ABSTRACT: Here we present the formation of predominantly sp²-coordinate carbon with magnetic- and heteroatom-induced structural defects in a graphene lattice by a stoichiometric dehalogenation of perchlorinated (hetero)aromatic precursors [hexachlorobenzene, C_6Cl_6 (HCB), and pentachloropyridine, NC_5Cl_5 (PCP)] with transition metals such as copper in a combustion synthesis. This route allows the build-up of a carbon lattice by a chemistry free of hydrogen and oxygen compared to other pyrolytic approaches and yields either nitrogen-doped or -undoped graphene domains depending on the precursor. The resulting carbon was characterized by scanning electron microscopy (SEM), transmission electron microscopy (TEM), Raman spectroscopy, photoelectron spectroscopy (XPS), and SQUID magnetometry to gain information on its morphological, chemical, and electronic structure and on the location of the nitrogen atoms within the carbon lattice. A significant lowering of the magnetization was observed for the nitrogen-doped carbon

obtained by this method, which exhibits less ordered graphene domains in the range of approximately 10−30 nm as per TEM analysis compared to the nondoped carbon resulting from the reaction of HCB with larger graphene domains as per TEM and the presence of a 2D mode in the Raman spectra. The decrease of the magnetization by nitrogen doping within the sp²-coordinate carbon lattice can be attributed to an increase in pyrrole-type defects along with a reduction in radical defects originating from five-membered carbon ring structures as well as changes in the π-electron density of edge states.
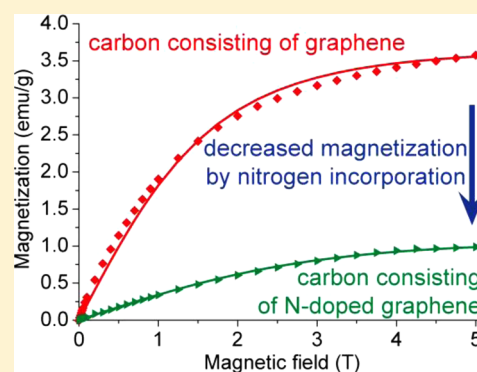

INTRODUCTION

Pure, blended, or functionally modified allotropes of carbon, especially those based on graphene,[1] which is formed from a hexagonal 2D array of sp²-coordinate carbon atoms, are considered for a manifold of new applications in organic electronics, catalysis, and electrochemistry due to its outstanding physical, chemical, and technological properties. Moreover, graphene-based, nitrogen-doped forms of sp²-coordinate carbon, with the heteroatom placed in defined lattice positions, become increasingly important for applications in conductive films, catalysts, fuel cells,[2−4] lithium batteries,[5] biosensors,[6] field-effect transistors,[7−9] capacitors,[10] and electrochemical sensors.[11] Therefore, an understanding of the influence of the structural imperfections on the magnetic and electronic properties is necessary. Such lattice defects can be either nonhexagonal atomic arrays or heteroatoms within the graphene lattice with optional charges. The N 1s XPS signal is generally used to identify the nature of the specific bonding of nitrogen atoms within a carbon lattice. The description used here is the current terminology found in the literature and XPS database references. The terminology is derived either from molecular structures (e.g., "pyridinic, pyrrolic") or resembles

the substitution of atoms in the lattice (e.g."substitutional, graphenic, graphitic"). In the literature, the nitrogen lattice positions within an sp²-coordinate graphene domain are usually categorized as pyridinic, graphitic (graphenic), pyrrolic, and aromatic sites, although a manifold of other structures is feasible and characterized by photoelectron spectroscopy (graphenic 398.1 eV, pyridinic 397.9 eV, pyrrolic 400.3 eV, graphitic: 400.5/401 eV, aromatic 399.3 eV, also including five-membered heteroaromatic structures with one or more nitrogen atoms).[12−18] Thus, nitrogen can be considered as a chameleon within a sp²-coordinate carbon lattice due to the manifold options of its positioning and bonding.[19] Some of these possibilities are illustrated in Figure 1. The replacement of nitrogen atoms in the graphene lattice results in changes in the electronic density of states (DOS),[20] and graphitic nitrogen can provide π-electrons close to the Fermi level of graphene in contrast to pyridinic and pyrrolic nitrogen atoms.[21] Whereas the electronic properties of carbon materials are widely investigated in the literature,[22,23] there are only a few reports
Figure 1. (a) Schematic illustration of the transition metal-assisted dehalogenation of perhalogenated (hetero)aromatic precursors upon pyrolysis; (b) potential active nitrogen sites in graphene; (c) formal valence bond interpretation, structures, and source of the origin for the observed magnetic properties from a chemical point of view indicated by the nitrogen electron lone pair.

dealing with their magnetic behavior. For example, edge states located at zigzag structures were identified by theory[24,25] and experiments[26–28] to contribute to the magnetism of graphene layers. There are still remaining key questions, e.g., how the magnetic properties of carbon materials are influenced by the introduction of dopants such as nitrogen atoms, or if other structural motifs, such as radicals,[29–31] are responsible for the magnetism. Doped carbon materials can be prepared by pyrolysis,[32] by chemical vapor deposition,[33] by combustion synthesis from halogenated hydrocarbons,[34–37] and by reactive etching from carbides.[38]

According to an approach dating back to Henry Moissan,[39,40] it is possible to treat perhalogenated aliphatic or (hetero)-aromatic molecular precursors in a stoichiometric reaction with reactive metals to form carbonaceous materials. Because pyridinic structural elements are discussed to effect electronic changes in the graphene lattice, pyridines and perhalogenated pyridines can especially be considered as suitable precursors to enhance these structural motifs in the resulting network of 3-fold-coordinate carbon atoms. Here we present a synthesis of graphene-based, nitrogen-doped carbonaceous materials by reacting perhalogenated molecular precursors (pentachloropyridine and hexachlorobenzene as a reference) with transition metals such as Cu, Ni, Fe, etc., in a stoichiometric ratio instead of using the more reactive alkaline and alkaline earth metals (cf., refs 5–8 and Figure 1). This route differs from either a strongly exothermic, stoichiometric combustion synthesis or a catalytic Ullmann-type reaction on surfaces[41] or in solutions and enables the scalable synthesis of hydrogen- and oxygen-free doped bulk carbons. A generalized equation of the reaction is given by

$$C_xHal_y + M \rightarrow C_{x-z} + M_aC_z + M_{1-a}Hal_y$$
Here C_xHal_y represents the perhalogenated precursor molecule, C_{x-z} the amount of the newly formed carbon material, M_aC_z a potentially formed metal carbide, and $M_{1-a}Hal_y$ the corresponding metal halide.

We describe in particular the reaction of copper with pentachloropyridine (C_5Cl_5N), because this transition metal is not showing a pronounced carbide formation or a high carbon solubility. The analogous nondoped carbon materials were

prepared in a similar manner from hexachlorobenzene (C_6Cl_6) for reference.

The morphological and Raman spectroscopic features, magnetic properties, and electron core level analysis of the obtained carbons are presented, and the influence of the synthesis parameters on the precursor decay and thermal stability of the doped lattice sites is discussed in view of kinetic and thermodynamic aspects.

■ RESULTS AND DISCUSSION

Pentachloropyridine (PCP) and hexachlorobenzene (HCB) were dehalogenated with copper (cf., Figure 1), and the recovered carbon samples were used for further characterization. The dehalogenation of pentachloropyridine (PCP) was performed according to eq 1 at 600 °C, 800 °C, and 1000 °C in an equimolar ratio of copper to chlorine to enable a stoichiometric formation of CuCl and post-treated with hydrochloric acid, and the resulting carbons were labeled as PCP600–HCl to PCP1000–HCl, respectively. The acidic quenching of the reaction products allows removal of copper residues and halide byproducts and separation of the sources and nature of the magnetic contributions.

$$C_5Cl_5N + 5Cu \rightarrow 5CuCl + C_xN \qquad (1)$$
To obtain nitrogen-free reference materials, the following reactions were additionally performed: (i) dehalogenation of pentachloropyridine at 1000 °C with a 1:2 molar ratio of copper to chlorine to enable the formation of $CuCl_2$ and workup in hydrochloric acid (PCP1000–HCl–halfCu); (ii) neat pyrolysis of pentachloropyridine at 1000 °C without copper and without acidic workup (PCP1000–nonHCl); (iii) synthesis of a nitrogen-free sample from hexachlorobenzene (HCB) at 1000 °C with a 1:1 molar ratio of Cu/Cl to enable stoichiometric CuCl formation followed by an acidic workup (HCB1000–HCl); (iv) neat pyrolysis of hexachlorobenzene at 1000 °C without hydrochloric acid workup (HCB1000–nonHCl). The resulting carbons were recovered as described in Experimental Section.

The product distribution of the resulting carbon structures strongly depends on parameters such as stoichiometry, onset temperature of the precursor decomposition and halide formation, tendency of carbide formation, and stability of the

corresponding metal halides, as well as the final annealing temperature. For example, the reaction of perhalogenated precursor molecules with alkali and alkaline earth metals, earth metals, or early transition metals can lead to the corresponding metal carbides and metal halides, whereas the reaction with late transition metals can end up in the formation of the corresponding halides and carbonaceous materials due to a reduced tendency of carbide formation.[42] Here copper was chosen for the dehalogenation reaction to avoid carbide formation, and in addition, the resulting copper compounds are either nonmagnetic or paramagnetic and their contribution to the magnetic measurements can be subtracted.

The morphology of the carbon materials obtained from the dehalogenation of PCP and HCB was characterized by SEM (Figure 2) and TEM (Figure 3). The formation of distinct plate-like structures is observed in the SEM images of the recovered carbon obtained from dehalogenation of PCP. These structural features start to occur at 600 °C in samples prepared from an equimolar copper/chlorine ratio and become more dominant at higher temperatures (cf., Figure 2a: individual plates of approximately 100 nm diameter at 1000 °C; Figure 2b: dense flakes or platelet-like aggregates at 800 °C; Figure 2c: dense platelet aggregates at 600 °C). In samples from a stoichiometry of a copper/chlorine ratio of 1:2, which allows formally the intermediate formation of copper(II) chloride (CuCl$_2$), these platelets were also observed (Figure 2d). The structures are more regular for a Cu/Cl ratio of 1:1 than for a Cu/Cl ratio of 1:2. The applied heat treatment will lead to a thermally induced decomposition of CuCl$_2$ to CuCl and chlorine due to the limited stability of CuCl$_2$,[43] which enables a different reaction mechanism during the carbon formation and thus affects the resulting morphology. These differences are

FFT images [insets in b and d] demonstrate a randomly orientated graphene lattice or more ordered graphene lattice, respectively, formed from HCB.

obvious by comparing Figure 2a [PCP1000−HCl] and Figure 2d [PCP1000−halfCu].
Figure 4. N 1s core level spectra for (a) PCP1000−HCl, (b), PCP800−HCl, and (c) PCP-600−HCl. The contributions of pyridinic nitrogen (at 398.6 eV) and pyrrolic-graphitic nitrogen (401 eV), as well as shakeup and potential oxidic nitrogen species at higher binding energy, according to the fitting routine, are included in the graphs.

The morphologies of the nitrogen- and non-nitrogen-containing carbons obtained from PCP [Figure 2a−d] and HCB [Figure 2f,g] indicate a different appearance irrespective of the presence of copper. A comparison of the product morphology resulting from the reaction of PCP with or without copper showed that the neat decomposition of PCP at 1000 °C [Figure 2e, PCP1000−nonHCl] displays a more regular plate-like appearance than the sample recovered from the reaction of a 1:2 Cu/Cl ratio at 1000 °C [Figure 2d, PCP1000−HCl−halfCu]. This is an indication that reactions with PCP generally have led to a more platelet-like growth morphology, which is not the case for HCB. The neat decomposition of HCB at 1000 °C produces an irregular, submicron structured carbon material with a rough surface (Figure 2g), whereas the dehalogenation of HCB with a Cu/Cl ratio of 1:1 at 1000 °C results in a more regular structure with holes up to 1 μm (Figure 2f).

The platelet-like appearance of the carbon recovered from PCP by neat decomposition and by dehalogenation with copper can be attributed to the decay chemistry of this precursor. Here the carbon formation takes place within the ternary system C−Cl−N or quaternary system C−Cl−Cu−N, avoiding any hydrogen or oxygen functionalities during the build-up of the carbon structure.

Figure 3 shows the TEM images of carbon materials recovered after pyrolysis of PCP and HCB at 1000 °C [neat decomposition and from an equimolar Cu:Cl ratio], and in both cases, the presence of carbon-containing individual graphene sheets was detected [Figure 3a−d]. The lattice reflections of the PCP samples [Figure 3b] reveal a disordered structure as indicated by a Debye−Scherrer ring, whereas the HBC sample has a more regularly ordered structure with a diffraction pattern of 6-fold symmetry [Figure 3d]. This analysis clearly demonstrates that the decomposition of HCB results in a carbon material containing high quality graphene layers. The reason for the higher degree of disorder observed for PCP must be attributed to the presence of nitrogen, which is randomly incorporated into the graphene lattice and therefore results in a breakdown of the symmetry.

An XRD powder diffraction pattern helped to identify the nature of the resulting copper halide (Figure S1, Supporting Information).[44,45] Before treatment with hydrochloric acid, the presence of CuCl as a major product is obvious, together with traces for reflections originating from CuCl$_2$. The copper halide peaks have disappeared after the acid treatment.

The nature of binding states of nitrogen atoms incorporated into the carbon lattice was confirmed by XPS. The carbon materials were obtained as powders and embedded in indium foil (containing carbon and oxygen impurities); therefore, only the N 1s results of the samples are discussed. Figure 4 shows the N 1s core level spectra of the samples made from PCP at different temperatures and recovered by acidic workup [PCP600−HCl, PCP800−HCl, and PCP1000−HCl]. All samples were measured under comparable conditions in indium foil and indicate the presence of nitrogen. The highest relative N 1s intensity is observed for the sample from the lowest preparation temperature (cf., Figure 4). References for N 1s binding energies are given for 397.9 eV for pyridine-type nitrogen, 398.1 eV for graphene-type nitrogen, and 400.3 eV for pyrrole-type nitrogen in carbon materials. The highest total nitrogen concentration as per signal intensity and the atomic concentration of pyridinic/graphene nitrogen to pyrrole/substitutional nitrogen changes from 1:5.6 [Figure 4a] to 1:3.3 [Figure 4b] to 1:2.3 [Figure 4c], which indicates a temperature-dependent selectivity for the formation of graphene-type nitrogen and pyridine-type nitrogen at lower temperatures. At higher temperatures, nitrogen is expelled from the carbon lattice (e.g., as CN radicals) and the residual nitrogen is resting predominantly at heteroaromatic sites at higher binding energy. Those heteroaromatic sites reveal the same shifts as pyrrole-type structures. Furthermore, it has to be noted that even a pyridine precursor needs to undergo a full ring opening and rearrangement to form a (nitrogen-substituted) graphene lattice, and thus also the generation of five-membered heteroaromatic ring structures is feasible. This also implies a structural rearrangement of the nitrogen sites during heat treatment and supports the chamaeleon-like behavior of nitrogen atoms in a sp^2-hybridized carbon atom network. A self-consistent fitting routine was performed, and the two major contributions were assigned to pyridinic nitrogen (maxima at 398.6 eV) and pyrrolic nitrogen. Pyrrolic-type nitrogen could not be well separated from other heteroaromatic types of nitrogen structures (both centered at approximately

401 eV) due to small differences in the binding energy of ca. 0.6 eV and were fitted as a single component.[46,47]

Little is known about the nature of XPS signals of carbonaceous groups containing nitrogen atoms in the energy region above 404 eV. Peaks at binding energies higher than 401 eV (Figure 4c, 406 eV) can be either due to shakeup processes (their relative intensities depend on the applied photon energies; complementary XPS experiments using synchrotron radiation for excitation were performed) or contain contributions from oxidized nitrogen species, or charged or coordinated nitrogen atoms of donor-type character. A weak intensity at the lower binding energy side of the pyridinic signal is due to spurious contribution from the molybdenum sample holder (control experiments did not show any spectral features below 398.6 eV).

Raman spectra (cf., Figure 5; Supporting Information Table 1) provided additional structural information on the carbon
Figure 5. Raman spectra of the reaction products obtained from transition metal dehalogenation of (nitrogen-containing) perhalogenated PAHs.

materials. The pyrolysis temperature dependence reveals less defective graphitic structures for the PCP samples with a decrease of the fwhm (Supporting Information Table1) as the preparation temperature increases. The direct formation of graphene domains from HCP is obvious by the presence of the 2D mode.

A comparison of the samples derived from PCP and HCB indicates a more graphitic structure for HCB due to the presence of the 2D Raman mode and thus correlates well to the TEM images in Figure 3. Moreover, the Cu-free samples show a higher degree of ordering due to a reduced line width and higher I_{2D}/I_G ratios. Magnetic measurements were performed by using a SQUID magnetometry setup to characterize the nitrogen doping effects. Figure 6 shows the magnetization curves at 2 K together with the corresponding Brillouin functions with different spin (S) fitted for all samples. The analysis of the carbon material obtained from a neat HCB decomposition (HCB1000−nonHCl) indicates a magnetic interaction resulting from S = 3/2. Because the point defect in graphene[31] leads to S = 1/2, this sample must contain magnetic clusters. Comparable magnetic clusters with S = 2 to 5/2 are reported for exfoliated HOPG.[48] Such a material reveals highly graphitic structures, and the magnetism is considered to result from zigzag edge structures.[27,49] Moreover, the Raman spectra show a considerable defect band intensity which can be attributed to a disordered lattice containing radical-type five-

ring structures derived from a corannulene-type connectivity.[50] Therefore, similar magnetic clusters [cf., Figure 1] might also be present. The dependence of the magnetization on the preparation temperature is depicted for an applied magnetic field of 1 T in Figure S2, Supporting Information, which all follow the Curie−Weiss law with negative Weiss temperatures. The detailed values of magnetization at 5 T, S, spin concentration (N_s), temperature independent susceptibility (χ_0), and Weiss temperature (K) were calculated from the fitted Brillouin functions and the Curie−Weiss law and are summarized in Table 1.

Table 1. Magnetic Properties of the Recovered Carbon Materials with or without Nitrogen [magnetic saturation moment (M), temperature independent susceptibility (χ_0), spin concentration (N_s), and Weiss temperature (K)]

	M (emu/g)	χ_0 (10^{-7} emu/g)	N_s (10^{19} spin/g)	Weiss temperature (K)

nanographene[30]	–	−7.3	4.2	−2.5

A comparison of the magnetic properties of the materials from the neat pyrolysis of HCB and PCP surprisingly reveals a significantly higher magnetization for the non-nitrogen-containing carbon sample. The higher magnetization observed for the material from HCB most likely results from more abundant radical centers, which can be linked to unpaired electronic states, such as radical-type five-membered ring defects incorporated into the hexagonal graphene lattice.

The decrease of the magnetization for N-doped samples can be explained by different models. One could attribute this effect to the disappearance of radical-type edge states in six-membered heteroatomar ring structures. For states in proximity

to zigzag edges regarding pyridinic and graphitic nitrogen positions, first principle calculations on the partial electron density of states (DOS) have been performed.[51]

In this model, the additional electron density supplied by nitrogen atoms on pyridinic and graphitic positions leads to typical diamagnetic features and a disappearance of magnetic edge states (cf., closed shell, illustrated in Figure 1), which can be explained more simply as chemical resonance effects. In addition, the higher electronegativity of the nitrogen atom in comparison to carbon results in a more localized electron density at the nitrogen positions, too, and thus also affects the DOS. Both effects imply that the magnetism of nitrogen-doped carbons will become smaller considering edge states only.

Because the bulk incorporation of nitrogen atoms outnumbers the amount of rather reactive and unstable edge states, it is also necessary to consider the stability influence of such bonding states (graphitic nitrogen vs pyrrole-type nitrogen in comparison to a radical-type five-membered carbon ring defect). It is in principle feasible that in nitrogen-doped carbon structures, an incorporation of nitrogen into five-membered ring structures leads to stable, nonradical type, electron-precise pyrrole-type lattice defects (cf., Figure 1c).

To investigate the observed decrease in magnetization by nitrogen incorporation experimentally, hydrochloric acid was used to quench any magnetic anionic-type radical defects (e.g., 5−7 defects, anionic radical defects, point defects).[52] The experimental results depicted in Figure 6 indicate lower values for the magnetization of the HCl-treated carbons obtained from PCP (cf., PCP1000−HCl/nonHCl and HCB1000−HCl/nonHCl). Therefore, the total number of radical defects decreases upon HCl treatment, while some magnetic contributions survive the HCl treatment. The magnetization of a sample derived from pentachloropyridine (PCP1000−HCl) is still lower after the HCl treatment compared to a sample obtained from hexachlorobenzene (HCB1000−HCl). The total number of five-membered radical defects is thus lower for nitrogen-doped samples. When nitrogen is replacing a carbon atom within a five-membered radical defect, it will become electron-precise by the additional electron from the nitrogen atom, which can contribute to the π-system of the carbon atom network.

Because the magnetization of PCP samples is smaller for lower reaction temperatures (these samples have a higher gross nitrogen content with additional pyridinic/graphitic nitrogen atoms besides pyrrolic nitrogen atoms as per XPS) and the magnetization increases with the reaction temperature (with a reduced gross nitrogen content in favor of pyrrolic sites), higher reaction temperatures lead to an expulsion of nitrogen from the carbon lattice (e.g., by stable CN radicals) and thus to an increase of the magnetization by generation of radical defects (cf., Supporting Information Figure 3). Thus, the chemical doping by nitrogen incorporation into the graphene lattice allows a reduction of the magnetic response if pyrrole-type positions are formed. This enables a tuning of the electronic density of states as well as the magnetic properties of such materials based on sp²-coordinate carbon.

CONCLUSION

The presented synthetic route based on a stoichiometric dehalogenation of perhalogenated arene and pyridine precursors by a transition metal enables the formation of sp²-coordinate carbon with graphene domains and the option to incorporate nitrogen especially on pyrrolic bonding sites as indicated by XPS. The formation of highly ordered graphene structures by this approach from HCB was confirmed by TEM and Debye−Scherrer diffraction and the presence of a 2D Raman mode. However, more disordered graphene structures were obtained by the use of an analogous nitrogen-containing precursor PCP with a pyridinic carbon ring system. The higher degree of structural imperfection can be attributed to differences in the precursor decay and incorporation of nitrogen atoms into the graphene lattice, which become mainly pyrrolic in nature at higher temperatures as determined by XPS. SQUID measurements indicate a complex origin of the magnetism, which is attributed to radical defects of five-membered ring faults within the graphene lattice.

We could thus demonstrate how nitrogen doping as induced by decomposition or dehalogenation of PCP results in a decrease of the magnetization. Bulk incorporation of nitrogen outnumbers the rim effects, and therefore the electronic and magnetic changes induced by lattice doping effects are considered to significantly contribute to the observed properties. Nitrogen atoms at pyrrolic positions were identified by XPS as the most stable sites in a carbon network at high temperatures and thus affect the structure and magnetic properties of doped graphene. This type of doping will influence the reactivity and electronic and magnetic properties of any kind of carbon material with similar defects. The multitude of positions and thus chamaeleon-like behavior of nitrogen atoms within the carbon network combined with their different influence on the electronic structure and magnetism indicates the necessity of a controlled tuning of the nitrogen doping. This can enable the preparation of new materials, e.g., for conducting films and bulk carbons, electrochemical applications in supercapacitors and batteries, and metal-decorated supports for catalytic applications (by either not removing the transition metals incorporated by the synthesis or by adding PCP complexes of active transition metals into the dehalogenation route). Furthermore, the dehalogenation of perhalogenated precursors by a stoichiometric reaction with transition metals can be used for a straightforward and scalable preparation of novel (doped) carbon materials with graphene-type structural elements and a controlled surface termination in gram scales, and similar reactions are feasible with other transition metals (e.g., Fe, Ni, Co, Mn), main group metals, and intermetallic systems.

EXPERIMENTAL SECTION

Precursors (0.8 mmol) of pentachloropyridine (PCP, 98%, Aldrich) and hexachlorobenzene (HCB, 99%, Fluka) were additionally purified by sublimation and introduced into quartz glass tubes (thickness: 1.5 mm) with Cu grains (99.5%, 5 equiv, Alfa Aesar), respectively. The ampules were evacuated for 30 min, sealed by melting, and heated to 600 °C, 800 °C, and 1000 °C for 20 h. Note for safety: The amounts used were calculated not to cause damage to the quartz ampules. After the heat treatment, the ampules were carefully opened with appropriate personal protection considering internal residual pressure (especially observed without the presence of copper). The recovered material was washed with hydrochloric acid (HCl, 37% in water) to remove residual copper byproducts and dried for 12 h at 120 °C. Small amounts of Cu-free samples were similarly prepared by direct heat treatment of the precursor. The morphology of the recovered samples was characterized by scanning electron microscopy (SEM; Zeiss LEO 1530 Gemini;1.0 keV) and transmission electron microscopy (TEM; FEI Tecnai F20; 200 kV). Samples were sonicated in 2-propanol for 1 h and transferred to a carbon-supported Cu grid, and images were recorded quickly to minimize electron beam damage. X-ray powder diffraction (XRD) patterns were measured with a Bruker D8

diffractometer (Cu Kα). The binding states of nitrogen atoms were characterized by X-ray photoelectron spectroscopy (XPS) with Al Kα excitation using a hemispherical electron analyzer (Scienta SES 100). The carbon materials were pressed onto an indium foil, fixed on a molybdenum sample holder, and measured in a customized UHV analysis chamber having a base pressure of 10^{-10} mbar. Raman spectra were measured using a Bruker Senterra spectrophotometer (488 nm). The temperature and magnetic field $(H(T))$ dependence of the magnetization $(M(\text{emu/g}))$ were measured with a Quantum Design MPMS-XL SQUID magnetometer up to a field of 5 T in a temperature range between 2 and 300 K. Background signals from the sample holder and temperature independent contributions were subtracted.
