#### Abstract

The aim of this study was to determine the best neutral $\mathrm{ML}_{3}$ metal complexes for activating and cleaving the multiple bonds in $\mathrm{CS}_{2}$ and CS. Current experimental results show that, so far, only one bond in $\mathrm{CS}_{2}$ can be cleaved, and that CS can be activated but the bond is not broken. In the work described in this paper, density functional theory calculations have been used to evaluate the effectiveness of different $\mathrm{ML}_{3}$ complexes to activate the $\mathrm{C}-\mathrm{S}$ bonds in $\mathrm{CS}_{2}$ and CS , with $\mathrm{M}=\mathrm{Mo}$, $\mathrm{Re}, \mathrm{W}$, and Ta and $\mathrm{L}=\mathrm{NH}_{2}$. These calculations show that the combination of Re and Ta in the $\mathrm{L}_{3} \mathrm{Re} / \mathrm{CS}_{2} / \mathrm{TaL}_{3}$ complex would be the most promising system for the cleavage of both $\mathrm{C}-\mathrm{S}$ bonds of $\mathrm{CS}_{2}$. The reaction to cleave both $\mathrm{C}-\mathrm{S}$ bonds is predicted to be exothermic by about $700 \mathrm{~kJ} \mathrm{~mol}^{-1}$ and to proceed in an almost barrierless fashion. In addition, we are able to rationalize why the breaking of the $\mathrm{C}-\mathrm{S}$ bond in CS has not been observed experimentally with $\mathrm{M}=\mathrm{Mo}$ : this reaction is strongly endothermic. There is a subtle interplay between charge transfer and $\pi$ back-donation, and it appears that the $\mathrm{Mo}-\mathrm{C}$ and $\mathrm{Mo}-\mathrm{S}$ bonds are not strong enough to compensate for the breaking of the $\mathrm{C}-\mathrm{S}$ bond. Our results suggest that, instead, CS could be cleaved with $\mathrm{ReL}_{3}$ or, even better, with a combination of $\mathrm{ReL}_{3}$ and $\mathrm{TaL}_{3}$. Molecular orbitals and Mulliken charges have been used to help explain these trends and to make predictions about the most promising systems for future experimental exploration.

## Introduction

The activation and cleavage of small molecules promoted by three-coordinate early transition metal complexes is one of the challenging subjects of recent research. Of the three-coordinate complexes, the molybdenum complex, $\mathrm{Mo}\left[\mathrm{N}(\mathrm{R}) \mathrm{Ar}_{3}\right]_{3}$, is commonly used in experimental studies as a catalyst. It is well known, for instance, that this complex cleaves $\mathrm{N}_{2}{ }^{1-5}$ to produce $2 \mathrm{Mo}^{\mathrm{VI}}-\mathrm{N}$ and cleaves $\mathrm{SO}_{2}{ }^{6}$ to produce $2 \mathrm{Mo}^{\mathrm{V}}-\mathrm{O}$ and $\mathrm{Mo}^{\mathrm{V}}-\mathrm{S}$. This complex is also capable of deoxygenating $\mathrm{NO}_{2}, \mathrm{OSMe}_{2}$, and $\mathrm{SO}_{2}{ }^{6}$ and of activating $\mathrm{CO},{ }^{7,8} \mathrm{NO},{ }^{9}$ and $\mathrm{CN}^{-} .{ }^{10}$
$\mathrm{CS}_{2}$ has been shown to undergo a variety of reactions with transition metals, including insertion and disproportionation, and there is a growing interest in the activation of $\mathrm{CS}_{2}$ from catalytic

and biological points of view. ${ }^{11-14}$ The cleavage of the $\mathrm{C}-\mathrm{S}$ bonds of $\mathrm{CS}_{2}$ by $\mathrm{Mo}\left[\mathrm{N}(\mathrm{R}) \mathrm{Ar}_{3}\left(\mathrm{R}=\mathrm{C}\left(\mathrm{CD}_{3}\right) \mathrm{CH}_{3}\right.\right.$ and $\mathrm{Ar}=$ $3,5-\mathrm{C}_{6} \mathrm{H}_{3} \mathrm{Me}_{2}$ ) has been reported by Cummins and co-workers. ${ }^{6}$ They showed that the addition of 1 equiv of $\mathrm{CS}_{2}$ to $\mathrm{Mo}[\mathrm{N}(\mathrm{R}) \mathrm{Ar}]_{3}$ leads to the formation of $\operatorname{Mo}(\mathrm{S})[\mathrm{N}(\mathrm{R}) \mathrm{Ar}]_{3}$ and $(\mu-\mathrm{CS})(\mathrm{Mo}[\mathrm{N}-$ $\left.(\mathrm{R}) \mathrm{Ar}]_{3}\right)_{2}$ (eq 1), demonstrating that, although $\mathrm{Mo}[\mathrm{N}(\mathrm{R}) \mathrm{Ar}]_{3}$ is able to break one of the $\mathrm{C}-\mathrm{S}$ bonds of $\mathrm{CS}_{2}$, the cleavage of the $\mathrm{C}-\mathrm{S}$ bond of CS is quite unfeasible. A similar result is also found for the reaction of $\mathrm{CS}_{2}$ with other transition metal complexes, ${ }^{15-17}$ such as $[\mathrm{Ru}(\mathrm{OEP})]$ (OEP $=$ octaethylporphyrinato). ${ }^{16}$

The most important driving force for the ease of the cleavage of $\mathrm{CS}_{2}$ versus CS is likely that the $\mathrm{C}-\mathrm{S}$ bond in $\mathrm{CS}_{2}\left(D^{\circ}{ }_{298}=\right.$

[^0]$\left.430.5 \pm 13 \mathrm{~kJ} \mathrm{~mol}^{-1}\right)$ is much weaker than in $\mathrm{CS}\left(D^{\circ}{ }_{298}=\right.$ $\left.714.1 \pm 1.2 \mathrm{~kJ} \mathrm{~mol}^{-1}\right) .{ }^{18}$ In contrast, as mentioned above, $\operatorname{Mo}[\mathrm{N}(\mathrm{R}) \mathrm{Ar}]_{3}$ is able to cleave the $\mathrm{N}-\mathrm{N}$ bond of $\mathrm{N}_{2}$, which is approximately $240 \mathrm{~kJ} \mathrm{~mol}^{-1}$ stronger than the $\mathrm{C}-\mathrm{S}$ bond of CS , due to the formation of a very strong $\mathrm{Mo}-\mathrm{N}$ bond. This implies that, for the case of CS, the molybdenum complex is not properly chosen to form thermodynamically optimized $M-C$ or $\mathrm{M}-\mathrm{S}$ bonds.
Recently, based on theoretical studies, a new approach for cleaving $\mathrm{CN}^{-19}$ and $\mathrm{CO}^{20,21}$ by neutral model complexes $\mathrm{M}\left[\mathrm{NH}_{2}\right]_{3}$ has been introduced. In these studies, the metal center M was chosen such that it gives the strongest $\mathrm{M}-\mathrm{L}$ bonds in the product, providing a thermodynamic driving force for the cleavage reactions. The results of a systematic study by Christian et al. on the bonding properties of neutral $\mathrm{L}-\mathrm{M}\left[\mathrm{NH}_{2}\right]_{3}$ complexes showed that $\mathrm{M}=\mathrm{Re}, \mathrm{W}$, and Ta form the strongest bonds with $\mathrm{L}=\mathrm{C}, \mathrm{N}$, and O , respectively. ${ }^{22}$ Therefore, it was predicted that the combination of $\mathrm{Re}\left[\mathrm{NH}_{3}\right]_{3}$ and $\mathrm{Ta}\left[\mathrm{NH}_{3}\right]_{3}$ is best suited to breaking CO , while the combination of $\mathrm{Re}\left[\mathrm{NH}_{2}\right]_{3}$ and $\mathrm{W}\left[\mathrm{NH}_{2}\right]_{3}$ is best suited to breaking $\mathrm{CN}^{-}$.

To date, the mechanism of cleavage of $\mathrm{N}_{2},{ }^{4,23-30} \mathrm{~N}_{2} \mathrm{O},{ }^{31,32}$ $\mathrm{CO},{ }^{7,8,20,21}$ and $\mathrm{CN}^{-10,19}$ by three-coordinate complexes has been well studied. However, an in-depth understanding of the mechanism of molybdenum-promoted $\mathrm{CS}_{2}$ cleavage reaction is still lacking. In this study, we attempt to provide a possible mechanism with the aid of B3LYP density functional theory (DFT) calculations, aimed at rationalizing why the cleavage of the $\mathrm{C}-\mathrm{S}$ bond of CS is not observed experimentally. We also wish to investigate theoretically which metal gives the strongest $\mathrm{M}-\mathrm{S}$ bond and to design promising catalysts capable of cleaving both $\mathrm{C}-\mathrm{S}$ bonds of $\mathrm{CS}_{2}$.

## Computational Details

GAUSSIAN $03^{33}$ was used to fully optimize all the structures reported in this paper at the B3LYP ${ }^{34-36}$ level of density functional theory. The effective core potentials of Hay and Wadt with double- $\zeta$

valence basis sets (LANL2DZ) ${ }^{37,38}$ were chosen to describe the transition metals. The $6-31 \mathrm{G}(\mathrm{d})^{39}$ basis set was used for other atoms. This basis set combination will be referred to as BS1. Frequency calculations at the same level of theory have also been performed to identify all of the stationary points as minima (zero imaginary frequencies) or transition structures (one imaginary frequency).

To test the accuracy of the medium-size basis set (BS1) used, we carried out single-point energy calculations for all structures by using a larger basis set, the LANL2augmented:6-311+G(2d,p) basis set, incorporating the LANL2 effective core potential, a large LANL2TZ $+(3 \mathrm{f})$ basis set on the transition metals (see Supporting Information), and the $6-311+G(2 d, p)$ basis set on other atoms. This basis set will be referred to as BS2. In the energy profile shown in Figures 1 and 8-11 (below), we used the B3LYP/BS2//B3LYP/ BS1 energies.

We further performed single-point $\operatorname{CCSD}(\mathrm{T}) / \mathrm{BS} 1$ calculations for several selected structures based on the B3LYP/BS1-optimized structures to test the effect of the electron correlation. The results show that the change in the relative energy is small (see Table A in the Supporting Information for more details).

Natural bond orbital (NBO) ${ }^{40}$ analysis was employed to evaluate the electron population. Mulliken population analyses were carried out using the MullPop program. ${ }^{41}$

## Results and Discussion

$\mathrm{MoL}_{3}+\mathbf{C S}_{2}$ and $\mathrm{MoL}_{3}+\mathbf{C S}$. As mentioned in the Introduction, we shall here investigate the mechanism of eq 1 and show why $\mathrm{Mo}\left[\mathrm{N}(\mathrm{R}) \mathrm{Ar}_{3}\right.$ is not capable of breaking CS to yield $\mathrm{Mo}(\mathrm{S})\left[\mathrm{N}(\mathrm{R}) \mathrm{Ar}_{3}\right.$ and $\mathrm{Mo}(\mathrm{C})[\mathrm{N}(\mathrm{R}) \mathrm{Ar}]_{3}$. To understand this, we used the model reactant complex $\mathrm{Mo}\left(\mathrm{NH}_{2}\right)_{3}{ }^{42}$ in these calculations, as was used previously. ${ }^{19-22,25,28,29,43}$ The overall reaction profile, showing the relative energies of the reactants, intermediates, and products for the reaction given in eq 1, is plotted in Figure 1. $\mathbf{N} \_\mathbf{X}$ and $\mathbf{N T S} \_\mathbf{X}$ are the nomenclatures used for the species on the potential energy surface (PES), where $\mathbf{X}=\mathbf{S}$ stands for singlet, $\mathbf{X}=\mathbf{D}$ for doublet, $\mathbf{X}=\mathbf{T}$ for triplet, and $\mathbf{X}=\mathbf{Q}$ for quartet spin states. $\mathbf{N}$ represents the minimum structures, and NTS corresponds to the transition structures on the B3LYP PES.
In accordance with the earlier studies, the quartet state of $\mathrm{Mo}\left(\mathrm{NH}_{2}\right)_{3}(\mathbf{1} \mathbf{Q})$ is calculated to be more stable than the doublet state, 1_D, by about $59.8 \mathrm{~kJ} \mathrm{~mol}^{-1}$. The first step of reaction 1 is surmised to be coordination of $\mathrm{CS}_{2}$ to $\mathrm{Mo}\left(\mathrm{NH}_{2}\right)_{3}$. The $\mathrm{CS}_{2}$ in singlet ground state binds to Mo via an $\eta^{2}$-side-on coordination and gives 2_D with an energy drop of $110.6 \mathrm{~kJ} \mathrm{~mol}^{-1}$. 2_D, having a doublet state, is about $114.0 \mathrm{~kJ} \mathrm{~mol}^{-1}$ more stable than 2_Q, having a quartet state. The barrier height for the $\mathbf{1} \mathbf{Q} \mathbf{Q}$ $+\mathrm{CS}_{2} \rightarrow \mathbf{2} \mathbf{Q}$ reaction is calculated to be $29.7 \mathrm{~kJ} \mathrm{~mol}^{-1}$. As can be seen from Figure 2, the $\mathrm{Mo}-\mathrm{C}$ and $\mathrm{Mo}-\mathrm{S} 1$ bond distances in 2_D are found to be about 0.262 and $0.199 \AA$ shorter than in $\mathbf{2} \mathbf{Q}$, respectively, indicating that the $\mathrm{Mo}-\mathrm{CS}_{2}$ bonding

[^1]

Figure 1. Potential energy surface for the reaction $3 \mathrm{Mo}\left(\mathrm{NH}_{2}\right)_{3}+\mathrm{CS}_{2}$.

Figure 2. Geometries and Mulliken charges for species involved in the initial coordination of $\mathrm{Mo}\left(\mathrm{NH}_{2}\right)_{3}$ to $\mathrm{CS}_{2}$.
interaction in $\mathbf{2}_{\mathbf{\prime}} \mathbf{D}$ is stronger than in $\mathbf{2} \mathbf{Q}$. In this coordination mode, $\mathrm{CS}_{2}$ appears to be a very good $\pi$-acid ligand, as judged from the substantial lengthening of the $\mathrm{C}-\mathrm{S}$ bond distances in 2_D and 2_Q compared to those in the free $\mathrm{CS}_{2}$ molecule (Figure 2). The Mulliken charge distribution calculated for $\mathrm{CS}_{2}$, $\mathbf{2} \mathbf{D}$, and $\mathbf{2} \mathbf{Q} \mathbf{Q}$ further supports the argument here. It follows from Figure 2 that the electron population of $\mathrm{CS}_{2}$ increases from 0.0 in the free $\mathrm{CS}_{2}$ molecule to -0.38 in $\mathbf{2}_{\mathbf{2}} \mathbf{D}$ and -0.39 in $\mathbf{2} \mathbf{Q}$, suggesting that $\pi$-back-donation plays a crucial role in the $\mathrm{Mo}-\mathrm{CS}_{2}$ bonding interaction. The $\eta^{1}$-S end-on coordination of $\mathrm{CS}_{2}$ does not correspond to a minimum on the PES of the doublet state, and all attempts led to 2_D. This result is consistent with the earlier findings that the $\eta^{1}-\mathrm{S}$ end-on coordination of $\mathrm{CS}_{2}$ is unfavorable for the metals that are susceptible to $\pi$-back-donation. ${ }^{44}$
(44) Schenk, W. A.; Schwletzke, T. Organometallics 1983, 2, 1905.

A qualitative evaluation of the molecular orbitals allows us to understand the causes of the differences in the $\mathrm{CS}_{2}$ binding energies between 2_D and 2_Q. Figure 3a shows schematically the $\pi$ orbitals for $\mathrm{CS}_{2}$. Of the four occupied $\pi$ orbitals, only $\pi_{1}$ and $\pi_{2}$, corresponding to the symmetry-adapted orbitals, act as donor orbitals (Figure 3b). Our calculated wave functions show that the $d_{y z}$ orbital of $\mathrm{Mo}\left[\mathrm{NH}_{2}\right]_{3}$ is stabilized through its interaction with $\pi_{3}$. For $\mathbf{2} \_\mathbf{D}$, the major contribution to the singly occupied highest occupied molecular orbital (HOMO) is from a bonding interaction between the $\mathrm{d}_{x z}$ orbital of $\mathrm{Mo}\left[\mathrm{NH}_{2}\right]_{3}$ and the $\pi_{3}{ }^{\prime}$ of $\mathrm{CS}_{2}$. For $\mathbf{2}_{\mathbf{2}} \mathbf{Q}$, one of the electrons occupies the $1 \sigma^{*}$ antibonding orbital, weakening the $\mathrm{Mo}-\mathrm{CS}_{2}$ bonding. This could explain why $\mathbf{2} \mathbf{D}$ is more stable than $\mathbf{2} \mathbf{Q} \mathbf{Q}$.

Since $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{Mo}$ has a quartet spin ground state and $\mathrm{CS}_{2}$ a singlet state, the reaction begins on the quartet surface. To reach the doublet encounter complex 2_D, an intersystem crossing occurs at the minimum energy crossing point (MECP). The MECP, A1, was located with the code of Harvey ${ }^{45,46}$ at the B3LYP level of theory with the BS1 basis set (Figure 4). A1 is calculated to lie only $0.08 \mathrm{~kJ} \mathrm{~mol}^{-1}$ higher than 2_Q (at the B3LYP/BS1 level). These results suggest that the formation of 2_D is a feasible process.

The next step of the reaction is expected to be coordination of the second fragment $\mathbf{1} \mathbf{Q} \mathbf{Q}$ to $\mathbf{2} \mathbf{Z} \mathbf{D}$. A dinuclear intermediate with a triplet state ( $\mathbf{3} \_\mathbf{T}$, Figure 5) should be produced via the process because the ground states of $\mathbf{1} \mathbf{Q} \mathbf{Q}$ and $\mathbf{2} \mathbf{D}$ are quartet

[^2]

Figure 3. Molecular orbital diagram for the coordination of $\operatorname{Mo}\left(\mathrm{NH}_{2}\right)_{3}$ to $\mathrm{CS}_{2}$.

Figure 4. Geometries for the minimum energy crossing points corresponding to Figure 1.
and doublet, respectively. The reaction 1_Q + 2_D $\rightarrow \mathbf{3}$ _T proceeds in a barrierless fashion and is found to be exothermic by $137.1 \mathrm{~kJ} \mathrm{~mol}^{-1}$. The singlet state of the binuclear complex $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{Mo}-\mathrm{CS}_{2}-\mathrm{Mo}\left[\mathrm{NH}_{2}\right]_{3}\left(\mathbf{3} \_\mathbf{S}\right)$ is about $5.4 \mathrm{~kJ} \mathrm{~mol}^{-1}$ higher in energy than the corresponding triplet-state complex. 3_T can be converted to the less stable intermediate $\mathbf{3}$ _S $\mathbf{S}$ via an intersystem crossing. The result obtained from the location of the MECP, A2, shows that the spin crossover barrier to the formation of $\mathbf{3}$ _ $\mathbf{S}$ is approximately $6.0 \mathrm{~kJ} \mathrm{~mol}^{-1}$ (at the B3LYP/ BS1 level, Figure 4). A comparison of the geometries of the

Figure 5. Geometries and Mulliken charges for species involved in breaking the first $\mathrm{C}-\mathrm{S}$ bond.
resting-state complexes 2_D and 3_S reveals that $\mathrm{CS}_{2}$ in $\mathbf{3}_{-} \mathbf{S}$ is more activated than in $\mathbf{2}_{-} \mathbf{D}$. The $\mathrm{C}-\mathrm{S} 1$ and $\mathrm{C}-\mathrm{S} 2$ bond distances are elongated from 1.665 and $1.663 \AA$ in 2_D to 1.737 and $1.736 \AA$ in 3_S. The Mo1-C bond is shortened from 1.994 Å in 2_D to $1.957 \AA$ An $\mathbf{3}$ _S. The charge carried by $\mathrm{CS}_{2}$ in $\mathbf{3}_{-} \mathbf{S}$ $(-0.55)$ is more negative than in $2 \_\mathbf{D}(-0.38)$. These results imply that the charge transfer from the metal fragments to $\mathrm{CS}_{2}$ in $\mathbf{3}_{-} \mathbf{S}$ is more significant. The calculations also indicate that the metal fragment $\operatorname{Mo} 1\left[\mathrm{NH}_{2}\right]_{3}(+0.42)$ in $\mathbf{3}_{-} \mathbf{S}$ is much more positively charged than $\operatorname{Mo} 2\left(\mathrm{NH}_{2}\right)_{3}(+0.13)$, suggesting that the contribution of $\mathrm{Mo}\left(\mathrm{NH}_{2}\right)_{3}$ to metal $\rightarrow \mathrm{CS}_{2}$ back-donation is significantly larger. This idea also finds support from the results of the NBO population analysis. In $\mathbf{3}_{-} \mathbf{S}$, the $\mathrm{d}_{x z}$ and $\mathrm{d}_{y z}$ orbitals of both Mo1 and Mo2 participate in the $\pi$-back-donation interaction, the population of which for Mo 1 (2.16e) is calculated to be smaller than for Mo2 (2.53e).
The cleavage of one of the $\mathrm{C}-\mathrm{S}$ bonds of $\mathrm{CS}_{2}$ can take place through both of the intermediates $\mathbf{3}_{-} \mathbf{T}$ and $\mathbf{3}_{-} \mathbf{S}$ and through the transition structures $\mathbf{3 T S}$ _T and $\mathbf{3 T S}$ _S to form the $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{MoS}$ (4) and $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{MoCS}(\mathbf{5})$ products in the doublet spin states. The reaction is predicted to be endothermic with respect to both intermediates $\mathbf{3}$ _T and $\mathbf{3}$ _S . Both transition states involve the breaking of the $\mathrm{C}-\mathrm{S} 2$ bond and the formation of a new $\mathrm{C}-\mathrm{S} 1 \pi$ bond. For example, in $\mathbf{3 T S} \_S$, the $\mathrm{C}-\mathrm{S} 2$ bond $(2.263 \AA)$ is longer and the $\mathrm{C}-\mathrm{S} 1$ bond $(1.634 \AA)$ is shorter than the corresponding bonds ( 1.736 and $1.751 \AA$, respectively) in 3_S. In the transition structure $\mathbf{3 T S}$ _T, Mo2 is substantially out of the S1-C-Mo1 plane, while 3TS_S adopts a structure with a coplanar orientation of the $\mathrm{Mo} 2-\mathrm{S} 2-\mathrm{C}$ plane with respect to the $\mathrm{Mo} 1-\mathrm{S} 1-\mathrm{C}$ plane. The $\mathrm{C}-\mathrm{S} 2$ distance in the triplet transition structure $\mathbf{3 T S} \_\mathbf{T}$ is $0.031 \AA$ longer than in the

## Scheme 1

singlet. This result points to a late transition state for $\mathbf{3 T S}$ _T compared to 3TS_S, consistent with the observation that 3TS_T lies higher in energy than singlet $\mathbf{3 T S}$ _S by $23.3 \mathrm{~kJ} \mathrm{~mol}^{-1}$. From this result, one may conclude that the $\mathrm{C}-\mathrm{S}$ bond cleavage of $\mathrm{CS}_{2}$ through the singlet surface should be kinetically favored over the process through the triplet.

Of the $d_{y z}$ orbitals having the appropriate symmetry for interaction with $\sigma^{*}{ }_{\mathrm{C}-\mathrm{S} 2}$ (Scheme 1), the $\mathrm{Mo} 2 \mathrm{~d}_{y z}$ orbital, which corresponds to HOMO in $\mathbf{3}$ _S and HOMO-1 in $\mathbf{3}_{-} \mathbf{T}$, is more available for this interaction. The Mo1 $\mathrm{d}_{y z}$ orbital, which is mainly stabilized by the $\mathrm{Mo} 1 \rightarrow \mathrm{CS}_{2}$ back-donation interaction, has a negligible contribution to the bond-breaking process. Upon going from 3_S to $\mathbf{3 T S} \mathbf{S}$ S, the $\sigma^{*}{ }^{\mathrm{C}-\mathrm{S} 2}$ orbital overlaps well with the doubly occupied $\mathrm{d}_{y z}$ orbital of Mo 2 and gives the planar transition-state structure for 3TS_S. On the other hand, the singly occupied $\mathrm{d}_{y z}$ orbital of Mo2 in the triplet state surface has one electron short of the configuration necessary to cleave the $\mathrm{C}-\mathrm{S} 2$ bond. As a result, the $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{Mo} 2$ is displaced out of the $\mathrm{S} 1-\mathrm{C}-\mathrm{Mo} 1$ plane to provide a bonding interaction between lower-lying occupied orbitals and $\sigma^{*}{ }_{\mathrm{C}-\mathrm{S} 2}$, leading to the nonplanarity and instability found in the transition state 3TS_T.

Once the cleavage process has completed, the reaction further proceeds via coordination of $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{MoCS}$ to a third $\mathrm{Mo}\left[\mathrm{NH}_{2}\right]_{3}$ complex. The triplet complex $\mathbf{6}$ _ $\mathbf{T}$ is expected to be the product of the coordination reaction because the ground states for $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{MoCS}$ and $\mathrm{Mo}\left[\mathrm{NH}_{2}\right]_{3}$ are doublet and quartet, respectively. The overall reaction $\mathrm{Mo}\left[\mathrm{NH}_{2}\right]_{3}+\mathbf{5} \rightarrow \mathbf{6} \mathbf{T}$ is predicted to be strongly exothermic by $144 \mathrm{~kJ} \mathrm{~mol}^{-1}$ and has no barrier. A spin crossover is required to form the singlet intermediate 6_S, which is $12.6 \mathrm{~kJ} \mathrm{~mol}^{-1}$ more stable than its triplet analogue. To estimate the activation energy for the spin crossing process, the MECP, A3, was identified by using the method of Harvey et al. ${ }^{45,46}$ as mentioned above (Figure 4). The calculations show that the spin crossover occurs with a barrier of $10.7 \mathrm{~kJ} \mathrm{~mol}^{-1}$ at the B3LYP/BS1 level of theory. The result that $\mathbf{6}_{-} \mathrm{S}$ is more stable than 6_T agrees well with the experimental findings that the dinuclear intermediate $\left[\mathrm{N}(\mathrm{R}) \mathrm{Ar}_{3} \mathrm{MoCSMo}[\mathrm{N}(\mathrm{R}) \mathrm{Ar}]\right.$ is diamagnetic. ${ }^{6}$ The selected calculated bond distances for the model complex 6_S are in fairly good agreement with their experimental values (in parentheses, Figure 6).

The $C-S$ bond distances in $\mathbf{6}_{-} \mathbf{S}$ and $\mathbf{6}_{-} \mathbf{T}$ are about $0.1 \AA$ longer than in 5, and the total charges on CS in $\mathbf{6}$ _ $\mathbf{S}(-0.326)$ and $\mathbf{6} \_\mathbf{T}(-0.308)$ are more negative than in $\mathbf{5}(-0.291)$ (Figure 6). These results imply that the Mo-to-CS back-donation in the dinuclear intermediates is considerably stronger than in $\mathbf{5}$. The calculations also show that, in agreement with the experimental observations, ${ }^{6}$ the $\mathrm{Mo} 3-\mathrm{S}-\mathrm{C}$ angle $\left(103.5^{\circ}\right)$ in $\mathbf{6}$-S is bent, whereas the $\mathrm{Mo} 1-\mathrm{C}-\mathrm{S}$ angle ( $174.9^{\circ}$ ) is roughly linear. This result is in contrast to the situation in the dinitrogen intermediates $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{Mo}-\mathrm{N}_{2}-\mathrm{Mo}\left[\mathrm{NH}_{2}\right]_{3}$, where both of the $\mathrm{Mo}-\mathrm{N}-\mathrm{N}$ angles are nearly linear. The singlet linear conformer $\mathbf{6 a} \mathbf{C} \mathbf{S}$, in which the $\mathrm{Mo} 3-\mathrm{S}-\mathrm{C}$ angle was kept fixed at $180^{\circ}$, is calculated to be $116.6 \mathrm{~kJ} \mathrm{~mol}^{-1}$ higher in energy than $\mathbf{6}$ _S. The driving

Figure 6. Geometries and Mulliken charges for products of the reaction $3 \mathrm{Mo}\left(\mathrm{NH}_{2}\right)_{3}+\mathrm{CS}_{2}$. (Experimental values in parentheses.)
force toward the nonlinearity in $\mathbf{6}$ _ $\mathbf{S}$ is most likely a result of the weak $\pi$-donor properties of Mo3 and strongly double-faced (i.e., having perpendicular $\pi$ orbitals) $\pi$-donor properties of Mo1. In contrast to the bonding characteristic in 6_S, both of the Mo metal centers in $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{Mo}-\mathrm{N}_{2}-\mathrm{Mo}\left[\mathrm{NH}_{2}\right]_{3}$ act as double-face $\pi$-donors with perpendicular $\pi$ orbitals and simultaneously interact with both of the $\mathrm{N}_{2} \pi$-antibonding orbitals. This electronic feature provides a strong driving force toward linearity for the $\mathrm{Mo}-\mathrm{N}-\mathrm{N}-\mathrm{Mo}$ linkage. Further support for the claim can also be found from the study of the frontier molecular orbitals of the singlet forms of $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{Mo}-\mathrm{N}_{2}-\mathrm{Mo}\left[\mathrm{NH}_{2}\right]_{3}$ and $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{Mo}-\mathrm{CS}-\mathrm{Mo}\left[\mathrm{NH}_{2}\right]_{3}$ (Chart 1). MO1 and MO2 are the orbitals derived from the bonding interactions between $\mathrm{N}_{2}$ $\pi$-antibonding orbitals and the antisymmetric combination of $\mathrm{d}_{\pi}$ orbitals on the Mo atoms (Chart 1a). The symmetric combination of $\mathrm{d}_{\pi}$ orbitals on the Mo atoms is destabilized as a result of the repulsive interaction with the $\mathrm{N}_{2} \pi$-bonding orbitals (MO3 and MO4). The percentage contribution of Mo1 (Mo2) in MO1 and MO2 is 33\% (33\%) and 22\% (22\%), respectively, indicating that the contributions of the Mo1 and Mo2 $\mathrm{d}_{\pi}$ orbitals to the $\pi$-bonding interactions in $\left[\mathrm{NH}_{2}\right]_{3}{ }^{-}$ $\mathrm{Mo} 1-\mathrm{N}_{2}-\mathrm{Mo} 2\left[\mathrm{NH}_{2}\right]_{3}$ are the same and significant (Chart 1a). In contrast, there is very little contribution from the Mo3 $\mathrm{d}_{\boldsymbol{\pi}}$ orbitals to the $\pi$-bonding orbitals (MO1' and MO2') of $\mathbf{6 a} \mathbf{a}_{-} \mathbf{S}$ (Chart 1b). This result substantiates the notion that the Mo3-to-CS back-donation contribution to the $\mathrm{Mo}-\mathrm{CS}-\mathrm{Mo} \pi$-bonding interactions is negligible. In such a case, a linear geometry suffers from the Mo3-S $\pi$-antibonding interaction shown in $\mathbf{M O 3}$. Thus, the Mo3-S-C angle decreases from $180^{\circ}$ in $\mathbf{6 a} \_\mathbf{S}$ to $103^{\circ}$ in 6_S to turn off the antibonding interaction. In addition, since the S -to-Mo3 $\sigma$-donation is the dominating bonding mode, the empty $\mathrm{d}_{\sigma}$ orbital of Mo3 preferentially interacts with the higher lying $\pi 1$ orbital of $\left(\mathrm{NH}_{2}\right)_{3} \mathrm{MoCS}$ rather than its lower lying $\sigma$ orbital (see MO1" and Chart 1c), leading to the formation of bent intermediate 6_S.

Our calculations, in reasonable agreement with experimental findings, ${ }^{6}$ predict a pseudo- $C_{3}$ symmetry around the Mo1 center and a pseudo- $C_{s}$ symmetry around the Mo3 center. This means

Chart 1. Comparison of the Molecular Orbitals in $\left(\mathrm{NH}_{2}\right)_{3} \mathrm{Mo}-\mathrm{N}=\mathrm{N}-\mathrm{Mo}\left(\mathrm{NH}_{2}\right)_{3}$ and $\left(\mathrm{NH}_{2}\right)_{3} \mathrm{Mo}{ }^{\prime} \mathrm{C}-\mathrm{S}-\mathrm{Mo}\left(\mathrm{NH}_{2}\right)_{3}$

that the ligand rotation only happens for one of the amide ligands of Mo3. In a recent study, we explored computationally in detail the structure and bonding of $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{Mo}-\mathrm{N}_{2}-\mathrm{Mo}\left[\mathrm{NH}_{2}\right]_{3}$ and showed that the lone pair on the rotated amide ligands is capable of interacting with the empty MO4 orbital, giving rise to the higher stability of the singlet form relative to its triplet analogue. ${ }^{47}$ It is expected that, in such an intermediate, the ligand rotation occurs at each metal center because the percentage contribution of Mo1 and Mo2 to MO4 is the same and
significant ( $38 \%$ ). In contrast, for $\mathbf{6}$ _S $\mathbf{S}$, the percentage contribution of the Mo3 $\mathrm{d}_{\boldsymbol{\pi}}$ orbital (64\%) to MO4" is much higher than that of the Mo1 $\mathrm{d}_{\pi}$ orbital (6\%). This imbalance in orbital size causes one amide group on Mo3 to rotate by $90^{\circ}$, while no rotation is observed on Mo1. Indeed, the imbalance comes from the fact that the $\pi$ back-donation interactions mainly occur from

[^3]
## Scheme 2

| $\left.\left.E(\mathrm{M}-\mathrm{S})=E\left(\mathrm{NH}_{2}\right)_{3} \mathrm{M}-\mathrm{S}\right]-\mathrm{E}[\mathrm{S}]-\mathrm{EM}\left(\mathrm{NH}_{2}\right)_{3}\right]$ |  |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| M | Mo | Nb | Hf | Ta | W | Re |  |
| $E(\mathrm{M}-\mathrm{S})(\mathrm{kJ} / \mathrm{mol})$ | 428.4 | 543.4 | 378.2 | 595.3 | 500.3 | 435.3 |  |

the $\mathrm{d}_{\pi}$ orbitals of Mo1 to CS. This electronic feature increases the Mo1 $\mathrm{d}_{\pi}$ orbital components and decreases the Mo3 $\mathrm{d}_{\pi}$ orbital components in MO1" and MO2", leaving the minimum Mo1 $\mathrm{d}_{\pi}$ orbital component and the maximum Mo3 $\mathrm{d}_{\pi}$ orbital component in MO3" and MO4".

Finally, we wish to point out that, although the dinuclear intermediates possess the required number of electrons to reductively cleave the $\mathrm{C}-\mathrm{S}$ bond, the conversion of $\mathbf{6}_{-} \mathrm{S}$ (or 6_T) to $\mathbf{4 + 7}$ is thermodynamically unfavorable because it is a highly endothermic process. This result is consistent with the experimental observation that $[\mathrm{N}(\mathrm{R}) \mathrm{Ar}]_{3} \mathrm{MoCSMo}[\mathrm{N}(\mathrm{R}) \mathrm{Ar}]$ and $[\mathrm{N}(\mathrm{R}) \mathrm{Ar}]_{3} \mathrm{MoS}$ are the only species formed when $[\mathrm{N}(\mathrm{R}) \mathrm{Ar}]_{3} \mathrm{Mo}$ is treated with $\mathrm{CS}_{2} .{ }^{6}$ The endothermicity of the step can be rationalized from the notion that the $\mathrm{Mo}-\mathrm{C}$ and $\mathrm{Mo}-\mathrm{S}$ bonds are not strong enough to provide the thermodynamic driving force for the cleavage of CS.
$\mathbf{M}-\mathbf{S}$ Bonds. In an earlier work, ${ }^{22}$ we showed that, for neutral $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{M}-\mathrm{C}$ complexes, the strongest $\mathrm{M}-\mathrm{C}$ bond occurs for $\mathrm{M}=\operatorname{Re}$ with $\mathrm{d}^{4}$ configuration. The $\mathrm{Re}^{\mathrm{III}}-\mathrm{C}$ bond was calculated to be $207 \mathrm{~kJ} \mathrm{~mol}^{-1}$ stronger than the $\mathrm{Mo}^{\mathrm{III}}-\mathrm{C}$ bond. To determine which metal gives the strongest $\mathrm{M}-\mathrm{S}$ bond, we calculated the $\mathrm{M}^{\mathrm{III}}-\mathrm{S}(\mathrm{M}=\mathrm{Hf}, \mathrm{Ta}, \mathrm{Mo}, \mathrm{W}, \mathrm{Re})$ bond strengths using the equation shown in Scheme 2, where the B3LYP/BS2// B3LYP/BS1 calculations were used. The results of the calculations show that the $\mathrm{M}-\mathrm{S}$ bond strength follows the order $\mathrm{M}=$ $\mathrm{Hf}<\mathrm{Mo}<\mathrm{Re}<\mathrm{W}<\mathrm{Nb}<\mathrm{Ta}$, with the $\mathrm{Ta}-\mathrm{S}$ bond being about $171 \mathrm{~kJ} \mathrm{~mol}^{-1}$ stronger than the $\mathrm{Mo}-\mathrm{S}$ bond. The $\mathrm{W}-\mathrm{S}$ bond is calculated to be stronger than the $\mathrm{Mo}-\mathrm{S}$ bond and the $\mathrm{Ta}-\mathrm{S}$ bond stronger than the $\mathrm{Nb}-\mathrm{S}$ bond. These results are consistent with those obtained for other $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{M}-\mathrm{L}$ systems, ${ }^{22}$ where the $\mathrm{M}-\mathrm{L}$ bond strength increases down a group. This trend was rationalized in terms of the more diffuse d orbitals of higher period transition metals, resulting in enhanced metal-ligand interaction.

The trend that the $\mathrm{M}-\mathrm{S}$ bond strength increases in the order $\mathrm{M}=\mathrm{Hf}<\mathrm{Re}<\mathrm{W}<\mathrm{Ta}$ can be explained partly by the molecular orbital diagram shown in Figure 7. For $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{TaS}$, the singly occupied orbitals of sulfur ( $\mathrm{p}_{z}$ and $\mathrm{p}_{x}$ ) interact with the $\mathrm{d}_{z^{2}}$ and $\mathrm{d}_{x z}$ metal orbitals, yielding the bonding and antibonding orbitals $1 \sigma, 1 \pi, 1 \sigma^{*}$, and $1 \pi^{*}$. The doubly occupied $\mathrm{p}_{y}$ orbital of sulfur can also interact with the unoccupied $\mathrm{d}_{y z}$ orbital of tantalum, yielding the bonding and antibonding orbitals $2 \pi$ and $2 \pi *$. Since $\operatorname{Re}$ (or W) has two (or one) electrons more than Ta , the antibonding orbital $2 \pi^{*}$ shown in Figure 7 is fully (or partially) occupied, weakening the $\mathrm{M}-\mathrm{S}$ bond. For $\mathrm{M}=$ Hf, the bonding orbital $2 \pi$ is singly occupied, resulting in the weaker $\mathrm{Hf}-\mathrm{S}$ bond compared to the $\mathrm{Ta}-\mathrm{S}$ bond.

Another reason for the stronger $\mathrm{Ta}-\mathrm{S}$ bond compared to $\mathrm{W}-\mathrm{S}$ and $\mathrm{Re}-\mathrm{S}$ can be explained as follows. During the course of the reaction of $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{M}+\mathrm{S} \rightarrow\left[\mathrm{NH}_{2}\right]_{3} \mathrm{MS}$, the oxidation state of M changes from $\mathrm{M}^{\mathrm{III}}$ to $\mathrm{M}^{\mathrm{V}}$. The ionization potential based on the equation $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{M} \rightarrow\left[\mathrm{NH}_{2}\right]_{3} \mathrm{M}^{2+}+2 \mathrm{e}$ is calculated to be $19.6,18.4$, and 17.6 eV for $\mathrm{M}=\mathrm{Re}, \mathrm{W}$, and Ta , respectively. Thus, it is predicted that $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{Ta}$ is capable of losing two electrons much more easily than its W and Re analogues. These results suggest that $\mathrm{M}=\mathrm{Ta}$ is intrinsically

Figure 7. Molecular orbital diagram for coordination of sulfur to the metal fragment.

Figure 8. Potential energy surface for the reaction $\operatorname{Re}\left(\mathrm{NH}_{2}\right)_{3}+\mathrm{CS}_{2}+$ $2 \mathrm{Ta}\left(\mathrm{NH}_{2}\right)_{3}$.
more susceptible than $\mathrm{M}=\mathrm{W}$ and Re to the formation of the complex $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{MS}$.

Activation of $\mathbf{C S}_{2}$. On the basis of these results, one may predict that a mixed-metal system involving $[\mathrm{N}(\mathrm{R}) \mathrm{Ar}]_{3} \operatorname{Re} / \mathrm{CS}_{2} /$ $\mathrm{Ta}[\mathrm{N}(\mathrm{R}) \mathrm{Ar}]_{3}$ and $[\mathrm{N}(\mathrm{R}) \mathrm{Ar}]_{3} \mathrm{Re} / \mathrm{CS} / \mathrm{Ta}[\mathrm{N}(\mathrm{R}) \mathrm{Ar}]_{3}$ is best suited to cleaving both $\mathrm{C}-\mathrm{S}$ bonds of $\mathrm{CS}_{2}$; in this system, the reaction conditions should be adjusted in such a way that $\mathrm{CS}_{2}$ (or CS) binds to $[\mathrm{N}(\mathrm{R}) \mathrm{Ar}]_{3} R e$ through carbon and to $[\mathrm{N}(\mathrm{R}) \mathrm{Ar}]_{3} \mathrm{Ta}$ through sulfur. ${ }^{48}$ Accordingly, we extended the study of $\mathrm{CS}_{2}$ cleavage reaction to the $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{Re} / \mathrm{CS}_{2} / \mathrm{Ta}\left[\mathrm{NH}_{2}\right]_{3}$ system to
(48) There is, of course, the possibility that the mixed-metal systems may not work because of reasons not considered in the calculations, such as unexpected side reactions.

Figure 9. Potential energy surface for the reaction $3 \operatorname{Re}\left(\mathrm{NH}_{2}\right)_{3}+\mathrm{CS}_{2}$.

Figure 10. Potential energy surface for the reaction $3 \mathrm{Ta}\left(\mathrm{NH}_{2}\right)_{3}+\mathrm{CS}_{2}$.
assess the effect of the mixed-metal fragments on the mechanism and energetics of the reaction. The calculations were also carried out on $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{Re} / \mathrm{CS}_{2} / \operatorname{Re}\left[\mathrm{NH}_{2}\right]_{3},\left[\mathrm{NH}_{2}\right]_{3} \mathrm{Ta} / \mathrm{CS}_{2} / \mathrm{Ta}\left[\mathrm{NH}_{2}\right]_{3}$, and $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{Ta} / \mathrm{CS}_{2} / \mathrm{Re}\left[\mathrm{NH}_{2}\right]_{3}$ systems for the purpose of comparison. Energy profiles of the $\mathrm{CS}_{2}$ cleavage reaction brought about by the mixed-metal systems are compared in Figures 8-11. It follows from such a comparison that the $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{Re} / \mathrm{CS}_{2} /$ $\mathrm{Ta}\left[\mathrm{NH}_{2}\right]_{3}$ system is, as expected, the most promising approach to $\mathrm{CS}_{2}$ cleavage. The reaction 3 ReTa_S $\rightarrow 4 \mathrm{Ta}+5 \operatorname{Re} \_S$ is exothermic by $94.7 \mathrm{~kJ} \mathrm{~mol}^{-1}$ and has a barrier of only 0.5 kJ $\mathrm{mol}^{-1}$. In addition, the reaction $\mathbf{5 R e} \mathbf{S}+\mathbf{1 T a} \mathrm{S} \rightarrow 4 \mathbf{T a}+7 \operatorname{Re}$ is even more exothermic, with $\Delta \bar{E}=200.7 \mathrm{~kJ} \mathrm{~mol}^{-1}$, and proceeds in a barrierless fashion.

In agreement with findings from previous studies, the groundstate configurations for $\mathrm{Re}\left(\mathrm{NH}_{2}\right)_{3}$ and $\mathrm{Ta}\left(\mathrm{NH}_{2}\right)_{3}$ are calculated to be triplet and singlet, respectively. The reaction of $\mathrm{Re}\left(\mathrm{NH}_{2}\right)_{3}$ with $\mathrm{CS}_{2}$ gives the singlet ground state $\mathbf{2 R e} \mathbf{R}$, preceded by a spin flip from the triplet to the singlet state (Figures 8 and 9). It is expected that, due to the occupancy of the $\mathrm{Re}-\mathrm{CS}_{2} \sigma^{*}$ antibonding orbital, the triplet state of $\left(\mathrm{NH}_{2}\right)_{3} \mathrm{Re}-\mathrm{CS}_{2}\left(\mathbf{2 R e} \_\mathbf{T}\right)$

Figure 11. Potential energy surface for the reaction $\mathrm{Ta}\left(\mathrm{NH}_{2}\right)_{3}+\mathrm{CS}_{2}+$ $2 \operatorname{Re}\left(\mathrm{NH}_{2}\right)_{3}$.
is less stable than $\mathbf{2 R e} \mathbf{R} \mathbf{S}$. The 2Ta_S with singlet spin state is formed upon coordination of $\mathrm{CS}_{2}$ to $\mathrm{Ta}\left(\mathrm{NH}_{2}\right)_{3}$ (Figure 10). The triplet state of $\left(\mathrm{NH}_{2}\right)_{3} \mathrm{Ta}-\mathrm{CS}_{2}(\mathbf{2 T a} \mathbf{T})$ is calculated to be less stable than 2Ta_S by $121.1 \mathrm{~kJ} \mathrm{~mol}^{-1}$. The $\mathrm{CS}_{2}$ binds 108.2 kJ $\mathrm{mol}^{-1}$ more strongly to $\mathrm{Ta}\left(\mathrm{NH}_{2}\right)_{3}$ than to $\mathrm{Re}\left(\mathrm{NH}_{2}\right)_{3}$. This result is in contrast to the previous findings that the binding of CO to $\operatorname{Re}\left(\mathrm{NH}_{2}\right)_{3}$ is about $124 \mathrm{~kJ} \mathrm{~mol}^{-1}$ stronger than that to $\mathrm{Ta}\left(\mathrm{NH}_{2}\right)_{3} .{ }^{21}$ The same is also applicable for coordination of CS. Our calculations show that the uptake of CS by $\operatorname{Re}\left(\mathrm{NH}_{2}\right)_{3}$ to form 5Re_S is more exothermic than the uptake by $\mathrm{Ta}\left(\mathrm{NH}_{2}\right)_{3}$ to form 5Ta_T ( $-376.5 \mathrm{~kJ} \mathrm{~mol}^{-1}$ for $\mathbf{5} \mathbf{R e} \_\mathbf{S}$ versus -285.9 kJ $\mathrm{mol}^{-1}$ for 5Ta_T, see Supporting Information). 5Ta_T, having a triplet state, is calculated to be about $31.8 \mathrm{~kJ} \mathrm{~mol}^{-1}$ more stable than 5Ta_S, having a singlet state (Figures 10 and 11). Ligands such as CS and CO, having two $\pi^{*}$ orbitals, are capable of stabilizing both of the doubly occupied metal orbitals ( $\mathrm{d}_{x z}$ and $\mathrm{d}_{y z}$ ) of $\operatorname{Re}\left(\mathrm{NH}_{2}\right)_{3}$ and provide optimal metal-ligand interaction. In contrast, $\mathrm{Ta}\left(\mathrm{NH}_{2}\right)_{3}$, with the electron configuration $\mathrm{d}^{2}$, cannot interact sufficiently with the double-face $\pi$-accepting ligands $(\mathrm{CO}$ and CS$)$, giving the relatively weaker $\left(\mathrm{NH}_{2}\right)_{3^{-}}$ $\mathrm{Ta}-\mathrm{CS}$ and $\left(\mathrm{NH}_{2}\right)_{3} \mathrm{Ta}-\mathrm{CO}$ bonds. The higher stability of 5Ta_T versus 5Ta_S (Figures 10 and 11) is likely a result of the fact that, in the former, both of the singly occupied $\mathrm{d}_{\pi}$ orbitals are stabilized by interaction with CS, while in the latter, only one of the $\mathrm{d}_{\pi}$ orbitals is stabilized (being doubly occupied). In comparison, $\mathrm{CS}_{2}$, being mainly a single-face $\pi$-acceptor ligand, can only interact with one of the metal $\mathrm{d}_{\pi}$ orbitals. ${ }^{49}$ The HOMO of the singlet state of $\mathrm{Ta}\left(\mathrm{NH}_{2}\right)_{3}$, lying 0.41 eV higher in energy than the HOMO of the singlet state of $\mathrm{Re}\left(\mathrm{NH}_{2}\right)_{3}$, is more prone to interact with $\mathrm{CS}_{2}$. Since $\mathrm{Ta}\left(\mathrm{NH}_{2}\right)_{3}$ is a better donor, the $\mathrm{Ta}-\mathrm{CS}_{2}$ bond is stronger than the $\mathrm{Re}-\mathrm{CS}_{2}$ bond. $\mathbf{2 T a} \_\mathbf{T}$ is less stable than $\mathbf{2 T a} \mathbf{T} \mathbf{S}$ because, among the two metal $d_{\pi}$ electrons, only one of them is mainly involved in interaction with $\mathrm{CS}_{2}$.

After the $\pi$-complexes are formed, $\left(\mathrm{NH}_{2}\right)_{3} \mathrm{M}-\mathrm{CS}_{2}(\mathrm{M}=\mathrm{Ta}$ or Re ) coordinates to either $\mathrm{Re}\left(\mathrm{NH}_{2}\right)_{3}$ with triplet state or $\mathrm{Ta}\left(\mathrm{NH}_{2}\right)_{3}$ with singlet state through both of the sulfur atoms, lowering the energy of the systems by $-296.1,-151.9,-239.9$, and $-98.7 \mathrm{~kJ} \mathrm{~mol}^{-1}$ for 3ReTa_S, 3ReRe_T, 3TaTa_S, and

3TaRe_T, respectively. Our calculations show that the ground states of all the dinuclear intermediates are singlet. Therefore, it is expected that the triplet intermediates 3ReRe_T (Figure 9) and $\mathbf{3 T a R e} \mathbf{T}$ (Figure 11) require a spin crossover to be converted into the thermodynamically more stable singlet states. While a tetrahedral coordination around M is observed in the dinuclear intermediates $\left[\left(\mathrm{NH}_{2}\right)_{3} \mathrm{M}-\mathrm{CS}_{2}-\mathrm{M}^{\prime}\left(\mathrm{NH}_{2}\right)_{3}\right]$, the coordination around $\mathrm{M}^{\prime}$ is described as trigonal-bipyramidal, with an $\mathrm{NH}_{2}$ group and a sulfur atom situated in the two axial positions. It is also worth noting that the formation of such a coordination of $\mathrm{CS}_{2}$ has been earlier well established experimentally for other metal fragments. ${ }^{13}$ Both of the $\mathrm{C}-\mathrm{S}$ bonds are significantly elongated upon coordination of $\left(\mathrm{NH}_{2}\right)_{3} \mathrm{MCS}_{2}$ to $\mathrm{M}^{\prime}\left(\mathrm{NH}_{2}\right)_{3}$, as shown from the comparison of $\mathrm{C}-\mathrm{S}$ bond distances given in Tables 1 and 2. This result shows that the $\mathrm{C}-\mathrm{S}$ bonds are more activated by $\mathrm{M}^{\prime}\left(\mathrm{NH}_{2}\right)_{3}$ coordinating to $\left(\mathrm{NH}_{2}\right)_{3} \mathrm{MCS}_{2}$. The $\mathrm{C}-\mathrm{S}$ bonds in the dinuclear intermediates are almost the same length as the $\mathrm{C}-\mathrm{S}$ single bond $(1.179 \AA$ ) calculated for $\mathrm{H}_{2} \mathrm{C}=\mathrm{C}(\mathrm{SH})_{2}$. Thus, the Lewis structure II seems to be a very good model for the bonding description in these compounds. An analysis of the Mulliken charge distribution reveals that $\mathrm{M}\left(\mathrm{NH}_{2}\right)_{3}$ in the dinuclear intermediates is more positively charged than $\mathrm{M}^{\prime}\left(\mathrm{NH}_{2}\right)_{3}$. It follows that the charge flow is mainly in the direction from $\mathrm{M}\left(\mathrm{NH}_{2}\right)_{3}$ to $\mathrm{CS}_{2}$. The charge on $\mathrm{M}^{\prime}\left(\mathrm{NH}_{2}\right)_{3}$ depends on the nature of the $\mathrm{M}^{\prime}$ metal center. The $\mathrm{M}^{\prime}\left(\mathrm{NH}_{2}\right)_{3}$ metal fragments with $\mathrm{M}^{\prime}=\mathrm{Re}$ carry a very small negative charge, while those with $\mathrm{M}^{\prime}=\mathrm{Ta}$ are positively charged. This indicates that the ionic character in the $\mathrm{Ta}-\mathrm{S}$ bonds of the compounds is higher than in the $\mathrm{Re}-\mathrm{S}$ bonds. Indeed, the larger propensity of Ta to have a formal oxidation state +V enhances the ionic character of the $\mathrm{Ta}-\mathrm{S}$ bond.

In the next step, the cleavage of the $\mathrm{C}-\mathrm{S}$ bond of $\mathrm{CS}_{2}$ takes place through the transition structures $\mathbf{1 M M} \mathbf{M}_{-}^{\prime} \mathbf{T S}$ _S, with energetic barriers of 0.5 and $20.2 \mathrm{~kJ} \mathrm{~mol}^{-1}$ for the 3ReTa_S $\rightarrow 4 \mathrm{Ta}+5 \operatorname{Re} \_S$ (Figure 8 ) and $\mathbf{3 R e R e \_ S ~} \rightarrow 4 \operatorname{Re}+5 \operatorname{Re} \_S$ (Figure 9) reactions, respectively. We were unable to locate the

transition structures connecting 3TaTa_S to 4Ta and 5Ta_S (Figure 10), as well as $\mathbf{3 T a R e} \_\mathbf{S}$ to $\mathbf{4 R e}$ and $\mathbf{5 T a} \_\mathbf{S}$ (Figure 11), due to the flatness of the PES near the transition states. The cleavage process is exothermic for the 3ReTa_S $\rightarrow 4 \mathrm{Ta}$ + 5Re_S (Figure 8) and 3ReRe_S $\rightarrow$ 4Re + 5Re_S (Figure 9) reactions but is endothermic for the $\mathbf{3 T a T a} \_S \rightarrow \mathbf{4 T a}+\mathbf{5 T a} \_S$ (Figure 10) and 3TaRe_S $\rightarrow \mathbf{4 R e}+\mathbf{5 T a} \_\mathbf{S}$ (Figure 11) reactions. 5Ta_S, derived from the cleavage process, is not stable and is subsequently converted to the more stable triplet analogue, 5Ta_T, via an intersystem crossing process (Figures 10 and 11). These results indicate that $\mathrm{CS}_{2}$ cleavage through only the $\left[\left(\mathrm{NH}_{2}\right)_{3} \mathrm{Re} / \mathrm{CS}_{2} / \mathrm{Ta}\left(\mathrm{NH}_{2}\right)_{3}\right]$ and $\left[\left(\mathrm{NH}_{2}\right)_{3} \mathrm{Re} / \mathrm{CS}_{2} /\right.$ $\mathrm{Re}\left(\mathrm{NH}_{2}\right)_{3}$ ] systems would be energetically favorable.

Activation of CS. After cleavage of $\mathrm{CS}_{2}$, both CS complexes $\mathbf{5 T a} \_\mathbf{T}$ and $\mathbf{5 R e \_ S}$ are capable of binding to either $\operatorname{Re}\left(\mathrm{NH}_{2}\right)_{3}$, with triplet state, or $\mathrm{Ta}\left(\mathrm{NH}_{2}\right)_{3}$, with singlet state, to form the intermediate dimer complexes $\left[\left(\mathrm{NH}_{2}\right)_{3} \mathrm{M}-\mathrm{CS}-\mathrm{M}^{\prime}\left(\mathrm{NH}_{2}\right)_{3}\right]$. All attempts to optimize the intermediate $\left[\left(\mathrm{NH}_{2}\right)_{3} \mathrm{Re}-\mathrm{CS}-\right.$ $\mathrm{Ta}\left(\mathrm{NH}_{2}\right)_{3}$ ] led to CS cleavage and the direct formation of $\left(\mathrm{NH}_{2}\right)_{3} \mathrm{ReC}(7 \mathrm{Re})$ and $\left(\mathrm{NH}_{2}\right)_{3} \mathrm{TaS}(4 \mathrm{Ta})$ (Figure 8). This step, which is extremely exothermic, lends further support to the above proposal that $[\mathrm{N}(\mathrm{R}) \mathrm{Ar}]_{3} \mathrm{Re} / \mathrm{CS} / \mathrm{Ta}[\mathrm{N}(\mathrm{R}) \mathrm{Ar}]_{3}$ is the best candidate for cleaving CS. The reaction of $\mathbf{5 R e} \_\mathbf{S}$ with $\operatorname{Re}\left(\mathrm{NH}_{2}\right)_{3}$ gives $\left[\left(\mathrm{NH}_{2}\right)_{3} \mathrm{Re}-\mathrm{CS}-\mathrm{Re}\left(\mathrm{NH}_{2}\right)_{3}\right]$ with a singlet ground state ( $\mathbf{6 R e R e}$ _S), preceded by a crossover from the triplet surface to the singlet surface (Figure 9). 6ReRe_S is $41.6 \mathrm{~kJ} \mathrm{~mol}^{-1}$ lower in energy than its triplet analogue ( $\mathbf{6} \mathbf{R e R e} \mathbf{R} \mathbf{T}$ ). Starting from 6ReRe_S, the next step is CS cleavage, leading to the formation of $\left(\mathrm{NH}_{2}\right)_{3} \mathrm{ReC}(7 \mathrm{Re})$ and $\left(\mathrm{NH}_{2}\right)_{3} \mathrm{ReS}$ (4Re). This step is calculated to be $30.5 \mathrm{~kJ} \mathrm{~mol}^{-1}$ exothermic and occurs via transition structure 2ReRe_TS_S, with an activation barrier of $34.0 \mathrm{~kJ} \mathrm{~mol}^{-1}$. Hence, it appears that CS cleavage through the $\left(\mathrm{NH}_{2}\right)_{3} \mathrm{Re} / \mathrm{CS} / \mathrm{Re}\left(\mathrm{NH}_{2}\right)_{3}$ system is thermodynamically and kinetically viable. However, comparing the two energy profiles shown in Figures 8 and 9, one may conclude that cleavage of

Figure 12. Molecular orbital diagram for the coordination of $\mathrm{M}^{\prime}\left(\mathrm{NH}_{2}\right)_{3}$ to $\left(\mathrm{NH}_{2}\right)_{3} \mathrm{M}=\mathrm{C}=\mathrm{S}$.
both of the $\mathrm{C}-\mathrm{S}$ bonds of $\mathrm{CS}_{2}$ by the $\left[\left(\mathrm{NH}_{2}\right)_{3} \mathrm{Re} / \mathrm{CS}_{2} / \mathrm{Ta}\left(\mathrm{NH}_{2}\right)_{3}\right]$ system is superior to that by the $\left[\left(\mathrm{NH}_{2}\right)_{3} \mathrm{Re} / \mathrm{CS}_{2} / \operatorname{Re}\left(\mathrm{NH}_{2}\right)_{3}\right]$ system.

Our calculations also predict that the $\left[\left(\mathrm{NH}_{2}\right)_{3} \mathrm{Ta}-\mathrm{CS}-\right.$ $\left.\mathrm{Ta}\left(\mathrm{NH}_{2}\right)_{3}\right]$ and $\left[\left(\mathrm{NH}_{2}\right)_{3} \mathrm{Ta}-\mathrm{CS}-\mathrm{Re}\left(\mathrm{NH}_{2}\right)_{3}\right]$ intermediates should be formed by the treatment of 5Ta-T with $\mathrm{Ta}\left(\mathrm{NH}_{2}\right)_{3}$ and $\mathbf{5 T a} \mathbf{T} \mathbf{T}$ with $\operatorname{Re}\left(\mathrm{NH}_{2}\right)_{3}$, respectively (Figures 10 and 11). Both reactions are calculated to be exothermic. Starting from 6TaTa_S and 6TaRe_S, the CS cleavage step is endothermic by 157.4 kJ $\mathrm{mol}^{-1}$ for 6TaTa_S $\rightarrow \mathbf{4 T a}+7 \mathbf{T a}$ _T and $256.4 \mathrm{~kJ} \mathrm{~mol}^{-1}$ for 6TaRe_S $\rightarrow$ 4Re + 7Ta_T. Thus, $C-S$ bond cleavage by these two metal systems is unlikely to occur, although both are capable of activating the $\mathrm{C}-\mathrm{S}$ bonds (Tables 3 and 4). The $\mathrm{C}-\mathrm{S}$ bond distances in 6TaTa_S and 6TaRe_S are lengthened when compared to those in 5Re_S and 5Ta_T. Regardless of what M is, the charge carried by the $\mathrm{M}\left(\mathrm{NH}_{2}\right)_{3}$ fragment is positive, suggesting that the metal-to-CS back-donation is mainly in the direction $\mathrm{M} \rightarrow \mathrm{CS}$.

Other Possible Candidates for Activation of $\mathbf{C S}_{2}$. For the sake of completeness, we also extended our calculations to other logical metal combinations such as $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{~W} / \mathrm{CS}_{2} / \mathrm{W}\left[\mathrm{NH}_{2}\right]_{3}$, $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{~W} / \mathrm{CS}_{2} / \mathrm{Ta}\left[\mathrm{NH}_{2}\right]_{3},\left[\mathrm{NH}_{2}\right]_{3} \mathrm{Re} / \mathrm{CS}_{2} / \mathrm{Nb}\left[\mathrm{NH}_{2}\right]_{3}$, and $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{Re} /$ $\mathrm{CS}_{2} / \mathrm{W}\left[\mathrm{NH}_{2}\right]_{3}$ in order to show whether these newly designed systems are capable of cleaving $\mathrm{CS}_{2}$. From the energy profiles shown in Figures A-D in the Supporting Information, one can easily find that, although all these four systems are able to cleave $\mathrm{CS}_{2}$, only the $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{Re} / \mathrm{CS}_{2} / \mathrm{W}\left[\mathrm{NH}_{2}\right]_{3}$ and $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{Re} / \mathrm{CS}_{2} /$ $\mathrm{Nb}\left[\mathrm{NH}_{2}\right]_{3}$ systems are feasible candidates for breaking of CS.

Comparing the energy profiles shown in Figures 1, 8-11, and $\mathrm{A}-\mathrm{D}$, one can find that the breaking of CS is possible only if
the mixed-metal systems $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{Re} / \mathrm{CS} / \mathrm{M}^{\prime}\left[\mathrm{NH}_{2}\right]_{3}\left(\mathrm{M}^{\prime}=\mathrm{Nb}\right.$, $\mathrm{Ta}, \mathrm{W}, \mathrm{Re}$ ) are considered. In other words, of the mixed-metal systems studied in this work, those involving the $d^{4} \mathrm{Re}^{\text {III }}$ center bound to C and the $\mathrm{d}^{n} \mathrm{M}^{\mathrm{III}}$ centers ( $n=2,3$, and 4 ) bound to S are thermodynamically suited for cleaving CS. This behavior can be mainly attributed to the fact that $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{MCS}+\left[\mathrm{NH}_{2}\right]_{3} \mathrm{M}^{\prime}$ $\rightarrow\left[\mathrm{NH}_{2}\right]_{3} \mathrm{M}-\mathrm{CS}-\mathrm{M}^{\prime}\left[\mathrm{NH}_{2}\right]_{3}$ is a moderately exothermic reaction when $\mathrm{M}=\mathrm{Re}$, while the same reaction is extremely exothermic when $M=M o, W$, and Ta . Indeed, the dinuclear intermediate $\left[\mathrm{N}(\mathrm{R}) \mathrm{Ar}_{3} \mathrm{MCSM}^{\prime}[\mathrm{N}(\mathrm{R}) \mathrm{Ar}](\mathrm{M}=\mathrm{Mo}, \mathrm{W}\right.$, and Ta$)$ serves as a thermodynamic sink from which it is infeasible to reach $[\mathrm{N}(\mathrm{R}) \mathrm{Ar}]_{3} \mathrm{MC}$ and $[\mathrm{N}(\mathrm{R}) \mathrm{Ar}] \mathrm{M}^{\prime} \mathrm{S}$. For example, although the CS cleavage reaction $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{WCS}+\left[\mathrm{NH}_{2}\right]_{3} \mathrm{Ta} \rightarrow\left[\mathrm{NH}_{2}\right]_{3} \mathrm{TaS}$ $+\left[\mathrm{NH}_{2}\right]_{3} \mathrm{WC}$ (Figure B) is exothermic ( $125.1 \mathrm{~kJ} \mathrm{~mol}^{-1}$ ), the much higher stability of $\mathbf{6 W T a} \mathbf{D}$ relative to $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{TaS}+$ $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{WC}\left(116.5 \mathrm{~kJ} \mathrm{~mol}^{-1}\right)$ is a crucial obstacle to the cleavage process.

To understand the reason behind this, let us again consider the molecular orbital interactions in such systems. Figure 12 shows the frontier orbitals for $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{MCS}$ and $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{M}-$ $\mathrm{CS}-\mathrm{M}^{\prime}\left[\mathrm{NH}_{2}\right]_{3}$. In the HOMO and HOMO-1 of $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{MCS}$, the metal(d)-to-CS $\left(\pi^{*}\right)$ back-bonding interaction can be seen (Figure 12a). For $\mathrm{M}=\mathrm{Ta}\left(\mathrm{d}^{2}\right)$ and $\mathrm{W}\left(\mathrm{d}^{3}\right)$, these two $\pi$ orbitals are partially occupied, while for $\mathrm{M}=\operatorname{Re}\left(\mathrm{d}^{4}\right)$, these orbitals are fully occupied (Figure 12a). On the other hand, the $\mathrm{d}_{\pi}$ orbitals of $\mathrm{M}^{\prime}\left[\mathrm{NH}_{2}\right]_{3}$ in $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{M}-\mathrm{CS}-\mathrm{M}^{\prime}\left[\mathrm{NH}_{2}\right]_{3}$ essentially remain nonbonding because the metal-to-CS back-donation is in the direction from M to CS (Figure 12b). Once $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{Ta}-\mathrm{CS}-\mathrm{M}^{\prime}\left[\mathrm{NH}_{2}\right]_{3}$ has formed, two electrons from $\mathbf{M}^{\prime}\left[\mathrm{NH}_{2}\right]_{3}$ are transferred to the $\pi$-bonding orbitals of MO1"
and MO2" (Figure 12b), increasingly enhancing the stability of the dinuclear intermediate relative to $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{TaCS}+$ $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{M}^{\prime}$. A similar explanation can also be applicable for the stability of $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{~W}-\mathrm{CS}-\mathrm{M}^{\prime}\left[\mathrm{NH}_{2}\right]_{3}$ relative to $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{WCS}$ $+\mathrm{M}^{\prime}\left[\mathrm{NH}_{2}\right]_{3}$, where the only difference is that one electron from $\mathrm{M}^{\prime}\left[\mathrm{NH}_{2}\right]_{3}$ is involved in the $\pi$-bonding interactions. In contrast, for the case of $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{Re}-\mathrm{CS}-\mathrm{M}^{\prime}\left[\mathrm{NH}_{2}\right]_{3}$, all the valence electrons of $\mathrm{M}^{\prime}\left[\mathrm{NH}_{2}\right]_{3}$ should be accommodated in the nonbonding orbitals MO3" ${ }^{\prime \prime}$ and MO4" or the $\sigma$ antibonding orbital MO5 ${ }^{\prime \prime}$. In such a case, the expected bonding interaction does not happen, and the stability of $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{Re}-\mathrm{CS}-\mathrm{M}^{\prime}\left[\mathrm{NH}_{2}\right]_{3}$ relative to $\left[\mathrm{NH}_{2}\right]_{3} \mathrm{ReCS}+\mathrm{M}^{\prime}\left[\mathrm{NH}_{2}\right]_{3}$ remains comparable. This argument finds further support from comparison of the energy difference between 6WTa_D and 6WTa_Q (see Supporting Information). 6WTa_D lies $241.6 \mathrm{~kJ} \mathrm{~mol}^{-1}$ below $5 \mathbf{W}+$ $\mathrm{Ta}\left[\mathrm{NH}_{2}\right]_{3}$, while $\mathbf{6 W T a} \mathbf{Q} \mathbf{Q}$ has a stability comparable to that of the same reactants (Figure B, Supporting Information). This difference comes from the fact that one of the d electrons of $\mathrm{Ta}\left[\mathrm{NH}_{2}\right]_{3}$ is involved in the bonding interactions of $\mathbf{6 W T a} \mathbf{D}$, whereas in $\mathbf{6 W T a} \mathbf{Q}$, both d electrons of $\mathrm{Ta}\left[\mathrm{NH}_{2}\right]_{3}$ occupy the nonbonding orbitals MO3" and MO4" (Figure 12b).

## Conclusions

The overall mechanism for the activation of $\mathrm{CS}_{2}$ is seen to follow this sequence: initial binding of the carbon of the $\mathrm{CS}_{2}$ molecule to the metal fragment $\mathrm{ML}_{3}$, binding of a second (possibly different) metal fragment $\mathrm{M}^{\prime} \mathrm{L}_{3}$ to bridge the two sulfur atoms, breaking of a $\mathrm{C}-\mathrm{S}$ bond and formation of $\mathrm{L}_{3} \mathrm{M}-\mathrm{CS}$ and $\mathrm{L}_{3} \mathrm{M}^{\prime} \mathrm{S}$, and finally binding of a third metal fragment $\mathrm{M}_{3}^{\prime}$ to the sulfur of CS, which may or may not lead to breaking of the second $\mathrm{C}-\mathrm{S}$ bond. When $\mathrm{M}=\mathrm{M}^{\prime}=\mathrm{Mo}$, our theoretical results show that breaking the second $\mathrm{C}-\mathrm{S}$ bond is endothermic by about $200 \mathrm{~kJ} \mathrm{~mol}^{-1}$, and so the reaction stops after breaking only the first $\mathrm{C}-\mathrm{S}$ bond. This is in perfect agreement with experimental findings and can be understood in terms of the relative strengths of the $\mathrm{Mo}-\mathrm{C}, \mathrm{Mo}-\mathrm{S}$, and $\mathrm{C}-\mathrm{S}$ bonds.

We have investigated further the nature of the $\mathrm{M}-\mathrm{S}$ bond. We have shown that the bond strength can be rationalized in terms of the interaction between the metal d and sulfur p orbitals and the occupancy of the resulting $\pi^{*}$ molecular orbital. The $\mathrm{M}-\mathrm{S}$ bond strength can also be understood in terms of the change in oxidation of the metal. On both counts, Ta is shown to be the metal of choice for forming bonds with sulfur.

Given the above information on the $\mathrm{M}-\mathrm{S}$ bond and our previous results indicating that Re forms a strong bond with carbon, it comes as no surprise, perhaps, that our conclusion from this paper is that the mixed-metal system $\mathrm{L}_{3} \mathrm{Re} / \mathrm{CS}_{2} / \mathrm{TaL}_{3}$ should provide the best possibility of the neutral $\mathrm{ML}_{3}$ fragments cleaving both $\mathrm{C}-\mathrm{S}$ bonds in $\mathrm{CS}_{2}$. Not only are the barriers very small, but the overall exothermicity of $700 \mathrm{~kJ} \mathrm{~mol}^{-1}$ provides a very strong driving force for the reaction. The present work shows that the $\mathrm{L}_{3} \mathrm{Re} / \mathrm{CS}_{2} / \mathrm{ReL}_{3}$ system can also cleave both $\mathrm{C}-\mathrm{S}$ bonds, and because of the lesser exothermicity of this reaction compared to that with a $\mathrm{Re}-\mathrm{Ta}$ system, it may provide a better basis for developing a catalytic cycle. The $\mathrm{L}_{3} \mathrm{Ta} / \mathrm{CS}_{2} / \mathrm{TaL}_{3}$ and $\mathrm{L}_{3} \mathrm{Ta} / \mathrm{CS}_{2} / \mathrm{ReL}_{3}$ systems are predicted to be unsuitable for $\mathrm{CS}_{2}$ activation, and the latter system may not even break the first $\mathrm{C}-\mathrm{S}$ bond under experimental conditions.

Finally, when we turn our attention to the CS molecule by itself, it is clear that the mechanism for activation of CS follows, in very broad terms, that outlined previously for other diatomic molecules with multiple bonds (e.g., $\mathrm{N}_{2}$ ). Although $\mathrm{ML}_{3^{-}}$ activated cleavage of the $\mathrm{C}-\mathrm{S}$ bond has not yet been observed experimentally, we have shown in this work that the $\mathrm{L}_{3} \mathrm{Re}-\mathrm{CS}-\mathrm{TaL}_{3}$ system is predicted to result in spontaneous $\mathrm{C}-\mathrm{S}$ bond cleavage and that $\mathrm{L}_{3} \mathrm{Re}-\mathrm{CS}-\mathrm{Re}_{3}$, while less dramatic, may also be a useful experimental system for the activation of CS.

This study has validated the use of simple $\mathrm{M}-\mathrm{X}$ bond strength arguments in predicting which mixed-metal systems are most likely to be of use in activating multiple bonds in small molecules. This study also reinforces the crucial role that the early transition metal complexes play in the activation of such molecules.
