Lamellar structures, consisting of alternating inorganic layers separated by organic moieties, have attracted much attention over a wide range of applications, such as polymer-clay composites,^{1,2} rheology control,³ and optoelectronic devices.^{4–6} Organosilanes are ideal candidates for such efforts due to their ability to self-assemble and the intrinsic hybrid configuration of organic/inorganic moieties. Yet, the main emphasis has been focused on alkylsilane, where an alkyl group is linked with a silane terminal, i.e., R–SiX₃ (R is alkane and X can be halogen or alkoxy). Construction of stacked monolayers of alkylsilane through chemisorption is possible. The demonstrated pathway usually takes place after the monolayer surface is converted to a hydroxylated one. This conversion can be realized by a chemical modification of a nonpolar terminal group to a hydroxyl group. Alternatively, Huo⁷ and Parikh⁸ found that long-chain alkylsilane could form a lamellar solid or stacked bilayer through solvophobic and van der Waals interactions. Kuroda^{9,10} reported the chain-length dependence study (C_nH_{2n+1}Si(OEt)₃, n = 12, 14, 16, and 18) of the bilayered structure. Maoz¹¹ further developed a protocol to grow stacks of bilayers by manipulating the interactions in a stepwise fashion. Collectively, all these studies concluded that the solvophobic and the van der Waals interactions between molecules with long chains were the main driving forces for such a complex assembly. Due to the rather weak interactions between alkylsilanes, the resulting assemblies are usually amorphous and instable at high temperatures; the issue of disturbed packing, as well as difficulties in chemical functionalization of alkyl chains, limits the potential applications for organosilane lamellae.

In this communication, we report the aromatic silane molecules, 2-(4-pyridylethyl)triethoxysilane (PTS, **a**) and *N*-(3-trimethoxysilylpropyl)pyrrole (**b**) (Chart 1), with dipoles on the aromatic ring could form a lamellae-like, stacked layer structure with the assistance of water, while the dipole-free phenethyltrichlorosilane (**c**) can not. Assembled structures by **a** and **b** kept layered stacking even at a high temperature of 350 °C, of which we focus only on PTS in this communication. The SEM image (Figure 1 inset) clearly reveals a striated surface morphology suggestive of the presence of lamellae and their graphite-like features. The lateral sizes of the lamellae are in micrometers. Figure 1 shows the X-ray diffraction patterns of the solids of PTS. Two sharp peaks, centering at ~20° and ~6.70°, correspond to *d* spacings of 4.42 Å and 14.28 Å, respectively. A *d* spacing of 4.42 Å can be roughly correlated to the lateral intermolecular spacing, which is different from the observed spacing in densely packed alkylsilanes.^{8,12} A *d* spacing of 14.28 Å is more intriguing and indicative of a lamellar motif. Calculated ordering (based on Scherer equation) in both the stacking and lateral directions are 44.0 and 9.0 Å, respectively. The presence

of two peaks indicates one stacking pattern only. In contrast, alkylsilanes can adopt three possible stacking modes: mixed trans-gauche bilayer, all-trans bilayer, and all-trans interdigitated monolayer.¹³ The dipole-dipole interaction, as well as the rather short alkyl chain in PTS, could all have helped to leave out the up-and-down interdigitated pattern and to reduce the possibility of adopting a gauche conformation. On the other hand, replacing the heterocyclic ring with benzene (Chart 1, **c**) canceled the dipole and changed the final product from a layered solid to a viscous gel. Lack of polarity in the latter compound certainly varied the interactions between molecules, which disfavored the lamellae formation process. These findings triggered our hypothesis that the dipole moment in an aromatic silane is a key player for the formation of lamellar stacking. Given the known richness of chemistry to functionalize aromatic rings, tailoring the chemical structure of the final lamellae can lead to many functional materials. This reported work may offer new opportunities for self-assembly and material design.

If the dipole in our polar silane (Chart 1, **a** and **b**) is assisting the self-assembly, it could play two active roles: (1) *repulsion* between the molecules and (2) *attraction* between the neighboring layers. In particular, when the water-induced silanolization or chemisorption takes place, individual silane molecules prefer a

standing up orientation, i.e., parallel to the surface normal. Dipoles in those aromatic silanes, thus, become repulsive to each other. As a result, the hydrocarbon chain, as well as the aromatic ring, could have much less entanglement, leading to an ordered packing inside a monolayer. When such a monolayer is formed, extra water molecules in the organic solvent could be attracted by the permanent dipole in the layer. Therefore, a repetition of the above process generates stacked multilayers, as in the modeled packing shown in Figure 2 (computational details are given in the Supporting Information). We propose a lamellar or bilayer-by-bilayer stacking, with water sandwiched between two PTS bilayers. The polar groups are arranged in an alternating up-and-down motif (Figure 2b) to minimize the steric hindrances between adjacent pyridylethyl groups. The optimized thickness for the PTS bilayer is 14.2 Å (in z -axis direction), which is in great agreement with the d spacing 14.28 Å derived from XRD. Another d spacing of 4.42 Å derived from XRD is considered to correlate with the smallest periodic length in the layer plane (xy plane in Figure 2), measured at 4.4 Å from the theoretical simulations. Simply this very length is the lateral intermolecular spacing aforementioned.

The large dipole on the polar aromatic ring provides strong electrostatic interactions between bilayers. The estimated binding energy between polar rings and water is 2.43 eV per unit cell; however, the binding energy for the phenyl silane with water is only 1.74 eV per unit cell. A repetition of these unit cells certainly could generate a much stronger binding between bilayers of pyridine compared to the phenyl ones. Such a strong interaction further resulted in thermally stable lamellar structures, which is confirmed by our combined thermogravimetric analysis (TGA) and XRD. The TGA profile (Figure 3) shows the presence of two discernible weight loss regions: a small transition at 144 °C and a large transition initiating around 450 °C. Apparently, the weight loss above 450 °C is due to the decomposition of the organic moiety. The first transition at 144 °C (inset) is assigned as the loss of physically adsorbed water. Whereas no additional weight loss was observed below 450 °C, this very first transition peak could manifest

only a moderate thermal resistance of the layered structure. However, further XRD analyses on our samples after the first peak in TGA clearly suggested otherwise, indicating a better packing and good thermal stability for the lamellae. The heated samples revealed an unchanged XRD pattern up to 350 °C. More interestingly, the peak at $\sim 6.70^\circ$ in XRD showed an increased sharpness after the annealing (Figure 1, black plot). Very likely, annealing at an elevated temperature has helped the lamellae to exclude some of the redundant, physically adsorbed waters between layered stacks, which in turn promoted a more periodic and compact stacking. In contrast, most layered alkylsilanes^{4,12} either were transformed to a liquid-like phase or became amorphous upon heating at a temperature much lower than 350 °C. It has been known that increasing the molecular dipole moment can effectively enhance the thermal stability of materials. We believe that the large dipole moment on the polar aromatic ring can also lead to strong electrostatic interactions between adjacent layers of pyridines and water molecules. This explains why the observed lamellar structure is thermally stable, as well as the absence of a layered stacking for the phenyl network.

In summary, aggravated van der Waals, π - π , and solvophobic interactions can all lead to the formation of lamellae. The importance of a dipole to the stacking is largely unknown. We report that a strong dipole-dipole interaction can be another important driving force for the lamellar formation. Controlled self-assembly of two polar aromatic silanes, i.e., pyridine- or pyrrole-terminated silane, supported this argument. Graphite-like features are clearly visible from SEM. In addition, XRD patterns suggest a d spacing of 14.28 Å along the z -axis and 4.42 Å in the xy plane, which are all in good agreement with our theoretical modeling. We expect that a future design of a series of polar molecules that will allow them to form rarely seen, thermally stable lamellae will add significantly to the body of knowledge regarding self-assembly and material design.
