

Ozone is a powerful but selective oxidant,¹ and an efficient but fleeting bactericide.^{2,3} Raising concerns about the toxic and mutagenic byproducts of water chlorination, and the implementation of more stringent regulations, have renewed interest in the use of O_3 , alone or in conjunction with H_2O_2 .⁴⁻⁷ Hydrogen peroxide enhances and expands the reactivity of ozone, 3,8,9 which is generally sluggish and almost inert toward saturated organic species despite favorable energetics.¹ This paper addresses the mechanism of such enhancement.^{10–14}

The chemistry of aqueous O_3 has been investigated for over 85 years.^{15–17} It is well established that O₃ decay rates increase

accord between calculated and experimental O₃ decomposition rates in pure water by invoking the presence of subsaturation (under atmospheric CO₂) levels of carbonate as a OH-radical scavenger, this expedient proves to be insufficient in the presence of H₂O₂.^{14,32} It has been speculated that the significant discrepancies remaining in this case could be due to wall effects or to the presence of unspecified amounts of dissolved organic carbon, DOC.23 Here, we delve further into the fact that experimental O₃ decay rates in slightly acidic H₂O₂ solutions are much slower than predicted by radical mechanisms, and arrive at a different conclusion.

The issue revolves around the actual stoichiometries of the $(O_3 + OH^-)$ and $(O_3 + HO_2^-)$ initiation reactions, reactions 1a-c, 2a-c, respectively (Table 1). Reactions 1a and 1b are mechanistically indistinguishable radical-forming processes that generate the rapidly interconvertible $\cdot OH$ and $\cdot O_2^-$ chain carriers, respectively.³³ In contrast, reaction 1c, which produces HO₂⁻, must be followed by reaction 2b to initiate a free radical chain. This is the currently preferred initiation pathway, which subsumes the decompositions of O₃ in pure water and in the presence of H₂O₂, the peroxone mixture, into a common freeradical mechanism.^{18,27} We now report deuterium isotope effects on O₃ decomposition rates in ultrapure water and in peroxone solutions that provide compelling evidence against the formation of free radicals in the reaction between O_3 and HO_2^- . The magnitude of the observed kinetic isotope effect is consistent a hydride transfer process yielding a closed-shell trioxide HO₃⁻, the conjugate anion of H_2O_3 .³⁴⁻⁵² H_2O_3 may be related to the

recently reported bactericidal trioxide formed in the antibodycatalyzed addition of ¹O₂ to H₂O.^{49,52}

Experimental Section

Decomposition rates of aqueous O3 solutions were measured in a capped silica cuvette (4 cm³, 1 cm optical depth) by kinetic spectrophotometry at $\lambda = 260$ nm ($\epsilon_{O_3} = 3292 \text{ M}^{-1} \text{ cm}^{-1}$)⁵³ using a Hewlett-Packard 8452A diode-array spectrophotometer. Solutions were stirred with a PTFE-coated spin bar, and kept at (15 ± 0.1) °C by means of a Hewlett-Packard 89090A Peltier temperature controller. Solutions were prepared by sparging water with O₃ produced by an Osmonics V10-0 ozone generator fed with prepurified O2 gas. We used Milli-Q Plus-UV water (resistivity $\rho = 18.2 \text{ M}\Omega$ cm), or ultrapure water obtained from a Corning MegaPure system (Barnstead/Thermolyne) that involves further purification by double distillation in a fused silica still. The $1 \leq [DOC]/ppbv \leq 5$ levels present in Milli-Q water (as reported by the manufacturer) are expected to be reduced to undetectable levels by double distillation. pH readings in D₂O as solvent were converted into pD by adding 0.41, i.e., $pD = pH_{reading} + 0.41$.^{54,55} pH was adjusted using concentrated HClO₄ rather than with buffers, because most anions (other than ClO₄⁻) are able to scavenge •OH-radicals.³³ We repeatedly verified that the pH/pD of all solutions remains within 0.1 pH units of the initial value after ozone is consumed.

Hydrogen peroxide (30% w/w, EM Science), D₂O (Cambridge Isotopes), KI (Sigma), and (NH₄)₆Mo₇O₂₄ · 4H₂O (Alfa Products) were used without further purification. Borosilicate glass wool (Corning) was washed with hot 16 M HNO3 (EM Science, Tracepur Plus), rinsed with purified water and dried. Since commercial H2O2 solutions contain stabilizers, we synthesized H₂O₂ by sonication of ultrapure water contained in a sealed all-glass reactor coupled to an external 358 kHz piezoelectric transducer operated at 100 W (Allied Signal-ELAC Nautik USW) under continuous argon sparging to prevent the fixation of atmospheric N₂ as NO₃^{-.56} H_2O_2 solutions were otherwise prepared by dilution of 30% H₂O₂ in purified H₂O or D₂O, adjusted to pH 5.0 or 5.3, respectively, prior to mixing with ozone solutions, and quantified by UV-spectroscopy at $\lambda = 248$ nm ($\epsilon_{H_2O_2} = 25$ M⁻¹cm⁻¹),⁵⁷ or by iodometry using ammonium molybdate (0.02% w/w, 1.1 mM) as a catalyst.⁵⁸ Notice that $H/D < 2 \times 10^{-5}$ for the $< 1 \text{ mM H}_2O_2$ solutions in D₂O used in these experiments, and that H₂O₂ instantly exchanges H/D when dissolved in D₂O. 57

Results and Discussion

Kinetic Measurements. Ozone dissolved in pure H₂O at pH 5.0, 15 °C, decays quasi-exponentially with a pseudo-first-order rate constant: ${}^{1H}k_{-O_3} = 6.0 \times 10^{-5} \text{ s}^{-1}$ (Figure 1) [the numerical superscript designates the apparent reaction order; H(D) refer to $H_2O(D_2O)$, and HP(DP) to $H_2O_2(D_2O_2)$]. The addition of H_2O_2 markedly accelerates decomposition rates, ${}^{HP}R_{-O_3} =$

Figure 2. O₃ decay ($[O_3]_0 = 110 \ \mu$ M) in the presence of $[H_2O_2] = 56 \ \mu$ M at pH 5.0. (1) —: experimental data; (2) \bigtriangledown : calculated with the mechanism of Table 1 using reactions 1a, or 1b, or (1c + 2b) as radical initiations; (3) \triangle : calculated with the mechanism of Table 1 using reactions 1a, or 1b, plus reaction 2a. Calculations performed assuming [HCO₃⁻] = 3 μ M. See Supporting Information for the full mechanism.

^{1HP} k_{-O_3} [O₃] = ^{2HP} k_{-O_3} [O₃] [H₂O₂], with ^{2HP} k_{-O_3} = ^{1HP} $k_{-O_3}/$ [H₂O₂] = 28 M⁻¹ s⁻¹, see Figures 2 and 3. We verified that the stoichiometry of the peroxone reaction varies from $\Delta O_3/$ $\Delta H_2O_2 \approx 2.7$ to 7.1 as [O₃]/[H₂O₂] increases from 0.5 to 2.1.

Discrepancies between experimental rates and those predicted by radical chain mechanism have been variously ascribed to unspecified DOC levels,²⁷ to spurious radical scavengers, either in the water or the reagents, or to wall reactions.^{20,23,31,59–61} Unidentified impurities could alternatively accelerate or retard reaction rates. Walls were to provide for additional radical termination channels. We checked these claims by using water purified in two successive stages, and by substantially modifying the surface-to-volume ratio, S/V, in our experiments. Milli-Q water, which is produced by ion exchange and filtration followed by UV mineralization, reportedly contains $\sim 5 \ \mu \text{gC L}^{-1}$. The Milli-Q water-fed Corning double-distillation system (see above) should yield ultrapure water. O₃ degradation rates (whether in the absence or presence of H₂O₂) were, however, independent (within experimental reproducibility) of water quality. We also

Figure 3. Experimental pseudo-first-order rate constants for the decay of O_3 , ${}^{1H(D)P}k_{-O_3}$, as function of $[H_2O_2]$. (1) \bigcirc : in H_2O at pH 5.0; (2) \square : in D_2O at pH 5.3. See text.

tested whether the trace Sn amounts used as stabilizer, or the nM levels of NO₃⁻, PO₄H₂⁻, and Cl⁻ present in \sim 100 μ M H₂O₂ solutions obtained by dilution of commercial H₂O₂, had a detectable effect on reaction rates, by synthesizing H₂O₂ via sonication of ultrapure water at 358 kHz under argon (see above). O₃ degradation rates were found to be independent of the H₂O₂ source.

Previous studies reported slightly faster ozone decomposition rates at low pH in vessels having smaller S/V's. The effect was ascribed to catalysis of radical terminations by reactor walls. Heterogeneous radical terminations seem unlikely to be competitive, however, under present conditions. For a stationary radical chain initiated by reaction 2b: $R_{2b} = 2.8 \times 10^6 \text{ M}^{-1}$ s⁻¹ [HO₂⁻][O₃], terminated by reaction 18: $R_{18} \approx 1 \times 10^{10}$ $M^{-1} s^{-1} [X]^2$ (see Table 1), where X is $\cdot OH/\cdot O_2^-$, at pH 5.0, $[O_3] = 10 \ \mu M$, $[H_2O_2] = 100 \ \mu M$, with $pK_a (H_2O_2) = 11.8$, the condition $R_{2b} = R_{18}$ leads to $[X]_{ss} \approx 2 \times 10^{-10}$ M. Thus, the half-life of X toward homogeneous radical recombination is of the order of a few seconds. Assuming a diffusion coefficient: $D \approx 2 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$, the average diffusional displacement experienced by X in such time scale: $\delta = (2 D t)^{1/2} \approx 6 \times$ 10^{-3} cm, is considerably shorter than the typical dimensions of any of our reactors. Accordingly, we found identical O_3 decomposition rates in the unpacked 605 mL, $S/V = 0.66 \text{ cm}^{-1}$ reactor, in the same reactor packed with glass wool up to S/V $= 2.06 \text{ cm}^{-1}$, or in the 3 mL, S/V = 4.5 cm⁻¹ cuvette.

Model Calculations. We simulated our experimental O_3 decay profiles by numerical integration of mechanisms based on the elementary reactions assembled in Table 1 (see Supporting Information for the complete mechanism) using the FACSIMILE software package.⁶² Reaction rate constants were obtained from updated literature reports.^{27,33} The concentration of bicarbonate, a pervasive and effective OH-radical scavenger under normal laboratory conditions,^{14,30,63} was used as an adjustable parameter to bring agreement between calculations and present measurements in neat H₂O at pH 5.0.

In the absence of added H_2O_2 , O_3 decomposition is initiated by its reaction with OH⁻. Three stoichiometries are possible: 1a and 1b that lead to \cdot OH, \cdot O₃⁻, HO₂ \cdot or \cdot O₂⁻ radicals, while

Ic yields HO_2^- , the conjugate base of H_2O_2 . Since HO_2^- deprotonates into $\cdot O_2^-$, reaction 8, and $\cdot O_3^-$ is rapidly converted into $\cdot OH$ via reactions 12 and 13, reactions 1a and 1b are expected to be operationally indistinguishable radical initiations (See Table 1). Our calculations confirm that either initiation yields identical O₃ decomposition rates, ${}^{H}R_{-O_3}$. In contrast, any HO_2^- produced in reaction 1c must react with O₃ via reaction 2b to trigger a radical chain. Since reaction 2b competes with the diffusion-controlled protonation of HO_2^- into relatively inert H_2O_2 , reaction 4, in this case the onset of a chain decomposition is delayed until [H_2O_2] reaches steady state.

Accordingly, we were able to simulate O₃ decay profiles in H₂O at pH 5.0 by alternatively using reactions 1a or 1b, with $[HCO_3^{-}] = 3 \ \mu M$, using literature rate parameters. Notice that the bicarbonate level required for the optimal fit is smaller than $[HCO_3^-]_{sat} = 5 \ \mu M$ in water saturated with atmospheric CO₂ at pH 5.0 (Figure 1).⁶⁴ We verified that calculated ${}^{H}R_{-O_3}$'s are inversely proportional to [HCO₃⁻]. However, we found that radical initiation via the sequence (1c + 2b) qualitatively and quantitatively fails to reproduce our ${}^{H}R_{-O_3}$ measurements (Figure 1, dashed line). The reason can be traced to the fact that the HO₂⁻ formed in reaction 1c is mostly converted into H_2O_2 via reaction 4, rather than into free radicals via reaction 2b. Since $pK_a(H_2O_2) = 11.8$, and H_2O_2 is largely consumed by OH-radicals in reaction 6 (see Table 1), [H₂O₂] slowly builds up at pH 5.0, while maintaining [HO₂⁻] at very low levels throughout: $[HO_2^-]_{ss} < 6 \times 10^{-15}$ M. Thus, current radical mechanisms are actually inconsistent with reaction 1c being either the exclusive or major reaction pathway in OH⁻ attack on O₃.

In the presence of modest H_2O_2 concentrations, O_3 largely reacts with HO_2^- , reactions 2a-c, rather than with $OH^{-,7}$ Of the three possible stoichiometries, reaction 2a produces HO₃⁻, the conjugate anion of HOOOH, via hydride transfer. Since reaction 2c yields inert products, it would lead to $\Delta O_3/\Delta H_2O_2$ = 1, at variance with observations. Our calculations show that in the presence of 56 μ M H₂O₂, at the same total bicarbonate levels ([HCO₃⁻] = 3μ M) required to fit O₃ losses in neat water at pH 5.0, a radical mechanism initiated by reaction 2b leads to calculated O_3 decay rates about 37 times faster than measured values (Figure 2). The reason for the exaggerated kinetic response to H₂O₂ additions predicted by the mechanism is, of course, that HO_2^- is in equilibrium with H_2O_2 , i.e.,: $[HO_2^{-}] = 1.6 \times 10^{-7} [H_2O_2]$ at pH 5.0. The addition of 56 μ M H₂O₂ thus increases [HO₂⁻]_{ss} from 6 × 10⁻¹⁵ M to 9.0 × 10^{-12} M, and radical initiation rates by more than 3 orders of magnitude. It should be apparent that any radical scheme pivoting on reaction 2b as radical initiation will be just as sensitive to H₂O₂ additions regardless of other mechanistic features, and that the magnitude of the discrepancy lies beyond the combined uncertainties of reported rate parameters. Furthermore, notice that any other acceptable (i.e., within reported error limits) set of propagation and/or termination reaction rate parameters chosen to minimize the divergence between calculated and experimental O₃ decomposition rates in peroxone solutions will worsen the accord achieved in neat water. Since it is difficult to conceive alternative terminations for the •OH/ $\cdot O_2^-$ carriers faster than the diffusionally controlled reactions 17 and 18 (see Table 1), and disregarding unidentifed DOC as radicals scavengers, or radical annihilation on walls (which, incidentally, should have a detrimental effect on O_3 decay rates in neat H₂O as well) we do not envision any obvious mechanistic expedient that could attenuate the incidence of reaction 2b on calculated rates. Therefore, the significant failure of model calculations under specific conditions, i.e., at pH 5.0, exposes a basic flaw of radical mechanisms that seems circumscribed to reactions 1c and 2b. This negative result, by excluding the formation of paramagnetic species in the reaction between O_3 and HO_2^- within a limited set of stoichiometries, suggests an alternative pathway involving a hydride transfer mechanism, reaction 2a. Below, we show that solvent deuteration experiments confirm this possibility.

Isotope Effects. We found that solvent deuteration leads to a small deuterium kinetic isotope effect, KIE, in pure water: ${}^{H}R_{-O_3}{}^{/D}R_{-O_3}=1.5$ \pm 0.3, but dramatically depresses rates in the peroxone mixture: ${}^{HP}R_{-O_3}/{}^{DP}R_{-O_3} = 19.6 \pm 4.0$ (Figure 3). Since it is well established that O_3 decay rates are proportional to [OH⁻] and [HO₂⁻] respectively,⁶⁵ it is necessary to normalize relative rates in H₂O/D₂O by the actual [OH⁻]/ $[OD^{-}]$ and $[HO_{2}^{-}]/[DO_{2}^{-}]$ ratios prevalent in each set of experiments to arrive at the KIEs. The difference $pK_w(D_2O)$ – $pK_W(H_2O) = 0.71$, is almost independent of temperature between 15 °C and 25 °C.66 Therefore [OH-] in H₂O at pH 5.0 is essentially identical to $[OD^-]$ in D₂O at pD 5.71, or, considering that pD = pH + 0.41,⁵⁵ in D₂O at pH 5.3. Thus, the ratio of ${}^{1H}k_{-O_3}$ measured in H₂O at pH 5.0 over ${}^{1D}k_{-O_3}$ determined in D₂O at pH 5.3: ${}^{1H}k_{-O_3}/{}^{1D}k_{-O_3} = 1.5 \pm 0.3$, is the KIE. Similarly, since: $pK_a(D_2O_2) - pK_a(H_2O_2) = 0.69^{67}$ the ratio: $[HO_2^-]/[DO_2^-] = 1.0$, also applies to peroxone solutions in H₂O and D₂O at pH 5.0, and 5.3, respectively. Therefore, the experimental ratio: ${}^{HP}R_{-O_3} / {}^{DP}R_{-O_3} = 19.6 \pm$ 4.0, is the KIE for the $(O_3 + HO_2^{-})$ reaction.⁶⁸ The reported errors reflect the experimental dispersion, but do not incorporate the uncertainties of the ancillary pK_a data.

A rough estimate of the KIE: ${}^{H}k^{D}k \approx \exp(1.44 \text{ }\Delta \text{ZPE/T}) =$ 13.5 at 288 K, expected for transferring H/H⁻ from HO₂⁻ to a generic acceptor can be obtained by assuming negligible H–O₂⁻ bonding in the transition state, and by omitting the role of bending coordinates. $\Delta \text{ZPE} = 517 \text{ cm}^{-1}$ is the difference of zero point energies associated with O–H(D) stretching vibrations in HO₂⁻, $\bar{\nu}_{\text{O}-\text{H}} = 3810 \text{ cm}^{-1}$, and DO₂⁻, $\bar{\nu}_{\text{O}-\text{D}} = 2776 \text{ cm}^{-1.68,69}$ Against this backdrop, the experimental KIE value represents strong evidence of a primary kinetic isotope effect associated with an elementary H/H⁻ transfer from HO₂⁻ into O₃ as the rate determining step.

Reactions 2a and 2b both involve $H-O_2^-$ bond breaking and should display similar primary KIE's. However, the deuterium KIE of a putative reaction 2b will not be directly expressed in the overall rates of the radical chain decomposition of O₃ that would ensue. The reason is that a chain initiated by a bimolecular reaction between O₃ and HO₂⁻, driven by bimolecular reactions between O₃ and radical carriers, and terminated by second-order radical associations, proceeds with

rates ${}^{\rm HP}R_{-O_3}$ which are proportional to $k_{2b}{}^{1/2}$. We verified this statement by evaluating the sensitivity of calculated O₃ decomposition rates to k_{2b} variations using a radical mechanism for peroxone chemistry exclusively initiated by reaction 2b: a 20fold reduction of O₃ decomposition rates upon deuteration would require an untenably large KIE: ${}^{H}k_{2b}/{}^{D}k_{2b} \approx 400$. Therefore, the magnitude of the deuterium KIE for the decomposition of O₃ in peroxone, vis a vis the small KIE for the decomposition of O₃ in pure water, clearly rules out a radical chain mechanism for the $O_3 + H_2O_2$ reaction.

Thermochemical Considerations. It is possible to establish that the proposed reaction 2a is exothermic by reference to the ab initio heat of the following process in the gas-phase

$$HO_3^{-} \rightarrow HO_2^{-} + O(^{3}P)$$
 (26)

The calculated value: $\Delta E_{26} = +264 \text{ kJ mol}^{-1},^{43}$ together with: $\Delta_f H(O^3 P)_g = 249 \text{ kJ mol}^{-1}$, and $\Delta_f H(O_3)_g = 143 \text{ kJ}$ mol^{-1,70} leads to: $\Delta H_{2a} \approx \Delta_{\rm f} H({\rm O}^3 {\rm P})_{\rm g} - \Delta_{\rm f} H({\rm O}_3)_{\rm g} - \Delta E_{26} \approx$ -158 ± 20 kJ mol⁻¹, by disregarding small solvation energy differences between HO_2^{-}/HO_3^{-} and $O_3/O(^{3}P)$ species. The fate of HO₃⁻/H₂O₃ may involve reaction with O₃ and H₂O₂, or decomposition, reactions 27 and 28³⁹

$$\mathrm{HO}_{3}^{-} \rightarrow \mathrm{OH}^{-} + \mathrm{O}_{2} \tag{27}$$

$$\mathrm{HO}_{3}^{-} \rightarrow \mathbf{\cdot}\mathrm{OH} + \mathbf{\cdot}\mathrm{O}_{2}^{-} \tag{28}$$

From $\Delta_{\rm f} H({\rm HO_2}^-)_{\rm g} = -94.6 \text{ kJ mol}^{-1},^{71} \Delta_{\rm f} H({\rm HO_2}^-)_{\rm aq} = -$ 160.3 kJ mol⁻¹,⁷² we derive: $\Delta H_{solv}(HO_2^-) = -65.7$ kJ mol⁻¹. Therefore, from $\Delta_{\rm f} H(\cdot O_2^{-})_{\rm g} = -43.5 \text{ kJ mol}^{-1}, ^{73} \Delta_{\rm f} H({\rm HO}_3^{-})_{\rm g}$ = - 109.2 kJ mol⁻¹,⁴³ and assuming $\Delta H_{solv}(HO_2^{-1}) \approx$ $\Delta H_{\rm solv}({\rm HO}_3^-) \approx \Delta H_{\rm solv}(\cdot {\rm O}_2^-)$ to within $\pm 10 \text{ kJ mol}^{-1}$, we get $\Delta_{\rm f} H(\bullet O_2^-)_{\rm aq} \approx -109 \text{ kJ mol}^{-1}$, and $\Delta_{\rm f} H({\rm HO}_3^-)_{\rm aq} \approx -175 \text{ kJ}$ mol⁻¹. Combining the preceding estimates with: $\Delta_{\rm f} H({\rm HO}^{-})_{\rm aq}$ = $-230.0 \text{ kJ mol}^{-1,72} \Delta_{\rm f} H(\cdot \text{OH})_{\rm aq} \approx 0 \text{ kJ mol}^{-1,74} \Delta_{\rm f} H(\text{O}_2)$ $X^{3}\Sigma_{g}^{-})_{aq} = -6.7 \text{ kJ mol}^{-1}, \Delta_{f}H(O_{2}^{-1}\Delta_{g})_{aq} = 87.4 \text{ kJ mol}^{-1}$ (from ref 73, and assuming $\Delta H_{solv}(O_2) = -\Delta H_{vap}(O_2) = -6.7$ kJ mol⁻¹) we estimate: $\Delta H_{27} = -62$ kJ mol⁻¹, or $\Delta H_{27} = +$ 32 kJ mol⁻¹, whether $O_2(X^3\Sigma_g^{-1})$ or $O_2(^1\Delta_g)$ are formed as a products, respectively. Thus, the relative stability of groundstate HO_3^- (C_s , ${}^1A'$) is not thermochemical but derives from the fact that its exothermic decomposition into $O_2(X^3\Sigma_g^{-})$ is spin forbidden.43 In contrast, reaction 28 is considerably

endothermic: $\Delta H_{28} = +66 \text{ kJ mol}^{-1}$, and therefore disallowed. Thus, neither HO_3^- nor its decomposition products are able to initiate the radical chain decomposition of O₃• H₂O₃ had been previously detected chemically and spectroscopically as the marginally stable species (half-life $\tau_{1/2} \approx 2$ s at pH 1.5, 298 K) formed by association of •OH and HO2• radicals during the radiolysis of oxygenated aqueous solutions.45-47 Recently, H2O3 has been positively identified as a product of the reaction of O₃ with alcohols, 1,3-dioxolanes, and 1,2 disubstituted hydrazines in nonaqueous solvents.^{40,42,75} H₂O₃ has a half-life of $\tau_{1/2} = 16$ min in dry acetone- d_6 at 293 K, and water catalyzes its decomposition. Wentworth et al., recently proposed the formation of a bactericidal trioxide in the antibody-catalyzed oxidation of water,⁵⁰ that, in contradistinction with O₃, can hydroxylate benzoic acid such as the OH-radical. Thus, HO₃⁻/H₂O₃ behaves as an oxidizer that simulates the chemistry of the hydroxyl radical.50,52 The general reactivity pattern of HO3-/H2O3 in aqueous solution is being elucidated.⁷⁶

Finally, we could calculate HPR-O3 rates in satisfactory agreement with experimental values (Figure 2), by using $k_{2a} =$ $2.75 \times 10^{6} \text{ M}^{-1} \text{ s}^{-1}, k_{2b} = 5.0 \times 10^{4} \text{ M}^{-1} \text{ s}^{-1}, \text{ i.e.: } k_{2a} + k_{2b}$ $= 2.8 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$, $k_{2b}/k_{2a} = 0.018$, within the framework of the mechanism of Table 1. In other words, only a small contribution, if any, of the radical-forming channel, reaction 2b, to the overall stoichiometry of the $(O_3 + HO_2)$ reaction is required to simulate the effect of H₂O₂ additions on O₃ decomposition rates in water at pH 5.0.

Conclusions

The magnitude of the deuterium kinetic isotope effect (KIE) for the reaction between O₃ and HO₂⁻ in aqueous solutions at 288 K precludes a radical chain mechanism for peroxone chemistry. The proposed stoichiometry: $O_3 + HO_2 \xrightarrow{2a} HO_3^{-1}$ + O₂, is thermochemically feasible and, at variance with: O₃ + $HO_2^- \xrightarrow{2b} HO_3 \cdot + \cdot O_2^-$, leads to predicted O_3 decomposition rates in agreement with experimental values at pH 5.0.
