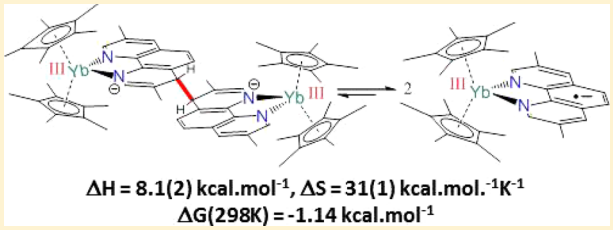
Supporting Information

ABSTRACT: The electronic structure and associated magnetic properties of the 1,10-phenanthroline adducts of Cp^*_2Yb are dramatically different from those of the 2,2′-bipyridine adducts. The monomeric phenanthroline adducts are ground state triplets that are based upon trivalent Yb(III), f^{13}, and $(phen^{\bullet -})$ that are only weakly exchange coupled, which is in contrast to the bipyridine adducts whose ground states are multiconfigurational, open-shell singlets in which ytterbium is intermediate valent (*J. Am. Chem. Soc* **2009**, *131*, 6480; *J. Am. Chem. Soc* **2010**, *132*, 17537). The origin of these different physical properties is traced to the number and symmetry of the LUMO and LUMO+1 of the heterocyclic diimine ligands. The $bipy^{\bullet -}$ has only one π^*_1 orbital of b_1 symmetry of accessible energy, but $phen^{\bullet -}$ has two π^* orbitals of b_1 and a_2 symmetry that are energetically accessible. The carbon p_π-orbitals have different nodal properties and coefficients and their energies, and therefore their populations change depending on the position and number of methyl substitutions on the ring. A chemical ramification of the change in electronic structure is that $Cp^*_2Yb(phen)$ is a dimer when crystallized from toluene solution, but a monomer when sublimed at 180–190 °C. When 3,8-Me_2phenanthroline is used, the adduct $Cp^*_2Yb(3,8\text{-}Me_2phen)$ exists in the solution in a dimer–monomer equilibrium in which ΔG is near zero. The adducts with 3-Me, 4-Me, 5-Me, 3,8-Me_2, and 5,6-Me_2-phenanthroline are isolated and characterized by solid state X-ray crystallography, magnetic susceptibility and L_{III}-edge XANES spectroscopy as a function of temperature and variable-temperature ^{1}H NMR spectroscopy.



INTRODUCTION

The concept of a ligand in a metal compound acting as a single-electron acceptor is a topic of much recent interest [e.g. see "Forum" *Inorganic Chemistry* **2011**, *50*(20), 9737].[1] The accessibility of an empty orbital on a ligand in a coordination complex was originally referred to as a "non-innocent" ligand, but this terminology does not clearly distinguish between metal/ligand back-bonding in which a pair of electrons is transferred to an empty orbital and metal-to-ligand charge transfer (MLCT) where a single electron is transferred to an empty ligand orbital. The latter process generates an electron-transfer complex in which an electron resides in the ligand LUMO, an electron hole remains in the metal-based orbital, and the ligand is referred to as a "redox active" ligand. The ground state electronic structure is then determined by how the biradical correlates the two electrons forming either a triplet state ($S = 1$), in which the electrons are ferromagnetically coupled, or an open-shell singlet state ($S = 0$), in which the electrons are antiferromagnetically coupled.

Complexes of d-transition metals with redox active ligands have been extensively and intensively studied.[1] In contrast, complexes of the f-block metals, although they are known, are not as well studied, with most of the work only appearing recently.[2−14] The 2,2′-bipyridine adducts of Cp^*_2Yb, in particular, have been shown by experimental and computational methodologies to have multiconfigurational open-shell singlet ground states in which ytterbium is intermediate valent.[4,5] In this context, an article by Scarborough and Wieghardt[15] is particularly informative as they systematize and classify the often confusing and/or contradictory literature of the 2,2′-bipyridine and related adducts of d-transition metal metallocenes using a density functional theory (DFT) broken-symmetry (BS) methodology. A comparison between the electronic ground state of $(C_5H_5)_2Ti(bipy)$[16] and $(C_5Me_5)_2Yb(bipy)$ is enlightening. Both adducts have an open-shell singlet ground state (S)[5,15] but the triplet state (T) in $Cp_2Ti(bipy)$ lies close enough to the ground state ($-2J = 600$ cm^{-1}) that it is a spin equilibrium molecule, $S(S = 0) \rightleftharpoons T(S = 1)$, whereas the triplet in $Cp^*_2Yb(bipy)$ lies 0.28 eV (calculated) or $-2J = 0.11$

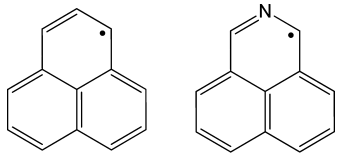
[a]The graphic shows the numbering scheme for the carbon positions on phenanthroline. [b]The magnetic moments correspond to the formulation given in the first column.

eV (920 cm^{-1}, experimental)[11] above the open-shell singlet state and the triplet is not significantly populated at 300 K. These physical properties show that strong exchange coupling does indeed occur in these 4f-block metal compounds.

Although bipyridine and related ligands, such as diazadienes, attached to d- and f-block metallocences have attracted the most attention, adducts with 1,10-phenanthroline have been largely ignored. Previous studies of $Cp^*_2Yb(phen)$ showed that $Cp^*_2Yb(phen)$ and $Cp^*_2Yb(bipy)$ are analogous in many respects,[6,14] in particular, the electrochemistry of the two complexes is almost identical.[6] In this article, it is shown that the ground state of $Cp^*_2Yb(phen)$ is a triplet (T), in contrast to the open-shell singlet ground state of $Cp^*_2Yb(bipy)$. One chemical ramification of the triplet electronic configuration is that the phenanthroline ligands in the individual monomer units are coupled by formation of a C−C σ bond at the 4,4′-positions resulting in a dimer. The related adduct, $Cp^*_2Yb(3,8\text{-}Me_2\text{-}phen)$ exists in solution as a dimer ⇌ monomer equilibrium, and analysis of solid state structure and ^1H NMR spectra show that the C−C bond is long (1.592(16) Å) and weak (ΔH = −8 kcal·mol^{-1}).

The thermochemistry for a dimer ⇌ monomer equilibrium, D ⇌ 2M, where M is an organic σ-radical, σ-R, and D is the dimer, σ-R_2, is of fundamental interest since the value of ΔH is the bond dissociation enthalpy, BDE, for the σ-R_2 single bond. Although BDE's for organic compounds are well-known, only a few examples of BDE's for a specific σ-carbon−carbon single bond and the associated bond distance in the dimer are known. The oldest dimer−monomer equilibrium is that of Gomberg's dimer, for which the value of ΔH of 11 kcal·mol^{-1} has been measured,[17−19] is not a simple σ-R_2 ⇌ 2σ-R dissociation due to the structure of the dimer. Recently, the thermochemistry of the σ-dimerization of the phenalenyl σ-dimer and the related aza-analogue have been measured.[20−22] The ΔH values of D ⇌ 2 M for **I** and **II** in CCl_4 are 10 kcal·mol^{-1} and 11 kcal·mol^{-1}, respectively, and the associated ΔS values are 15 and 18 cal·mol^{-1}·K^{-1}, respectively. The C−C bond length in the copper bis(trifluoroactetylacetonate) complex of the dimer of **II** is 1.58 Å. This value is identical to that calculated for the σ−C-C distance in the σ-dimer of **I**, for which the calculated value of the BDE is 16 kcal·mol^{-1}. More recently, the ΔH value for the D ⇌ 2M, M is 2,6-di-*tert*-butyl-4-methoxyphenoxy radical of 6 kcal·mol^{-1} has been obtained along with the σ−C-C distance in the dimer of 1.605(2) Å.[23] The reversible coupling of two pyridine ligands in a β-diketiminate iron complex has recently been published in which the C−C distance of 1.563(6) Å was measured and a ΔH value of 11 kcal·mol^{-1} was estimated.[24]



I **II**

The dimer of the phenalenyl radical also forms π-dimers when Me_3C groups are attached to the arene rings.[25−27] Although the ΔH values are similar to the σ-dimers, the π−C-C distances are much longer, as they range from 3.201(8) Å to 3.323(6) Å in the π-dimer of 1,4,7-$(Me_3C)_3C_{12}H_6$ in D_{3d} symmetry.

This article shows that single electron transfer (SET) to a π-symmetry LUMO of a close-shell ligand results in a stretched and weakened C−C bond, σ-R_2 for which $\Delta G \approx 0$.

RESULTS

Synthesis. The syntheses of $Cp^*_2Yb(phen)$ and $[Cp^*_2Yb(phen)]I$ were reported in an earlier paper,[14] and the new neutral adducts are prepared in a similar manner, eq 1. Some physical properties of the adducts are shown in Table 1.

$$Cp^*_2Yb(OEt_2) + 1,10\text{-phenanthroline} \rightarrow Cp^*_2Yb(phen) + OEt_2 \quad (1)$$

The neutral phen adducts of Cp^*_2Yb, $Cp^*_2Yb(x\text{-}phen)$, where x is H, 3-Me, 4-Me, or 5-Me (The atom numbering system is shown in the graphic in Table 1) are sparingly soluble in toluene and tetrahydrofuran, they decompose in dichloromethane, and may be crystallized from a dilute solution of warm toluene. The $3,8\text{-}Me_2phen$ adduct is somewhat more soluble in toluene, but all of the neutral adducts are much less soluble than the 2,2′-bipyridine adducts described in earlier papers.[4,5,14,28] The solid-state and solution-state physical properties of the adducts are quite different and these properties are described in the separate sections that follow. The neutral phenanthroline adduct was sublimed at 190 °C under reduced pressure as dark purple crystals. The products of

dx.doi.org/10.1021/ja502271q | J. Am. Chem. Soc. 2014, 136, 8626−8641

the crystallization and sublimation of $Cp^*_2Yb(phen)$, **1**, are referred to as **1-crystallized** and **1-sublimed** in Table 1.

RESULTS: PHYSICAL PROPERTIES, SOLID STATE

Magnetism. Plots of the effective magnetic moment per Yb, μ_{eff}, as a function of temperature for the six neutral adducts **1-crystallized**, **1-sublimed** and **3**–**7**, each obtained by crystallization from toluene and the cation $[Cp^*_2Yb(phen)]^+I$ (**2**), are shown in Figures 1 and 2 (Plots of χ, χT, 1/χ, and χT as a function of temperature are available in SI) and μ_{eff} at 300 K are given in Table 1. The striking feature of the data in Figures 1 and 2 is that the curves have similar shapes that differ mainly by a scaling factor for the neutral and cationic adducts, although the overall magnitude of the μ_{eff} value for **7** is noticeably smaller over the entire temperature range. This similarity is in contrast to what was observed for the various bipyridine adducts of Cp^*_2Yb described in earlier work in which the neutral bipy adducts have substantially lower μ_{eff} values relative to those of their cationic derivatives.[4,5,28]

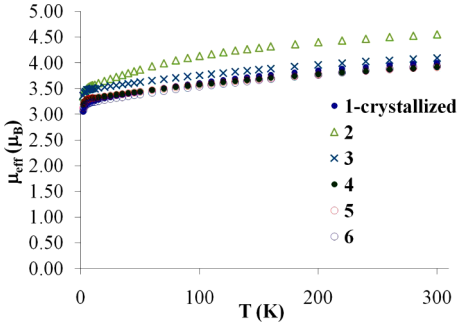


Figure 1. Plot of the effective magnetic moment, μ_{eff} per Yb, as a function of temperature for **1**–**6** in the 2–300 K temperature range. These adducts are obtained by crystallization.

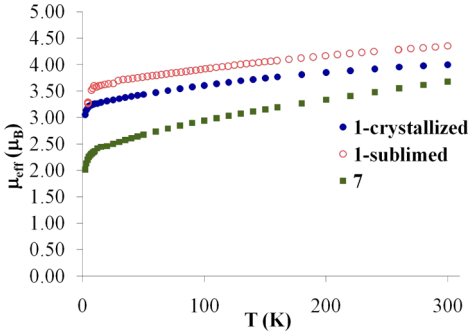

Figure 2. Plot of the effective magnetic moment, μ_{eff} per Yb, as a function of temperature for **1-monomer** after sublimation (red open dots), see Figure 5, **1-dimer** after crystallization (blue filled dots), see Figure 8, and 7 after crystallization (green squares), see Figure 7, in the 2–300 K temperature range.

The effective magnetic moments of most of the neutral adducts have a slight temperature dependence as μ_{eff} decreases from about 4 μ_B to 3.2 μ_B as the temperature decreases from 300 to 5 K. The value of μ_{eff} is somewhat lower than expected for two uncorrelated spin carriers Yb(III), $^2F_{7/2}$, and phen radical anion, $^2S_{1/2}$, for which a value of 4.83 μ_B is expected at 300 K. The value of 4.54 μ_B is expected for an isolated Yb(III) ion, $^2F_{7/2}$, in agreement with the value found for the cationic adduct, $[Cp^*_2Yb(phen)]^+I^-$ (**2**), at 300 K. The similarity of the magnetic moments of the neutral adducts in Figures 1 and 2 with that of the cation begets the question of the identity of the anion in these neutral adducts. This question is amplified by the difference between the room temperature magnetic moment of sublimed, **1-sublimed**, 4.5 μ_B, and that of the recrystallized, complex, **1-crystallized** 4.0 μ_B. Although it has similar magnetic behavior, μ_{eff} of **7** decreases from 3.5 μ_B to below 2.5 μ_B as the temperature decreases from 300 to 5 K.

Yb L_{III}-Edge XANES Spectra. Yb L_{III}-edge XANES spectra of the six neutral adducts, **1-crystallized** and **3**–**7**, are shown in Figure 3 for data collected at both 30 and 300 K. No significant change is observed over this temperature range. All the spectra are characterized by a single white-line feature at about 8946 eV. This feature is indicative of the f^{13} configuration. Another peak at 8939 eV, indicating the f^{14} configuration as shown in Figure 3 by data on the intermediate valent Cp^*_2Yb(4-Me-bipy) compound,[4] **8**, is not clearly visible in the phen adduct spectra. These spectra were fit with methods described previously,[5] giving estimates of n_f as shown in Table 2. The Yb in these samples is found to be close to trivalent, Yb(III), with a f-hole occupancy $n_f \approx 1$.

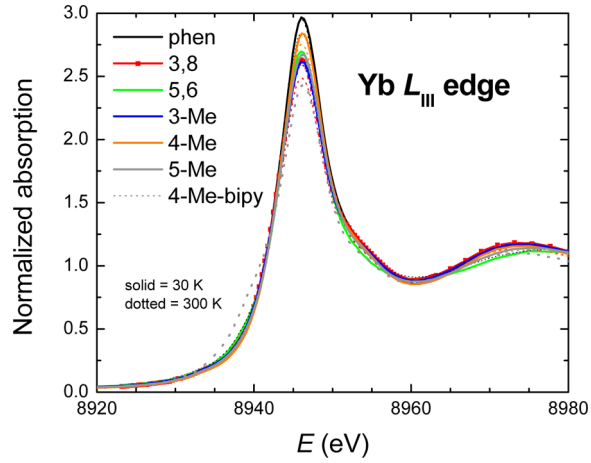

Figure 3. Yb L_{III}-edge XANES spectra for **1-crystallized** and **3**–**7** at 30 K (solid) and at 300 K (dotted). Also shown are previous data[4] on Cp^*_2Yb(4-Me-bipy) (n_f = 0.79) for comparison. The shoulder at 8939 eV below the main peak at 8946 eV is indicative of the Yb(II) contribution, which is clearly seen in the bipy adduct data. The strong overlap of all the measured phen adduct data emphasizes the overall similarity in f-orbital occupancy. The small shoulder for each of the phen adducts indicates these samples are close to trivalent Yb.

Table 2. Estimated f-hole Occupancy, n_f, Determined by Yb L_{III}-edge XANES Measurements[a]

cmpd	n_f
$Cp^*_2Yb(phen)$ (**1-crystallized**)	0.99(3)
$Cp^*_2Yb(3,8\text{-}Me_2phen)$ (**3**)	0.96(3)
$Cp^*_2Yb(3\text{-}Mephen)$ (**4**)	0.95(3)
$Cp^*_2Yb(4\text{-}Mephen)$ (**5**)	0.98(3)
$Cp^*_2Yb(5\text{-}Mephen)$ (**6**)	0.97(3)
$Cp^*_2Yb(5,6\text{-}Me_2phen)$ (**7**)	0.96(3)
Cp^*_2Yb(4-Me-bipy) (**8**)	0.79[4]

[a]No temperature dependence was observed between 30 and 300 K. The estimated absolute error in the last digit n_f is shown in parentheses; the random error between separate traces is much smaller.

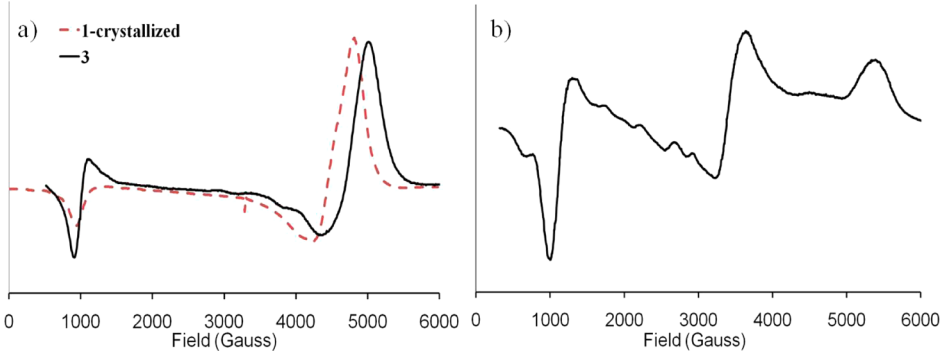

Figure 4. EPR spectra recorded in the solid state (powder) at 2 K for (a) $Cp^*_2Yb(phen)$ (**1-crystallized**, dashed red line) and $Cp^*_2Yb(3,8\text{-}Me_2phen)$ (**3**, solid black line) and (b) $[Cp^*_2Yb(phen)]I$ (**2**).

Table 3. EPR data for 1-crystallized−7

	EPR data	μ_{eff} (EPR)[a]	μ_{eff} (0 K)[b]
$Cp^*_2Yb(phen)$ (**1-crystallized**)	$g_1 = 6.85$, $g_2 = 1.47$, $g_3 = 1.40$	3.57 μ_B	3.21 μ_B
$[Cp^*_2Yb(phen)]^+I^-$ (**2**)	$g_1 = 6.70$, $g_2 = 1.92$, $g_3 = 1.21$	3.54 μ_B	3.49 μ_B
$Cp^*_2Yb(3,8\text{-}Me_2phen)$ (**3**)	$g_1 = 7.01$, $g_2 = 1.41$, $g_3 = 1.33$	3.64 μ_B	3.46 μ_B
$Cp^*_2Yb(3\text{-}Mephen)$ (**4**)	$g_1 = 7.02$, $g_2 = 1.21$, $g_3 = 1.21$	3.61 μ_B	3.29 μ_B
$Cp^*_2Yb(4\text{-}Mephen)$ (**5**)	$g_1 = 6.47$, $g_2 = 1.31$, $g_3 = 1.31$	3.37 μ_B	3.28 μ_B
$Cp^*_2Yb(5\text{-}Mephen)$ (**6**)	$g_1 = 6.45$, $g_2 = 1.42$, $g_3 = 1.21$	3.35 μ_B	3.19 μ_B
$Cp^*_2Yb(5,6\text{-}Me_2phen)$ (**7**)	EPR silent	–	2.33 μ_B

[a] $\mu_{eff}(EPR) = (1/2)(g_1^2 + g_2^2 + g_3^2)^{1/2}$ [b] μ_{eff} (0 K) was determined by using a linear fit of χT from 12 to 45 K, and determining μ_{eff} from χT extrapolated to 0 K.

It is clear from Figure 3 that the Cp^*_2Yb fragments are based upon Yb(III), f^{13}, which again begets the question raised from the magnetic data about the identity of the anion in the neutral adducts. The genesis of an answer is indicated by the EPR spectra.

EPR Spectra. The EPR spectra at 2 K of $Cp^*_2Yb(phen)$ (**1-crystallized**) and $Cp^*_2Yb(3,8\text{-}Me_2phen)$ (**3**) are shown in Figure 4a and that of $[Cp^*_2Yb(phen)]I$ (**2**) is shown in Figure 4b. EPR spectra of the monomethyl adducts of Cp^*_2Yb, **4**−**6** are shown in Supporting Information (SI). The *g*-values are given in Table 3. Because of the high sensitivity of EPR, it is important to compare the EPR and magnetic susceptibility results to determine whether they are consistent. At the temperature at which the EPR spectra are obtained (∼2 K), only the ground state is occupied in most cases. The effective magnetic moment of the ground state is determined from the EPR *g*-values using $\mu_{eff} = 0.5\ (g_1^2 + g_2^2 + g_3^2)^{1/2}$, which may be compared to the magnetic susceptibility data by extrapolating χT to 0 K then determining μ_{eff} (0 K). As shown in Table 3, the effective magnetic moments determined from the EPR *g*-values are consistent with those determined by magnetic susceptibility, so the EPR spectra can be assigned to the Yb complexes rather than to impurities.

The EPR spectrum of **2** is a highly anisotropic rhombic spectrum as expected for $Cp^*_2Yb(III)$ cation. Compounds **1** and **3** have similar spectra. The nature of the anionic ligand coordinated to the $[Cp^*_2Yb]^+$ fragment has a significant effect on the EPR spectrum as previously illustrated by $[Cp^*_2Yb(bipy)]I$ and $Cp^*_2Yb(bipy)$.[29] In $[Cp^*_2Yb(bipy)]I$, $[Cp^*_2Yb]^+$ is coordinated by a neutral, closed-shell bipy ligand, and the complex has EPR parameters similar to those of **2**. On the other hand, $Cp^*_2Yb(bipy)$ is EPR silent at 2 K since the ground state is a singlet state that is multiconfigurational and composed of open-shell singlet and closed-shell singlet configurations.[30]

The compounds **1-crystallized**−**6** are EPR active; compound **2** contains a Yb(III) cation, and the diamagnetic iodide is the anion. The other compounds give similar EPR spectra, indicating that a $Cp^*_2Yb(III)$ cation is also present and the anion is derived from the phenanthroline ligand, which is in sharp contrast to $Cp^*_2Yb(bipy)$.

As do the magnetic susceptibility data, the EPR results call into question the identity of the anion in these neutral adducts. Since the EPR spectra and the magnetic susceptibility data are consistent with the presence of a $Cp^*_2Yb(III)$ cation, a diamagnetic anion must also be present that is based on the phenanthroline ligand in these neutral adducts.

X-ray Crystal Structures. The nature of the bonding in these complexes and the reason why **1-crystallized** and **3**−**6** are EPR active, in contrast to **7**, is clarified by their crystal structures. Although the phen adduct and substituted phen adducts are sparingly soluble in hydrocarbons and they have high melting points, Table 1, the phen adduct sublimes at 180−190 °C in an ampule sealed under reduced pressure. The sublimation temperature must be maintained in this 10 °C range, since heating to a higher temperature results in substantial decomposition. In the 180−190 °C range, a small number of well formed crystals grow during a month, which are suitable for X-ray diffraction. The ORTEP in Figure 5 shows that the sublimed crystals are well-separated monomers of Cp*Yb(phen) (**1-monomer** is now used to distinguish the sublimed compound from the crystallized compound, labeled as **1-dimer**). The ORTEP of $Cp_2^*Yb(5,6\text{-}Me_2phen)$ (**7**) in Figure 6 shows the three independent molecules in the unit cell of the monomeric adduct obtained by crystallization from cyclohexane. The crystal structure of $Cp^*_2Yb(5,6\text{-}Me_2phen)$, obtained by sublimation in a sealed ampule under reduced pressure at 195 °C over two months and labeled **7-sublimed**, is shown in Figure 7a, along with a crystal packing diagram of two

dx.doi.org/10.1021/ja502271q | J. Am. Chem. Soc. 2014, 136, 8626−8641

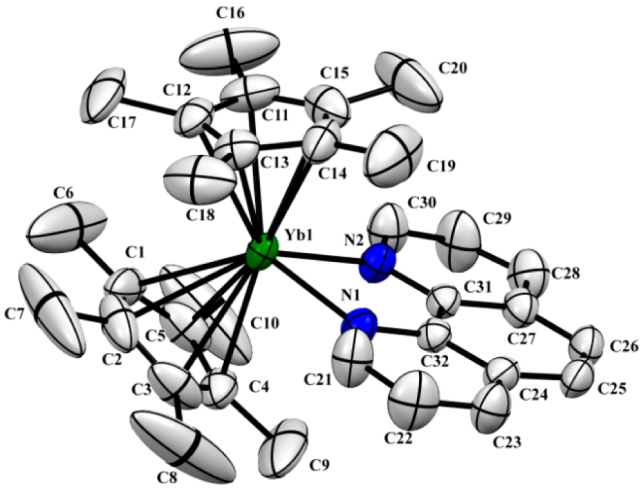

Figure 5. ORTEP for sublimed $Cp^*_2Yb(phen)$ (**1-monomer, sublimed**) (thermal ellipsoids at 50% level). Ytterbium atom is in green, nitrogen atoms in blue, and carbon atoms in gray. All non-hydrogen atoms are refined anisotropically, and the hydrogen atoms are placed in calculated positions but not refined. Hydrogen atoms have been omitted for clarity.

molecules in the unit cell shown in Figure 7b. These results contrast with the X-ray crystal structures of crystallized Cp*Yb(phen) (**1-dimer, crystallized**) and Cp*Yb(3,8-Me_2phen) (**3**), which are dimers. Crystals of the latter two compounds, obtained from toluene solution are deep blue and deep purple in color, respectively. ORTEP's of **1-dimer** and **3** are shown in Figure 8 and Figure 9, respectively. It is clear that the anionic partner is derived by dimerization of two phenantholine radical anions by formation of a C−C bond at the 4,4′-positions, forming the diamagnetic dianionic partner. Similar, reductively driven bond formation between f-metal complexes is observed in uranium Schiff base complexes in which C−C bonds are formed upon reduction.[31,32]

These results provide a simple explanation for the questions raised by the solid state magnetic moments and EPR spectra of the neutral adducts. In **1-dimer** and **3**−**6**, the substituted phen radical anions are coupled, forming a diamagnetic, dianionic ligand, which bridges two cationic [Cp^*_2Yb] fragments. Accordingly, all of these compounds are EPR active, and their magnetic moments and XANES spectra are consistent with the presence of Yb(III). Only two compounds, **1-monomer** and **7-monomer**, actually contain radical anionic ligands, which can be seen in the increase in the magnetic moment of **1-monomer** relative to that of **1-dimer** and in the EPR inactivity of **7-monomer**.[30]

Bond distances and angles in the phenanthroline adducts of ytterbocenes are shown in Table 4. The Yb−C(Cp*) distances in the neutral and cationic adducts of Cp^*_2Yb are identical, given the large range in the individual values. The Yb−C(Cp*) distances are approximately 0.1 Å shorter than in $Cp^*_2Yb(py)_2$[33] and [1,3-$(Me_3Si)_2C_5H_3$]Yb(phen),[14] consistent with the higher oxidation number of ytterbium in the phenanthroline adducts of Cp^*_2Yb. It is particularly noteworthy that the Yb−C(Cp*) distances are identical in the monomeric and dimeric forms of $Cp^*_2Yb(phen)$.

The Yb−N distances, however, show significant differences in the neutral adducts, depending upon whether they are monomers or dimers. In monomeric $Cp^*_2Yb(phen)$, the average Yb−N distance is 2.311 ± 0.002 Å, identical to that in $Cp^*_2Yb(5,6\text{-}Me_2phen)$ of 2.318 ± 0.007 Å. In the dimeric forms of $Cp^*_2Yb(phen)$ and $Cp^*_2Yb(3,8\text{-}Me_2phen)$, the average Yb−N distances of 2.322 ± 0.018 Å and 2.324 ± 0.016 Å are the same as those found in the monomers, but the individual distances differ by 0.08 to 0.06 Å, respectively. Thus, the Yb−N(1) distances of 2.358(5) Å and 2.366(4) Å in **1-dimer** and **3**, respectively, are similar to those found in

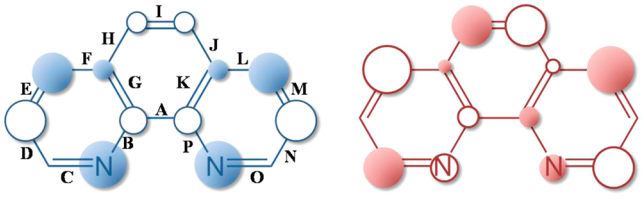
[Cp*$_2$Yb(phen)]I of 2.339(8) Å and 2.382(8) Å,[14] but the Yb−N(2) distances of 2.285(4) Å and 2.301(5) Å, respectively, are shorter and indicative of an amide nitrogen-to-Yb(III) bond. This conjecture, viz., that longer Yb−N bond lengths in the dimers are due to a Yb(III)−N (dative) bond and the shorter distances are due to a Yb(III)−N (anionic) bond is supported by comparison between the C−N and C−C bond distances in the individual pyridyl rings in **1-dimer** and **3** shown in Table 7 (see below). The trends in these bond lengths in the phenanthroline rings in both dimers are consistent with the formulation of the N(1) pyridine ring as a neutral pyridine and the N(2) ring as 4-hydropyridyl, in which N(2) carries a negative charge. These bond lengths are in sharp contrast to those observed in the monomeric adducts, Cp*$_2$Yb(phen) and Cp*$_2$Yb(5,6-Me$_2$phen), as shown in Table 8 (see below). In these two adducts, the small differences between C−N and C−C distances in the pyridine rings containing N(1) and N(2) are consistent with their formulation as delocalized radical anions.

In the Cp*$_2$Yb(x,x′-bipy) adducts, the changes in the C(2)−C(2′) provide qualitative insights into the ground state electronic structure of these adducts.[4,5] In these charge-transfer complexes, the SOMO of the bipyridine radical-anion has b_1 symmetry (in C_{2v} symmetry), and the C(2)−C(2′) distance, represented by A in Scheme 1, shortens relative to the

Scheme 1. b_1 and a_2 Representations and Bond Labeling



equivalent distance in the free bipyridine ligand, since these C-pπ-orbitals are a bonding combination. A related analysis of the C−N and C−C distances in the phenanthroline adducts is not as straightforward since (i) the distance represented by A is part of a rigid-ring system and (ii) the LUMO and LUMO+1 orbitals of b_1 and a_2 symmetry (in C_{2v} symmetry), respectively, are close in energy, Figure 10, and population of these bonding and antibonding orbitals results in a complex pattern of bond length alterations since these pπ-orbitals have different nodal properties and coefficients. However, a systematic examination of all the anticipated changes when either b_1 or a_2-symmetry

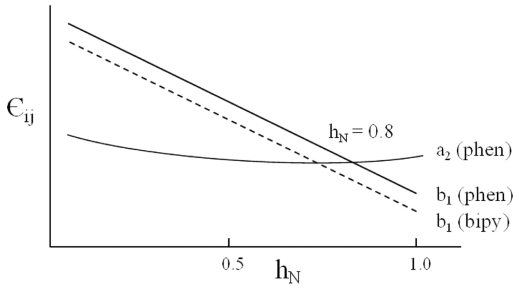


Figure 10. Relative energy diagram of the b_1 and a_2 symmetry orbitals in bipy radical anion and phen radical anion as a function of the Coulombic integral on N, h_N.[42]

orbitals are singly occupied generates an informative pattern. The four pairs of distances labeled as C and O, E and M, D and K, G and N in Scheme 1 change in identical ways when either b_1 or a_2 is singly occupied. In contrast the distances labeled A, I,; F and L, B and P, H and J change in opposite directions as shown in Tables 5 and 6.

Table 5. Anticipated Bond Lengths Changes in LUMO and LUMO+1 of Phenanthroline Radical Anion

	orbital[a]	
bond	LUMO, b_1	LUMO+1, a_2
A	−	+
I	−	+
F,L	−	+
B,P	+	−
H,J	+	−

[a]+ means the distance increases, − means the distance decreases, when these orbitals are occupied.

The pattern of bond length changes in monomeric Cp*$_2$Yb(phen) is inconsistent with population of either b_1- or a_2-orbitals but consistent with population of both orbitals. The pattern of bond length alteration in Cp*$_2$Yb(5,6-Me$_2$phen) is somewhat different from that found in Cp*$_2$Yb(phen), which implies that the b_1/a_2 ratio is higher in the former adduct and that methyl groups in the 5,6-positions stabilize the b_1 orbital. These inferences are consistent with the calculational results described below.

The geometry of the phenanthroline ligands in the two dimers, Cp*$_2$Yb(phen), **1**, and Cp*$_2$Yb(3,8-Me$_2$phen), **3**, is similar, but the crystallographic details are different (Figures 8 and 9). In **1**, the C(28)−C(28′) atoms have well-behaved

Csp^3−Csp^3 bond lengths of 1.507 Å (σ = 0.015 Å).[36] The C − N distances, Table 7, are also in the range of Csp^3−N distances of 1.358 Å (σ = 0.015 Å).[35] These distances and angles in the N(2)-ring indicate that the pyridyl ring is represented by a quinoid distortion and the nitrogen atom carries a negative charge.

The orientation of the two phenanthrolyl rings in the crystal structure is shown by the Newman projection down the C(28)−C(28′) bond, Scheme 2. The molecule in the left-hand drawing has C_i symmetry, and the inversion center is the midpoint of C(28)−C(28′). The Newman projection of another rotomer of C_2 symmetry is shown in the right-hand drawing.

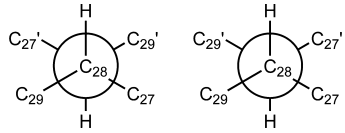
Scheme 2



The description of the geometry around C(28) in the $Cp^*_2Yb(3,8\text{-}Me_2phen)$, **3** is less straightforward since two positions for the C(28) atom are occupied (C(28) and C(28B)). While solving the structure, a singularity appeared at atom C28. The problem is addressed in two ways: (i) the C28 atom is forced to remain in the mean plane of ring 2 and (ii) a positional disorder model in which C28 and C28B are assigned an occupancy ratio of 0.67:0.33, respectively. Solution (i) led to an elongated thermal ellipsoid perpendicular to the mean plane of ring 2; Figure S22 representing this tentative solution is shown in the SI. In this representation the C(28)−C(28′) distance is 3.00 Å. Solution (ii) led to well-behaved thermal ellipsoids for C(28) and C(28B), but their positions differ; C(28) is comparable to that of the C(28) atom in **1-dimer** with elongated C(28)−C(29,27) distances (see Table 7) of 1.529(9) Å and 1.547(9) Å, respectively, and a C(28)−C(28′) distance of 1.592(16) Å. This is compatible with the presence of a σ-dimer; that is, the bond between C(28)−C(28′) is classified as a σ-bond between two sp^3 carbons. On the other hand, C(28B) is found close to the mean plane of ring 2 with C(28B)−C(29,27) distances of 1.478(18) Å and 1.417(19) Å and a C(28B)−C(28B′) distance of 3.39 Å (calculated), compatible with its classification as a π-dimer, that is, a bond formed by interaction between the p_π-orbitals on the sp^2 hybridized carbon atoms. The disorder in $Cp^*_2Yb(3,8\text{-}Me_2phen)$, **3**, may be viewed as the average between these two forms (σ-dimer and π-dimer) in which the energy difference between them is small.

RESULTS: SOLUTION PROPERTIES

Vis−NIR Spectra. The vis−NIR spectra in the 400−950 nm range in toluene solution at 20 °C for the crystallized adducts of 4-Mephen (**5**) and 5-Mephen (**6**) are similar to the spectrum of $Cp^*_2Yb(phen)$ (**1**) reported in an earlier paper.[14] The spectra are available in SI. Morris and co-workers have given a detailed analysis of the solution spectra from 400 to 2500 nm of $[Cp^*_2Yb(phen)]^{0,+}$.[6] The key point that emerges from these spectroscopic studies is that the spectra of the neutral adducts contain features associated with the phenanthroline radical anion, an absorption around 500 nm, along with f−f transitions at longer wavelengths.

^{1}H NMR Spectra. The chemical shifts in C_6D_6 or C_7D_8 at 300 K for the neutral adducts are given and assigned in Table 9. The $Cp^*_2Yb(phen)$, $Cp^*_2Yb(3,8\text{-}Me_2phen)$ and $Cp^*_2Yb(5,6\text{-}Me_2phen)$ adducts have four resonances due to the phenanthroline ligands in the general region of δH ≈ 100, ∼50, ∼15, and ∼0 ppm, in addition to the Cp* resonance at δH ≈ 4 ppm. The resonances that can be assigned with certainty are those at δH ≈ 15 ppm since these are replaced by a resonance due to the Me-groups at δH ≈ −10 ppm in **3**, and therefore, the δH ∼ 15 ppm resonance is due to $\delta_{3,8}$. The resonances at δH ≈ 0.5 ppm are replaced by a resonance due to the Me-groups at δH ≈ 0.03 ppm in **7**, and therefore, the δH ≈ 0.5 ppm is due to $\delta_{5,6}$. The most deshielded resonances are assigned to $\delta_{2,9}$ since these are closest to the paramagnetic center, and the remaining resonances at δH ≈ 50 ppm are due to $\delta_{4,7}$. The appearance of four phen resonances shows that the adducts have C_{2v} symmetry in solution at 300 K. The chemical shifts of $Cp^*_2Yb(3,8\text{-}Me_2phen)$ depend upon the solvent; in THF the most downfield resonance in C_7D_8 moves upfield by about 20 ppm, while the other resonances shift by a lesser amount (see Experimental Section). The eight resonances in the 5-Mephen adduct are consistent with a single isomer of C_s symmetry at 300 K, but those in the 4-Mephen adduct are not observed at 300 K, while only some of the resonances for the 3-Mephen adduct are observed. The low solubility of the neutral adducts precludes a more detailed study with exception of the $3,8\text{-}Me_2phen$ and $5,6\text{-}Me_2phen$ adducts that are somewhat more soluble in THF and toluene.

Variable-Temperature ^{1}H NMR of $Cp^*_2Yb(3,8\text{-}Me_2phen)$ (3). Dissolution of the crystals of the complex **3** in toluene and THF is kinetically slow, in agreement with strong packing forces in the solid state, but gently warming (60 °C) the solution over a period of 1 or 2 days gives saturated solutions that allow ^{1}H NMR spectroscopic measurements at variable temperatures. At room temperature, both toluene-d_8 and THF-d_8 solution of **3** are deep red and show one major set of five resonances in a 2:2:2:30:6 ratio. This is in agreement with the presence of monomeric $Cp^*_2Yb(3,8\text{-}Me_2phen)$ with C_{2v} symmetry in which the phenanthroline ligand is symmetrically disposed relative to the Cp^*_2Yb fragment, and these resonances are designated by the letter S for "symmetric". Small resonances are also present, contributing less than 5% of the peak intensity. When the toluene-d_8 and THF-d_8 solutions are cooled, these low-intensity resonances grow at the expense of the resonances assigned to the monomeric $Cp^*_2Yb(3,8\text{-}Me_2phen)$ complex (S). The solutions change color from deep red at room temperature to purple at 250 K and blue at 200 K. The ^{1}H NMR spectra at low temperature in both solvents show three different sets of resonances; one set of five resonances attributed to the S isomer, the monomeric form of **3**, and in two other sets of resonances, labeled A_1 and A_2 (A for asymmetric), in which the methyl resonances are not equivalent, in agreement with the formation of a dimer, Figure 9 and Scheme 2. Ten resonances are expected for each isomer in a ratio 2:2:2:2:2:2:6:6:30, although some resonances were not located in a −100 to 100 ppm window. The ratio of the two asymmetric isomers A_1 and A_2 is approximately 60:40 in toluene and 55:45 in THF, and the ratio is only slightly dependent on temperature, given the errors of the integration.

Two pairs of A resonances are attributed to the methyl groups based on the integration ratio and are highlighted by the red dots in Figure 11. These resonances are integrated and related to the S-methyl resonance that is highlighted by a blue dot in Figure 11. The relative change in population of these methyl group resonances is used to obtain the van't Hoff plot in Figure 12; the details are provided in the Experimental Section. The thermodynamic parameters for the equilibrium shown in eq 2, where M is the symmetric (S) monomer and D the asymmetric (A_1 + A_2), dimer, set of resonances, are determined from this plot.

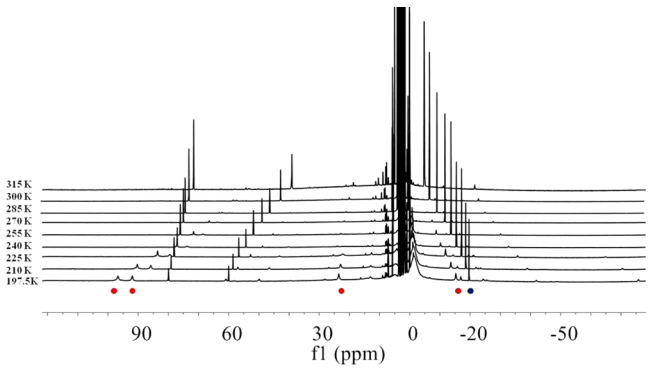

Figure 11. Stacked plot of ^{1}H NMR spectra in function of the temperature in THF. Red dots are the resonances used for integration of the asymmetric species and the blue dot for the symmetrical species.

$$2M \overset{K_1}{\rightleftharpoons} D \qquad (2)$$

dx.doi.org/10.1021/ja502271q | J. Am. Chem. Soc. 2014, 136, 8626−8641

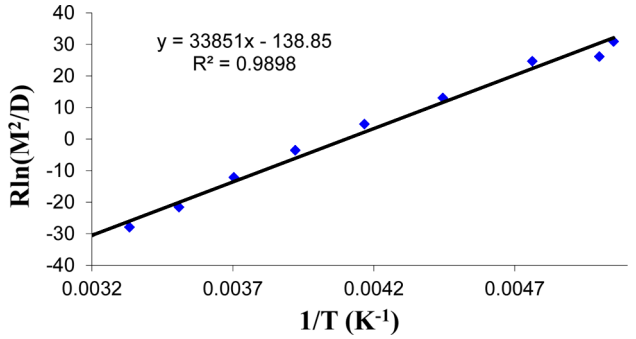

Figure 12. van't Hoff plot of the equilibrium reaction 2 M = D in toluene (M is **3** as a monomer, D corresponds to the two dimeric isomers). The plot of $R\ \ln(K)$ ($K_1 = D/M^2$) vs $1/T$ yields ΔH^0 = −8.1(2) kcal/mol, ΔS^0 = −31(1) cal/mol/K and K_1 (25 °C) = 0.48 M^{-1}.

The resulting ΔH values are −5.8 kcal/mol and −8.1 kcal/mol in THF and toluene, respectively, and the ΔS values are −26 kcal/mol/K and −31 kcal/mol/K in THF and toluene, respectively. At 298 K, the value of the dimerization constant (K_1) is 0.050 ± 0.005 M^{-1} in THF and 0.48 ± 0.01 M^{-1} in toluene. A similar pattern of ΔH and ΔS values are reported by Kochi and co-workers for the π-radical tricyclic phenalenyl.[37] When a large excess of dihydroanthracene is added to a C_7D_8 solution of Cp^*_2Yb(phen) and heated to 60 °C for a period of 2 days, no anthracene is formed, implying that the phenanthrolyl radical does not behave as a free radical.

CALCULATIONS

The CASSCF methodology used in previous papers for the bipyridine adducts of Cp^*_2Yb is extended to the monomeric phenanthroline adducts, Cp^*_2Yb(phen) (**1**), Cp^*_2Yb(3,8-Me_2phen) (**3**) and Cp^*_2Yb(5,6-Me_2phen) (**7**). The calculated ground state of Cp^*_2Yb(phen) is composed of two nearly degenerate triplet states, T_1 and T_2, which are 2.12 eV lower in energy than an open-shell singlet state. The state configuration for the f-orbitals are therefore pure (100%) f^{13} and the T_1 and T_2 configuration for the π^*-orbitals are 0.72 π^*_1 + 0.28 π^*_2 and 0.28 π^*_1 + 0.72 π^*_2, respectively. The calculated charge-transfer ground state is in accord with the observation of two LMCT bands near 500 cm^{-1} in the vis−NIR spectrum in toluene solution.[6] The calculated ground states for the 3,8-Me_2phen and 5,6-Me_2phen adducts are similar to each other but somewhat different than that of the unsubstituted phenanthroline adduct. Thus, the calculated ground states are spin triplets (pure f^{13}), but the open-shell singlet states are only 0.08 and 0.09 eV higher in energy, respectively. The excited-state open-shell singlets are multiconfigurational in which the dominant configuration is f^{13}; in 3,8-Me_2phen, the f^{13}:f^{14} contributions are 0.75:0.25, and the π^*_1 is the only configuration that contributes. In the 5,6-Me_2phen adduct, the f^{13}:f^{14} contributions in the excited open-shell singlet state are 0.85:0.15, and the π^*_1 and π^*_2 contributions are 0.95 and 0.05, respectively.

The calculated spin triplet ground states in these three phenanthroline adducts are in dramatic contrast with the open-shell singlet ground states obtained in all the bipyridine adducts of Cp^*_2Yb. The calculated singlet−triplet separation is 0.28 eV in Cp^*_2Yb(bipy), singlet lowest and 2.12 eV in Cp^*_2Yb(phen) with the triplet lowest. Thus, the triplet energies and therefore the ground state electronic structure change by 2.4 eV, about 60 kcal·mol^{-1}, just by changing the ligands.

The dimerization reaction is studied by DFT calculations. The Cp* rings are replaced by Cp in these calculations since the full system for the dimer is prohibitively large. A transition state is calculated to be 15.4 kcal·mol^{-1} (in Gibbs energy) above the monomers, and the dimerization reaction is exoergic by 3.1 kcal·mol^{-1} (Figure 13), consistent with the experimental

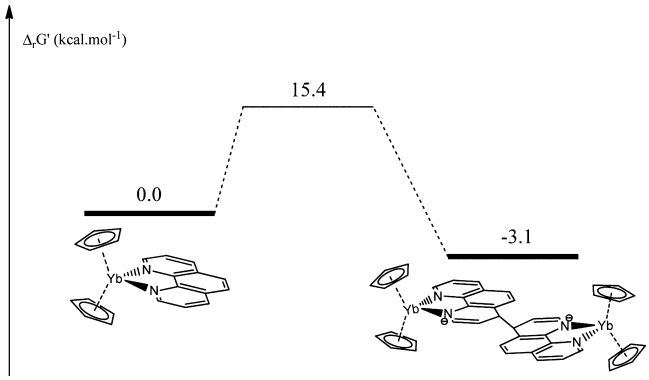

Figure 13. Reaction coordinate diagram for dimerization of Cp_2Yb-(phen).

observation that Cp^*_2Yb(phen) is a dimer. The calculated distance of the C−C bond formed in 4,4′-positions (1.596 Å) is in reasonable agreement with the elongated C−C bond found in the solid state structure (1.619 Å). The transition state, Figure S26 in SI, involves two molecules of Cp_2Yb(phen) with bond distances similar to those calculated for the dimer, but with a σ C−C bond distance of 1.800 Å.

DISCUSSION

Although the molecular geometry of monomeric Cp^*_2Yb-(phen) is similar to that found in the wide range of bipyridine adducts, their electronic structures are different.[4,5,14] The ground state electronic structure of the bipyridine adducts are open-shell singlets that are multiconfigurational in which the ground state wave function, Ψ is $C_1|f^{13}$, $bipy^{\bullet-}$> + $C_2|f^{14}$, bipy>, where C_1 and C_2 are coefficients of the two configurations. For Cp^*_2Yb(bipy), C_1^2 = 0.83.[4] This results in the ytterbium atom being intermediate valent; that is, it is neither Yb(III), f^{13}, nor Yb(II), f^{14} but in between these extreme values in which the f^{13} configuration is dominant. The open-shell singlet ground state (or states) determines the magnetic properties of these adducts, and in the case of the 4,5-diazafluorene adduct, is postulated to be the origin of the chemical reactivity.[38]

In contrast, the monomeric phenanthroline adducts, Cp^*_2Yb(phen) and Cp^*_2Yb(5,6-Me_2phen), have open-shell triplet ground states, and the valence of ytterbium is fully trivalent. The CASSCF computational studies on Cp^*_2Yb-(phen) indicate that two open-shell triplets are nearly degenerate and are some 2 eV lower in energy than the open-shell singlet state, consistent with the magnetic studies and the L_{III} edge XANES. The computational studies on Cp^*_2Yb(5,6-Me_2phen) indicate that the triplet lies below the open-shell singlet by only 0.09 eV. A model that accounts for the different electronic ground states in the bipy and phen adducts is outlined next; the model is offered as a qualitative guide for what is known and as a guide for future experimental studies.

Whether a monomeric ytterbocene diimine complex has a triplet or singlet ground state is largely governed by kinetic

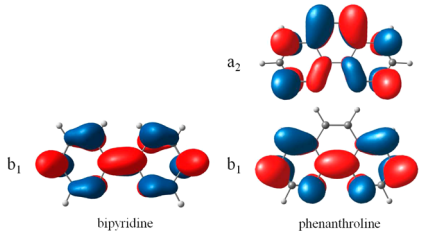
dx.doi.org/10.1021/ja502271q | J. Am. Chem. Soc. 2014, 136, 8626−8641

exchange, that is, by mixing of excited state configurations into the ground state.[39,40] The interaction between the half-occupied ligand orbital and a half-occupied 4f-orbital stabilizes the singlet state, while interactions between the half-occupied ligand orbital and the empty metal-based orbitals on the Cp^*_2Yb fragment, especially the 5d-orbitals, stabilize the triplet state. To a first approximation, the strength of the interactions between the half-occupied ligand orbital and the metal orbitals are proportional to the square of the overlap and inversely proportional to the difference in energy between the ligand and metal orbitals. Since the overlap between the ligand orbitals and the Yb 5d orbitals is anticipated to be significantly larger than the overlap with the Yb 4f orbitals, whether the ground state is a singlet or triplet depends in large part on the energies of the ligand orbitals.[42] If the half-occupied ligand orbital is close in energy to the 4f-orbitals and has the proper symmetry to overlap with the lone half-filled Yb 4f-orbital, the singlet state is likely to be lowest in energy. However, if the half-occupied ligand orbital is not close in energy to the 4f orbitals or does not have the proper symmetry to overlap with the half-occupied Yb 4f orbital, the interaction between the half-occupied ligand orbital and the Yb 5d orbitals will be stronger, and the triplet state will be stabilized. If the ligand has empty orbitals close in energy to the half-occupied orbital, the ground state could be either a singlet or triplet, depending on whether the interaction between the ligand orbitals and the singly occupied 4f-orbital is greater or weaker than the interactions with the empty 5d orbitals.

In Cp^*_2Yb(bipy), the open-shell singlet is calculated to be 0.28 eV below the triplet, and the experimental value of the singlet−triplet energy difference is about 0.1 eV by comparing to the Hubbard model.[11] When an f-electron is transferred to the LUMO, only one of the four possible π^*-orbitals, the b_1-orbital, is of sufficiently low energy to be populated, and the unpaired spin density is distributed among the pπ-orbitals on the C and N atoms of the bipyridine ligand. In this case, the half-occupied ligand orbital and the half-occupied Yb 4f orbital are close in energy and have the same symmetry, b_1, so the kinetic exchange configuration interaction stabilizes the open-shell singlet. This model fits all of the experimental and computational studies associated with the bipy adducts.[4,5]

In contrast, the LUMO and LUMO+1 of phenanthroline are close in energy (Figure 10, Chart 1) so that when electron

Chart 1



transfer occurs, the electron occupies either the π^*_1 and/or π^*_2 orbitals, which have b_1 and a_2 symmetry, respectively (in C_{2v} symmetry). The ordering of these orbitals can be inverted by methyl group substituents in the solvent separated radical-anions as shown by EPR studies. Thus, $phen^{\bullet-}$,[42] 2,9-$Me_2phen^{\bullet-}$,[43] 4,7-$Me_2phen^{\bullet-}$,[42] and 5,6-$Me_2phen^{\bullet-}$[43] have $^2B_1$ ground states but 3,4,7,8-$Me_4phen^{\bullet-}$ has a $^2A_2$ ground state.[44] As in Cp^*_2Yb(bipy), the b_1 orbital will be stabilized by interaction with the half-filled Yb 4f-orbital, which stabilizes the singlet state. This assumes that the orbital from which the electron on the close-shell Cp^*_2Yb metallocene is removed does not undergo reorganization; that is, the hole remains in a b_1 symmetry orbital. The a_2 orbital will not be stabilized by Yb 4f-orbitals since the single half-occupied orbital has b_1 symmetry. The ligand a_2 orbital can be stabilized by interaction with the empty Yb 5d orbitals. If the a_2 orbital is half-occupied, the triplet ground state will be stabilized, which is the case for all of the monomeric ytterbocene phenanthroline complexes reported here.

The difference between the bipyridine and phenanthroline adducts can be illustrated using a MO diagram as illustrated in Figure 14. While the MO model does not capture the

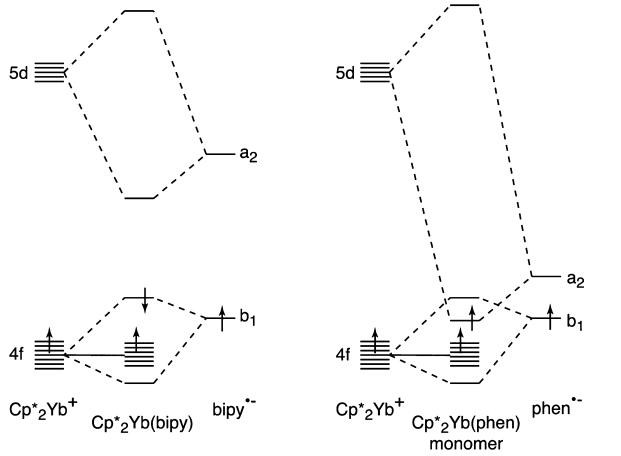


Figure 14. Qualitative MO diagram comparing bonding in Cp^*_2Yb(bipy) and Cp^*_2Yb(phen) monomer. Only the unpaired 4f electron is illustrated; the orbitals below those with arrows are filled. The direction of the arrows indicates the ground state; Cp^*_2Yb(bipy) has a singlet ground state, while Cp^*_2Yb(phen) has a triplet ground state.

stabilization of the triplet or singlet state due to configuration interaction, the stable spin state is indicated by the relative spins of the electrons as indicated by the arrows in Figure 14. Figure 14 illustrates two extreme cases that are possible for two spins. This diagram may be extended to the specific examples of Cp^*_2Yb(diimine) since the symmetry orbitals of bent sandwich metallocenes are well-known.[45,46] The d-orbitals that are empty, once the diimine σ-bonds are created, are the nonbonding $a_1(d_{x2-y2})$ metal-based orbital and the higher-lying Cp*−Yb antibonding $d_{xy,yz}$ ortbitals of b_1 and a_2 symmetry. The seven f-orbitals occupied by 13 electrons are considered to be nonbonding and much lower in energy than the d-parentage orbitals. In the bipy adducts, Figure 14, left-hand side, the hole in the f-orbitals has b_1-symmetry as does the electron in the ligand-based orbital. As these two electrons have the same symmetry, they can mix to give a singlet state, following the Pauli principle. This model accounts for the electronic ground states of Cp^*_2Yb(bipy).[4,5]

Extending this MO model to the phenanthroline adducts is complicated by the fact that either the b_1 or a_2 orbitals or both are populated, depending upon their relative energies, Figure 10. Thus, three idealized cases may be considered, (i) b_1 lies lower than a_2, (ii) a_2 lies lower than b_1, and (iii) b_1 and a_2 are of similar energy. Case (i) results in an orbital pattern found in bipy, Figure 14, left-hand side. Case (ii) results in a similar orbital pattern, except that the b_1 and a_2 orbital are

dx.doi.org/10.1021/ja502271q | J. Am. Chem. Soc. 2014, 136, 8626−8641

interchanged. Both of these cases can result in singlet ground states. Case (iii), Figure 14, right-hand side, is applicable to the phen adducts described above. Thus, an electron in the a_2-ligand-based orbital is stabilized by interaction with a d_π orbital of a_2 symmetry on the Cp^*_2Yb metallocene resulting in the a_2-MO below the b_1-MO, resulting in a spin-triplet ground state, since the hole in the f-manifold is in a b_1 symmetry orbital. Case (iii) illustrates how methyl substitutents change the relative energies of the b_1 and a_2-orbitals, generating a model for how the magnetic properties are controlled by the b_1-a_2 separation.

Inspection of the b_1-orbital in $phen^{\bullet-}$ shows that the spin density is more likely to reside on N, C(2,9), C(3,8), and C(4,7) whereas in the a_2-orbital the spin density is likely to be found on C(2,9), C(4,7) and C(5,6), Chart 1. Thus, the unpaired spin density on N is greater in the b_1-orbital than in the a_2-orbital. Population of the a_2-orbital increases spin density on pπ-orbitals of C(4,7), which is the site of C−C bond formation in the dimer. Thus, substituents on the phenanthroline ring in the ytterbocene adducts modulates the unpaired spin density of the pπ-orbitals and the radical character at a given site and therefore the site at which chemical reactions occurs.

Dimerization of two σ-carbon radicals forming a σ-C_2 single bond involves two enthalpy changes with opposite signs. The exothermic term involves C−C bond formation, about 80−85 kcal·mol^{-1}, and the endothermic term is due to loss of resonance stabilization in the σ-radical, estimated to be about 35 kcal·mol^{-1} per radical.[37] The net enthalpy changes favor dimerization but loss of entropy results in ΔG being close to zero.

CONCLUSION

The key conclusion in this article is that the electronic ground states for Cp^*_2Yb(phen), the 3,8-, and the 5,6-dimethyl adducts are different from those of Cp^*_2Yb(bipy) and its methyl and dimethyl-substituted adducts; the ground state of monomeric Cp^*_2Yb(phen) and its adducts is a spin triplet, and the valence of ytterbium is trivalent. In contrast, the ground state of Cp^*_2Yb(bipy) is a multiconfigurational open-shell singlet, and ytterbium is intermediate valent. The chemical manifestation of this difference is that the solid state structure of the sublimed phenanthroline adduct is a monomer, but that of the crystallized adduct is a dimer in which the phenanthroline ligands are coupled by formation of a C−C bond between the carbons at the 4-position. The 3,8-Me_2phenanthroline adduct is similar, but in this case the monomer and dimer are in equilibrium in toluene-d_8 or in tetrahydrofuran-d_8 with values of ΔH of −8.1 kcal/mol and −5.8 kcal/mol, respectively, and ΔS values of −31 kcal/mol/K and −26 kcal/mol/K, respectively. The origin of the different physical and chemical properties is postulated to arise from the different symmetry orbitals available in the $phen^{\bullet-}$ and $bipy^{\bullet-}$; the former has two accessible orbitals of b_1 and a_2 symmetry (in C_{2v}), while the later has only one of b_1 symmetry. Even though the ground state electronic structure of Cp^*_2Yb(bipy) and Cp^*_2Yb(phen) are different, the solution (thf) electrochemistry study of these two adducts shows that both of the charge-transfer ground states are stabilized by the same amount, 0.79 V (18.4 kcal·mol^{-1}) relative to Cp^*_2Yb(II) in thf.[6] This difference results in the same value of the comproportionation constant, K_c = $10^{-13.4}$ for each adduct, eq 3.

$$Cp^*_2Yb(III)(L) + Cp^*_2Yb(II)(L^-) \rightleftharpoons 2Cp^*_2Yb(III)(L^-) \quad (3)$$

At first glance, this thermodynamic statement is surprising given the different electronic ground states; however, the major contribution to the bond enthalpy in both adducts is from interaction between the cationic and anionic fragments, and the change in electronic structure is a small contribution to ΔG.

EXPERIMENTAL SECTION

General Considerations. All reactions were performed using standard Schlenk-line techniques or in a drybox (MBraun). All glassware was dried at 150 °C for at least 12 h prior to use. Toluene, pentane, and diethyl ether were dried over sodium and distilled, while CH_2Cl_2 was purified by passage through a column of activated alumina. Toluene-d_8 was dried over sodium, and CH_2Cl_2-d_2 was dried over calcium hydride. All the solvents were degassed prior to use. ^{1}H NMR spectra were recorded on Bruker AVB-400 MHz, DRX-500 MHz, AVB-600 MHz and Avance 300 MHz spectrometers. ^{1}H chemical shifts are in δ units relative to TMS, and coupling constants (J) are given in Hz. Infrared spectra were recorded as Nujol mulls between KBr plates on a Thermo Scientific Nicolet IS10 spectrometer. Samples for UV−vis−NIR spectroscopy were contained in a Schlenk-adapted quartz cuvette and obtained on a Varian Cary 50 scanning spectrometer. Melting points were determined in sealed capillaries prepared under nitrogen and are uncorrected. Elemental analyses were determined at the Microanalytical Laboratory of the College of Chemistry, University of California, Berkeley. X-ray structural determinations were performed at CHEXRAY, University of California, Berkeley. Magnetic susceptibility measurements were made for all samples at 1, 5, and 40 kOe in a 7 T Quantum Design Magnetic Properties Measurement System that utilizes a superconducting quantum interference device (SQUID). Sample containment and other experimental details have been described previously.[47] It is important to note that the susceptibility values obtained when the samples were contained in Kef-F containers and quartz tube are identical within experimental errors.[14] Diamagnetic corrections were made using Pascal's constants. The samples were prepared for X-ray absorption experiments as described previously, and the same methods were used to protect these air-sensitive compounds from oxygen and water contamination.[5] The samples were loaded into a LHe-flow cryostat and X-ray absorption measurements performed at the Stanford Synchrotron Radiation Lightsource on beamline 11-2. Data were collected at temperatures ranging from 30 to 300 K, using a Si(220) double-crystal monochromator. Fit methods were the same as described previously.[5] Reported spectra were energy calibrated by setting the first inflection point of the absorption spectrum on a Yb_2O_3 reference sample to 8943 eV. Low temperature (~2 K) EPR spectra were obtained with a Varian E-12 spectrometer equipped with an EIP-547 microwave frequency counter and a Varian E-500 gaussmeter, which was calibrated using 2,2-diphenyl-1-picrylhydrazyl (DPPH, g = 2.0036).

Calculations. The ytterbium atom was treated with a small-core relativistic pseudopotential (RECP) ([Ar] + 3d)[48] in combination with its adapted basis set (segmented basis set that includes up to g functions). The carbon, nitrogen, and hydrogen atoms were treated with an all-electron double-ζ, 6-31G(d,p).[49] All the calculations were carried out with the *Gaussian* 03 suite of programs,[50] *ORCA* suite of programs,[51] either at the density functional theory (DFT) level using the B3PW91[52] hybrid functional or at the CASSCF level; only one active space and inactive orbitals were used in the calculation. The geometry optimizations were performed without any symmetry constraints at either the DFT or the CASSCF level. The electrons were distributed over four 4f orbitals and the two π^* orbitals of phenanthroline.

Syntheses. The ligands, 1-10-phenanthroline (phen) and 4-methylphenanthroline (4-Mephen) were purchased from Aldrich, while 5-methylphenanthroline (5-Mephen) was obtained from Tokyo Kasei Kokyo Co. All ligands were purified by sublimation between 80

and 200 °C/10^{-2} mm prior to use. The ligands, 3-methyl-1,10-phenanthroline (3-Mephen) and 3,8-dimethyl-1,10-phenanthroline (3,8-Me_2phen), were synthesized according to a published procedure[53] and sublimed at 140 °C/10^{-2} mmHg prior to use. ^{1}H NMR (3-Mephen): (CD_3Cl, 295 K, δ (ppm)) 9.18 (d, J = 7.8 Hz, 1H), 9.03 (s, 1H), 8.23 (d, J = 7.8 Hz, 1H), 8.02 (s, 1H), 7.74 (dd, J = 7.6, 3.2 Hz, 1H), 7.74 (d, J = 7.2 Hz, 1H), 7.61 (dd, J = 7.3, 3.2 Hz, 1H), 2.61 (s, 3H). ^{1}H NMR (3,8-Me_2phen): (CD_3Cl, 296 K, δ (ppm)) 9.05 (s, 2H), 8.64 (s, 2H), 7.74 (s, 2H), 2.64 (s, 6H).

$Cp^*_2Yb(phen)$ (1). The complex $Cp^*_2Yb(OEt_2)$ (0.217 g, 0.420 mmol) was combined with 1,10-phenanthroline (0.095g, 0.420 mmol), and toluene (30 mL) was added at room temperature. The resulting purple/blue solution was stirred for 2 h at room temperature as a dark powder formed. The suspension was cooled at −20 °C, and the dark-colored powder was collected by filtration (125 mg, 83%). The dark powder was washed with toluene (3 × 5 mL) and was heated in toluene (20 mL, 80 °C), filtered while hot, and slowly cooled at room temperature and then at −20 °C. The dark, microcrystalline purple powder was collected by filtration and dried under reduced pressure (70 mg, 47%). An alternative method was used in order to obtain crystals suitable for X-ray diffraction data collection by crystallization from toluene. A toluene solution of 1,10-phenanthroline (0.033 g, 0.186 mmol) was carefully layered at the top of a toluene solution of $Cp^*_2Yb(OEt_2)$ (0.096 g, 0.186 mmol). Slow diffusion of the two solutions overnight (16 h) resulted in formation of X-ray quality crystals at the interface and along the walls of the Schlenk flask that were collected by filtration and dried under reduced pressure (75 mg, 68%). Mp 295−297 °C (lit 297−300 °C).[14] ^{1}H NMR: (toluene-d_8, 299 K, δ (ppm)) 139.94 (2H, phen), 47.87 (2H, phen), 14.02 (2H, phen), 4.14 (30H, Cp*), 0.47 (2H, phen). Crystals of $Cp^*_2Yb(phen)$ are sparingly soluble in C_7D_8 or THF-d_8. The ^{1}H NMR spectrum was obtained from a warmed concentrated C_7D_8 solution measured at 299 K. Anal. Calcd for $C_{32}H_{38}N_2Yb$: C, 61.62; H, 6.14; N, 4.49. Found: C, 61.99; H, 6.04; N, 4.45. $Cp^*_2Yb(3,8\text{-}Me_2phen)\cdot(C_7H_8)$ (3). The complex $Cp^*_2Yb(OEt_2)$ (0.100 g, 0.192 mmol) was combined with 3,8-dimethyl-1,10-phenanthroline (3,8-Me_2phen, 0.040 g, 0.192 mmol), and toluene (10 mL) was added at room temperature. The deep-purple solution

dx.doi.org/10.1021/ja502271q | J. Am. Chem. Soc. 2014, 136, 8626−8641

was stirred for 2 h at room temperature, concentrated to ∼5 mL, warmed to dissolve the dark residue, and the resulting dark solution was filtered while warm. The filtrate was slowly cooled at −20 °C. Dark purple-red crystals suitable for X-ray crystallography formed overnight. A second crop was obtained. (Combined yield, 82 mg, 66%). Mp: 286−288 °C. Anal. Calcd for $C_{34}H_{42}N_2Yb{\cdot}C_7H_8$: C, 66.20; H, 6.77; N, 3.77. Found: C, 65.76; H, 6.65; N, 3.38. IR (cm^{-1}): 1625 (w), 1573 (w), 1461 (s), 1410 (w), 1377 (s), 1261 (s), 1214 (w), 1153 (m), 1079 (s), 1020 (s), 861 (w), 799 (s), 728 (m), 692 (m).

Cp^*_2Yb(5-Mephen) (4). The complex $Cp^*_2Yb(OEt_2)$ (0.160 g, 0.309 mmol) was combined with 5-methyl-1,10-phenanthroline (5-Mephen, 0.060 g, 0.309 mmol). Toluene (10 mL) was added at room temperature, and the purple solution was stirred for 2 h at room temperature. The volume of solvent was concentrated to 5 mL, then cooled at −20 °C. A dark powder formed overnight which was crystallized from warm toluene (152 mg, 77%). NMR: (toluene-d_8, 300 K, δ (ppm) 138.72 (1H, phen), 138.59 (1H, phen), 47.92 (1H, phen), 39.33 (1H, phen), 14.18 (1H, Phen), 11.40 (1H, phen), 4.09 (30H, C_5Me_5), 0.06 (1H, phen), −0.58 (3H, Me-phen). mp: 280−283 °C. Anal. Calcd for $C_{33}H_{40}N_2Yb$: C, 62.15; H, 6.32; N, 4.39. Found: C, 61.74; H, 6.02; N, 4.32. IR (cm^{-1}): 1626 (m), 1605 (w), 1578 (w), 1550 (w), 1504 (m), 1444 (s), 1377 (vw), 1355 (s), 1322 (s), 1281 (m), 1221 (vw), 1161 (m), 1136 (m), 1085 (vw), 1054 (m), 994 (w), 878 (m), 807 (w), 787 (w), 773 (m), 709 (w), 696 (m).

Cp^*_2Yb(4-Mephen) (5). The complex $Cp^*_2Yb(OEt_2)$ (0.304 g, 0.588 mmol) was dissolved in diethyl ether and added dropwise over 30 min to a cold diethyl ether suspension (10 mL, −77 °C) of 4-methyl-1,10-phenanthroline (4-Mephen, 0.114 g, 0.588 mmol). While adding the phenanthroline, the suspension progressively turned to deep blue. When the addition was complete, the suspension was stirred at −77 °C for 2 h and filtered to afford a dark blue-green powder (210 mg, 56%) which was washed with cold diethyl ether (2 × 10 mL, −77 °C) and dried under reduced pressure. ^{1}H NMR: (C_6D_6, 295 K, δ (ppm), 4.03 (Cp^*), the only discernible peak. Mp: 254−256 °C. Anal. Calcd for $C_{33}H_{40}N_2Yb$: C, 62.15; H, 6.32; N, 4.39. Found: C, 62.06; H, 6.43; N, 4.55. IR (cm^{-1}): 3069 (w), 3021 (w), 2954 (s), 2724 (w), 1634 (m), 1618 (m), 1512 (m), 1445 (s), 1401 (w), 1376 (w), 1354 (m), 1321 (w), 1301 (s), 1261 (w), 1190 (w), 1157 (w), 1086 (m), 1062 (w), 1048 (w), 1022 (w), 898 (s), 858 (m), 824 (m), 800 (s), 779 (w), 767 (w), 737 (w), 691 (w), 665 (w).

Cp^*_2Yb(3-Mephen)·0.5(C_7H_8) (6). The complex $Cp^*_2Yb(OEt_2)$ (0.105 g, 0.203 mmol) was combined with 3-methyl-1,10-phenanthroline (3-Mephen, 0.040 g, 0.203 mmol), and toluene (10 mL) was added at room temperature. The deep-purple solution was stirred for 2 h at room temperature, and a dark precipitate formed. The suspension was warmed to dissolve the dark powder, and the resulting solution was filtered while warm. The filtrate was slowly cooled to −20 °C to yield a dark microcrystalline powder. Two crops were obtained (combined yield, 85 mg, 65%). ^{1}H NMR: (toluene-d_8, 295 K, δ (ppm) 121.47 (1H, phen), 118.38 (1H, phen), 59.15 (1H, phen), 57.17 (1H, phen), 55.02 (1H, Phen), 52.07 (1H, phen), 18.69 (1H, phen), 3.79 (30H, C_5Me_5), −9.51 (3H, Me-phen). Mp: 270−272 °C. Anal. Calcd for $C_{33}H_{40}N_2Yb{\cdot}0.5(C_7H_8)$: C, 64.11; H, 6.49; N, 4.10. Found: C, 64.40; H, 6.49; N, 3.96. ^{1}H NMR spectrum confirmed the presence of the toluene. MS: {Cp^*_2Yb(3-Mephen)}, m/z = 638. IR (cm^{-1}): 1612 (m), 1554 (w), 1494 (w), 1377 (s), 1364 (s), 1320 (s), 1297 (s), 1229 (m), 1174 (m), 1118 (m), 1065 (m), 1022 (w), 886 (m), 880 (m), 776 (m), 731 (s), 696 (m), 675 (m).

Cp^*_2Yb(5,6-Me_2phen) (7). The complex $Cp^*_2Yb(OEt_2)$ (0.208 g, 0.403 mmol) was combined with 5,6-dimethyl-1,10-phenanthroline (5,6-Me_2phen, 0.0838 g, 0.403 mmol), and toluene (20 mL) was added at room temperature. The deep-purple solution was stirred for 16 h at room temperature, concentrated to ∼5 mL, warmed to dissolve the dark residue, and filtered while hot. The filtrate was slowly cooled at −20 °C. A dark purple microcrystalline powder formed (204 mg, 78%) which was crystallized in warm cyclohexane, yielding block-like purple X-ray suitable crystals (125 mg, 48%). ^{1}H NMR: (toluene-d_8, 300 K) δ (ppm) 137.44 (2H, phen), 44.10 (2H, phen), 14.66 (2H), 3.95 (30H, C_5Me_5), 0.03 (6H, Me-phen). Mp: 285−287 °C. Anal. Calcd for Anal. Calcd for $C_{34}H_{42}N_2Yb$: C, 62.66; H, 6.50; N, 4.30. Found: C, 62.74; H, 6.43; N, 4.37. IR (cm^{-1}): 1605 (m), 1584 (w), 1480 (w), 1426 (s), 1375 (m), 1345 (w), 1305 (w), 1275 (vw), 1218 (vw), 1190 (w), 1167 (w), 1145 (w), 1073 (w), 1019 (w), 943 (w), 804 (s), 758 (w), 736 (s), 686 (m). The crystal data, Table 10, for **7-crystallized** (monomer) were obtained on crystals obtained by crystallization from cyclohexane. The crystal data, Table 10, for **7-sublimed** (monomer as well), were obtained on crystals that were crystallized from cyclohexane then sublimed in an ampule sealed under vacuum at 195 °C over a period of two months. The sublimate contained needles and block-like crystals that were separated manually. The needles had the same unit cell parameters as those obtained for **7-crystallized**. The block-like crystals crystallized in the same crystal system and space group but with different cell parameters and contained only one molecule in the unit cell, Table 10.

Variable-Temperature ^{1}H NMR Spectra of 3. *Toluene-d_8.* ^{1}H NMR: (toluene-d_8, 300 K) A major species, labeled S, was observed at δ (ppm) 95.54 (2H, phen), 51.07 (2H), 3.83 (2H, phen), 3.63 (30H, C_5Me_5), −10.02 (6H, Me-phen) and two minor species (labeled A_1 and A_2 accounting for less than 5% of the total) were observed. When the NMR tube was cooled, the two minor species observed at room temperature increased in intensity that represent two unsymmetrical (the position 2 and 9, 3 and 8, 4, and 7 and 5 and 6 are not equivalent) complexes in agreement with the formation of two isomeric dimers. The three different species are labeled S, for the symmetrical monomer, A_1 and A_2 for the two asymmetric isomeric dimers. In toluene, one proton could not be observed for A_1 and A_2, presumably because it was under the toluene resonances. The amount of A_1/A_2 is 40%/60% at 210 K, and this ratio is only slightly temperature dependent. ^{1}H NMR: (toluene-d_8, 210 K) δ (ppm) 105.21 (0.13H, phen-S), **89.95** (0.6H, Me-A_1), **85.51** (1H, Me-A_2), 74.24 (0.13H, phen-S), 56.20 (0.2H, phen-A_1), 45.99 (0.33H, phen-A_2), **22.66** (1H, Me-A_2), 14.06 (0.50H, br, phen-A_1 + phenA_2), 4.41 (0.13H, phen-S), 3.63 (2H, Cp*-S), −0.85 (16.5H, br, $\nu_{1/2}$ = 1100 Hz, Cp^*-A_1+A_2), −**13.44** (0.6H, Me-A_1), −15.42 (0.33H, phen-A_2), −21.20 (0.2H, phen-A_1), −**27.10** (0.4H, Me-S), −43.25 (0.2H, phen-A_1), −70.24 (0.33H, phen-A_2), −111.47 (0.33H, phen-A_2), −113.58 (0.2H, phen-A_1). **THF-d_8.** ^{1}H NMR: (THF-d_8, 300 K) δ (ppm) 72.72 (2H, phen), 42.33 (2H), 5.21 (2H, phen), 2.79 (30H, C_5Me_5), −7.01 (6H, Me-phen) and two minor species (less than 5% total). In THF, two protons could not be detected for each dimer (A_1 and A_2). The amount of the isomers A_1 and A_2 is 55%−45% at 198 K and is only slightly temperature dependent. ^{1}H NMR: (THF-d_8, 198 K) δ (ppm) **96.76** (1H, Me-A_1), **92.01** (0.8H, Me-A_2), 79.94 (0.27H, phen-S), 60.91 (0.22H, phen-A_2), 60.04 (0.27H, phen-S), 49.99 (0.25H, phen-A_1), **23.55** (0.8H, Me-A_2), 13.03 (0.5H, br, phen-A_1 + phenA_2), 5.70 (0.27H, phen-S), 2.91 (4.1H, Cp*-S), −1.52 (18H, br, $\nu_{1/2}$ = 1200 Hz, Cp^*-A_1 + A_2), −**15.09** (1H, Me-A_1), −16.74 (0.25H, phen-A_1), −**19.44** (0.8H, Me-S), −24.38 (0.22H, phen-A_2), −42.09 (0.25H, phen-A_1), −75.78 (0.22H, phen-A_2).

Resonances in bold were the resonances used for the integration and the calculation of equilibrium constants. They were used because they are singlets whose resonances are clearly visible over the temperature range of the study (197.5−315 K). These calculations assume that the reaction shown in eq 2, where M is the symmetric set, S, and D the asymmetric sets of resonances, A_1 and A_2.

X-RAY CRYSTALLOGRAPHY

Single crystals of the compounds **1-dimer**, crystallized and sublimed, and **3** were coated in Paratone-N oil and mounted on a Kaptan loop. The loop was transferred to a Bruker SMART APEX, diffractometer equipped with a CCD area detector.[54] Preliminary orientation matrixes and cell constants were determined by collection of 10 s frames for **3**, **7-crystallized**, and **7-sublimed** and 20 s for **1-dimer crystallized** and 10 s for **1-monomer sublimed**, followed by spot integration and least-squares refinement. Data were integrated by the program SAINT[55] to a maximum 2θ value of 50.94° for **1-dimer**, crystallized, 50.83° for **1-monomer**, sublimed and 50.70° for **3**,

dx.doi.org/10.1021/ja502271q | J. Am. Chem. Soc. 2014, 136, 8626−8641

50.48° for **7-crystallized** and 50.88° for **7-sublimed**. The data were corrected for Lorentz and polarization effects. Data were analyzed for agreement and possible absorption using XPREP. An semiempirical multiscan absorption correction was applied using SADABS.[56] This models the absorption surface using a spherical harmonic series based on differences between equivalent data. The structures were solved by direct methods using SHELX[57] or SIR-97 and the WinGX program.[58] Non-hydrogen atoms were refined anisotropically and hydrogen atoms were placed in calculated positions and not refined for **3** and **1-dimer sublimed**, **7-crystallized** but found in the Fourier map and refined isotropically for **7-sublimed**. For **1-dimer, crystallized**, only H28 was refined. (The hydrogen located at the carbon atom where the coupling occurs.) All the others were placed in calculated positions and not refined.

■ ACKNOWLEDGMENTS

G.N. would like to thank CNRS and Ecole polytechnique for funding. Work at University of California, Berkeley and at Lawrence Berkeley National Laboratory was supported by the Director, Office of Energy Research, Office of Basic Energy Sciences, Chemical Sciences, Geosciences and Biosciences Division, Heavy Element Chemistry Program of the U.S. Department of Energy under Contract No. DE-AC02-05CH11231. X-ray absorption data were collected at the Stanford Synchrotron Radiation Lightsource, a Directorate of SLAC National Accelerator Laboratory and an Office of Science User Facility operated for the U.S. Department of Energy Office of Science by Stanford University. We thank Antonio DiPasquale at CHEXRAY Berkeley for his help with crystal structures. L.M. is member of the Institut Universitaire de France. Cines and CALMIP are acknowledged for a generous grant of computing time. L.M. would also like to thank the Humboldt Foundation for a fellowship. The authors thank a referee for suggestions that resulted in an improved manuscript.

(30) The reason for the lack of an EPR spectrum at 2 K for **7** is not clear. The magnetic susceptibility, Figure 2, shows that it is not a ground state singlet. Three possible reasons may be advanced. (i) The ground state is a triplet with a large zero-field splitting, (ii) *g*-perpendicular is zero, or (iii) the ground state is a normal triplet but spin−lattice coupling is large and rapid relaxation broadens the spectrum into the baseline. Given the lack of a spectrum, it is not possible to distinguish between these possible reasons.
