**Abstract:** A highly enantioselective method for the catalytic addition of terminal 1,3-diynes to aldehydes was developed using our dinuclear zinc ProPhenol (**1**) system. Furthermore, triphenylphosphine oxide was found to interact synergistically with the catalyst to substantially enhance the chiral recognition. The generality of this catalytic transformation was demonstrated with aryl,  $\alpha,\beta$ -unsaturated and saturated aldehydes, of which the latter were previously limited in alkynyl zinc additions. The chiral diynol products are also versatile building blocks that can be readily elaborated; this was illustrated through highly selective *trans*-hydrosilylations, which enabled the synthesis of a  $\beta$ -hydroxyketone and enyne. Additionally, the development of this method allowed for the rapid total syntheses of several biologically important diynol-containing natural products.

### Introduction

Conjugated diynes are potentially intriguing building blocks due to the unique behavior of acetylenes, especially in transition metal-catalyzed processes.<sup>1</sup> The unique juxtaposition of two acetylene units in a 1,3-diyne begets unusual properties, both from a chemical as well as biological point-of-view. Diyne carbinols are of particular interest because of the additional reactivity imparted by the propargyl alcohol, as well as its presence in many fascinating bioactive, fatty acid-derived polyacetylenic natural products (Figure 1).<sup>2,3</sup> These optically active propargyl alcohols exhibit a broad array of important biological properties, ranging from antifungal to anticancer activity.<sup>2</sup>

In spite of the growing recognition of the therapeutic potential of these secondary metabolites, the conventional synthetic routes to these classes of molecules are limited and lengthy. The most common strategy employed in the total syntheses of these molecules relies upon asymmetric ynone reductions to form the chiral alcohol, followed by copper-catalyzed Cadiot–Chodkiewicz cross-coupling to introduce the second acetylene unit (eq 1).<sup>3</sup>

A complementary strategy for accessing a chiral diynol is the direct addition of a terminal 1,3-diyne into an aldehyde (eq

2). This rapid approach would set the stereocenter of the secondary alcohol and introduce the diyne moiety in a single chemical operation. While there are many effective catalyst systems for the asymmetric nucleophilic addition of alkynes into aldehydes,<sup>4</sup> no known protocols exist for which the analogous transformation can be performed with a diyne. In spite of the structural similarities between an alkyne and 1,3-diyne, due to hyperconjugative effects<sup>5</sup> the two acetylenic species possess inherently differential reactivity. Notably, the uniqueness of the 1,3-diyne was observed in practice by Carreira and co-workers: use of their  $Zn(OTf)_2/N$ -methylephedrine<sup>6a</sup> system allows for the catalytic asymmetric synthesis of chiral propargyl alcohols,<sup>6b</sup> however, for the coupling of diynes, a superstoichiometric quantity (4 equiv each) of both zinc and chiral inducing agent were required.<sup>7</sup>

Stimulated by our interest in exploring the synthetic potential of diyne carbinols as building blocks, their presence as key structural elements in biological metabolites and the difficulties associated with their asymmetric syntheses, we set out to determine if our ProPhenol (**1**) catalyst, which has been successfully employed in the alkylation of aldehydes,<sup>8</sup> could also effect a catalytic asymmetric addition of terminal 1,3-diynes to carbonyl groups. Moreover, we wanted to identify a modular

diyne nucleophile which could serve as a 1,3-butadiyne equivalent. This would provide access to a lynchpin approach to rapidly generate both stereo- and structural complexity about both ends of the diyne. Herein, we report the details of our efforts to develop a catalytic asymmetric diynylation reaction and the synthetic utility of this transformation.

## Results and Discussion

**Proposed Catalytic Cycle.** It is believed that a dinuclear zinc ProPhenol (**1**)-catalyzed terminal 1,3-diyne addition would proceed in a fashion similar to the known alkylation (Scheme 1).<sup>8a</sup> The chiral ligand **1** could react with 2 equiv of a diynylmethylzinc species to generate the dinuclear zinc acetylide **A**. We hypothesize that in intermediate **A** the Zn acetylide is also coordinated to the nitrogen of the prolinol moiety and oxygen of the phenol. These hypervalent interactions serve to give the acetylide more anionic character, that is the nucleophile is an activated diynyl zincate species.<sup>9</sup> Furthermore, the active catalyst contains a Lewis acidic Zn alkoxide which can bind an aldehyde (**B**). Preorganization of the diyne and aldehyde allows for a directed addition reaction to form the propargyl zinc alkoxide **C**. Transmetalation between **C** and another molecule of diynylmethylzinc liberates the desired product and turns over the catalytic cycle.

**Reaction Optimization.** To establish that our dinuclear zinc ProPhenol (**1**) catalyst system could facilitate the addition of a terminal 1,3-diyne to an aldehyde, we evaluated the reaction of protected penta-2,4-diyne-1-ols with octanal (eq 3). Under the previously developed conditions,<sup>8a</sup> when *tert*-butyldimethyl-(penta-2,4-diynyloxy)silane<sup>7</sup> (**2a**) was used as the donor, propargyl alcohol **3a** was isolated in 48% ee and 68% yield;

however, penta-2,4-diyne ethanoate (**2b**) furnished the corresponding product **3b** with significantly better selectivity (62% ee).

Since the nonreactive terminus of the 1,3-diyne is far removed from the active site of the catalyst (see Scheme 1), it was surprising that such a subtle substituent change impacted the selectivity so significantly. Given that 3 equiv of donor was used, we postulated perhaps the Lewis basic acetate of diyne **2b** could be interacting with the Zn catalyst. This observation is consistent with previous outcomes where methyl propiolate was shown to be a more effective nucleophile than (trimethylsilyl)acetylene in alkylation with the ProPhenol (**1**) catalyst.<sup>8a,b</sup> Based on these results we sought to identify an exogenous, substoichiometric Lewis base additive that could enhance the enantioselectivity of the diynylation.

In the evaluation of Lewis base additives for the ProPhenol-catalyzed diynylation, we chose to employ buta-1,3-diyntriisopropylsilane (**4**) as the nucleophile. The reason for doing so was two-fold: this particular diyne lacked any Lewis basic sites which could potentially interfere with the action of the additive, and furthermore, the cleavable TIPS group could allow for further functionalization of the diynol product. Diyne **4** was reacted with octanal using 10 mol % ProPhenol ligand **1**, 3 equiv of  $\text{Me}_2\text{Zn}$  and a catalytic amount of an additive (eq 4). Working under the assumption that our active catalyst was a dinuclear zinc species, we added an equivalent of Lewis base per Zn atom (Table 1).

<sup>a</sup> Reaction run with 3 equiv of diyne **4**. <sup>b</sup> Isolated yield. <sup>c</sup> Enantiomeric excess determined by chiral HPLC. <sup>d</sup> Amount of molecular sieves added based on 100 mg/mmol of octanal.

In the absence of any additive, the catalytic coupling of **4** with octanal yielded propargyl alcohol **5** in only 50% ee (entry 1). The use of 4 Å molecular sieves, a common practice in the ProPhenol/dinuclear zinc aldol reactions,<sup>10</sup> proved detrimental to the enantioselectivity (entry 2). Since the acetate moiety of diyne **2b** had a unique effect on the enantioselectivity, carbonyl-type Lewis bases were primarily examined. Although ethyl acetate and ethylene carbonate gave only modest improvements in the selectivity of the diyne addition (entries 4 and 5, respectively), they proved that a catalytic additive could enhance the reaction. The Trost<sup>10a,11</sup> and Shibasaki<sup>12</sup> groups previously demonstrated that oxidized phosphines could significantly impact both the reactivity and diastereoselectivity, respectively, of dinuclear zinc-catalyzed aldol reactions. Moreover, Shibasaki and co-workers have repeatedly exploited this phenomenon for 1,2-additions of various nucleophiles to aldehydes with poly-metallic catalysts.<sup>13</sup> When triphenylphosphine sulfide, which should have a high affinity for zinc, was evaluated, diynol **5** was isolated in only 58% ee (entry 6); however, with only 20 mol % triphenylphosphine oxide (TPPO) the enantioselectivity of the diynylation improved to 79% ee (entry 7).

Once TPPO was identified as a beneficial cocatalyst, an array of tertiary phosphine oxides were subsequently examined in the addition of TIPS diyne **4** to octanal (Table 2). Tri(2-furyl)phosphine oxide, which has multiple Lewis basic sites, proved to be less effective than TPPO in the diynylation (68% ee, entry 2). The sterically demanding tris(2,6-dimethoxyphenyl)phosphine oxide, which the Shibasaki group has utilized quite successfully,<sup>13</sup> furnished diynol **5** in only 57% ee (entry 3). A trialkylphosphine oxide was examined, but did not perform as well as TPPO (entry 4). Bidentate phosphine oxides were

**Figure 2.** (a) Top-down, quadrant view of proposed TPPO coordination to the dinuclear zinc catalyst. (b) Side view of the dinuclear zinc/TPPO catalyst with diyne and aldehyde substrates bound.

evaluated, however, they were also found to be suboptimal cocatalysts (entries 5–7), giving enantioselectivities similar to the diynylation with no additive. Thus, triphenylphosphine oxide was found to be the most effective cocatalyst for this transformation.

Next, optimization of the triphenylphosphine oxide stoichiometry was performed (Table 3). In the coupling of TIPS diyne **4** with octanal, only 20 mol % TPPO (relative to 10 mol % ProPhenol ligand) was required to maximize the enantioselectivity (entry 2). Decreasing the cocatalyst loading led to a marginally less selective diynylation (entry 1), while increasing the amount of TPPO beyond 20 mol % did not further enhance the enantioselectivity (entries 3 and 4).

The optimal 2:1 ratio of TPPO:ProPhenol suggests that each zinc atom in the active catalyst is coordinated by a single phosphine oxide. Based on this observation, as well as crystallographic data of the dinuclear zinc catalyst,<sup>14</sup> where a molecule of THF is bound to each Zn atom, we hypothesize that the triphenylphosphine oxides are “trans” to one another (Figure 2a). This proposed structure also explains why bidentate phosphine oxides, which cannot achieve the necessary binding geometry, were not beneficial (Table 2, entries 5–7). Furthermore, illustrated in Figure 2b is the putative TPPO/dinuclear

zinc catalyst with the diyne and aldehyde substrates bound. It is likely the improved enantioselectivity is a result of the triphenylphosphine oxides reinforcing the chiral pocket created by the diphenylprolinol scaffold.

**Scope of the Diyne Addition.** Having identified optimal conditions for the asymmetric diyne addition, we then set out to investigate the scope of this transformation (Tables 4 and 5). In the diynylation of  $\alpha,\beta$ -unsaturated aldehydes, it is noteworthy that utilization of the TPPO cocatalyst allowed for reduction of the amount of diyne and dimethylzinc used from 3 to 2 equiv without impacting either the reactivity or enantioselectivity. Although excess diyne is still required for good reactivity, the unreacted equivalents could be recovered.

Under the standard catalytic conditions (10 mol % ProPhenol ligand **1** and 20 mol % TPPO), aromatic aldehydes were suitable electrophiles; for instance TIPS diyne **4** reacted with 2-furfural in 98% ee and 95% yield (Table 4, entry 2). Acrolein, a typically difficult substrate, was a competent acceptor, furnishing propargyl alcohol **6c** in up to 86% ee and 89% yield (entry 3). Substitution at either the  $\alpha$ - or  $\beta$ -positions of the aldehyde was also well-tolerated. In spite of the increased steric congestion at the  $\alpha$ -position, the diynylation of methacrolein provided alcohol **6d** in 87% ee and 94% yield (entry 4). Sensitive functional groups such as a vinylcyclopropane (**6e**: 97% ee, entry 5) and allylic dimethylacetal (**6f**: 95% ee, entry 6) were unperturbed under the reaction conditions. The coupling of diyne **4** with a simple *trans*-unsaturated aldehyde such as *trans*-2-decenal led to diynol **6h** being formed in 97% ee (entry 8); however, discrimination of the enantiotopic  $\pi$ -faces of a *cis*-

<sup>a</sup> Reaction performed with 1 equiv of aldehyde and 3 equiv of diyne donor. <sup>b</sup> Isolated yields. <sup>c</sup> Enantiomeric excess determined by chiral HPLC. <sup>d</sup> Reaction was performed with 2 equiv of diyne and Me<sub>2</sub>Zn. <sup>e</sup> Catalyst loading was increased to 20 mol % **1** and 40 mol % TPPO.

$\alpha,\beta$ -unsaturated aldehyde by the dinuclear zinc catalyst was less effective (entry 9).

Saturated aldehydes were also suitable electrophiles in the enantioselective diynylation (Table 4, entries 10–12). The coupling of **4** with 4-(4-methoxybenzyloxy)butanal using 10 mol % (*S,S*)-**1**, 20 mol % TPPO and 3 equiv of Me<sub>2</sub>Zn furnished the chiral alcohol in up to 80% ee (entry 10). Even bulky  $\alpha$ -substituted aldehydes proceeded with interesting levels of enantiomeric excess: cyclohexane carboxaldehyde furnished the corresponding diynol in 67% ee, while 2,2-dimethyl-4-pentenal reacted with **4** in 83% ee (entries 11 and 12, respectively).

Having demonstrated the effectiveness of TIPS diyne **4** as a nucleophile in the asymmetric addition, we then examined the substitution tolerated on the donor (Table 5). As previously shown (eq 3), the presence of primary propargyl ethers was tolerated. While the enantiomeric excesses were vastly improved with the addition of 20 mol % triphenylphosphine oxide, the selectivity was still highly dependent on the protecting group used. The *tert*-butyldimethylsilyl-protected diyne **2a** now coupled with octanal in 65% ee and 76% yield (**3a**, entry 1), whereas the analogous reaction with penta-2,4-diynyl ethanoate **2b** proceeded in 82% ee and 73% yield (**3b**, entry 2). More importantly, the mild nature of the reaction conditions allows for the presence of an activated ester with no side effects. Use of an  $\alpha,\beta$ -unsaturated aldehyde was also successful: the reaction of *trans*-2-nonenal with acetate-protected diyne **2b** furnished diynol **7a** in 97% ee and 93% yield (entry 3). More elaborate linear saturated aldehydes were also suitable acceptors for the diyne addition: donor **2b** was used to quickly access chiral propargyl alcohols **7b** and **7c**, precursors to strongyloidiols A

Scheme 2. Selective Synthetic Manipulations of the Chiral Diynol

and B, with good reactivity and enantioselectivity (entries 4 and 5, respectively).

Unfunctionalized 1,3-diynes were also viable donors with our dinuclear zinc catalyst system. Buta-1,3-diynylcyclohexane reacted with an  $\alpha,\beta$ -unsaturated aldehyde to furnish diynol **7d** in 91% ee (entry 6) and octanal to afford **7e** in 73% ee (entry 7). The electronic nature of the diyne was varied by extending the conjugation of the  $\pi$ -system; addition of a cyclohexenediynyl into *trans*-4-methyl-2-pentenal afforded propargyl alcohol **7f** quantitatively in 88% ee (entry 8).

**Selective Functionalization of the Diynols.** Given the versatile nature of the alkyne, we envisioned our optically active diyne carbinols could be useful synthetic building blocks. Previous studies in the Trost group demonstrated the use of  $[\text{Cp}^*\text{Ru}(\text{MeCN})_3][\text{PF}_6]$  ( $\text{Cp}^*$  = pentamethylcyclopentadienyl) as a catalyst for the regioselective *trans*-hydrosilylation of propargyl alcohols.<sup>15</sup> Furthermore, the resulting vinylsilane is a useful functional handle; in particular, it can be rendered to a ketone.<sup>16</sup> Given the highly selective nature of this ruthenium catalyst, we were interested in using it to exploit the directing ability of the propargyl alcohol to distinguish between the two alkynyl units and chemoselectively functionalize the proximal alkyne (Scheme 2).

Subjection of a diynol to a hydrosilylation/oxidation sequence would furnish the corresponding aldol adduct, a  $\beta$ -hydroxy ynone. The direct aldol reaction with methyl ynone was previously accomplished using the ProPhenol dinuclear zinc catalyst,<sup>17</sup> however, the addition was limited to  $\alpha,\alpha$ -disubstituted aldehydes. Moreover, conventional aldol reaction methods involving electron-deficient aldehydes give competing elimination to form the unsaturated ketone. In the context of the asymmetric addition, our diyne nucleophile would serve as a methyl ynone surrogate for a challenging class of aldol reactions (eq 5 in Scheme 2). Treatment of furyl diynol **6b** with ethoxydimethylsilane and 5 mol %  $[\text{Cp}^*\text{Ru}]$  afforded the cyclic vinylsiloxane **8** quantitatively as observed by  $^1\text{H}$  NMR spectroscopy. It is of note that this hydrosilylation proceeded with exquisite chemo- and regioselectivity; the other possible isomers were not observed. Subsequent Tamao–Fleming oxidation of intermediate **8** with  $\text{KHF}_2$  and mCPBA furnished the desired  $\beta$ -hydroxyketone **9** in 70% overall yield from diyne **6b**.

Given the *trans*-selectivity of the ruthenium-catalyzed hydrosilylation, we also envisioned employing this as a method for the partial reduction of alkynes to *trans*-olefins (Scheme 2, eq 6).<sup>18</sup> Treatment of diynol **7d** with benzyldimethylsilane (BDMS-H) and 2 mol %  $[\text{Cp}^*\text{Ru}(\text{MeCN})_3][\text{PF}_6]$  furnished the resulting vinylsilane **10** exclusively. Replacing the bulky triisopropylsilyl group on the diyne terminus (see eq 5 in Scheme 2) with a smaller cyclohexyl substituent did not impact the chemoselectivity, suggesting the hydrosilylation is indeed directed by the propargyl alcohol. Facile protodesilylation was achieved by treatment of **10** with tetrabutylammonium fluoride in THF to afford enyne **11** in 75% yield over two steps.

**Natural Product Synthesis.** The versatility of the asymmetric diynylation was also established through the total syntheses of a variety of optically active polyacetylenic natural products. Stronglydiols A (**12**) and B (**13**) were isolated from an Okinawan marine sponge of the genus and exhibited micromolar activity against several human cancer cell lines.<sup>19</sup> As shown earlier, penta-2,4-diynyl ethanoate (**2b**) was an effective nucleophile for the coupling with saturated aldehydes and offered quick access to two stronglydiol precursors (Table 5, entries 4 and 5). While these stronglydiols have been previously synthesized,<sup>7,20</sup> the overall efficiency of the ProPhenol-catalyzed transformation allows for a more atom-economical<sup>21</sup> approach. Following the key diynylation step, stronglydiol A (**12**) was isolated in quantitative yield from **7b** through a base-mediated cleavage of the primary propargyl acetate (Scheme 3, eq 7); stronglydiol B (**13**) was also synthesized in a similar manner (eq 8 in Scheme 3).

As previously mentioned, we chose to use TIPS diyne **4** because it is a surrogate for 1,3-butadiyne. We sought to demonstrate the versatility of this nucleophile in the total synthesis of panaxytriol (**14**), an active component of red ginseng which is commonly used in traditional Asian medicine.<sup>22</sup> Aside from its well-known analeptic and erythropoietic properties, panaxytriol is also cytotoxic against a variety of

<sup>a</sup> Conditions: (a)  $\text{Bu}_4\text{N}^+\text{F}^-$ , THF, 0 °C, >99%; (b) 1) BuLi, THF, -78 °C, then  $\text{BF}_3 \cdot \text{Et}_2\text{O}$ ; 2) **16**, THF; 3)  $\text{Bu}_4\text{N}^+\text{F}^-$ , 70%.

cancer cell lines.<sup>23</sup> Furthermore, recent studies have shown that the anticancer properties of **14** are a result of a cytoprotective mechanism.<sup>24,25</sup> Due to its important biological properties, many total syntheses of panaxytriol have been accomplished,<sup>26</sup> where the C3 stereocenter has been derived from sugar degradation,<sup>26a,b,e</sup> enzymatic resolution,<sup>26d</sup> or asymmetric ynone reduction,<sup>26f,g</sup> but not through direct asymmetric diyne addition (Scheme 4).

Treatment of diynol **6c**, formed in 86% ee from the addition of TIPS diyne **4** into acrolein, with TBAF revealed terminal diyne **15**. Next, double deprotonation of **15** with BuLi generated the dianion which was complexed with  $\text{BF}_3 \cdot \text{Et}_2\text{O}$  to form the diyne borate. The reaction of this acetylide with siloxy epoxide **16** led to regioselective ring-opening of the epoxide. An *in situ* quench of the ring-opened intermediate with TBAF furnished (3*R*,9*R*,10*R*)-panaxytriol in 70% yield. This lynchpin diyne alkylation strategy not only allowed for rapid enantioselective construction of the diyne carbinol, but also facile coupling of two chiral fragments without the need to discretely preactivate either piece. Through our sequence, (3*R*,9*R*,10*R*)-panaxytriol was prepared in 70% yield over three steps from acrolein.

In the synthesis of panaxytriol, a chiral diyne was coupled with a fragment containing its own chirality; however, we were

<sup>a</sup> Conditions: (a) 1)  $\text{Ac}_2\text{O}$ ,  $\text{Et}_3\text{N}$ , 10 mol % DMAP,  $\text{CH}_2\text{Cl}_2$ ; 2)  $\text{Bu}_4\text{N}^+\text{F}^-$ , AcOH, THF, 0 °C, 70% over 2 steps; (b) decyl aldehyde, 20 mol % (*R,R*)-**1**, 40 mol % TPPO, 3 equiv  $\text{Me}_2\text{Zn}$ , toluene, 4 °C, 67%.

also interested in constructing a molecule using sequential asymmetric diyne additions. 8-Hydroxyheptadeca-1-en-4,6-diyn-3-yl ethanoate (**17**), an unnamed natural product, was an ideal target with which to demonstrate this principle (Figure 3). Isolated from the Tanzanian medicinal plant *Cussonia zimmermannii*, polyacetylene **17** exhibited potent antiprotozoal activity and also cytotoxicity.<sup>27</sup> Although the structure was elucidated by NMR spectroscopy, no stereochemical assignment was reported. As this molecule had not been previously synthesized, a total synthesis would serve to confirm the structural assignment and establish the absolute and relative stereochemistry. Given the structural similarity of **17** with (3*S*,8*S*)-falcariindiol,<sup>28</sup> we hypothesized the target compound also possesses the (3*S*,8*S*)-configuration.

Since (*S,S*)-ProPhenol (**1**) affords the (*R*)-diynol, use of the (*R,R*)-enantiomer was required to prepare *ent*-**6c** with the correct stereochemistry (Scheme 5). The absolute configuration of the diyne addition was verified by the *O*-methylmandelate ester method.<sup>29,30</sup> Treatment of *ent*-**6c** with acetic anhydride, followed by cleavage of the TIPS group with TBAF, furnished **18** in 70% yield. The resulting terminal diyne was then utilized in a subsequent ProPhenol-catalyzed diyne alkylation; this double-barreled approach allows for the rapid construction of two challenging stereocenters. Under the reaction conditions with catalytic (*R,R*)-**1** and TPPO, diyne **18** coupled with decyl aldehyde to furnish polyacetylene **17** in 67% yield.

The measured optical rotation of the synthetic natural product was consistent with the literature report, confirming our hypothesis that naturally occurring **17** is of the (3*S*,8*S*)-configuration. Furthermore, the stereochemistry of the propargyl alcohol at C8 was verified using the *O*-methylmandelate ester method;<sup>30</sup> this derivitization also revealed the diastereoselectivity (>8.2:1 dr) of the second addition. Also of note is that the chiral acetoxy group in diyne **18** did not appear to interfere with the stereoselectivity of the second diyne alkylation. Since the formation of the two stereogenic centers was catalyst controlled, the other

diastereomers of **17** can be rapidly accessed simply by interchanging the ProPhenol ligand.

## Conclusion

In conclusion, a catalytic and enantioselective process for terminal 1,3-diyne additions to aldehydes has been developed. Notably, in combination with the ProPhenol (**1**) catalyst, triphenylphosphine oxide served to enhance the chiral recognition of the dinuclear zinc acetylide species, a unique effect that was not previously observed in our aldol additions. The ProPhenol-catalyzed diynylation exhibited good generality with a variety of silyl- and alkyl-substituted diyne nucleophiles. Furthermore, we evaluated a range of aldehydes and demonstrated that aryl,  $\alpha,\beta$ -unsaturated, and the potentially enolizable saturated aldehydes are all well-tolerated by the dinuclear zinc catalyst system.

The chiral diynols formed were also used as synthetic building blocks; by taking advantage of the directing effect of the propargyl alcohol, the proximal alkyne moiety could be manipulated in a highly chemo- and regioselective fashion. Through a hydrosilylation/Tamao–Fleming oxidation sequence, we showed that the diyne carbinol is a  $\beta$ -hydroxy-ynone surrogate. Additionally, the 1,3-diyne could be partially reduced to the olefin in a *trans*-selective manner to furnish highly functionalized allylic alcohols.

The synthetic utility of this method was further demonstrated in the total syntheses of four biologically active polyacetylenic natural products. The cytotoxic strongylodiols A and B (**12** and **13**, respectively) were synthesized in a straightforward manner using a catalytic asymmetric addition of diyne **2b** into the corresponding saturated aldehydes with good levels of enantioselectivity. Employment of a lynchpin strategy, where silyldiyne **4** served as a 1,3-butadiyne surrogate, enabled the rapid preparation of (3*R*,9*R*,10*R*)-panaxytriol (**14**) in only six steps in the longest linear sequence. Although the diynylation with saturated aldehydes did not always yield the highest enantiose-

lectivities, they were still effective substrates as exemplified in the expedient total synthesis of the antifungal (3*S*,8*S*)-8-hydroxyheptadeca-1-en-4,6-diyne-3-yl ethanoate (**17**), where we verified the structure and assigned the stereochemistry of the natural product. Most importantly, use of this lynchpin approach allowed for the direct and facile generation of molecular complexity around the butadiyne moiety.

## Experimental Section

**Typical Procedure for Asymmetric Diyne Addition into Aldehydes.** A flame-dried microwave vial equipped with a stir bar was charged with triphenylphosphine oxide (8.7 mg, 0.031 mmol, 0.2 equiv), ProPhenol ligand **1** (10 mg, 0.016 mmol, 0.1 equiv), and toluene (1.0 mL) under argon. The TIPS diyne **4** (77  $\mu$ L, 0.31 mmol, 2 equiv) was added via syringe, followed by dimethylzinc (261  $\mu$ L, 0.31 mmol, 2 equiv, 1.2 M in toluene). The alkynyl zinc solution was stirred at room temperature for 30 min, and then the reaction solution was cooled to 0 °C and the appropriate aldehyde added (0.16 mmol, 1 equiv). The reaction was left to proceed under argon at 4 °C. After 24 h, the reaction solution was quenched with aqueous, saturated NH<sub>4</sub>Cl (2 mL) and stirred vigorously for 10 min. The toluene phase was separated, and the aqueous phase was extracted with Et<sub>2</sub>O (4  $\times$  2 mL). The combined organic fractions were dried over sodium sulfate, filtered, and concentrated on a rotary evaporator. The crude product was then purified by flash column chromatography on silica gel.

**Acknowledgment.** We thank the NSF and the NIH (GM 33049) for their generous support of our programs. We also thank Sigma-Aldrich for donating ProPhenol ligand. V.S.C. acknowledges Dr. J. P. Lumb for insightful discussions.
